Finally, the genotypic variability in HDV has resulted in tentative identification of three genotypes. The majority of HDV infection is with the genotype I (80% nucleotide sequence similarity among strains). The genotype II was found in an isolate from Japan (75% sequence similarity with genotype I). Three viral isolates from South America constituting genotype III have shown only 60–65% sequence similarity with the other two genotypes and have been responsible for fulminant hepatitis. The presence of HDV quasi-species within individual patients have also been noted. Its RNA genome is consistent with poor fidelity during replication and a mutation rate has been estimated of 3×10^{-2} to 3×10^{-3} substitutions/nucleotide/year.

THERAPIES

The therapies are extremely limited. Patients with acute hepatitis are treated symptomatically because most cases resolve spontaneously. If fulminant hepatitis develops, intensive care management is necessary and orthotopic liver transplantation (OLT) may be lifesaving. The pharmacokinetics of drugs may be altered in the presence of liver disease and this needs careful consideration.

The availability of effective drugs to inhibit viral replication has been unsatisfactory. A variety of nucleoside analogs and other compounds have been ineffective. The largest experience has been with IFN-α, which inhibits the HBV DNA polymerase and also suppresses HCV replication. There are three kinds of interferons (α, β, and γ), which are endogenous, naturally occurring glycoproteins with antiviral, antiproliferative and immunomodulatory activities. IFN-α is derived from leukocytes, IFN-β from fibroblasts, and IFN-γ from T lymphocytes. Although IFN-α and -β are similar and share the same cell surface receptor, IFN-γ is a different molecule with a separate receptor. Most antiviral studies in HBV and HCV have been with IFN-α, as IFN-β is unstable. The mass of data concerning therapeutic trial of IFN-α in HBV and HCV is too large to discuss here. However, the drug benefits by decreasing viral replication, hepatic inflammation, and fibrosis. Patients with relatively low level of serum HBV DNA or serum HCV RNA, along with younger age, less advanced or prolonged disease, and possibly with HCV genotype other than type I are likely to benefit most. Despite the best circumstances, however, viral clearance is extremely rare, responses are most often temporary, side effects are multiple, and IFN-α therapy is expensive. Recently, lamivudine, a nucleoside analog, has shown promise in suppressing HBV replication, although rapid appearance of mutant strains in this situation is a limitation.

Searches for alternative therapies have continued and include consideration of gene therapy approaches. The use of antisense gene sequences to suppress transcription offers a novel therapeutic approach, which is most attractive because of its potential specificity. In principle, stretches of nucleotides in a reversed orientation to the native mRNA sequences will hybridize and inactivate mRNAs. The suggested mechanisms in antisense gene regulation include perturbations in splicing at exon/intron junctions, mRNA transport from nucleus to cytoplasm, initiation factor-binding for translation, assembly of ribosomal subunits at start codons, and interference with ribosome travel along coding mRNA sequences. Studies with synthetic oligonucleotides have identified potential targets for HBV antisense sequences. Recently, HBsAg expression has been inhibited in vitro with the use of antisense oligonucleotides against HBsAg coding regions. The use of receptor-mediated endocytosis to deliver oligonucleotides specifically to the liver may potentially increase local drug delivery. In addition, antisense oligonucleotides against early preS or DR2 regions were effective in vivo, although continuous infusions and very high doses were required. However, despite these successes, extensive body distribution of oligonucleotides and low cellular uptake and degradation of oligonucleotides pose problems in in vivo applications. An alternative could be to express antisense sequences using cDNAs introduced into infected cells. This has not been extensively tested because unless dominant negative targets could be identified, such antisense strategies could potentially be defeated by the stochastic requirements of inactivating each and every mRNA transcribed. It may be possible to use cDNA sequences to covalently target and repress transcriptionally active DNA domains, but this requires more study. The use of dominant negative HBcAg mutants that markedly inhibit wild-type HBV replication has also been proposed. Using cell lines supporting viral replication, expression of the inhibitory HBcAg mutants with retroviral or adenoviral vectors almost completely suppresses HBV replication.

Efforts have also been ongoing to identify suitable genetic targets for treating HCV. The conserved 5' structural sequences are particularly attractive for this purpose. If expression of HCV core antigen could be suppressed, virion assembly and replication should be significantly affected. Studies with antisense oligonucleotides complementary to the HCV core antigen have shown marked inhibition of viral replication. Similarly, if ribosomal attachment to the IRES could be inhibited, polyprotein translation should be affected, with major effects on all aspects of the virus.

Additional therapies could potentially be devised with better insights into mechanisms of viral persistence and molecular biology of specific viruses. The knowledge concerning the role of individual gene products is necessary for defining suitable genetic targets. The potential therapies could well involve novel antiviral compounds, such as the recently investigated BMS-200475, which is a proprietary guanosine analog. Whether immunological mechanisms could be harnessed for therapeutic purpose, such as by adoptive transfer or induction of antiviral CTL requires further work. Another potential mechanism could be to induce resistance in hepatocytes against viral infection. Similarly, intimate knowledge of the viral receptors would help develop novel drugs to block viral entry into cells. An understanding of viral transcriptional regulatory mechanisms would help develop novel drugs to block viral entry into cells. Also, it is clear that viruses are capable of infecting animals in a species-specific manner depending on the presence or absence of their receptors in cells. Although specific receptors responsible for internalizing hepatitis viruses into cells have not been fully characterized, further work could offer additional therapeutic targets. On the other hand, transplantation of cells or organs from another species resistant to viral hepatitis could offer means to treat patients in end-stage liver failure. Patients with chronic HCV are able to undergo OLT with meaningful survival despite reinfection of the transplanted liver, which is not the case in chronic HBV carriers. Starzl and colleagues proposed that transplantation of liver from baboons, which are not susceptible to HBV, will be successful if allograft rejection were prevented. However, in chronic HBV carriers that were subjected to OLT with baboon livers, survival was limited to only a few weeks, although the transplanted livers showed normal function. It was most likely that the baboon livers were rejected, and further work concerning xenograft tolerance is necessary if such an approach is to be seriously considered.

VACCINES Prevention is the most effective strategy for reducing the burden of viral hepatitis. Success in culturing HAV and HBV has led to the development of highly successful vaccines. The early HBV vaccines were prepared from inactivated virus or HBsAg purified from pooled plasma of HBV carriers. Recombinant HBsAg vaccines contain smaller nonglycosylated HBsAg particles (17–25 nM) compared with the natural vaccine and are produced commercially by expressing HBV cDNAs in yeast. The recombinant HBV vaccines have been proven to be safe and highly effective (90–95%), although adequate levels of anti-HBs require three doses during 6 months and additional boosters after several years. Similarly, effective vaccines have been developed for HAV (97% protection), although currently available vaccines use inactivated virus. Recombinant HAV vaccines based upon the P1 region or the simian HAV epitopes are under study.

Despite significant efficacy, conventional vaccines are disadvantaged by the requirement for multiple doses, several months to adequate immunity, boosters to sustain antibody response, and large amounts of antigens, which are expensive to produce. Recently, interest has developed in the use of genetic vaccines, whereby specific viral proteins are expressed by intramuscular injection of cDNAs. Such genetic vaccines against HBV and HCV have been shown in animals to efficiently express recombinant proteins and to rapidly generate high titer antibodies. The genetic vaccines have potential in converting nonresponders with no antibodies after HBV vaccination. In addition, repeated administration of genetic vaccines is being explored to induce antibody or CTL responses for clearing HBV in chronic carriers.

FUTURE DIRECTIONS AND CONCLUSIONS

Further advances in our understanding of the molecular biology of hepatitis viruses is critical for pathophysiological and therapeutic insights. The availability of effective cell culture systems for several viruses, including HCV, HDV, and HEV will greatly facilitate analysis of molecular mechanisms and vaccine development. Recent progress in culturing HCV and HEV has been encouraging. Similarly, the availability of convenient animal models will be helpful and further allow testing of novel therapies in vivo. Transgenic mouse models will be helpful in analyzing the role of individual viral gene products. Information is necessary to fill gaps in our knowledge of viral life cycles, host-virus interactions, and viral pathogenesis. Parallel advances in gene transfer vectors and mechanisms regulating expression of introduced genes will facilitate gene therapy strategies while appropriate genetic targets are identified. The current pace of molecular discoveries suggests that the next decade will bring forth enormously exciting novel tools for unraveling the pathophysiology of viral hepatitis, as well as revolutionary ways to treat infected individuals.

44 Pancreatic Exocrine Dysfunction

David Whitcomb and Jonathan Cohn

INTRODUCTION

The pancreas is a retroperitoneal gland with both endocrine and exocrine functions. Pancreatic endocrine hormones are released by the islets into the circulation where they are essential for the regulation of intermediary metabolism (*see* Chapter 47). Pancreatic exocrine secretions (pancreatic juice), produced by the concerted action of pancreatic acinar and ductal cells, are delivered into the duodenum where they are essential for normal digestion. Different pancreatic enzymes promote the efficient digestion of complex carbohydrates, lipids, proteins, and other nutrients (Table 44-1). It is noteworthy that many of these digestive enzymes have the potential to digest components of the pancreas itself. Such autodigestion is normally prevented by several mechanisms. For example, many digestive enzymes exist in an inactive (proenzyme) form until they reach the duodenum. Other mechanisms either prevent activation of proenzymes inside the pancreas or inhibit the enzymes if they are inadvertently activated prematurely.

Pancreatic exocrine dysfunction can present clinically either as an acute illness (acute pancreatitis) or as a chronic process (pancreatic insufficiency with or without chronic pancreatitis). Inherited causes of pancreatic exocrine disease include hereditary pancreatitis and cystic fibrosis (CF). In both conditions, the responsible gene is now known and information is rapidly emerging concerning the role of the gene's protein product during normal pancreatic function and during the pathogenesis of pancreatic exocrine dysfunction.

ACUTE PANCREATITIS

BACKGROUND   Acute pancreatitis is defined clinically as pancreatic inflammation characterized by the sudden onset of abdominal pain in association with elevation in blood or urine pancreatic enzyme levels. In about 80% of the cases, acute pancreatitis is mild and recovery is expected. However, in the remaining cases, acute pancreatitis is severe and can produce potentially life-threatening complications. The keys to clinical management are early recognition of severe acute pancreatitis, anticipation of complications, and prevention of recurrence.

CLINICAL FEATURES   Acute pancreatitis usually causes epigastric abdominal pain of acute onset. The pain tends to be constant and may radiate to the mid-back. Vomiting occurs in 80% of cases and provides little pain relief. Abdominal tenderness with guarding

occurs in half of cases but tends to be less severe than anticipated based on either the severity of reported pain or the degree of pancreatic inflammation (by abdominal CT or ultrasound), and this discrepancy results from the retroperitoneal location of the pancreas.

DIAGNOSIS   In a patient presenting with typical abdominal pain, a serum amylase or lipase level more then 2.5 times the upper limit of normal strongly suggests the diagnosis of acute pancreatitis. CT with intravenous contrast is the most sensitive method of assessing the degree of pancreatic injury, pancreatic necrosis, and local extrapancreatic complications but is usually unnecessary in mild pancreatitis. In most cases, acute pancreatitis is associated with an identifiable cause, with gallstones and alcohol ingestion being the most common factors (Table 44-2). When the cause of pancreatitis is identified early, this may suggest strategies to prevent ongoing pancreatic injury and to prevent recurrence.

MOLECULAR PATHOPHYSIOLOGY   A breakthrough in understanding the nature of acute pancreatitis came in 1896 when Chiari proposed that this condition represents autodigestion, rather than infection, of the pancreas. Autodigestion of the pancreas is a major threat because this organ normally produces enormous quantities of potentially dangerous digestive enzymes. To prevent autodigestion, three types of protective strategies are employed. In the first strategy, many enzymes (except amylase and lipase) are synthesized as proenzymes requiring enzymatic cleavage for activation. Activation normally occurs after the proenzymes are secreted by the pancreas into the intestinal lumen, where the intestinal brush border enzyme, enterokinase, cleaves trypsinogen activation peptide (TAP) from trypsinogen (the proenzyme) to generate trypsin (the active enzyme). Trypsin also activates trypsinogen and efficiently activates all other pancreatic digestive enzymes. Thus, the activation of trypsin in the duodenum is highly desirable as a key element in the rapid propagation of the digestive enzyme activation cascade.

In the pancreas, however, widespread activation of trypsin may be disastrous. This is especially important in humans because human trypsinogen has a propensity to autoactivate. Additional protective strategies are therefore necessary to prevent autoactivation of the digestive enzyme cascade in the pancreas. For example, within the acinar cell, autoactivation of trypsinogen and other digestive enzymes is limited by maintenance of low intracellular calcium, by maintenance of a neutral pH, and by the subcellular isolation of zymogen granules. Furthermore, because of a constant background of trypsinogen autoactivation, a limited amount of pancreatic secretory trypsin inhibitor (PSTI) is synthe-

sized with trypsinogen. If trypsin activity in the acinar cells exceeds the inhibitory capacity of PSTI, then a trypsin self-destruct mechanism is initiated in which the peptide chain connecting the two globular domains of trypsin is cut at arganine II (R117) by trypsin and mesotrypsin. Cleavage at this site permanently inactivates trypsin and other digestive enzymes with this design because the two halves of the molecule separate, thereby eliminating the active site of the enzyme. Finally, if active digestive enzymes escape from the pancreatic acinar cells into the intracellular space or plasma, they are inactivated by hepatocyte-derived α_2-macroglobulin and α_1-protease inhibitors. Thus, multiple protective strategies exist to prevent pancreatic autodigestion and acute pancreatitis.

The sequence of events initiating acute pancreatitis at the cellular level remains controversial, but several features are common to most models of experimental pancreatitis. Microscopically, zymogen granules accumulate at the apex of the acinar cells without being secreted. This functional block of secretion reflects the disruption of normal intracellular mechanisms, including the organization of microtubules and other proteins, which are necessary for exocytosis. The second feature is premature activation of digestive enzymes within the acinar cells. Although the intracellular site and mechanism responsible for digestive enzyme activation is uncertain, it seems clear that activation of these enzymes promotes "autodigestion" of pancreatic cells and initiates an inflammatory reaction.

Once an episode of acute pancreatitis is triggered, a characteristic inflammatory reaction occurs that is independent of the initiating factors. When acinar cells are damaged, they begin leaking activated digestive enzymes and other cellular elements into the interstitial space. This triggers an inflammatory response with the release of proinflammatory mediators, including interleukin-1 (IL-1), IL-2, IL-6, IL-8, tumor necrosis factor-α (TNF-α), and platelet-activating factor (PAF) (*see* Chapter 30). If pancreatic injury is mild, then the inflammatory response is self-limited and the process contained. However, if pancreatic injury is severe, then a more intense inflammatory response ensues. This inflammatory response is responsible for many of the local and systemic complications of acute pancreatitis. For example, the acute phase reaction and hypermetabolic state in severe acute pancreatitis with fever, decreased peripheral vascular resistance, and increased cardiac output are driven by cytokines. The pulmonary complications of hypoxia and adult respiratory distress syndrome (ARDS) largely develop because of the release of phospholipase A$_2$ from activated macrophages. Finally, the progression of pancreatic edema to

pancreatic necrosis may be driven, in part, by TNF-α. In animal models of acute pancreatitis, when proinflammatory cytokines are inhibited (i.e., PAF inhibitors) or the anti-inflammatory cytokine IL-10 is given, the severity of pancreatic injury is reduced, and survival improves. Although clinical intervention at the initiation of acute pancreatitis is impossible in most cases, the severity of acute pancreatitis may be reduced by early administration of agents that modify the immune response. Specific PAF inhibitors, for example, show great promise in this regard. Thus, acute pancreatitis could be considered to progress through three general phases: an acute injury from a variety of causes, a characteristic inflammatory response that depends on the severity of injury, followed by a healing phase.

GENETIC PREDISPOSITION TO ACUTE PANCREATITIS
Hereditary pancreatitis and familial hypertrygliceridemia predispose affected family members to acute pancreatitis. Hereditary pancreatitis represents a primary disorder of the pancreas, whereas patients with familial hypertrygliceridemia suffer from pancreatitis secondary to markedly elevated tryglycerides. Hereditary pancreatitis is a chronic, recurrent inflammatory disorder of the pancreas affecting family members in multiple generations. This disorder encompasses all features of acute pancreatitis and chronic pancreatitis. Thus, understanding the molecular basis

of pancreatic injury in hereditary pancreatitis may provide insight into the pathogenesis of other forms of acute and chronic pancreatitis.

Hereditary pancreatitis is inherited as an autosomal dominant trait with 80% penetration and variable expression. Nearly 100 kindreds have been reported since the genetic nature of this disorder was recognized by Comfort and Steinberg in 1952. The cause of hereditary pancreatitis was determined after the gene was localized to chromosome VII and then identified by sequencing of candidate genes. This analysis showed that hereditary pancreatitis is caused by a mutation that was in a cationic trypsinogen gene, resulting in an arginine to histidine (R-H) substitution at residue 117. This R117H mutation was observed in all patients with hereditary pancreatitis and in all obligate carriers from five kindreds, but not in individuals who married into the families nor in 140 unrelated individuals.

The effect of the R117H mutation on trypsinogen regulation has been studied through the X-ray crystal structure, molecular modeling, and protein digest analyses. Taken together, these data suggest that R117 occurs in a trypsin-sensitive site in the chain connecting the two globular domains of trypsinogen, and that the R117H mutation eliminates the final control of excessive trypsin activity in the pancreas by removing the natural cleavage site of the trypsin-like enzymes (Fig. 44-1). This finding explains why hereditary pancreatitis is an autosomal-dominant disorder. Even if only half of the trypsinogen molecules resist proteolytic degradation, this is sufficient to initiate the digestive enzyme activation cascade in the pancreas and therefore express the phenotype. This also explains why attacks of acute pancreatitis occur episodically rather than continually: Attacks occur when the rate of intrapancreatic trypsinogen activation overwhelms the protective effects of PSTI.

The discovery of the hereditary pancreatitis gene has had important implications for understanding the pathogenesis of pancreatitis in general. First, it showed that intrapancreatic protease activation is sufficient to cause acute pancreatitis in humans. Second, it emphasizes the importance of trypsinogen autoactivation in humans and may explain why it has been difficult to study acute pancreatitis in animal models in which trypsinogen is more stable. Finally, it demonstrates a direct link between recurrent acute pancreatitis and chronic pancreatitis.

MANAGEMENT AND TREATMENT Mild pancreatitis tends to be a self-limited process. Treatment is supportive and includes pancreatic rest (nothing by mouth), intravenous hydration, and analgesics. Patients usually recover within 3 days and can be discharged from the hospital when oral intake is adequate to prevent dehydration.

By contrast, severe pancreatitis can result in life-threatening complications requiring aggressive management. Because these patients are at risk for sudden death, ICU admission is often indicated during the initial phase of severe acute pancreatitis. To predict which patients with acute pancreatitis are most likely to develop life-threatening complications, several prognostic schemes have been developed (*see* Table 44-3). These schemes remain useful for assisting in identification of the subset of patient with acute pancreatitis for whom intensive monitoring is most appropriate.

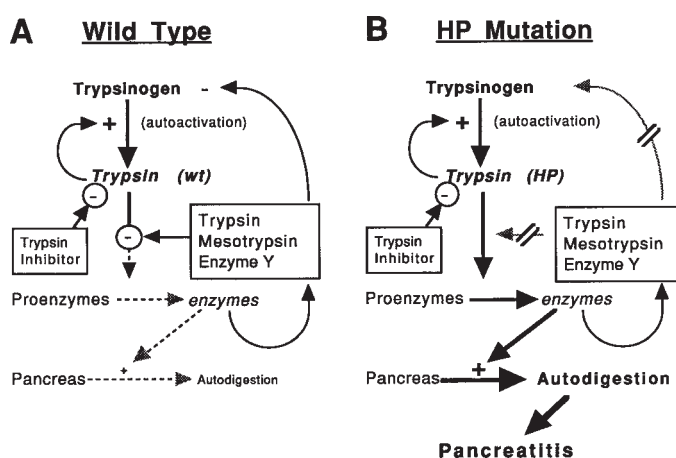
Early recognition is key to the management of the most common life-threatening complications of severe acute pancreatitis. Cardiovascular collapse and respiratory failure each may occur rapidly and require aggressive support. Multiorgan failure may develop as nutritional stores are depleted, and early nutritional support should


Figure 44-1 Model of trypsin self-destruct mechanism preventing pancreatic autodigestion. **(A)** Autoactivation and enzymatic activation of trypsinogen generate trace amounts of active trypsin within pancreatic acinar cells. Active trypsin is inhibited by a limited supply of trypsin inhibitor (PSTI). If trypsin activity exceeds the inhibitory capacity of PSTI, then proenzymes, including mesotrypsin and enzyme Y, are activated. These enzymes feed-back to inactivate wild-type (wt) trypsinogen, trypsin, and other zymogens. **(B)** Activation of mutant (HP) trypsin in amounts that exceed the inhibitory capacity of PSTI results in activation of proenzymes. Since the Arg 117 cleavage site for trypsin-like enzymes is replaced by His in the HP mutant trypsin, trypsin continues to activate trypsinogen and other zymogens unabated, leading to autodigestion of the pancreas and pancreatitis.

Table 44-3
Prognostic Criteria in Acute Pancreatitis

Ranson Criteria[a]	On admission
	Age >55 years
	Leukocyte count >16,000/mm^3
	Blood glucose >200 mg/dL
	Serum LDH >350 IU/L
	Serum GOT (SGOT/AST) >250 IU/dL
	At 48 h Hematocrit decreases >10%
	BUN rises >5 mg/dL
	Serum calcium <8 mg/dL
	Arterial PO2 <60 mmHg
	Base deficit >4 mEq/L
	Estimated fluid sequestration >6 L
Glasgow Criteria[b]	On Admission
	Age >55 years
	WBC count >15,000/µL
	Glucose > 180 mg/dL
	BUN >45 mg/dL
	PO2 <60 mmHg
	Albumin <3.2 g/dL
	Calcium <8 mg/dL
	LDH >600 IU/L

[a]Each factor is one point. Three or more points suggest severe acute pancreatitis

[b]Each factor is one point. Three or more points suggest severe acute pancreatitis

be considered. Sepsis and infected pancreatic necrosis also are commonly occurring complications. Prophylactic broad spectrum antibiotics such as imipenem or cefuroxime may reduce the frequency of these serious infectious complications.

FUTURE DIRECTIONS   Because the injury phase of acute pancreatitis is usually brief and early recognition is difficult, prevention is important. Understanding the sites and mechanisms of early enzyme activation, the factors controlling the inflammatory response, and the resulting pathologic events may be helpful in limiting pancreatic damage when pancreatic injury occurs. Now that the cause of hereditary pancreatitis is known and the gene has been cloned, transgene animal models can be developed to aid in the study of human pancreatitis, and strategies to prevent hereditary pancreatitis and other forms of pancreatitis can be developed.

Increasing knowledge of the cytokine networks are also important. PAF inhibitors that have been designed through computer simulations may be clinically useful in reducing the severity of severe acute pancreatitis if given within 24–48 hours. These advances offer new hope in the prevention and treatment of acute pancreatitis.

PANCREATIC INSUFFICIENCY

BACKGROUND   Chronic pancreatitis differs from acute pancreatitis in that there is permanent loss of exocrine function, resulting in pancreatic insufficiency. This is often associated with persistent pancreatic inflammation, leading to fibrosis and atrophy of the pancreas and to dilatation and distortion of the ducts. In adults, the most common cause of chronic pancreatitis and of pancreatic insufficiency is alcohol. In children, CF is the most frequent cause of pancreatic insufficiency, and chronic pancreatitis rarely occurs.

CF is a common disease with an incidence of 1/2000 in the United States. Roughly 90% of patients with CF develop pancreatic insufficiency, and pancreatic dysfunction is such a prominent feature of CF that the disease was initially termed fibrocystic disease of the pancreas. This section will discuss pancreatic insufficiency with an emphasis on the molecular pathogenesis of pancreatic insufficiency in CF.

CLINICAL FEATURES   The most important manifestations of pancreatic insufficiency result from malabsorption of incompletely digested nutrients. Malabsorption of fat and fat-soluble vitamins is usually prominent, leading to steatorrhea associated with delayed growth or weight loss. In patients with CF, meconium ileus or pulmonary symptoms often suggest the diagnosis before pancreatic insufficiency is evident. (The clinical features of CF are described further in Chapter 37.) In adults, the most common cause of pancreatic insufficiency is chronic pancreatitis resulting from alcoholism. Prominent symptoms include chronic midepigastric pain (often postprandial), weight loss (largely as a result of food avoidance), and steatorrhea. In addition, diabetes mellitus sometimes accompanies pancreatic insufficiency resulting from CF or advanced chronic pancreatitis.

DIAGNOSIS   A diagnosis of pancreatic insufficiency is suggested by the combination of steatorrhea (malabsorption of more than 5% of ingested fat during a 24- or 72-h stool collection) with normal bowel mucosal morphology (by biopsy) and function (e.g., D-xylose absorption). The diagnosis is supported by a clear response to pancreatic enzyme replacement therapy. When the diagnosis is uncertain, the reference standard for documenting pancreatic insufficiency is the secretin test. In this test, the duodenum is intubated to measure the amount of HCO_3^- and fluid secreted by the pancreas in response to secretin. Pancreatic insufficiency can also be detected by noninvasive tests such as the dual-label Schilling test, benteromide test, or Sudan stain.

In children and young adults with pancreatic insufficiency, a diagnosis of CF is most commonly established by the sweat test (quantitative pilocarpine iontophoresis). When a child with pancreatic insufficiency has a normal sweat test, the differential diagnosis includes Shwachman's syndrome (an autosomal recessive condition associated with neutropenia) and rare enzyme deficiencies (e.g., congenital lipase deficiency).

In adults, pancreatic insufficiency most often results from chronic pancreatitis. The most common cause of chronic pancreatitis is alcohol, although other conditions causing recurrent episodes of acute pancreatitis may also lead to chronic pancreatitis, including hereditary pancreatitis. The diagnosis of chronic pancreatitis is usually supported by evidence of pancreatic atrophy, ductal dilatation or calcification, or a mass/pseudocyst, as detected by one or more imaging procedures (abdominal radiograph, sonogram, CT or ERCP). It is noteworthy that serum amylase, lipase and trypsinogen levels are elevated in acute pancreatitis, but that these tests are usually within or below normal limits in patients with pancreatic insufficiency or chronic pancreatitis.

GENETIC BASIS OF DISEASE   The genetics of CF are presented in Chapter 37. Briefly, the inheritance pattern of CF is autosomal recessive, the gene causing CF was mapped to chromosome VII by linkage analysis, and this gene was identified by positional cloning. The protein product of this gene was named the CF transmembrane conductance regulator (CFTR), based on the anticipated function of the protein. The *CFTR* gene contains 27 exons, spans 250 kb, and encodes an integral membrane protein containing 1480 amino acids. In many types of epithelial cells, CFTR regulates ion fluxes across the plasma membrane by functioning as a cAMP-regulated Cl^- channel and as a regulator of other ion channels.

Much has been learned from mutational analyses of the *CFTR* gene. A single mutation, deletion of the phenylalanine normally in position 508 (ΔF508), accounts for roughly 70% of CF alleles. To date, over 700 additional mutations have been identified in other abnormal CF alleles, of which none account for more than 4% of CF alleles. CF patients vary widely with respect to the severity and progression of their pulmonary and pancreatic disease. In the case of CF pulmonary disease, it has been difficult to correlate subsets of CF-causing *CFTR* mutations with mild vs severe disease. This suggests that factors other than genotype play an important role in determining the progression of CF pulmonary disease. In the case of CF pancreatic disease, by contrast, clear genotype-phenotype correlations do exist. These correlations are so striking that they were recognized as part of the initial identification of the *CFTR* gene, in which it was noted that almost all ΔF508 homozygotes have pancreatic insufficiency. By contrast, pancreatic insufficiency is exceptional in compound heterozygotes with certain less common mutations (e.g., ΔF508/R117H). Thus, the *CFTR* genotype is the predominant factor determining the severity of CF pancreatic disease, whereas other factors play a greater role in determining the progression of CF lung disease.

Apart from CF, Shwachman's syndrome and hereditary pancreatitis are additional examples of inherited diseases in which a primary defect in pancreatic function leads to pancreatic insufficiency. It is not known whether genetic factors predispose to chronic pancreatitis or pancreatic insufficiency associated with other conditions such as alcoholism.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE   CF pancreatic disease is associated with characteristic pathologic and
Figure 44-2   A model summarizing the role of the cystic fibrosis transmembrane conductance regulator, CFTR, during exocrine secretion by the pancreas. CFTR normally occurs at the apical membranes of the epithelial cells lining small pancreatic ducts. When activated by cAMP, CFTR allows CL$^-$ ions to flow across the apical membrane into the duct lumen. Cl$^-$ ions in the duct lumen lead to HCO$_3^-$/Cl$^-$ exchange, and this tends to alkalinize the pancreatic juice. The secreted anions also draw Na$^+$ ions and H$_2$O into the lumen, thereby diluting the pancreatic juice. In cystic fibrosis, the absence of CFTR causes defective dilution and alkalinization of the pancreatic juice as it passes through the duct, leading eventually to obstruction of the ducts by inspissated secretions. (From Marino CR, Matovcik LM, Gorelick FS, Cohn JA. Localization of the cystic fibrosis transmembrane conductance regulator in pancreas. J Clin Invest 1991;88:712.)

physiologic abnormalities. Obstruction of the intralobular pancreatic ducts is an early pathologic event and impaired pancreatic secretion of bicarbonate is an early physiologic defect. These findings suggest that CFTR may normally function to prevent obstruction of the intralobular ducts and to promote bicarbonate secretion. These concepts are supported by available data concerning the localization of CFTR in human pancreas. The predominant site of CFTR mRNA and protein in pancreas is in the cells lining the proximal ductules. Within these duct epithelial cells, CFTR protein is predominantly detected as a component of the apical plasma membrane.

The distribution of CFTR in pancreas supports the model shown in Fig. 44-2, which postulates an important role for CFTR-associated Cl$^-$ channels in the regulation of ductular secretion. According to this model, secretory stimuli act via cAMP to activate CFTR and thereby open Cl$^-$ channels at the apical membrane of the duct cell. Because of the driving force provided by the Na$^+$/K$^+$–ATPase at the basolateral membrane, opening apical Cl$^-$ channels results in Cl$^-$ efflux across the apical membrane, leading to movement of Na$^+$ and water into the lumen and thereby diluting the pancreatic juice. Increased lumenal Cl$^-$ also activates Cl$^-$/HCO$_3^-$ exchange at the duct-cell apical membrane, and this alkalinizes the pancreatic juice. This model suggests that CFTR in the duct cell contributes to the normal dilution and alkalinization of pancreatic juice. In humans with CF, the ultimate result of the absence of CFTR at this site is a defect in the dilution and alkalinization of the protein-rich acinar secretions in the duct lumen, leading to the formation of protein plugs and thereby to pancreatic injury in CF.

Uncertainty remains concerning the precise mechanism by which pancreatic injury results from defective dilution and alkalinization of the pancreatic juice in CF. Dilution and alkalinization both may help to prevent precipitation of proteins as the pancreatic juice flows through the ducts. Beyond this, data from in vitro

models suggest that alkalinization of the lumen of the pancreatic duct system may also be important for maintaining normal acinar cell function during exocytosis.

MANAGEMENT AND THERAPY   Pancreatic enzyme replacement is the cornerstone of therapy for pancreatic insufficiency. Widely used enzyme preparations include a combination of lipase, amylase, and proteases. Because lipase is rapidly degraded at low pH, replacement enzymes are commonly administered either as enteric-coated microspheres or in combination with an H$_2$-receptor antagonist. Moderate enzyme doses are usually sufficient to achieve partial correction of steatorrhea with marked improvement in nutrition. Complete correction of steatorrhea is usually not possible even when very high enzyme doses are administered. High enzyme doses should be used with caution because they have been associated with colonic strictures.

Pain control is often the predominant issue in treating chronic pancreatitis. Structural causes for pain include ductal obstruction as a result of strictures, tumor, pseudocyts or stones, and a parenchymal compartment syndrome in which exocrine tissue is encased by fibrosis. Pain resulting from structural causes is typically intermittent and often occurs when serum cholecystokinin levels increase after a fat- or protein-rich meal. Medical therapy for this type of pain can include using gastric acid suppression, or pancreatic enzyme supplements. Narcotics may be added for more severe pain and may also reduce pancreatic exocrine secretion. Surgical options include procedures designed to relieve areas of ductal obstruction or fibrotic encasement of functional parenchyma. Chronic pancreatitis can also cause pain resulting from inflammation. This pain can be severe and unremitting, and surgical resection and celiac ganglion ablation are important management options.

FUTURE DIRECTIONS   To date, the genes causing two forms of pancreatic insufficiency have been identified, hereditary pancreatitis and CF. For both diseases, exciting progress has been made in defining the mechanisms leading to pancreatic dysfunction. As these mechanisms become better understood, this knowledge may lead to new strategies for delaying the progression of pancreatic injury. Such strategies could benefit patients with hereditary pancreatitis or CF and might also be of benefit to patients with exocrine pancreatic injury resulting from other causes. More generally, it is noteworthy that, even though alcohol is the most common cause of chronic pancreatic dysfunction, this condition only develops in a small fraction (<5%) of alcoholics. It seems plausible that genetic factors may predispose to pancreatic disease among alcoholics, and testing this hypothesis will be an important goal of future work.

45 Small- and Large-Bowel Dysfunction

Deborah C. Rubin

BACKGROUND

In the past 10–15 years, the application of molecular biological and genetic techniques to research in the luminal gastrointestinal tract epithelium has led to exciting advances in several broad areas. Many enterocyte-specific genes that play critical roles in the digestion and absorption of luminal nutrients have been cloned and sequenced. Their chromosomal localization, structure, and regulation of expression have been at least partially characterized. These studies have provided the groundwork for understanding the pathophysiology of several rare but well-described genetic disorders of small intestinal transport and have begun to clarify the mechanisms underlying more common gastrointestinal problems, such as lactase deficiency. In addition, sophisticated genetic and molecular techniques are finally being applied to the study of complex, multifaceted disorders, such as the inflammatory bowel diseases (IBDs), providing novel animal models to be used to understand their pathophysiology and to design new therapies. Of great potential clinical importance are the identification of a disease-susceptibility locus for Crohn's disease and of very specific susceptibility loci for celiac sprue. This chapter will attempt to summarize the important molecular and genetic developments relevant to the study of inflammatory bowel disease, celiac sprue, lactase deficiency, glucose-galactose malabsorption, and abeta-lipoproteinemia as several prominent examples of how molecular techniques can help advance the practice of gastrointestinal medicine.

INFLAMMATORY BOWEL DISEASE

CLINICAL FEATURES The inflammatory bowel diseases (IBDs) include Crohn's disease and ulcerative colitis. These are chronic inflammatory disorders of the gastrointestinal tract that are manifested by symptoms of diarrhea and abdominal pain. Although the clinical presentation may be quite similar, important differences in their underlying pathophysiology result in unique complications and long-term sequelae. In ulcerative colitis, the colon is the primary organ that is affected, but Crohn's disease can occur in any part of the gastrointestinal tract from mouth to anus. Ulcerative colitis is characterized by a predominantly superficial mucosal inflammation. In Crohn's disease, the inflammatory process is transmural and granulomatous, affecting all layers of the gastrointestinal tract, from mucosa to serosa (Table 45-1).

The etiology of these disorders is presently unknown. Recent studies of mice with targeted disruption of several cytokine or T-cell receptor genes, or of chimeric transgenic mice with disruption of the N cadherin gene, have provided promising new models of inflammatory bowel disease. These novel systems may help clarify the etiology and pathogenesis of these disorders and aid in the design of new therapeutic agents.

EPIDEMIOLOGY There are marked geographic differences in the incidence of IBD. The highest incidence rates are found in northern Europe and North America among Caucasians, ranging from 2–10 per 100,000. IBD appears to be more common in Jews of European or Ashkenazic origin, but not of Sephardic (African and Mediterranean) origin. The peak age of onset is from 15–25 years, and a second peak between 55–65 years of age has been suggested. There is a slight female predominance in the prevalence of both disorders. Although the disease is most common in Caucasians, the incidence in African Americans appears to be increasing. Cigaret smoking increases the risk of Crohn's disease but appears to be protective in ulcerative colitis.

CROHN'S DISEASE

Location of Disease, Signs, and Symptoms Crohn's disease can affect any part of the gastrointestinal tract. The most frequently involved sites are the ileocolon (40%), the small intestine alone (30%), or the colon alone (25%). Other regions of the gastrointestinal tract may also be involved, including the mouth, esophagus, and stomach. Anal involvement is common. Inflammation may involve the bowel in a segmental fashion, with "skip" areas of normal small and large intestine intermixed with patches of inflamed mucosa. Symptoms resulting from the inflammatory process include abdominal pain (especially in the right lower quadrant as a result of to terminal ileal involvement) and diarrhea. Other frequent symptoms include fever, weight loss, and malaise. A variety of extraintestinal manifestations including arthritis, uveitis/iritis, and skin diseases, such as erythema nodosum and pyoderma gangrenosum, are associated with inflammatory bowel disease. Signs of active Crohn's disease include right lower quadrant abdominal fullness, mass or tenderness, and a chronically ill appearance.

There are multiple causes of diarrhea in Crohn's disease. Enhanced secretion occurs in the small bowel and colon resulting from inflammation. Patients with ileal disease or ileal resection may malabsorb bile salts, since specific receptors and transport proteins are expressed only in the ileum. Unabsorbed bile acids then enter the colon where they produce a secretory diarrhea. Extensive terminal ileal involvement or resection of greater than

Table 45-1
Comparison of Crohn's Disease and Ulcerative Colitis

Clinical feature	Crohn's disease	Ulcerative colitis
Site of involvement	Entire gastrointestinal tract	Colon only
Pathology	Transmural granulomas	Mucosal inflammation
Extraintestinal manifestations	Skin Eyes Joints	Skin Eyes Joints
Complications	Strictures, fistulas, abscesses	Strictures, colon cancer, toxic megacolon
Treatment	Surgical removal of diseased segments avoided because of disease recurrence	Surgical removal of diseased colon is curative

100 cm of ileum results in fatty acid diarrhea from excessive loss of bile salts that cannot be replaced by enhanced hepatic production. Fat malabsorption may also result from bacterial overgrowth because of strictures of the small bowel, leading to deconjugation of bile salts. Crohn's disease has also been associated with lactase deficiency, resulting in maldigestion of milk and milk products. Undigested lactose then produces an osmotic diarrhea.

Complications   The transmural inflammatory process characteristic of Crohn's disease leads to many complications.

Fistulae   Inflammation may lead to ulceration through all layers of the bowel, resulting in the formation of fistulous tracts. Fistulas can form between the gut and any neighboring organ. Enteroenteric, enterocolonic, and enterocutaneous fistulas are frequently found in Crohn's disease. Less common are enterovesicular and enterovaginal fistulae.

Strictures   Strictures of the small or large bowel may result from chronic inflammation and can lead to intestinal obstruction. If severe and unremitting despite conservative management, strictures may require surgical resection to permit the continuation of normal enteral nutrition.

Perforations and Abscess Formation   Perforation of the small bowel or colon may precipitate the onset of an acute abdomen requiring immediate surgical intervention. Alternatively, perforations and fistulas may produce intraabdominal abscesses, another common complication of Crohn's disease. Abscesses may occur anywhere in the peritoneal cavity and must be drained to control sepsis.

Malnutrition and Malabsorption   Patients who have undergone surgical resection or who have extensive small bowel inflammation, fistulas, or strictures may suffer from short bowel syndrome with excessive diarrhea, volume loss, and malabsorption. These patients frequently require treatment with total parenteral nutrition (TPN) to maintain a normal nutritional and fluid and electrolyte status. As indicated above, loss of functional ileum may lead to fat malabsorption. Because of these complications, surgery is avoided whenever possible.

Nephrolithiasis   Kidney stones are most frequently composed of oxalate and are found in patients with ileal disease and fat malabsorption. Calcium, which normally binds to oxalate to produce insoluble calcium oxalate, is instead bound by fatty acids. This leads to the formation of sodium oxalate, which is readily absorbed through the colon, leading to hyperoxaluria and stone formation.

ULCERATIVE COLITIS

Location of Disease, Signs and Symptoms   Ulcerative colitis is characterized by a continuous mucosal inflammatory process affecting the colon. Inflammation may be confined to the rectum alone (ulcerative proctitis), may extend from the rectum to the left colon, or may involve the entire colon. Unlike Crohn's disease, at least part of the rectum is always involved, and the inflammatory process is continuous in affected areas (i.e., there are no skip regions). Abdominal pain, diarrhea, and gastrointestinal bleeding are common clinical presentations of this disorder. Anorexia and weight loss are occasionally present but are not common. Unlike Crohn's disease, which frequently follows a low-grade, chronic course, ulcerative colitis patients may present with fulminant colitis necessitating urgent colectomy. Physical findings include abdominal tenderness and grossly bloody stool on rectal examination. In fulminant cases, abdominal distention, massive hemorrhage, fever, and tachycardia may be present.

Complications   Toxic megacolon may occur in patients with acute fulminant colitis. The colon becomes atonic and dilated because of severe inflammation and can perforate if untreated. Toxic megacolon requires emergent surgical consultation and in many cases, removal of the colon. Strictures may result from chronic inflammation. Colon cancer is an important complication of long-standing ulcerative colitis. Although the precise risk of colon cancer is not clear, it is increased in patients with disease for greater than 8–10 years and is higher in patients with pan-colitis compared to left-sided colitis alone. To prevent colon cancer, either prophylactic colectomy or yearly colonoscopic screening for dysplasia/cancer is recommended, depending on the patient's preference and disease activity. A recent important advance has been the development of the ileoanal anastomosis. Instead of an ileostomy, bowel continuity is maintained by creating an ileal reservoir in place of the rectum. This has led to greater acceptance of surgical options in the treatment of ulcerative colitis.

EXTRAINTESTINAL MANIFESTATIONS   There are multiple extraintestinal manifestations of IBD, including arthritis, skin and ocular diseases, liver involvement, kidney stones, and osteoporosis. The arthritic complaints include colitic arthritis, ankylosing spondylitis, and sacroiliitis. The large joints are generally involved in colitic arthritis. Arthritic complaints generally respond to adequate treatment of the bowel disease. Symptoms resulting from ankylosing spondylitis and sacroiliitis may be severe and more refractory to treatment. Skin manifestations of IBD include pyoderma gangrenosum and erythema nodosum. Ocular diseases include uveitis and episcleritis. Liver involvement may manifest as sclerosing cholangitis or pericholangitis. Cholesterol gallstones occur in Crohn's disease if there is ileal involvement or after resection, resulting in bile salt malabsorption. Finally, kidney stones may form in patients with small intestinal Crohn's disease and fat malabsorption and are usually composed of calcium oxalate or urate. Osteoporosis may result from chronic fat malabsorption, leading to calcium and vitamin D deficiency, and from chronic corticosteroid therapy.

DIAGNOSIS

History and Physical Exam   A history of bloody diarrhea, abdominal pain, and fever should lead to a strong suspicion for ulcerative colitis. Symptoms in Crohn's disease are frequently more indolent and chronic, including intermittent diarrhea and fevers, abdominal pain, and weight loss. Physical findings in

ulcerative colitis may include abdominal tenderness, and in fulminant disease, distention, decreased bowel sounds, and an acute abdomen. In Crohn's disease, abdominal tenderness and an inflammatory abdominal mass may be present, particularly in the right lower quadrant. The perianal and perirectal regions should be examined for signs of fistulization and abscess. Signs of extraintestinal disease, including arthritis, ocular inflammation, and skin nodules or ulcers may be detected.

Laboratory and Pathologic Examinations   There is no specific laboratory test that is diagnostic of ulcerative colitis or Crohn's disease. An elevated white blood cell count can be seen in active disease or may be an indicator of sepsis as a result of perforation or abscess formation in Crohn's disease. Anemia may result from gastrointestinal bleeding or nutrient deficiencies (e.g., vitamin B_{12} from ileal Crohn's disease, decreased iron absorption in duodenal Crohn's disease). Erythrocyte sedimentation rate may be elevated in active disease. Nutritional parameters such as blood total protein and albumin levels may also be deranged in Crohn's disease.

Pathologic specimens (endoscopic biopsies or surgical resection) may reveal evidence of active inflammation. A characteristic finding of colitis are crypt abscesses, in which neutrophils invade the crypts. Granulomas are more characteristic of Crohn's disease. Crypt atrophy and distortion are also seen, as is acute and chronic inflammation with lymphocytes and eosinophils, and mucin depletion. Ulceration of the mucosa occurs in ulcerative colitis, but the presence of transmural inflammation is most characteristic of Crohn's disease.

Radiological and Endoscopic Studies   Evaluation of the mucosa for the presence of active disease can be achieved by endoscopic examination. In patients with symptoms of colitis, colonoscopy may aid in the initial diagnosis and is required to determine the extent of disease activity. The mucosal surface is observed for the presence of erythema, edema, granularity, friability, and ulceration. The extent of colonic involvement may help differentiate Crohn's disease from ulcerative colitis. The presence of skip areas, in which normal mucosa is intermixed with inflamed mucosa, is most characteristic of Crohn's disease, whereas, in ulcerative colitis, inflammation is continuous. During colonoscopy, the terminal ileum may be entered and evaluated for involvement by Crohn's disease. Direct visualization of the upper gastrointestinal tract by routine upper endoscopy or small-bowel enteroscopy may also help to establish the presence of Crohn's disease.

Radiological examination is an important part of the diagnostic evaluation of patients with IBD. Contrast studies are useful for detecting strictures and fistulas, as well as for assessing disease activity in regions of the small intestine that are inaccessible to routine endoscopy. Patients with ulcerative colitis may demonstrate typical findings on barium enema, including straightening and shortening of the colon, loss of normal haustrations, and inflammatory polyps or malignancy. Mucosal detail is more difficult to assess with radiography; endoscopic examination is generally preferred. In patients with very active colitis, radiographic examination is avoided because of the fear of inducing toxic megacolon as a result of the introduction of air and barium. Similarly, colonoscopic testing is performed with caution and usually in a limited manner. Computerized axial tomographic scanning is an important diagnostic modality, particularly for abscess detection in Crohn's disease. If accessible, CT-directed drainage of abscess collections may be performed.

Genetic Basis   Genetic factors have been suggested to play a role in the pathogenesis of IBD because of an increased incidence in families, specific ethnic groups, and in twins. Approximately 10–20% of patients with IBD have a family history, and the risk for first-degree relatives to develop IBD is 2–5%. Twin studies indicate that monozygotic twins have a higher concordance rate than dizygotic twins. The complex clinical manifestations of these diseases suggest a heterogeneous genetic basis, confirmed by heterogeneity in HLA class II and antineutrophil cytoplasmic antibody markers in ulcerative colitis. Since inflammatory T cells appear to play a role in IBD pathogenesis, attention has focused on MHC class II genes. By using a PCR-sequence-specific oligonucleotide approach to type HLA class II DRB1, DRB3, DRB4, and DRB5 loci in patients and matched controls, a positive association was observed with the HLA-DRB3*0301 allele in Crohn's disease, but not in ulcerative colitis. Yet, a recent study of two families with Crohn's disease has identified a disease-susceptibility locus on chromosome 16, centered around loci D16S409 and D16S419. A nonparametric two-point sibling-pair linkage method was utilized. This region of the genome contains several genes that may be involved in the pathogenesis of Crohn's disease, including CD11 integrin cluster, CD19, sialophorin, and the IL-4 receptor. However, the relative risk for siblings of patients with Crohn's disease with this locus was estimated to be 1.3, indicating that surely there are other susceptibility loci.

Molecular Pathophysiology   The etiology of the IBDs is presently unknown. One widely accepted hypothesis is that IBD results from an abnormal host immune response to normal gut components such as microflora, nutrients, or cellular constituents. This may also be accompanied by a primary defect in gut permeability that allows antigens to nonspecifically "leak" through the mucosa and thereby stimulate an inflammatory response. The possible role of an infectious agent such as Mycobacterium paratuberculosis has also been postulated.

The search for the underlying host immune defect(s) has been the subject of much research. A variety of immune abnormalities have been identified in patients with IBD but the molecular basis has not yet been clarified. However, recent studies using embryonic stem cell techniques to selectively delete immune mediator and other genes have produced novel animal models of IBD that have provided some insight into the molecular pathophysiology.

Disruption of Immunoregulatory Genes or N-cadherin Leads to IBD in Mice   The specific role of a gene can be determined in the whole animal in "loss of function" experiments that utilize embryonic stem-cell techniques. Mutations in specific target genes can be created in these cells to delete the gene or produce a sequence that encodes a nonfunctional protein. The mutated stem cells are injected into a mouse blastocyst and grown in a host mouse. Heterozygous mice are then backcrossed to create homozygous mutants.

In this manner, targeted deletion of various immune mediator genes has been performed. Interestingly, when IL-2, IL-10, major histocompatibility class II or T-cell receptor α or β genes are deleted, gross inflammation of the bowel is produced in mice. Similarly, a dominant negative N-cadherin mutation, specifically targeted to intestinal cells by a gut-specific promoter, produced a marked depletion in E-cadherin expression in the crypt and villus and resulted in inflammation of the small bowel.

IL-2 is produced by activated T cells and is an important regulator of immune responses. It increases T cell proliferation, leads to differentiation of B cells, and activates macrophages, NK cells,

and LAK cells. IL-10 is produced by T helper cell subset 2, macrophages, keratinocytes, Ly-1 B cells, and thymocytes. It increases MHC class II expression on B cells and suppresses macrophage activation in vitro. IL-10 inhibits IL-1, IL-6, and tumor necrosis factor-α (TNF-α) production by activated macrophages.

Deletion of the IL-2 or IL-10 gene produced inflammation of the intestine, but with different clinical features. Deletion of IL-2 led to colonic disease, with diarrhea, rectal prolapse, and bleeding. Pathological examination of the colon showed crypt abscesses, ulceration, goblet-cell depletion, and epithelial dysplasia. MHC class II expression, normally limited to the small intestine, was seen in the colon. In contrast, deletion of IL-10 led to a chronic enterocolitis affecting the entire gastrointestinal tract, with growth retardation and iron deficiency anemia. Mucosal inflammation, with villus loss, mucosal gastrointestinal erosions, and crypt hyperplasia were found in small intestine and colon. MHC class II expression was aberrantly enhanced in small bowel and colonic epithelium. The onset of disease in the majority of mice was relatively rapid; by 3–4 weeks, growth retardation was noted.

Interestingly, in both models, maintenance in a pathogen-free environment greatly diminished the intestinal inflammation. IL-10 mice had disease limited to the proximal colon only, and IL-2 mice were disease-free. A third model of inflammatory bowel disease was generated in T cell receptor α or β mutants, which lack $\alpha\beta$ T cells. These mice developed colonic inflammation but no diarrhea or bleeding.

Not only can immune cell defects produce intestinal inflammation, but disruption of the protective epithelial barrier may also lead to IBD. Recent studies focused on the function of E-cadherin in the intestine. A dominant negative N-cadherin mutant was linked to an intestine-specific promoter and thus was selectively disrupted in the gut, in villus as well as crypt cells. This resulted in markedly decreased expression of E-cadherin, with gross disruption of the epithelial barrier and severe mucosal inflammation. The small intestine was selectively affected, with lymphoid hyperplasia, blunted villi, cryptitis and crypt abscesses, mucosal ulcerations, and eventually adenoma formation.

Although these models of IBD are diverse, they support several hypotheses regarding the etiology of these disorders. Disruption of the epithelial barrier can lead to intestinal inflammation, even in the presence of a normal immune system. Selective immune defects that lead to the unopposed action of B cells can produce inflammation of the gut. Also, the intestine is clearly vulnerable to inflammation because of constant external antigen exposure and the presence of luminal substances.

MANAGEMENT

Medical Therapy   (Table 45-2) Since the underlying cause of IBD is still unknown, therapy is presently directed toward controlling the intestinal inflammatory response. One of the mainstays of treatment are oral and enema compounds containing 5 aminosalicylic acid (5-ASA), available in several different forms. These compounds are effective as single agents in the treatment of mild to moderate ulcerative or Crohn's colitis. They are used in conjunction with corticosteroids in the treatment of severe disease. Although their precise mechanism of action is unknown, these drugs are thought to inhibit leukotriene synthesis via their inhibition of neutrophil lipoxygenase, particularly LTB4. Sulfasalazine was the first of these agents and consists of 5-ASA bound to a sulfapyridine residue to prevent its premature absorption in the small intestine. Colonic bacteria are required to release the

5-ASA component. However, many side effects result predominantly from the sulfapyridine component, including dose-related effects, such as headache, nausea, vomiting, anorexia, fever, and rash. Idiosyncratic, hypersensitivity responses include rash, hemolytic and aplastic anemia, and agranulocytosis. Also, long-term usage in young men is frequently limited by its adverse effects on sperm count and morphology. Therefore, several compounds have been formulated containing 5-ASA alone, with various modifications to facilitate its delivery to the small intestine and colon, or preferentially to the ileum and colon, without excessive systemic absorption prior to reaching its preferred site. These include Pentasa, Asacol, and Dipentum. Pentasa and Asacol are released by pH-dependent mechanisms. Pentasa is an ethylcellulose-coated form of mesalamine (5-ASA) that is released throughout the small intestine and colon. Asacol is coated with an acrylic-based resin that dissolves at pH7.0 or greater, facilitating its release only at the terminal ileum and colon. Dipentum consists of two 5-ASA molecules linked by an azo bond that is cleaved in the colon. These newer formulations clearly have fewer side effects than sulfasalazine and thus have led to an expanded pharmacologic armamentarium. Mesalamine in enema form (Rowasa enemas) is a valuable treatment for ulcerative proctitis.

Corticosteroids are important in the therapy of moderate to severe IBD because of their broad anti-inflammatory actions. Corticosteroids are used in the treatment of active ulcerative colitis as well as Crohn's disease of the small and large bowel. Because of the numerous side effects attendant with chronic glucocorticoid usage, long-term therapy for IBD is avoided. There are no data supporting its use in maintaining disease remission, unlike 5-aminosalicylate-containing compounds in colitis.

Antibiotics are critical for the treatment of infectious complications of Crohn's disease, such as sepsis, abscess formation, and small-bowel bacterial overgrowth. Metronidazole has been used successfully to treat perianal disease and colonic Crohn's disease.

Immunosuppressive agents such as azathioprine and its metabolite, 6 mercaptopurine, are used in Crohn's disease, and to a lesser extent in ulcerative colitis, for steroid-dependent and poorly controlled patients. Treatment is generally begun in patients who cannot be tapered from corticosteroids because of recurrent symptoms and who have major side effects from them, such as osteoporosis, hypertension, cataracts, or glucose intolerance. Alternatively, immunosuppressive agents may be added to treat the patient with refractory disease inadequately treated with corticosteroid and 5-ASA compounds. Immunosuppressive agents are also used in patients with ulcerative colitis and refractory proctitis, but less commonly.

Less-well-studied, but presently being actively investigated for use in severe ulcerative colitis and Crohn's disease, are methotrexate and cyclosporine. There are data that support the use of intravenous cyclosporine for severe colitis as a last-ditch medical effort to avoid surgical intervention. Methotrexate may be used as an alternative medication for steroid-dependent patients, but its efficacy is still unproved.

Surgical Treatment In fulminant ulcerative colitis that is refractory to medical therapy, total colectomy may be unavoidable. In addition, surgical resection may be required for corticosteroid-dependent patients with ulcerative colitis who have major steroid-induced side effects. Colectomy may also be performed in patients with colonic dysplasia or carcinoma, or prophylactically to prevent colon cancer in patients with >10-year history of active ulcerative colitis. As an alternative to prophylactic colectomy, yearly colonoscopic screening for colon cancer may be performed after 8–10 years of disease. The major problems with this approach are that cancers in ulcerative colitis arise from flat mucosa and therefore may be missed, and accurate grading of dysplasia is difficult. Colectomy is curative in ulcerative colitis, and ileoanal anastomotic procedures eliminate the need for an ileostomy. This surgical procedure is not an option for patients with Crohn's disease, since there is a high incidence of recurrent disease in the ileal pouch leading to diarrhea, bleeding, pain, severe malfunction of the pouch, and, eventually, the need for revision. In addition, surgery is not curative in Crohn's disease since it recurs commonly, in all parts of the intestinal tract. Therefore, the approach to patients with Crohn's disease is very cautious, and surgical intervention is avoided whenever possible. However, limited resection is often performed to relieve obstruction as a result of strictures, to repair perforations, or for abscess drainage.

Future Directions Targeted gene knockout studies in mice and attempts to localize a susceptibility locus for Crohn's disease have been very exciting developments in the past several years. The novel mouse models should prove useful for elucidating the pathogenesis of these disorders and for designing more effective therapies. The identification of the gene(s) that are responsible for the familial risk of IBD will undoubtedly continue to be a major research focus.

CELIAC SPRUE

CLINICAL FEATURES Celiac sprue is a chronic disease of the small intestinal mucosa resulting from exposure to dietary proteins contained in wheat, rye, and barley. The alcohol-soluble component of wheat-derived gluten, or gliadin, and similar proteins derived from rye, barley, and oats, are toxic to the mucosa of susceptible individuals. In classic celiac sprue, the small bowel demonstrates complete villus atrophy and marked crypt hyper-

plasia, resulting in malabsorption and diarrhea. It is clear that specific host genetic factors are required in combination with exposure to gliadin to damage the epithelium. Linkage to histocompatibility antigen loci has been recognized for many years. Recent progress has been made in identifying specific peptide motifs in gliadin that are responsible for the adverse small bowel effects, in defining the features of the immune response, and in clarifying the genetic basis of celiac sprue.

CLINICAL PRESENTATION Patients with celiac sprue exhibit a broad spectrum of clinical presentations. In children, the disease tends to occur in the first 3 years of life. In adults, the peak incidence is in the third decade, but may occur at any age. In the classic clinical presentation, extensive loss of normal villi throughout the small intestine leads to gross malabsorption and steatorrhea, severe weight loss, wasting, multiple vitamin deficiencies, and abdominal distention. The vitamin deficiencies may lead to anemia (B12, folate, iron) or a bleeding diathesis (vitamin K). Neurologic symptoms such as peripheral neuropathy and paresthesias are also common. In other cases, patients may be asymptomatic or complain only of mild abdominal discomfort, malaise, bloating, and diarrhea. Those with more patchy proximal intestinal involvement may present simply with iron or folate deficiency or osteomalacia. Relatives of patients with celiac sprue who are screened for the disease often have mild illness or may be completely asymptomatic.

Celiac sprue is frequently associated with other disorders. Dermatitis herpetiformis is characterized by severely pruritic papulovesicular lesions of the skin. The majority of afflicted patients show intestinal biopsy findings characteristic of celiac sprue. These patients are often only mildly affected by the gut lesion and may even be asymptomatic. Isolated nutrient deficiencies may be the only clinical manifestation. Both the intestinal and skin lesions resolve with gluten withdrawal.

Other diseases that are associated with celiac sprue include insulin-dependent diabetes mellitus (50-fold higher incidence of celiac disease in patients with diabetes), thyroid disease, and selective IgA deficiency, which share similar HLA haplotypes. Complications of celiac sprue include the development of T-cell lymphoma or other gastrointestinal malignancies. Ulcerative jejunoileitis is a serious complication resulting in ulceration and stricture of the small bowel with bleeding, perforation, and obstruction. Finally, patients may become refractory to removal of gluten from the diet and may require treatment with corticosteroids or immunosuppressive agents.

EPIDEMIOLOGY Celiac sprue is most prevalent in Caucasians, particularly in Northern Europe. The highest prevalence has been reported in Ireland at a frequency of 1:300 but the more typical incidence in Europe is 1–2/10,000 population. Asians from India and Pakistan are also frequently affected, but the disease is rare in Japanese, Chinese, and African peoples. A study of Minnesota residents who were symptomatic and had celiac sprue documented by biopsy and response to a gluten-free diet revealed an incidence of celiac sprue of 1.2/100,000 person-years in the United States, with a prevalence of 21.8/100,000. Recent studies have indicated a decrease in the prevalence of childhood celiac sprue in several European countries, perhaps as a result of changes in feeding or other unidentified environmental factors.

DIAGNOSIS A valuable test for the diagnosis of celiac sprue is the small intestinal biopsy. Forceps biopsies of the duodenum or proximal jejunum can be obtained during routine upper endoscopy,

or peroral capsule biopsy techniques may be used. Biopsy should be performed prior to the initiation of gluten withdrawal and can also be repeated after removal of gluten from the diet to document an adequate response. Typical findings on biopsy are absence or atrophy of villi, crypt elongation and hyperplasia, and increased immune cell infiltrate. There is a marked increase in intraepithelial lymphocytes and infiltration of the lamina propria with lymphocytes, eosinophils, and macrophages. Since the biopsy findings in celiac sprue are not unique and can be seen in tropical sprue, lymphoma, viral or eosinophilic gastroenteritis, common variable immunodeficiency, or parasitic infection, the clinical response to removal of gluten in conjunction with biopsy is critical for definitively making the diagnosis. Rechallenge with gluten and rebiopsy is rarely recommended (except in equivocal cases).

Antibody tests have also been used in conjunction with small bowel biopsy to confirm the diagnosis. Serum antigliadin antibodies are positive in approximately 90% of patients with untreated sprue but are also found in other disorders such as sarcoidosis and rheumatoid arthritis. Antiendomysial antibodies, which are directed against extracellular matrix components, are also elevated in patients with histologic abnormalities on biopsy, detecting >95% of untreated patients. Antireticulin antibodies may also be elevated, but are much less sensitive, although more specific than the antigliadin antibody.

GENETIC BASIS   Genetics plays an important role in celiac sprue, but in conjunction with environmental and other factors. The evidence for a genetic basis comes from family and twin studies. Approximately 8–12% of family members of patients with celiac sprue are also affected, as determined by intestinal biopsy. Interestingly, only 50% of all family members with abnormal biopsies manifest symptoms of the disease. In identical twins, there is 70% concordance for celiac sprue, indicating that factors other than genetics play a role in disease susceptibility.

The linkage of celiac sprue with specific major histocompatibility complex genes has been recognized for many years. There is a very strong association with HLA Class II haplotypes. In Northern Europeans, the DR w17 and DQ w2 serologic specificities are very common. HLA DQ2 is present in 90% of patients with celiac sprue. Molecular analysis indicates that a specific DQ alpha and beta chain molecule encoded by DQA1*0501 and DQB1*0201 is found in 99% of Scandinavians with sprue. In Southern European populations, the same HLA-DQ molecule is expressed on an HLA-DR7 and DR5 (or DR11/DR7, DR12/DR7) haplotype, as opposed to HLA DR3, DQ2 (or HLA-DR17) in Northern Europeans. These molecules are necessary but not sufficient for developing the disease, since HLA identical siblings have only 40–50% concordance for this disease, and only a small percentage of the population that carries these alleles develops sprue. In addition, some populations do not demonstrate the same very high percentage of patients with HLA-DQ2, but instead are DR4-positive. Sequence analysis of the HLA DQ alleles from patients with celiac disease revealed no mutations when compared to normal individuals. This suggests that molecules encoded in regions outside of this HLA locus are required for generating the disease, and there may be different genetic subgroups.

MOLECULAR PATHOPHYSIOLOGY   The biochemistry of gluten and gliadin has been intensively studied to identify the protein moieties that are responsible for toxicity. The alcohol-soluble component of gluten, gliadin, appears to be responsible for the disease. Gliadin and similar proteins derived from barley and rye contain many proline and glutamine residues, and intestinal injury is dependent on the presence of these amino acids. Oral or rectal challenge with purified oligopeptides, derived from various parts of the gliadins containing proline and glutamine residues, indicates that specific motifs produce mucosal damage. Oral challenge with oligopeptides showed a C-terminal peptide and one derived from amino acids 31–49 of A-gliadin produced histological changes consistent with sprue. Rectal challenge with gliadin leads to a mucosal inflammatory response, with an influx of intraepithelial lymphocytes and adhesion molecule expression.

Based on its sequence homology to A-gliadin, another environmental factor that may play a role in the pathogenesis of celiac sprue is a history of adenovirus 12 infection. There is a region of homology between the adenovirus serotype 12 E1b protein to A-gliadin that spans 12 amino acids, with 8 identical residues. In addition, almost 90% of patients with untreated celiac sprue had serologic evidence of prior adenovirus 12 infection, compared to only 17% of disease controls. These data suggest that mechanisms of molecular mimicry may be involved in the pathogenesis of this disorder, in which T cells recognize peptides in common to gliadin and viral proteins. However, adenovirus 12 DNA has not been detected in intestinal samples, and peptide challenge with an oligopeptide derived from the homologous region has not been shown to produce intestinal injury.

MANAGEMENT   Removal of all gluten from the diet is the primary therapy for celiac sprue. Wheat, rye, oats, and barley-containing products must be eliminated from the diet, since gluten and other related prolamins can produce injury. This restricted diet must be maintained lifelong. Patients may initially exhibit lactose intolerance because of villus atrophy and brush border enzyme deficiency, but this should resolve with treatment.

DISORDERS OF SMALL INTESTINAL ABSORPTION AND TRANSPORT

The brush border of the small intestinal enterocyte contains disaccharidases, peptidases, and transport proteins that are responsible for the absorption of ingested nutrients. In the past several years, progress has been made in clarifying the molecular basis of several disorders characterized by selective malabsorption of carbohydrates or lipids. In this section, a summary of recent advances in understanding the pathophysiology underlying several of the more common of these defects is presented.

LACTASE DEFICIENCY

CLINICAL FEATURES AND EPIDEMIOLOGY   Lactase is one of the best-studied of the brush border enzymes. It is responsible for the hydrolysis of lactose into glucose and galactose. Several clinical categories of lactase deficiency have been described. Congenital lactase deficiency is a rare autosomal recessive disorder, resulting in milk intolerance from birth. Much more common is the onset of diminished enzyme activity in childhood or adolescence and lasting into adulthood, also known as adult-onset hypolactasia. Loss of brush border lactase activity may also result from other small intestinal disorders, such as Crohn's disease, celiac sprue, viral illnesses, or other infections.

Loss of lactase activity beginning in childhood/adolescence occurs in the majority of humans throughout the world except for Caucasian populations. In particular, most white northern Europeans and their descendants in North America and Australia (populations that were traditionally cattle farmers and thus persistent

milk drinkers) retain high lactase activity lifelong. The prevalence of lactase deficiency throughout the world supports the hypothesis that the decline in lactase activity with age is a "normal" event in response to weaning, common to all land mammals. Persistence of lactase activity has therefore been postulated to be the result of a genetic mutation that occurred in milk-drinking populations, leading to a survival advantage, since milk drinkers might be healthier. Alternatively, it was thought that milk-drinking past normal weaning from the breast might directly influence lactase activity, but this has been disproved.

Ingestion of milk and milk products in deficient individuals leads to abdominal pain, diarrhea, bloating, and excessive flatulence resulting from unabsorbed lactose in the lumen. This results in increased small-bowel fluid. Fermentation of lactose in the colon produces hydrogen, methane, and carbon dioxide gas. Removal of lactose-containing products in the diet leads to resolution of these symptoms.

DIAGNOSIS A lactose tolerance test may be performed, which consists of administering 50 g of lactose orally. If sufficient lactase activity is present, blood glucose levels will rise by >20 mg/dL over a 2-h period. Lactase deficiency is diagnosed by the lack of serum glucose elevation and, frequently, the onset of symptoms of malabsorption, with gas, diarrhea, bloating, and abdominal pain. If the serum glucose increases, yet symptoms also occur, one must consider occult diabetes mellitus. Alternatively, hydrogen breath testing a trial of dietary lactose avoidance may be attempted. After restriction of oral intake of milk and milk products, the patient is assessed for symptom resolution. Finally, small bowel biopsy allows for definitive diagnosis, but is unnecessary given the adequacy of the other two approaches.

GENETIC BASIS AND MOLECULAR PATHOPHYSIOLOGY As determined by population and family studies, adult-onset hypolactasia is an autosomal-recessive trait, and persistence of lactase activity is autosomal-dominant. The molecular basis for lactase persistence/nonpersistence has been the subject of intensive investigation. In the majority of studies, lactase-specific activity and protein levels correlate very well with mRNA concentrations, indicating transcriptional regulation of lactase expression. However, sequence analysis of the lactase cDNA and 1 kb of its promoter region has not revealed differences between sequences from persistent and nonpersistent patients. Yet, recent studies using known DNA marker polymorphisms in the exons of the lactase gene have suggested that *cis*-acting elements are responsible for the persistence/nonpersistence phenotype, based on differences in level of expression of lactase comparing one allele to the other. On the other hand, characterization of trans-acting factors that regulate lactase expression have revealed that levels of NF-LPH-1, an intestine-specific transactivator that binds to a sequence close to the TATA box, are high in newborn pigs with high lactase activity and low in adult pigs with low lactase activity. Still other data suggest that there is a second phenotype of lactase deficiency, in which posttranslational processing of lactase-phlorizin is altered. Thus, the precise molecular mechanisms underlying lactase persistence/nonpersistence are still controversial.

MANAGEMENT The treatment of symptomatic lactase deficiency consists of removal of lactose-containing nutrients from the diet and/or the use of oral enzyme replacement therapy. It is preferable to continue some milk and dairy food ingestion because of their rich calcium stores, especially in children and in women who are prone to osteoporosis. Lactase oral preparations are available in capsules or tablets and can be chewed. Replacement pills are taken with meals and titrated to diminish symptoms. Lactase may also be added directly to milk and ingested after an overnight incubation, or pretreated milk can be purchased.

FUTURE DIRECTIONS The ready availability of oral lactase capsules and the ease of treatment of symptoms by dietary avoidance or supplementation makes more sophisticated approaches to treatment, such as gene therapy, unnecessary. The major research interest still lies in determining how epidemiologic observations are linked to genetics; i.e., what are the genetic alterations that led to lactase persistence in the milk-drinking populations of the world, and are there differences among different ethnic or racial groups? These are questions of great interest to population and evolutionary geneticists.

GLUCOSE–GALACTOSE MALABSORPTION

CLINICAL FEATURES Glucose–galactose malabsorption is a rare congenital disorder in which enterocytic transport of glucose and galactose is absent, resulting from mutation of the gene encoding the Na$^+$/glucose cotransporter SGLT-1. This disease is characterized by the onset of profuse watery diarrhea in newborns that responds to the removal of dietary sources of glucose and galactose. Diarrhea usually develops within 4 d of birth. The diarrhea is so severe that dehydration is frequent. As in other diseases of carbohydrate absorption, the presence of unabsorbed sugars leads to an increased osmotic load in the small intestine with increased luminal fluid. Laboratory findings include an acidic stool pH because of colonic bacterial metabolism of unabsorbed sugar. In addition, sugar is found in the urine, consistent with the expression of SGLT-1 in the kidney. Oral monosaccharide tolerance tests reveal that absorption of glucose and galactose, but not fructose, is impaired.

GENETICS AND MOLECULAR PATHOPHYSIOLOGY Glucose galactose malabsorption is an autosomal recessive disease. The precise incidence of this disorder has not been determined, but it is clearly rare, as indicated by the few case reports in the literature. Frequently, there is a history of consanguineous marriage.

Expression cloning of the cDNA that encodes SGLT-1, the Na/glucose cotransporter, by Wright's group, provided a major breakthrough in understanding pathophysiology of this disorder. Specific mutations in SGLT-1 lead to loss of transporter function in humans, resulting in glucose and galactose malabsorption. Analysis of cDNA reverse-transcribed from RNA from intestinal biopsies of two affected sisters showed a single missense mutation, with a single base change from G to A at position 92, changing an aspartate to an asparagine. Their parents were heterozygous for this mutation. The autosomal recessive inheritance of this disorder was confirmed. The mutant SGLT1 mRNA was expressed in *Xenopus laevis* oocytes and compared to the normal SGLT1 mRNA for ability to transport a glucose analog, α-methyl d glucopyranoside. As anticipated, the mutant SGLT1 demonstrated no detectable transport activity.

Subsequently, 30 other patients have been screened for mutations in SGLT1. The mutations included missense, nonsense, and frame shift mutations, and some occurred in splice sites at intron-exon boundaries. Two areas were identified as "hot spots" for missense mutations, between residues 289–304 and 369–405. Analysis of the mutant proteins indicated that loss of transporter activity was a result of production of truncated or nonfunctional

protein, defective trafficking of the transporter, or defects in the transport cycle. The SGLT1 gene has been localized to chromosome 22 on the distal q arm.

MANAGEMENT The treatment of glucose–galactose malabsorption is the immediate removal of lactose, glucose, and galactose-containing substances from the diet. Fructose is well-tolerated, and a fructose-based formula can be substituted, with rapid resolution of symptoms. There are reports of increasing tolerance to glucose and galactose with age. Rechallenge with small amounts of these sugars may be possible.

FUTURE DIRECTIONS The cloning of the SGLT-1 cDNA and the identification of naturally occurring mutations has already led to notable advances in our knowledge of the basic mechanisms of sugar transport. The regulation of expression of this and other cotransporters, their mode of insertion in the membrane, and structure–function correlation may be addressed in the research laboratory. With the identification of the SGLT1 gene, gene therapy may eventually be considered. However, in the near future, this is unlikely because of the relative ease of treatment by elimination diets, and the rarity of this disorder.

ABETALIPOPROTEINEMIA

CLINICAL FEATURES Abetalipoproteinemia is a rare disorder, characterized by the absence of apolipoprotein (apo) B containing lipoproteins in plasma. Patients present in infancy with diarrhea resulting from severe fat malabsorption, poor weight gain, and acanthocytosis. Atypical retinitis pigmentosa and spinocerebellar degeneration become apparent at older ages. Ocular symptoms include decreased night and color vision, and neurologic signs of ataxia, spastic gait and dysmetria, loss of deep tendon reflexes, and decreased vibratory and proprioceptive sense appear in the second decade. Spontaneous hemorrhage characteristic of a bleeding diathesis may occur because of vitamin K deficiency.

DIAGNOSIS The hallmark of this disorder is an abnormal plasma lipid profile, in association with signs of spinocerebellar degeneration and a pigmented retinopathy. Total cholesterol and triglyceride plasma levels are extremely low, and there is an absence of apo B-containing plasma lipoproteins, including chylomicrons, VLDLs, and LDLs. Most patients are anemic as a result of enhanced hemolysis of abnormal red blood cells (acanthocytes). Fat malabsorption leads to deficiency of fat soluble vitamins. In particular, vitamins E, K, and A are affected since they are transported in chylomicrons. Vitamin E deficiency is most severe, because its absorption from the intestine, transport to the liver, and circulation in the plasma are dependent on apo B-containing lipoproteins. Vitamin E deficiency is clinically important since it is thought to be responsible for the development of neurologic and retinal sequelae. Intestinal biopsy reveals lipid-laden enterocytes but normal villi and is useful for distinguishing this disorder from other intestinal illnesses associated with fat malabsorption.

GENETICS AND MOLECULAR PATHOPHYSIOLOGY Abetalipoproteinemia is a rare autosomal recessive disorder. Consanguinity is common in these families. An absence of plasma lipoproteins containing apo B led to the hypothesis that this disorder is a result of a defect in the apo B gene. However, linkage between apo B and abetalipoproteinemia in families has not been established by restriction fragment-length polymorphism analysis, and defects in the apo B gene have not been identified. Since assembly or secretion of apo B-containing lipoproteins were

most likely defective in this disorder, the microsomal triglyceride transport (MTP) protein was examined in affected individuals. This gene, located on chromosome 4q22-24, encodes a protein that catalyzes the transport of triglyceride, cholesteryl ester, and phospholipid between membranes. It is a heterodimer composed of a protein disulphide isomerase, and an 88-kDa subunit that is responsible for the lipid transport activity. This larger subunit shares homology with lipovitellin 1, a member of the lipid-binding lipovitellin complex that serves as a source for lipid in the developing embryo. Wetterau and colleagues showed that MTP activity, and particularly the 88-kDa subunit, normally present in microsomes from liver and intestine, was absent in intestinal biopsies from patients. Sequence analysis of cDNA and genomic DNA from patients with abetalipoproteinemia revealed homozygous frameshift and nonsense mutations in the gene encoding the 88-kDa subunit, resulting in truncated proteins. Analysis of additional patients indicated frameshift and splice site mutations, most of which lead to the formation of a truncated protein. Transfection of Cos-1 cells with mutant MTP cDNAs lacking part of the carboxy-terminus show decreased lipid transfer activity, supporting the hypothesis that alterations of this protein are the primary cause of abetalipoproteinemia.

MANAGEMENT A low-fat diet and supplementation with high doses of vitamin E as well as vitamins A and K are required. In particular, it is critical to avoid vitamin E deficiency, since this appears to be the primary cause of the severe and irreversible neurologic and ocular changes characteristic of this disease.

FUTURE DIRECTIONS The cloning of the cDNA encoding the microsomal triglyceride transport protein raises the possibility of gene therapy in the future. Although many of the devastating neurologic and ocular sequelae may be avoided by high doses of vitamin E, there may be a role for gene replacement in refractory patients. Also, rapid, definitive diagnosis is crucial, so that prenatal screening of siblings may be useful. Finally, since patients with MTP deficiency have very low cholesterol and triglyceride levels, identification of selective inhibitors of its activity may prove to be a valuable addition to the treatment of hypercholesterolemia.

46 Mechanisms of Hormone Action

*William L. Lowe, Jr., Richard G. Pestell, Laird D. Madison,
and J. Larry Jameson*

INTRODUCTION

Hormones provide a form of communication between different cells and from one organ to another. The dramatic effects of hormones on physiologic functions such as growth and metabolism have allowed relatively sophisticated studies to elucidate their sources of production, sites of action, and how they are controlled. Because hormones act by binding to specific receptors, studies that have defined their mechanisms of action have also provided important paradigms for how receptors activate intracellular signaling cascades that lead to altered cellular responses.

Endocrine disorders ultimately involve abnormalities of hormone production or action. A relatively large number of these diseases have a well-defined genetic basis. There are now many examples of mutations that occur in genes that encode hormones, their receptors, second messenger signaling pathways, and the transcription factors that transduce hormone signals. The purpose of this chapter is to review basic principles of hormone signaling through their receptors. There has been a remarkable expansion of knowledge in this area in recent years. The structures and signal transduction networks for membrane receptors are finally coming into focus; nuclear receptors were cloned within the last decade and have revealed an unexpectedly complex family of proteins that serve as direct regulators of gene expression. The impact of this new information on our understanding of the pathophysiology of disease is already being felt in terms of the ability to predict specific receptors or pathways that may harbor mutations in different disorders. In this chapter, we will cite selected examples of such mutations, and the reader is referred to other chapters in this section for more detailed discussions of these disorders.

CLASSIFICATION OF HORMONES AND RECEPTORS

Hormones can be divided generally into three major classes: (1) derivatives of amino acids (e.g., dopamine and catecholamines); (2) peptides and proteins (e.g., thyrotropin-releasing hormone or insulin); and (3) derivatives of steroids (e.g., estrogen or cortisol). For the most part, amino acid derivatives and peptide hormones interact with membrane receptors on the cell surface, whereas the steroid hormones act by crossing the plasma membrane to interact with intracellular receptors.

As described in detail below, membrane receptors can be divided into several distinct classes. After binding hormones, these receptors activate a complex array of second messenger signaling pathways that often involve cascades of kinases. Nuclear receptors, such as the glucocorticoid or progesterone receptors, bind hormones in the cytoplasm before translocation into the nucleus (Fig. 46-1). Other receptors in this family, such as the thyroid hormone receptor, bind hormone in the nucleus without a separate hormone-induced translocation step. In the nucleus, these receptors interact with DNA target sites to either stimulate or repress the expression of specific genes.

Regardless of the class of receptors, certain principles apply to hormone–receptor interactions. Hormones bind to receptors with high affinity and specificity to allow appropriate physiologic responses. Most receptors bind hormones with affinity constants that approach the circulating levels of hormones (usually $<10^{-9}$ *M*) to allow responses over a dynamic range of physiologically relevant changes in hormone levels. Receptor numbers vary greatly in different target tissues, providing one of the major determinants of specific cellular responses to widely circulating hormones. For example, luteinizing hormone (LH) receptors are located almost exclusively in the gonads. In contrast, insulin receptors are widely distributed, reflecting the need for insulin-induced metabolic responses in most tissues.

Receptor specificity is a reflection of differential affinities of the receptor for structurally related molecules. Although structurally similar, LH, follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH) are highly selective for their individual receptors. Similarly, steroids such as progesterone, estrogen, and glucocorticoid exhibit no physiologically significant crossreactivity among their receptors. There are important exceptions to these examples of specificity. Parathyroid hormone (PTH) and parathyroid hormone-related peptide (PTH-RP) appear to share a common receptor. Insulin, insulin-like growth factor-1 (IGF-I), and IGF-II crossreact to some degree with their respective receptors. This latter circumstance may explain why some malignancies that overproduce IGF-II can cause hypoglycemia because of inappropriate stimulation of insulin receptors by IGF-II.

FEEDBACK REGULATION IN ENDOCRINE AXES

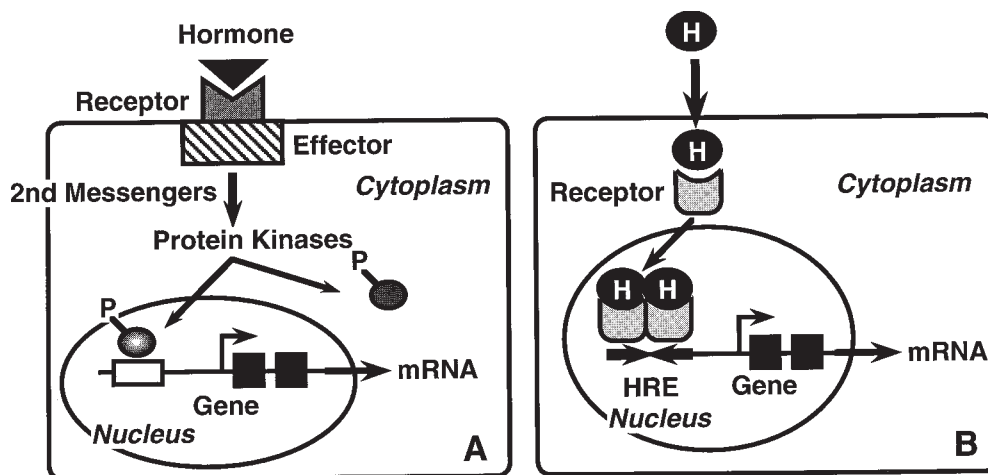
Feedback regulatory systems are pervasive in the field of endocrinology. Each of the major hypothalamic–pituitary hormone axes are governed by negative feedback, which serves to maintain


Figure 46-1   Membrane and nuclear receptors that mediate hormone action. A membrane receptor is shown on the left. Hormones and growth factors bind with high affinity to the extracellular domain of the receptors. Membrane receptors **(A)** communicate to intracellular signaling pathways, which typically include cascades of protein kinases. These kinases act on many different cellular targets, including other receptors, ion channels, the cytoskeleton, metabolic pathways, and transcription factors. Nuclear receptors **(B)** reside within the cytoplasm or the nucleus before hormone binding. Hormones traverse the plasma membrane and induce nuclear translocation and receptor activation. The activated receptors act as transcription factors to alter levels of gene expression. (After Jameson JL. Principles of hormone action. Oxford Textbook of Medicine, 1996. Reprinted with permission from Oxford University Press.)

hormone levels within a very narrow range. The principle of feedback control is well-illustrated by the example of the hypothalamic–pituitary–thyroid axis (Fig. 46-2). Thyrotropin-releasing hormone (TRH) stimulates TSH secretion from the pituitary. TSH stimulates the synthesis and secretion of thyroid hormone (T4 and T3), which in turn suppresses the production of hypothalamic TRH and pituitary TSH. A typical regulatory loop therefore has both positive (TRH, TSH) and negative (T4, T3) components, providing exquisite control over hormone levels and action.

In addition to classic endocrine feedback loops in which hormones are produced by one gland and act on a different gland, a variety of local regulatory systems have also been characterized (Fig. 46-3). These so-called autocrine and paracrine systems are used commonly during development and by most growth factors. Local control of growth factor production and action helps to restrict their sites of action. For example, circulating levels of activin are relatively low, but local production in the gonads and pituitary may permit localized biologic effects without a requirement for systemic exposure to high levels of hormone. In many cases, the distinction between endocrine and paracrine actions may become blurred. For example, IGF-I appears to act as both a true hormone and a paracrine factor. In the liver, growth hormone increases production of circulating IGF-I. However, in most other tissues, the production of IGF-I is also regulated locally.

The clinical practice of endocrinology is intimately linked to these principles of feedback control systems and hormone action. Using these concepts, one can often localize whether a disorder is caused by hormone excess or deficiency, or by an abnormality in tissue sensitivity to hormone action. Advances in molecular genetics are allowing these diagnostic algorithms to expand by another dimension. In addition to measuring hormone levels, it is now possible to test for enzyme deficiencies by identifying mutations in affected genes (e.g., 21-hydroxylase), or to predict genetic risk in inherited syndromes such as the multiple endocrine neoplasia syndromes.
Figure 46-2   Positive and negative feedback regulation by hormones. The hypothalamic–pituitary–thyroid axis provides a prototypical example of feedback regulatory pathways in the endocrine system. Hypothalamic thyrotropin releasing hormone (TRH) stimulates thyroid stimulating hormone (TSH) secretion by the pituitary gland. TSH stimulates the biosynthesis and secretion of thyroid hormones (T4 and T3) from the thyroid gland. Thyroid hormones feed back to inhibit the production of TRH and TSH. Because the pituitary integrates both positive and negative regulation, it establishes a setpoint for TSH and consequently, thyroid hormone levels. (After Jameson JL. Principles of hormone action. Oxford Textbook of Medicine, 1996. Reprinted with permission from Oxford University Press.)
Figure 46-3   Hormones and growth factors can act at a distance or locally. Endocrine action refers to hormones that are secreted from one gland and enter the circulation to act on a different target gland. Paracrine action involves hormones or growth factors that are produced by one cell but act locally on an adjacent cell. In autocrine action, a growth factor acts on the same cell from which it is produced. Intracrine action suggests that some hormones act on intracellular receptors in the same cells in which they are produced. (After Jameson JL. Principles of hormone action. Oxford Textbook of Medicine, 1996. Reprinted with permission from Oxford University Press.)

MEMBRANE RECEPTORS

Receptors on the surfaces of cells provide an essential component of communication with extracellular ligands. These membrane receptors fall into three general classes based on their structure and mechanisms of signal transduction: (1) the single transmembrane domain receptors; (2) the seven transmembrane domain receptors; and (3) the four transmembrane domain receptors. The latter class functions as transmitter-gated ion channels and will not be described further in this chapter.

SINGLE TRANSMEMBRANE DOMAIN RECEPTORS

TYROSINE KINASE RECEPTOR FAMILY   The tyrosine kinase receptors represent a large family of receptors that are involved in many facets of cell growth responses. As their name implies, members of this receptor family possess intrinsic tyrosine kinase activity. Although there are at least seven different subfamilies, certain generalizations can be made about the entire family of receptors (Fig. 46-4). With the exception of the insulin receptor family, these receptors consist of a single subunit and dimerize on ligand binding. Dimerization is followed by autophosphorylation, which actually occurs as a result of transphosphorylation (e.g., one cytoplasmic domain phosphorylates the other cytoplasmic domain in the dimer). The initial transphosphorylation reaction increases the tyrosine kinase activity of the receptor and results in phosphorylation of other specific tyrosines within the cytoplasmic domain. These phosphotyrosines then serve as recognition sites for a variety of intracellular signal transduction molecules. For example, binding to the phosphorylated receptor can occur via Src homology 2 (SH2) domains that are present in signal transduction adaptor molecules. SH2 domains are regions of ~100 amino acids that are folded to form a binding pocket for phosphotyrosine. Because the cytoplasmic domain of growth factor receptors is typically phosphorylated on multiple tyrosines, a variety of different SH2-containing molecules can bind to the receptor (Fig. 46-4). Another recently identified domain, the phosphotyrosine-binding (PTB) domain, also facilitates interactions between signaling molecules and receptors by binding to phosphotyrosine.

In addition to forming homodimers, receptor tyrosine kinases can also form heterodimers with other members of their family, greatly increasing the diversity of signal transduction molecules that are potentially activated by a single ligand. This phenomenon is illustrated by the epidermal growth factor (EGF) receptor family, which appears to be important in the growth of several different tumors, including breast and uterine cancers. One member of that family, ErbB3, has several repeats of a Tyr-X-X-Met (where X is any amino acid) motif in its cytoplasmic domain. When the tyrosine in this motif is phosphorylated, it is recognized by the SH2 domain of phosphoinositol-3-kinase (PI3-kinase). This amino acid motif is not present in the EGF receptor. EGF-induced heterodimerization of the EGF receptor and ErbB3 results, therefore, in activation of PI3-kinase activity, as well as pathways that are otherwise stimulated by homodimerization of the EGF receptor.

The insulin and IGF-I receptors represent an exception to the rule of ligand-induced dimerization of tyrosine kinase receptors. In the absence of ligand, these receptors form disulfide-linked homo- or heterodimers. Ligand binding presumably induces a conformational change in the receptor that stimulates activation and "autophosphorylation" (actually transphosphorylation as described above). Another difference exhibited by this subfamily of receptors is that the phosphotyrosines on the insulin and IGF-I receptor are poor binding sites for SH2 domains. Rather, these receptors phosphorylate insulin-related substrates 1 and 2 (IRS-1, IRS-2), which have at least 20 potential sites for tyrosine phosphorylation, and appear to serve as adaptors for the insulin family of receptors. A variety of proteins with SH2 domains have been shown to interact with IRS-1 and IRS-2.

Several different diseases involve alterations in the function of the insulin receptor. Distinct mutations affect multiple aspects of insulin receptor function, including receptor biosynthesis, processing of the proreceptor, transport of the receptor to the cell surface, affinity for insulin, and receptor tyrosine kinase activity. These mutations result in the syndrome of type A extreme insulin resistance (Online Mendelian inheritance of man number [OMIM] 147670). In many cases, the mutations cause more severe insulin resistance than would be anticipated for a 50% reduction in functional receptors. This phenomenon may result from the formation of a heterodimer between normal and mutated receptors with dominant negative inhibition of normal receptor function. Patients with leprechaunism (OMIM 246200), a syndrome that is characterized by intrauterine growth retardation and characteristic physical abnormalities, exhibit insulin resistance that is more severe than that seen in patients with the type A syndrome. This syndrome is inherited in an autosomal recessive manner and may be caused by the inheritance of two abnormal insulin receptor alleles. Although mutations in the insulin receptor are rare, the phenomenon of insulin resistance is quite common, and is the major cause of diabetes mellitus in adults. Few mutations have been identified in the
Figure 46-4　A tyrosine kinase receptor and interacting proteins. Different tyrosine kinases interact with an array of intracellular adaptor molecules such as Grb2, which serve as recognition sites for other cellular proteins. Phosphorylation of tyrosine kinases, often by a dimeric partner, creates recognition sites for proteins, such as Shc, Src, SOS, PI3-kinase, phospholipase C (PLC), and protein tyrosine phosphatases (PTP). The exact repertoire of adaptors and enzymes that interact with a tyrosine kinase is variable and provides a mechanism for generating diverse cellular responses.

insulin receptor in patients with this more common form of insulin resistance. Rather, this acquired form of insulin resistance presumably involves postreceptor defects in the insulin signaling pathway, although the exact steps that are affected remain to be delineated.

CYTOKINE RECEPTOR FAMILY　Cytokines include traditional hormones, such as growth hormone (GH) and erythropoietin, as well as colony-stimulating factors and interleukins. In several cases, such as the interleukins, a variety of different endocrine, neural, hepatic, and hematopoietic systems are targets of the cytokines. The structural features of the cytokine receptors are similar to tyrosine kinase receptors except that the cytoplasmic domain does not contain motifs indicative of kinase activity. Moreover, although some of the cytokine receptors are monomers (e.g., growth hormone, prolactin, erythropoietin, leptin), others consist of several subunits, some of which are shared among different cytokine receptors. In addition, some members of this receptor family secrete soluble forms of the receptor that can bind circulating ligands. For example, in the case of the GH receptor, the extracellular domain is shed into the circulation and functions as a GH binding protein.

The mechanism of cytokine-induced signal transduction was poorly understood for many years in view of the lack of intrinsic enzyme activity in the cytoplasmic domain of these receptors. However, the cytokine receptors have now been shown to activate the Janus kinases (JAKs). The JAK kinase family members, which include JAK1, JAK2, JAK3, and Tyk2, are cytoplasmic protein tyrosine kinases that associate with the cytoplasmic domain of

cytokine receptors via conserved receptor motifs. The activated JAKs phosphorylate tyrosines in the cytoplasmic domain of the cytokine receptors, which creates binding sites for signal transduction molecules that contain SH2 domains. In addition, the JAKs transmit intracellular signals by phosphorylating a family of latent transcription factors called the STAT proteins (signal transducers and activators of transcription). It is likely that each specific receptor elicits responses from a unique constellation of kinases and STAT proteins.

Endocrine diseases associated with mutations of cytokine receptors include alterations in growth. Patients with familial growth hormone resistance or Laron-type dwarfism (OMIM 245590) have proportionate short stature associated with elevated plasma growth hormone levels and do not respond to exogenous treatment with growth hormone. In most cases, the syndrome is inherited in an autosomal recessive fashion, and patients lack functional growth hormone receptors secondary to gene deletions or point mutations in the receptor. More recently, the growth hormone receptor from some patients with this syndrome was shown to have a point mutation in the extracellular domain that results in a small reduction in receptor affinity, but abrogates the ability of the receptor to dimerize, thus demonstrating the importance of receptor dimerization in signal transduction. Finally, in a selected group of children with idiopathic short stature, about one-third were found to have mutations in the growth hormone receptor that affected the level of receptor expression or its affinity for growth hormone.

SERINE-THREONINE KINASE RECEPTOR FAMILY A more recently described family of receptors contain endogenous serine-threonine kinase activity. These receptors bind to and transmit the signals of the transforming growth factor-β (TGF-β) family of ligands. These growth factors include the TGF-βs, activins, bone morphogenic proteins, and müllerian-inhibiting substance. The TGF-β and activin receptors are the prototypical and best characterized receptors in this family.

Activin and TGF-β receptor complexes are composed of two different subunits, the type I and type II receptors. Both of these receptors are transmembrane proteins with intrinsic serine-threonine kinase activity, and both are required for ligand-induced signal transduction. The type II receptors have high affinity for their ligands and a long cytoplasmic domain that possesses serine-threonine kinase activity. Multiple isoforms of the type II receptor subunit have been described, and, similarly, there are at least six different type I receptors. The type I receptors are similar in structure to the type II receptors, including the presence of the serine-threonine kinase domain. Unlike the type II receptors, these receptors appear to have no ability to bind ligand.

Ligand binding to the type II receptor recruits the type I receptor, resulting in the formation of a hetero-oligomeric complex that likely is a heterotetramer of two type I and two type II receptors. The type II receptor appears to phosphorylate the type I receptor after it is recruited into the complex by ligand binding. The type I receptor subsequently phosphorylates other downstream substrates, including the Smad proteins. At least eight different Smad proteins have now been identified. Interestingly, the gene encoding one of these proteins, Smad 4, is deleted in ~50% of pancreatic carcinomas. When tested, growth of these tumors was not inhibited by TGF-β. The diversity of signals that can be generated by the activins and TGF-βs is increased by the ability of multiple type II receptors to interact with multiple type I receptors, each of which may transmit selective signals. Different components of this receptor family have been knocked out in transgenic mice, confirming a pleomorphic role in development. In addition, mutations in the receptor for müllerian-inhibiting substance causes retained müllerian structure in males.

GUANYLYL CYCLASE RECEPTOR FAMILY The guanylyl cyclase family of receptors contains an extracellular ligand-binding domain and a single transmembrane domain. The cytoplasmic domain contains a catalytic cyclase domain that is responsible for ligand-induced conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP), which activates protein kinases, phosphodiesterases, and ion channels. To date, four different receptors with guanylyl cyclase activity have been cloned. The prototype for this family is the GC-A receptor for atrial natriuretic peptide (ANP) and brain natriuretic peptide. The ability of cGMP analogs to mimic the effect of ANP in cells confirms that cGMP generation mediates ligand-induced signal transduction by these receptors. In mice, disruption of the gene encoding the GC-A receptor results in salt-resistant hypertension. A second receptor, the GC-B receptor, binds type C natriuretic peptide, and another receptor with guanylyl cyclase activity (GC-C receptor) binds to guanylin, a recently identified peptide that is produced by epithelial cells.

PHOSPHOTYROSINE PHOSPHATASE FAMILY Although much work has focused on kinases, a series of protein tyrosine phosphatases (PTPs) have recently been cloned and play an important role in cellular function. Some of these proteins contain recep-

tor-like structures that are characterized by an extracellular domain, a transmembrane domain, and a cytoplasmic domain that contains one or two catalytic domains.

CD45 was one of the first transmembrane protein tyrosine phosphatases to be recognized. It is required for T-cell function and activates two members of the Src family of protein tyrosine kinases, p56[lck] and p59[fyn], by dephosphorylating a phosphotyrosine at the C-terminus of these proteins. This phosphotyrosine inhibits the kinase activity of p56[lck] and p59[fyn]. Another group of tyrosine phosphatases contains an extracellular domain that is similar to cell adhesion molecules. These proteins may be involved in cell–cell interactions, although regulated activity of these phosphatases has not been demonstrated. When gene targeting was used to knock out one member of this family, the LAR receptor-like protein tyrosine phosphatase, impaired terminal differentiation of breast alveoli was present, suggesting a role in breast development. PTPβ is representative of a final class of protein tyrosine phosphatases. The extracellular domain of PTPβ has the structure of a proteoglycan and is capable of interacting with the extracellular matrix protein tenascin.

SEVEN TRANSMEMBRANE DOMAIN RECEPTORS

The seven transmembrane domain family of receptors contain several hundred members. These receptors have a conserved structure that is characterized by seven hydrophobic domains that are inserted into the membrane (Fig. 46-5). These receptors bind a wide variety of ligands including: (1) small molecules such as biogenic amines (e.g., epinephrine and norepinephrine) and odorants; (2) ions such as Ca^{2+}; (3) small peptides like vasopressin and thyrotropin releasing hormone; and (4) large protein hormones such as parathyroid hormone and the glycoprotein hormones. These ligands bind to regions of the extracellular domain, and in some instances make contacts with the receptor within the transmembrane domain.

The seven transmembrane domain receptors are coupled to G proteins, which serve as effectors to initiate signal transduction. Although the composition and regulation of G proteins is rather complex, the components of this system are well-characterized and play an important role in several endocrine diseases. G proteins are heterotrimers that consist of an α-subunit and a combined β–γ-subunit. There are at least sixteen different α-subunit genes as well as several different β- and γ-subunits (Table 46-1). Within any given cell type, multiple different receptors, G proteins, and effectors are present. This diversity of G protein subunits requires specific interactions that appear to be mediated by the intracellular loops and C-terminus of the receptor.

In the absence of ligand, the α-subunit is bound to GDP and remains associated with the β–γ-subunits. Ligand binding to the receptor induces a conformational change in the receptor that promotes binding of a G protein to the receptor. After coupling to the receptor, guanosine diphosphate (GDP) is exchanged for GTP on the α-subunit and the β–γ-subunit is dissociated. These steps activate the G protein and initiate interactions with downstream effector molecules (e.g., adenylyl cyclase). The α-subunit contains an intrinsic GTPase activity that converts GTP to GDP, which restores the inactive state and allows reassociation with the β–γ-subunits. Regulation of GTPase activity therefore represents an important point of control of G protein function. The β–γ-subunits may also play a role in the activation of effector molecules. They appear to mediate tyrosine phosphorylation of the adaptor molecule Shc,
Figure 46-5 Structure of a seven transmembrane domain receptor. The G-protein coupled receptors share several structural features, including the characteristic seven transmembrane-spanning domains. The amino-terminal (NH_2) domain is located extracellularly and is involved in hormone interaction for some receptors. The seven transmembrane domains are connected by intra- and extracellular loops of amino acids. In three dimensions, the hydrophobic "barrels" are thought to be circularized when viewed from above. For many receptors, the ligands bind within the transmembrane domains. The intracellular loops and carboxy-terminal tail (COOH) are involved in coupling to G proteins and in intracellular signaling. Phosphorylation of the cytoplasmic tail and interactions with cellular proteins, such as arrestin, modulate receptor signaling, desensitization, and recycling. (After Jameson JL. Principles of hormone action. Oxford Textbook of Medicine, 1996. Reprinted with permission from Oxford University Press.)

which leads to activation of *Ras* and subsequently mitogen-activated protein kinase *(see below)* via a pathway that requires tyrosine kinases.

The relationship of G proteins to endocrine diseases was first postulated for Albright's hereditary osteodystrophy (OMIM 300800), which is characterized by variable resistance to a variety of hormones that are coupled to G proteins (e.g., PTH, TSH, glucagon). These patients have a variety of different mutations that affect the amount or function of Gsα-subunits. Although this provides a rational explanation for multiple hormone resistance, it remains unclear why some Gsα-coupled receptors are affected more severely than others. Remarkably, Albright also described a syndrome caused by activation rather than inactivation of the Gsα-subunit. This disorder, referred to as McCune-Albright syndrome (OMIM 174800), is characterized by polyostotic fibrous dysplasia, *cafe au lait* spots, hyperfunctioning ovarian cysts, and autonomous function in other glands, including the thyroid and pituitary glands. Patients with McCune-Albright syndrome have mutations in Gsα that inhibit the intrinsic GTPase. Consequently, the G protein cannot hydrolyze GTP, and it remains in an "activated" state, resulting in constitutive stimulation of downstream signaling pathways. In many ways, these mutations are analogous to those which occur in the structurally similar *Ras* proto-oncogene *(see below)*. *Ras* mutations also inhibit GTPase activity and are associated with constitutive signaling and enhanced cellular growth. The clinical manifestations of McCune-Albright syndrome reflect the activa-

tion of pathways that are normally stimulated by G-protein-coupled receptors. Thus, skin pigmentation likely mimics melanocyte stimulating hormone, bone dysplasia reflects overactivity of the PTH pathway, and ovarian cysts may reflect activation of gonadotropin pathways. The G-protein mutations in McCune-Albright syndrome are sporadic and postzygotic (all patients are mosaic for the mutation). It is presumed that germline mutations would be lethal.

The spectrum of known G-protein mutations has expanded considerably in recent years. On the basis of the observation that a subset of growth hormone-secreting pituitary adenomas had high levels of cyclic adenosine monophosphate (cAMP) production, it was discovered that Gsα mutations occur in 30–40% of cases with this type of pituitary tumor. These mutations are analogous to those in McCune-Albright syndrome. They occur in the same locations of the G protein and also result in constitutive activation. The primary difference is that the mutations are only found in the tumor tissue, and are therefore somatic in origin. G-protein mutations have now been found in other endocrine tumors, including hyperfunctioning adenomas of the thyroid, and a form of precocious puberty that results from activation of G proteins in Leydig cells of the testis (causing a premature increase in testosterone).

Activating mutations in seven transmembrane domain receptors have also been described and have cellular effects that are similar to those of Gsα mutations in the specific tissues in which the receptors are expressed (Table 46-2). For example, activating mutations of the TSH receptor have been identified in autonomously functioning thyroid nodules (*see* Chapter 50). These mutations, which are distributed throughout the transmembrane domain, result in constitutive activation of G-protein signaling. Constitutive activation of the cAMP pathway leads to cellular proliferation, as well as enhanced thyroid cell function. Analogous mutations have been identified in the LH receptor and cause precocious puberty in males. In the PTH receptor, activating mutations cause bone dysplasia. In the calcium receptor, activating mutations are responsible for familial hypocalcemia because they mimic feedback suppression of PTH by calcium. Given that a variety of different G-protein-coupled receptors have been shown to be activated by mutations, it is likely that the spectrum of diseases caused by this group of receptors will continue to expand.

Inactivating mutations of several G-protein coupled receptors have also been described (Table 46-2). These mutations are inherited in an X-linked or autosomal recessive manner and typically cause resistance to the hormone that normally activates the receptor. For example, vasopressin receptor mutations cause a form of nephrogenic diabetes insipidus that is unresponsive to exogenous vasopressin, and TSH receptor mutations cause resistance to TSH. In other cases, the phenotype is more complex, perhaps because receptor function is also required for normal development. Genotypic males with LH receptor mutations can present with pseudohermaphroditism, reflecting incomplete sexual differentiation. Heterozygous inactivating calcium receptor mutations cause the syndrome of familial hypocalciuric hypercalcemia (FHH) (OMIM 145980), and homozygous mutations cause severe neonatal hypercalcemia (*see* Chapter 51).

INTRACELLULAR SIGNALING PATHWAYS

As described above, membrane receptors represent a critical cellular link to the extracellular environment. Within the cell, an intricate set of signaling pathways communicate receptor

Table 46-1
Mammalian G-Protein α-Subunits

a-Subunit	Expression	Effector molecule(s)
G_s	Ubiquitous	Increases adenylyl cyclase and Ca^{2+} channel activity
G_{olf}	Olfactory	Increases adenylyl cyclase activity
G_{t1}	Rod photoreceptors	Increases cGMP phosphodiesterase activity
G_{t2}	Cone photoreceptors	Increases cGMP phosphodiesterase activity
G_{gust}	Taste cells	Unknown
G_{i1}	Neural > other	Decreases adenylyl cyclase and K^+ channel activity
G_{i2}	Ubiquitous	Decreases adenylyl cyclase and K^+ channel activity
G_{i3}	Other tissues > neural	Decreases adenylyl cyclase and K^+ channel activity
G_o	Neural, endocrine	Decreases Ca^{2+} channel activity
G_z	Neural, platelets	Unknown

responses to other receptors, as well as to the cytoplasmic and nuclear compartments. For the most part, these signaling pathways consist of enzyme cascades, although there are exceptions, including gases such as nitric oxide (NO), lipids, and transcription factors (such as the STAT proteins). In many cases, receptors activate several different signaling pathways. The strategy of using combinations of pathways provides an important mechanism for generating specific cellular responses. Another characteristic of signal transduction pathways is the potential for "crosstalk" in which one pathway may activate or inhibit another pathway. Again, this generates the potential for diverse responses. In the section below, specific examples are provided for some of the better studied signaling pathways that play a key role in endocrine responses.

p21*ras* AND MITOGEN-ACTIVATED PROTEIN KINASES

Because growth factors induce a variety of cellular responses, including proliferation, there has been great interest in delineating the pathways that mediate growth factor responses. Recently, there has been tremendous progress in the elucidation of numerous cytoplasmic and nuclear kinases involved in growth responses.

The number of different kinases is enormous, and they have been estimated to account for as many as 5–10% of transcribed genes. The family of mitogen-activated protein kinases (MAPKs) includes the extracellular signal-regulated kinases (ERKs), stress-activated or c-Jun N-terminal protein kinases (SAPKs on JNKs), and p38-kinases (Fig. 46-6). As noted above, tyrosine phosphory-lation of growth factor receptors, such as EGF, creates a binding site for a variety of adaptor proteins. One adaptor, growth factor receptor-binding protein 2 (Grb-2), binds to tyrosine-phosphory-lated proteins through its central SH2 domain. Grb-2 contains flanking SH3 domains that recruit proline-rich guanine nucleotide exchange factors, such as SOS (*Drosophila* son of sevenless). After growth factor treatment (e.g., EGF), the Grb-2–SOS complex associates with the tyrosine-phosphorylated receptor, which leads to the activation of p21*ras* and induction of downstream kinases.

The signal transduction pathways downstream of growth factor receptors involve a complex interplay of parallel, diverging, and converging pathways. The Ras proteins link growth factor recep-tor activation to protein phosphorylation and gene regulation through cascades of protein kinases. Induction of MAPKs requires dual phosphorylation on threonine and tyrosine residues by MAPK kinases (MAPKK) or MEKs. Several different protein kinases are capable of functioning as MEK kinases (MEKKs), including Raf-1 (Fig. 46-6). In some cell types, the SAPKs and p38 kinases are activated by cellular stresses, including specific stimuli such as tumor necrosis factor-α (TNF-α), UV irradiation, or genotoxic alkylating chemicals. The mechanisms by which one particular MAPK module is activated in response to a particular stimulus may depend on which combinations of kinases are present as well as interactions among various signaling cascades.

Transcription factors (e.g., c-Jun, c-Fos, ATF-2, Elk-1) are one of the targets of MAPK cascades and provide an important mecha-nism for altering patterns of gene expression in response to extra-cellular signals. Phosphorylation of the transcription factor can alter interactions with transcriptional partners, change DNA bind-ing affinity for a particular DNA sequence, or affect the activation surfaces that interact with the basal transcription apparatus. As an example, c-Jun is phosphorylated by several different kinases, including ERKs and SAPKs. Amino-terminal phosphorylation of c-Jun by the SAPKs enhances transactivation function, whereas phosphorylation of c-Jun near its DNA binding domain enhances DNA binding.

As with hormone regulatory systems, negative feedback is criti-cal for dampening signal transduction systems once they have been activated. Because most of these pathways involve reversible protein phosphorylation, protein phosphatases provide a mecha-nism for temporally modulating specific signals. It has been esti-mated that there may be as many as 1000 distinct protein phosphatase genes. The physiologic importance of these phos-phatases is exemplified by the ability of SV40 small t antigen to exert its cellular transforming effects by inhibiting protein phos-phatase 2A (PP2A), with consequent induction of MEK and ERK activity in the cell. Various growth factors induce phosphatases differentially. This may explain, in part, why treatment with one growth factor can result in sustained activation of ERK, whereas another factor causes transient stimulation of the kinase.

CALCIUM SIGNALING

Many cellular responses involve alterations in intracellular calcium as a mechanism for transmitting signals. There are two main pathways that initiate Ca^{2+} signaling. In nonexcitable cells,
Figure 46-6 Signal transduction cascades. Most cells express a wide variety of different growth factor receptors. Each of these receptors can activate an array of signaling pathways, not all of which are shown. Tyrosine kinases induce the binding of SH2 domain proteins, such as Grb2. Grb2 binds to guanine nucleotide exchange factors, such as son of sevenless (SOS). This pathway can also be activated by the insulin receptor via insulin-related substrate (IRS) or by cytokine receptors via Janus-activated kinases (JAK). Although Gsα-coupled receptors act primarily through the cAMP pathway, they can also activate mito-gen-activated kinases (MAPK) through their β–γ-subunits. This fig-ure emphasizes the observation that different receptors can activate the *ras* pathway along with one or more downstream kinase cascades. *Ras* activates several downstream kinases in a cell type-specific man-ner. The preferential activation of a particular MAPK module, such as activation of the extracellular regulated kinase (ERK) rather than the SAPK pathway, provides a mechanism for specific responses. There are many cellular targets of these kinases, including a variety of tran-scription factors that are involved in cellular growth responses.

the slow inositol pathway (inositol 1,4,5-trisphosphate [IP_3]) predominates, initiated either by receptor tyrosine kinases or by G-protein-coupled receptors of the seven transmembrane domain class. Receptor tyrosine kinases stimulate phospholipase Cγ to produce IP_3, which acts as a second messenger to trigger the release of Ca^{2+} from the endoplasmic reticulum. The G-protein-coupled receptors can increase intracellular Ca^{2+} by activating phospholipase Cβ. In excitable cells, voltage-dependent Ca^{2+} channels trigger more dramatic Ca^{2+} fluxes. Calcium binds to calmodulin (CaM), which serves as an intracellular sensor of calcium concentration. CaM binds to a number of enzymes (CaM kinases 1–5) protein phosphatases, and adenylate cyclases. The p21*ras*–MAPK signal-ing pathway is also activated by alterations in intracellular Ca^{2+}.
Figure 46-7 cAMP stimulation of transcriptional responses. G-protein-coupled receptors provide a major pathway for the generation of cAMP by adenylate cyclase. Increased cAMP levels within the cell cause dissociation of the tetrameric protein kinase A (PKA) holoenzyme leading to the release of the active catalytic subunit of PKA. The active catalytic subunit is translocated to the nucleus, where it phosphorylates transcription factor CREB, which binds as a homodimer to specific cAMP response elements (CREs) on target genes. The phosphorylation of CREB induces the binding of the coactivator, CREB-binding protein (CBP), which is also a substrate for phosphorylation. These transcription factors act by interacting with basal transcription factors such as TFIIB and TFIID. Several other kinases may phosphorylate CREB, including the calcium-regulated kinases.

Cyclic AMP response element binding protein (CREB) has been implicated as one of several transcription factors that can be activated by alterations in intracellular calcium. Ca^{2+}-induced phosphorylation of CREB requires a novel p21*ras*-dependent 105-kDa kinase. This novel kinase leads to phosphorylation of CREB at Ser 133, and thereby enhances transactivation function *(see below)*. Activation of these transcription factors by Ca^{2+} leads to the induction of temporally distinct immediate-early and delayed response genes.

cAMP-DEPENDENT SIGNALING

cAMP-dependent signaling cascades are typically initiated by the binding of peptide hormones to their membrane receptors. However, intracellular cAMP concentrations are also modulated by processes intrinsic to the cell, such as the cell cycle. The pleiotropic array of cellular effects of cAMP are primarily mediated by protein kinase A, which acts on a number of cellular substrates, including enzymes, the cytoskeleton, and transcription factors. As depicted in Fig. 46-7, cAMP binds to a regulatory subunit of protein kinase A, leading to dissociation of an active catalytic subunit that phosphorylates specific substrates.

In addition to receptors, ion channels, cytoskeletal proteins, and enzymes, a group of transcription factors are important targets of the protein kinase A pathway. These include the CREBs and activating transcription factors (ATFs) that are members of the B-Zip class of transcription factors. Posttranslational modification of CREB by phosphorylation at serine residues induces conformational changes that alter the affinity of CREB for coactivator proteins, such as CREB-binding protein (CBP) or the TATA box-binding protein coactivator TAF$_{II}$ 110. CBP is thought to form a bridge between CREB and the basal transcription apparatus

(Fig. 46-7). CBP also interacts with other B-Zip proteins, such as c-Jun and c-Fos, other transcription factors, including c-Myb, as well as specific kinases. In addition to a clear role in cAMP signaling, CBP has also been implicated in mitogenic signaling. Consistent with its role in multiple cell signaling pathways, mutations of CBP cause Rubinstein-Tabi syndrome (OMIM 180849), which is associated with mental retardation, multiple congenital anomalies, and predisposition to malignancy. The B-Zip dimerization structure of the CREB and ATF proteins provides the basis for numerous combinations of different members of this family. The closely related cAMP response element modulator (CREM) gene product can act as a transdominant negative regulator of CREB transcriptional activity, either by forming inactive heterodimers with CREB or by binding to the CRE as an inactive complex.

In addition to the canonical CRE, several other DNA regulatory elements and transcription factors are capable of stimulating gene transcription in response to cAMP. The transcription factor, activator protein 2 (AP-2), also functions in basal, phorbol ester, and cAMP-mediated transcriptional induction. The CAAT enhancer binding protein (C/EBP) induces transcription of the adipocyte protein 2 gene promoter (aP2 gene) and stearoyl acyl CoA desaturase (SCD-1) through a region that is also regulated by cAMP. cAMP-responsive regions of several genes appear to overlap with binding sites for nuclear receptors, some of which may also transduce cAMP effects.

CELL-CYCLE REGULATORY SIGNAL TRANSDUCTION PATHWAYS

Phosphorylation plays an essential regulatory role in the cell cycle, and a large array of cyclin-dependent kinases (CDKs) have been identified (*see* Chapter 6). The regulatory subunits of the

CDKs, known as cyclins, form complexes with their catalytic partners, to function as heterodimeric holoenzymes that phosphorylate specific proteins, including the tumor suppressor protein pRB (*see* Chapter 105). Phosphorylation of pRB blocks its critical inhibitory function, allowing cell-cycle progression and differentiation to occur. Several proteins capable of binding cyclins and inhibiting CDK activity have been identified and are referred to as CDKIs. The CDKIs inhibit cell-cycle progression and inhibit tumor formation. Translocation of the cyclin D1 gene has been associated with certain cases of hyperparathyroidism (*see* Chapter 51), and actually led to the identification of cyclin D1 in humans. In these cases, a somatic inversion of chromosome 11 brings cyclin D1 under the control of the PTH promoter. Consequently, cyclin D1 is overexpressed in the parathyroid cell and results in cellular proliferation.

NUCLEAR RECEPTORS

OVERVIEW OF NUCLEAR RECEPTOR ACTION   The nuclear receptor superfamily consists of several hundred structurally related proteins that function by increasing or decreasing the rate of gene transcription (*see* Chapter 3). The nuclear receptors mediate the physiologic actions of small cell-permeable hormones, such as the sex steroid molecules (estrogen, testosterone, and progesterone), cortisol, aldosterone, and vitamin D, as well as retinoids that are derived from dietary vitamin A. There is also a large subfamily of nuclear receptors for which no ligand has been identified, or which may not require the binding of a ligand for functional activation. This group of receptors are referred to as orphan nuclear receptors. Nuclear receptors interact with specific DNA sequences, known as hormone response elements (HREs), that are typically located in the promoter regions of target genes. After the receptor binds to DNA, it is positioned to interact with other transcription factors to alter rates of gene transcription.

STRUCTURE AND CLASSIFICATION OF NUCLEAR RECEPTORS   Although nuclear receptors can be classified based on their ligands, structural similarities and DNA recognition sites provide a particularly useful classification system because it allows predictions to be made for receptor members that have not been characterized extensively. The DNA-binding domain (DBD) is the most highly conserved region of nuclear receptors (Fig. 46-8). The DBD consists of two centrally located zinc fingers, the structure of which has been well characterized using X-ray crystallography and nuclear magnetic resonance studies. The amino acid sequence at the carboxyterminal base of the first zinc finger is the primary determinant of DNA binding specificity, and provides a convenient means for classifying subfamilies of receptors that bind to related DNA elements. Other domains of nuclear receptors have also been clearly delineated. The ligand-binding domain (LBD) is located in the carboxyterminus of the receptor. This region of nuclear receptors has several overlapping functional domains, including regions required for dimerization and for transcriptional activation and repression. The structure of the ligand-binding domain has also been solved by X-ray crystallography, and several lines of evidence indicate that ligand binding induces significant conformational changes in the receptor. The amino-terminal region of nuclear receptors is the most variable and the least characterized. In some cases, it has been shown to contain additional transcription-activating domains.

Nuclear receptors can generally be divided into two groups (Table 46-3). The classic steroid receptors share a similar DNA-binding domain and DNA recognition sequence. This group includes receptors for glucocorticoids, mineralocorticoid, progesterone, and testosterone. Of note, even though the estrogen receptor (ER) binds to a steroid hormone, it shares more in common with the second group of nuclear receptors *(see below)*. The steroid receptors often reside in the cytoplasm of the cell, complexed with proteins of the heat shock family. After ligand binds to the receptors, they disassociate from the heat shock proteins, translocate to the nucleus, and bind to hormone response elements in target genes. The steroid group of receptors bind to DNA only as homodimers, and their DNA binding sites reflect this twofold symmetry by being configured as palindromic pairs of monomeric "half-sites."

A second major group of nuclear receptors includes thyroid hormone receptor (TR), retinoic acid receptor (RAR), ER, and many others that share a similar DNA recognition sequence in the first zinc finger, and bind to a related DNA sequence, AGGTCA. This group of receptors also shows great flexibility in terms of dimerization. Many of these receptors can bind to DNA as monomers (particularly orphan receptors), but several bind to DNA as heterodimers as well as homodimers. The heterodimer partners typically include other members of this receptor subfamily. The retinoid X receptors (RXRs) serve as heterodimeric partners for several different nuclear receptors, including RARs, TRs, vitamin D receptor (VDR), and peroxisome proliferator-activating receptors (PPARs). The heterodimers typically bind to hormone response elements that are arranged as direct repeats rather than in a palindromic manner. The spacing between these half-sites, and variations in some of the contextual bases, provide specificity to different receptors, providing a partial explanation for how so many different receptors can share a common binding motif but elicit distinct cellular responses. Most members of this subfamily bind nonsteroid molecules and are located in the nucleus before ligand binding. They are able to bind to DNA in the absence of ligand, often with specific regulatory effects (e.g., gene silencing). Thus, the regulation of this group of receptors represents a complex interplay of receptor dimers, interactions with different DNA elements, and binding by specific ligands.

A subject of great interest is whether orphan receptors function without ligands, or whether the ligand remains to be identified. The RXRs were initially classified as orphan receptors, but are now known to bind 9-*cis* retinoic acid. The PPARγ receptors have been found to bind a variety of eicosanoids, as well as thiazolidinediones that are used to treat non–insulin-dependent diabetes. Other orphan receptors may be regulated by posttranslational modifications such as phosphorylation.

There has been rapid progress toward defining the mechanism by which nuclear receptors influence gene transcription. Several of the nuclear receptors have been found to physically interact with the basal transcription factor, TFIIB. Using in vitro transcription analysis, the nuclear receptors have been shown to facilitate the rate of assembly and stabilize basal transcription factors in the preinitiation complex that forms at the TATA box. An additional level of transcriptional control occurs through nuclear receptor interactions with "coactivator" or "corepressor" proteins, which in turn interact with proteins of the basal transcription factor complex. Several of these proteins have been identified on the basis of their ability to interact with nuclear receptors, but their role in transcriptional modulation is still being defined. Coactivators and corepressors may contribute to the development of specific diseases. Recently, a region of chromosome 20q that is often ampli-
Figure 46-8 Nuclear hormone receptors. The nuclear receptors contain conserved modular functional domains. The central DNA-binding domain (C) is the most highly conserved region. Characteristic zinc finger domains are depicted. The carboxy-terminal region (E/F) contains several functional domains, including ligand binding, dimerization, and transcriptional activation region. A region (D) between the ligand-binding domain and the DNA-binding domain mediates nuclear localization and binds transcriptional corepressors. In most receptors, the amino-terminal domain (A/B) contains motifs involved in transcriptional activation.

Table 46-3
Ligands and Antagonists for Nuclear Receptors

Receptor	Ligand	Antagonists	DNA response element	P box
Glucocorticoid subfamily				
GR	Cortisol	RU-486	TGAACATGTTCT	GSCKV
PR	Progesterone	RU-486	TGAACATGTTCT	GSCKV
MR	Aldosterone, cortisol	Spironolactone	TGAACATGTTCT	GSCKV
AR	Dihydrotestosterone	Flutamide, cyproterone acetate	TGAACATGTTCT	GSCKV
ER/TR Family				
ER	Estrogen	Tamoxifen, clomiphene, ICI 164, 384	AGGTCAnnnTGACCT	EGCKA
TR	Triiodothyronine (T3)	None	AGGTCAnnnnAGGTCA	EGCKG
VDR	1,25-Dihydroxyvitamin D	None	AGGTCAnnnAGGTCA	EGCKG
RAR	All-*trans* retinoic acid	Ro 41-5253	AGGTCAnnnnnAGGTCA	EGCKG
RXR	9-*cis* Retinoic acid	None	AGGTCAnAGGTCA	EGCKG
PPARγ	Prostaglandin J$_2$, thiazolidinedione	None	AGGTCAnAGGTCA	EGCKG

PR, progesterone receptor; GR, glucocorticoid receptor; MR, mineralocorticoid receptor; AR, androgen receptor; ER, estrogen receptor; TR, thyroid hormone receptor; VDR, vitamin D receptor; RAR, retinoic acid receptor; RXR, 9-*cis* retinoic acid receptor; PPAR, peroxisome proliferator activated receptor. The P-box refers to a five-amino acid sequence (in single letter code) at the base of the first zinc finger in the DNA-binding domain of the nuclear receptors. The half-sites refer to a consensus nucleotide sequence recognized by the DNA-binding domains of the receptor subfamilies.

fied in breast cancers was shown to encode a steroid receptor coactivator, AIB1, that enhances estrogen-dependent transcription and is overexpressed in ~65% of breast cancers. The CBP gene is also translocated in a subset of treatment-induced cases of acute myelogenous leukemias. Another important aspect of nuclear receptor action is their ability to crosstalk with other regulatory pathways. For example, growth factor pathways can alter the function of some nuclear receptors, such as the ER and progesterone receptor (PR). Certain nuclear receptors, including the glucocorticoid receptor (GR), TR, and RAR, interact with c-Jun or c-Fos, resulting in mutual antagonism. There is also evidence for nuclear receptor interactions with CBP, providing another means to inhibit the pathways (e.g., CREB, c-Jun, c-Fos) that converge on the CPB integrator protein. Finally, several nuclear receptors have been found to alter the conformation of DNA and associated chromatin, and in this manner may be able to alter the access of other transcription factors to the regulatory regions of genes.

PHYSIOLOGIC EFFECTS OF NUCLEAR RECEPTORS
Nuclear receptors serve an important role in development, cell differentiation, metabolism, and reproduction. Some of these func-

tions will be described briefly to provide examples of how nuclear receptors impact on physiology. The orphan receptor, steroidogenic factor-1 (SF-1) provides a good example of a receptor that plays a critical developmental role. SF-1 is selectively expressed in the adrenal gland and in reproductive tissues. Targeted disruption of SF-1 has been shown to prevent adrenal development and causes dysfunction at multiple levels of the reproductive axis. SF-1 appears to play dual role in cell viability and the direct regulation of a variety of steroidogenic enzyme genes.

The glucocorticoid receptor mediates the widespread effects of cortisol on blood pressure, blood glucose levels and insulin action, neuropsychiatric status, diurnal variation in body temperature, and immune responses. The closely related mineralocorticoid receptor binds aldosterone and regulates the renal handling of potassium and sodium.

The sex steroid receptors determine the phenotypic appearance of secondary sexual characteristics and control the production of oocytes and sperm. Testosterone itself binds relatively weakly to the androgen receptor, but it is converted to the more active metabolite, dehydrotestosterone, by the enzyme 5α-reductase,

Table 46-4
Disorders Caused by Mutations in Nuclear Receptors

Receptor	Disorder	OMIM no.	Mechanism	Inheritance
Androgen receptor	Androgen insensitivity	313700	Premature stop codon, DNA-binding domain mutation	X-linked
Androgen receptor	Prostate cancer		Point mutations	Somatic
Estrogen receptor	Estrogen resistance	133430	Point mutations, deletions	Autosomal recessive
Estrogen receptor	Breast cancer		? Postreceptor	Somatic
Glucocorticoid receptor	Glucocorticoid resistance	138040	Point mutations	Autosomal dominant
Thyroid hormone receptor β	Resistance to thyroid hormone	188570	Ligand-binding mutations	Autosomal dominant
Vitamin D receptor	Vitamin D-resistant rickets	277440	DNA-binding mutant, ligand-binding mutant	Autosomal recessive
Retinoic acid receptor	Promyelocytic leukemia	180240	Fusion protein lacking RAR DNA-binding domain	Somatic translocation

OMIM, Mendelian inheritance of man; RAR, retinoic acid receptor.

which is expressed at high levels in many androgen-responsive tissues. Therefore, tissue specific variation in 5α-reductase expression can influence the extent of androgen responsiveness. The reproductive nuclear receptors are also notable because of the existence of clinically useful receptor antagonists (Table 46-3). RU-486 binds with high affinity to the progesterone receptor ligand-binding domain (it also binds the glucocorticoid receptor) in such a manner that its transcriptional activating properties are blocked. Similarly, tamoxifen binds to the estrogen receptor ligand-binding domain but fails to convert the receptor to a transcriptionally active form. The development of specific receptor antagonists for reproductive and other nuclear receptors is an active area of investigation, and promises to provide a plethora of useful new drugs and experimental tools.

The nonsteroid nuclear receptors (e.g., thyroid hormone, retinoid, vitamin D, and the orphan receptors) mediate a variety of developmental and metabolic pathways. In several cases, multiple receptor isoforms provide an additional level of control. For example, there are two separate genes for TRs, three for all-*trans* RARs, and three for the retinoic 9-*cis* RXRs. In addition, many of these genes generate multiple receptor subtypes by virtue of alternate mRNA splicing or alternate promoter usage. The function of individual isoforms is not clear, but there is a complex pattern of overlapping tissue-specific expression. Receptor subtype expression is highly regulated during development, and there is striking tissue-specific expression of various nuclear receptor isoforms in adult organs. Therefore, like the peptide hormone receptors, tissue responsiveness to the hormone signal is regulated at its most fundamental level by selective expression of the nuclear receptor in responsive tissues.

Nuclear receptors have been found to play a prominent role in human disease, many of which are described in detail in subsequent chapters (Table 46-4). The most well-described disorders are those of resistance to nuclear hormone action, caused by deletion or mutation of the receptors. Such hormone-resistance syndromes have been described for the estrogen, glucocorticoid, androgen, vitamin D, and thyroid hormone receptors. As an example, androgen resistance is inherited in an X-linked fashion, reflecting the X-chromosomal location of the androgen receptor. More than 50 complete or partially inactivating mutations of the androgen receptor have been described (*see* Chapter 56). In the fully resistant form (testicular feminization), 46,X,Y individuals have female secondary sexual features, but milder cases of resis-

tance can result in more subtle forms of feminization. Resistance to thyroid hormone is unusual because it is inherited in an autosomal dominant manner (*see* Chapter 50). In this disorder, the mutations are limited to the carboxy-terminal domain of the receptor, and result in loss of thyroid hormone binding or transactivation. However, because dimerization and DNA binding are preserved, the inactive mutant receptors can still bind to target genes and act as antagonists. This "dominant negative" property appears to explain the dominant pattern of inheritance. Another important example of nuclear receptor mutations causing human disease involves a translocation of the RAR receptor (t15; 17) in acute promyelocytic leukemia in which the RAR-α recombines with a putative tumor suppressor, PML. Treatment with high doses of retinoids causes the maturation of the leukemic cells and can result in clinical remission. Somatic mutations of other receptors (estrogen, androgen) are thought to play a role in hormonally responsive tumors, such as breast and prostate cancer. Recently, environmental toxins, such as DDT and halogenated aromatic hydrocarbons, have been found to interact with the nuclear receptors for androgens and estrogen. Finally, our knowledge of nuclear receptor biology will eventually allow a better understanding of conditions of nuclear hormone excess and deficiency states, such as Cushing's disease, adrenal insufficiency, hyperthyroidism, and hypothyroidism.

47 Diabetes Mellitus

WILLIAM L. LOWE, JR.

INTRODUCTION

Diabetes mellitus affects approximately 5% of the general population with its prevalence varying between ethnic groups and geographic regions. The majority of cases are accounted for by two different types of diabetes, type 1 and 2, which account for approximately 10 and 90% of cases of diabetes, respectively. Although these two disorders share a common phenotype, fasting and postprandial hyperglycemia, their etiology is distinct. Type 1 diabetes is characterized by pancreatic β-cell deficiency with a resulting absolute deficiency of insulin. The β-cell deficiency is most commonly secondary to autoimmune-mediated destruction. Type 2 diabetes, in contrast, is characterized by a deficiency of insulin action as a result of a combination of insulin resistance and β-cell dysfunction that is manifest as inadequate insulin secretion in the face of insulin resistance and hyperglycemia.

The familial clustering of both type 1 and 2 diabetes has long suggested a genetic contribution to the origin of the diseases. In the case of type 1 diabetes, the concordance rate among monozygotic twins is 25–50%, whereas the relative risk to an individual with a first-degree relative with type 1 diabetes is approximately 5–10% compared with the 0.4% risk in the general population. Although these data are consistent with a genetic contribution to the origin of the disease, the lack of 100% concordance in monozygotic twins suggests that environmental factors also make a significant contribution to the pathogenesis of the disease. These environmental factors have not been clearly defined, but seasonal variation in the onset of type 1 diabetes and its association with preceding episodes of specific viral infections suggest that viruses may be one of the important environmental factors. Familial clustering of disease is much more apparent in type 2 diabetes. The concordance rate among monozygotic twins has been shown to be 50–95%, whereas approximately 40% of siblings and approximately 30% of offspring of affected individuals develop either type 2 diabetes or impaired glucose tolerance. Again, these data are consistent with a significant genetic contribution to the development of type 2 diabetes but suggest that environmental influences are also important in its etiology.

With the advent of molecular genetics, significant progress has been made in defining the genetics of rare, monogenic forms of diabetes as well as more typical type 1 and 2 diabetes. This progress is reflected in the recent reclassification of diabetes that includes diagnostic categories of genetic defects in β-cell function and insulin action. This chapter will describe the recent advances in the genetics of both type 1 and 2 diabetes as well as monogenic forms of diabetes.

GENETICS OF TYPE 1 DIABETES MELLITUS

Type 1 diabetes often presents abruptly with marked hyperglycemia, polyuria, and ketoacidosis, which occur as a result of insulin deficiency. This dramatic presentation of the disease suggested initially that type 1 diabetes was the result of an acute event, but with an improved understanding of the pathogenesis of the disease, it is now clear that onset of the disease is a chronic process that can be divided into a series of stages. As will be discussed below, individuals have a genetic predisposition for diabetes. In certain of these individuals, an autoimmune process is initiated, presumably in response to some environmental exposure. There is then a period of active autoimmunity characterized by the presence of autoantibodies and progressive β-cell destruction but with maintenance of normal blood sugars and glucose tolerance. With sufficient β-cell destruction, impaired glucose tolerance, which is typically not clinically evident, and, subsequently, diabetes develop. Depending on the rate of decline of β-cell function, older patients may be presumed to have type 2 diabetes mellitus because of residual insulin secretion, albeit not sufficient insulin secretion to maintain euglycemia. As destruction of the residual β cells continues, a new stress, e.g., infection, often results in the acute presentation of diabetes. Ultimately, absolute insulin dependence develops because of total or near total β-cell destruction.

The autoimmune-mediated destruction of pancreatic β cells is characterized by two features, autoantibodies and insulitis. Autoantibodies present in type 1 diabetes mellitus are directed against a variety of β-cell antigens, including insulin, glutamic acid decarboxylase (GAD65 and 67), membrane proteins that are homologous to tyrosine phosphatases (ICA512 and IA-2), and islet neuroendocrine ganglioside. Although the presence of two or more of these antibodies is predictive of progression to diabetes in relatives of affected individuals, their role in the immune-mediated destruction of the islets cells is still unclear. Insulitis is characterized by inflammatory infiltrates in the islets consisting primarily of CD8 cells but also of CD4 cells, B cells, macrophages, and natural killer cells. The cause of type 1 diabetes mellitus, and, thus, the trigger for the autoimmune process, is complex and involves both a genetic predisposition and environmental factors. The genetics of type 1 diabetes mellitus are now being defined.

Type 1 diabetes does not follow a simple Mendelian pattern of inheritance. As demonstrated by studies in identical twins, there is not a 100% concordance between a susceptible genotype and disease presence. Presumably the penetrance of the disease genes is influenced by environmental factors that are, as yet, undefined. Moreover, studies in both mice and now humans clearly demonstrate that the disease is polygenic, suggesting that a sufficient

complement of genes must be inherited to confer susceptibility to diabetes. Two approaches have been used to define genes that predispose to type 1 diabetes—identifying candidate genes by comparing the frequency of alleles of specific genes in diabetic and control populations (case-control or association studies) and genome scanning to identify chromosomal loci associated with disease susceptibility. Given the autoimmune origin of type 1 diabetes, the major histocompatibility locus (MHC) or human leukocyte antigen (HLA) region was examined initially as a candidate susceptibility locus. Association studies identified this region as a potential susceptibility locus, and this was confirmed in subsequent linkage studies. This locus is now referred to as *IDDM1*. The degree of family clustering of a disease is referred to as λ_s and can be estimated by comparing the disease risk in siblings of affected individuals to the prevalence of the disease in the general population. For type 1 diabetes, the λ_s is 15, whereas the λ_s for *IDDM1* is estimated to be 2.6, suggesting that *IDDM1* accounts for 35–40% of the familial inheritance of the disease.

Progress has been made in defining how *IDDM1* confers susceptibility to disease. The MHC is located on the short arm of chromosome 6 (6p21) and encodes proteins involved in the regulation of the immune process (*see* Chapter 31). The MHC consists of three major regions, A, B, and C, that encode class I genes, and the D region, which encodes class II genes. The class I molecules are highly polymorphic and present peptide fragments of foreign antigens to cytotoxic T lymphocytes. The class II molecules present foreign processed antigen to helper T cells and, thus, are involved in initiating the immune response. Class II molecules consist of an α and β chain that are encoded by different genes. There are two major classes of class II genes, the DR and DQ genes. The β but not the α chain in the DR molecules is polymorphic, whereas both the α and β chains are polymorphic in DQ molecules.

Initially an association between class I alleles and type 1 diabetes was demonstrated, but it is now clear that class II molecules are more important in conferring risk. The original association with class I molecules was likely caused by the nonrandom association of class I alleles with the class D alleles (linkage disequilibrium). Moreover, linkage disequilibrium of the DQ and DR alleles has created extended haplotypes (the presence of several genes on the same chromosome). Some of these class II alleles predict susceptibility to type 1 diabetes, whereas others either confer protection or are neutral. It is likely that both DR and DQ alleles are important in regulating susceptibility to type 1 diabetes. Interestingly, all of the DQ β chain alleles encoding a gene product with an aspartic acid at position 57 are either protective or neutral. In contrast, alleles with alanine or valine at position 57 confer susceptibility, whereas the one allele with serine at position 57 confers weak susceptibility. Position 57 of the DQ β chain is not, however, the sole determinant of risk; susceptibility and protection are also conferred by other residues in the DQ β chain and by different alleles of the other chains. The biologic consequences of these and other amino acid differences are still being defined, but changes in peptide-binding sites of these class II molecules may alter the specificity of the immune response to foreign or self-antigens by affecting the binding affinity of different peptide antigens for the class II molecules.

A second susceptibility locus that has been identified using a candidate gene approach is the insulin gene locus on chromosome 11p15.5. Linkage of this region, which is referred to as *IDDM2*, has also been demonstrated to type 1 diabetes. Among the polymorphisms in this region is the variable number of tandem repeats (VNTR) locus in the 5'-flanking region of the insulin gene. The

Table 47-1
Susceptibility Loci for Type 1 Diabetes Mellitus

Susceptibility locus	Chromosome	Linked markers	λ_s
IDDM1[a]	6p21	HLA-DQB1, -DRB1	2.60
IDDM2[a]	11p15	Insulin VNTR	1.29

[a]Linkage confirmed in independent studies using independent data sets.
Adapted from Todd and Farrall (1996) and Cordell and Todd (1995).

VNTR consists of tandem repeats of a 14- to 15-bp core sequence. Three different alleles have been identified. The class I allele contains 34 to 45 repeats and is associated with a two- to fivefold increased risk of type 1 diabetes. The class III allele contains 141 to 209 repeats and has a dominant protective effect. The class II allele has approximately 80 repeats but is rare, and its association with disease susceptibility has not been defined. The λ_s for *IDDM2* is 1.3, and it accounts for 10% of the familial inheritance of type 1 diabetes.

IDDM2 is located within a 50-kbp region of chromosome 11 that contains the genes encoding tyrosine hydroxylase, insulin, and insulin-like growth factor-II (IGF-II). Multiple polymorphisms are present within this region, but an extensive series of genetic analyses mapped the *IDDM2* susceptibility locus to the VNTR in the 5'-flanking region of the insulin gene, suggesting that the variable number of repeats in some manner confers susceptibility to disease, perhaps because of effects on insulin gene expression. In vitro studies using the VNTR in reporter gene constructs have demonstrated that the VNTR modulates insulin gene expression, although conflicting data were obtained regarding the effect of the class III compared with class I allele on gene expression. In vivo studies have demonstrated that the class III allele is associated with decreased pancreatic insulin gene expression compared with transcription from the class I allele. A mechanism by which the VNTR could affect disease susceptibility via its effects on pancreatic expression of the insulin gene was not obvious. Subsequent studies, however, have examined effects of the VNTR on prenatal and postnatal expression of the insulin gene in the human thymus. Interestingly, the class III allele is associated with an approximately 2.5-fold increase in insulin gene expression in the thymus compared with the class I allele. Similarly, increased levels of proinsulin are present in thymi from class III/I heterozygotes compared with class I/I homozygotes. Increased expression of insulin in the thymus might facilitate tolerance to insulin by promoting deletion of insulin-specific T lymphocytes, and, thus, provide protection from type 1 diabetes.

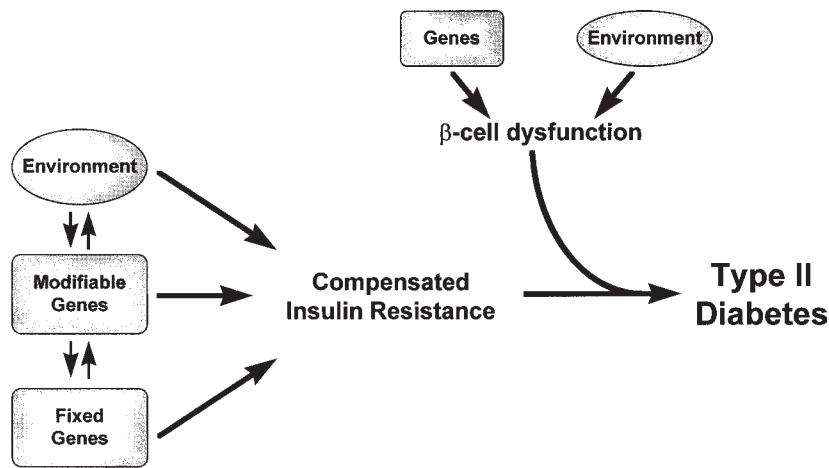
Because *IDDM1* and *IDDM2* account for only approximately 50% of the familial clustering of type 1 diabetes, additional genes must be involved. To identify these genes, genome scans have been performed using DNA from sibling pairs affected by type 1 diabetes. The aim of genome scans using affected sib pairs is to scan the entire genome with a collection of genetic markers, calculate the degree of allele sharing at each marker or locus, and identify those chromosomal loci in which allele sharing by the affected siblings occurs with greater frequency than expected,


Figure 47-1 Schematic model of the origin of type 2 diabetes mellitus. Type 2 diabetes is secondary to both insulin resistance and inadequate insulin secretion secondary to β-cell dysfunction. With sufficient β-cell function, euglycemia or impaired glucose tolerance is maintained in the presence of insulin resistance at the expense of hyperinsulinemia (compensated insulin resistance). With concomitant β-cell dysfunction, however, inadequate insulin secretion to compensate for the insulin resistance results in the onset of type 2 diabetes. Similarly, a primary defect in β-cell function may result in type 2 diabetes in the presence of some degree of insulin resistance. Both insulin resistance and β-cell dysfunction are influenced by genetic and environmental factors. Type 2 diabetes is multigenic, and its penetrance is secondary to the expression of several different genes, some of which are likely fixed and act independently of environmental factors. Other predisposing genes might be modifiable in that their expression or action is influenced by environmental factors. Interactions between genes are also likely to contribute to insulin resistance and β-cell dysfunction.

based on the frequency of the allele in the population. Increased sharing of alleles at a specific locus suggests that a gene(s) within that chromosomal locus contributes to the pathogenesis of the disease. Genome scans have now identified additional type 1 diabetes susceptibility loci (Table 47-1). Some of these loci have been confirmed by replication using additional families, whereas others await replication. None of these loci has an effect of the magnitude of *IDDM1*, but each may confer risk similar to that conferred by *IDDM2*. The genes at these loci that are responsible for conferring susceptibility to type 1 diabetes still await definition. As an increasing number of susceptibility loci are identified, an additional question that is raised is whether these different loci are acting epistatically. Epistasis, or interaction, between loci, indicates that the genotype at one locus affects the contribution of another locus. One implication of this is that loci that act epistatically may be acting through the same or related pathways. In contrast to epistasis is genetic heterogeneity, which indicates that two loci confer disease susceptibility independently, implying that the two loci confer risk via their effects on separate biologic pathways. This lack of interaction would suggest that an alteration in either pathway is associated with susceptibility to disease. *IDDM1* and *IDDM2* appear to act epistatically, whereas the action of *IDDM1* and *IDDM4* best fits a model of genetic heterogeneity. The potential interaction, or lack thereof, of the other susceptibility loci awaits further study.

Definition of the genetic etiology of type 1 diabetes will have several clinical implications. Currently, the vast majority of affected individuals are identified subsequent to the onset of diabetes when nearly complete β-cell destruction has occurred. A relatively limited subset of individuals at risk for developing type 1 diabetes can be identified before the onset of disease based on a family history of type 1 diabetes and the presence of antibodies directed against islet cells. Not all such individuals develop type 1 diabetes, however, and the risk of developing diabetes in these individuals is defined by the degree of loss of first phase insulin

secretion during an intravenous glucose tolerance test. This loss of first phase insulin secretion occurs secondary to β-cell destruction and indicates activity of the autoimmune process. Currently, treatment of at risk individuals with insulin before the onset of altered glucose homeostasis is being tested as a means of preventing or delaying the onset of diabetes. On the basis of studies in animal models of diabetes, "vaccination" with insulin or a peptide that contains the epitope against which the majority of anti-insulin antibodies are directed is also being considered. Because a significant decrease in first phase insulin secretion indicates that marked β-cell destruction has already occurred, if susceptible individuals can be identified earlier, based on their complement of susceptibility genes, and screening can be extended beyond those with a positive family history, it may be possible to intervene earlier, before the onset of β-cell destruction, and, thus, have a much greater impact on delaying or preventing the onset of type 1 diabetes. Second, as the pathways that are responsible for initiating the autoimmune process are identified, new therapies designed to interfere specifically with these pathways and prevent β-cell destruction can be developed. These therapies will likely be more efficacious in preventing the onset of diabetes than those that are currently available.

GENETICS OF TYPE 2 DIABETES MELLITUS

Type 2 diabetes mellitus is a heterogeneous disorder that develops in response to both genetic and environmental factors (Fig. 47-1). In contrast to type 1 diabetes, type 2 diabetes is often diagnosed during routine screening by the detection of hyperglycemia or because of mild symptoms of hyperglycemia, e.g., polyuria. Much like type 1 diabetes, individuals with type 2 diabetes pass through a series of phases before the onset of diabetes. Initially, plasma insulin levels are increased because of insulin resistance, but euglycemia is maintained. In the second phase, postprandial hyperglycemia is present despite persistent hyperinsulinemia. Finally, insulin secretion declines in the face of persistent insulin resistance, which results in diabetes. Thus, affected individuals

demonstrate both insulin resistance, manifest as hyperinsulinemia and decreased insulin-stimulated glucose uptake into tissues, and abnormal β-cell function, manifest as altered glucose-induced insulin secretion. Obesity is an additional contributing factor to type 2 diabetes via its effects on insulin sensitivity. Obesity, in turn, is affected by both energy expenditure and intake. Energy expenditure is dependent to a large degree on resting metabolic rate, whereas energy intake is regulated by the central nervous system and behavioral regulation of eating and satiety. All of the above processes are in part heritable, but complex, and depend on a variety of different gene products, each of which may have the potential to contribute to the genetic predisposition to type 2 diabetes.

Consistent with the heterogeneity of type 2 diabetes and the multiple contributing factors described above, mathematical modeling has suggested that type 2 diabetes is a polygenic disease. Consequently, onset of the disease likely requires the simultaneous presence of a subset of genes that affect the above processes. Because different subsets of genes are probably sufficient to confer susceptibility to type 2 diabetes, susceptibility genes likely vary between and, possibly, within populations. Moreover, environmental factors that have still not been fully defined contribute to the development of type 2 diabetes. Thus, disease susceptibility genes may be present in unaffected individuals because they lack a required complement of disease susceptibility genes or needed environmental factors to induce diabetes. This has and will continue to complicate attempts to define susceptibility genes for type 2 diabetes. An additional complication in defining the genetics of type 2 diabetes is that it is of late onset. Typically, parents, especially affected parents who may have succumbed to the complications of diabetes, are not available for study, and offspring are unlikely to be affected. Thus, family studies of type 2 diabetes are difficult. Finally, although it is clear that type 2 diabetes is polygenic and genetically heterogeneous, it is still unclear whether there are two or three major variants of the disease with additional minor variants or whether type 2 diabetes is truly heterogeneous with multiple variants, each of which accounts for a small percentage of affected individuals.

Despite the above challenges, progress has been made in defining the genetics of late-onset type 2 diabetes. As with type 1 diabetes, the candidate gene approach and genome scanning have been used to identify genes that confer susceptibility to type 2 diabetes, but these studies have been complicated by all of the issues described above. Moreover, unlike *IDDM1*, which is a major susceptibility locus for type 1 diabetes, it is possible that there is not a major susceptibility gene for type 2 diabetes; rather, multiple genes that confer a limited degree of susceptibility may exist.

GENETICALLY DEFINED FORMS OF TYPE 2 DIABETES
Given the complexities of the genetics of type 2 diabetes, substantial effort has been applied using both candidate gene and positional cloning approaches to define the genetics of rare, but monogenic, forms of diabetes with the hope that this will provide insight into the genetics of type 2 diabetes.

Mitochondrial Diabetes Mellitus   The role of mutations in mitochondrial DNA as a cause of disease is becoming increasingly appreciated (*see* Chapter 103). Mitochondrial DNA is inherited maternally and encodes 13 polypeptide subunits involved in oxidative phosphorylation and the respiratory pathway, 22 transfer RNAs (tRNAs), and 2 ribosomal RNAs. Mitochondrial DNA is vulnerable to mutation because it is composed almost exclusively of coding sequences, lacks protection by histones, has inefficient repair mechanisms, and is exposed to reactive oxygen species produced during oxidative phosphorylation. Mitochondrial DNA undergoes mutation 5–10 times faster than nuclear DNA. The possibility that mitochondrial DNA mutations might contribute to the pathogenesis of diabetes mellitus was suggested by the association of diabetes with several mitochondrial diseases and by the maternal inheritance of mitochondrial DNA, given the slight preference for maternal transmission of type 2 diabetes.

Initially, a syndrome of diabetes mellitus and deafness caused by sensorineural hearing loss was identified in two pedigrees. In both, an A/G exchange at nucleotide 3243 in the mitochondrial tRNA^Leu(UUR) gene was noted. This particular mutation was located within a mitochondrial DNA-binding site for a protein that contributes to the termination of transcription at the boundary between the 16S ribosomal RNA and tRNA^Leu(UUR) genes. Thus, this mutation alters both tRNA^Leu(UUR) synthesis and mitochondrial protein synthesis in general. Interestingly, tRNA^Leu(UUR) is a hot spot for mutations; 10 disease-related mutations have been identified within this gene, 4 of which are associated with diabetes mellitus.

Identification of these syndromes raised the question as to the role of mitochondrial DNA mutations in the pathogenesis of diabetes mellitus. A variety of studies have determined that of patients with type 1 and 2 diabetes mellitus, the A/G exchange in the tRNA^Leu(UUR) gene is present in 0.5–1.5% of patients. If only those patients with a family history of diabetes are considered, the prevalence of the mutation is two to five times higher. Characterization of affected individuals and their siblings demonstrated that 48% presented with diabetes and deafness, 21% had diabetes alone, 15% had deafness alone, 3% had deafness associated with some neurologic changes, and 13% had diabetes, deafness, and the findings of the MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, and strokelike episodes). The phenotypic variation is presumably caused by variable numbers of mitochondria containing normal compared with abnormal mitochondrial DNA (heteroplasmy) between tissues. Heteroplasmy results from unequal separation of mitochondrial populations during mitosis and differential accumulation of subsequent mitochondrial mutations.

Although patients with mitochondrial DNA mutations were initially diagnosed as having either type 1 or 2 diabetes mellitus, there were differences between these patients and those with "typical" type 1 or 2 diabetes. Those diagnosed initially as having type 1 diabetes in general lacked anti–islet cell antibodies and did not typically have a history of diabetic ketoacidosis, whereas those initially diagnosed as having type 2 diabetes tended to be leaner and to be more likely to be treated with insulin compared with general populations with type 2 diabetes. Subsequent studies to define the etiology of diabetes in patients with mitochondrial mutations demonstrated decreased insulin secretion in response to an oral glucose tolerance test, whereas measures of glucose utilization demonstrated essentially normal insulin sensitivity. The above findings suggest that the primary defect in patients with mitochondrial mutations is in the pancreatic β cell. The pathway of glucose-induced insulin secretion is still being elucidated, but oxidative phosphorylation and ATP generation are thought to play an important role in insulin secretion (Fig. 47-2), so mutations in β-cell mitochondrial DNA would likely interfere with insulin secretion because of insufficient ATP generation.

In patients with diabetes accompanied by hearing loss, a diagnosis of mitochondrial DNA mutations as the cause of the diabetes should be considered. Patients with these mutations should be advised that they will be much more likely to require insulin therapy because of the insulin deficiency that develops. Moreover, family members need to be carefully screened for both diabetes and evidence of sensorineural hearing. Frequently, the hearing
Figure 47-2 Schematic representation of glucose-stimulated insulin secretion by the pancreatic β cell. Glucose uptake is mediated by GLUT2, and glucose is phosphorylated by glucokinase to generate glucose-6-phosphate. Metabolism of glucose-6-phosphate via glycolysis yields pyruvate, which enters the tricarboxylic acid cycle in the mitochondria to generate ATP. The generation of ATP increases the ATP to ADP ratio in the cytoplasm, which inhibits activity of the ATP-sensitive K$^+$ channels. The ATP-sensitive K$^+$ channel is a complex of the sulfonylurea receptor (SUR) and an inwardly rectifying K$^+$-channel protein (KIR6.2). Inhibition of these channels results in membrane depolarization and opening of voltage-dependent Ca^{2+} channels. The resulting increase in the intracellular concentration of Ca^{2+} stimulates insulin secretion. β-cell development and insulin production are regulated by a variety of factors, including several different transcription factors.

loss develops after the onset of diabetes, so those patients with diabetes need to be examined over time for hearing loss.

Maturity Onset Diabetes of the Young (MODY) MODY is a subtype of diabetes that is monogenic and provides a model for studying the molecular genetics of type 2 diabetes. MODY is characterized by an early age of onset of diabetes and an autosomal dominant mode of inheritance that is based on the demonstration of a positive family history in three successive generations. Disease onset often occurs between 9 and 13 years of age and typically, although not universally, occurs before 25 years of age.

Characterization of MODY patients from different kindreds revealed phenotypic differences between patients suggesting heterogeneity, which molecular genetic analyses confirmed. Linkage to polymorphisms in the glucokinase gene on chromosome 7p was demonstrated in some patients, whereas in other patients positional cloning techniques demonstrated linkage to markers on either chromosome 20q or 12q. Subsequent genetic analyses demonstrated that the kindred described as having MODY1 had a mutation in the hepatocyte nuclear factor (HNF)-4α gene on chromosome 20q, whereas kindreds with MODY3 had mutations in HNF-1α on chromosome 12q. Mutations in the glucokinase gene were shown to cause diabetes in kindreds with MODY2. Finally, a kindred was described recently in which early-onset type 2 diabetes (MODY4) cosegregated with an inactivating mutation in the insulin promoter factoral (IPF-1) gene. Mutations in these genes do not account for all cases of MODY, suggesting that additional MODY genes await description.

The phenotypic differences between patients with the different forms of MODY provide some insight into the function of the responsible genes. Glucokinase is a key enzyme in glucose metabolism in β cells and hepatocytes and catalyzes the formation

of glucose-6-phosphate from glucose. Glucokinase participates in glucose sensing and links glucose to insulin secretion. In patients with glucokinase mutations, the severity of enzyme impairment is correlated to the degree of hyperglycemia. Because of the decreased sensitivity of the β cells to glucose in these patients, the dose–response curve for glucose-induced insulin secretion is shifted to the right, but increased insulin secretion is observed with increasing degrees of hyperglycemia. Whether altered glucose metabolism in hepatocytes contributes to the hyperglycemia is not known. Because of the underlying origin of the hyperglycemia, patients with MODY2 typically present early in life, usually before puberty, with mild fasting hyperglycemia that does not worsen over time.

As noted, MODY1, MODY3, and MODY4 are caused by mutations in HNF-4α, HNF-1α, and IPF-1, respectively. HNF-4α is a transcription factor that is a member of the steroid–thyroid superfamily of nuclear receptors. Members of this receptor family are typically ligand-activated, but whether there is a ligand that activates HNF-4α is unknown. HNF-1α is a homeodomain transcription factor that functions either as a homodimer or as a heterodimer with the structurally related transcription factor HNF-1β. As their names imply, both of these factors are important for hepatic gene expression, but they are expressed in other tissues, including pancreatic islets. How mutations in these factors cause diabetes is unknown, although HNF-1α is known to be a weak *trans*-activator of the rat insulin I gene. HNF-4α is a positive regulator of HNF-1α expression and, thus, decreased HNF-1α production likely contributes to the cause of diabetes in patients with HNF-4α mutations. Little else is known about the function of HNF-1α and HNF-4α in pancreatic islets, but elucidation of their function will likely provide insight into islet cell development and function. IPF-1 is a transcription factor that regulates both pancreatic development and insulin

gene transcription. The other issue that has not been resolved is why MODY1, MODY3, and MODY4 are autosomal dominant diseases, implying that mutation of one allele results in disease. It is unclear whether the product of the mutant allele functions in a dominant negative fashion and inhibits activity of the product of the wild-type allele or whether a reduction in the amount of active transcription factor causes disease (haploinsufficiency).

The phenotype of patients with MODY1 and MODY3 provides some insight into how mutations in HNF-1α and HNF-4α confer susceptibility to diabetes. The primary defect in patients with MODY1 and MODY3 is in the β cell. These patients have normal insulin sensitivity but demonstrate decreased insulin secretion in response to glucose. Unlike patients with MODY2, a progressive increase in insulin secretion with increasing hyperglycemia is not observed, suggesting a reduced capacity for insulin secretion. Similar defects, albeit not as severe, are present in individuals who have mutations in HNF-1α or HNF-4α but are not, as yet, diabetic. Thus, mutations in HNF-1α and HNF-4α appear to affect the regulation of insulin secretion or β-cell development.

As noted, patients with MODY2 typically have mild fasting hyperglycemia and are much less susceptible to the microvascular and macrovascular complications of diabetes compared with patients with type 2 diabetes. Patients with MODY1 and MODY3, in contrast, exhibit the microvascular and macrovascular complications associated with diabetes, but do not have the phenotype commonly associated with late-onset type 2 diabetes, obesity, hypertension, and hypercholesterolemia. These observations raise the issue of the contribution of mutations in the MODY genes to the etiology of late-onset type 2 diabetes. Although approximately 5% of women with gestational diabetes mellitus and a first-degree relative with diabetes have mutations in the glucokinase gene, neither linkage studies nor mutational analyses suggest that mutations in glucokinase account for significant numbers of cases of late-onset type 2 diabetes. Mutations in HNF-4α appear to be rare, since only a single kindred with MODY1 has been described. Moreover, the mutation in HNF-4α associated with MODY1 was not present in a large population of Japanese with late-onset type 2 diabetes. Similarly, there is no evidence for linkage of the HNF-4α locus to type 2 diabetes. Further studies need to be done, but to date, there are no data to suggest that HNF-4α mutations account for a significant number of cases of late-onset type 2 diabetes. Mutations in HNF-1α appear to be more common. In studies of patients with early onset diabetes (<40 years old) and a family history of diabetes, many of whom represent previously undescribed cases of MODY, mutations in HNF-1α have been found in 7–36% of patients, whereas in patients with more typical late-onset type 2 diabetes, mutations in HNF-1α are rare. More intriguing, however, is a recent study in an isolated population in Finland that examined people with late-onset type 2 diabetes (age of onset less than 60 years of age with a mean age of onset of 58 years), and a strong family history of diabetes. In the subgroup of patients with the lowest quartile of insulin secretion during an oral glucose tolerance test, linkage to the MODY3 locus on chromosome 12q was demonstrated. Mutations in HNF-1α have not yet been demonstrated in this population, but this study suggests that milder mutations in HNF-1α may contribute to a subset of late-onset type 2 diabetes. Weak linkage to the MODY3 locus was found in whites with late-onset type 2 diabetes complicated by diabetic nephropathy, but no evidence for linkage has been found in other populations, including African Americans and Mexican Americans. Thus, there is some evidence to suggest that mutations of HNF-1α con-

tribute to late-onset type 2 diabetes in some subgroups of patients, but the exact role of HNF-1α still remains to be defined.

Now that the MODY genes have been defined, genetic testing will be available to family members from MODY kindreds. This will have implications for disease screening in these individuals, as well as institution of preventive measures, e.g., exercise, diet, and weight control, to minimize insulin resistance. Secondly, as the role of the hepatocyte nuclear factors in pancreatic development is elucidated, new therapeutic targets to enhance β-cell function may become available.

Insulin Gene   Insulin is a primary hormone in the regulation of glucose homeostasis and, thus, represents a natural candidate gene for type 2 diabetes. Six different mutations that affect insulin processing and action have been described, but these mutations are rare. Three of these mutations alter the primary sequence of the A or B chain of insulin. These mutations affect insulin binding to its receptor and, thus, decrease the efficacy of insulin. Individuals with these mutations typically have mild hyperglycemia in association with hyperinsulinemia. Three mutations that affect proinsulin processing have also been described. These mutations have only a minimal effect on glucose homeostasis but result in hyperproinsulinemia. Because of their rarity, most individuals who bear insulin gene mutations are heterozygotes who have minimal impairment of glucose homeostasis, although this can be modified by obesity and increasing age. Insulin gene mutations are present in low prevalence in type 2 diabetes suggesting they do not make a major contribution to the disease. Moreover, linkage studies have not demonstrated linkage of the insulin gene locus to type 2 diabetes.

Because insufficient insulin secretion to compensate for insulin resistance contributes to the cause of type 2 diabetes, the role of mutations in the insulin gene promoter has also been examined. Promoter variants, including an 8-bp insertion in the promoter of some African Americans, have been described, but there is no evidence to suggest that insulin gene promoter variants contribute significantly to type 2 diabetes. Moreover, the role of the VNTR in the insulin gene promoter has also been examined. Again, no clear association of any of the alleles with type 2 diabetes has been demonstrated.

Insulin Receptor Gene   As the most proximal site of insulin action, the insulin receptor is a second candidate gene for type 2 diabetes. The insulin receptor is a transmembrane receptor with tyrosine kinase activity that is activated on insulin binding (*see* Chapter 46 for details of signal transduction via tyrosine kinases). Normal tyrosine kinase activity is critical for transmission of a signal via the insulin receptor.

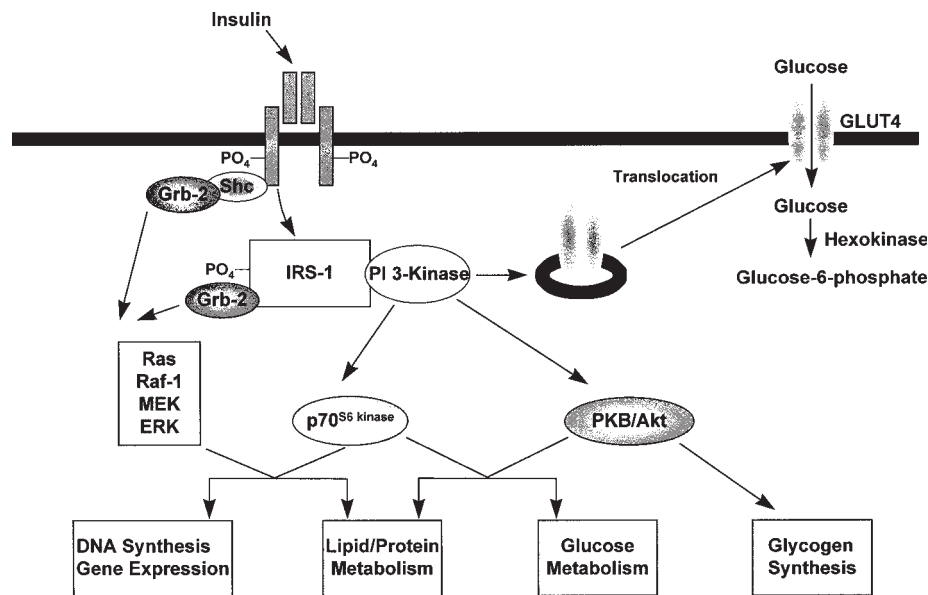
The potential role of insulin receptor mutations in diabetes mellitus was revealed by the demonstration that insulin receptor mutations were associated with specific syndromes of extreme insulin resistance, including leprechaunism, Rabson-Mendenhall syndrome, and type A extreme insulin resistance. These syndromes differ phenotypically because of different degrees of insulin resistance. Leprechaunism is associated with the greatest degree of insulin resistance and is characterized by intrauterine and postnatal growth retardation, dysmorphic facies, lipoatrophy, acanthosis nigricans (a cutaneous manifestation of insulin resistance), and death in early infancy. Rabson-Mendenhall presents in early childhood and is characterized by insulin-resistant diabetes mellitus, abnormal facies, dental dysplasia, thickened nails, hirsutism, precocious puberty, and acanthosis nigricans. Although these patients exhibit severe insulin resistance, they exhibit a lesser degree of insulin resistance than patients with leprechaunism. Finally, type A insulin resistance is characterized by extreme insulin resistance,


Figure 47-3 Schematic representation of insulin-induced signaling. Insulin signaling is initiated by insulin binding to the insulin receptor and activation of the receptor's intrinsic tyrosine kinase activity. Substrates for the tyrosine kinase include insulin receptor substrate-1 (IRS-1) and Shc. Through an interaction with Grb-2, both IRS-1 and Shc are able to activate a mitogen-activated protein kinase (MEK) and subsequently the mitogen-activated protein kinases (MAPKs), ERK1 and 2. Activation of phosphatidylinositol 3-kinase (PI 3-kinase), through its interaction with IRS-1, results in translocation of the insulin-responsive glucose transporter, GLUT4, to the plasma membrane and activation of two additional kinases, p70$^{S6\ kinase}$ and protein kinase B (PKB) or Akt. Activation of PKB has recently been shown to result in activation of glycogen synthase. Not shown are additional substrates of the insulin receptor, including IRS-2, pp60 (IRS-3), a novel 160-kDa protein that is phosphorylated in response to insulin (IRS-4), and the proto-oncogene c-Cbl, which is an adipocyte-specific substrate for the insulin receptor. The contribution of these and other signaling pathways to insulin-induced effects is still being elucidated, but the likely contribution of multiple pathways to these different effects is illustrated. The relative contribution of the different pathways probably varies in different cell types, and it is likely that additional pathways not shown here also contribute to insulin-induced effects. Alteration of any of the molecules in these different signaling pathways would be expected to have an effect on insulin sensitivity and contribute to the development of insulin resistance.

albeit of lesser degree than that seen in the above two syndromes, and is often associated with normal or only mildly impaired glucose homeostasis and acanthosis nigricans. Women with this syndrome typically exhibit hyperandrogenism, hirsutism, and polycystic ovaries. The varying degree of insulin resistance present in these different syndromes is determined by the number of mutant alleles inherited, as well as the severity of the mutations. Patients with leprechaunism typically inherit two mutant alleles, whereas patients with the Rabson-Mendenhall syndrome and type A insulin resistance inherit one or two alleles with mutations that confer different degrees of receptor dysfunction. To date, more than 40 mutations in the insulin receptor have been described. These mutations occur throughout the receptor with effects on receptor synthesis or processing, insulin binding, or tyrosine kinase activity.

The role of insulin receptor mutations as a causative factor in type 2 diabetes is not as clear. Receptor mutations that induce more subtle defects in receptor activity than those described above have been identified but are rare. It has been estimated that no more than 1–2% of patients with type 2 diabetes have mutations in the tyrosine kinase domain of the insulin receptor that affect receptor function. Studies designed to demonstrate association of restriction fragment length polymorphisms (RFLPs) in the insulin receptor with type 2 diabetes have been largely negative, and linkage of the insulin receptor to type 2 diabetes has not been demonstrated. Thus, there is no evidence to suggest that insulin receptor mutations contribute significantly to the pathogenesis of type 2 diabetes.

GENETICS OF LATE-ONSET TYPE 2 DIABETES Despite significant progress in defining the genetics of monogenic forms

of diabetes, genetic abnormalities that contribute to the majority of cases of late-onset type 2 diabetes have yet to be identified using this approach. For that reason, both candidate gene and genome scanning and positional cloning approaches have been used to define the genetics of type 2 diabetes.

Candidate Genes for Late-Onset Type 2 Diabetes The candidate gene approach depends on the use of educated guesses to choose gene products that may have an effect on glucose homeostasis and, thus, predispose an individual to the development of type 2 diabetes. Logical candidates would include genes that affect insulin production, glucose metabolism in pancreatic β cells, insulin processing and secretion, insulin action and glucose metabolism in peripheral tissues, genes that regulate body weight, eating behavior, and satiety, and genes that encode inhibitors of insulin action (Figs. 47-2 and 47-3). Because of the frequent association of altered cholesterol and triglyceride metabolism with diabetes, genes that affect lipid metabolism have also been considered as candidate genes for type 2 diabetes. A summary of the results of studies using the candidate gene approach is presented in Tables 47-2 through 47-7.

An association of specific missense mutations or other polymorphisms with type 2 diabetes has been demonstrated for several genes, including the sulfonylurea receptor, glucagon receptor, prohormone convertase 2, insulin receptor substrate 1 (IRS-1), glycogen synthase, amylin, and Rad (Ras-related protein associated with diabetes) genes. In each case, however, other studies have been unable to replicate the findings in different populations or only a single study has been performed. Moreover, with the

Table 47-2
Candidate Genes for Type 2 Diabetes With Effects on Insulin Production, Processing, or Secretion

Candidate genes	Findings
Genes that regulate β-cell development and function	
Hepatocyte nuclear factor-1α	Mutations of this gene are responsible for MODY3. Linkage of the MODY3 locus on chromosome 12q to late-onset type 2 diabetes in Finnish population with low insulin secretion has been demonstrated. Role in late-onset type 2 diabetes otherwise has not been defined.
Hepatocyte nuclear factor-4α	Mutations in this gene are responsible for MODY1. Mutation responsible for MODY1 was not present in a population of Japanese with late-onset type 2 diabetes. Linkage of the MODY1 locus to type 2 diabetes has not been demonstrated.
Insulin promoter factor (IPF-1 or IDX1)	Homozygous mutation of this transcription factor that regulates β-cell development and insulin gene transcription results in pancreatic agenesis. Heterozygous state cosegregates with early-onset type 2 diabetes (MODY4).
Genes that regulate insulin gene transcription	
Islet-1 *(Isl-1)*	No association of polymorphisms with type 2 diabetes or evidence for linkage.
Caudal-type homeodomain 3 *(CDX3)*	No evidence for linkage with type 2 diabetes.
Genes with an effect on insulin secretion	
Inwardly rectifying K⁺-channel subunit *(Kir6.2)*	No evidence for linkage with type 2 diabetes. No association of multiple missense mutations and silent polymorphisms with type 2 diabetes.
G-protein-coupled muscarinic potassium channel *(KCNJ3)*	No evidence for association of any alleles with type 2 diabetes or of linkage with type 2 diabetes.
G-protein-coupled inwardly rectifying potassium channel-2 *(KCNJ7)*	No mutations noted in patients with type 2 diabetes. No association of different alleles with type 2 diabetes. No evidence of linkage with type 2 diabetes.
Sulfonylurea receptor	Demonstration of association of a silent polymorphism with type 2 diabetes in two different populations. No evidence of linkage with type 2 diabetes in multiple populations.
Glucagon	No evidence for linkage with type 2 diabetes.
Glucagon receptor	Missense mutation associated with type 2 diabetes in two populations but this same missense mutation was not detected in other populations.
Glucagon-like peptide-1 receptor	No evidence for association of different alleles with type 2 diabetes. No evidence for linkage with type 2 diabetes.
Gastric inhibitory polypeptide receptor	No association between missense mutations and type 2 diabetes.
Glucokinase regulatory protein	No evidence for linkage with type 2 diabetes.
Amylin	Association of a missense mutation with type 2 diabetes but no evidence for linkage in multiple different populations.
Genes with an effect on insulin processing	
Prohormone convertase 2	Association of a specific allele defined with microsatellite markers with type 2 diabetes. No evidence for linkage with type 2 diabetes.

MODY, mature onset diabetes of the young.

Table 47-3
Candidate Genes for Type 2 Diabetes With an Effect on β-Cell Glucose Metabolism

Candidate genes	Findings
Mitochondrial FAD-linked glycerophosphate dehydrogenase *(GPD2)*	No evidence for association of specific alleles with type 2 diabetes. No evidence for linkage with type 2 diabetes.
Pyruvate kinase *(PKM)*	No evidence for linkage with type 2 diabetes.
Glucose transporter 2 *(GLUT2)*	No evidence for association of missense mutations with type 2 diabetes. No evidence for linkage with type 2 diabetes.
Hexokinase I *(HK1)*	No evidence for linkage with type 2 diabetes.

FAD, flavin adenine dinucleotide.

exception of IRS-1, which has shown weak linkage to the age of onset of type 2 diabetes but not to the disease itself, there is no evidence for linkage of any of these genes to type 2 diabetes. Linkage studies using candidate genes have also been of limited utility, although a few positive findings have been reported. Fatty acid binding protein 2 (FABP2) is not linked to type 2 diabetes, but linkage of this locus to fasting and insulin-stimulated glucose levels has been demonstrated. Moreover, association of a specific missense mutation in the FABP2 gene with fasting and glucose-stimulated insulin levels was demonstrated in Pima Indians, but this finding was not replicated in a white population. Weak evidence for linkage of the apolipoprotein A₂ gene was found in a

single study that has not been replicated, whereas a trend toward linkage of the phosphoenolpyruvate carboxykinase (PEPCK) gene to type 2 diabetes in patients with an onset before 46 years of age was demonstrated in one study, but no evidence for linkage was found in another study. Thus, to date, a gene that makes a significant contribution to type 2 diabetes in a majority of cases has not been identified. Because type 2 diabetes appears to be a polygenic disorder with significant heterogeneity between affected individuals, however, a major "diabetogene" that is important in all affected individuals may not exist, and the importance of different "diabetogenes" in conferring risk for type 2 diabetes may vary between different populations. For these reasons, studies that fail

Table 47-4
Candidate Genes for Type 2 Diabetes With an Effect on Insulin Action and Glucose Metabolism

Candidate genes	Findings
Insulin receptor substrate 1 (IRS-1)	Multiple missense mutations have been identified with one, Gly972Arg, being found with increased prevalence in patients with type 2 diabetes in some studies but not others. No evidence for linkage of IRS-1 with type 2 diabetes in one study whereas another found possible weak linkage of IRS-1 with a gene affecting age of onset of type 2 diabetes.
Phosphatidylinositol 3-kinase (PI3-K)	No association of a missense mutation with type 2 diabetes, although in homozygous state the missense mutation was associated with decreased insulin sensitivity and glucose disappearance constant.
Glycogen synthase (GYS1)	Increased association of specific alleles identified by either microsatellite markers or RFLP with type 2 diabetes in some populations, but no mutations found in the gene. In other studies, no evidence for association of the same alleles with type 2 diabetes. No evidence for linkage with type 2 diabetes.
Inhibitor 2 of type 1 protein phosphatase (PPP1R2)	No evidence of mutations in coding sequence of the gene in insulin-resistant compared with insulin-sensitive Pima Indians.
Protein serine–threonine phosphatase 1β (PPP1CB)	No evidence for linkage with type 2 diabetes.
Glucose transporter 1 (GLUT1)	Association of an allele defined by RFLP analysis with type 2 diabetes in obese overweight women. No evidence for linkage with type 2 diabetes.
Glucose transporter 4 (GLUT4)	No association of RFLP or missense mutation with type 2 diabetes. No evidence of linkage to type 2 diabetes.
Hexokinase II	No evidence of association of multiple missense mutations with type 2 diabetes, except for possibly one missense mutation present in 2.7% of patients with type 2 diabetes but not in control subjects. No evidence for linkage to type 2 diabetes.
Fructose 1,6-bisphosphatase	No evidence for linkage with type 2 diabetes.
Hepatic phosphofructose kinase	No evidence for linkage with type 2 diabetes.
Phosphoenolpyruvate carboxykinase	Trend toward linkage in sib pairs diagnosed with type 2 diabetes before age 46, whereas no evidence for linkage in another family study.
Pyruvate kinase (PKL)	No evidence for linkage with type 2 diabetes

RFLP, restriction fragment length polymorphism.

Table 47-5
Candidate Genes for Type 2 Diabetes That Regulate Eating Behavior and Adiposity

Candidate genes	Findings
Leptin (ob)	No evidence for mutations in ob gene in patients with type 2 diabetes. No evidence for linkage with type 2 diabetes.
Tubby (TUB)	No evidence for linkage with type 2 diabetes.
Cholecystokinin receptor B	In sib pairs with type 2 diabetes diagnosed before age 45, suggestive evidence for linkage of locus on chromosome 11 where cholecystokinin B receptor is located with type 2 diabetes.

Table 47-6
Candidate Genes for Type 2 Diabetes That Are Inhibitors of Insulin Action

Candidate genes	Findings
Growth hormone	Weak evidence for linkage of growth hormone locus with type 2 diabetes.
Rad (RAD1)	Evidence for association of minor alleles of an intronic trinucleotide repeat with type 2 diabetes. No association of this polymorphism with type 2 diabetes found in a second study. No evidence for linkage with type 2 diabetes.
TNF-α	No evidence for linkage with type 2 diabetes.
TNF-β	No evidence for linkage between TNF-β and age of onset of type 2 diabetes.

Rad, Ras-related protein associated with diabetes; TNF, tumor necrosis factor.

to demonstrate association or linkage of a candidate gene to type 2 diabetes may be misleading, and larger studies or studies using specific at-risk populations may be required to document the role of specific candidate genes in the pathogenesis of type 2 diabetes.

Identification of Susceptibility Loci for Late-Onset Type 2 Diabetes Less information is available using genome scanning and positional cloning techniques to identify susceptibility loci for late-onset type 2 diabetes. An early approach to this problem was to examine for linkage of specific traits that are altered in affected individuals. In Pima Indians, linkage of a locus on chromosome 1 to the acute response of insulin to intravenous glucose was observed using microsatellite markers. Interestingly, this locus is close to the recently identified leptin receptor. Leptin has been shown to have an

effect on insulin secretion, although neither linkage of the leptin receptor itself to the acute insulin response nor mutations in the leptin receptor in Pima Indians have been demonstrated. Studies examining linkage of loci on specific chromosomes to type 2 diabetes have yielded limited results. Suggestive evidence for linkage of a region of chromosome 11 with type 2 diabetes has been demonstrated in whites of Northern European descent, whereas two studies examining loci on chromosome 20 demonstrated evidence for linkage of a specific region of chromosome 20q, which is distinct from the MODY1 locus, to type 2 diabetes in white sib pairs. Interestingly, no evidence for linkage of this region was observed in African Americans, consistent with the idea of genetic heterogeneity between populations. Moreover, the IDDM loci described in Table 47-1 are not linked to type 2

Table 47-7
Candidate Genes for Type 2 Diabetes With an Effect on Lipid Metabolism

Candidate genes	Findings
Fatty acid binding protein 2 (FABP2)	No evidence for linkage with type 2 diabetes. Linkage of FABP2 locus to 2-h postglucose insulin level in Mexican American sib pairs. In Pina Indians, linkage of locus to maximal insulin-stimulated glucose uptakeand fat oxidation. In Finnish population, weak association of the missense mutation with fasting and glucose-stimulated insulin levels but not fat oxidation.
Hormone-sensitive lipase	No association of missense mutation with type 2 diabetes.
Lipoprotein lipase	No evidence for linkage with type 2 diabetes or age of onset of type 2 diabetes.
Hepatic triglyceride lipase	No evidence for association with type 2 diabetes.
Very-low-density lipoprotein receptor	No evidence for linkage with type 2 diabetes.
Apolipoprotein CII	No evidence for linkage with type 2 diabtetes. No evidence for association of alleles identified using microsatellite markers with type 2 diabetes.
Apolipoprotein A_2	Weak evidence for linkage with type 2 diabetes in a study of white families.
Apolipoprotein B	No evidence for linkage with type 2 diabetes.
Cholesterol ester-transfer protein	No evidence for linkage with type 2 diabetes.

diabetes. Finally, a genome scan that was designed to identify susceptibility loci for type 2 diabetes in Mexican American sib pairs demonstrated a single susceptibility locus on chromosome 2, now referred to as *NIDDM1*. In white French sib pairs, suggestive evidence for linkage of *NIDDM1* with type 2 diabetes was observed. Candidate genes within this region of chromosome 2 have not yet been identified. Genome scanning to identify susceptibility loci for type 2 diabetes is still in its early stages, but as methods for identifying susceptibility loci for complex diseases and for performing genome scans improve, additional susceptibility loci will be identified.

Clinical Implications   Defining the genetics of type 2 diabetes will not only elucidate the molecular basis for the disease, but it will also have important clinical implications. First, understanding the molecular basis for the disease will facilitate the development of new therapeutic modalities. Second, as susceptibility genes are defined, the genetic burden of a given individual can be determined. In appropriate individuals, aggressive preventive measures might be instituted. Moreover, type 2 diabetes can be subclassified based on the predisposing genes present in a patient and that subclassification can be used to direct therapeutic interventions in that patient on the basis of the probable underlying pathophysiology.

48 Pituitary Function and Neoplasia

SHLOMO MELMED

INTRODUCTION

The cell types of the mature adenohypophysis are derived embryologically from somatic ectoderm associated with Rathke's pouch. Highly specific trophic factors determine a precise temporal and spatial development of cells expressing unique gene products. The six hormones of the anterior pituitary gland are expressed by at least five distinct hormone-producing cell populations, including corticotrophs (pro-opiomelanocortin, POMC), somatotrophs (growth hormone, GH), lactotrophs (prolactin, PRL), thyrotrophs (thyroid-stimulating hormone, TSH), and gonadotrophs (follicle-stimulating hormone, FSH, and luteinizing hormone, LH) (Table 48-1). Each of these cells are identified by specific assays of polypeptide gene expression, including single-cell mRNA, immunoelectron microscopy, and immunocytochemical assays. The temporal ontogeny of these gene products is initially adrenocorticotropic hormone (ACTH) and α-subunit. After the appearance of Pit-1, a pou-domain transcription factor, mixed mammosomatroph products appear. Distinct GH- and PRL-expressing cells PRL-expressing cells follow and TSH, LH, and FSH are the final IPII types to mature at 12 weeks.

Each of the anterior pituitary trophic hormones is induced by a respective hypothalamic releasing hormone, and their transcription is regulated by negative feedback inhibition of their respective target hormone (Table 48-2).

CORTICOTROPH CELLS

The corticotrophs constitute between 15 and 20% of the adenohypophyseal cell population, and express strong granular cytoplasmic immunopositivity for ACTH and other POMC fragments.

Corticotrophin-releasing hormone (CRH) and glucocorticoids exert opposite effects on POMC gene transcription; CRH increases POMC mRNA and protein content via cyclic adenosine monophosphate (cAMP), whereas the glucocorticoid negative feedback effect is probably mediated through binding of the glucocorticoid receptor complex to *cis*-active POMC promoter sequences. Several enhancer elements have been identified on the POMC gene promoter. These appear to act synergistically in regulating POMC transcription. POMC transcription is also induced by β-adrenergic activation and insulin-induced hypoglycemia.

REGULATION OF ACTH

Ligand activation of the CRH receptor (Gs protein containing seven transmembrane domains) on the corticotroph stimulates ACTH synthesis as well as release. POMC transcriptional regulation is mediated by cAMP as well as indirectly by c-fos activation. Arginine vasopressin (AVP), physical stress, exercise, acute illness, and hypoglycemia all increase ACTH levels. Several cytokines mediating inflammatory and or immune responses, including tumor necrosis factor-α, interleukin-1 (IL-1), IL-6, and leukemia-inhibitory factor (LIF), also stimulate ACTH, whereas glucocorticoids and opiates inhibit ACTH transcription and release. This neuroimmune endocrine interface appears to occur directly at the level of POMC gene expression. ACTH secretion is pulsatile, with an endogenous circadian rhythm associated with a parallel diurnal pattern of glucocorticoid secretion. Both ACTH and cortisol are higher in the early morning and decline at night.

Hypercortisolism may be caused by pituitary corticotroph adenomas (Cushing's disease) (70%), ectopic ACTH production (12%), cortisol-producing adrenal adenomas, carcinoma and hyperplasia (18%), and, rarely, ectopic CRH production. Iatrogenic hypercortisolism caused by prolonged administration of glucocorticoids produces a similar clinical syndrome.

ACTH-CELL ADENOMA   About 10–15% of all pituitary adenomas are ACTH-producing tumors that are usually well-differentiated microadenomas. About 5% are silent corticotroph adenomas. Secretory granules in tumor cells immunostain positively for ACTH, β-endorphin, β-LPH, and N-terminal peptide. Although these adenomas exhibit unrestrained ACTH secretion with resultant hypercortisolemia, they often retain suppressibility in the face of high doses of administered glucocorticoids.

ECTOPIC ACTH SECRETION   ACTH production by small cell lung carcinomas and bronchial and thymic carcinoids may result in florid manifestations of Cushing's syndrome. The POMC mRNA transcript derived from nonpituitary ACTH-secreting tumors may be longer than the normal transcript or that detected in pituitary tumors. CLIP and β-MSH fragments may also be detected in ectopic tumors, indicating alternative POMC processing. Glucocorticoids do not suppress POMC mRNA expression in small cell lung cell lines, thus highlighting their unrestrained gene expression.

CUSHING'S SYNDROME   Patients typically present with truncal obesity, hirsutism (also associated with a "moon facies" and "buffalo hump"), cutaneous striae, muscle weakness, osteoporosis, acne, hypertension, depression, and ovarian dysfunction. Because hypercortisolemia is associated with insulin resistance,

Table 48-1
Human Anterior Pituitary Hormone Gene Expression and Regulation

Cell	Fetal appearance	Hormone	Chromosomal gene locus	Protein	Size, kDa	Amino acid number
Corticotroph	6 wk	POMC	2p	Polypeptide	ACTH-4.5	266 (ACTH-39)

patients may also have impaired glucose tolerance. Ectopic Cushing's syndrome associated with small cell lung carcinoma is usually more acute with relatively rapid onset of hypertension, edema, hypokalemia, glucose intolerance, and hyperpigmentation. The most direct way to demonstrate ACTH hypersecretion of pituitary origin is by catheterization of the inferior petrosal venous sinuses. ACTH measurements in petrosal and peripheral venous plasma before and after CRH stimulation may document a central-to-peripheral venous gradient of ACTH concentrations.

ACTH hypersecretion by a corticotroph adenoma is usually suppressible by high doses of dexamethasone, whereas ectopic ACTH secretion persists despite high doses of dexamethasone. High-resolution pituitary magnetic resonance imaging (MRI) with gadolinium enhancement with a sensitivity of 2 mm is useful in determining the location of corticotroph adenomas. The treatment of choice is trans-sphenoidal adenomectomy, with a cure rate as high as 80% in experienced centers.

GROWTH HORMONE

Somatotrophs comprise more than 40% of pituitary cells and reveal intense cytoplasmic immunopositivity for GH. The GH genomic locus consists of five highly conserved genes, including hGH (exclusively expressed in somatotrophs), whereas the others are also expressed in placental tissue. *Cis*-elements within 300 bp of 5' flanking DNA of the GH promoter mediate both pituitary-specific and hormone-specific signaling. These include Pit-1, a 33-kDa tissue-specific transcription factor, which binds to specific promoter sites on the GH, PRL, and TSH-β genes regulating their respective transcription. The T3 receptor may synergize with

Pit-1 in stimulating GH transcription, although this effect may be species specific. Pit-1 also appears to be a determinant of growth hormone-releasing hormone (GHRH) receptor function, inasmuch as Pit-1 mutations may block GHRH-induced somatotroph proliferation.

Pulsatile GH secretion is associated with low or undetectable basal levels between peaks. In children, maximum GH secretory peaks occur within an hour of deep sleep onset. Somatostatin (SRIF) and GHRH interact to generate pulsatile GH release. GHRH stimulates GH synthesis and secretion, whereas SRIF, as well as the target hormone insulin-like growth factor-1 (IGF-I), inhibit GH secretion. GHRH signaling is mediated by cAMP, and several additional signals regulate GH gene expression, including glucocorticoids, IGF-I, activin, T3, and phorbol esters.

The GH receptor is expressed mainly in the liver and in other tissues. GH binding proteins are soluble short forms of the hepatic GH receptor and are identical to its cleaved extracellular domain. These proteins may prolong circulating GH half-life and may also competitively inhibit GH binding to peripheral surface receptors.

ACROMEGALY   Tumor-derived GH hypersecretion leading to acromegaly may be caused by excess GHRH or excess GH elaboration. More than 95% of patients with acromegaly harbor a GH-secreting pituitary adenoma, two-thirds have pure GH-cell tumors, and the others have plurihormonal tumors, usually expressing PRL in addition to GH.

These patients have elevated GH and IGF-I levels and normal GHRH concentrations. Ectopic acromegaly may be central as a result of excess GHRH production by functional hypothalamic tumors, or peripheral as a result of rare extrapituitary GH-secret-

ing tumors (pancreas) and the more common tumors secreting GHRH (carcinoid, pancreas, small cell lung cancer). Patients with ectopic acromegaly exhibit normal (central) or elevated (peripheral) GHRH levels. Interestingly, somatotroph hyperplasia and ultimately true GH-cell adenomas may develop in these latter patients.

The clinical manifestations of acromegaly include acral enlargement and visceromegaly. Tongue, salivary glands, thyroid, heart, and soft organs all enlarge. Skeletal overgrowth leads to mandibular prognathism, frontal bossing, increased hand, foot, and hat size, and wide incisor spacing. These features result in voice deepening, headaches, painful arthropathy and carpal tunnel syndrome, muscle weakness and fatigue, oily skin and hyperhydrosis, hypertension and left ventricular hypertrophy, and sleep apnea. Glucose intolerance because of insulin antagonism by GH commonly occurs. Overall mortality is increased in acromegaly because of an increased incidence of cardiovascular disorders, malignancy, and respiratory disease. Mortality rates correlate well with GH levels, and effective therapeutic suppression of GH may lead to normalized mortality outcomes. *Trans*-sphenoidal adenoma resection is the indicated treatment for GH-secreting pituitary adenoma. Octreotide, a long-acting somatostatin analog, significantly attenuates GH and IGF-I levels in most patients, and chronic administration of the long-acting octapeptide is also accompanied by marked clinical improvement.

PROLACTIN

The acidophilic lactotrophs contain PRL-immunostaining secretory granules and constitute 15% of adenohypophysial cells. PRL is highly homologous to GH and placental lactogen (PL), which may all have originally arisen from a common ancestral gene.

The PRL gene has two lactotroph-specific transcription activation regions, a proximal promoter (−422 to +33) and a distal enhancer element (−1831 to −1530), both containing specific binding sites for Pit-1. Dopamine, a potent inhibitor of PRL, acts through the D2 dopamine receptor to decrease intracellular cAMP and PRL gene transcription, synthesis, and release. Dopamine effects are mediated by the phosphoinositide-calcium pathway. Vasoactive intestinal polypeptide (VIP) induces, whereas glucocorticoids and thyroid hormones suppress, PRL transcription and secretion. Estrogens and TRH induce PRL transcription and secretion by either *trans*-activating an estrogen-responsive PRL enhancer element or by inducing the phosphoinositide–protein kinase C pathway. The estrogen receptor may in fact directly synergize with Pit-1 to induce PRL transcription.

Although PRL receptors are widely distributed, their hormonal regulation is tissue specific. High progesterone levels during pregnancy limit breast PRL receptor number, but early in lactation their numbers increase markedly. Prostatic PRL receptor levels are increased by testosterone and decreased by estrogens.

Prolactinomas are the most common hormone-secreting pituitary adenomas and, depending on their size, are classified as microprolactinomas (<10 mm, 90% of which affect women), or macroprolactinomas (>10 mm, 60% of which affect men). PRL serum levels greater than 200 μg/L are usually associated with a prolactinoma. Hyperprolactinemia presents as hypogonadism with amenorrhea and galactorrhea in women, and impotence and infertility in men. Patients harboring macroadenomas are usually males, and their clinical presentation may be associated with local mass effect signs of headaches and visual field disturbances. Most

patients are successfully treated with dopamine agonists while trans-sphenoidal surgery is reserved for drug-resistant tumors, which comprise about 5–10% of patients.

THYROID-STIMULATING HORMONE

Thyrotrophs comprise 5% of the anterior pituitary cell population. TSH and the glycoproteins, LH, FSH, and human chorionic gonadotropin (hCG), are composed of two noncovalently linked subunits, a common α and a specific β. Although the α-subunit is expressed in pituitary thyrotrophs and gonadotrophs and in placental cells, cell-specific expression depends on different promoter regions. Tissue specificity is determined by the β-subunit despite their 75% structural homology. Although Pit-1 binds to the β-subunit promoter, it is not required for α-subunit expression. Both α- and β-subunit transcriptions are induced by TRH and inhibited by triiodothyronine(T_3) and dopamine. TSH secretion is stimulated by TRH, whereas thyroid hormones, dopamine, SRIF, and glucocorticoids suppress TSH.

TSH-producing pituitary adenomas comprise less than 1% of all pituitary tumors and secrete both TSH α- and β-subunits. The tumor-derived α-subunit is synthesized in excess of the β-subunit, a characteristic useful for differential diagnosis. TSH-secreting tumors fail to respond to thyroid hormone-negative feedback but are suppressed by somatostatin. Clinical presentation usually includes hyperthyroidism and diffuse goiter, with elevated or inappropriately normal TSH levels in the presence of elevated thyroid hormones. Tumors are usually large and often invasive with commonly observed local mass effects. Trans-sphenoidal pituitary surgery is the preferred initial therapeutic approach, but surgical cure is elusive and most patients require adjuvant medical or radiation therapy. The somatostatin analog, octreotide, suppresses TSH and may attenuate further tumor growth. Thyroid ablation to cure hyperthyroxinemia is not recommended because of the potential risk of pituitary tumor expansion as a result of disinhibition of the thyrotroph cells from negative feedback.

FOLLICLE-STIMULATING HORMONE AND LUTEINIZING HORMONE

Gonadotrophs represent up to 10% of anterior pituitary cells and express both FSH and LH-β-subunits. Gonadotropin-releasing hormone (GnRH) induces the transcription of all three gonadotropin subunits, whereas estrogen attenuates their transcription, in part by inhibiting hypothalamic GnRH. However, estrogen may exert positive pituitary feedback and may actually increase LH-β mRNA under several physiologic conditions. A novel gonadotroph-specific protein (SF-1) appears to regulate pituitary α-subunit gene expression distinct from placental regulation of this gene.

GONADOTROPH CELL TUMORS Gonadotroph adenomas are among the most common pituitary adenomas. These "nonsecreting" adenomas are clinically nonfunctional because the gonadotropins and their subunits are either not released or are inefficiently secreted and usually do not produce a distinct clinical syndrome. These tumors result in elevated α- and FSH-β-subunit and, rarely, LH-β serum levels. Some adenomas secrete α-subunits but not intact FSH or LH. TRH administration usually induces secretion of gonadotropins or their subunits, in patients harboring these non-functional adenomas, unlike the absent TRH response seen in normal subjects. Most nonsecreting adenomas immunostain positively for intact FSH and LH, or α-, FSH-β-, and LH-β-subunits. Excessive secretion of FSH or LH may occasion-

Table 48-3
Pituitary Failure Associated with Pit-1 Mutations

Mutation	Clinical phenotype	Autosomal inheritance
DNA binding domain		
143Arg→Gln	Growth retardation	Recessive
158Ala→Pro	Hypothyroid; growth retardation	Recessive
172Arg→Stop	Hypothyroid	Recessive
271Arg→Trp	Growth retardation; impaired thyroid reserve	Dominant
135Phe→Cys	Growth retardation; hypothyroidism	Recessive
Activation domain		
24Pro→Leu	Growth retardation	Dominant

Table 48-4
Classification of Pituitary Adenomas[a]

Adenoma cell origin	Hormone product	Clinical syndrome
Lactotroph	PRL	Hypogonadism, galactorrhea[b]
Gonadotroph	FSH, LH, subunits	Silent or hypogonadism
Somatotroph	GH	Acromegaly, gigantism
Corticotroph	ACTH	Cushing's disease
Mixed growth hormone and prolactin cell	GH, PRL	Acromegaly, hypogonadism
Other plurihormonal cell	Any	
Acidophil stem cell	PRL, GH	Hypogonadism, acromegaly
Mammosomatotroph	PRL, GH	Hypogonadism, acromegaly
Thyrotroph	TSH	Hyperthyroidism
Null cell	None	Pituitary failure
Oncocytoma	None	Pituitary failure

[a]Hormone-secreting tumors are listed in decreasing order of frequency. All tumors may cause local pressure effects, including visual disturbances, cranial nerve palsy, and headache.
[b]Females present with amenorrhea and infertility and males present with impotence or infertility.

ally downregulate the reproductive axis resulting in clinical hypogonadism. Mass effects, including optic chiasm pressure and other neurologic symptoms, may be the initial symptoms of large gonadotroph tumors. Surgical excision is the most effective therapy and pharmacologic agents are largely ineffective in shrinking these tumor masses.

ANTERIOR PITUITARY FAILURE As discussed above, Pit-1 appears to be a critical transcription factor in determining tissue-specific expression of GH, PRL, and TSH. Studies in dwarf mice indicate that intact Pit-1 is required to sustain these functional anterior pituitary cell types. Several transgenic mice models expressing dysfunctional GH transcriptional regulation exhibit markedly attenuated or absent GH gene expression. For example, the snell dwarf mouse has a Pit-1 point mutation. In humans, sporadic and familial cases of Pit-1 mutation have recently been described exhibiting varying degrees of combined GH, PRL, and TSH basal deficiency, or impaired reserve. Some of those patients may exhibit a hypoplastic pituitary gland (Table 48-3). The autosomal dominant or recessive Pit-1 mutations associated with this heterogenous clinical syndrome include dysfunctional point mutations with defective binding to pituitary gene promoters (e.g., 158 A to P), and dominant negative missense mutations (e.g., 271 Arg to Trp). Once Pit-1 function and regulation are clarified, further genetic disorders associated with combined pituitary hormone deficiency or possibly hyperfunction should become apparent.

A missense mutation (77 Cys → Arg) in the GH molecule also leads to short stature. This mutant GH has weakened signal-trans-ducing capacity, and may also function as a dominant negative inhibitor of wild-type GH.

PATHOGENESIS OF PITUITARY TUMORS

Each of the anterior pituitary cell types may give rise to monoclonal benign neoplasms that are either hormonally functional or nonfunctional (Table 48-4). Functional tumors are characterized by autonomous trophic hormone secretion, leading to clinical hormone excess syndromes, including hyperprolactinemia, acromegaly or Cushing's disease. Nonfunctioning pituitary adenomas secrete clinically inactive glycoprotein hormones or their free subunits. True pituitary carcinomas are extremely rare, and less than 40 cases have been unequivocally documented.

CLONAL ORIGIN OF PITUITARY ADENOMAS Complete resection of well-circumscribed pituitary adenomas often results in a cure of unrestrained or paradoxical hormone hypersecretion. This observation prompted the question as to whether these tumors were clonal expansions of a single disordered cell. Disordered hypothalamic regulation would likely give rise to a generalized polyclonal cellular hyperplasia, as is seen in patients harboring extrapituitary tumors elaborating hypothalamic releasing hormones (e.g., GRH, CRH). Alternatively, an intrinsic genetic defect within the pituitary would likely be associated with clonal proliferation.

Using X-chromosomal inactivation analysis of female patients heterozygous for sex-linked genes, several groups have confirmed the monoclonal origin of functional and nonfunctional pituitary tumors. When clonal analysis was performed on tumor DNA for

hypoxanthine phosphoribosyl transferase (HPRT) or phosphoglycerate kinase (PGK) in heterozygous patients with acromegaly, Cushing's disease, prolactinomas, and nonfunctioning tumors, a preferential loss of the inactive X-chromosome allele was observed after digestion with methylation-sensitive enzymes. The monoclonal origin of these tumors has been confirmed by the high allelic cleavage ratio of the visualized demethylated vs nondemethylated DNA restriction bands.

These observations have prompted the quest for unraveling an intrinsic pituitary genetic defect resulting in either activation of a cell stimulator or inactivation of an inhibitor of cell proliferation.

HYPOTHALAMIC ORIGIN OF PITUITARY ADENOMAS

Hypothalamic hormones regulate expression of the respective pituitary hormone genes by binding to specific cell surface receptors. In addition, these peptides may also induce DNA synthesis and enhanced mitotic activity in their target pituitary cells. Thus, mice expressing a GHRH transgene will exhibit somatotroph hyperplasia and ultimately adenoma. Patients harboring tumors elaborating ectopic GHRH or CRH may also present with GH-cell or ACTH-cell hyperplasia or adenomas, in addition to the hormone hypersecretory syndrome. Recently pituitary tumor-derived GHRH, SRIF, and TRH have been characterized by in situ or reverse transcriptase polymerase chain reaction (RT-PCR) techniques. These observations of intrapituitary peptide expression may in fact imply a paracrine role for the hypothalamic peptides in pituitary tumorigenesis.

***gsp* MUTATIONS** Peptide hormone signal transduction involves coupling of activated cell surface receptors with membrane G proteins, consisting of three polypeptides: an α-chain that binds to guanine nucleotide, and a β- and γ-chain. Ligand-induced activation of the receptor induces the binding of GTP, which causes a conformational change in G protein, releasing the α-subunit from βγ, allowing it to interact with target proteins. Hydrolysis of bound GTP to GDP by the intrinsic GTPase activity of the α-subunit terminates the ligand-induced signal (Fig. 48-1). GHRH, by binding to its somatotroph receptor coupled to G proteins, uses cAMP as a second messenger to stimulate GH secretion and somatotroph proliferation. A subset of GH-secreting pituitary tumors contains elevated intracellular cAMP levels and increased in vitro GH secretion, and is not responsive to further GHRH stimulation. Intratumoral adenylyl cyclase levels are constitutively enhanced about 10-fold compared with levels in unaffected patients. The GHRH-independent induction of cAMP in these tumors could conceivably occur as a result of either constitutive activation of GHRH receptor or the catalytic domain of adenylyl cyclase or the stimulatory subunit of G protein. In fact, point mutations of Gsα were identified in about a third of these tumors. These missense mutations occur either in Arg-201 (Arg → Cys or His) or in Gln-227 (Gln → Arg), in a region of the Gsα that is involved in GTP hydrolysis. Thus, these *gsp* mutations activate Gsα by inhibiting its intrinsic GTPase activity. In the cAMP-responsive somatotroph cells, therefore, conversion of Gsα into an activating oncogene, *gsp*, may explain the pathogenesis of unrestrained cell proliferation and GH hypersecretion in these tumors. Gsα activation also induces both the Pit-1 promoter and serine phosphorylation of the cAMP response-protein (CREB) in acromegalic tissue, thus promoting somatotroph cell proliferation. In fact, CREB phosphorylation appears to be a universal finding in GH-cell adenomas, and is significantly lower in clinically silent gonadotroph cell adenomas. Interestingly, the *gsp* mutation is detected at a negligible
Figure 48-1 Inhibition of GTPase results in constitutively elevated cAMP and, consequently, enhanced growth hormone (GH) secretion. (Adapted from Spada.)

frequency in Japanese patients, implying a geographic selection for the mutation. Unfortunately, no significant clinical phenotype is associated with *gsp* mutations, and ultimate tumor behavior and response to therapy is not altered in these patients. It would therefore appear that additional cAMP-associated signaling genes are involved in GH-cell tumorigenesis.

ras Transduction of intrapituitary hypothalamic, peripheral hormonal, and paracrine growth factor signals uses pathways other than those coupled to G proteins. The product of the proto-oncogene *ras* plays an important role in growth factor signal transduction. There are three functional *ras* genes, H-, N-, and K-*ras*, that encode a 21-kDa protein, p21^{ras}. The guanine nucleotide-binding protein p21^{ras} possesses intrinsic GTPase activity and is associated with the plasma membrane. Downstream *ras* signaling involves protein kinase cascades that transduce the incoming signal to the nucleus. Point mutations of the *ras* gene can convert it to a constitutively active oncogene that has been implicated in the development of a variety of tumors, and represents one of the most common mutations detected in human neoplasia. *Ras* gene mutations, however, occur very rarely in pituitary tumors. Only a single invasive prolactinoma was found to harbor a missense *ras* mutation. *Ras* mutations were also detected in metastatic deposits of pituitary carcinomas, but not in the respective primary pituitary tumors. These findings suggest that activation of *ras* is not an initial event in pituitary tumorigenesis; however, point mutations of *ras* may be important for the development or growth of metastases originating from rarely occurring pituitary carcinomas.

Recently, an activating transforming gene *(PTTG)* was isolated from rat and human pituitary tumors and is located on chromosome 5q33. This locus has been implicated as a marker for several other malignances.

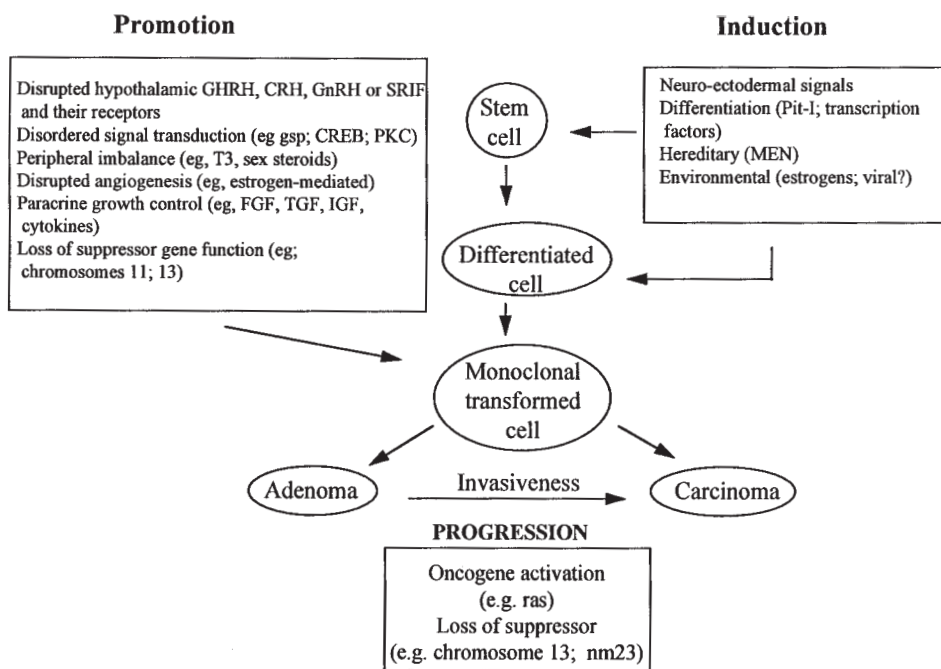
TUMOR SUPPRESSOR GENES Studies of the *MEN-I* gene locus surprisingly yielded evidence for tumor suppressor gene participation in pituitary tumorigenesis. Loss of heterozygosity of chromosome 11q13 is present not only in hereditary pituitary tumors associated with *MEN-I*, but also in up to 20% of sporadically occurring pituitary adenomas, including GH-, PRL-, and ACTH-cell adenomas, as well as some nonfunctional tumors. Several of these tumors exhibiting 11q13 loss of heterozygosity


Figure 48-2 Summary of known subcellular events leading to pituitary tumor formation. (Adapted from Melmed et al. J Clin Endocrinol Metab 1995;80:3395–3402.)

concurrently were shown to harbor a *gsp* mutation, lending further credence to a multistep cause of pituitary tumors. Recently, the gene for *MEN-I (menin)* has been cloned. However, it appears that sporadic pituitary tumors do not manifest mutations of this tumor suppressor gland, even in the presence of chromosone II LOH.

The retinoblastoma susceptibility gene *(RB)* is inactivated in a variety of human tumors. Individuals with germline mutations on one *RB* allele have >90% chance of developing a childhood retinoblastoma. The *RB* gene maps to chromosome 13ql4, and loss of heterozygosity at this locus is seen in retinoblastoma cells. The *RB* gene product is a major determinant of cell cycle control and acts as a signal transducer interfacing the cell cycle with specific transcriptional activation. The RB protein is phosphorylated in a cell cycle-dependent manner, being maximal at the start of the S phase and low after mitosis and entry into G1, and its activity appears regulated by the state of phosphorylation. Loss of RB protein function deprives the cell of an important mechanism for restraining cell proliferation.

The role of the *RB* gene in pituitary tumor formation was initially suggested by observations made in transgenic mice, in which one allele of the *RB* gene was disrupted. Although homozygous *RB* mutations are lethal early in fetal life, mice heterozygous for the *RB* gene mutation are not predisposed to retinoblastoma, but interestingly demonstrate pituitary tumors at a high frequency. These tumors originate from the pars intermedia of the pituitary, and express POMC immunoreactive products. The wild-type *RB* allele is absent in these pituitary tumors, whereas the mutant allele is retained. Pituitary tumor tissue derived from these mice also expresses a truncated dysfunctional RB protein.

In benign human pituitary microadenomas no loss of heterozygosity at the *RB* locus has been detected. However, in invasive pituitary macroadenomas and in pituitary carcinomas, allelic deletions at the *RB* locus were observed. Therefore, loss of heterozygosity at the *RB* locus is unlikely to be an initiating event in

pituitary tumorigenesis, but rather *RB* or an associated tumor suppressor gene may play a role in progression of benign tumors to more invasive and malignant phenotypes. Since immunoreactive RB protein appears to be present in these tumors, it is likely that another tumor suppressor gene is located on chromosome 13 in close proximity to the *RB* locus and might be involved in pituitary tumor progression.

nM23, a disphosphate kinase gene associated with suppression of breast cancer and melanoma metastases, has been shown to be highly expressed in small noninvasive pituitary adenomas. Pituitary *nM23* expression correlates inversely with cavernous sinus invasiveness and is markedly attenuated in large invasive tumors.

Interestingly, although *p53* tumor suppressor gene mutations have been detected in a wide variety of human tumors, no *p53* mutation has been detected in a comprehensive screening of pituitary tumors.

INTRAPITUITARY PARACRINE GROWTH FACTORS
Several intrapituitary growth factors and cytokines are expressed in normal and tumorous tissue. Their paracrine or autocrine regulation of specific pituitary function involves several trophic hormones either singly or in combination. These factors include epidermal growth factor (EGF), nerve growth factor (NGF), IGF-I, activin, and endothelin. Cytokines, including IL-6, IL-2, and LIF, also participate in paracrine regulation of trophic hormones. Although several in vitro and in vivo rat models have demonstrated growth factor-mediated pituitary mitogenesis, most of the information yielded from studies of human pituitary tumors is largely descriptive. The paucity of human tissue, as well as the failure of human pituitary cells to proliferate in vitro, has largely limited the subcellular regulatory studies required to establish a direct tumorigenic link for these growth factors.

The most compelling evidence in favor of a growth factor role in pituitary pathogenesis is that derived from studying the fibroblast growth factor (FGF) family. Basic FGF (bFGF) is abun-

dantly expressed in the pituitary, regulates PRL and TSH secretion, and also may stimulate human pituitary cell mitogenesis in vitro. Interestingly, circulating bFGF, as well as bFGF auto-antibodies, is detectable before pituitary tumor resection in patients with *MEN I*, and bFGF levels fall after surgery. These observations imply that at least in MEN-I, the pituitary adenoma may be a source of this mitogen. FGF-4, which may behave as a transforming proto-oncogene is expressed in human prolactinomas and has recently also been shown to induce PRL transcription. The FGF family may also mediate estrogen-induced pituitary angiogenesis, thus lowering portal concentrations of dopamine and facilitating lactotroph proliferation.

Other paracrine growth factors that have been implicated in pituitary tumorigenesis include EGF, transforming growth factor-α (TGF-α) and -β, and IGF-I. The gp-130 family of cytokines, including IL-6 and LIF, are expressed in functional pituitary adenomas, regulate POMC transcription, and may in fact be inhibitory for pituicyte mitogenesis.

In summary, the molecular pathogenesis of pituitary adenomas appears multifactorial (Fig. 48-2). Clearly early proximal DNA-altering events may occur. These may involve transcription factor dysregulation (e.g., Pit-1), hereditary mutations (e.g., MEN), or possible viral insults. Multiple promoting influences may subsequently impinge on the previously "initiated" cell and determine clonal expansion. These factors include disordered hypothalamic hormone receptor signaling (e.g., *gsp*); overstimulation by ectopic (or paracrine?) hypothalamic hormones (e.g., GRH, CRH); disordered paracrine growth factor action (e.g., FGF-4, bFGF); disordered signal transduction (e.g., PKC); loss of negative feedback inhibition (e.g., hypothyroidism or hypogonadism); estrogen-mediated or paracrine angiogenesis (e.g., vascular endothelial growth factor; LIF); and loss of tumor suppressor activity (e.g., chromosomes 11 and 13). Once the cell has been transformed, its ultimate growth characteristics and neoplastic behavior appear to be determined by several genes acting relatively distally, including *ras* and *nm23*.

49 Growth Hormone Deficiency Disorders

Joy D. Cogan and John A. Phillips III

INTRODUCTION

Growth hormone (GH) is a multifunctional hormone produced in the pituitary that promotes postnatal growth of skeletal and soft tissues through a variety of effects (Fig. 49-1). Controversy remains about the relative contribution of direct and indirect actions of GH. On the one hand, the direct effects of GH have been demonstrated in a variety of tissues and organs and GH receptors have been documented in a number of cell types. On the other, a substantial amount of data indicates that a major portion of the effects of GH are mediated through the actions of GH-dependent insulin-like growth factor I (IGF-I). IGF-1 is produced in many tissues, primarily the liver, and acts through its own receptor to enhance the proliferation and maturation of many tissues, including bone, cartilage, and skeletal muscle. In addition to promoting growth of tissues, GH has also been shown to exert a variety of other biologic effects, including lactogenic, diabetogenic, lipolytic, and protein anabolic effects, as well as sodium and water retention.

At the cellular level, a single GH molecule binds two GH receptor molecules (GHR) causing them to dimerize (*see* Chapter 46). Dimerization of the two GH-bound GHR molecules is believed to be necessary for signal transduction, which is associated with the tyrosine kinase JAK-2. It has been suggested that the diverse effects of GH may be mediated by a single type of GHR molecule that can possess different cytoplasmic domains or phosphorylation sites in different tissues. When activated by JAK-2, these differing cytoplasmic domains can lead to distinct phosphorylation pathways, one for growth effects and others for various metabolic effects.

The frequency of GH deficiency (either isolated or concomitant with other pituitary hormone deficiencies) is estimated to range from 1/4,000 to 1/10,000 in various studies. Most cases are sporadic and are assumed to arise from cerebral insults or defects that include cerebral edema, chromosomal anomalies, histiocytosis, infections, radiation, septo-optic dysplasia, trauma, or tumors affecting the hypothalamus or pituitary. Magnetic resonance imaging examinations detect hypothalamic or pituitary anomalies in about 12% of patients who have isolated GH deficiency (IGHD).

Interestingly, estimates of the proportion of GH-deficient cases having an affected parent, sib, or child range from 3 to 30% in different studies. This occurrence of familial clustering suggests that a significant proportion of cases may have a genetic basis. The genetics and molecular pathophysiology of familial IGHD and panhypopituitary dwarfism will be discussed in the following sections.

CLINICAL FEATURES   Adequate amounts of GH are needed throughout childhood to maintain normal growth. Newborns with GH deficiency are usually of normal length and weight. Some may have micropenis or fasting hypoglycemia in addition to their low linear growth, which becomes progressively retarded with age. In those with IGHD, skeletal maturation is usually delayed in proportion to their retardation height. Truncal obesity, facial appearance younger than expected for their chronologic age, delayed secondary dentition, and high-pitched voice are often present. Puberty may be delayed until the late teens but normal fertility usually occurs. Fine, wrinkled skin appearing similar to that of premature aging is seen in affected adults. Concomitant deficiencies of other pituitary hormones—e.g., luteinizing hormone (LH), follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and adrenocorticotropin hormone (ACTH)—in addition to GH, is called panhypopituitary dwarfism. With these additional hormone deficiencies, the retardation of growth and skeletal maturation is often more severe and spontaneous puberty may not occur.

Laron syndrome is an autosomal recessive disorder caused by target resistance to the action of GH (Online Mendelian inheritance of man number [OMIM] 245590). Subjects with Laron syndrome are similar in clinical appearance to those with severe isolated GH deficiency. At the biochemical level, Laron syndrome subjects have low levels of IGF-I, despite increased circulating levels of GH. This contrasts with the low levels of both IGF-I and GH that are seen in GH deficiency. Molecular analyses have identified heterogeneous exon deletions and base substitutions in the GHR genes of a large number of Laron syndrome patients. Although treatment with exogenous GH is ineffective in those with GHR dysfunction, replacement therapy with recombinant IGF-I has been shown to be effective.

DIAGNOSIS   Although short stature, delayed growth velocity, and delayed skeletal maturation are all seen with GH deficiency, none of these is specific for this disorder. Patients should be evaluated for other systemic diseases before provocative tests of GH deficiency. These provocative tests include postexcercise, L-Dopa, insulin-tolerance, arginine, insulin-arginine, clonidine, glucagon, and propranolol. Inadequate GH peak responses (usually <7–10 ng/mL) differ from test to test. Testing for concomitant deficiencies of LH, FSH, TSH, ACTH should be done to obtain a more accurate diagnosis and to plan optimal treatment.

FAMILIAL ISOLATED GH DEFICIENCY

GENETIC BASIS AND MOLECULAR PATHOPHYSIOLOGY OF DISEASE   Familial IGHD is associated with at least
Figure 49-1 Schematic overview of the GH gene cluster, including the protein products and expression patterns of its component genes.

four Mendelian disorders (OMIM 139250 and 307200). These include two forms that have autosomal recessive (IGHD IA and IB) inheritance, as well as autosomal dominant (IGHD II) and X-linked (IGHD III) forms. Recently, a variety of molecular defects have been detected that cause these disorders (*see* Table 49-1). These defects will be reviewed on the basis of the type of inheritance (IGHD I–III) that they cause.

IGHD IA The most severe form of IGHD, called IGHD IA, has an autosomal recessive mode of inheritance. Affected individuals occasionally have short lengths at birth and hypoglycemia in infancy, but uniformly develop severe dwarfism by 6 months of age. In response to replacement therapy with exogenous GH, IGHD IA subjects have a strong initial anabolic and growth response that is frequently followed by the development of anti-GH antibodies in sufficient titer to block the response to GH replacement.

Deletions Initially, all individuals with IGHD IA were found to be homozygous for GH1 gene deletions and developed anti-GH antibodies with treatment. Subsequently, additional cases with GH1 gene deletions have been described who also have complete GH deficiency, but respond well to GH replacement. Thus, the clinical outcomes of subjects with the same molecular findings vary, making the presence of anti-GH antibodies an inconsistent finding in IGHD IA cases.

At a molecular level, Southern blot analysis showed deletions of approximately 6.7, 7.0, or 7.6 kb, with most (approximately 75%) being 6.7 kb. DNA sequence analysis of the fusion fragments associated with GH1 gene deletions have shown that homologous recombination between sequences flanking the GH1 gene cause these deletions (Fig. 49-1). Currently, GH1 gene deletions are detected using polymerase chain reaction (PCR) amplification of the homologous regions flanking the GH1 gene and the fusion fragments associated with GH1 gene deletions (*see* Fig. 49-2). Because the fusion fragments associated with 6.7-kb deletions differ in the size of fragments produced by certain restriction enzymes (*see Sma*I sites indicated by solid circle in Fig. 49-2), homozygosity or heterozygosity for these deletions can easily be detected by enzyme digestion of PCR products. A variety of studies suggest that 13–15% of subjects with severe IGHD (>–4.5 SD in height) have GH1 gene deletions. Recently, frameshift and nonsense mutations have also been found in subjects with the IGHD IA phenotype, such that this disorder may best be described as complete GH deficiency as a result of GH1 gene defects, rather than gene deletions alone.

Deletion and Frameshift Mutations Two affected sibs diagnosed with IGHD IA have been reported who are compound heterozygotes for deletion and frameshift mutations of the GH1 gene. Southern blot analysis showed the patients to be heterozygous for the 6.7-kb GH gene deletion. DNA sequence analysis of the retained GH1 gene showed it had a cytosine deleted in the 18th codon of the prohormone sequence. This single base deletion results in a frameshift within the signal peptide coding region that prevents the synthesis of any mature GH protein. These patients presented with severe growth failure, and after an initial growth response to treatment with exogenous GH, had high titers of anti-GH antibodies.

Nonsense Mutations A G→A transition in the 20th codon that converts a Trp codon (TGG) to a Stop codon (TAG) of the GH-N signal peptide has been reported in a consanguineous Turkish family with IGHD IA. This results in the termination of translation after residue 19 of the signal peptide and no production of mature GH. Patients homozygous for this mutation have no detectable GH and produce anti-GH antibodies in response to exogenous GH treatment. Interestingly, this mutation generates a new *Alu*I site that can be readily screened for by PCR amplification of the GH gene followed by *Alu*I digestion and gel electrophoresis (Fig. 49-3).

IGHD IB Patients with IGHD IB are characterized by low, but detectable levels of GH, stature more than 2 SD below the mean for age and sex, an autosomal recessive mode of inheritance, and a positive response and immunologic tolerance to treatment with exogenous GH. Some patients clinically diagnosed as IGHD IA because of an apparent lack of endogenous GH are actually type IB. In these patients, their GH gene defects result in a mutant GH protein that cannot be effectively measured by radioimmunoassay (RIA). The presence of this protein may explain their good response to GH therapy and lack of anti-GH antibodies. A diagram showing all of the IGHD IA and IB mutations is shown in Fig. 49-4.

Splicing Mutations A G→C transversion in the first base of the donor splice site of intron IV has been detected in a consanguineous Saudi Arabian family. The effect of this mutation on mRNA splicing was determined by transfecting the mutant gene into cultured mammalian cells and DNA sequencing of the resulting GH cDNAs. The mutation was found to cause the activation of a cryptic splice site 73 bases upstream of the exon IV donor splice site. This altered splicing results in the loss of amino acids 103→126 of exon IV and creates a frameshift that alters the amino acid encoded for by exon V. Such changes in the amino acids encoded by exons IV and V may not only affect the stability and biologic activity of the mutant GH protein, but as studies with bovine GH mutants have shown, also derange intracellular targeting of GH protein products to the secretory granule.

A G→T transversion has been identified at the same site in another consanguineous Saudi family. Analysis of GH mRNA transcripts from the lymphoblastoid cells of affected patients confirmed that the G→T transversion had the same effect on splicing as the G→C transversion. Both of these mutations destroy an *Hph*I site that enables their detection by restriction digestion of GH gene PCR products followed by gel electrophoresis. Patients homozygous for these defects responded well to exogenous GH treatment and did not make anti-GH antibodies.

A G→C transversion of the fifth base of intron IV was identified in a highly consanguineous family diagnosed with IGHD I. This mutation created a new *Mae*II site that was used to screen all

Figure 49-3 Detection of the GH G→A codon 20 (Trp→Stop) mutation by restriction enzyme digestion with *Alu*I and gel electrophoresis. Note when this mutation is present a new *Alu*I recognition site occurs and the normal 204-bp fragments are cleaved to 121 and 83 bp.

family members for the mutation. Reverse transcriptase-polymerase chain reaction (RT-PCR) analysis of GH mRNA transcripts from the lymphoblastoid cells of an affected patient demonstrated that the mutation destroyed the intron IV donor splice site and had the same overall effect on splicing as the +1G→C transversion described above.

Deletion and Frameshift An IGHD patient with severe growth retardation was found to have two GH gene defects. The first GH allele was a 6.7-kb deletion and the second had a 2-bp deletion in exon III. This 2-bp deletion results in a frameshift within exon III and generates a premature stop codon at the position of amino acid residue 132 in exon IV. The patient had a positive response to GH replacement therapy and did not produce anti-GH antibodies, again suggesting that some GH-related protein is produced.

IGHD II IGHD II has an autosomal dominant mode of inheritance. Patients diagnosed with IGHD II have a single affected parent, vary in clinical severity between kindreds, and respond well to GH treatment. All IGHD II patients with GH gene defects reported to date have mutations in intron III that alter splicing of GH transcripts resulting in skipping of exon III (*see* Fig. 49-5A). The mechanism by which the mutant, truncated GH protein inactivates the normal GH protein is not proven, but is thought to be through disruption of normal intracellular protein transport or the formation of GH heterodimers (Fig. 49-5B).

Dominant-Negative Mutations A T→C transition of the 6th base of the donor splice site of intron III was the first mutation associated with IGHD II. The mutant GH gene was transfected

Figure 49-5 Schematic representation of (**A**) the GH1 gene showing the locations of various IGHD II mutations and (**B**) the mRNA splicing patterns of the normal GH and IGHD II mutant GH genes. Note that the deleted amino acids corresponding to exon III are shaded in the normal peptide (left) and absent in the mutant peptide (right).
Figure 49-6 DNA sequence analysis of normal (right) and IGHD II mutant (left) GH cDNAs showing exon III skipping in the latter.

into cultured mammalian cells and the GH mRNA transcripts analyzed by direct sequencing of their corresponding cDNAs. The mutation was found to inactivate the intron III donor splice site causing deletion or skipping of exon III and the loss of amino acids 32→71 from the corresponding mature GH-N protein products (*see* Fig. 49-6). All of the affected patients in this family were heterozygous for the intron III +6T→C change and had low, but measurable, GH levels after provocative stimulation. Affected subjects responded well to treatment with exogenous GH without forming significant levels of anti-GH antibodies.

Two additional IGHD II mutations have been identified that both alter the first base of the intron III donor splice site. One is a G→C transversion and the other is a recurring G→A transition. The latter has been identified in three nonrelated kindreds and is believed to arise because of the high mutation frequency of CpG dinucleotides. Both mutations were shown to cause exon III skipping in lymphoblastoid cells and transfection studies, respectively.

Two intron III mutations that alter splicing and do not occur within the branch consensus, donor, or acceptor sites have been recently identified. The first deletes 18 bp, del+28→45, and the second is a G→A transition of the 28th base of intron III. Transfection studies and sequencing of the GH RT-PCR products demonstrated that the overall effect on splicing was the same as the other IGHD II donor splice site mutations. The mechanism by which these two mutations alter splicing is unknown, but may involve secondary structure or a protein-binding site.

IGHD III IGHD III has an X-linked mode of inheritance, but distinct clinical findings in different families. Affected individuals in some kindreds have agammaglobulinemia associated with their IGHD, but others do not. This suggests that contiguous gene defects of Xq21.3→q22 may occur in some cases. Interestingly, other cases of IGHD have been found to have an interstitial deletion of Xp22.3 or duplication of Xq13.3→q 21.2 suggesting that multiple loci may cause IGHD III.

BIODEFECTIVE GH Kowarski et al. studied two unrelated boys, with growth retardation, delayed bone ages, and low levels of somatomedin (but normal GH levels) after stimulation. Treat-

[a]Codon number from the translation start site.

ment with exogenous human GH induced normal levels of somatomedin and a significant increase in growth rate. While the family data did not support a specific mode of inheritance, a mutation resulting in a biologically ineffective GH molecule was speculated. Valenta et al. described a similar case and confirmed a structural abnormality of the GH molecule: 60–90% of circulating GH was in the form of tetramers and dimers (normal, 14–39% in plasma) and the patients' GH polymers were abnormally resistant to conversion into monomers by urea.

Subsequently, Takahashi et al. reported a boy who was short at birth (39 cm at 41 weeks' gestation) and –6.1 SD below the mean at 4.9 years when his bone age was 2 years. He had normal body proportions, but a prominent forehead and saddle nose. His IGF-I was 34 ng/mL (normal 35–293). Basal GH levels were 7–14 ng/mL and peak levels after insulin induced hypoglycemia; arginine and levodopa administration were 38, 15, and 35 ng/mL, respectively. Serum IGF-I was unchanged after 3 days of daily subcutaneous injections of 0.1 U of recombinant human GH/kg body weight (0.035 mg/kg). During prolonged treatment with GH (0.18 mg/kg/wk), his serum IGF-I was 200 ng/mL and his rate of linear growth increased to 6.0 cm/yr from 3.9 cm/yr before treatment. Assay of the bioactivity of his GH was below the normal range, and isoelectric focusing of his serum showed an abnormal GH peak in addition to a normal peak, whereas serum from his father and normal controls contained only one peak. The affected son was heterozygous for a C→T transition that encodes an Arg→Cys substitution at codon 77 (Arg77Cys) of his GH1 gene. Inexplicably, his father, also heterozygous for this mutation, was of normal height, had a peak GH level of 23.7, and normal isoelectric focusing results.

GHRH RECEPTOR MUTATIONS   Lin et al. demonstrated that the molecular basis for the "little" (lit) mouse phenotype, characterized by a hypoplastic anterior pituitary gland, is a point mutation in the growth hormone-releasing factor receptor (GHRHR) gene that results in an Asp→Gly substitution at residue 60 (Asp60Gly). Anterior pituitaries of mutant mice showed spatially distinct proliferative zones of GH-producing stem cells and mature somatotrophs, each regulated by a different trophic factor.

Wajnrajch et al. found a nonsense mutation in the human GHRHR gene in two first cousins, a boy and a girl, of a consanguineous Indian Moslem family with profound GH deficiency. The phenotypes of the 3.5-year-old girl and her 16-year-old cousin were poor growth since infancy and both were extremely short. They were prepubertal with frontal bossing and predominantly

truncal obesity. While both failed to produce GH in response to standard provocative tests and to repetitive stimulation with GHRH, they responded to administration of GH. The affected individuals were homozygous for a G→T transversion at position 265 of their GHRHR genes, resulting in a premature termination mutation (Glu72Stop). The mutation introduced a *Bfa*I restriction site into the amplified GHRHR gene fragment which could be used to detect the mutation in DNA samples from family members. Wajnrajch et al. noted that, since both GH releasing peptide (a synthetic hepapeptide) and nonpeptidyl benzamines can stimulate GH release without involvement of the GHRH receptor, they might be useful in therapy of this disorder. Subsequently, Maheshwari et al. found the same GHRHR mutation in an isolate from the Indus valley of Pakistan.

FAMILIAL COMBINED PITUITARY HORMONE DEFICIENCY

GENETIC BASIS AND MOLECULAR PATHOPHYSIOLOGY OF DISEASE   Familial combined pituitary hormone deficiency (CPHD) is characterized by deficiency of one or more of the other pituitary trophic hormones (ACTH, FSH, LH, or TSH) in addition to GH deficiency (OMIM 262600). Whereas the great majority of cases are sporadic, there are Mendelian forms with autosomal recessive, autosomal dominant, or X-linked modes of inheritance. Mutations of the Pit-1 and Prop-1 genes are associated with CPHD in humans. Both of these genes are members of the POU (Pit-1, Oct-1, Unc-86) homeodomain family of transcription factors and they each play an important role in pituitary development.

Pit-1   The Pit-1 gene (OMIM 173110) encodes a protein that binds to and transactivates promoters of the GH1 and PrL genes and is required for differentiation and proliferation of somatotropes, lactotropes, and thyrotropes. At least eight different Pit-1 mutations have been found in humans in a subtype of CPHD associated with GH, PrL, and TSH deficiency (*see* Table 49-2).

Autosomal Recessive Pit-1 Mutations   The first and second Pit-1 mutations reported were found in two consanguineous Japanese families. In one family, a C→T transition in codon 172 converted a CGA (arginine)→TGA (stop). Both parents were heterozygous and the affected child was homozygous for the mutation. In the second family, an A→G transition in codon 143 changing a CGA (arginine)→CAA (glutamine) was found. The patient was shown to be homozygous for this mutation, while the parents and two unaffected siblings were shown to be heterozy-

gous. Both mutations occur in the POU-specific domain and are believed to affect binding of the Pit-1 protein to the DNA.

The third and fourth Pit-1 mutations were found in two Dutch families who had postnatal growth failure with complete deficiencies of GH and PrL, while the T4 levels were low or normal prior to or following GH replacement. Subjects in one family who had normal T4 levels were homozygous for a G→C substitution in codon 158 changing GCA (alanine)→CCA (proline). This mutation interferes with formation of Pit-1 homodimers and dramatically reduces the altered Pit-1's ability to activate transcription. Subjects in the second family with low T4 levels were found to have one deleted Pit-1 gene and one Pit-1 gene with the previous mutation. These cases emphasize the importance of determining PrL levels and TSH responses to TRH in evaluating CPHD. Since GH and TSH deficiency often occur together, finding a low PrL level and absent TSH responses should raise the question of their having Pit-1 gene defects.

A fifth Pit-1 mutation was identified in a Thai patient with deficiency of GH, TSH, and PrL. Both parents were healthy and found to be heterozygous for a G→T transversion in codon 250, which converted a GAA(Glu)→TAA(Stop) codon. The CPHD patient was found to be homozygous for the mutation. This mutation resulted in complete loss of the POU-homeodomain, which is necessary for DNA binding.

A sixth Pit-1 mutation has been reported in a consanguineous family of Tunisian descent. All four affected sibs were found to be homozygous for a T→G transversion in codon 135 converting a TTT(Phe)→TGT(Cys) in the POU-specific domain of Pit-1. The patients were found to have pituitary hypoplasia and deficiencies of GH, TSH, and PrL.

Autosomal Dominant Pit-1 Mutations   The first dominant-negative mutation identified in the Pit-1 gene was a G→T substitution in codon 271 converting a GGG (arginine)→TGG (tryptophan). This mutation is located in the POU-homeodomain and does not affect binding of the mutant Pit-1 protein to DNA but functions as a dominant inhibitor of Pit-1 action by some, as of yet unknown mechanism. Three unrelated patients have been reported to be heterozygous for this mutation. Two of the patients were evaluated as adults and found to have pituitary hypoplasia and deficiencies of GH, PrL, and TSH. The third patient was identified at only 2 months of age and found to have a normal pituitary and normal basal levels of TSH but a delayed TSH response in a TRH stimulation test. The authors suggest that, since Pit-1 may be necessary for anterior pituitary cell survival, the affected patient will develop hypolasia and TSH deficiencies with age.

The second dominant-negative Pit-1 gene mutation was a T→C transition in the 24th codon, converting a CCT (proline)→CTT (leucine). This proline residue resides within the major transactivating domain of Pit-1 and is highly conserved in different species. The mechanism by which this mutation exerts its dominant-negative effect is also not known.

Prop-1   Ames dwarf (df/df) mice have CPHD and hypocellular anterior pituitaries that lack somatotropes, lactotropes, thyrotropes, and GH transcripts. Since df/+ but not df/df mice expressing the hGHRH transgene have somatotrope hyperplasia, the df gene product is thought to be required before e16.5 of development. The genetic defect associated with the Ames dwarf phenotype has recently been found in the gene called Prophet of Pit-1 (Prop-1) (OMIM 601538) that encodes a pituitary specific homeodomain factor. Sequence analysis of the Prop-1 cDNA in the df/df mouse re-

vealed a T→C transition in codon 83 that causes a Ser→Pro amino acid change in the first helix of its homeodomain. While Prop-1 is required for expression of Pit-1, the mechanism of its action remains uncertain.

Wei et al. recently reported finding three human Prop-1 gene defects in studies of four families with familial autosomal recessive CPHD. In addition to the GH, PrL, and TSH deficiency seen with Pit-1 defects, Prop-1–deficient subjects also have LH and FSH deficiency, which prevents the onset of spontaneous puberty. Family I had three affected sibs, all homozygous for a C→T transition in codon 120 of the Prop-1 gene. This mutation encoded a TGC(Arg)→CGC(Cys) substitution in the third helix of the homeodomain, which greatly reduced the protein's DNA-binding and transactivating abilities. Families II and III were found to have the same 2-bp AG deletion in codon 101 that causes a frameshift that results in a premature stop at codon 109. The truncated protein product was found to have no DNA binding or transactivating abilities. The patient in family IV had two different Prop-1 gene mutations (compound heterozygosity). One allele had the 2-bp AG deletion described above and the second allele had a T→A transversion that encodes a TTC(Phe)→ATC(Ile) substitution at codon 117. The resulting protein product exhibited both greatly reduced DNA-binding and transactivating abilities.

CURRENT TREATMENT

Recombinant derived GH is available worldwide and is administered by subcutaneous injection. To obtain an optimal outcome, children with GHD should be started on replacement therapy as soon as their diagnosis is established. The initial dosage of recombinant GH is based on body weight, but the exact amount used and the frequency of administration may vary between different protocols. The dosage increases with increasing body weight to a maximum during puberty and is usually discontinued by approximately 17 years of age.

Conditions that are treated with GH include (1) those in which it has proven efficacy and (2) a variety of others in which its use has been reported but its use is not accepted as standard practice. Disorders in which GH treatment is of proven efficacy include GH deficiency, either isolated or in association with CPHD and Turner's syndrome. The clinical responses of individuals with the first two disorders to GH replacement therapy varies depending on (1) the severity and age at which treatment is begun, (2) recognition and response to treatment of associated deficiencies such as thyroid hormone deficiency, and (3) whether treatment is complicated by the development of anti-GH antibodies. The outcome of Turner's syndrome subjects varies with the severity of their short stature, chromosomal complement, and age at which treatment was begun.

Additional disorders in which the use of GH has been reported but for which its efficacy is not accepted as standard practice include treatment of (1) selected skeletal dysplasias such as achondroplasia, (2) Prader-Willi syndrome, (3) growth suppression secondary to exogenous steroids such as chronic autoimmune diseases, (4) chronic renal failure, (5) extreme idiopathic short stature, (6) Silver-Russell syndrome, and (7) intrauterine growth retardation. There is, in general, insufficient data to establish the efficacy of GH replacement therapy in treating these disorders because of the limited number of subjects and lack of use of standardized protocols.

FUTURE DIRECTIONS

Several problems contribute to incomplete ascertainment of affected individuals, which in turn can result in less than optimal outcomes. These problems in ascertainment include the spectrum of severity, lack of a single provocative test that is both very sensitive and specific, and lack of an assay to test for qualitative changes in endogenous GH. Improvements in techniques that address these problems could facilitate the detection of and improve the outcome of treated patients in the future.

A number of genetic defects in GH biosynthesis have been documented that prevent some affected individuals from secreting GH. These include those defects that result in the synthesis of truncated GH molecules, lack of GHRH receptor function, and mutant GH products that have dominant-negative effects on the normal GH products that are present. In the future, agonists of GH secretion, for example, that complement the function of GHRH, may be found that can enhance release of the stored GH that is found in some of these cases. The efficacy of IGF-I in treating Laron dwarfism and IGHD patients who are resistant to exogenous GH because of anti-GH antibodies has been proven. Additional uses of IGF-I or perhaps isoforms of IGF-I that have prolonged half-lives may provide improved efficacy in the future.

Although potential applications of gene therapy to somatic cells are feasible, targeted and regulated expression that is pituitary specific remains impractical. Thus, potential applications of gene therapy to achieve appropriate hormonal regulation less dangerously than with exogenous GH replacement seem remote.

50 Thyroid Disorders

Peter Kopp and J. Larry Jameson

INTRODUCTION

The thyroid is controlled by a classic hormonal feedback system, the hypothalamic–pituitary thyroid axis (Fig. 50-1). The hypothalamic peptide, TRH (thyrotropin-releasing hormone), stimulates the production and secretion of the glycoprotein hormone TSH (thyroid-stimulating hormone) in the pituitary. TSH in turn stimulates growth and function of thyroid follicular cells resulting in the production of the thyroid hormones, thyroxine (T4) and triiododothyronine (T3). Thyroid hormone has multiple effects on differentiation, growth, and metabolism of peripheral tissues. At the level of the cell, thyroid hormone action is primarily mediated by nuclear receptors that regulate gene transcription.

After the characterization of thyroid disorders at the clinical and biochemical level, the cloning of many key genes responsible for thyroid hormone synthesis and action provides the tools for unraveling underlying molecular defects (Table 50-1). These findings continue to broaden our insights into the mechanisms governing thyroid cell growth and function under physiologic conditions, as well as in thyroid disease.

Disorders affecting thyroid function result either in hypothyroidism or hyperthyroidism. The cardinal clinical characteristics of these hormonal states are summarized in Table 2. Hypothyroidism is the most common disorder of thyroid function and, besides iodine deficinecy, it is most frequently caused by chronic autoimmune Hashimoto's thyroiditis. The most frequent cause of hyperthyroidism is also an autoimmune disorder, Graves' disease, followed in prevalence by toxic multinodular goiters and toxic adenomas. All other causes of decreased or elevated thyroid function are rare. Congenital hypothyroidism, which affects 1 in 3000 to 4000 newborns, may occur sporadically or as an inherited disorder. The sporadic form of congenital hypothyroidism is caused by thyroid agenesis or dysgenesis. The molecular causes underlying sporadic thyroid dysgenesis have not been elucidated. Besides environmental factors, alterations in thyroid-specific transcription factors involved in thyroid embryogenesis are likely candidates. Thyroid hypoplasia may be caused by inherited loss-of-function mutations in the TSH receptor. In hereditary congenital hypothyroidism, there are defects in one or more steps in thyroid hormone biosynthesis. Dyshormogenesis is much rarer than thyroid dysgenesis. The cloning of many of the genes encoding the involved proteins will allow further characterization of these disorders at the molecular level.

Defects resulting in hyperthyroidism or hypothyroidism have been localized at all levels of the hypothalamic–pituitary–thyroid axis. Deficiency in hypothalamic TRH and mutations in the pituitary-specific transcription factor, Pit-1, or in the gene encoding TSH-β, lead to congenital central hypothyroidism. TSH-secreting pituitary adenomas result in hyperthyroidism. At the level of the thyroid gland, insensitivity to TSH or defects in hormone synthesis and secretion cause hypothyroidism. Autosomal dominant, non–autoimmune familial hyperthyroidism caused by constitutively activating mutations in the TSH receptor (TSHR) gene has been recognized as a new pathophysiologic entity. Congenital hyperthyroidism is rare and usually caused by transplacental passage of autoantibodies from a hyperthyroid mother, but may also occur through sporadic TSHR mutations in the germline. Somatic mutations in the TSHR, or in the α-subunit of the stimulatory G protein (Gsα), can result in hyperfunctioning adenomas.

The transport of T4 is altered by a variety of defects in binding proteins. At the level of the target organs, mutations in the nuclear thyroid hormone receptors may cause the syndrome of resistance to thyroid hormones.

Although the molecular defects underlying the pathogenesis of thyroid nodules as well as papillary, follicular, and anaplastic thyroid cancers, are far from being completely understood, the tools of molecular biology are providing important new insights. A majority of thyroid nodules are of monoclonal origin, making somatic mutations in growth-controlling genes a likely cause for their development. Defects in proto-oncogenes or tumor suppressor genes have been implicated in all forms of benign and malignant thyroid tumors (*see* Chapter 7). Among other important insights, the detection of certain molecular defects has already impacted the clinical management of patients with multiple endocrine neoplasia type 2 (MEN2) (*see* Chapter 54).

Although this chapter does not review all thyroid disorders comprehensively, it provides an overview of the genetic defects affecting thyroid function and growth at all levels of the axis.

THYROTROPIN-RELEASING HORMONE DEFICIENCY

TRH is a hypothalamic tripeptide (Glu-His-Pro) generated from a large prohormone of 27 kDa. Besides its role as a stimulator of the pituitary gland, where it releases thyrotropin (TSH) and prolactin (PRL), TRH is found in numerous areas of the brain and in some peripheral organs.

A few patients with congenital hypothyroidism have isolated TRH deficiency in the absence of apparent destructive hypotha-
Figure 50-1   The hypothalamic–pituitary–thyroid axis. The hypothalamic hormone, thyrotropin-releasing hormone (TRH), enhances production and secretion of the pituitary hormone, thyroid-stimulating hormone (TSH), which then stimulates thyroid hormone synthesis in follicular cells. Thyroid hormones act on multiple target genes in peripheral cells through nuclear receptors that regulate gene transcription. T3 regulates TSH and TRH through a negative feedback mechanism.

lamic lesions. The diagnosis of central hypothalamic hypothyroidism is made on the basis of the constellation of low basal TSH that increases after administration of exogenous TRH. The molecular defect underlying these cases remains elusive, but could result from a defect in the synthesis or secretion of TRH, or from abnormal development of hypothalamic TRH-producing neurons.

AUTONOMOUS PRODUCTION OF TSH

TSH is a heterodimeric glycoprotein hormone. It shares a common α chain with the pituitary hormones, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), as well as the placental hormone choriogonadotropin (CG). Each of these hormones has a unique β chain; the gene for the TSH-β–subunit has been localized to chromosome 1p22, the α chain is encoded on chromosome 6.

Hypersecretion of TSH by thyrotroph pituitary adenomas is a rare cause of hyperthyroidism. Biochemically, these patients are characterized by an inappropriate secretion of TSH and hyperthyroxinemia. Typically, there is also excessive secretion of free α-subunit, and this feature can help to make the diagnosis. In about 20%–30% of cases, there is cosecretion of growth hormone (GH). Magnetic resonance imaging or computed tomograph scan can be used to confirm the diagnosis.

The molecular defects that result in autonomous growth and function of the thyrotrophs have not been elucidated yet. Clonal analysis with the X-inactivation technique in a small number of tumors showed that they are of monoclonal origin, suggesting a somatic mutation or the loss of tumor suppressor genes. Screening of several candidate genes *(Gsα, Gqα, G11α, TRH receptor)* in nine tumors did not show alterations in these genes.

In most cases, therapy consists of trans-sphenoidal removal of the pituitary adenoma. The somatostatin analog, octreotide, can suppress TSH in some patients. Preoperatively, hyperthyroid patients should be controlled with antithyroid drugs. Adjunctive radiation therapy is required in most patients with pituitary macroadenomas.

DEFECTIVE BIOSYNTHESIS OF TSH

TSH deficiency may occur in the setting of panhypopituitarism, most commonly because of a pituitary adenoma. Rare causes include familial panhypopituitarism and familial pituitary agenesis, which likely involve defects in pituitary development, but specific genes have not been identified yet. Two well-characterized defects that cause TSH deficiency include mutations in the Pit-1 gene and in the gene encoding the β-subunit of TSH. Isolated central hypothyroidism has also been described in a boy who was a compound heterozygote for inactivating mutations in the TRH receptor.

PIT-1 MUTATIONS   Pit-1 (also referred to as growth hormone factor 1, GHF-1) is a pituitary-specific transcription factor of 33 kDa that regulates the development of somatotrophs, lactotrophs, and thyrotrophs, as well as expression of the *growth hormone, prolactin,* and *TSH-β subunit* genes. It is a member of the POU family of transcription factors, an eponym that was created after the identification of the first three members of this group, Pit-1, Oct-1, and Unc-86. Pit-1 contains two main functional domains, an activation domain and a DNA-binding domain that is formed by a POU-specific domain and a homeodomain. The homeodomain is similar to the homeobox-containing genes in *Drosophila* that control development of specific body segments. DNA sequences that bind the transcription factor are found in the promoters of the *GH, PRL, TSH-β*, and *Pit-1* genes. Several splice variants with different activation domains have been reported (Pit-1β, Pit-1T).

Pit-1 mutations were initially identified in strains of dwarf mice with hypoplastic pituitaries and lack of somatotrophs, lactotrophs, and thyrotrophs. The Jackson mouse has a genomic rearrangement of Pit-1 that results in a truncated protein. The Snell mouse has a point mutation resulting in an amino acid substitution in the homeodomain (tryptophan 261 to cysteine).

In humans, a variety of Pit-1 mutations have now been described. The first mutation was a homozygous point mutation that results in a truncated protein lacking the entire POU-homeodomain. The affected girl presented with cretinism and deficiency of thyrotropin, growth hormone, and prolactin. The parents, who were second cousins, were both heterozygous and had no hormonal abnormalities. This report was followed by further descriptions of Pit-1 mutations in different locations of the gene in patients with GH, PRL, and TSH deficiencies. Mutant proteins that cannot bind to DNA are inherited as autosomal recessive traits, whereas the mutations that lose transactivation, but retain DNA binding capacity, are inherited in an autosomal dominant manner. The latter mutants inhibit the function of the normal Pit-1 protein and, therefore, display a dominant-negative effect.

Table 50-1
Molecular Defects in Thyroid Disease[a]

Gene/protein	Disease	Pathophysiology	Molecular defect	Inheritance	Chromosome
TRH	Hypothalamic hypopituitarism	Isolated TRH deficiency	Unknown	AR	3
TRH-receptor	TSH-deficient hypothyroidism	Unresponsiveness to TRH	Inactivating mutations	AR	8q23
TSH	TSH-deficient hypothyroidism	TSH-β–subunit mutation, bioinactive TSH	Mutations in β chain	AR	α chain:6p21
	TSH-secreting adenomas/hyperthyroidism	Oversecretion of TSH, molecular defect unknown	Unknown	Sporadic	β chain:1p22
Pit-1	Combined pituitary hormone deficiency (GH, PRL, TSH); mouse: Snell, Jackson dwarf mice	Abnormal pituitary development; diminished GH, PRL, TSH synthesis and secretion	Mutation in *Pit-1* gene	AD, AR	3p11
TSH-receptor	Familial and sporadic congenital non-autoimmune hyperthyroidism	Constitutive activation with increased basal secretion of cAMP	Activating mutation	AD, sporadic	
	Toxic adenomas			Somatic	14q31
	Hypothyroidism, euthyroid hyperthyrotropinemia	Unresponsiveness to TSH	Inactivating mutations	AR	
Gsα (α-subunit of stimulatory G protein)	Toxic adenoma	Activation of cAMP cascade: enhancement of growth/function	Activating point mutations	Sporadic	
	McCune-Albright syndrome			Sporadic (mosaicism)	20q.13.2
	Pseudohypoparathyroidism Ia	Resistance to stimulus of G-protein-coupled receptors, incl. mutations TSH receptor	Inactivating point mutations	AD	
Thyroid hormone synthesis					
Sodium/iodide symporter	Congenital hypothyroidism, goiter	Defective iodine uptake	Inactivating point mutations	AR	19p12–13.2
Thyroperoxidase	Congenital hypothyroidism, goiter	Defective organification of iodide point mutations	Insertions, frameshift, stops,	AR	2p25
Pendred's syndrome	Sensorineural deafness, goiter	Partial organification defect	Inactivating mutations	AR	7q21–34
Thyroglobulin	Goiter; hypothyroidism, subclinical hypothyroidism, or euthyroidism; several animal models with goiter	Defective organification of iodide because of qualitative or quantitative Tg defects	Mutation in splice donor site; premature stop/alternate splicing; nonsense mutation	AR (AD in one kindred)	8q24
Dehalogenase	Congenital hypothyroidism, goiter	Loss of iodine through secretion of DIT, MIT	Unknown	AR	Unknown
Binding proteins					
Thyroxine-binding globulin	Decreased total T4 levels, euthyroidism	TBG deficiency	Deletions, frameshifts, premature stops, point mutations	X-linked recessive	Xq11–q23
	Increased total T4 levels, euthyroidism	TBG excess	Unknown	Probably X-linked recessive	
Transthyretin	Hyperthyroxinemia; familial amyloidotic polyneuropathy	Increased affinity for T4, T3	Point mutations	AD	18
Albumin	Familial dysalbuminemic hyperthyroxinemia	Increased affinity for T4, T3	Point mutations	AD	4q11–13
Nuclear thyroid hormone receptors/transcription factors					
Thyroid hormone receptor	Resistance to thyroid hormone; goiter, variable degrees of hypo- and hyperthyroidism	Elevated peripheral hormones with elevated TSH because of impaired peripheral hormone action coding region of TRβ)	Point mutations, deletions, frameshifts (one kindred with total deletion of coding region of TRβ)	AD, sporadic (AR in one kindred with total deletion (no mutations detected in TRα)	TRβ 3p24.3 TRα17q11.2
TTF-1	Congenital goiter, thyroglobulin deficiency	Absence of TTF-1 expression	Unknown	AR (?)	14q12–q21
TTF-2	…	…	…	… (indirect evidence)	9q
Pax-8	…	…	…	…	2q12–q14

[a]Abbreviations: TRH, thyrotropin-releasing hormone; TRH-receptor, thyrotropin-releasing hormone receptor; TSH, thyroid-stimulating hormone; Pit-1, pituitary-specific transcription factor 1; TSH-receptor, thyroid-stimulating hormone receptor; Gsα, G protein stimulatory α-subunit; TTF-1, thyroid transcription factor 1; TTF-2, thyroid transcription factor 2; PAX-8, paired domain transcription factor 8; GH, growth hormone; PRL, prolactin; T4, thyroxine; CAMP, cyclic AMP; DIT, diiodothyronine; MIT, monoiodothyronine; TBG, thyroxine-binding globulin; AR, autosomal recessive; AD, autosomal dominant; TR, thyroid hormone receptor.

Table 50-2
Main Clinical and Biochemical Findings
in Hyper- and Hypothyroidism

Hyperthyroidism	*Hypothyroidism*
Signs	
Hyperactivity	Lethargy
Tachycardia/arrhythmia	Bradycardia
Hyperthermia	Cold intolerance
Increased perspiration	Dry skin
Hyperreflexia	Hyporeflexia
Muscle weakness	Myxedema
Tremor	Hoarseness
Weight loss	Weight gain
Eyelid retraction	
Exophthalmos (Graves' disease)	
Diffuse or nodular goiter	
Intrauterine/neonatal	Intrauterine/neonatal
Mental retardation possible	Mental retardation
Advanced bone age	Neurologic deficit
	Retarded bone age/growth
Symptoms	
Nervousness	Fatigue, sleepiness
Weakness	Depression
Palpitation	Constipation
Increased appetite	Decreased appetite
Irregular menses	Irregular menses
	Paresthesia
Laboratory	
Primary	
T4 ↑, T3 ↑, TSH ↓	T4 ↓, T3 ↓, TSH ↑
Central

Figure 50-2 Thyroid hormone synthesis in a follicular cell. (For details, *see text.*) (TPO, thyroperoxidase; Tg, thyroglobulin; MIT, DIT, mono- and diiodothyronine; AC, adenylyl cyclase; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; IGF-I, IGF-I R, insulin-like growth factor I [receptor]).

An unusual case of Pit-1 deficiency because of a heterozygous, dominant-negative point mutation in a mother and her fetus led to severe fetal hypothyroidism with delays in respiratory, cardiovascular, neurologic, and bone maturation. The absence of Pit-1 and the ensuing hypoprolactinemia in the mother resulted in puerperal alactogenesis. This case illustrates the importance of Pit-1 in the control of different endocrine axes and the importance of prenatal thyroid hormone for normal fetal maturation.

TSH-β MUTATIONS Congenital hypothyroidism caused by isolated hereditary TSH deficiency is rare and results from autosomal recessive mutations in the TSH-β chain. The disorder is characterized by low T4 and low TSH that is not increased by administration of TRH. In one Japanese family, two sisters presented with cretinism. The parents were second cousins, and two other families from the same island were reported to harbor the same defect. A homozygous mutation (glycine 29 to alanine) affecting the so-called CAGYC region of TSH-β was identified in these Japanese families and in a family of Portuguese origin living in France. This amino acid sequence is highly conserved among all glycoprotein hormone β-subunits, and it is essential for normal heterodimerization with the α chain. The heterozygous members of these families had normal thyroid function.

In two related Greek families with congenital TSH-deficient hypothyroidism, a mutation in the *TSH*-β gene resulted in a truncated peptide including only the first 11 amino acids. A frameshift mutation was also reported in a Brazilian family. These mutants are unable to dimerize with the α-subunit and TSH was undetectable in affected family members. A mutation in the carboxy-termi-

nal part of the TSH-β subunit (cysteine 105 to valine) affected a cysteine that is involved in the formation of a disulfide bond (cysteine 19 with cysteine 105). This conformational change results in inefficient hormone synthesis and loss of bioactivity.

AUTONOMOUS FUNCTION OF THE TSHR

TSH exerts its effects on thyroid follicular cells through the TSHR, a member of the G-protein-coupled seven transmembrane domain receptors (Figs. 50-2 and 50-3). Together with the receptors for FSH and LH, it forms a distinct subfamily defined by a large amino-terminal extracellular domain involved in binding of the hormone. The 744-amino acid receptor is encoded by a gene containing 10 exons. The TSHR is coupled to Gsα and thus to the adenylyl cyclase cascade, which is the predominant signaling pathway for growth and function of the thyrocyte. It is, however, also coupled to Gq and also activates the inositol phosphate pathway.

Recently, mutations in several G-protein-coupled seven transmembrane domain receptors were found to confer constitutive activation to these receptors, a mechanism that defines an important new pathophysiologic entity. This type of activating mutation has been found in rhodopsin as a cause of retinitis pigmentosa, in the LH-CG receptor in male-limited precocious puberty, and in the TSHR, causing hyperthyroidism. Furthermore, point mutations in the Ca^{2+}-sensing receptor lead to familial hypocalciuric hypercalcemia and in the PTH receptor to metaphyseal chondrodysplasia.

Figure 50-3 The thyroid-stimulating hormone receptor (TSHR) is a member of the G-protein-coupled seven transmembrane domain receptors. Naturally occurring activating mutations lead to enhanced growth and function and result in non–autoimmune hyperthyroidism. Inactivating mutations lead to compensated or overt hypothyroidism. *Compound heterozygote mutations.

Somatic mutations in the TSHR have been found in a number of toxic adenomas. In one series, they were present in 9 of 11 tumors, suggesting that most toxic adenomas contain mutations in this receptor (Fig. 50-3). In other studies, however, they were only

present in a minority of tumors. This apparent discrepancy might be explained by differences in the prevalence in various geographic regions, selection of the tumors, or differences in the technical approach. Functionally, these mutations increase basal cAMP levels, and some of the mutants also activate the phospholipase C cascade. In contrast to activating mutations in other seven transmembrane domain receptors, there is a striking diversity in the affected residues, which are scattered over virtually the entire transmembrane domain of the TSHR, and they even occur in the extracellular domain (Fig. 50-3).

TSHR mutations occurring in the germline give rise to non–autoimmune familial hyperthyroidism. Gain-of-function mutations are by definition dominant and one mutated allele is thus sufficient to result in disease. The subsequent activation of the adenylyl cyclase pathway increases function and growth of thyroid follicular cells, resulting in hyperplasia and hyperthyroidism. The typical signs associated with autoimmune hyperthyroidism, such as exophthalmos, myxedema, stimulating autoantibodies, and lymphocytic infiltration of the thyroid gland, are absent. Five families with non–autoimmune familial hyperthyroidism and documented TSHR mutations have been reported (Fig. 50-3). Interestingly, the onset of hyperthyroidism may vary in carriers of the same mutation in a given kindred, suggesting that other factors (genetic background, iodine intake) can modify the phenotypic expression of the activated receptor. *De novo* germline mutations in the TSHR have been found in a few patients as a cause of sporadic non–autoimmune congenital hyperthyroidism.

Activating mutations in the TSHR have been found in a few cases of well-differentiated thyroid carcinomas, but they seem to be rare in these tumors. These naturally occurring mutations in the TSHR provide important new insights into receptor structure–function. It has been hypothesized that these mutations result in conformational changes converting the receptor from a "repressed" state into an activated state that couples to signal transduction pathways. The recognition of this new cause of hyperthyroidism also has clinical implications in that these patients often require a more aggressive therapeutic approach (surgery, ablative radiotherapy), and in families with non–autoimmune hyperthyroidism, molecular diagnostics allows early diagnosis and treatment.

INSENSITIVITY TO TSH AND INACTIVATING MUTATIONS OF THE TSHR

TSH insensitivity results in reduced synthesis and secretion of thyroid hormones and a small thyroid gland. It has been described in a kindred in which two affected individuals had normal thyroid hormone levels but high levels of TSH. In this family, the disorder was transmitted in an autosomal recessive mode and the patients were compound heterozygotes. The patients inherited a missense mutation in the TSHR from the father (asparagine 167 to isoleucine) and a distinct mutation from the mother (proline 162 to alanine), both affecting the extracellular, TSH-binding domain of the receptor (Fig. 50-3). In a few cases with congenital hypothyroidism and a normally located, hypoplastic gland, loss-of-function mutations have been found in the affected patients. Remarkably, these patients seem to have a normal or elevated thyroglobulin. However, inactivating mutations in the *TSH receptor* gene probably account for a minority of cases with congenital hypothyroidism. A study of 23 kindreds with familial congenital hypothyroidism did not find any evidence of linkage to the TSHR locus.

Severe congenital hypothyroidism caused by an inactivating mutation in the fourth transmembrane domain of the TSHR has been reported in the congenitally hypothyroid hyt/hyt mouse. The disorder is transmitted in an autosomal recessive manner, and thyroid tissue from homozygous mice shows unresponsiveness to TSH in vivo and in vitro. The mutation (proline 556 to leucine) eliminates TSH binding and receptor function, but the membrane localization of the receptor is preserved.

ACTIVATING AND INACTIVATING MUTATIONS IN GSα

Analogous to the mutations in the TSHR, gain-of-function mutations in the α-subunit of the stimulatory G protein (Gsα), referred to as *gsp* mutations, lead to constitutive activation of the cAMP pathway, resulting in increased function and growth of thyroid follicular cells. In the thyroid, somatic mutations in *gsp* have been found with variable frequencies in nonfunctioning adenomas, toxic adenomas, and differentiated thyroid carcinomas. The most commonly affected amino acids are arginine 201 and glutamine 227. These mutations impair the hydrolysis of GTP to GDP, resulting in persistent activation of adenylyl cyclase. The same Gsα mutations are found in 35%–40% of somatotroph tumors in acromegalic patients. Gsα mutations also cause other endocrine syndromes (*see* Chapter 46). Sporadic mutations in Gsα that occur early in development cause the McCune-Albright syndrome.

In pseudohypoparathyroidism (PHP) type Ia, also referred to as Albright's hereditary osteodystrophy (AHO), the affected subjects show resistance to a variety of hormones that couple to G-protein coupled receptors (e.g., parathyroid hormone [PTH], TSH). Multiple hormone resistance is caused by reduced expression of the stimulatory Gsα-subunit, and a variety of loss-of-function mutations have been identified.

DEFECTIVE THYROID HORMONE SYNTHESIS

The major steps involved in thyroid hormone synthesis are summarized in Fig. 50-2. Iodide is actively transported into the thyroid follicular cell by a recently cloned sodium-iodide symporter, and it is then transferred to the apical side of the cells that faces the follicular lumen. Thyroperoxidase (TPO), which is localized in the apical membrane, oxidizes iodide and subsequently iodinates tyrosyl residues of the intrafollicular thyroglobulin (organification or iodination) in the presence of hydrogen peroxide. The iodotyrosines, mono- and diiodotyrosyl (MIT, DIT), are coupled to form T4 or T3 in a reaction that is also catalyzed by TPO (coupling). Thyroglobulin (Tg) molecules that contain T4, T3, and iodotyrosines are internalized into the follicular cell by pinocytosis and are digested in lysosomes. The thyronines, T4 and T3, are released into the circulation, whereas MIT and DIT are deiodinated by a dehalogenase and the released iodide is recycled.

Disorders resulting in congenital hypothyroidism have been identified at all major steps involved in hormonogenesis. The vast majority of disorders are caused by defects in Tg or TPO. Traditionally, organification defects are distinguished from coupling defects. Although this distinction is valuable, it is important to note that several proteins or cofactors (TPO, Tg, H_2O_2 generation) are involved in both steps. In other words, an abnormal TPO may be capable of iodinating Tg, but unable to couple MIT and DIT to T3 and T4. Similarly, Tg defects may result in an inability to organify iodine or, alternatively, they may only impede the coupling of iodotyrosines.

DEFECTS OF IODIDE TRANSPORT   More than 20 cases suggestive of a defect of iodide uptake have been reported. There is a positive family history in about half of these cases, and consanguinity was present in about one-fourth of cases, suggesting an autosomal recessive trait. The clinical features include goiter, primary hypothyroidism, and little or no uptake of radioiodide. The salivary and gastric glands are also unable to concentrate iodide.

The recent cloning and characterization of a cDNA encoding the thyroid sodium-iodide symporter *(NIS)* will be useful for further defining the molecular defects in these disorders. This perchlorate-sensitive sodium-iodide symporter was cloned after functional screening of a rat cDNA library in *Xenopus laevis* oocytes. The isolated cDNA encodes a 618-amino acid protein and the secondary structure predicts that it contains 12 transmembrane domains. The human homolog has been cloned and mapped to chromosome 19p12–13.2. A homozygous missense mutation (threonine 354 to proline) in the *NIS* gene has been reported in a patient with congenital hypothyroidism as a result of an iodide transport defect. The parents of the patient were consanguineous and heterozygous for the defect.

Autoantibodies reacting with rat NIS have been detected in patients with autoimmune thyroid disease. Thus, it is likely that the NIS can be added to the list of thyroidal autoantigens, which includes TPO, Tg, and the TSHR.

THYROPEROXIDASE   TPO, a glycosylated hemoprotein, catalyzes several pivotal reactions required for thyroid hormone synthesis: oxidation of iodide, the iodination of tyrosine residues in thyroglobulin, and the coupling of iodinated tyrosines to generate T4 and T3. The gene encoding TPO has been assigned to 2pter–p12, and it contains 17 exons. A number of polymorphisms result in restriction fragment length polymorphisms (RFLP), providing a convenient tool for linkage studies. Two cDNAs are generated by alternative splicing and result in two functional forms of the protein (105 and 110 kDa). TPO is historically referred to as the microsomal antigen in autoimmune thyroid disease. It is anchored in the membrane and its catalytic site is exposed to the follicular lumen.

TPO defects are believed to be the most frequent cause of inborn abnormalities of thyroid hormone synthesis. The first mutation in the *TPO* gene was reported in a hypothyroid boy with an iodide organification defect and congenital goiter. A homozygous duplication of four basepairs (GGCC) was found in exon eight. This insertion causes a frameshift and predicts a severely truncated protein. Analysis of the transcripts revealed, however, the presence of a cryptic splice site that restores the reading frame further downstream. Thus, the insertion leads to the substitution of amino acids in the middle of the protein without truncating the carboxy-terminal portion. Further mutations have been found in the *TPO* gene in nine families with a total organification defect. Besides various frameshift mutations (20-bp insertion in exon 2, 4-bp duplication in exon 8, C insertion at position 2505 in exon 14), point mutations are also found in scattered locations resulting in premature stops, substitutions of single residues, and alteration of splicing (border of exon 10 and intron 10). In four families, the patients were homozygous for one of these mutations, and there were compound heterozygotes in five families.

PENDRED'S SYNDROME   In 1896, Pendred described a kindred with four sisters and a brother in which two of the girls were deaf-mutes and had large goiters. The association of goiter with deafness, together with a positive perchlorate discharge test, is now known as Pendred's syndrome. Metabolically, these patients present with mild hypothyroidism or euthyroidism. Tg levels are usually elevated because of chronic TSH stimulation. The deaf-mutism in Pendred's syndrome is associated with a defect in the cochlea, referred to as Mondini's cochlea, in which there is a single cavity consisting of only two turns instead of the normal three coils. The syndrome is inherited in an autosomal recessive pattern. Iodide is trapped by the thyroid gland, but its organification is impaired. This feature can be demonstrated by a positive perchlorate test after the administration of radiolabeled iodine. Normally, the trapped iodide is organified and bound to Tg; after the administration of perchlorate, which blocks iodide transport, only unbound iodide is released from the thyroid. A loss of iodide after perchlorate administration is thus indicative of an organification defect.

It has been postulated that both the goiter and deafness are related to a pleiotropic effect of a mutated gene in homozygous individuals. After demonstrating absence of linkage to the *TPO* and *Tg* genes, two groups established linkage of Pendred's syndrome with a locus on the long arm of chromosome 7 (7q21–34). Using a positional cloning strategy, the Pendred syndrome gene *(PDS)* has been identified very recently. It encodes a putative sulfate transporter, pendrin, which is expressed predominantly in the thyroid gland. Its exact role in the development and function of the inner ear and the thyroid remains to be defined.

HYDROGEN PEROXIDE GENERATION H_2O_2 is an essential factor in the iodination and coupling reactions. Although the ability of follicular cells to produce H_2O_2 has been known for more than three decades, the nicotinamide adenine dinucleotide phosphate (NADPH)-dependent oxidoreductase remains ill-defined. Deficiency in H_2O_2 generation may impede the organification of iodide. Two cases of euthyroid goiter and abnormal iodide organification associated with defective H_2O_2 generation have been reported. Addition of an H_2O_2-generating system to thyroid homogenates restored normal organification in vitro.

THYROGLOBULIN   Tg is produced by thyroid follicular cells and is secreted into the follicular lumen. Some of its tyrosine residues are iodinated by TPO (organification and iodination), and the iodinated tyrosines, MIT and DIT, are subsequently coupled to form T3 and T4. Tg is, therefore, considered to be a thyroid hormone precursor. Besides its importance for hormone synthesis, Tg allows storage of iodine and thyroid hormone, which can be important under conditions of scarce iodine supply.

Tg is a large glycosylated protein of 2748 amino acids with a molecular mass of 330 kDa and a sedimentation rate of 12 S. The mature protein is formed by two noncovalent subunits (19 S thyroglobulin). Glycosylation plays an important role in the structure of the protein and accounts for 10% of total weight. The Tg monomer contains 20 glycosylation sites and there is extensive microheterogeneity in the composition of carbohydrates.

The *Tg* gene is one of the largest mammalian genes known to date, and it spans more than 300 kb. It has been mapped to chromosome 8q24 and contains 42 exons. Most exons are small (100 to 200 bp) with the exception of exons 9 and 10, which contain 1101 and 588 bp, respectively. The mature transcript contains an open reading frame of 8301 bp. The promoter has been well characterized and contains regulatory elements for the thyroid-specific transcription factors 1 and 2 *(see below)*, a ubiquitous factor, and cAMP response element binding proteins. TSH, the main regulator of the thyroid, acts via the cAMP signaling pathway.

Tg contains 67 tyrosines, but only a minority of these residues, localized in the carboxy- and amino-terminus, are hormonogenic sites. Complete hydrolysis of iodinated Tg yields only two to four molecules of the iodothyroxines, T4 and T3.

Defects of Tg synthesis or secretion have been studied extensively in animals and man. Tg abnormalities have been classified as quantitative or qualitative defects. Qualitative defects encompass structurally defective Tg, defective export from thyroid follicular cells, and defects in glycosylation. In individuals with structurally abnormal Tg, the coupling of iodotyrosines may be impaired. Thus, the majority of iodine bound to Tg is present in the form of MIT and DIT.

Clinically, these patients present with goiter and a metabolic status that may be hypothyroid, subclinically hypothyroid, or euthyroid. Tg defects are transmitted in an autosomal recessive manner, and in most cases, there is a history of consanguinity. However, RFLP analysis clearly demonstrated an autosomal dominant mode of inheritance in one kindred. Based on screening for neonatal hypothyroidism, the prevalence has been estimated to be 1 in 40,000 newborns. Goiter is typically present in early childhood. Thyroid radioiodine uptake is invariably elevated.

Tg can now be measured by radioimmunoassay (RIA); low or borderline Tg may indicate a quantitative defect, whereas patients with qualitative defects have normal or even an elevated Tg. After stimulation with TSH, no increase of Tg is observed in quantitative defects. The presence of abnormal iodoproteins in the serum is also suggestive of abnormal Tg synthesis. In the absence of sufficient Tg, albumin as well as other proteins are iodinated, generating iodotyrosines and iodohistidines. Ion-exchange chromatography after administration of iodine/125 results in elution of low T3 and T4, normal MIT and DIT, and high iodoproteins.

Although it is possible to diagnose Tg defects at the molecular level, this is not a trivial task considering the extremely large size of the gene. Further studies of patients with Tg abnormalities will be important for a more detailed understanding of the structure–function relationships in Tg.

The first models of Tg variants to be studied at the molecular level were the Afrikander cattle and the Dutch goat. The Afrikander cattle are characterized by large goiters and euthyroid metabolic status. The disorder is autosomal recessive. A mutation in exon 9 (arginine 697) leads to a premature stop codon. An alternative splice mechanism allows rescue to some degree by producing a misspliced 7.3-kb message missing exon 9. The original reading frame is maintained in this transcript and it is translated into a functional protein missing the part encoded by exon 9. Both transcripts are, however, present at much lower levels than normal. The Dutch goat is goitrous as well and, provided that the iodine intake is high, euthyroidism can be maintained. A nonsense mutation (tyrosine 296 to stop) in exon 8 results in a truncated protein. The fact that the goats can remain euthyroid despite this truncation is indirect evidence that the major hormonogenic sites are in the amino-terminal part of the protein.

Other animal species with Tg defects include the South Australian merino sheep (goiter, hypothyroidism, no normal intrathyroidal Tg), the bongo antelope (goiter, euthyroidism, absence of 660-kDa Tg), a cattle strain in Serbia (goiter, euthyroidism, decrease in 19 S Tg, increase in 12 S monomer), and the cog/cog mice (goiter, hypothyroidism, marked Tg deficiency).

In a well-studied human pedigree with congenital goiter and consanguineous parents, an RFLP in the *Tg* gene was found to segregate with the disease. Subsequently, a deletion of exon 4 because of a C to G transversion at position –3 in the acceptor splice site of intron 3 was found. This deletion removes one of the potential hormonogenic sites (tyrosine 130) from the Tg molecule. A family with two affected siblings revealed a point mutation creating a stop codon at position 1510; however, analogous to the Afrikander cattle, the mutation is removed by differential splicing that generates an mRNA shortened by 171 nucleotides. Recently, a quantitative Tg defect was found to be caused by the absence of thyroid-specific transcription factor (TTF-1) in a patient with congenital goiter *(see below)*.

DEHALOGENASE DEFECTS   After entering the follicular cell, Tg is hydrolyzed, and T4 and T3 are secreted into the blood. The iodotyrosines, MIT and DIT, which are much more abundant in the Tg molecule, are deiodinated by an intrathyroidal dehalogenase and recirculated for hormone synthesis. In case of a defective dehalogenase system, MIT and DIT leak into the circulation and are excreted in the urine. This leads to severe iodine loss, and if the iodine supply is scarce, goiter and hypothyroidism ensue.

Clinically, patients with a deiodinase defect present with congenital hypothyroidism and a goitrous gland. The diagnosis is established by administration of radiolabeled DIT. Normally, DIT will be deiodinated, whereas in the case of a defective dehalogenase, the majority will be secreted unaltered in the urine. Administration of iodide in sufficient amounts to compensate for the increased loss, will reestablish a euthyroid metabolic state. The disorder is inherited in an autosomal recessive fashion. Biochemical testing in heterozygotes demonstrates an increased secretion of labeled DIT in the urine. The gene for the intrathyroidal dehalogenase has not been cloned.

SERUM-BINDING PROTEIN DEFECTS

Thyroid hormones circulate bound to plasma proteins. The three major binding proteins are thyroxine-binding globulin (TBG), transthyretin (TTR, formerly referred to as thyroxine-binding prealbumin), and albumin. Under physiologic conditions, only 0.03% of T4 and 0.3% of T3 circulate as free hormone.

Abnormalities in transport proteins can lead to either a decrease or an increase in total T4 levels. However, free hormone levels are within the normal range and the patients are clinically euthyroid. Failure to recognize these entities results in inappropriate treatment aimed at normalizing the total thyroid hormone levels. TTR variants are of additional clinical importance because some are associated with a form of amyloidosis.

THYROXINE-BINDING GLOBULIN   TBG, which carries about 75–80% of T4, is an acidic glycoprotein synthesized in the liver. The mature protein contains 395 amino acids with four heterosaccharide chains with five to nine sialic acids. It contains a single T4-binding site. Like corticosteroid-binding globulin, it shows high homology with α1-antichymotrypsin and α1-antitrypsin proteases. The carbohydrates play a minor role in T4 binding, but have important effects on TBG stability and hepatic clearance rate. An increase in sialylation (e.g., induced by estrogens) lowers the hepatic clearance and thus increases TBG levels. Multiple other drugs either increase or decrease TBG concentrations by altering the synthesis rate or the degree of sialylation. The single copy gene encoding TBG is localized on the X-chromosome (Xq11–q23).

Inherited TBG abnormalities are classified into complete or partial deficiencies, or as TBG excess. Complete TBG-deficiency (TBG-CD) is defined as absence of TBG in the serum of hemizygous (XY) individuals. The heterozygous females in these kindreds have about half the normal amount of TBG because random X-inactivation results on average in a 50% reduction of the protein. The prevalence of complete deficiency has been estimated at 1:15,000. Partial deficiency is the most common form of TBG deficiency. In white and mixed populations, it is found with a frequency of 1:4,000. About 50% of Australian Aborigines have an abnormal TBG (TBG-A), and slow TBG (TBG-S) is found in African and Pacific island populations. Some of these TBG-variants have a reduced affinity for T4 (TBG-A, TBG San Diego). In some variants, an accelerated rate of degradation is responsible for low serum concentrations. The mutations in the *TBG* gene characterized so far are caused by deletions of single nucleotides resulting in frameshift and early termination or single base substitutions that alter the amino acid sequence.

TBG excess is not as frequent as TBG deficiency, and has an incidence of about 1 in 25,000 births. TBG and T4 levels are elevated three- to fivefold in hemizygotes and two- to threefold in heterozygous females. Because no mutations have been found in the coding sequence of the *TBG* gene in these cases, a defect in the promoter region has been postulated.

TRANSTHYRETIN   TTR is a homotetramer formed of subunits containing 127 amino acids. It contains two T4 binding sites, but negative cooperativity allows occupancy of only one site at a given time. The *TTR gene* contains four exons and is localized on chromosome 18. TTR is predominantly synthesized in the liver, but also in the choroid plexus. Although the exact role of TTR in the brain is not known, it has been postulated that T4 binds to TTR in the epithelial cells of the choroid plexus and is then released into the cerebrospinal fluid.

A large number of TTR variants have been reported, and their impact on T4 affinity is highly variable. Many of the point mutations have been associated with distinct forms of amyloidosis. The inheritance is autosomal dominant in most instances. Although the clinical manifestations vary, most have polyneuropathy, and are sometimes referred to as familial amyloidotic polyneuropathy (FAP).

ALBUMIN   Albumin is a monomer of 69 kDa and transports a wide variety of endogenous and exogenous hydrophobic compounds. About 5–10% of T4 is bound to albumin. Familial dysalbuminemic hyperthyroxinemia (FDH) is the most frequent form of euthyroid hyperthyroxinemia. The disorder is inherited in an autosomal dominant fashion and characterized by an albumin with an increased affinity for T4. After the demonstration of tight linkage between the FDH phenotype and the albumin gene, a point mutation at nucleotide 653 causing a substitution of arginine by histidine was identified in all cases reported so far.

PERIPHERAL MONODEIODINATION

T4 and T3 are generally thought to enter the peripheral tissues as unbound hormones. T4 is metabolized into the more active compound, T3, by intracellular 5'-monodeiodination, or into the inactive metabolite, reverse T3 (rT3), by 5-monodeiodination. Because roughly 80% of T3 is generated by monodeiodination, T4 is sometimes considered a prohormone. Several selenoenzymes with different tissue distributions are involved in 5'-mono-deiodination. 5'-monodeiodinase type I is expressed primarily in liver, muscle, kidney, and skin. Type II 5'-monodeiodinase is expressed in the anterior pituitary, the brain cortex, brown adipose tissue, and, at high levels, in the thyroid gland. The type III deiodinase catalyzes the conversion from T4 and T3 into inactive metabolites by 5-monodeiodination. This selenoprotein is abundant in the placenta and regulates circulating fetal thyroid hormone concentrations during gestation. cDNAs have been cloned for each of the enzymes.

Defects in deiodination are very rare. A description of six females of three generations with hyperthyroidism and high T4 and T3, but unsuppressed TSH, was suggested to be caused by an inherited 5'-deiodinase type II defect. In two instances, high T4 and rT3, but normal T3, concentrations were reported and may be explained by a 5'-deiodinase defect.

RESISTANCE TO THYROID HORMONE

The thyroid hormones, T4 and T3, exert their multiple cellular effects through nuclear thyroid hormone receptors (TR), transcription factors that act by altering patterns of gene expression. The TRs were cloned on the basis of their relationship to other members of the steroid receptor superfamily, which share a characteristic central DNA-binding domain and a carboxy-terminal ligand-binding domain. In the TR, the carboxy-terminus of the receptor also contains nuclear localization signals, dimerization domains, and transactivation functions. The functional properties of the amino-terminal region of the receptor are not well-characterized, but it also seems to be involved in transactivation.

There are two thyroid hormone receptors, TRα and TRβ, that are encoded by separate genes located on chromosomes 17 and 3, respectively. They each bind thyroid hormones with high affinity, but TRα and TRβ differ in their developmental patterns of expression, tissue distribution, and the patterns of splicing to create additional isoforms. The TRs act in conjunction with thyroid receptor accessory proteins (TRAPs), like retinoid X receptor (RXR), that dimerize with the TR and enhance their binding to DNA. The TR binds as a monomer, or with greater affinity as homodimers or heterodimers, to thyroid hormone response elements (TREs) in specific target genes. Moreover, several factors that act as nuclear corepressors, such as SMRTs (silencing mediators for retinoid and thyroid hormone receptors) or NCoRs (nuclear receptor corepressors), have been cloned recently (*see* Chapter 3). The first cDNA encoding a nuclear receptor corepressor (NCoR 270 kDa) mediates ligand-independent inhibition of gene transcription by TR and other receptors. In genes regulated positively by thyroid hormones, the corepressor is proposed to interact with unliganded TR to inhibit transcription; this interaction is disrupted by T3, allowing putative coactivators to interact with the TR and activate gene transcription (Fig. 50-4).

Although there is considerable heterogeneity in the TREs of different target genes, most TREs contain two or more "half-sites" that correspond to the minimal recognition motif for a receptor monomer. The consensus TRE half-site consists of the DNA sequence, AGGTCA. These half-sites can be arranged as a palindrome, a direct repeat spaced by four nucleotides, or as an inverted repeat, also called lap (a term created by inversion of palindrome). Remarkably, TRs can bind to these TREs with different orientations as homodimers or heterodimers with RXRs, indicating flexibility in the determinants of the protein–protein interface.

Resistance to thyroid hormone (RTH) was first reported in 1967 by Refetoff, DeWind, and DeGroot, who described two sibs of a
Figure 50-4   Model of thyroid hormone action on a positively regulated gene. In the absence of thyroid hormone, corepressors interact with thyroid hormone receptor (TR) homo- or heterodimers and silence transcription. Thyroid hormone causes displacement of corepressors and recruitment of coactivators and factors of the basal transcription apparatus to initiate gene expression.

consanguineous marriage presenting with goiter, high levels of protein-bound iodine, deaf-mutism, delayed bone age, and stippled epiphyses, but without signs of hyperthyroidism. It was postulated that hormone resistance in peripheral tissues was the explanation for the absence of signs and symptoms of thyrotoxicosis. After the cloning of the TRs, linkage analysis demonstrated that the *TRβ gene* is tightly linked to RTH, whereas no association could be demonstrated for *TRα*. The ultimate proof that a defect in the receptor is the cause of RTH was provided in 1989 by the demonstration of mutations in the *TRβ* gene, a finding that has been confirmed in multiple reports. Although the true incidence of RTH is unknown, it is a relatively rare disorder and approximately 400 patients have been reported. With the growing awareness of the existence of the disorder and the availability of genetic testing, this list is continuing to increase.

Biochemically, RTH is defined by elevated circulating levels of free thyroid hormones as a result of reduced target tissue responsiveness and normal, or elevated, levels of TSH. This "inappropriate" TSH level contrasts with the situation in hyperthyroidism, in which the pituitary secretion of TSH is suppressed. Patients with RTH typically present with goiter and a euthyroid or mildly hypothyroid metabolic state. Thus, pituitary resistance results in hypersecretion of TSH that compensates, at least partially, for hormone resistance in peripheral tissues. Despite this compensation, the clinical signs of RTH can include short stature, delayed bone maturation, hyperactivity and learning disabilities, and hearing defects, as well as variable degrees of hyperthyroidism and hypothyroidism.

With the exception of a single family harboring a deletion of the entire coding sequence of the entire *TRβ gene* and a recessive pattern of inheritance, all other reports of RTH demonstrate autosomal dominant inheritance. The mutant receptors act in a dominant-negative fashion to block the activity of normal TRα and TRβ receptors. It is striking that, with a few exceptions, the mutations are clustered within two domains in the carboxy-terminal region of the receptor between amino acids 310 and 347 (domain I) and amino acids 438–461 (domain II) (Fig. 50-5). Many mutations occur in CpG dinucleotide sequences, and in most cases, these nucleotide substitutions result in single amino acid changes. No mutations have been found within the DNA-binding domain or in the amino-terminus. In general, the mutations preserve critical

receptor functions such as dimerization and DNA binding, while inactivating other activities such as T3 binding and transcriptional activation. The mechanism underlying the dominant-negative activity of mutant TRs seems to be caused predominantly by competition at the level of DNA binding.

These defects continue to provide important insights into the mechanisms of thyroid hormone action and the structure–function relationship of the TRs, as well as the molecular mechanisms of dominant-negative activity. The study of the recently developed murine knockout models and transgenic mice bearing mutant thyroid hormone receptors provide additional insights into the molecular basis of thyroid hormone action and RTH. For example, TRβ –/– mice display defective maturation of auditory function, demonstrating that TRβ is essential for the development of hearing.

TRANSCRIPTION FACTORS

THYROID TRANSCRIPTION FACTOR-1 (TTF-1)   TTF-1 is a 38-kDa nuclear protein that mediates thyroid-specific gene transcription. The human gene contains a homeobox domain and a motif that is found in the NKX2 family of transcription factors. The gene has been localized to chromosome 14q12–q21. TTF-1 is involved in thyroid development and it stimulates thyroglobulin, and to a lesser degree, thyroperoxidase gene transcription. Besides the thyroid, TTF-1 is also expressed in brain tissues and in the lung. A murine knockout model of TTF-1, which is also known as T/EBP (thyroid-specific enhancer protein), led to severe alterations of forebrain, lung, and thyroid development.

Absence of TTF-1 expression has been found to cause defective thyroglobulin synthesis and congenital goiter. The disorder is probably recessive. Pax8 mRNA levels were normal in this patient and there was very little thyroglobulin mRNA. Thyroperoxidase mRNA was more abundant than in control tissues. In two recent studies, no alterations in the *TTF-1* gene were found in a large number of patients with congenital hypothyroidism. This suggests that TTF-1 mutations are unlikely to be an important cause of thyroid dysgenesis or agenesis.

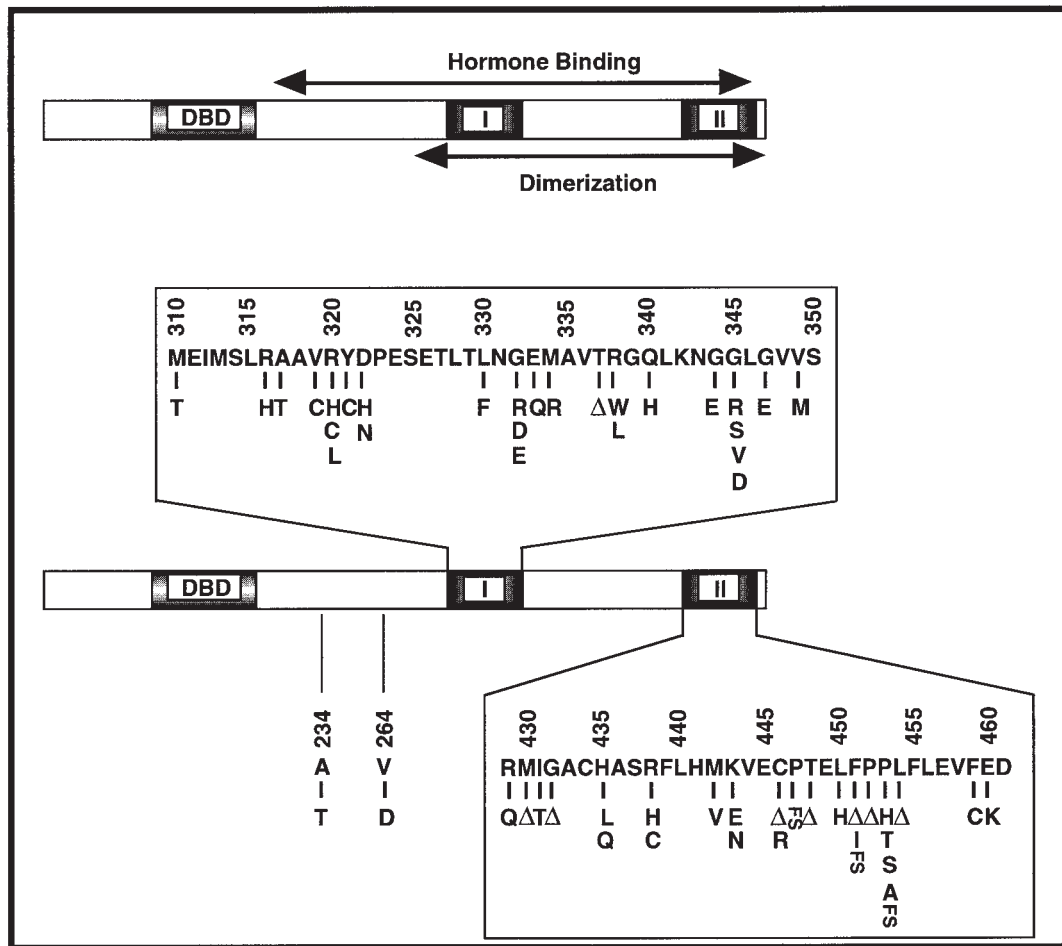
THYROID TRANSCRIPTION FACTOR-2 (TTF-2)   TTF-2 is a forkhead domain-containing transcription factor that binds to both the *Tg* and the *TPO* gene promoters. It is transiently expressed in the developing thyroid and anterior pituitary gland. In the thy-


Figure 50-5 Structure of TRβ receptor and synopsis of mutations in TRβ in patients with resistance to thyroid hormone. With a few exceptions, the mutations are clustered in two domains in the carboxy-terminus of the receptor flanking the dimerization domain. (DBD, DNA-binding domain.)

roid, TTF-2 expression is downregulated just before the onset of *Tg* and *TPO* gene expression, suggesting that this transcription factor is a negative regulator of thyroid-specific gene expression during development. At later stages, IGF-I modulates the level of TTF-2 and results in increased expression of the *Tg* gene in vitro. TTF-2 expression is lost in cell lines transformed with Ki-*ras*, Ha-*ras* and polyoma middle-T oncogenes. So far, no human thyroid disease is known to be caused by defects or absence of TTF-2.

PAX-8 Pax-8 is a paired domain thyroid-specific transcription factor responsible for thyroid development and for *Tg* and *TPO* gene expression. In contrast to TTF-1, Pax-8 binds predominantly to the TPO promoter and, with less affinity, to the *Tg* promoter.

AUTOIMMUNE DISORDERS

Autoimmune thyroid disorders, such as Hashimoto's thyroiditis and Graves' disease, are by far the most common diseases affecting the gland. Both disorders are found more frequently in women than in men (4:1 to 10:1), a difference that is most commonly explained by influences of sex steroids on immunoregulatory mechanisms. The incidence of Graves' disease in the general population has been estimated at 0.2–1%. Autoimmune thyroiditis has been reported to occur in 3–4.5% of women. Thyroid autoantibodies are found in up to 15% of elderly women.

Both disorders are familial and are thought to be polygenic. However, environmental factors probably modulate their phenotypic expression.

GRAVES' DISEASE The hereditary predisposition to Graves' disease has been addressed in many studies. Graves' disease occurs in about 3–9% of dizygotic and 30–60% of monozygotic twins. As in other autoimmune diseases, associations have been established between the disease and the presence of certain constellations of human leukocyte antigens (HLA). The activation of T cells requires interaction of T-cell receptors with an antigen and the HLA molecules of the major histocompatibility complex (MHC) I and II on the antigen-presenting cell (*see* Chapter 31). Subsequently, the T cell releases lymphokines and stimulates the production of (auto)antibodies in B cells. Graves' disease was one of the first autoimmune disorders with documented associations with certain HLA types, predominantly DR3 and B8 in whites, B17 in blacks of West Africa and African Americans, and B35 in Japanese. There are, however, many variations in these associations. The frequency of HLA-DR5 seems to be reduced in patients with Graves' disease.

Because stimulating autoantibodies against the TSHR (TSAb) are the cause of Graves' disease, their assessment can be helpful for establishing the diagnosis and they are potentially helpful in follow-up. The cloning of the *TSHR* led to the development of new

bioassays that allow the measurement of TSAb. In these new assay systems, the *TSHR* has been stably transfected into cell lines and measurement of cAMP in response to a patient's serum allows a bioassay for thyroid autoantibodies. These assays allow distinction between TSab from antibodies that block the receptor (TBAb); these blocking antibodies may also be present in autoimmune thyroid disease. Several regions of the extracellular domain have been identified as possible epitopes for TSab, but so far no unifying model has been established.

HASHIMOTO'S THYROIDITIS   Molecular biology established that the microsomal antigen in autoimmune thyroiditis is in fact TPO. The epitopes within the TPO enzyme that are the targets of autoantibodies are, however, still a matter of debate. Recombinant TPO is now used for assays of autoantibodies.

HLA correlations differ in part from those reported for Graves' disease and include primarily HLA-DR3, DR4, and DR5 haplotypes. It is noteworthy that members of the same family can be affected by either Graves' or Hashimoto's disease, suggesting that the immunogenetic predisposition for both entities is closely related.

THYROID CANCER

Thyroid cancers account for about 0.6–1.6% of all malignancies, and the incidence is 1 to 10 per 100,000 in most countries. The most common thyroid malignancies are papillary thyroid carcinomas (PTC) and follicular thyroid carcinomas (FTC), both originating from follicular cells, and accounting for about 60–90% of tumors. Their relative distribution is variable, but papillary carcinoma is generally 5–10 times more common. The incidence of FTC increases in regions with iodine deficiency. Besides the clinically relevant forms of papillary thyroid cancer, occult papillary thyroid cancer (<1 cm) is found in up to 25% of autopsies. The highly malignant anaplastic carcinoma (ATC) and several unusual variants of thyroid cancers (Hürthle cell carcinoma, insular thyroid carcinoma, primary squamous carcinoma, and lymphoma of the thyroid) are much rarer forms of thyroid malignancies. ATC is thought to arise from pre-existing well-differentiated carcinomas.

Radiation is a major risk factor for the development of benign and malignant thyroid neoplasms. This was recognized after the use of external radiation for medical treatment of benign and malignant conditions of the head and neck and more dramatically after releases of ionizing radiation from atomic explosions and accidents in nuclear facilities.

Papillary thyroid cancer, which presents with several distinct histologic subtypes, may occur in the setting of some rare autosomal dominant syndromes with disseminated neoplasias: familial adenomatous polyposis and Gardner's syndrome, as well as Cowden's syndrome, a condition characterized by multiple hamartomas with benign and malignant breast tumors, gastrointestinal polyps, ovarian cysts, and mucocutaneous papulae. In the latter case, germline mutations in the *PTEN* gene, a protein tyrosine–dual-specificity phosphatase, have been identified in four of five families. In some instances, the familial accumulation of PTC may, however, be the result of exposure to a shared risk factor rather than a familial disease in the strict sense. Also, familial aggregation of FTC seems to occur in some families with dyshormonogenesis. Cytogenetic alterations have been identified in some cases of papillary thyroid cancer (chromosome 1, unbalanced rearrangement with trisomy 5 and monosomy 16, 10, 17). The inversions on chromosome 10 prompted the discovery of the papillary thyroid cancer and *ret* rearrangement *(see below).*

Several molecular mechanisms involved in the development of thyroid neoplasms have been elucidated during the last decade. By analogy to colon cancer, in which a multistep progression from polyclonal hyperplastic lesion to monoclonal adenoma and to carcinoma seems to occur, a stepwise linear model has also been proposed for thyroid malignancies (*see* Chapter 7). Although some features are consistent with such a scenario, the picture is far from being complete and further efforts are needed to fully understand thyroid oncogenesis.

CLONAL ANALYSIS   Analysis of clonality has been performed in thyroid nodules, adenomas, and cancers using the X-inactivation technique in females. Studies of clonality of thyroid neoplasms revealed that the majority of thyroid nodules are monoclonal in origin, i.e., true adenomas. In multinodular goiters, polyclonal nodules coexist with monoclonal nodules, and the latter may have distinct clonal origins within the same gland. As expected, cancers are of monoclonal origin. The few reported exceptions are probably caused by contributions by stromal tissue.

Besides clonal analysis by means of the X-inactivation approach, loss of heterozygosity (LOH) has been demonstrated in follicular thyroid cancer (chromosome 3p; chromosome 11q13, harboring the gene linked to multiple endocrine neoplasia type 1, menin, and others). Taken together, these results suggest that somatic mutations in growth-related genes or loss of tumor suppressor genes occur in most of these tumors.

GROWTH FACTORS AND ONCOGENES   Many growth factors are expressed abnormally in benign and malignant thyroid tumors (Table 50-3). In part, these alterations are probably secondary events because no structural abnormalities have been detected in the involved genes or the respective chromosomal locations.

Amplification of the *met* gene, encoding a heterodimeric tyrosine kinase whose ligand is the hepatic growth factor (HGF), has been reported in 70% of papillary thyroid cancer and undifferentiated thyroid cancer and in 25% of follicular cancer, and it is associated with an aggressive clinical and histologic phenotype. The expression of transcription factor c-*myc* increases in less differentiated thyroid tumors, and c-*myc* mRNA may correlate inversely with that of the TSHR.

Mutations in the three *ras* genes, Ha-*ras*, K-*ras*, and N-*ras*, which encode closely related 21-kDa proteins involved in signal transduction, have been found in numerous human tumors, including thyroid neoplasms. The most frequently mutated codons are 12, 13, and 61, and these mutations lead to a reduction of the GTPase activity, resulting in constitutive activation of the protein. Although mutations have been detected in both benign and malignant thyroid tumors, there is considerable variation in the reported prevalence of these mutations. This might be in part because of geographic differences or the techniques used to detect the mutations. *Ras* mutations appear to be most frequent in follicular cancer.

Rearrangements of the *ret* locus were found on the basis of characterization of an inversion in chromosome 10 in several papillary cancers. Ret is a transmembrane tyrosine kinase. Its ligand, glia-derived neurotrophic factor (GDNF) has been identified very recently. Normally, the ret proto-oncogene is not expressed in thyroid follicular cells but it is found in calcitonin-producing thyroid C cells. Several distinct types of translocations place different promoters upstream of the ret tyrosine kinase domain. Ret-papillary thyroid cancer rearrangements seem to be relatively specific for papillary thyroid cancer and occur in about 10–40% of cases.

Table 50-3
Molecular Alterations in Benign and Malignant Thyroid Tumors[a]

Gene	Chromosomal location	Molecular Defect	Tumor
TSHR	14q31	Point mutations	Toxic adenoma, differentiated carcinoma
Gsα	20q13.2	Point mutations	Adenoma, toxic adenoma, differentiated carcinomas
ret/PTC	10q11.2	Rearrangements PTC1: (inv(10)q11.2q21); PTC2: (t(10;17)(q11.2;q23)); PTC3: ele1/TK	PTC
ret	10q11.2	Point mutations	MEN, MTC
Trk	1q23–24	Rearrangements: NTRK1/ TPM3; NTRK1/TPR; NTRK1/TAG	MNG, PTC
ras	H-ras 11p15.5 K-ras 12p12.1 N-ras 1p13.2	Point mutations	Adenoma, differentiated thyroid carcinoma
p53	17p13	Point mutations, deletion, insertion	Differentiated carcinoma, anaplastic carcinoma
Rb	13q14.1–14	mRNA variants	Differentiated carcinoma, anaplastic carcinoma
p16 (MTS1, CDKN2A)	9p21	Deletions	Cell lines of differentiated carcinomas
p21/WAF	6p21.2	Overexpression	ATC, FTC, PTC
met	7q31	Overexpression	FTC
c-myc	8q24.12.–13	Overexpression	Differentiated carcinoma
PTEN	10q23	Point mutations	PTC in Cowden's syndrome
Loss of heterozygosity	3p 11q13 and other loci		FTC

[a]Abbreviations: *TSHR*, thyroid-stimulating hormone receptor; *Gs*α, G-protein stimulating α-subunit; *ret/PTC*, *ret* proto-oncogene/papillary thyroid carcinoma; *ret*, *ret* (rearranged during transfection) proto-oncogene; *Trk*, rearrangement of neurotrophic tyrosine kinase receptor type 1; and nonmuscle tropomyosin; *ras*, *ras* (rat sarcoma) proto-oncogene; *p53*, *p53* tumor antigen; *Rb*, retinoblastoma gene; *p16 (MTS1, CKN2a)*, tumor suppressor *p16* (multiple tumor suppressor1, cyclin-dependent kinase inhibitor-2A); *p21/WAF*, tumor suppressor *p21* (cyclin-dependent kinase inhibitor-1A, wild-type *p53*-activated fragment 1); *met*, *met* proto-oncogene (hepatocyte growth factor receptor); c-*myc*, c-*myc* (myelocytomatosis virus) proto-oncogene; *PTEN*, phosphatase and tensin homolog; *ele1/TK*, *ret*-activating gene *ele1*; *NTRK*, neurotrophic tyrosine kinase receptor; *TPM3*, tropomyosin 3; *TPR*, translocated promoter region; *TAG*, tyrosine kinase receptor-activating gene; MEN, multiple endocrine neoplasia; MTC, medullary thyroid carcinoma; MGN, multinodular goiter; ATC, anaplastic thyroid carcinoma; FTC, follicular thyroid carcinoma.

A second type of chimeric oncogene has been described in papillary thyroid cancer. The *TRK* gene, encoding a receptor for the nerve growth factor (NGF), can come under the control of several unrelated sequences through intrachromosomal rearrangements on chromosome 1q23–24: the tropomyosin gene, the *TPR* gene, and a gene referred to as *TAG* (TRK-activating gene).

Somatic *gsp* mutations, activating mutations in the α-subunit of the stimulatory G protein, occur in toxic adenomas *(see above)*. In comparison to toxic adenomas where they occur in up to 20% of all cases, *gsp* mutations are relatively uncommon in papillary thyroid cancer and FTC.

The tumor suppressor genes that have been studied in thyroid malignancies include the retinoblastoma susceptibility gene *(Rb)*, the *p53* gene, and *P16*. *Rb* maps to chromosome 13q14 and encodes a 110-kDa protein that regulates cell cycle control. When studied at the genomic or protein level, no *Rb* abnormalities have been found in thyroid carcinomas. This contrasts with a report on mRNA abnormalities in 55% of thyroid carcinomas.

P16, also referred to as *MTS1*, is an inhibitor of cyclin-dependent kinases (CDK) involved in the phosphorylation of *Rb* (*see* Chapter 6). The recent demonstration of homozygous deletions of *P16*, localized on chromosome 9p21, in two of three FTC and two of four papillary thyroid cancer cell lines suggests that *P16* might be an important tumor suppressor gene involved in the pathogenesis of thyroid malignancies.

The *p53* gene plays an important role in the development and progression of several human cancers. It exerts its function as a tumor suppressor by arresting cells in the G1 phase of the cell cycle, thus enabling repair of DNA damage. The *p53* gene is localized on chromosome 17p13. Germline mutations of *p53* are found in the Li-Fraumeni syndrome, familial breast cancer (*see* Chapter 7), and a wide variety of other human malignancies. As in other malignancies, mutations in *p53* are also thought to be involved in the progression of thyroid carcinomas and to play an important role in the process of dedifferentiation. Although they are more frequently found in anaplastic carcinomas, they may also occur in some follicular adenomas and differentiated carcinomas. Mutations occur predominantly at CpG dinucleotides, with positions 248 and 273 representing mutational hot spots.

MEDULLARY THYROID CANCER AND MULTIPLE ENDOCRINE NEOPLASIA Multiple endocrine neoplasia (MEN), familial and sporadic medullary thyroid cancer (FMTC/MTC) are more thoroughly reviewed in Chapter 54. MEN 2A is an autosomal dominant disease characterized by the association of MTC, parathyroid adenomas, and pheochromocytoma. In MEN 2B, parathyroid disease is absent, but the patients have mucocutaneous ganglioneuromas and some have a marfanoid habitus. FMTC is a familial cancer syndrome without other manifestations of the MEN complex.

Several mutations in the *ret* tyrosine kinase receptor have been identified as the cause of MEN 2A and FMTC. Most of these mutations affect conserved cysteines in the cysteine-rich domain that is thought to be involved in receptor dimerization and activation. In MEN 2B, a mutation at position 918, substituting methionine to threonine, has been found in 95% of the patients.

Although genetic testing for the diagnosis of cancer predisposition remains controversial, the recognition of mutations in the *ret* gene as cause of MEN 2A and FMTC has profound clinical implications. Before the availability of genetic testing, families with MEN 2A and FMTC were evaluated on a regular basis by measuring calcitonin levels after stimulation with pentagastrin or calcium. This test is hampered, however, by relatively low specificity and a requirement for repeated testing. The possibility of identifying genotype by mutational analysis allows accurate detection of affected and unaffected family members. Consequently, thyroidectomy can be performed in early childhood to prevent the development of MTC that occurs in about 90% of affected patients. This procedure is, therefore, likely to be associated with improved diagnostic accuracy, better cure rates, and reduced long-term costs.

RECOMBINANT HUMAN TSH AS DIAGNOSTIC TOOL IN THE FOLLOW-UP OF DIFFERENTIATED THYROID CARCINOMA
After surgical procedures, patients with differentiated carcinomas of the thyroid are routinely evaluated by means of radioiodine scans and measurements of thyroglobulin. To achieve high sensitivity, these tests are traditionally performed after withdrawal of the suppressive treatment with thyroxine to achieve an increase in TSH to allow a high uptake of radioiodine in residual tissue. Withdrawal of thyroxine leads to hypothyroidism. Moreover, the increase in TSH may potentially lead to proliferation of residual tumor cells. To avoid these problems, exogenous TSH has been successfully administered during uninterrupted treatment with thyroxine before performing radioiodine scans and thyroglobulin measurements. These procedures were initially performed with bovine TSH or human TSH from autopsies, sources that are no longer acceptable because of the possibility of anaphylactic reactions and the transmission of infectious diseases (e.g., Jakob-Creutzfeld). After the cloning of the α- and β-subunits of human TSH, the production of recombinant TSH is now possible. Administration of recombinant human TSH is being evaluated in controlled protocols for the follow-up of patients with differentiated thyroid cancer and is likely to become a standard procedure.

TRANSGENIC MODELS

Important new insights into the pathophysiologic mechanisms controlling goiter and thyroid tumor formation have been gained using transgenic mice as models. The characterization of the Tg promoter has allowed tissue-specific expression of several transgenes in the thyroid. A first model expressed the chloramphenicol acetyltransferase (CAT) in the thyroid; CAT activity was detected only in thyroid tissue indicating that the *cis* regulatory elements present in the first 2000 bp of the promoter are sufficient for thyroid-specific expression.

Overexpression in the thyroid of the large T antigen of *SV40*, one of the most potent known viral oncogenes, resulted in rapidly growing undifferentiated goiters with progressive dedifferentiation with increasing age. The loss of differentiation was accompanied by marked hypothyroidism. Most of these animals died early, primarily from tracheal compression. The *E7* oncogene on the human papillomavirus type 16 inactivates the Rb tumor suppressor protein. Transgenic mice expressing *E7* develop hyperplastic goiters with large follicles and well-differentiated follicular cells.

By overexpression of the *herpes virus thymidine kinase 1* gene and treatment with the antiviral drug ganciclovir, thyroid follicular cells have been selectively ablated. Expression of the adenosine A2a receptor, a constitutive activator of the adenylyl cyclase pathway, resulted in severe hyperthyroidism, tachyarrhythmias, and premature deaths as a result of congestive heart failure. These transgenic animals develop huge goiters, which are initially diffuse but develop nodules later in development, and provide an interesting model for hyperthyroidism and formation of nodular goiters. Other models have studied the oncogenic potential of targeted overexpression of mutated Ki-*ras*, Ha-*ras*, Gsα, the cholera toxin A1 subunit, and a mutated α1β-adrenergic receptor. In the latter case, the expression of the transgene resulted in the activation of both the cAMP and the phospholipase C pathways. This dual stimulation led to enhanced growth, hyperfunction, the development of invading malignant thyroid tumors, and, in older animals, differentiated metastases.

The targeted expression of the *ret*-papillary thyroid cancer 1 oncogene in a transgenic model led to carcinomas that resemble human papillary cancers. Targeted expression of the *ret* gene altered by an MEN 2A mutation in C cells under the control of the calcitonin gene-related peptide and calcitonin promoter led to overt bilateral C-cell hyperplasia and multifocal and bilateral MTC. These results provide evidence that the mutated *ret* gene is indeed oncogenic in parafollicular C cells.

51 Disorders of the Parathyroid Gland

ANDREW ARNOLD AND ANDREW F. STEWART

INTRODUCTION

PARATHYROID HORMONE STRUCTURE, BIOSYNTHESIS, AND SECRETION   The parathyroid hormone (PTH) gene is located on the short arm of chromosome 11. Its 3 exons encode mature PTH (84 amino acids), as well as its signal (25 amino acids) and "pro" (6 amino acids) peptides. The study of the structure and regulation of the PTH gene and the intricacies of PTH biosynthesis, posttranslational processing, and intracellular targeting have led to the accrual of a body of information that is as complete as that for any other peptide hormone. In the sections that follow, these areas are briefly reviewed as an introduction to the molecular disorders of the parathyroid gland. The reader is referred to several up-to-date extensive reviews at the end of this chapter for a more detailed treatment of the subject.

The Extracellular Calcium-Sensing Receptor   Increases in the serum ionized calcium inhibit the secretion of PTH. Conversely, reductions in serum ionized calcium stimulate the cascade of events that lead to the secretion of PTH. This inverse sigmoidal relationship between serum calcium and PTH secretion is precisely controlled, is the key physiologic feature of the parathyroid gland, and accounts for the tight minute-to-minute regulation of PTH secretion and the strict maintenance of serum calcium. Recently, the cloning of a parathyroid calcium receptor has been reported (Fig. 51-1). The calcium receptor is expressed in a restricted number of tissues (including the parathyroid gland, the thyroid C cell, the renal tubule, and the central nervous system [CNS]), is present on the surface of parathyroid cells, and is coupled by G proteins to the cytosolic calcium–inositol phosphate–phospholipase C intracellular signaling pathways. The receptor also has the structural features of a seven transmembrane spanning G-protein coupled receptor with a large extracellular domain and has been demonstrated using cRNA injection into *Xenopus* oocytes to serve as a receptor for calcium in that it can recognize extracellular calcium in physiologic concentrations and can couple extracellular calcium signals to appropriate intracellular signals. The gene encoding the calcium receptor has been localized to chromosome 3q.

Transcriptional and Posttranscriptional Control   PTH gene transcription is subject to both positive and negative regulation primarily through the combined regulatory effects of serum calcium concentration and of $1,25(OH)_2D$, the active form of vitamin D. Reductions in serum calcium and reductions in circu-

From: *Principles of Molecular Medicine* (J. L. Jameson, ed.), ©1998 Humana Press Inc., Totowa, NJ.

lating $1,25(OH)_2D$ lead to activation of PTH gene transcription. Conversely, increases in serum calcium and in circulating $1,25(OH)_2D$ inhibit PTH gene transcription. These effects occur during a period of hours to days and are viewed as being important in the long-term or tonic regulation of PTH secretion.

PTH Biosynthesis   PTH synthesis requires translation of the PTH mRNA on ribosomes, entry of the nascent preproPTH into the cistern of the endoplasmic reticulum (ER), cleavage of the signal peptide cotranslationally by signal peptidase on the lumenal side of the ER, passage of the immature peptide through the lamellae of the Golgi apparatus, targeting of the peptide into the secretory granules of the regulated secretory pathway, and cleavage of the "pro" segment of the peptide, presumably within the Golgi compartment. In addition, the quantity of stored hormone within secretory granules appears to be subject to regulation through degradation of mature PTH within secretory granules or within phagolysosomes, a process referred to as "crinophagy."

Control of Secretion   During the short term, PTH secretion is regulated by the serum ionized calcium concentration. Changes in serum calcium concentration lead to immediate (minutes) and opposite changes in PTH secretion. The key features of this acute regulation appear to be those observed in other neuroendocrine peptide secretory systems (i.e., storage of preformed, completely processed hormone in dense core secretory granules, with secretory granule fusion to the cell membrane leading to immediate secretion) with one important difference: in most neuroendocrine cell types, fusion of secretory granules with the cell membrane is triggered by an increase in cytosolic calcium. The reverse is true in the parathyroid. The cellular mechanisms governing this inverse secretion–stimulus coupling in the parathyroid gland are incompletely understood.

FAMILIAL HYPOCALCIURIC HYPERCALCEMIA AND NEONATAL SEVERE HYPERPARATHYROIDISM

Familial hypocalciuric hypercalcemia (FHH, also referred to as familial benign hypercalcemia or FBH) is a disorder that is typically discovered incidentally on routine serum calcium screening. The hypercalcemia is usually mild (i.e., in the 10.5–12.0 mg/dL range), is lifelong, is generally not associated with the symptoms of hypercalcemia, and is associated with a reduction in the urinary excretion of calcium. Historically, patients with FHH were confused with patients with primary hyperparathyroidism, with the unfortunate consequence that affected patients underwent unsuccessful partial parathyroidectomy or complete parathyroidectomy with the development of surgical hypoparathyroidism. Since the initial description of the
Figure 51-1   The structure of the calcium receptor. This figure shows the structure of the bovine calcium receptor or sensor. The important structural features are the seven putative transmembrane-spanning domains, the extracellular amino-terminal domain, and the cytoplasmic carboxy-terminus. As can be seen from the key within the figure, both activating (causing hypoparathyroidism) and inactivating (causing familial hypocalciuric hypercalcemia) mutations can occur. (Reproduced with permission from Brown et al. N Engl J Med 1995;333:234–240.)

syndrome in the 1970s, it has become clear that these patients do have a mild form of primary hyperparathyroidism with slightly elevated or inappropriately normal serum PTH concentrations, that they have inappropriately efficient renal reabsorption of calcium, that the parathyroid glands appear to have a defective ability to sense the hypercalcemia, and that multiple family members are typically involved, usually in an autosomal dominant fashion.

Recently, several groups have demonstrated that inherited inactivating mutations in the parathyroid cell surface calcium receptor appear to be responsible for the features of the syn-

drome in most affected kindreds (Fig. 51-1). The responsible mutations generally involve either the extracellular domain (presumably adversely influencing calcium binding to the receptor) or one of the transmembrane loops (presumably interfering with conformational changes that in turn lead to the activation of signal transduction pathways). In general, affected patients have been heterozygous for the mutant calcium receptor allele. Interestingly, however, infants have been described who appear to have a particularly malignant form of the syndrome, characterized by severe hypercalcemia (sometimes in the 20-mg/dL range)

and prominent parathyroid hypercellularity. This form of the syndrome has been referred to as neonatal severe hyperparathyroidism (NSHPT). The syndrome in some of these infants has now been reported to result from a double dose of the mutant, inactivated calcium receptor gene, events that resulted in turn from consanguineous parentage.

In support of the concept that inactive mutant forms of the calcium receptor are responsible for the syndrome, it has been reported that expression in *Xenopus* oocytes of calcium receptors containing the same mutations as those encountered in humans with the disease results in impaired ability to sense extracellular calcium Also, an FHH-like phenotype is found in mice whose extracellular calcium receptor gene has been heterozygously knocked out, and a more severe phenotype similar to NSHPT is seen in mice with no functional copy of the gene. At the time of this writing, 15 mutations have been described in the calcium receptor in families with FHH (Fig. 51-1). In addition, other FHH families who map to the 3q region have been defined that do not display mutations in the coding region of the calcium receptor gene. These findings suggest that mutations in the intronic or regulatory regions of the calcium receptor gene may explain additional kindreds. Further, it is important to note that mutations in other genes will undoubtedly be demonstrated in the future; for some families with what appears to be standard FHH, the disease locus maps to chromosome 19p or other locations distinct from chromosomes 19 or 3. It is presumed that the genes at these other loci encode other proteins that play a role in the calcium sensing machinery.

HEREDITARY FORMS OF HYPOPARATHYROIDISM

The majority of patients with hypoparathyroidism have surgical or acquired autoimmune hypoparathyroidism. In contrast to these acquired forms of hypoparathyroidism, familial forms of congenital and acquired hypoparathyroidism have been described. These can be subdivided into familial syndromes in which hypoparathyroidism is accompanied by abnormalities in multiple other organ systems, and familial forms of hypoparathyroidism that are unaccompanied by other abnormalities (Table 51-1). These various syndromes are discussed below.

FAMILIAL VARIETIES OF HYPOPARATHYROIDISM ASSOCIATED WITH MULTIPLE ORGAN SYSTEM ABNORMALITIES These syndromes are of interest in that they represent genetic syndromes associated with hypoparathyroidism, but given their multisystem abnormalities, it is intuitive that the parathyroid gland abnormalities are not intrinsic to defects within the parathyroid gland but are in some fashion secondary to other developmental or regulatory abnormalities.

Hypoparathyroidism Associated With the Polyglandular Failure Syndrome This syndrome is composed of at least two subtypes. Hypoparathyroidism is most often associated with the pediatric variant of the syndrome, termed the HAM syndrome, an acronym for the hypoparathyroidism, Addison's disease, mucocutaneous candidiasis syndrome. The syndrome is an autoimmune disease that is associated with autoimmune destruction of the parathyroid glands and the adrenal glands, and is coupled with T-cell abnormalities that lead to mucocutaneous candidiasis. It is inherited in an autosomal recessive fashion, and is linked to chromosome 21q22.3. Circulating antibodies directed against parathyroid surface antigens have been difficult to demonstrate. One recent preliminary report suggests that a cell surface target of circulating autoimmune antisera in some affected patients is the calcium receptor.

Table 51-1
Hereditary Forms of Hypoparathyroidism

Familial hypoparathyroidism associated with multiple organ system abnormalities
  Polyglandular failure type I or HAM syndrome
  DiGeorge syndrome
  Renal dysgenesis/sensorineural deafness syndromes
    Autosomal recessive
    Autosomal dominant
Isolated familial hypoparathyroidism syndromes
  X-linked hypoparathyroidism
  Autosomal recessive syndromes
    PTH gene intron splice site mutation
    Others
  Autosomal dominant syndromes
    Parathyroid hormone signal peptide mutation
    Constitutively activating calcium receptor mutations
    Others

The DiGeorge Syndrome The DiGeorge syndrome (*see* Chapter 120) is a complex of developmental disorders centered on the third and fourth branchial pouches that includes: (1) cardiac and conotruncal defects (such as ventricular septal defects, tetralogy of Fallot); (2) T-cell deficiency as a result of partial or incomplete development of the thymus gland; (3) craniofacial abnormalities; and (4) partial or complete hypoparathyroidism as a result of congenital absence or hypoplasia of the parathyroid glands. It may occur in both sporadic and inherited forms. The pattern of inheritance in the latter is consistent with an autosomal dominant mode of transmission. The vast majority of inherited and sporadic cases display deletions or translocations in the 22q11 region. The broad spectrum of abnormalities in patients with the DiGeorge syndrome together with the large region of DNA typically affected by these deletions and rearrangements suggests that defects in multiple adjacent genes at 22q11 may collectively account for the abnormalities observed. Candidate genes include *DGCR2/LAN*, which appears to encode a membrane-bound adhesion molecule; the *CTP* (human citrate transporter protein) gene; and *DGCR3*, which encodes what appears to be a DNA-binding protein. The last of these is particularly interesting for it appears to span the region of a 22q11 rearrangement breakpoint, and therefore its disruption seems likely to be functionally important.

Hypoparathyroidism Associated With Renal Dysgenesis and Sensorineural Hearing Loss This syndrome has been reported by several groups. Both autosomal dominant and autosomal recessive patterns of inheritance have been described. Linkage studies defining chromosomal locations for the putative responsible gene or genes have not been described.

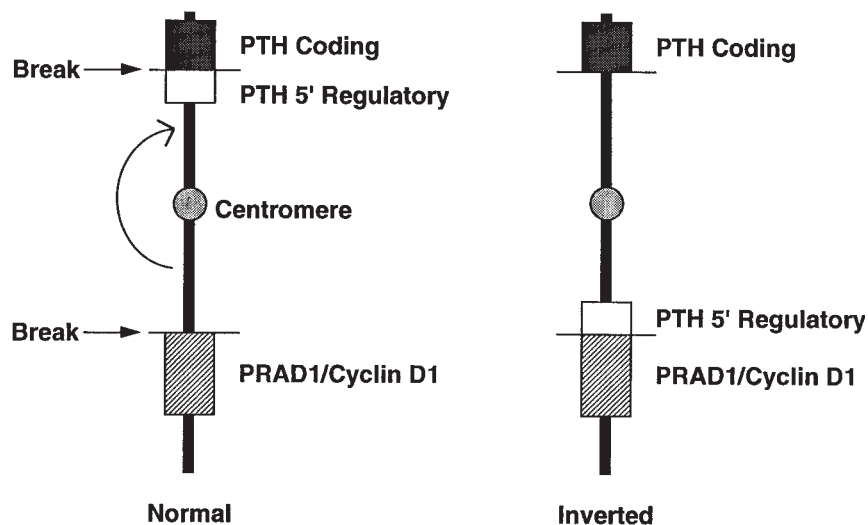
FAMILIAL ISOLATED HYPOPARATHYROIDISM In contrast to the syndromes described above, several forms of familial hypoparathyroidism have been described in which hypoparathyroidism is the sole abnormality. These syndromes will certainly prove to represent a group of several disorders with differing molecular pathogenesis. Some are still poorly defined in molecular terms such as most autosomal recessive forms of the disorder and certain autosomal dominant forms. Others are partially defined in molecular terms, such as the X-linked form of the syndrome, which has recently been mapped to the Xq26–q27 region. Still others, including an autosomal dominant form, are well-understood in genetic and biochemical terms. In this situa-


Figure 51-2   Schematic diagram illustrating the pericentromeric inversion of chromosome 11 deduced to have caused the observed rearrangement involving the *PTH* gene and the *PRAD1* gene in a subset of parathyroid adenomas. The tumor's other copy of chromosome 11, which contains an intact *PTH* gene, is not shown. (Reproduced with permission from Arnold A. Genetic basis of endocrine disease 5: molecular genetics of parathyroid gland neoplasia. J Clin Endocrinol Metab 1993;77:1108-1112.)

tion hypoparathyroidism results from a mutation that causes a Cys to Arg substitution in the middle of the hydrophobic core of preproPTH's signal peptide. The resultant mutant form of preproPTH is unable to be processed with normal efficiency. One curious aspect of this disorder is the question as to why a disabling mutation in only one allele of the PTH gene should lead to hypoparathyroidism. It is possible that accumulation of bound but poorly processed mutant preproPTH molecules in the endoplasmic reticulum might deny access of the normal allele's product to the processing apparatus, or otherwise interfere with the function of the parathyroid cell. Interestingly, this preproPTH mutation was the first signal peptide mutation reported to cause human disease, and signal peptide mutations have subsequently been found in preprovasopressin (causing diabetes insipidus) and in Factor X (causing a coagulopathy).

A family has been described with autosomal recessive hypoparathyroidism that appears to be caused by a splice junction mutation in intron 2 of the PTH gene. The resulting mRNA would have the sequences derived from exon 2, which contains the signal peptide, spliced out, and thereby lead to the production of a PTH species that could not enter the secretory pathway.

Recently, another mechanism underlying familial isolated hypoparathyroidism has been described. With the demonstration that familial hypocalciuric hypercalcemia may result from inactivating mutations in the extracellular calcium-sensing receptor (discussed above), it was logical to speculate that some cases of hereditary hypoparathyroidism might result from activating mutations in the calcium receptor. This type of syndrome has now been reported (Fig. 51-1). As would be expected, this kindred displays an autosomal dominant pattern of inheritance, and expression of the mutant calcium receptor in oocytes leads to constitutive activation of the inositol phosphate signal transduction pathway. The host parathyroid cell, therefore, behaves as though it were being exposed to higher than normal concentration of extracellular calcium and appropriately fails to secrete PTH. Similar mutations have also been identified in cases of sporadic hypoparathyroidism.

MOLECULAR GENETICS OF PARATHYROID GLAND NEOPLASIA

Primary hyperparathyroidism is caused by excessive secretion of PTH, resulting in hypercalcemia. Patients with primary hyperparathyroidism have both an excessive parathyroid cell mass and a resetting of the setpoint by which PTH secretion is tightly coupled to the parathyroid cell's ambient calcium level. In the large majority (>80%) of patients with primary hyperparathyroidism, a single benign parathyroid tumor (adenoma) is responsible, whereas multiple hypercellular glands are present in about 15% (primary hyperplasia). Parathyroid carcinoma is extremely rare, as is the ectopic secretion of PTH from nonparathyroid tumors. A comprehensive molecular description of parathyroid tumorigenesis will eventually need to fully explain the development of these types of tumors, as well as a variety of other special features such as the increased incidence of parathyroid tumors after exposure to neck irradiation and the disease's epidemiologic weighting toward postmenopausal women. Detailed molecular understanding will likely yield information of diagnostic, prognostic, preventative, or therapeutic importance, and recent progress gives cause for optimism in this regard.

CLONALITY IN PARATHYROID TUMORIGENESIS   The monoclonality or polyclonality of human tumors is an informative reflection of their underlying pathogenetic mechanism. Early data measuring isoforms of the X-chromosome-encoded protein G6PD in parathyroid adenomas in heterozygous women had indicated that apparently single parathyroid adenomas were polyclonal growths, likely to result solely from a generalized growth stimulus. These results, however, proved to be misleading, since modern molecular methods have now solidly established the monoclonality of typical parathyroid adenomas, both by X-chromosome inactivation analysis and by the direct demonstration of monoclonal genetic alterations in parathyroid adenomas *(see below)*. Monoclonality highlights the concept that parathyroid adenomas are true neoplasms, consistent with clinical experience that surgical removal of the enlarged gland is generally curative. Neoplasia is a genetic disease, with most relevant DNA damage occurring somati-

cally. Monoclonality implies that the necessary accumulation of multiple mutations in a tumor progenitor cell occurs only rarely in a large population of cells within a tissue, conferring a selective growth advantage critical in tumor outgrowth or clonal evolution. The search is now on for the specific oncogenes and tumor suppressor genes that are clonally activated or inactivated, respectively, in parathyroid tumors. Two notable successes and several important leads, described below, have already emerged in this search.

The clonal status of parathyroid tumors other than adenomas has also been investigated. As expected, parathyroid carcinomas, like all cancers, are monoclonal. Much more surprisingly, however, a substantial percentage of parathyroid tumors in the setting of primary hyperplasia and severe secondary hyperparathyroidism of uremia has recently been shown to be monoclonal, indicating that clonal somatic mutations have given selected cells a growth advantage over their already hyperplastic neighbors. Monoclonality in the majority of MEN-1–associated parathyroid tumors examined suggests a similar process in this syndrome. It is quite conceivable that the "conversion" from polyclonality to monoclonality may be a key factor in the increasing autonomy of PTH secretion that develops in many hemodialysis patients, making them refractory to standard medical therapy. Future identification of the specific molecular culprits in such clonal outgrowths may lead to rational new therapy or preventative measures for this important clinical problem.

GENETIC DERANGEMENTS IN BENIGN PARATHYROID TUMORS

THE CYCLIN *D1/PRAD1* ONCOGENE   Cyclin *D1/PRAD1*, to date the only oncogene implicated in sporadic parathyroid neoplasia, was discovered by virtue of its proximity to a clonal chromosomal breakpoint in a subset of parathyroid adenomas. Fig. 51-2 is a diagram of this chromosomal inversion, which causes overexpression of the cyclin *D1/PRAD1* gene by placing it in proximity to the strong tissue-specific enhancer of the *PTH* gene.

Cyclin *D1/PRAD1* is recognized to have a crucial role in regulating progression through the G1 phase of the cell division cycle. To do so, the cyclin D1 protein is believed to act as an activating regulatory subunit for its partner cyclin-dependent kinase(s), cdk4 or cdk6. One action of active cdk4 or cdk6 may be phosphorylation

of the retinoblastoma gene product pRB, moving the cell toward S phase, but this mechanism has not yet been established in parathyroid tissue. A still-uncertain fraction of parathyroid adenomas contain an activated form of the cyclin *D1/PRAD1* oncogene; one recent study showed overexpression of the cyclin D1 protein in about 20% of adenomas. Cyclin D1 activation has also been incriminated in a variety of other human tumors, including B-cell lymphoma, breast, and esophageal cancers.

PUTATIVE TUMOR SUPPRESSOR GENES   Inactivation of both alleles of a tumor suppressor gene is typically necessary to sufficiently eliminate its antioncogenic product, and somatic deletion of a sometimes large stretch of DNA that includes the relevant gene is a common inactivating mechanism. Thus, identification of genomic regions that are clonally and nonrandomly lost in parathyroid adenomas can point to the locations of putative parathyroid tumor suppressor genes. A growing proportion, now more than 70%, of parathyroid adenomas can be shown to bear at least one such clonal chromosomal defect.

The most common molecular defect described to date in parathyroid tumors is allelic loss on chromosome arm 1p, found in about 40% of adenomas; the putative tumor suppressor gene in this region has not yet been isolated. About 25% of adenomas contain allelic losses of chromosome 11 DNA, the region to which the *MEN-1* gene has been mapped. The gene responsible for *MEN-1* has been cloned using positional cloning techniques. The gene product, menin, is a 610-amino acid protein that lacks both a signal sequence and nuclear localization signal. Mutations in the affected individuals predict loss of function of the protein, suggesting that the *MEN-1* gene is a tumor suppressor gene. In a recent study of parathyroid tumors not associated with MEN-1, somatic mutations in *MEN-1* were present in 4 of 24 adenomas. All of the tumors with mutations in *MEN-1* exhibited loss of heterozygosity on 11q13 at the *MEN-1* locus. Thus, the tumors were hemizygous for the mutant allele. Still other regions of nonrandom clonal allelic loss in parathyroid adenomas, highlighting the locations of novel tumor suppressor genes, have been found on chromosome arms 1q, 6q, 9p, and 15q. These data emphasize the molecular heterogeneity underlying parathyroid adenomatosis.

OTHER GENETIC ASPECTS   Some genes responsible for rare inherited predispositions to certain tumors have also proved

important in more common, sporadic forms of the same tumors. The *MEN-1* gene, as mentioned above, is an example. The recent discovery of *Ret* proto-oncogene germline mutation in MEN-2A made this gene a candidate for involvement in nonfamilial hyperparathyroidism. However, studies have so far failed to document somatic *Ret* mutations in sporadic parathyroid adenomas. Similarly, inactivating mutations of the extracellular calcium-sensing receptor have been sought but not found in sporadic adenomas. It remains possible that somatic mutation in other genes involved in the calcium-sensing pathway may contribute to adenoma development, with the primary clonal setpoint defect driving the proliferative response. Finally, the gene responsible for an autosomal dominant predisposition to recurrent parathyroid adenomas and benign jaw tumors has been mapped to the long arm of chromosome 1; its ultimate identification may also provide insight into more common forms of hyperparathyroidism.

MOLECULAR PATHOGENESIS OF PARATHYROID CARCINOMA

The discovery that the cell-cycle regulator cyclin *D1*/PRAD1 can be involved in parathyroid tumorigenesis has raised the possibility that other cell-cycle regulatory genes may also contribute to parathyroid neoplasia. One example, the *RB* tumor suppressor gene implicated in retinoblastoma and a narrow spectrum of often aggressive malignancies, may be a key factor in the pathogenesis of many parathyroid carcinomas, although a neighboring gene on 13q might be the target of the frequent DNA deletions in this region. Genetic lesions that are confirmed to be enriched in malignant as opposed to benign parathyroid tumors could be clinically useful in molecular diagnosis, given the difficulties in making such distinctions histopathologically.

ECTOPIC SECRETION OF PTH

The ectopic secretion of PTH by nonparathyroid tumors is a rare cause of primary hyperparathyroidism. The molecular basis of ectopic PTH production in one such case, an ovarian carcinoma, was found to be a DNA rearrangement in the regulatory region of the tumor's PTH gene (Fig. 51-3). Similar detailed molecular pathology has yet to be described in other examples of human ectopic hormone excess, and might involve analogous DNA rearrangements or, alternatively, a change in the tumor tissue's characteristic DNA-binding proteins.

52 Congenital Adrenal Hyperplasia

ROBERT C. WILSON AND MARIA I. NEW

INTRODUCTION

The disorder congenital adrenal hyperplasia (CAH) is an autosomal recessive disease caused by mutations in genes that encode enzymes involved in various steps of adrenal steroid synthesis (Table 52-1). These defects result in the absence or decreased synthesis of cortisol from cholesterol. The anterior pituitary secretes excess adrenocorticotrophic hormone (ACTH) because of the loss of feedback regulation by cortisol, which results in overstimulation of the adrenals and causes hyperplasia.

Symptoms caused by CAH can vary from mild to severe depending on the degree of the enzymatic defect. In the classic forms of CAH, defects in the cytochrome P450 21-hydroxylase (21-OH) or 11β-hydroxylase (11β-OH) cause varying degrees of genital ambiguity in females owing to shunting of excess cortisol precursors to the androgen synthesis pathway (Fig. 52-1). Prenatal adrenal androgen excess causes virilization of female genitalia and postnatally results in advanced bone age and puberty in both females and males. Abnormalities in androgen synthesis as a result of defects in 3β-hydroxysteroid dehydrogenase (3β-HSD)–Δ^5, 4-isomerase, in 17α-hydroxylase (17α-OH)/17,20-lyase, and in the steroidogenic acute regulatory protein (StAR) result in inadequate prenatal virilization of males and depressed puberty in both sexes. Less severe, nonclassic forms of CAH present postnatally as signs of androgen excess.

ADRENAL STEROIDOGENESIS

Aldosterone, cortisol (compound F), and testosterone are derived from cholesterol and use many of the same enzymes for their synthesis in the adrenal cortex (Fig. 52-1). Therefore, defects in any of the enzymes that are common to the synthesis pathway of these hormones can result in the loss of a combination of some or all of these products.

Cortisol and aldosterone are synthesized in distinct zones of the adrenal cortex called the zona fasciculata (ZF) and zona glomerulosa (ZG), respectively. In addition, regulation of cortisol and aldosterone synthesis is controlled by different mechanisms. Cortisol synthesis is regulated by a negative feedback loop in which high serum levels of cortisol inhibit the release of ACTH from the pituitary, whereas low serum levels of cortisol stimulate the release of ACTH. This defines the hypothalamo–pituitary–adrenal axis (Fig. 52-2).

Aldosterone is required for the regulation of sodium reabsorption across the tight epithelium of the renal distal tubule, which indirectly controls fluid volume. Aldosterone synthesis is regulated by the renin-angiotensin system and serum potassium. Angiotensin II (a potent vasoconstrictor) directly stimulates the secretion of aldosterone by the ZG when there is a reduction in renal perfusion because of an increase in plasma renin. Serum potassium also regulates the synthesis of aldosterone, though independently of volume status.

21-HYDROXYLASE DEFICIENCY

More than 90% of classic CAH is caused by 21-hydroxylase deficiency (21-OHD). The syndrome is divided into three forms: classic salt-wasting, classic simple virilizing, and nonclassic.

CLASSIC SIMPLE VIRILIZING   Fetal adrenocortical function begins in the third month of gestation. At this time reduction or loss of 21-hydroxylase activity will result in the build-up of 17α-hydroxyprogesterone (17-OHP). Because 17-OHP is a precursor of testosterone, elevated levels of 17-OHP are shunted to the androgen pathway, thus producing excess androgens. This excess adrenal androgen production coincides with the time of sexual development of the fetus and will result in varying degrees of genital ambiguity in newborn females. In extreme cases, the urethra extends the full length of the phallus and cannot be distinguished from that of a normal male. In most cases, however, the excess androgens result in an enlarged clitoris with fusion of the labioscrotal folds; it can also result in a urogenital sinus. For these females, the internal genitalia are normal with normal development of ovaries and Müllerian structures.

Males affected with 21-OHD are born with normal genitalia. After birth, both females and males develop signs of androgen excess, such as precocious development of pubic and axillary hair, acne, phallic enlargement, rapid growth, and musculoskeletal development. Though initial growth in these patients is rapid, potential height is reduced and short adult stature results because of premature epiphyseal fusion. Diagnosis may be delayed in males, because the genital ambiguity that leads to diagnosis at birth in females is absent in males. Even if diagnosis is not delayed and adrenal androgen excess is controlled, patients do not generally achieve their target height.

CLASSIC SALT-WASTING   Salt-wasting 21-OHD makes up approximately 75% of classic 21-OHD. Depending on the severity of the loss of 21-hydroxylase function, adrenal aldosterone secretion may not be sufficient for regulating sodium reabsorption by distal renal tubules. Patients with insufficient aldosterone can suf-

Table 52-1
Forms of Adrenal Hyperplasia

Deficiency	Syndrome	Ambiguous genitalia	Postnatal virilization	Salt metabolism	Steroids increased	Steroids decreased	Chromosomal location
Steroidogenic acute regulatory protein (StAR)	Lipoid hyperplasia	Males		No salt wasting	None	All	8p11.2
3β-Hydroxysteriod dehydrogenase	Classic	Males	Yes	Salt wasting	DHEA, 17-OH-pregnenolone	Aldo, T, cortisol	1p13.1
	Nonclassic	No	Yes	Normal	DHEA, 17-OH-pregnenolone	—	?
17α-Hydroxylase	—	Males	No	Hypertension	DOC, corticosterone	Cortisol, T	10q24-25
21-Hydroxylase	Salt wasting	Females	Yes	Salt wasting	17-OHP, Δ^4-A	Aldo, cortisol	6p21.3
	Simple virilizing	Females	Yes	Normal	17-OHP, Δ^4-A	Cortisol	6p21.3
	Nonclassic	No	Yes	Normal	17-OHP, Δ^4-A	—	6p21.3
11β-Hydroxylase	Classic	Females	Yes	Hypertension	DOC, 11-deoxycortisol	Cortisol, ± aldo	8q21-22
	Nonclassic	No	Yes	Normal	11-deoxycortisol, ± DOC	—	8q21-22
Corticosterone methyl oxidase type II	Salt wasting	No	No	Salt wasting	18-OH-corticosterone	Aldo	8q21-22

Aldo, aldosterone; T, testosterone; Δ^4-A, Δ^4-androstenedione; DHEA, dephydropeiandrosterone; DOC, 11-deoxycorticosterone; 17-OHP, 17α-hydroxyprogesterone.
Figure 52-1 Pathways of steroid biosynthesis. Enzymatic activities catalyzing each bioconversion are enclosed in boxes. For those activities mediated by specific P450 cytochromes, systematic names of the enzymes (CYP followed by number) are listed in parentheses. Other bioconversions (marked with an asterisk) are mediated by different enzymes in various tissues. The planar structures of cholesterol, aldosterone, cortisol, dihydrotestosterone, and estradiol are placed near the corresponding labels.

A
NORMAL

B

fer from salt-wasting 21-OHD. These patients exhibit the same symptoms as those with simple virilizing 21-OHD but with the potential of adrenal crisis (azotemia, vascular collapse, shock, and death) because of renal salt-wasting. Adrenal crisis can occur as early as in the first 1–4 weeks of life. Although salt-wasting 21-OHD females may be diagnosed at birth because of ambiguous genitalia, affected males are at high risk of salt-wasting adrenal crisis since their normal genitalia do not make the condition obvious.

NONCLASSIC   Nonclassic 21-OHD (NC21-OHD) may present at any time, in childhood, adolescence, or adulthood. Symptoms of NC21-OHD may be acne, premature development of pubic hair, advanced bone age, accelerated linear growth velocity, and as in classic 21-OHD, reduced adult stature as a result of premature epiphyseal fusion.

Females affected with NC21-OHD are born with normal genitalia, though postnatal symptoms may include hirsutism, temporal baldness, severe cystic acne, delayed menarche, menstrual irregularities, and infertility. A subset of female patients with NC21-OHD develop polycystic ovaries.

Boys manifesting NC21-OHD may have early beard growth, acne, early growth spurt, premature pubic hair, and an enlarged phallus. Proportionately small testes as compared with the size of the phallus is a reliable indication of adrenal androgen excess as opposed to testicular androgen excess. Adrenal androgen excess in men is not easily detectable and may only be manifested by short stature or oligozoospermia and diminished fertility.

No clinical signs are present in a limited number of males and females who are affected with NC21-OHD, as discovered during family studies. However, they are biochemically similar to affected patients.

EPIDEMIOLOGY   The estimated worldwide frequency of classic 21-OHD is 1/13,000 live births. However, in two isolates the frequency is much higher (Yupik Eskimos in Alaska, 1/282, and the inhabitants of La Réunion island in France, 1/2141). Neonatal screening for 21-OHD has been initiated in 13 states in America.

It has been suggested that NC21-OHD is the most common autosomal recessive disorder. In some ethnic populations, the frequency of NC21-OHD is so high as to be the most frequent autosomal recessive defect. The disease frequency is 1/27 for

Ashkenazi Jews, 1/53 for Hispanics, 1/63 for Yugoslavs, 1/100 in a heterogeneous white New York City population, and 1/333 for Italians.

MOLECULAR GENETICS   In 1977, molecular genetic studies of 21-OHD showed linkage with certain human leukocyte antigens (HLA), in the human major histocompatibility complex, on the short arm of chromosome 6. For many years HLA linkage was used for establishing the affected status in family studies. However, in some cases in which the parents shared the same HLA antigens or if intra-HLA recombination occurred, HLA typing was not diagnostic.

It was not until 1984 that the gene for 21-hydroxylase was cloned. The gene for 21-hydroxylase is termed *CYP21*, after the nomenclature for cytochrome P450. Southern blot analysis determined that the *CYP21* gene was located within the serum complement component C4. This region of chromosome was duplicated, resulting in two isoforms of C4 (C4A and C4B) and what initially looked like two isoforms of *CYP21*. Sequence analysis of the two *CYP21* genes revealed that one of the isoforms contained a sequence that on translation would result in a truncated nonfunctional protein, and it was therefore termed *CYP21P* for pseudogene. The nonfunctionality of *CYP21P* was confirmed in families without any hormonal abnormalities in which the *CYP21P* gene was completely missing.

CYP21 and *CYP21P* are 96% to 98% homologous (Fig. 52-3) and are arranged in tandem within C4A and C4B, separated by approximately 30 kb. The duplication of the locus containing *CYP21* allows for misalignment of chromatids during meiosis, resulting in unequal crossing over. This results in a high frequency of deletions of the *CYP21* and *C4B* genes. Duplications also occur, but without any clinical consequence. Deletions of *CYP21* are found in approximately 20% of the patients with classic 21-OHD.

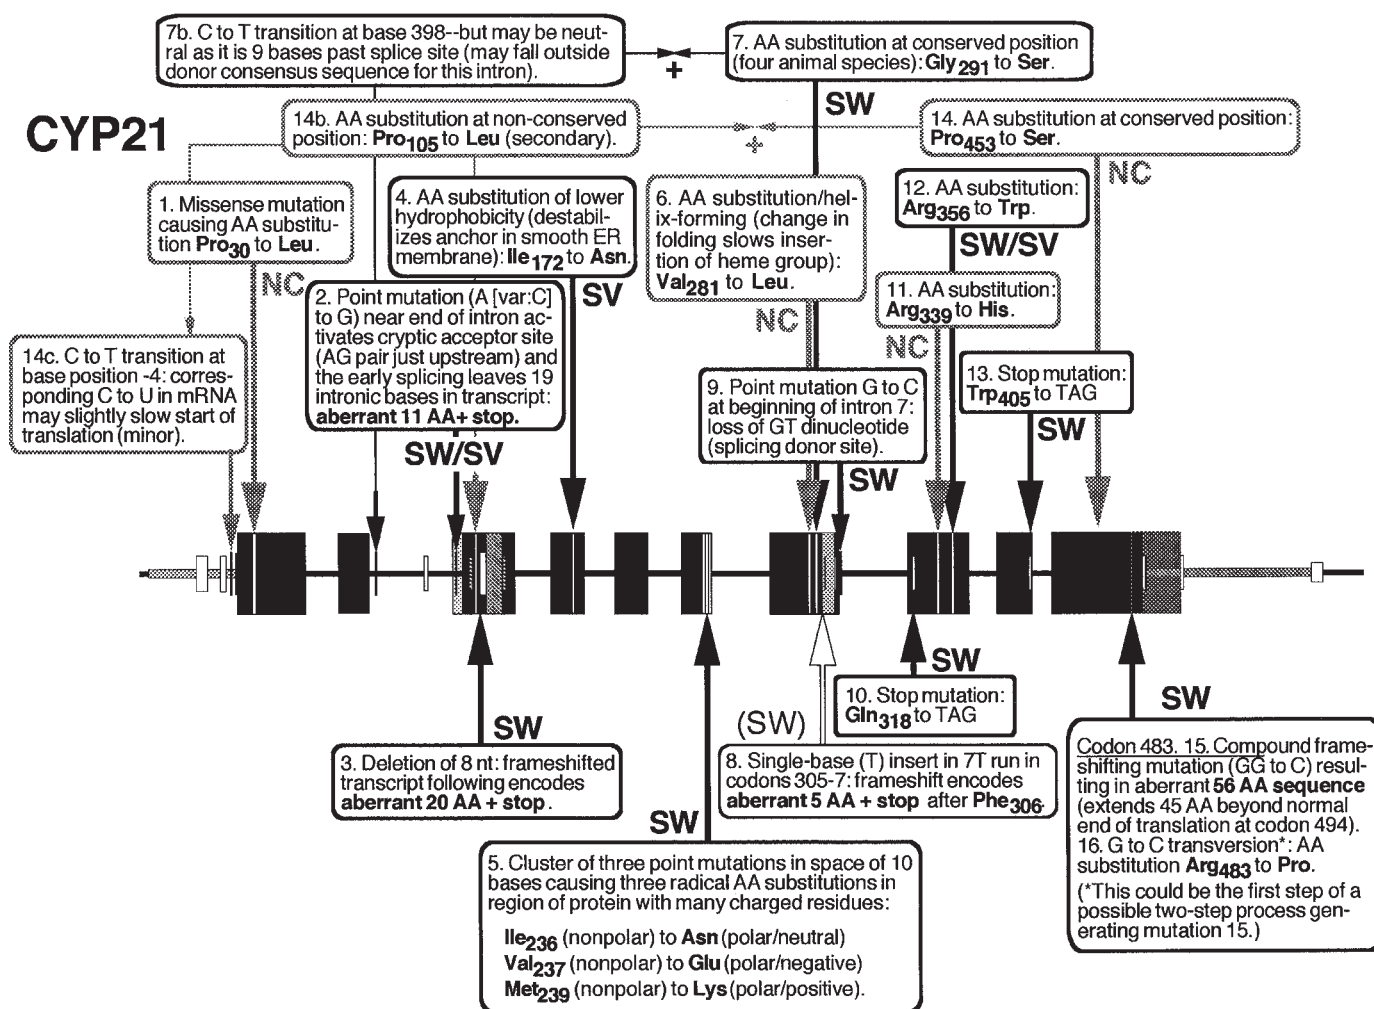
CYP21 and *CYP21P* consist of 10 exons spanning approximately 5 kb. Most of the 21-OHD patients carry mutations found in *CYP21P* (Fig. 52-4). The generally accepted mechanism by which these deleterious mutations are transferred to the active *CYP21* gene from the homologous position in *CYP21P* is through gene conversion. There are nine of these mutations that can be transferred to the active *CYP21* gene (Table 52-2). Four of these mutations result in truncated proteins as a result of premature termination of translation and are associated with the salt-wasting phenotype: (1) a point mutation in the second intron near the 3' splice site results in aberrant splicing 19 nucleotides upstream of the normal splice site; (2) in the third exon, an 8-base deletion can occur, resulting in nonsense amino acids and the occurrence of a stop codon 20 amino acids toward the carboxy-terminus; (3) in exon 7, one T nucleotide can be inserted into a run of seven T nucleotides, resulting in a frameshift that produces five aberrant amino acids and premature termination; and (4) a point mutation in exon 8 in codon 318 changes a glutamine to a stop codon. The five other mutations that can be transferred from *CYP21P* to *CYP21* result in amino acid substitutions: (1) A point mutation in exon 1 causes a substitution of proline by a leucine at codon 30 (P30L). This mutation has 60% of the activity of normal 21-hydroxylase when expressed in cell culture. The P30L mutation has been found to be associated with the nonclassic phenotype; (2) A point mutation in exon 4 causes a substitution of isoleucine by an asparagine at codon 172 (I172N) and is most often associated with the simple virilizing phenotype. This mutation results in less than 2% of normal 21-hydroxylase activity in in vitro expression studies; (3) A
Figure 52-3 The two homologs: *CYP21* (the active gene) and *CYP21P* (the pseudogene). Noncorrespondent bases number less than 90 over a distance of 5.1 kb of DNA. Numbered are the pseudogene base changes that are frequently identified on mutant *CYP21* genes responsible for 21-hydroxylase deficiency through an apparent process termed gene conversion. (1) Missense mutation Pro-30 to Leu. (2) Point mutation in intron 2 causes new acceptor 3' site to be recognized by intron splicing mechanism. (3) Eight-basepair deletion shifts the reading frame. (4) Missense mutation Ile-172 to Asn. (5) Cluster of 3 nonconservative amino acid substitutions. (6) Conservative amino acid substitution Val-281 to Leu. (7) Single-base T insert shifts reading frame. (8) Nonsense mutation Gln to TAG. (9) Radical amino acid substitution (Arg-356 to Trp). KEY: BTE, basic transcriptional element; large boxes/line spaces, exons/introns (to scale); light shading, out-of-frame coding; half-height open boxes, stop codons; vertical lines not numbered, neutral amino acid polymorphisms; half-height vertical lines, silent mutations.


Figure 52-4 Mutations in the 21-hydroxylase gene *(CYP21)*. CAH phenotypes: SW, salt-wasting; SV, simple virilizing; NC, nonclassical.

cluster mutation in exon 6 as a result of the exchange of four nucleotides results in three amino acid substitutions and one polymorphism (the change codes for the original amino acid); (4) A point mutation in codon 281 substitutes a valine with a leucine (V281L). This mutation is associated with the nonclassic phenotype. Expression studies of the V281L mutation show 20–50% of

normal 21-hydroxylase activity; and (5) A point mutation in exon 8 results in the substitution of arginine with tryptophan (R356W). This mutation is associated with the salt-wasting phenotype. Assignment of a phenotype to each of the individual mutations was done with patients that were either homozygous for the mutation or hemizygous for the mutation (the other allele had under-

gone a deletion). In addition to the nine mutations found in the pseudogene, several other mutations have been described in patients affected with 21-OHD.

HORMONAL DIAGNOSIS Baseline serum concentrations of 17-OHP are diagnostic of classic 21-OHD. The best method for hormonal diagnosis of 21-OHD is comparing baseline serum 17-OHP concentration and serum 17-OHP concentrations after adrenal stimulation by administration of synthetic ACTH (Cortrosyn). In NC21-OHD, diagnosis is made during the diurnal peak of cortisol production because serum 17-OHP concentrations are elevated, though random basal serum concentrations may not differ from that of normal. Nomogram plots of baseline vs stimulated 17-OHP concentrations result in three distinguishable groups (Fig. 52-5): Patients with classic 21-OHD have the highest coordinates, followed by patients with NC21-OHD, followed by plots of heterozygotes and genetically unaffected individuals, which overlap and cannot be distinguished.

Newborn diagnostic screening for classic 21-OHD has been instituted in about 12 states. Blood from a heel-prick is spotted onto filter paper and is tested for 17-OHP levels by radioimmunoassay. NC21-OHD can also be screened by measuring morning salivary 17-OHP, which correlates well with serum concentrations. It should be noted that serum 17-OHP may be elevated in premature infants and infants under stress, which can result in false-positive results.

PRENATAL DIAGNOSIS AND TREATMENT Prenatal diagnosis of 21-OHD has been performed for several decades. Originally, second trimester amniotic fluid was tested for elevated 17-OHP levels. However, in most cases when the fetus is a non–salt-waster (simple virilizer, or nonclassic), amniotic fluid 17-OHP levels are not elevated.

When HLA was found to be linked to 21-OHD, prenatal diagnoses using HLA serotyping of cultured fetal cells from amniocytes were performed. This procedure resulted in errors because of recombination or haplotype sharing between parents.

After mutations in the *CYP21* gene were found to be the cause of 21-OHD, prenatal diagnosis by direct molecular analysis was initiated. Fetal DNA is obtained from either cultured amniocytes or cultured cells obtained by chorionic villus sampling (CVS) and is used for specific amplification of the *CYP21* gene using the polymerase chain reaction (PCR). The PCR products are dot-blotted, followed by hybridization with radiolabeled allele-specific probes. However, this method is time consuming. We recently developed a method that only requires PCR with allele-specific primers, which reduces the time for prenatal diagnosis from about 2 weeks to only a few days, thus allowing unnecessary prenatal treatment to be terminated promptly *(see below)*.

It has been shown that the prenatal treatment (Fig. 52-6) of female fetuses affected with 21-OHD can greatly reduce or prevent virilization of external genitalia, preventing the need for later genital surgery. For this outcome, prenatal treatment must be initiated before 10 weeks of gestation. Dexamethasone (20 µg/kg) given orally to at-risk mothers, blind to the status of the fetus, suppresses fetal adrenal androgen secretion. Depending on which procedure is available, either CVS (10–12 weeks of gestation) or amniocentesis (15–18 weeks of gestation) is performed. Fetal cells are cultured for karyotyping and DNA analysis. If the fetus is male or the fetus is an unaffected female, prenatal treatment is terminated. Prenatal treatment is continued to term for affected female fetuses.

Prenatal treatment for the fetus with low doses of dexamethasone does not appear to have any side effects. Some patients have been followed in excess of 10 years of age without reported side effects. This is in spite of the findings in rodents that high doses of dexamethasone resulted in cleft palate formation *in utero* and placental degeneration with fetal death.

Maternal side effects as a result of prenatal dexamethasone treatment can include mood changes, weight gain, pedal and leg edema, striae, elevated blood pressure, and general discomfort. All complications disappeared on discontinuation of treatment, and because of the positive genital outcome of their prenatally treated daughters, all women with complications reported that they would undergo dexamethasone treatment again if they became pregnant. Therefore, the risk–benefit ratio is highly in favor of prenatal dexamethasone treatment of female fetuses affected with 21-OHD.

11β-HYDROXYLASE DEFICIENCY

Patients with 11β-hydroxylase deficiency (11β-OHD) are unable to convert 11-deoxycortisol (compound S) to cortisol. 11β-OHD is the second most common cause of CAH. The frequency of 11β-OHD is in the order of 1 in 100,000 births in the white population. As with 21-hydroxylase deficiency, cases of mild, late-onset forms of 11β-OHD also have been reported.

As in 21-OHD, 11β-OHD results in shunting of excess 17-OHP to the androgen pathway, causing prenatal virilization of external genitalia in affected females at birth. Also, as in 21-OHD, both males and females undergo premature virilization, resulting in precocious adrenarche and premature epiphyseal closure.

Patients with 11β-OHD also have a defective 17-deoxysteroid pathway. In 11β-OHD, 11-deoxycorticosterone (DOC) cannot be converted to corticosterone, which is eventually converted to aldosterone. In most cases, because of their mineralocorticoid activity, elevated serum levels of DOC and its metabolites induce hypokalemia with metabolic alkalosis and hypertension. High levels of serum S and DOC, and their corresponding urinary tetrahydrometabolites, are diagnostic of 11β-OHD.

MOLECULAR GENETICS There are two known isoforms of 11β-hydroxylase in humans. The genes that encode these isoforms are *CYP11B1* and *CYP11B2*, located on chromosome 8, region q21–22, and separated by 30 kb. These isozymes have 93% identity between their amino acid sequences. *CYP11B1* is highly expressed in all zones of the adrenal cortex and is regulated by ACTH. *CYP11B2* is expressed in the zona glomerulosa under the control of angiotensin II and potassium ion. Mutations in the *CYP11B1* gene are responsible for 11β-OHD.

Mutations in the *CYP11B2* gene cause a less frequently inherited disease (CMO II) in which aldosterone cannot be synthesized. This isoform is now termed aldosterone synthase. Aldosterone synthase, in addition to 11β-hydroxylase activity, also was found in vitro to have 18-hydroxylase and 18-oxidase activities.

CYP11B1 (11β-HYDROXYLASE) Mutations found in the *CYP11B1* gene causing 11β-OHD are shown in Fig. 52-7. The first mutation in the *CYP11B1* gene was found in families from Israel. A single point mutation in exon 8 was found in many of these families, resulting in a substitution of the arginine at codon 448 with a histidine. This mutation in these families was traced back to Moroccan Jewish settlements. A 2-base insert in exon 7 resulting in a frameshift was identified in a Turkish Jewish pedigree. This mutation completely altered the heme-binding domain,

Table 52-2
Steroidogenic Enzymes: Gene Mutation

Gene	Exon	Mutation name/type	NT	AA	Comments	
CYP21	1	Missense mutation (conversion)	CCG→CTG	P30L	Nonclassic (NC) phenotype	
	—	Aberrant splicing of intron 2 (conversion)	a [or c] →g	b656	Part of intron (end 19 bases) retained in mRNA processing: frameshift	Seen in more than 20% of nondeleted alleles

resulting in an inactive enzyme. Within a heterogeneous population, eight other mutations have been identified: four missense mutations, a frameshift mutation (a single base deletion), and three point mutations. A mutation in codon 116 in exon 2, found in a Japanese patient, resulted in a substitution of tryptophan with a stop codon. Recently another mutation, a 5-base duplication, was found in exon 2.

CYP11B2 (ALDOSTERONE SYNTHASE) Defects in the last two steps of aldosterone synthesis result in salt-wasting syndromes (CMO I, 18-hydroxylation; CMO II, 18-oxidation) in infancy. Two homozygous mutations were identified in patients with CMO II in seven kindreds of Iranian-Jewish origin, a substitution of arginine with tryptophan at codon 181 (R181W), and a substitution of valine with an alanine at codon 386 (V386A). Three other Iranian-Jewish families also had the same mutations. Family members homozygous for either of the mutations alone were asymptomatic. In vitro studies of the individual mutations showed that the R181W mutation was deficient in 18-oxidase activity with reduced 18-hydroxylase activity and intact 11β-hydroxylase, whereas the V386A mutation had reduced 18-hydroxylase activity only.

Recently a 5-base deletion in exon 1 of *CYP11B2* was identified in a patient that had the biochemically CMO I phenotype. This frameshift mutation results in early termination at the end of exon 1 with complete lack of enzymatic activity in homozygous individuals.

CYP11B1–CYP11B2 CHIMERA A form of aldosteronism known as dexamethasone-suppressible or glucocorticoid-remediable hyperaldosteronism (DSH or GRH) is caused by the fusion of *CYP11B1* and *CYP11B2* (in addition to a normal copy of each). The chimeric gene contains the 5' end of *CYP11B1* and the 3' end of *CYP11B2*. Therefore, the regulation of this chimeric gene is under the control of ACTH, resulting in high levels of 18-oxocortisol from cortisol and abnormal 17α,18-hydroxysteroids. One copy of this chimeric gene is sufficient to produce the syndrome, hence this disorder is autosomal dominant. Dexamethasone treatment results in a prompt and sustained reduction of aldosterone. Patients with GRH have abnormal serum and urinary elevations of 18-hydroxy and 18-oxocortisol steroids.

PRENATAL DIAGNOSIS AND TREATMENT In 1996, the first case of prenatal treatment of a female fetus affected with 11β-OHD was reported. As with 21-hydroxylase deficiency, treatment of this fetus was initiated before a diagnosis could be completed. The molecular diagnosis revealed a homozygous missense mutation in *CYP11B1* identical to the mutation of her two affected sisters, who were both severely virilized at birth. However, prenatal dexamethasone treatment of this fetus resulted in normal genitalia at birth.

3β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY

A rare deficiency in the 3β-hydroxysteroid dehydrogenase/$\Delta^{5,4}$-isomerase (3β-HSD) enzyme results in a high ratio of Δ^5 to Δ^4 steroids, characterized by elevated serum Δ^5-steroids pregnenolone, 17-hydroxypregnenolone, and dihydroepiandrosterone (DHEA), with increased urinary Δ^5 metabolites pregnenetriol and 16-pregnenetriol. Because 3β-HSD is required for both adrenal and gonadal steroidogenesis, affected males may have incomplete genital development, resulting in sexual ambiguity at birth. Affected females may have very high levels of circulating DHEA with some peripheral conversion to more potent androgens, which leads to limited clitoral enlargement. A complete deficiency of 3β-HSD results in impaired aldosterone synthesis, causing salt wasting.

As with 21-hydroxylase and 11β-hydroxylase deficiencies, there is a spectrum of the level of 3β-HSD deficiency. The variations include a nonclassic form with postadrenarchal or peripubertal onset.

MOLECULAR GENETICS Two human isoforms of 3β-HSD have so far been identified by cloning of cDNA (several isoforms have been identified in rodents). Type I enzyme is expressed in the placenta, skin, and adipose tissue, and type II is expressed in the adrenal gland and the gonads.

The gene *HSD3B1* encodes the type I isoenzyme, and *HSD3B2* encodes the type II isoenzyme. Classically affected patients have mutations in the *HSD3B2* gene, of which several missense mutations have been found (Fig. 52-8). Patients with impaired aldosterone synthesis carry nonsense or frameshift mutations, or missense mutations that were shown to destroy enzymatic activity completely, when mutant cDNA was expressed in cultured cells. So far, no mutations have been found in the gene for type I. It is not yet known whether nonclassic 3β-HSD deficiency is caused by allelism of type II or whether a defect in another 3β-HSD is responsible for this phenotype. Genomic blot analysis suggests that there are as many as six *HSD3B* genes in humans.

17α-HYDROXYLASE/17,20-LYASE DEFICIENCY

Defects of the *CYP17* gene produce 17α-hydroxylase deficiency CAH, which is a combined 17α-hydroxylase/17,20-lyase deficiency. Patients with 17α-hydroxylase deficiency are unable to convert pregnenolone and progesterone to 17α-hydroxypregnenolone and 17-OHP, respectively, and subsequently are unable to convert these hormones to DHEA and Δ^4-androstenedione, respectively, by 17,20-lyase activity. With a decreased ability to synthesize cortisol, elevated ACTH increases serum levels of DOC and especially corticosterone. Both adrenal glucocorticoids and sex steroids are diminished. Isolated 17,20-lyase has also been observed, which results in deficient C19 sex steroids in the adrenals and gonads. Patients with defective 17,20-lyase activity have increased levels of pregnanetriolone, a metabolite of 17-OHP.

A deficiency in 17α-hydroxylase activity results in low-renin hypertension, hypokalemia, and metabolic alkalosis. Affected females have normal genitalia at birth, but at pubertal age present with primary amenorrhea, lack of axillary and pubic hair, and no pubertal development, leading to hypoplastic breasts in adolescence. Affected males can be born with external female genitalia because of their deficient gonadal testosterone production, though a uterus and fallopian tubes do not develop because anti–Müllerian hormone secretion by Sertoli cells inhibits Müllerian duct development. The Wolffian ducts, however, are incompletely developed as well.

Steroid 17α-hydroxylase deficiency is a relatively rare cause of CAH, accounting for about 1% of cases overall. Between 100 and 120 cases of 17α-hydroxylase deficiency have been described, and only about 20 cases of 17,20-lyase deficiency have been reported.

MOLECULAR GENETICS A single gene, *CYP17*, encodes the 17α-hydroxylase enzyme (also a cytochrome P450); it exists in a single active copy and is identically transcribed in both adrenal and testis. *CYP17* is located on chromosome 10, region q24–q25, and to date about 17 mutations have been described (Fig. 52-9). These mutations appear to be random and hence do not appear to be caused by a predisposing mechanism.

Both compound heterozygotes and homozygotes have been described. Although homozygosity for a rare mutation is often taken to suggest consanguinity, an exception to this (an insertion mutation of four nucleotides in codon 480) was found in the homozygous state in several Mennonites, a small Anabaptist sect found in a number of communities across North America. The same mutation was also identified in patients from Friesland, the region in the Netherlands where the Mennonites first formed, suggesting an earlier founder effect.

Partial deficiencies are associated with missense mutations or, in one case, deletion of a single codon (ΔF53 or 54) maintaining the reading frame of translation. Complete deficiency of *CYP17* has also been found and is associated with frameshifts and nonsense mutations.

LIPOID CONGENITAL ADRENAL HYPERPLASIA

Lipoid congenital adrenal hyperplasia (LCAH) is extremely rare. The biochemical defect responsible for LCAH resides in the cholesterol side-chain cleavage system, causing a deficiency in the conversion of cholesterol to pregnenolone and resulting in profoundly impaired synthesis of all steroids. The term "lipoid" refers to the abnormal appearance of the adrenals at autopsy, now known to be the result of massive accumulations of cholesterol and cholesterol esters. Males are born with female-appearing external genitalia but have undescended testes, and females have a normal genital phenotype at birth but remain sexually infantile without treatment.

If not detected and treated, LCAH is fatal in newborn infants; death can occur within days to weeks of birth. Severe fluid and electrolyte disturbances, low levels of all steroids in plasma and urine and addisonian pigmentation are present. Very poor stress response and great susceptibility to infection are also seen.

MOLECULAR GENETICS It was originally thought that a defect in the cholesterol side-chain cleavage enzyme, cytochrome P450scc, was responsible for this disease, because P450scc produces pregnenolone from cholesterol. However, this enzyme was shown to be normal in patients with LCAH. Recently a new enzyme

CYP17

2. Contraction of TTCTTC to TTC (mechanism?): loss in polypeptide sequence of one of **Phe₅₃-Phe₅₄**.

3. Point mutation T→ C changing coding triplet TCC to CCC (missense): **Ser₁₀₆** to **Pro**.

6. Point mutation C[→A]CA (**Pro₃₄₂** to **Thr**).

7. Point mutation CAG (**Gln₄₆₁**) to TAG (**stop**). Result is truncation of short C-terminal peptide sequence--but protein is still able to incorporate heme group (catalytic center) and may function.

9. Missense mutation CGC to TGC (**Arg₄₉₆** to **Cys**).

1. Point mutation G→A changes TGG (**Trp₁₇**) to TGA specifying termination (a 'non'-sense mutation).

4. Insert (duplication of 7 bases) and frameshift: reads for aberrant 37 AA sequence and stop.

5. Point mutation C→T changes CGA (**Arg₂₃₉**) to stop codon TGA.

8. Repeat of quadruplet CATC (insert and frameshift) causes reading of aberrant 26-AA sequence in place of final 29 AA of normal cytochrome P450₍C17₎.

DNA mutations of this sort cause error at many levels to preclude expression of the specific biochemical activities encoded for: (a) a primary transcript may not survive nuclear processing, (b) abnormal mRNA is likely to be prematurely degraded in cytoplasm, and (c) any possible translation product (drastically truncated) would also be subject to misrouting and rapid clearance or, if finding its cell compartment would be devoid of function.

has been discovered that is required for steroidogenesis, steroidogenic acute regulatory protein (StAR). StAR is involved in the transfer of cholesterol from the outer to the inner mitochondrial membrane, where it is then converted to pregnenolone. The gene encoding StAR is on chromosome 8, region p11.2, and a StAR pseudogene is located on chromosome 13. Mutations found in the gene encoding StAR were found to cause LCAH (Fig. 52-10). In three patients, a C-to-T transition in this gene resulted in premature termination. This was confirmed by Western analysis and in vitro studies, showing that these mutations produced completely

inactive. In another report, a patient was found to have a splice site mutation caused by a T-to-A transversion in intron 4, resulting in the elimination of 185 nucleotides from the StAR mRNA. Six other mutations in the gene encoding StAR were reported from four patients in 1996.

TREATMENT

Treatment of CAH as a result of 21-hydroxylase deficiency has been ongoing since 1950. Glucocorticoid replacement therapy not only replaces the deficient hormone but also reduces the over-

stimulation of the adrenal cortex by reducing the release of ACTH, thereby suppressing the overproduction of adrenal androgens. Hydrocortisone (cortisol) is the compound most often used for replacement therapy for 21-OHD, 11β-OHD, and 17α-hydroxylase deficiency. Proper replacement therapy in 21-OHD and 11β-OHD ameliorates the effects of oversecretion of adrenal androgens, thus preventing further virilization, slowing accelerated growth and bone age advancement to a more normal rate, and allowing a normal onset of puberty. In 11β-OHD and 17α-hydroxylase deficiency, glucocorticoid treatment suppresses the oversecretion of DOC leading to the remission of hypertension. Excessive glucocorticoid administration can cause cushingoid facies, growth retardation, and inhibition of epiphyseal maturation.

Hydrocortisone is the physiologic hormone and therefore, minimizes complications. Oral administration is the usual mode of treatment, conventionally given daily in divided doses. It is believed that divided doses better suppress the production adrenal androgens. Hydrocortisone given in two equally divided doses of 10–20 mg/m^2 daily is adequate for the otherwise healthy child. The dosage may have to be increased for a few days to two to three times that of the normal daily dosage during times of non–life-threatening illness or stress. Families are given injection kits of hydrocortisone (50 mg for young children; 100 mg for older patients) for times of emergency. Up to 5–10 times the daily dosage may be required during surgical procedures.

Patients who show a poor response to the standard dosage of hydrocortisone may have their dosage increased to 20–30 mg/m^2 per day or their regimen may have to be changed to a synthetic hormone analog such as prednisone or dexamethasone. The use of these analogs requires critical dosage adjustment since they are more potent and longer acting.

Patients with salt-wasting CAH may also require mineralocorticoid replacement. A cortisol analog, 21-acetyloxy-9α-fluorohydrocortisone (Florinef: 9α-FF), is used for its potent mineralocorticoid activity. A combination of hydrocortisone and Florinef has proven to be quite effective in treatment of patients with salt-wasting 21-OHD.

In simple virilizing patients, it is common to find elevated plasma renin activity (PRA) because of the interaction of the renin–angiotensin–aldosterone system and the hypothalamo–pituitary–adrenal axis. Florinef given in these cases reduces the PRA, which in turn lowers ACTH levels further, resulting in better control of androgens without increased glucocorticoid dose.

Patients with NC21-OHD and nonclassical 3β-HSD deficiency are treated with low doses of dexamethasone. Excess ovarian androgen production may have to be suppressed by the use of progestational and estrogenic agents, which suppress the release of gonadotrophin. Other antiandrogen agents that may help include spironolactone and cyproterone acetate, and the androgen receptor blocker, flutamide. The aim of treatment in these patients is to minimize symptoms without giving rise to glucocorticoid side effects.

In lipoid congenital adrenal hyperplasia, because all steroidogenic enzymes are normal, a substrate for steroidogenesis can be used for effective treatment of patients. Freely diffusible 20α-hydroxycholesterol is recommended, which must be implemented as a lifelong treatment plan. Successful continuing management of a patient for 18 years was reported in 1985 using replacement glucocorticoids and mineralocorticoids in physiologic doses, and estrogen replacement induced a pubertal growth spurt.

FUTURE DIRECTIONS

For many diseases that are reasonably well-defined at a clinical, genetic, and molecular level, there remains the enigma of genotype not strictly correlating with phenotype, in which variation exists in the clinical phenotype associated with the same disease-producing mutation as defined by molecular techniques. Steroid 21-hydroxylase provides an example of this phenomenon. More than 200 patients were assessed for phenotypic characteristics by: (1) genital status with respect to virilization in females, (2) ACTH stimulation tests to evaluate secretion of androgens and 17-hydroxyprogesterone, and (3) salt-deprivation studies when safe to assess aldosterone deficiency and salt wasting. After dividing patients into 26 mutation-identical groups, it was found that half the groups did not conform to the genotype.

Because the mechanism for this phenomenon remains elusive, future studies should include investigation of the promoter and regulatory areas of the 21-hydroxylase gene. The surrounding genes may play a role in altering gene expression, though the different phenotypes of mutation-identical sibs cast doubt on this explanation. Activity of transcription factors, transport proteins, and other modifiers must also be studied.

53 Adrenal Diseases

Constantine A. Stratakis and George P. Chrousos

INTRODUCTION

The adrenal glands became known as *gladulae renis incumbentes* through the work of Bartolommeo Eustachio, nearly five centuries ago. These anatomic structures, however, did not enter the realm of clinical medicine until the middle of the 19th century, when T. Addison described the first patients with adrenal insufficiency. In the years that followed, the three zonae of the adrenal cortex were defined and several clinical and pathologic abnormalities were described. Recently, a number of adrenocortical disorders have had their pathophysiology elucidated at the physiologic and molecular levels. This chapter reviews diseases associated with adrenocortical dysfunction, whose molecular pathogenesis is either known or under investigation. These include primary glucocorticoid and corticotropin resistance (hereditary isolated glucocorticoid deficiency, triple A syndrome), adrenal hypoplasia congenita, pseudohypoaldosteronism, adrenoleukodystrophy and adrenomyeloneuropathy, the apparent mineralocorticoid excess syndrome, and Carney complex. Adrenocortical cancer is discussed separately, since in its inherited forms (Li-Fraumeni and Beckwith-Wiedemann syndromes) the molecular pathogenesis has been elucidated to some extent, whereas little is known about the molecular mechanisms leading to sporadic carcinomas. The congenital adrenal hyperplasia syndromes and Liddle syndrome and other causes of hypertension are described elsewhere.

PRIMARY FAMILIAL OR SPORADIC GENERALIZED GLUCOCORTICOID RESISTANCE

BACKGROUND   Primary familial or sporadic generalized glucocorticoid resistance (FGR or GGR, respectively—OMIM 138040) is a rare hereditary disorder characterized by hypercortisolism and the absence of stigmata of Cushing's syndrome. Glucocorticoids are crucial regulators of affect and behavior, metabolism, cardiovascular function, inflammation, and immunity. Complete inability of glucocorticoids to exert their effects on target tissues would be incompatible with life in primates. Thus, only syndromes of partial or incomplete glucocorticoid resistance exist and are caused by defects of the ubiquitous, classic glucocorticoid receptor (GR) (type II), which mediates most of glucocorticoid (GC) actions. GGR was the penultimate nuclear hormone resistance syndrome to be described, as late as 1976, and to date has been reported in several unrelated kindreds and, recently, in individual subjects.

CLINICAL FEATURES AND DIAGNOSIS   The daily production of GC is tightly controlled by an elaborate feedback system, in which GC exert negative feedback on hypothalamic secretion of corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP) and on pituitary secretion of corticotropin (ACTH). In states of resistance, this complex system is insensitive to concentrations of cortisol considered normal for the general population and the hypothalamic–pituitary–adrenal (HPA) axis is reset to a higher level because of compensatory increases of ACTH and cortisol secretion. Because the defect of the receptor is partial, adequate compensation for the end-organ insensitivity appears to be achieved by the elevated circulating cortisol; however, the excess ACTH secretion results in increased production of adrenal steroids with salt-retaining or androgenic activity. Because in GGR the peripheral tissues are presumably normally sensitive to mineralocorticoids and androgens, the clinical characteristics of the condition reflect the increased production of these hormones. Corticosterone, deoxycorticosterone, and even cortisol, through their interaction with the mineralocorticoid receptor, cause symptoms and signs of mineralocorticoid excess, such as hypertension or hypokalemic alkalosis. The excess androgens, such as Δ4-androstenedione, dehydroepiandrosterone (DHEA), and DHEA-sulfate (DHEA-S), on the other hand, lead to signs and symptoms of hyperandrogenism. The latter in women include cystic acne, hirsutism, male pattern baldness, menstrual irregularities, anovulation, amenorrhea, and infertility. In children, the excessive and early prepubertal adrenal androgen secretion can cause sexual precocity. Finally, the interference of adrenal androgens with the regulation of pituitary secretion of follicle-stimulating hormone (FSH) or ACTH-induced intratesticular growth of adrenal rests appears to be responsible for abnormal spermatogenesis and infertility in men with GGR. These clinical manifestations were not reported in all patients with FGR, and presentation varied even within families, including asymptomatic members.

The diagnosis of GGR is made by demonstrating a high cortisol production rate, i.e., high plasma total and free cortisol, elevated 24-hour urinary free cortisol (UFC) or 17-OH-corticosteroid excretion, resistance to dexamethasone suppression, and maintenance of the circadian and stress-induced patterns of GC secretion, albeit at higher levels, along with absence of Cushing's syndrome stigmata.

GENETIC BASIS OF DISEASE   Inherited or spontaneous mutations of the GR gene causing quantitative or qualitative alterations in the function of the receptor protein had been suspected in this syndrome, because receptor studies in cells from affected
Figure 53-1 Genomic, cDNA, and protein structure of the human glucocorticoid receptor (hGRα): **(A)** The gene consists of 10 exons of variable length. The hGRβ is the product of alternative splicing and does not bind glucocorticoids. **(B)** The main domains of the hGR are represented in a linear model and the three identified mutations in kindreds-A and -B *(see text)* and the one reported by Malchoff et al. are shown at positions 641, 363, and 729 of the hGR protein, respectively. (HSP, heat shock protein; NLS, nuclear localization sequences.) **(C)** Homologies of the five other classes of steroid and sterol receptors to the hGR expressed as percent identity in primary sequence (MR, PR, AR, ER, and VDR are mineralocorticoid, progesterone, androgen, estrogen, and 1,25(OH)$_2$-vitamin D3 receptor, respectively.) (Modified from Stratakis et al. Ann NY Acad Sci 1994;746:362–376.)

individuals and their relatives had shown decreases in the receptor concentration and ligand-binding affinity, thermolability, and abnormal interactions with DNA. The cloning of the complementary DNA (cDNA) of the human GR in 1985 allowed the deduction of its primary structure, definition of its functional domains, and cloning of its gene, and permitted further studies on the molecular mechanisms of glucocorticoid resistance (Fig. 53-1). The GR gene is located on chromosome 5 and consists of 10 exons. The 777-amino acid GR has three main functional domains: the ligand-binding domain in the carboxy-terminus of the protein, the DNA-binding domain in the middle, and the amino-terminal domain, which was originally characterized by its property of providing antigenic epitopes for the generation of antireceptor antibodies and, hence, was called the "immunogenic domain." The first family in which the molecular basis of GGR was investigated was a large kindred (kindred-A), in which the propositus had no features of Cushing's syndrome despite a sevenfold elevation of free cortisol in serum. Less severe but unequivocal cortisol excess and dexamethasone resistance were found in one brother and a son. Borderline cortisol excess was detected in 6 of 27 additional relatives from three generations consistent with an autosomal

codominant mode of inheritance, in which heterozygotes were affected either mildly or only biochemically. Studies of the GR in intact mononuclear leukocytes and cultured skin fibroblasts from the patients showed normal concentrations of the GR with diminished affinity for the hormonal ligand. The GR of Epstein-Barr virus (EBV)-transformed lymphoblast lines from the propositus and his mildly affected relatives, on the other hand, showed GR mRNA of the expected size but decreased ligand-binding affinity, increased thermolability, and reduced binding to DNA-cellulose after thermal activation. It was concluded from these studies that the most likely molecular defect was a mutation of the GR gene affecting the ability of the receptor to bind efficiently with the ligand.

The 2,3-kb coding region of the GR cDNA from the EBV-transformed lymphoblast lines established from three patients of kindred-A was amplified by PCR and sequenced. There was complete concordance with the published normal GR cDNA nucleotide sequence for all three patients, except at position 2054, where a thymidine (T) residue was present in place of the normal adenosine (A), resulting in a nonconservative amino acid substitution at position 641 of the GR protein and changing the aspartic acid

codon (GAC) to the valine codon (GTC). The propositus was homozygous for the Val-641 mutation, whereas the amplified GR cDNAs from the mildly affected son and nephew contained both A and T residues at position 2054, suggesting heterozygosity. The functional significance of the identified mutation was tested by its introduction into the wild-type GR by PCR site-directed mutagenesis and use in transient cotransfection assays. Despite its normal expression, the mutant GR was not able to bind ligand and transactivate a GC-responsive gene in vitro.

A second family (kindred-B) was then investigated, in which the propositus was an adult woman with symptoms and signs of hyperandrogenism and elevated plasma cortisol concentrations. She, her father, and two brothers were biochemically affected to the same degree, with cortisol production indices within the Cushing's syndrome range; the male members, however, were completely asymptomatic. Glucocorticoid binding analysis in circulating mononuclear leukocytes from affected members demonstrated a 50% decrease of receptor concentrations and normal binding affinity for dexamethasone. The GR gene of the proband, her two affected brothers, and two unaffected siblings was studied also by PCR amplification and sequencing. A 4-bp deletion (Δ4) was identified at the 3' boundary of exon and intron 6 in all three affected subjects studied. The deletion removed a donor splice site in one allele, affecting the last two bases of the exon and the first two nucleotides of intron 6. This deletion segregated with the presence of glucocorticoid resistance, and all three affected members of the kindred were heterozygous for it. The Δ4 allele was not transcribed in vitro, a finding that was compatible with the reduction of the GR number by 50% in the patients' cells.

In a third family, a guanine-to-adenine point mutation was found in GR cDNA position 2317, leading to an amino acid substitution at position 729 of the GR protein within the ligand-binding domain. The mutation also led to decreased affinity and apparently compromised the functional ability of the GR. The propositus in this family is the only patient with FGR reported to present with isosexual precocious puberty, adding not only genetic but also clinical variability to the syndrome.

CLINICAL MANAGEMENT Patients with FGR are easily managed with high doses of synthetic glucocorticoids, such as dexamethasone, with no mineralocorticoid activity, which should be carefully titrated per individual. Monitoring of clinical and biochemical parameters is essential to avoid glucocorticoid excess.

FUTURE DIRECTIONS Glucocorticoid resistance may be more prevalent than previously believed and may have important implications for human pathophysiology. The variety of phenotypes and abnormal receptor studies described so far, as well as the complexity of the GR structure and its multitude of interactions within the cell, can with certainty predict that many more genetic defects will be identified as causes of glucocorticoid resistance in humans. The latter may include not only alterations of the GR gene structure and function, but also of other molecules that are important for defining glucocorticoid responsiveness of target tissues, including the β-isoform of the GR (GRβ), which does not bind ligand but has dominant negative activity on the classic isoform; the heat shock protein (hsp)-90 and hsp-70 and the immunophilins, which coexist as heteroligomers with the cytosolic GR; and several transcription factors, which physically and functionally interact with the receptor, such as c-*jun*, c-*fos*, and NFκB, as well as coactivator and corepressor molecules. GGR appears to be relatively frequent among women with hyperandrogenism and should

be ruled out in these cases. States of GGR may also include local tissue unresponsiveness to GC, such as that observed in lymphoid and corticotroph neoplasia, autoimmune and allergic diseases, and, probably, psychiatric disorders.

HEREDITARY ISOLATED GLUCOCORTICOID DEFICIENCY AND THE TRIPLE A SYNDROME

BACKGROUND Hereditary isolated glucocorticoid deficiency (IGD—OMIM 202200) is a rare autosomal recessive disorder characterized by primary adrenal insufficiency without mineralocorticoid deficiency. Affected children usually have recurrent hypoglycemia, convulsions, or coma, which may result in death within the first 2 years of life. Unless recognized and treated early, this condition may lead to cachexia and failure to thrive. The disorder is occasionally associated with alacrima and achalasia of the esophagus (adrenal insufficiency, alacrima, achalasia, the "triple-A" or Allgrove syndrome), a disorder which is familial and inherited in an autosomal recessive manner (OMIM 200440).

CLINICAL FEATURES AND DIAGNOSIS Patients with IGD have adrenocortical resistance to ACTH, which presents in early infancy with hypoglycemia, hyperpigmentation, low urinary 17-hydroxycorticosteroids (17-OHCS), and absence of a cortisol, aldosterone and 17-OHCS response to ACTH stimulation. They retain, however, normal aldosterone responses to activation of the renin–angiotensin axis by salt restriction, orthostasis, and furosemide-induced diuresis. Accordingly, the zonae fasciculata and reticularis in these patients are atrophic, reduced to a narrow band of fibrous tissue, whereas the zona glomerulosa is relatively well-preserved.

GENETIC BASIS OF DISEASE The adrenocortical unresponsiveness to ACTH that underlies the pathogenesis of isolated glucocorticoid deficiency suggests that the defect responsible could be anywhere in the signaling cascade, from the membrane-bound G-protein-coupled ACTH receptor to the kinases stimulating steroidogenesis. Recently, the human ACTH receptor gene was cloned and its sequence was determined. It encodes a 297-amino acid protein, which, together with the melanocyte-stimulating hormone receptors, constitute a class of G-protein-coupled seven transmembrane domain (TMD) receptors whose genes are intronless. Abnormalities of the ACTH receptor (melanocortin receptor-2 *[MC2R]*) gene, which has been localized to chromosome 18p11.2, were found in four families with hereditary IGD. In one kindred, a G-to-T substitution was found at codon 74 of the MC2 gene, within TMD-II of the protein. The proband, a Scottish boy who was born to nonconsaguineous parents and exhibited hypoglycemia and hyperpigmentation early in infancy, was homozygote for this mutation, which was later described in two other apparently unrelated families from Scotland. In another kindred, the proband was a 5-year-old African-American boy with generalized hyperpigmentation and history of severe hypoglycemia since infancy, who was studied in our laboratory. This patient had two different point mutations in the coding region of the MC2 gene, each in either of the two alleles. The first mutation was a substitution of C by T at the first position of codon 201, normally encoding arginine, introducing the stop codon TGA. The site of this mutation corresponds to the beginning of the third intracellular loop of the ACTH receptor protein. The second mutation was a substitution of C by G at the third position of codon 120, causing a nonconservative amino acid substitution from serine to arginine in TMD-III of the receptor, thus disrupting ligand binding. The

proband's asymptomatic parents and grandparents were carriers for each of the two mutations.

Although mutations of the MC2 gene appear to be responsible for the IGD syndrome in several families, in others the genetic defect remains elusive. In fact, genetic heterogeneity was recently demonstrated for this disease by the exclusion of the chromosome 18p11.2 locus of the MC2 gene with the use of an informative dinucleotide repeat marker *(D18S40)* in three families with IGD. In two additional families, the MC2 gene was sequenced and no mutations were found. In one of these, peripheral blood lymphocytes from the two affected siblings failed to respond to ACTH with an increase of adenylate cyclase levels. On the other hand, the *D18S40* marker segregated with the disease in four newly studied families with the syndrome. Thus, it appears that a little less than half of the cases of IGD may not be caused by mutations of the MC2 gene coding region.

Patients with the triple A syndrome have also been investigated and found not to have any genetic changes of the MC2 gene. Because adrenocortical insufficiency in this disorder is associated with alacrima and autonomic and other neurologic abnormalities, a contiguous gene deletion has been suggested for the etiopathogenesis of this disorder. The gene(s) was (were) recently mapped to human chromosome 12q13.

CLINICAL MANAGEMENT   Patients with IGD are treated with replacement doses of hydrocortisone ($12–15$ mg/m^2/d) or equivalent doses of other glucocorticoids. They achieve normal growth and intellectual development if diagnosed and treated early, in contrast to patients with the triple A syndrome, who demonstrate progression of their neurologic deficits with age independently of the time of onset of glucocorticoid replacement and the number of hypoglycemic episodes.

ADRENAL HYPOPLASIA CONGENITA

BACKGROUND   Adrenal hypoplasia congenita (AHC—OMIM 300200) is a developmental disorder of the adrenal gland that results in severe adrenal insufficiency and death in early infancy if left untreated. Two distinct forms, the autosomal recessive miniature (OMIM 240200) and the X-linked cytomegalic form have been described. The first reports of familial adrenal hypoplasia were published in the 1950s, when several pedigrees of affected male siblings and their maternal uncles were described, indicating X-linked inheritance. The autopsies in these patients showed structural disorganization and absence of the normal zonae of the adrenal glands. The biochemical profile of these patients was remarkable for low or absent serum levels of glucocorticoids and mineralocorticoids, low serum androgens, and failure of adrenal steroids to respond to ACTH. Several patients had ambiguous genitalia or cryptorchidism and were found to have hypogonadotropic hypogonadism (HHG) of pituitary or hypothalamic origin, and occasionally, other abnormalities, including glycerol kinase deficiency (GKD), hearing loss, and Duchenne's muscular dystrophy (DMD). The autosomal recessive form of the disease, on the other hand, is not associated with HHG or the other abnormalities seen in the X-linked form.

CLINICAL MANIFESTATIONS   Both forms of AHC usually present in infancy as failure to thrive, vomiting, feeding difficulties, neonatal cyanosis and apnea, and seizures. Hypoglycemia, hyponatremia, and hyperkalemia are caused by the extremely low cortisol and aldosterone levels that fail to respond to endogenous or exogenous ACTH. Although ambiguous genitalia or cryptorchidism may be present in the autosomal recessive form also, HHG with no or minimal response of gonadotropins to gonadotropin-releasing hormone (GnRH) administration is only present in the X-linked form. The latter may also be associated with progressive high-frequency hearing loss and other neurologic abnormalities; however, association of the autosomal recessive AHC with anencephaly or isolated pituitary abnormalities has also been reported. The histologic findings differ in the X-linked and autosomal recessive forms of AHC. In the former, which is referred to as the "cytomegalic" type, the adrenal cortex shows disorganization with poor differentiation of cortical zones and presence of scattered clumps of eosinophilic cells. In the latter, which is called the miniature adult type, there is absence or nearabsence of both fetal and permanent cortex.

GENETIC BASIS OF DISEASE   The description of patients with the X-linked type of AHC and/or HHG, GKD, hearing loss, and DMD pointed to a contiguous gene deletion syndrome. Indeed, in 1992 an AHC locus was mapped to Xp21 in proximity to the DMD locus on the basis of the identification of several patients with deletions of this region. The region encompassing the DMD, GKD, and AHC loci was cloned, and the AHC locus mapped to a 250- to 500-kb region, telomeric to the GKD locus. Subsequently, the X-linked locus DSS (dosage-sensitive sex reversal) was mapped to Xp21 by microscopic duplications found in 46, XY phenotypically female patients, narrowing the AHC region to approximately 160 kb. The *DAX-1* (DSS-AHC critical region on the X chromosome) gene was then cloned from a phage contig spanning the region. It encodes a new member of the nuclear hormone receptor superfamily that has a novel DNA-binding domain, and acts as a dominant-negative regulator of transcription mediated by the retinoic acid receptor. The gene contains a single, long open reading frame, and its coding sequence is interrupted by a single, 3-kb-long intron. The *DAX-1* mRNA is only found in steroidogenic tissues (testes, ovaries, adrenals) as a single 1.9-kb RNA species and has been highly preserved in all species tested. Mutations of the *DAX-1* gene (nonsense, missense, and frameshift mutations and a single amino acid deletion) were found in patients with both X-linked AHC and HHG, who had no other genetic abnormality of the chromosome Xp critical region. On the other hand, patients with AHC and DMD or GKD had contiguous gene deletions, from which the following gene order was deduced for this portion of the short arm of chromosome X:Xpter-*AHC-GKD-DMD*-cen. No mutations in *DAX-1* were found in five other AHC patients, including one with histologically confirmed cytomegalic type of the disease. Thus, genetic heterogeneity exists even for the X-linked AHC. The genetic locus or the gene for the autosomal recessive type of AHC remains elusive.

CLINICAL MANAGEMENT   Patients with AHC are given replacement glucocorticoids, fludrocortisone ($0.1–0.4$ mg/d), and salt supplementation in infancy and early childhood ($1–2$ g/d). Serum testosterone levels and a GnRH stimulation test are indicated in patients with AHC and normal testicular descent, because the absence of bilateral or unilateral cryptorchidism does not preclude HHG.

FUTURE DIRECTIONS   As patients with AHC demonstrate, disruption of *DAX-1* does not prevent the initial stages of gonadal development in the human male but inhibits maturation of the hypothalamic–pituitary–gonadal axis and prevents differentiation of the adrenal gland beyond the fetal stage. Thus, *DAX-1* plays the role of a late developmental regulator of adrenal and gonadal ste-

roidogenesis and, perhaps, pituitary function, that is comparable to that played by another orphan nuclear receptor protein, steroidogenic factor-1 (SF-1) in earlier developmental stages (*see* Chapter 57). Indeed, a putative SF-1 response element was recently identified in the *DAX-1* gene promoter region, indicating a coordination of expression of the two factors. Because genetic heterogeneity exists even for the X-linked AHC cases, other genes with similar roles in the regulation of steroidogenesis are expected to be found in the near future on the X and other chromosomes.

ADRENOLEUKODYSTROPHY AND ADRENOMYELONEUROPATHY

BACKGROUND Adrenoleukodystrophy (ALD, OMIM 300100) was first reported as an X-linked syndrome of Addison's disease and cerebral sclerosis in the 1960s. A decade later, it was found that cholesterol esters in the brain and adrenal tissue of these patients contained an excess amount of fatty acids with a chain length of 24–30 carbon atoms. The clinical phenotype varied considerably leading to the description of four different forms based on the age of onset and clinical severity. A defective peroxisomal β-oxidation system was found in skin fibroblasts from the patients in the early 1980s. Genetic studies in patients with ALD and other defects led to the recent (1993) identification of the *ALDP* gene.

CLINICAL MANIFESTATIONS ALD is a progressive, degenerative neurologic disorder with spastic paraplegia, peripheral neuropathy, limp and truncal ataxia, slurred speech, blindness, and cognitive hearing loss, associated with primary adrenal insufficiency and hypogonadism. Four distinct phenotypes have been recognized: a neonatal form that is manifested by severe neurologic deficits in infancy and leads to death in early childhood; classic ALD that affects young children, who usually die before they reach adulthood; adrenomyeloneuropathy (AMN), which is usually first manifested by adrenal insufficiency during the second and third decade of life, affects primarily the spinal cord, and gradually leads to severe neurologic deficits; and adult ALD that is present in female heterozygote carriers and is manifested by progressive spinal cord disease and ataxia. Patients with adrenal insufficiency only, or a form limited to the cerebrum, have also been described. As in the nervous system and elsewhere, the adrenal pathology of ALD is characterized by the accumulation of lipid inclusions. Plasma levels of very long chain fatty acids (VLCFA, C26:0) are elevated and there are abnormal C26:0/C22:0 and C24:0/C22:0 ratios. The determination of circulating hexahecosanoate can be used not only for the diagnosis of ALD, but also for the prenatal detection of the disease and for the identification of female carriers. An ACTH stimulation test is essential in every patient with ALD to identify the extent of impaired adrenal reserve, so that replacement therapy can be instituted promptly.

GENETIC BASIS OF DISEASE The earlier linkage of the ALD gene to the chromosome X locus of the glucose-6-phosphate dehydrogenase (G-6-PD) gene in women heterozygous for both ALD and electrophoretic variants of G-6-PD was confirmed by linkage analysis through the use of the *DXS52* DNA probe. Linkage to the Xq28 locus of this probe was established with a lod score of 13.76 with no recombinations (θ = 0). By positional cloning and the use of structural deletions of the Xq chromosome found in patients who had both ALD and color blindness, the putative ALD gene was mapped in close proximity to and at the 5' end of the

color gene cluster. The identification, in 1993, of a transcript from this genomic region designated ALDP (ALD protein) was followed by the report of several deletions and other mutations of the *ALDP* gene in patients with ALD or AMN. Comparison with the amino acid sequences of known genes suggests that ALDP is a member of the ATP-binding cassette (ABC) transmembrane transporter protein superfamily. Thus, ALDP appears to be a peroxisomal membrane transporter directly involved in the import of the peroxisomal enzyme lignoceroyl-CoA synthetase (VLCFA synthetase), the enzyme whose activity appears defective in ALD. The ALDP transcript has a 38.8% homology with that of the peroxisomal protein PXMP 1. Although there is no direct proof that ALDP is located in the peroxisomal membrane, and the peptide has no homology to any of the other known peroxisomal proteins or fatty acid CoA synthetases, it is postulated that mutations of the ALDP have an indirect effect on the β-oxidation of VLCFA by affecting VLCFA synthetase activity. In a recent study of 28 unrelated kindreds, defects of the ALDP gene were found in all of the patients, mostly nonsense or missense mutations.

CLINICAL MANAGEMENT Patients with ALD have multiple neurologic problems that are treated symptomatically. If adrenal insufficiency is present, replacement with hydrocortisone and fludrocortisone is needed. Accordingly, treatment with gonadal steroids may be needed if hypogonadism is present. There is no known improvement of the endocrine manifestations of ALD with the administration of "Lorenzo's oil," although a substantial decrease of serum VLCFA levels has been documented with its use and additional dietary therapy. Bone marrow transplantation was recently tried in patients with ALD and a multicenter study is now in progress.

FUTURE IMPLICATIONS The cloning of the ALDP gene provided a significant molecular insight into the function and structure of the peroxisomes, organelles that contain many enzymes and are involved not only in fatty acid oxidation, but also in prostaglandin degradation and amino acid metabolism, the formation of bile acids, and the biosynthesis of cholesterol and plasmalogens. Research is ongoing to further elucidate the role of the peroxisomes in steroidogenesis and other endocrine functions.

PSEUDOHYPOALDOSTERONISM

BACKGROUND Cheek and Perry first reported pseudohypoaldosteronism (PHA) in an infant with a severe salt-wasting syndrome in 1958. The syndrome was subsequently reported in more than 70 patients. Approximately one-fifth of these cases were familial. The disease is inherited in an autosomal recessive manner, although dominant inheritance cannot be excluded in several pedigrees. It is referred to as PHA type-I (OMIM 264350) to distinguish it from Gordon syndrome or hyporeninemic hypoaldosteronism (PHA-type II, OMIM 145260), which is characterized by renal tubular unresponsiveness to the kaliuretic, but not the sodium and chloride reabsortive, effect of aldosterone. The latter is inherited in an autosomal dominant manner.

CLINICAL MANIFESTATIONS Type-I PHA is manifested early in infancy with salt wasting, vomiting, and feeding difficulties that lead to severe dehydration and death if untreated. Hyponatremia, hyperkalemia, and acidosis are present despite marked renin excess and hyperaldosteronemia, and normal 17-hydroxysteroid excretion. Unresponsiveness to aldosterone may be limited to the renal tubule or generalized, in which case sodium excretion is increased not only in the urine, but also in sweat, saliva, and stool.

The sweat chloride test is positive. The symptoms improve with age and older patients with PHA require smaller doses of salt supplements and salt-retaining steroids.

GENETIC BASIS OF DISEASE   A number of reports suggested that quantitative or qualitative defects of the mineralocorticoid receptor (MR) might be responsible for PHA, on the basis of studies that reported absent or decreased [^{3}H]-aldosterone binding to circulating leukocytes from patients with the disorder. The human MR was cloned in 1987 and its chromosomal locus was mapped to chromosome 4q31.1–2. A number of patients with type-I PHA have been studied for mutations of the coding and 5' regulatory regions of the human MR and no changes have been identified, with the exception of polymorphisms in the immunogenic domain of the receptor that did not segregate with the disease. Recently, the chromosome 4q31.1–2 locus of the human MR was excluded by homozygosity mapping of 10 inbred families with one or more affected individuals with type-I PHA. Subsequent genome scans for type-I PHA genes using DNA from 11 consanguineous families with PHA1 demonstrated linkage to a locus on chromosome 16, 16p12.2–13.11, in 6 families and to 12q13.1–pter in 5 families. These chromosomal regions contain the genes that encode the β-, γ-, and α-subunits of the amiloride-sensitive epithelial sodium channel (ENaC), *SCNN1B* and *SCNN1G* on chromosome 16 and *SCNN1A* on chromosome 12. Activating mutations of *SCNN1B* and *SCNN1G* cause Liddle's syndrome, which is characterized by hypertension associated with vascular expansion, hypokalemia, and alkalosis. This is essentially the converse phenotype of type-I PHA. Inactivating mutations in the different subunits of ENaC in patients with type-I PHA have now been reported. Two kindreds with premature termination of the α-subunit of ENaC have been identified. A missense mutation, substitution of serine for glycine at residue 37 (G37S), has also been identified in the β-subunit of ENaC. This missense mutation apparently changes the channel open probability (P_o) and results in a channel characterized by short open times and long closed times. Finally, a G-to-A substitution in a 3' acceptor splice site has been identified in mRNA encoding the γ-subunit. This mutation results in production of one of two aberrant proteins, either a truncated protein or a protein that lacks three highly conserved amino acids adjacent to the first transmembrane domain.

CLINICAL MANAGEMENT   Patients with type-I PHA are aggressively treated in early infancy with salt supplementation (0.5–1.5 g/kg/d in four to six divided doses). Close monitoring of the sodium balance is needed especially during infancy, when plasma renin activity is not useful because of the large variation of this parameter in the first year of life. After the age of 2 years, the reduction of sodium supplement is often possible with gradual improvement of the symptoms and decrease of the dehydration crises. Recently, carbenoxolone, an inhibitor of 11-β-hydroxysteroid dehydrogenase (11-β-HSD), was used successfully in the treatment of type-I PHA.

FUTURE DIRECTIONS   The identification of the responsible genes for type-I PHA undoubtedly offer significantly to the understanding of aldosterone physiology. Indeed, the genetic defects in PHA may involve postreceptor mechanisms in aldosterone action, such as the transport of sodium by the mineralocorticoid-responsive amiloride-sensitive sodium channel subunits. New therapeutic regimens for the patients with this disease are expected to be developed based on identification of the responsible genetic defects.

SYNDROME OF APPARENT MINERALOCORTICOID EXCESS

BACKGROUND   The syndrome of apparent mineralocorticoid excess (AME—OMIM 218030) was first described in 1977 as a syndrome of hypertension, hypokalemia, and low plasma renin activity associated with normal cortisol, and subnormal aldosterone levels. Through the 1980s, the disease was investigated in several children and few adults; an abnormal cortisol-to-cortisone ratio was described in all these patients, suggesting that the defect was related to the oxidation of cortisol to its inactive metabolite. This reaction is mediated through the action of 11-β-hydroxysteroid dehydrogenase (HSD), an enzyme that is inhibited by licorice (glycyrrhetinic acid) and carbenoxolone. Licorice induces a clinical and biochemical syndrome that mimics that of AME when chronically ingested. Mutations of one of the two isoforms of this enzyme were recently found to be responsible for congenital AME, which is inherited in an autosomal recessive manner. So far, 25 patients with AME have been reported worldwide. A normal cortisol-to-cortisone ratio, however, has been identified in few of these patients, who do not appear to have an HSD defect (AME-type II, OMIM 207765).

CLINICAL MANIFESTATIONS   Both types of AME present in early childhood (1–5 years of age) with severe hypertension, hypokalemic alakalosis, low plasma renin activity, and low to normal aldosterone levels. If left untreated, long-standing hypertension may lead to left ventricular hypertrophy, strokes, and retinopathy before the teenage years, although adult patients with milder manifestations of the syndrome have also been described. Type-I AME can readily be diagnosed by determination of the urinary tetrahydrocortisol and tetrahydrocortisone or serum cortisol-to-cortisone ratios.

GENETIC BASIS OF DISEASE   HSD is a microsomal enzyme complex responsible for the interconversion of cortisol and cortisone. Two isoforms, encoded by two different genes, have been described; the type I isoform (HSD11B1) has two separate enzymatic activities: 11-β-dehydrogenase (which converts cortisol to cortisone) and 11-oxoreductase (which converts cortisone to cortisol). The type II isoform (HSD11B2) has only the first activity. Aldosterone is normally a much stronger mineralocorticoid than cortisol in vivo, yet both steroids have identical affinities in vitro for the aldosterone receptor. *In vivo*, certain tissues with this receptor are aldosterone selective (e.g., kidney and parotid), whereas others with the same receptor are not (e.g., hippocampus and heart). Thus, the dehydrogenase activity of HSD11B2, by converting cortisol to the inactive cortisone, is thought to be necessary to protect the renal mineralocorticoid receptor from the circulating cortisol (which has normally manyfold higher serum levels than aldosterone), allowing aldosterone to regulate sodium homeostasis in the renal tubule. The gene for HSD11B1 on chromosome 1 was first investigated for mutations in patients with AME, with negative results. The HSD11B2 gene was then cloned and mapped to chromosome 16q22. The HSDK gene shares only 14% homology with that of HSD11B1, has a total length of 6.2 kb, and consists of five exons. Defects of this gene were recently reported in eight kindreds with AME. All of the mutations were in or close to the catalytic domain of the enzyme, and resulted in decreased activity when tested in vitro. Partial correlation between phenotype and genotype was evident in these studies because patients with no detectable enzymatic activity of the in vitro mutant protein

had the highest tetrahydrocortisol and tetrahydrocortisone ratio. Interestingly, intrauterine growth retardation (IUGR), a previously unrecognized manifestation of AME, was seen in the majority of the patients. Because HSD11B2 is highly expressed in the placenta, IUGR in AME patients was attributed to the placental deficiency of the enzyme. One of the investigated kindreds did not harbor mutations of the *HSDK* gene demonstrating genetic heterogeneity for the disease.

CLINICAL MANAGEMENT Patients with congenital AME respond to treatment with spironolactone (50–200 mg/d) and low-sodium diet. Early diagnosis and treatment are essential to avoid complications of hypertension.

IMPLICATIONS FOR FUTURE AND PATHOPHYSIOLOGY The finding that patients with AME and mutations of the *HSDK* gene have IUGR correlates well with the observation that low-birth-weight infants are at increased risk for developing essential hypertension in later life. It is possible that genetic variations of HSD11B2 enzymatic activity have significant effects on fetal growth and on subsequent risk of hypertension. The *HSDK* gene may, thus, be one of the polygenes that cause essential hypertension.

CARNEY COMPLEX

BACKGROUND Carney complex (CC, OMIM 160980) is a familial multiple neoplasia (endocrine tumors and myxomas) and lentiginosis syndrome that is inherited in an autosomal dominant manner. Although the existence of the complex as an unrecognized, inherited syndrome was first suggested in 1985, combinations of several components of the syndrome and their familial occurrence had been reported earlier. Thus, the characteristic pathologic findings of the adrenal glands (primary pigmented nodular adrenocortical disease [PPNAD])—multiple, small, pigmented, adrenocortical nodules and internodular cortical atrophy—and a pituitary-independent, primary adrenal form of hypercortisolism were described in children and young adults with Cushing's syndrome as early as 1949. In the late 1970s, several familial cases of cutaneous and cardiac myxomas associated with lentigines (lentigo simplex) or ephelides and blue nevi of the skin and mucosae had been described under the acronyms, NAME (for nevi, atrial myxoma, myxoid neurofibromata, and ephelides) and LAMB (for lentigines, atrial myxoma, mucocutaneous myxoma, blue nevi) syndromes. The presence of "adrenal-stimulating immunoglobulins" leading to corticotropin-independent adrenocortical nodular hyperplasia in affected subjects was suggested in 1989.

CLINICAL MANIFESTATIONS Carney complex is manifested in children and young adults with at least two of the following: (1) PPNAD that can lead to Cushing's syndrome; (2) lentigines, ephelides, and blue nevi of the skin and mucosae; and (3) a variety of nonendocrine and endocrine tumors. The latter include myxomas of the skin, heart, breast, and other sites, psammomatous melanotic schwannoma, growth hormone-producing pituitary adenoma, testicular Sertoli cell tumor, and possibly other benign and malignant neoplasms, including tumors of the thyroid gland and ductal adenoma of the breast.

GENETIC BASIS OF DISEASE The chromosomal loci, where the genes for Carney complex reside were recently mapped by linkage analysis on chromosomes 2 and 17 (Fig. 53-2). Eleven kindreds with the disease were investigated with the use of highly polymorphic markers from areas of the human genome likely to be involved. Because telomeric translocations of chromosome 2 had
Figure 53-2 (A) Cytogenetic map of chromosome 2p16 with the corresponding genetic map. The genetic distances are expressed in centiMorgans (cM). The Carney complex critical region is bordered by markers D2S123 and D2S378. The gene responsible for microsatellite stability in dividing human cells *hMSH2* was excluded as a potential candidate for Carney complex, although it is located in close proximity to the disease locus. (B) Loss of heterozygosity and other changes in tumors from patients with Carney complex. B, blood; T, tumor. The disease is genetically heterogeneous.

been observed in cardiac myxomas and the gene that codes for POMC is located on the short arm of chromosome 2 (2p), this chromosome was examined for linkage. A maximal two-point lod score greater than 3 was obtained for three markers on the short arm of chromosome 2. The markers CA-5, CA-2, and *D2S123* produced lod scores of 3.26 ($\theta = 0.07$), 5.97 ($\theta = 0.03$), and 3.73 ($\theta = 0.04$), respectively. The *D2S123* locus has been linked to hereditary non–polyposis colorectal cancer (HNPCC) and a detailed map of this area of the short arm of chromosome 2p is available. A polymorphic marker from within the coding sequence of the POMC gene excluded the latter as a candidate gene for this disorder. Another gene located in the area, the *hMSH2* gene, responsible for DNA stability and tumor suppression, which was found mutated in HNPCC, was also excluded by the recombination events observed in chromosomes of patients with the disease. Multipoint linkage analysis defined a region approximately 4 cM long bordered by the CA-2 and *D2S378* markers as the most likely area harboring the responsible gene(s). The absence of other polymorphic markers from the area precluded a more refined mapping at the time. An additional genetic locus was recently identified, indicating that Carney complex is genetically heterogeneous.

CLINICAL MANAGEMENT Patients with the diagnosis of Carney complex need to undergo extensive and frequent monitoring for the detection and early treatment of the multiple tumors that are associated with this condition. Heart myxomas, if undiagnosed, can lead to sudden death, strokes, or peripheral embolization; thus, annual screening by echocardiography is recommended in patients with the complex and their families. If PPNAD is diagnosed, then bilateral adrenalectomy and lifelong glucocorticoid and mineralocorticoid replacement are recommended.

IMPLICATIONS FOR FUTURE   The lesions associated with the complex originate from cells of mesenchymal (myxomas) or neural crest origin (spotty skin pigmentation, endocrine tumors). These features suggest that the genetic defects leading to Carney complex are involved in early development, growth, and proliferation of affected cells. Thus, candidate genes include those involved in tumor suppression and the control of the cell cycle, as well as those with specific effects on the function and growth of mesenchymal and zona fasciculata cells and melanocytes. Because there is considerable overlap between Carney complex and the familial lentiginosis syndromes (Peutz-Jeghers syndrome and others), it is expected that the Carney complex genes will contribute to the identification of the as-yet-unknown genetic defects responsible for the various lentiginoses.

ADRENAL CORTEX NEOPLASMS

BACKGROUND   Cushing's syndrome because of adrenocortical tumors was reported at the turn of the century, almost a decade before the description of the syndrome and homonymous disease by Harvey Cushing. Since then, a great deal about adrenocortical tumors has been learned, although the treatment of adrenocortical malignancies has remained an utter frustration for the clinician. Hope for new treatments, however, recently sprang from the identification of at least two genetic defects leading to adrenal cancer. Somatic and germline mutations of the *p53* tumor suppressor gene are responsible for sporadic and inherited adrenal cancer, respectively. The latter is part of Li-Fraumeni syndrome (LFS, OMIM 151623), a familial multiple neoplasia syndrome that is inherited in an autosomal dominant manner. Another genetic condition associated with adrenal carcinoma and other tumors is the Beckwith-Wiedemann syndrome (BWS, OMIM 130650), which has been mapped to chromosome 11p15.5, and its inheritance is autosomal dominant but influenced by genomic imprinting and uniparental disomy.

CLINICAL MANIFESTATIONS   Small benign adrenocortical tumors are present in up to 7% of adults older than 50 years of age. Usually, they are discovered incidentally, in the context of abdominal computed tomography (CT) or magnetic resonance imaging (MRI) scans performed for other reasons. The vast majority of these tumors are hormonally silent. Hormone-secreting benign adrenal adenomas are rare, and equally rare are hormonally silent or hormone-secreting adrenocortical carcinomas. Malignant neoplasias of the adrenal cortex account for 0.05–0.2% of all cancers. They occur in all ages, from early infancy to the seventh and eighth decades of life, although a bimodal age distribution has been reported with the first peak occurring before 5 years of age, and the second in the fourth to fifth decade. The most common syndrome associated with adrenal tumors is Cushing's syndrome, which is present in 30–40% of adult patients with adrenal cancer. Virilization, on the other hand, is present in 20–30% of adults, but is the most common clinical syndrome encountered in children with adrenocortical carcinoma. It is caused by hypersecretion of DHEA and its sulfated derivative (DHEA-S), as well as other adrenal androgens and steroid precursors, by the tumor. Feminization and hyperaldosteronism are rare clinical syndromes associated with hormonally active adrenal tumors. Hormonally silent tumors are either found incidentally or present with abdominal pain and fullness or by the symptoms of metastatic disease, which can involve locally the kidneys and inferior vena cava, and distally the liver, lungs, and bones.

GENETIC BASIS OF DISEASE   Adrenal neoplasms were recently found to be monoclonal, like most other tumors, by X-chromosome inactivation analysis. Components of the G protein signaling pathway and the receptors coupled to it have been considered good candidate genetic defects leading to adrenal cancer. However, mutations of the ACTH receptor (MC2) or the Gs and Giα2 genes are not present in large series of sporadic adrenal tumors that have been investigated, although mutations of the Gsα gene cause macronodular adrenal disease and can lead to ACTH-independent Cushing's syndrome in McCune-Albright syndrome. A single case of an activating mutation of the MC2 gene leading to adrenal macronodular disease and Cushing's syndrome has also been reported.

Mutations of the *p53* tumor suppressor gene have been found in patients with LFS and many sporadic adrenal carcinomas. These are genetic defects that lead to loss of the normal inhibitory function of the p53 protein on the cell cycle and are concentrated in a highly conserved region of the gene between exons 5 and 8. The *p53* gene is located on chromosome 17p13.1; loss of heterozygosity (LOH) at this locus in a cell that has either undergone a somatic mutation or carries a germline genetic defect of the *p53* gene in the remaining allele leads to tumorigenesis ("two hit" or Knudson's hypothesis) (*see* Chapter 7). A locus on chromosome 11p15.5 has been implicated in BWS. One of the genes in this region encodes p57^{KIP2}, which is a potent inhibitor of several of the G1 cyclin/Cdk complexes and a negative regulator of cell proliferation. Like other genes in this region, p57^{KIP2} is imprinted, and the maternal allele is expressed. In a series of nine patients with BWS, two were heterozygous for mutations in p57^{KIP2}. One was a missense mutation that resulted in a severely truncated protein, whereas the other was a frameshift mutation that would alter protein function. In the case of the missense mutation, transmission of the mutated allele from the mother was documented; thus the single allele expressed in the patient was the mutant allele. Whether the other patients have reduced expression of p57^{KIP2} or involvement of another locus has not yet been determined. Consistent with a role of p57^{KIP2} in BWS, knockout of the p57^{KIP2} gene in mice results in a syndrome with phenotypic features seen in BWS, including adrenocortical hyperplasia.

CLINICAL MANAGEMENT   The treatment of all primary adrenal tumors is surgical. Adrenal adenomas should be removed with the whole ipsilateral adrenal gland, and the contralateral gland should be examined for tumor. Complete resection of the tumor is the treatment of choice for adrenal carcinoma. If the patient does not have surgically curable disease, therapy with o,p'-DDD (mitotane) is usually initiated. o,p'-DDD, an adrenocytolytic agent given at maximally tolerated oral doses (up to 10 g/m^2/d), ameliorates the endocrine syndrome in approximately two-thirds of patients. Tumor regression or arrest of growth has been observed on as many as one third of patients. However, mean survival does not appear to be altered, although there are patients with unresectable carcinomas who achieved long-term survival. The prognosis of primary adrenal adenomas is excellent, but that of adrenal carcinomas generally poor, with a mean survival of approximately 18 months, although cures have been achieved for patients operated on early, while the tumor was still encapsulated.

CONCLUDING REMARKS

In addition to the diseases discussed, the genes for a number of genetic conditions that involve the adrenal glands or their targets

have been cloned during the last decade. These include the genes for multiple endocrine neoplasia (MEN)-2A and -2B (*RET* proto-oncogene) and Von Hippel-Lindau's disease, which are associated with pheochromocytoma, the genes for other phacomatoses, such as neurofibromatosis -I and -II and tuberous sclerosis, which are associated with tumors of primarily the adrenal medulla and sympathetic ganglia, and the gene for MEN-1, which is associated with adrenal benign nodules. The genetic locus for multiple autoimmune endocrinopathy type-I (MAE-I), which is associated with autoimmune Addison's disease and failure of other endocrine glands, has been mapped to chromosome 21p, and was just cloned (the APECED gene). Additionally, new genes have been identified that appear to play an important role in adrenal development and physiology in transgenic animal studies, although a human disease has not been reported to be caused by them as yet. The most important appears to be a cell-specific orphan nuclear receptor, designated steroidogenic factor 1 (SF-1), which is a key regulator of the steroidogenic enzymes in the adrenal glands and elsewhere. Targeted disruption of the *Ftz-F1* gene, which encodes SF-1 in mice, caused congenital absence of the adrenal glands and gonads in both sexes, and gender reversal of the male animals. It has been suggested that mutations of the human SF-1 gene will also result in adrenal hypoplasia or aplasia and gonadal dysgenesis. Since the era of molecular medicine continues unabated, many new exciting discoveries are expected in the molecular medicine of the adrenal glands in the years to come.

54 Multiple Endocrine Neoplasia Type 2

ROBERT F. GAGEL, SARAH SHEFELBINE, AND GILBERT COTE

BACKGROUND

Less than four decades ago, John Sipple first described components of the clinical syndrome that now bears his name. Recognizing the association of thyroid cancer and bilateral pheochromocytomas in a patient at autopsy he reported this case along with several others in a 1961 article. Others more clearly defined the type of thyroid carcinoma and separated the clinical features of this syndrome, defined as multiple endocrine neoplasia type 2 (MEN-2), from multiple endocrine neoplasia type 1 (OMIM 131100) (Table 54-1).

CLINICAL FEATURES

MEN-2 consists of medullary thyroid carcinoma (MTC), pheochromocytoma, and hyperparathyroidism inherited as an autosomal dominant trait. The nomenclature for this disease syndrome has evolved during the decades since its initial description; a current classification system that reflects the clinical features and molecular causes is shown in Table 54-1. The syndrome originally described by Sipple has been classified as MEN-2A (OMIM 171400). It consists of MTC in nearly all gene carriers, pheochromocytoma in one-half, and hyperparathyroidism in 10–20% (Table 54-1). Characteristics of all neoplastic components associated with MEN-2 are bilaterality and multicentricity. This is especially important for MTC in which surgical cure is possible only by removal of all thyroid tissue.

There are three variants of MEN-2A: familial medullary thyroid carcinoma (FMTC); MEN-2A with cutaneous lichen amyloidosis (MEN-2A/CLA); and MEN-2A with Hirschsprung disease (Table 54-1). Medullary thyroid carcinoma in FMTC is inherited as an autosomal dominant trait without other features of MEN-2A. The MTC associated with FMTC tends to be less aggressive and is most likely to be confused with sporadic MTC because other manifestations of MEN-2A are not present, and many affected family members may be asymptomatic. A diagnosis of FMTC should be made only in large, multigenerational families because of the incomplete penetrance (50% or less) for other manifestations of MEN-2A. The MEN-2A/CLA variant, found in approximately 18 kindreds worldwide, is the association of MEN-2A with a characteristic pruritic skin lesion located over the central upper back. The clinical features, other than the skin lesion, are identical to classic MEN-2A, although hyperparathyroidism appears to be less common. Finally, a handful of families have been described

with MEN-2A and Hirschsprung disease. The penetrance of the Hirschsprung phenotype is variable, ranging from complete penetration to a single affected member.

MEN-2B (OMIM 162300) is characterized by MTC and pheochromocytoma, as well as a unique phenotype of marfanoid habitus and mucosal, oral, and intestinal ganglioneuromatosis (Table 54-1). This disorder is transmitted as an autosomal dominant trait, although the majority of cases represent *de novo* mutations; the mutant allele is inherited from the father and the mutation is thought to occur during spermatogenesis. Medullary thyroid carcinoma associated with MEN-2B is more aggressive than that observed in MEN-2A. Development of carcinoma during the first year of life is common, and early death from metastatic MTC occurs in 30–40% of patients. The prognosis, however, is not universally poor. A number of multigeneration families suggests considerable variability in the outcome.

DIAGNOSIS

MEN-2 is a clinical syndrome that affects multiple endocrine organs. Medullary thyroid carcinoma and pheochromocytoma are the most common causes of morbidity and death. Hyperparathyroidism and its associated findings of hypercalcemia, nephrolithiasis, and bone loss are less commonly a clinical problem.

The C cell, the cell type comprising MTC, produces a small peptide hormone, calcitonin. The circulating concentration of this peptide is normally less than 10 pg/mL. In patients with MTC, serum calcitonin values are characteristically elevated and secretion may be stimulated 3- to 20-fold higher by intravenous pentagastrin, calcium, or a combination of the two. Prospective studies using provocative testing with pentagastrin or the combination of calcium and pentagastrin have been used successfully to identify MTC early in the course of the disease. Prospective pentagastrin screening and thyroidectomy have improved survival and quality of life in these kindreds, although not all children or young adults are cured with this approach. As many as 10–15% of these patients have evidence of recurrent disease in long-term follow-up studies. Whether earlier or more complete thyroidectomy based on genetic testing (to be discussed in the next section) will improve outcome is not certain and is currently under investigation.

Pheochromocytoma occurs in approximately 50% of family members with MEN-2. These tumors cause palpitations, headaches, and attacks of nervousness early in the course of tumor development; hypertension is infrequently found at this stage. In patients with large or bilateral tumors, hypertension and cardiac

Table 54-1
The Multiple Endocrine Neoplasia Syndromes

Multiple endocrine neoplasia type 1 (MEN-1)
 Pituitary tumors
 Parathyroid neoplasia
 Islet cell neoplasia
Multiple endocrine neoplasia type 2 (MEN-2)
 Multiple endocrine neoplasia type 2A (MEN-2A)
  Medullary thyroid carcinoma 100%
  Pheochromocytoma 50%
  Parathyroid neoplasia (10–20%)
 Variants of MEN-2A
  Familial medullary thyroid carcinoma (FMTC)
  MEN-2A with cutaneous lichen amyloidosis (MEN-2A/CLA)
  MEN-2A with Hirschsprung disease
 Multiple endocrine neoplasia type 2B
  Medullary thyroid carcinoma (100%)
  Pheochromocytoma (50%)
  No parathyroid disease
  Marfanoid habitus (nearly 100%)
  Intestinal ganglioneuromatosis and mucosal neuromas (nearly 100%)

---

arrhythmias may occur. Before the recognition of this syndrome in 1961 at least one-half of the deaths in MEN-2 kindreds occurred suddenly and were attributed to cardiac disease; many were no doubt related to pheochromocytoma. The goal of screening for pheochromocytoma in kindreds with MEN-2 is to identify an adrenal tumor before it causes significant or life-threatening manifestations of catecholamine excess. One successful approach is the routine annual collection of a 12- or 24-h urine for catecholamines or metanephrines. Symptomatic patients will frequently have an elevation of either the plasma or urine catecholamines or metanephrine. Patients with abnormal values should have imaging studies. Computerized tomography provides better definition of the adrenal medulla and is less expensive. Magnetic resonance imaging provides greater specificity if the adrenal medulla lights up on T2-weighted images.

The major diagnostic problems occur at the transition between the normal and slightly abnormal state. Patients may have symptoms suggestive of pheochromocytoma with normal catecholamine measurements and imaging studies. In this situation the differentiation between intermittent abnormal catecholamine secretion and an anxiety disorder can be difficult. A trial of adrenergic blockade or inhibition of catecholamine synthesis with α-methyltyrosine may help separate these two possibilities. If the patient is improved by pharmacologic intervention and surgery is contemplated, the choice of which adrenal to remove may be difficult. Two approaches have been applied in this situation. The first is to continue adrenergic blockade or catecholamine synthesis inhibition for 1–2 years, during which time a radiologic abnormality may appear; second, octreotide or met iodobenzylguanidine scanning may occasionally identify the abnormal adrenal medulla.

GENETIC BASIS OF MEN-2

MAPPING THE CAUSATIVE GENE   The identification of polymorphic DNA sequences throughout the human genome in the late 1970s led to a resurgence of interest in genetic linkage approaches to the identification of disease genes. A well-defined phenotype and large families made MEN-2 an ideal syndrome in which to apply this new technology. Progress was slow because of the lack of evenly spaced polymorphic markers throughout the genome and the necessity to use Southern blotting techniques rather than the current polymerase chain reaction techniques. The gene was mapped to centromeric chromosome 10 in 1987. Subsequent work by many groups narrowed the region containing the MEN-2 gene, leading to the identification of mutations of the c-*ret* proto-oncogene (OMIM 164760) in 1993 (Fig. 54-1).

The c-*ret* proto-oncogene was first discovered in 1985 when a rearranged form of this gene was shown to cause transformation. The c-*ret* proto-oncogene encodes a tyrosine kinase receptor. A naturally occurring rearrangement was subsequently identified in 10–35% of papillary thyroid carcinomas and named the papillary thyroid carcinoma or PTC oncogene. Three different PTC variants exist, each resulting from a chromosome 10 rearrangement that places the tyrosine kinase domain of the c-*ret* proto-oncogene under the transcriptional control of another constitutively expressed gene (OMIM 164761 and 188550). There is compelling evidence that the c-*ret* rearrangement causes transformation of the thyroid follicular cell in animal models of papillary thyroid carcinoma.

THE RET/GLIAL CELL-DERIVED NEUROTROPHIC FACTOR RECEPTOR SYSTEM   A remarkable series of studies during the past 3 years have defined a tyrosine kinase receptor signaling system important for the development of the gastrointestinal neuronal system, the kidney, and several components of the sympathetic nervous system. The first important discovery was the development of profound gastrointestinal and renal abnormalities in mice in which the c-*ret* proto-oncogene was inactivated. Detailed studies in these animals showed gastrointestinal neuronal features analogous to those found in Hirschsprung disease with incomplete development of the enteric nervous system. There was also a complete lack of renal development in these animals. Components of the sympathetic nervous system, including the superior cervical ganglion, were also underdeveloped. The second important discovery was the finding that mice in which the gene for glial cell-derived neurotrophic factor (GDNF; OMIM 600837) had been inactivated demonstrated a phenotype analogous to that seen in the animals with a c-*ret* proto-oncogene knockout. These studies also illuminated the mechanism by which GDNF and Ret interact to promote normal renal development (Fig. 54-2). The ureteric bud (the developing renal ureteral collecting system) normally penetrates the metanephric blastema and branches to form the collecting system (Fig. 54-3). Recent studies have shown that the peptide GDNF is expressed in the developing metanephric blastema and interacts with the Ret receptor in the ureteric bud to promote normal interaction and branching of the ureteric bud into the developing kidney. Available facts suggest a similar pattern of interaction between Ret and GDNF in the developing enteric neuronal system. What is clear is that Ret is expressed in neural crest cells associated with somites 1–5. These Ret-positive cells migrate into the spinal cord and into the developing gastrointestinal tract during embryonic life. The finding of incomplete neuronal development in both the Ret and GDNF knockouts provides compelling evidence for an interaction between the ligand–receptor system of importance in neuronal innervation of the intestine (Fig. 54-3).

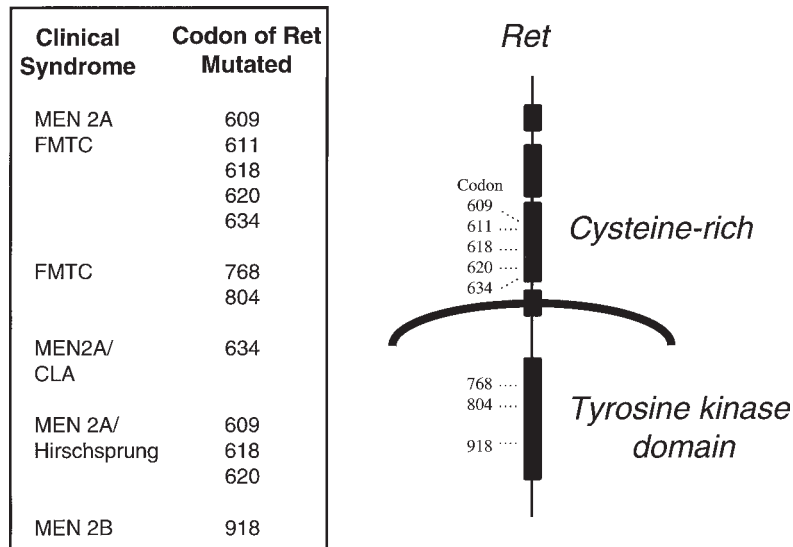
In an independent series of experiments, researchers discovered a receptor for GDNF, termed GDNFR-α, and showed it to complex with the Ret tyrosine kinase receptor to form a receptor for GDNF (OMIM 601496). This receptor system is unique because GDNFR-α is an extracellular protein that complexes with the Ret receptor, although specific details are sketchy (Fig. 54-2).


Figure 54-1 Mutations of the c-*ret* proto-oncogene associated with hereditary medullary thyroid carcinoma. The most common mutations affect two regions of the Ret tyrosine kinase. Mutations of an extracellular cysteine domain (codons 609, 611, 618, 620, 630, 634), important for dimerization of the receptor, cause MEN-2A and its variants. Mutations of the tyrosine kinase domain are found in MEN-2B (codons 918, 883) and a few families with FMTC (768, 804, 891). Mutations of codons 790 and 791 have been identified in MEN-2A. MEN-2A, multiple endocrine neoplasia type 2A; FMTC, familial medullary thyroid carcinoma; MEN-2A/CLA, MEN-2A/cutaneous lichen amyloidosis; MEN-2A/Hirschsprung, MEN-2A/Hirschsprung disease variant; and MEN-2B, multiple endocrine neoplasia type 2B.
Figure 54-2 The Ret/GDNFR-α signaling system and the effect of c-*ret* proto-oncogene mutations on signaling. **(A)** Proposed model for the Ret/GDNFR-α receptor system. It is known that GDNF will bind to GDNFR-α. It is hypothesized that GDNFR-α transmits the signal to Ret to effect autophosphorylation and phosphorylation of downstream effector proteins. **(B)** Effect of a codon 634 mutation on Ret activation. Mutation of the extracellular domain results in dimerization of Ret, autophosphorylation, and phosphorylation of downstream substrates in the absence of GDNF. There is currently no evidence for or against participation of GDNFR-α in this process. **(C)** Effect of a codon 918 mutation on Ret activation. Mutation of the tyrosine kinase domain causes autophosphorylation and phosphorylation of a different set of downstream substrate proteins in the absence of Ret dimerization. There is currently no knowledge of GDNFR-α participation.

In the broader perspective these studies provide insight into an important neural crest development pathway. Studies of Ret expression in developing embryos have shown Ret expression in neural crest derived from somites one to five. Between days 9 and 10.5 there is migration of Ret-positive cells from the neural crest into the developing spinal cord and gastrointestinal tract (Fig. 54-4). It is possible to envision a trophic effect of GDNF interaction with Ret (and possibly GDNFR-α) to entice neural crest cells into their normal developmental location. Further studies of this system will lead to a greater understanding of these pathways.

MUTATIONS OF THE c-*ret* PROTO-ONCOGENE ASSOCIATED WITH MTC   The mutations of c-*ret* in MEN-2 affect two domains within the Ret tyrosine kinase receptor. Mutations of a cysteine-rich region of the extracellular domain are the most common mutations found in MEN-2 and its variants (Fig. 54-1). Each of these point mutations convert a conserved cysteine at codons 609, 611, 618, 620, or 634 to another amino acid. A single mutation, Cys634Arg, accounts for more than 50% of all mutations associated with hereditary MTC, and more than 75% of all mutations affect codon 634. Genotype–phenotype correlation shows that a codon 634 mutation is most commonly associated
Figure 54-3   Schematic view showing mouse embryonic kidney development. The ureteric bud, derived from the Wolffian duct, normally migrates into the developing metanephric blastema to form the collecting system. In either Ret (Ret –/–) or GDNF (GDNF –/–) knockouts there is a defect in migration of the ureteric bud into the metanephric blastema resulting in a failure of normal kidney development.
Figure 54-4   Migration of neural crest cells expressing the Ret tyrosine kinase into the developing spinal cord and gastrointestinal tract. Ret-expressing cells form the superior cervical ganglion (SCG), parts of the dorsal root of the spinal cord, and the enteric neuronal plexus of the gastrointestinal tract.

with classic MEN-2A or Sipple's syndrome. Mutations of the codons found in exon 10 (609, 611, 618, 620) are most commonly found in FMTC. Despite these correlative efforts, any of the extracellular cysteine mutations can be associated with MEN-2A or FMTC, a point of importance in the clinical management of kindreds with these mutations. More recently, codon 790 and 791 mutations have been identified in MEN-2A and FMTC. A clinician should not conclude that an individual with an exon 10 mu-

tation will not develop a pheochromocytoma unless there are multiple generations within a family that have not developed pheochromocytoma. All patients with the MEN-2A/CLA syndrome have codon 634 mutations.

Germline mutations of the tyrosine kinase domain are found in MEN-2B (Met918Thr) and FMTC (Glu768Asp and Val804Leu) (Fig. 54-1). Two families with FMTC and germline codon 891 mutations have been identified. Ninety-five percent of patients

with MEN-2B have the Met918Thr substitution or a mutation at codon 883 (Fig. 54-1); the mutation in the remaining 5% has not been identified. In the handful of kindreds with the codon 768 and 804 mutations the only clinical phenotype is familial MTC (Fig. 54-1).

Additional evidence for the oncogenicity of these mutations came from studies in which expression of mutant c-*ret* proto-oncogene in NIH-3T3 cells caused transformation. These studies showed that codon 634 mutation resulted in dimerization of the Ret tyrosine kinase receptor in the absence of its ligand, leading to autophosphorylation and phosphorylation of downstream proteins (Fig. 54-2). Transfection of the c-*ret* cDNA containing the Met918Thr mutation also causes transformation, although dimerization of the receptor does not occur and a different set of substrate proteins are phosphorylated (Fig. 54-2). Although not described, mutations of GDNF or GDNFR-α may be found in the small percentage of kindreds in whom mutations of the c-*ret* proto-oncogene have not been identified.

MUTATIONS OF THE c-*ret* PROTO-ONCOGENE ASSOCIATED WITH HIRSCHSPRUNG DISEASE

Two independent lines of analysis led to the identification of mutations of the c-*ret* proto-oncogene in patients with Hirschsprung disease (OMIM 142623). The identification of a chromosome 10 deletion in a child with Hirschsprung disease led to mapping studies in familial Hirschsprung disease, which localized the causative gene to proximal chromosome 10q. Subsequent investigations identified inactivating and presumed activating mutations of the Ret tyrosine kinase in Hirschsprung disease. Analyses of kindreds in which MEN-2A and Hirschsprung disease cosegregate (Table 54-1) have identified codon 609, 618, or 620 mutations of the c-*ret* proto-oncogene. Mutations of the endothelin-B receptor gene (OMIM 131244) and its ligand, endothelin-3 (OMIM 131242), have also been identified in Hirschsprung disease. There are preliminary reports of mutations of the GDNF gene in Hirschsprung disease, although their significance is unclear; it seems likely that mutations of the GDNFR-α gene will be identified in this disorder.

Mutation analysis is readily available from several commercial sources.* Several techniques have been applied to detection of mutations, including direct DNA sequencing and restriction analysis for specific mutations, denaturing gradient gel electrophoresis, and reverse dot-blot analysis. All of these techniques are reproducible and performed on a whole blood sample from the patient. There are a few caveats. Genetic testing, like most other forms of laboratory analysis, will be associated with a small error rate caused by sample mixup, contamination of the PCR reaction, failure of specific primers to amplify the mutant allele, or technician copying errors, collectively estimated in the range of 5%. Before a decision is made to consider surgical intervention in a gene carrier or to eliminate an MEN-2 kindred member with a normal analysis from further screening, the test should be performed on a separately obtained and independently analyzed blood sample.

MUTATIONS OF THE c-*ret* PROTO-ONCOGENE IN SPORADIC MTC

Somatic Met918Thr mutations of the c-*ret* proto-oncogene have been identified in approximately 25% of sporadic MTCs. There is suggestive but incomplete evidence that suggests that tumors with this particular mutation may pursue a more aggressive clinical course. It is important to consider c-*ret* proto-oncogene analysis in patients with apparent sporadic MTC because a compilation of available information suggests that 5–7% of patients with apparent sporadic MTC have germline mutations of the c-*ret* proto-oncogene.

MANAGEMENT AND TREATMENT

MANAGEMENT OF MEDULLARY THYROID CARCINOMA

Negative Genetic Test Results   The availability of reliable genetic testing makes it possible to identify gene carriers with near certainty. Children with negative test results in a kindred in which a c-*ret* mutation has been identified can be excluded from further screening studies. It is important to repeat the analysis on more than one blood sample to be certain of the test results. This is especially true of individuals who have a normal Ret analysis and will receive no further screening.

Positive Genetic Test Results   There is incomplete agreement on how gene carriers should be managed. One approach is to continue pentagastrin testing on an annual basis with removal of the thyroid gland at the time of a first abnormal test. A 25-year experience with prospective screening using calcitonin measurements after pentagastrin stimulation indicates that 85–90% of children with MEN-2A can be cured by early thyroidectomy performed at the time of first positive pentagastrin or calcium-pentagastrin test. However, 5–15% of children with abnormalities detected by pentagastrin testing have developed probable metastatic MTC at a later date, suggesting either undetected metastatic spread at the time of thyroidectomy or incomplete thyroidectomy with subsequent transformation of residual C cells. This issue and the identification of a 6-year-old child with metastatic MTC in the context of MEN-2A has led a large percentage of clinicians who deal with this disease to recommend thyroidectomy based solely on genetic testing. The age of 5 years has been somewhat arbitrarily chosen as an appropriate age at which to perform thyroidectomy for several reasons: the child is old enough to understand the procedure; the surgical anatomy of the neck is easily delineated; and parents have less anxiety about performance of a thyroidectomy at this age. The belief is that early and complete thyroidectomy will improve the cure rate beyond the earlier reported figures of 85–90%, a rationale for which there is no current proof.

The completeness of thyroidectomy may be important. It is difficult to perform a total thyroidectomy without damage to the posterior capsule of the thyroid gland, leading to a higher incidence of hypoparathyroidism, a situation most surgeons choose to avoid. A few normal C cells in residual thyroid tissue attached to the posterior capsule may be of little concern in a 40- to 50-year-old patient, but there is the real possibility that a few normal cells expressing mutant Ret in a 5-year-old child may transform during a several decade follow-up. This concern has led some clinicians to recommend a total thyroidectomy, including the posterior capsule, central lymph node dissection, and transplantation of parathyroid tissue to the nondominant arm. Whether this approach will improve the already excellent long-term cure rate for this disease is unclear but seems worthy of investigation.

Another reason to consider thyroidectomy based on genetic testing is the relative insensitivity of pentagastrin testing. Thyroidectomy based on genetic testing has identified microscopic or macroscopic MTC in approximately one-half of patients with normal pentagastrin or calcium-pentagastrin tests. These results indicate that pentagastrin or combined calcium-pentagastrin testing is an insensitive technique for detection of early MTC in MEN-2A or FMTC, leaving open the possibility that metastasis may already have occurred in some patients at the time of thyroidectomy. When one combines all of these factors, performance of a thyroidectomy at the earliest possible age seems the most prudent course.

Children with MEN-2B should have a thyroidectomy performed during the first months of life because of the high probability of early metastasis. Whether early intervention will alter the long-term course of this disease is not currently known.

MANAGEMENT OF PHEOCHROMOCYTOMA   The advent of genetic testing will have little impact on the management of pheochromocytoma in MEN-2 other than to exclude 50% of family members with normal genetic tests from further screening. Patients with pheochromocytomas should have unilateral or bilateral adrenalectomy. The issues related to unilateral or bilateral adrenalectomy in this disease have been discussed in detail elsewhere and will not be reviewed in this chapter. Patients with abnormal catecholamine secretion should have adrenal surgery performed before consideration of thyroidectomy.

MANAGEMENT OF HYPERPARATHYROIDISM   Hyperparathyroidism occurs infrequently in children who have received prophylactic thyroidectomy for MTC. In one series there have been no cases of hyperparathyroidism in children who received thyroidectomy at a mean age of 13 years with a mean follow-up period in excess of 20 years. There is debate about the appropriate management of parathyroid neoplasia in older patients. Either subtotal parathyroidectomy or total parathyroidectomy with transplantation of parathyroid tissue to the nondominant forearm has been advocated.

FUTURE DIRECTIONS

Hereditary MTC is a rare disorder, but the specific molecular defect that causes this neoplastic syndrome provides a useful model in which to study strategies for inactivation of mutant Ret tyrosine kinase activity. The fact that a single gene defect causes three different neoplastic manifestations makes it an interesting model for study. Future strategies for prevention or treatment of this disease could include preimplantation screening with selection of embryos for implantation that do not carry the mutant Ret allele or strategies to inactivate or modify the mutant Ret mRNA. Although the cost of preimplantation screening is currently high, it seems likely that these costs would be recovered in a single generation with positive effects extending into future generations.

55 Molecular Mechanisms of Hypoglycemia Associated with Increased Insulin Production

Pamela M. Thomas, Gilbert J. Cote, and Robert F. Gagel

BACKGROUND

The differential diagnosis of hypoglycemia in the pediatric age group is broad (Table 55-1). In the neonatal period, transient hypoglycemia caused by hyperinsulinemia is common. It is, however, the rare newborn who presents with profound and prolonged hypoglycemia requiring substantial glucose replacement. When this is detected, it most commonly is caused by hyperinsulinism.

Persistent hyperinsulinemic hypoglycemia of infancy (PHHI), also known as familial hyperinsulinism or nesidioblastosis, is characterized by severe pancreatic islet β-cell dysfunction, which is manifest by secretion of insulin in an unregulated fashion despite life-threatening hypoglycemia. It is the most common cause of prolonged and severe hypoglycemia associated with hyperinsulinism in children. Description of this disorder as a unique clinical syndrome began 25 years ago with the association of nesidioblastosis, defined as the budding of isolated endocrine cells and islets from pancreatic duct cells, and severe infantile hypoglycemia. Recent findings have elucidated the molecular cause for hyperinsulinism in some families with this disorder and provided additional insight into the regulation of insulin secretion.

CLINICAL FEATURES

PHHI occurs in the setting of a normal pregnancy and the absence of maternal diabetes or blood type incompatibility. Presenting signs and symptoms of hypoglycemia include jitteriness, hypotonia, poor feeding, cyanosis, seizure, and sudden death. In addition to the symptoms and signs of hypoglycemia, increased adiposity may be noted during an otherwise normal examination. Approximately one-third of the children with clinical features of Beckwith-Wiedemann syndrome have hyperinsulinemic hypoglycemia. The relationship between PHHI and the Beckwith-Wiedemann syndrome, if any, is unknown. The incidence of PHHI has been estimated at 1/50,000 live births annually in a randomly mating Western European population. However, in a Saudi Arabian population, in which 50% of marriages were consanguineous, the incidence of this disorder was established as 1/2,675.

DIAGNOSIS

The diagnostic features of PHHI, listed in Table 55-2, are all attributable to the presence of hyperinsulinemia, which usually presents within the first year of life. The degree and persistence of hyperinsulinemia in PHHI are not seen in transient forms of hyperinsulinism. Histopathologic diagnosis is based on the presence of ductuloinsular complexes, islet hypertrophy, or islet cell proliferation.

GENETIC BASIS OF DISEASE

Recognition of familial forms of PHHI occurred after reports of affected siblings. Inheritance is in an autosomal recessive pattern. The increased incidence present in inbred populations is consistent with autosomal recessive inheritance.

The availability of well-characterized families allowed use of genetic linkage analysis for mapping of this disease gene. Glaser et al. reported linkage in 15 independent families, of which 12 were Ashkenazi Jewish, to the 6.6-cM interval between markers D11S926 and D11S928 on chromosome 11p. Subsequent analysis revealed evidence for a founder effect in the Ashkenazi Jewish ethnic population.

Using the homozygosity gene mapping strategy, we confirmed and narrowed the assignment of Glaser et al. The homozygosity gene mapping strategy is based on the premise that a rare disease in the affected progeny of a consanguineous mating is caused by inheritance of two identical copies of the disease gene from the common ancestor, a situation termed "homozygosity by descent." In addition, regions flanking the disease gene, calculated to be of a median length of 28 cM in first-cousin matings, will be homozygous by descent in most cases. Other regions of the genome will also be homozygous by descent, but such regions will vary among affected children. For an informative, tightly linked marker, the calculations of Lander and Botstein revealed that three first-cousin matings, each with a single affected offspring, will provide a LOD score >3.0, the accepted threshold for linkage. Ten or more nonrelated nuclear families with affected pairs of siblings would be required to generate a similar score. Study of progeny of five consanguineous families of Saudi Arabian origin, using the homozygosity mapping approach, allowed placement of PHHI to a 5-cM interval on chromosome 11p14–15.1, between markers D11S1334 and D11S899 (Fig. 55-1).

Table 55-1
Differential Diagnosis of Hypoglycemia in Children

Transient hypoglycemia
  Prematurity
  Small for gestational age
  Infants with systemic disease
  Infants of diabetic mothers
  Infants with erythroblastosis fetalis
Persistent hypoglycemia
  Hyperinsulinemia
    Persistent hyperinsulinemic hypoglycemia of infancy
    β-Cell adenoma
    Beckwith-Wiedemann syndrome
    Leucine sensitivity
    Exogenous insulin abuse
    Sulfonylurea use
  Hormone deficiency
    Growth hormone
    Cortisol
    Glucagon
    Panhypopituitarism
  Inborn error of metabolism
    Glycogen storage diseases

    Amino acid metabolism disorders

Table 55-2
Characteristics of Persistent
Hyperinsulinemic Hypoglycemia of Infancy

Inappropriate elevation of serum insulin despite the presence of
  hypoglycemia
Nonketotic hypoglycemia
Increased glucose utilization rate (requires glucose infusion
  >15 mg · kg^{-1} · min^{-1} to maintain euglycemia)
Glycemic response to glucagon

In vitro studies of PHHI have suggested a defect of glucose-regulated insulin secretion in pancreatic islet β cells. Assignment of the PHHI locus to chromosome 11p excluded known genes involved in β-cell function, including the glucokinase, islet glucose transporter, and glucagon-like peptide-1 receptor loci, as candidates for PHHI. Current models of insulin secretion propose that, as a result of glucose metabolism, increases in the intracellular ATP/ADP ratio in pancreatic β cells inhibit ATP-sensitive potassium (K_{ATP}) channels leading to β-cell membrane depolarization, opening of voltage-gated calcium channels, and ultimately an increase in exocytosis of insulin (Fig. 55-2). Therefore, candidate genes for PHHI included those involved in the β-cell glucose sensing mechanism and insulin secretion.

The high-affinity sulfonylurea receptor (SUR1), a subunit of the β-cell K_{ATP} channel, was considered as a candidate for the PHHI gene on the basis of its role as a modulator of insulin secretion. The human homolog of the SUR1 gene was localized to chromosome 11p15.1, the previously defined site of the PHHI locus, by fluorescent *in situ* hybridization, and this provided the impetus to begin mutational analysis.

Because of the presence of two nucleotide-binding fold (NBF) consensus sequences, the SUR1 is classified as a member of the ATP-binding cassette superfamily. Contained within the NBF regions are highly conserved phosphate-binding loops, termed "Walker motifs," that form intimate contact with the phosphates of bound nucleotide triphosphates. In other superfamily members, NBF-1 and NBF-2 have functional importance in the control of channel activity, through their interaction with cytosolic nucleotides. This class of molecules is involved in selective transport of substrate across the cell membrane against a concentration gradient using ATP hydrolysis as an energy source. Although each transporter is specific for a given substrate, the spectrum of substrates pumped by family members is diverse and includes amino acids, sugars, inorganic ions, polysaccharides, and peptides. The

substrate for the SUR1 has not been elucidated. Other well-known members of this family include the multidrug resistance proteins, and the cystic fibrosis transmembrane conductance regulator (CFTR). Mutations in the CFTR have been shown to cause the autosomal recessive disorder cystic fibrosis, and the more frequent and severe disease alleles are located in the regions of the two NBFs.

A search for mutations in the SUR1 gene in a group of Saudi Arabian individuals affected with PHHI revealed two separate point mutations in splice sites of the NBF-2 region (Fig. 55-3). The first of these mutations, G1400D(23)X, causes skipping of exon 35 of the SUR mRNA transcript with inclusion of a premature stop 24 codons later. The second mutation (3992–9 G→A) was identified in the 3' splice site sequence of exon 33, the first exon of the NBF-2 region. In the presence of this splice site mutation, three cryptic 3' splice sites were used in place of the wild-type splicing pattern, resulting in a 7-bp addition, a 20-bp deletion, or a 30-bp deletion to exon 33.

Mutation of the NBF-1 region of SUR1, like disruption of the NBF-2 region, leads to the PHHI phenotype. Three mutations of the NBF-1 region of SUR1, including one point mutation that disrupts the Walker A motif (G716V), and two that alter RNA processing in the region (1672–20 A→G and 2552–1G→A), have been associated with familial PHHI. These additional mutations establish that both NBF regions of SUR1 are required for normal function, because mutation of either completely voids the ability of SUR1 to regulate insulin secretion and results in the PHHI phenotype.

Two additional mutations have been described in SUR1 in those affected with PHHI. The first is an in-frame deletion within the NBF-2 region (ΔF1388); the combination of the 3992–9 G→A and ΔF1388 mutations accounted for 88% of the PHHI chromosomes in the cohort of 25 Ashkenazi Jews studied. The second is a point mutation, again within the NBF2 region (G1479R) of SUR1, described in a single patient of unestablished ethnic origin; this mutation has been demonstrated to alter the sensitivity of SUR1 to MgADP. A summary of the published SUR1 mutations, depicting their relative locations within the NBF regions of the SUR1 gene, appears in Fig. 55-3.

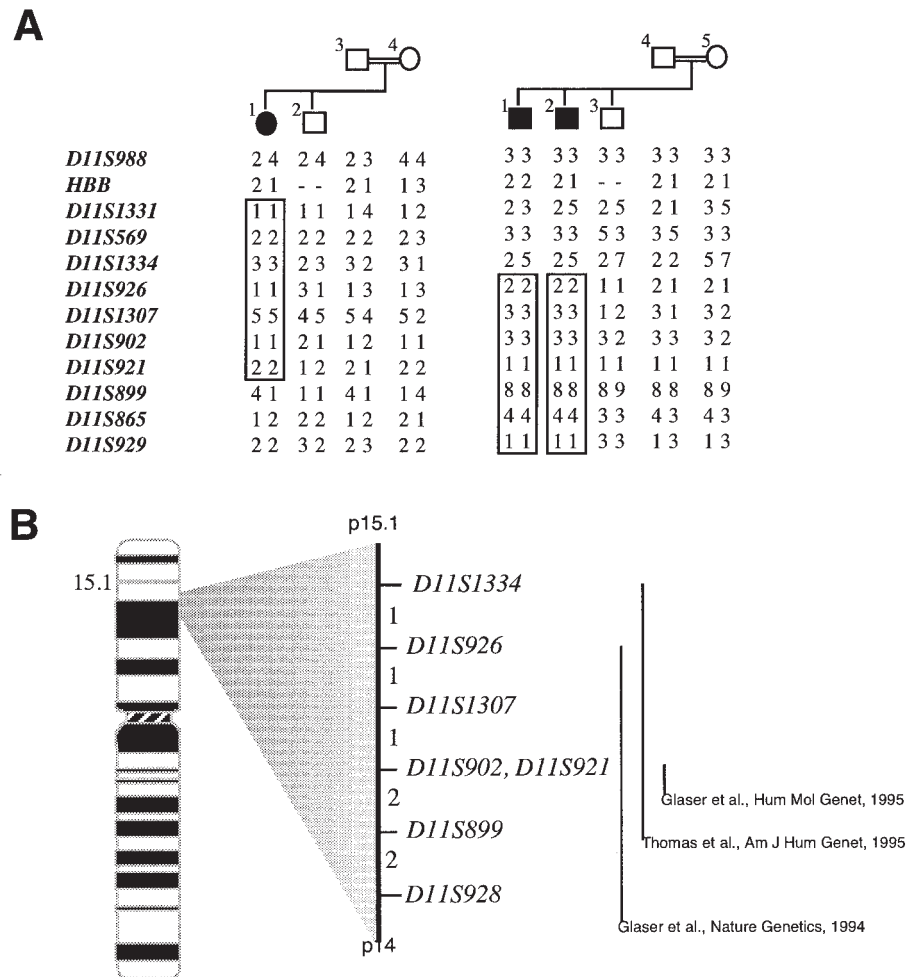
When expressed individually, SUR1 is unable to produce the β-cell ATP-sensitive potassium current I_{KATP}. However, I_{KATP} can be reconstituted by coexpression of the inward rectifier Kir6.2 with SUR1. Because the Kir6.2 locus is within 5 kb of the SUR1 gene on chromosome 11p15.1 and it is a necessary member of the β-cell K_{ATP} channel, we considered Kir6.2 as an additional candidate gene for PHHI. A homozygous point mutation (L147P), located in the conserved α-helical second transmembrane domain of Kir6.2, was identified in the genomic DNA of a severely affected child from a consanguineous Iranian family. No phenotypic dif-


Figure 55-1 Linkage of persistent hyperinsulinemic hypoglycemia of infancy (PHHI) to chromosome 11p15. (**A**) Linkage of PHHI to the interval between the chromosome 11 markers D11S1334 and D11S899 using the homozygosity gene mapping strategy. Shown are simplified pedigrees and genotypes in the region of homozygosity on chromosome 11 of members of two informative families affected with PHHI. Regions of homozygosity in affected children are boxed. In both families the parents are second cousins. Note that within each family the parents share the same disease allele haplotype, which presumably is derived from their common ancestor. (**B**) Summary of linkage data assigning PHHI to chromosome 11p15.1. Polymorphic repeat markers in the 11p15 region are detailed. The numbers between markers are approximate distances in centiMorgans. The vertical lines at the right represent the progressively narrowed regions to which PHHI was linked.

ference was discernible between this family and those with mutations of either the first or second NBF regions of SUR1. The identification of a mutation in Kir6.2 in those affected with PHHI demonstrates genetic heterogeneity for this disorder. In addition, demonstration that loss of function of either Kir6.2 or SUR1 leads to unregulated secretion of insulin and the PHHI phenotype supports the model that these two subunits cooperate in the formation of I_{KATP}.

The identified mutations do not represent the full spectrum of mutations in individuals affected with PHHI, because we are aware of many families that exhibit linkage to chromosome 11p15.1, yet demonstrate none of the mutations now described. By analogy to individuals affected with cystic fibrosis and adrenoleukodystrophy, both of which are caused by mutations in ATP-binding cassette superfamily members, the spectrum of mutations in familial PHHI may be very large. Except in those cases that may be attributed to founder effects, like the Saudi Arabian and Ashkenazi Jewish populations studied, the mutations found to date appear to be of low frequency in the general PHHI population. In

addition, the majority of those affected with PHHI exhibit sporadic, rather than familial, forms of the disease. Although sporadic forms of the disease are also associated with loss of K_{ATP} channel activity, it remains to be proven whether mutations of either SUR or Kir6.2 are responsible for these cases; it is possible that further genetic heterogeneity may be present and that additional genes with function related to K_{ATP} channel activity may be identified as responsible for sporadic forms of PHHI. Further comparison of phenotype and genotype status in those affected with PHHI is needed to ascertain whether a correlation may be made between specific mutations of K_{ATP} channel subunits and clinical course. Before prenatal diagnosis or genetic counseling may considered for clinical use for this disorder, further study to answer such questions is needed.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

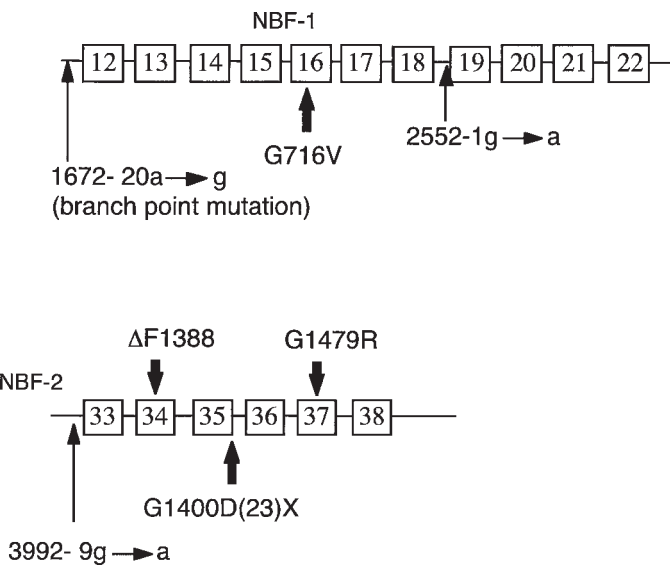
The resting membrane potential of pancreatic islet β cells is set by potassium channels. A link between the metabolic state of the cell and membrane electrical events is created by the inhibition of
Figure 55-2 A schematic drawing of events leading to insulin secretion by pancreatic islet β cells. Alterations in intracellular ATP level leads to closure of ATP-sensitive potassium (K_{ATP}) channels, which are composed at least of the sulfonylurea receptor (SUR) and the inward rectifier Kir6.2. Subsequent membrane depolarization, opening of voltage-gated calcium channels, and exocytosis of insulin follows. In the presence of mutations in either the SUR or Kir6.2, K_{ATP} channels are unresponsive to alterations in intracellular ATP levels, leading to inappropriate closure, membrane depolarization, elevated intracellular calcium levels, and, ultimately, unregulated exocytosis of insulin.


Figure 55-3 Mutations of SUR1 associated with persistent hyperinsulinemic hypoglycemia of infancy (PHHI). The SUR1 gene is composed of 39 exons. The nucleotide-binding fold regions (NBF-1 and -2) are diagrammed here, with NBF-1 in the upper, and NBF-2 in the lower, portion. Exons are represented as boxes and individual exon numbers are included.

K_{ATP} channels by ATP. As intracellular ATP level increases, inhibition of K_{ATP} channels progressively increases, leading to cell depolarization. The model for the molecular basis of PHHI, based on the molecular genetic data, predicts that disruption of either SUR1 or Kir6.2 results in both inappropriate closure of K_{ATP} channels and membrane depolarization, and subsequently to excessive unregulated insulin secretion. Direct support for this model has been obtained by patch-clamp analysis of primary cultured human islet cells obtained from a group of five infants affected with PHHI.

All evaluated pancreatic specimens lacked K_{ATP} channel activity. Furthermore, the PHHI β cells were found to be spontaneously electrically active and to exhibit high basal cytosolic calcium concentrations as a result of calcium influx. Therefore, it can be conclusively stated that the pathogenesis of PHHI, as predicted by genetic evidence and supported by direct electrophysiologic measurements of patient pancreatic samples, is caused by abnormalities of the pancreatic islet K_{ATP} channel.

MANAGEMENT AND TREATMENT

For individuals affected with PHHI, prompt recognition and treatment, with rapid resolution of hypoglycemia, is imperative to prevent permanent damage to the developing central nervous system. Treatment involves use of intravenous solutions of glucose and drugs, such as diazoxide and somatostatin analogs, which inhibit insulin secretion. These medical regimens are often not feasible for long-term use because of lack of treatment success, side effects, and practical problems with drug delivery. Near-complete (95%) pancreatectomy is frequently required for resolution of hypoglycemia. The need for additional treatment strategies remains apparent. Although patients who have undergone 95% pancreatectomy have demonstrated few ill effects during the short term, endocrine pancreatic insufficiency and growth failure is a significant problem affecting the majority of those examined for longer periods.

The elucidation of the molecular basis for PHHI may allow the development of more effective therapy for this difficult management situation. One potentially promising recent addition to the therapeutic options for treatment of PHHI is the use of the calcium channel blocking agent verapamil, as proposed by Lindley et al. The trial use of this drug was based on the molecular pathophysiology of PHHI, which includes inappropriate activation of voltage-gated calcium channels and elevated intracellular calcium levels. In a single affected child, with persistent hypoglycemia despite treatment with glucagon, somatostatin, diazoxide, and 95% pancreatectomy, blood glucose levels and duration of fasting time increased after treatment with nifedipine. Studies of the resected pancreatic specimen from this child demonstrated that the excess spontaneous electrical activity present was reversibly blocked by verapamil. Further study of this treatment approach is needed to define the role for calcium channel blockade in the management of PHHI.

FUTURE DIRECTIONS

Study of PHHI has demonstrated that this is a genetically heterogeneous disorder of pancreatic islet K_{ATP} channel dysfunction. Before PHHI may reasonably be considered as a candidate disease for gene replacement therapy, an understanding of the phenotype of specific mutations is required because with time, spontaneous abatement of clinical symptoms occurs in some cases. Further understanding of the molecular basis for PHHI, and the associated aberrant regulation of insulin secretion, may provide additional insight into effective therapeutic options for this and other disorders of pancreatic function and glucose metabolism.

56 Regulation of Reproduction

Michael J. McPhaul

INTRODUCTION

Reproduction involves the integration of biologic processes as diverse as behavior and specialized cell divisions. This integration is accomplished by a complex web of interrelated hormonal and neural circuits that employ a variety of signaling molecules and pathways. The goal of this overview is to introduce the major effectors and pathways that participate in this regulation. A basic tenet of this summary is that these pathways can be viewed as a cascade comprised of several different levels. Although many differences exist in this cascade between men and women, the general features and overall hierarchical organization are similar.

HYPOTHALAMUS

Early in embryogenesis, the cells destined to become gonadotropin-releasing hormone (GnRH)-secreting neurons migrate from the olfactory placode and became localized to specific regions of the preoptic and medial basal hypothalamus. Terminals of these neurons terminate on the long portal vessels, which carry the secreted GnRH to the gonadotropin-secreting cells of the anterior pituitary.

Although unique in many ways, one of the important characteristics of these GnRH-secreting neurons is the rhythmicity of their secretory patterns. For this reason, the complex of GnRH-secreting neurons has been collectively termed the "pulse generator." Episodic secretion of GnRH gives rise to measurable pulses of GnRH secretion approximately once each hour. Many influences that alter the secretion of gonadotropins can be traced to their effects on the pattern and amplitude of pulsatile GnRH release. This pattern of episodic secretion determines the activity of the other levels in the cascade below.

GnRH is an ancient molecule and its structure has been highly conserved in vertebrate species, from teleost fishes to humans. The mature GnRH molecule is a decapeptide and is derived from a precursor 82 amino acids in length that is processed into the mature GnRH peptide by specific endoproteases (Fig. 56-1). Of interest, in contrast to the high degree of evolutionary conservation of the structure of the GnRH decapeptide itself, surrounding regions of the GnRH precursor are less conserved. Although adjacent segments of the prohormone (e.g., the carboxy-terminal fragment known as GAP) may serve a distinct function, the sequences encoding this polypeptide are much less conserved between species. This lesser degree of conservation suggests that

although it may play a distinct role in vertebrate physiology (one that has not yet been defined), its principal function may simply be its participation in the folding and processing of the mature hormone.

PITUITARY

SECRETION OF LUTEINIZING HORMONE AND FOLLICLE-STIMULATING HORMONE

The anterior pituitary is derived from the pharyngeal epithelium and comprises of five cell types that secrete six polypeptide hormones. Unlike the other cell types of the pituitary, gonadotrophs secrete both follicle-stimulating hormone (FSH) and luteinizing hormone (LH). This departure from the "one cell, one hormone" rule that characterizes the other cell types of the anterior pituitary poses an apparent paradox, because FSH and LH can have different secretory patterns. Although the mechanisms by which this is accomplished have not been completely defined, it seems likely that the documented morphologic and functional heterogeneity of gonadotrophs is sufficient to account for the differential regulation of these hormones.

After delivery to the pituitary via the long portal vessels, GnRH binds to a specific receptor on the surface of the gonadotropin-secreting cells. This receptor is a member of a large gene family of membrane receptors that is predicted from its primary amino acid sequence to span the plasma membrane seven times and is most closely related to receptors from the same gene family that bind oxytocin and vasopressin (Fig. 56-2). In addition to those on the surface of the pituitary gonadotrophs, GnRH receptors have been detected in the gonads, prostate, and within selected regions of the brain (particularly GnRH-secreting cells of the hypothalamus). Although signal transduction is likely to involve a number of second messenger signaling pathways, the principal pathway appears to be via the G-protein-mediated stimulation of phospholipase C, rises in inositol 1,4,5-trisphosphate (IP_3), and changes in intracellular calcium levels. Activation of the mitogen-activated protein kinase (MAPK) cascade by GnRH has also been demonstrated. An important feature of this step in the hypothalamic–pituitary–gonadal (HPG) axis is that the episodic secretion of GnRH by the GnRH-secreting neurons causes GnRH to be presented to the receptor in an intermittent fashion. Furthermore, it is clear that this pulsatile binding of GnRH to its receptor on gonadotrophs is a critical attribute of this signaling pathway. Binding of GnRH to the GnRH receptor in a manner that is not pulsatile will lead to the induction of a state of tachyphylaxis and result in the cessation of LH and FSH secretion.

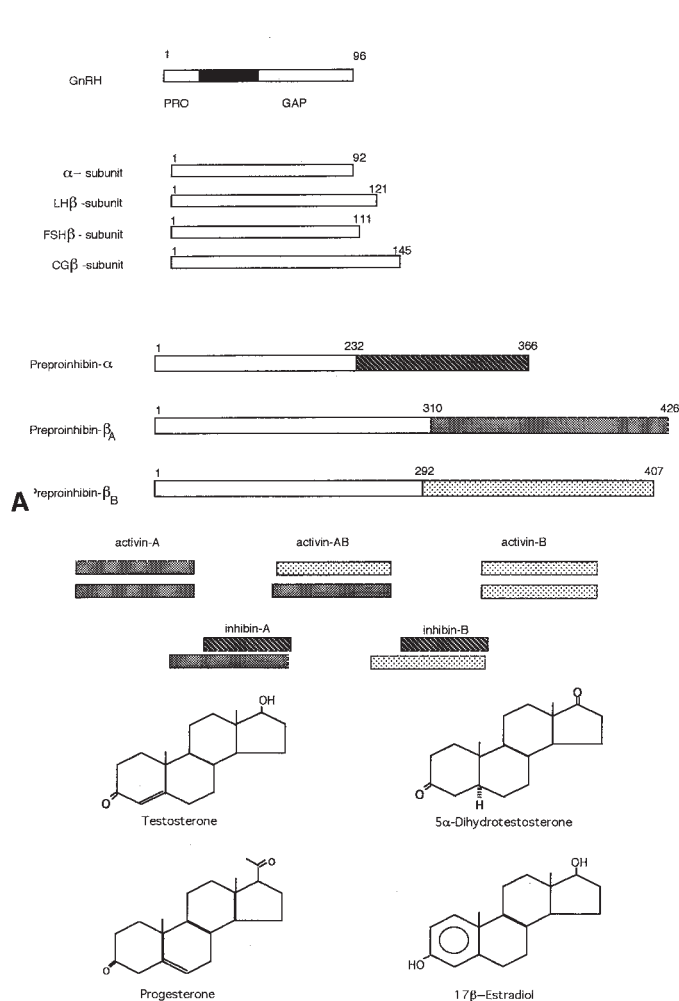
The principal effect of GnRH binding to its receptor on the surface of gonadotrophs is to stimulate the synthesis and release of


Figure 56-1 Reproductive hormones. The structures of the major classes of peptide involved in the process of reproduction are depicted. (Upper Panel) The positions of the pro- and GAP peptides are shown relative to the positions of the mature gonadotropin-releasing hormone (GnRH) molecule (shown as a dark bar). Luteinizing hormone (LH), follicle-stimulating hormone (FSH), and chorionic gonadotropin (CG) are heterodimeric glycoprotein hormones composed of a common α-subunit and a β-subunit that is unique for each hormone. (Middle panel) The structures of the hormones and subunits of inhibin and activin are presented. The two β-subunits and the single α-subunit are processed from larger precursors. As shown, combinations of these subunits give rise to a number of different heterodimeric (inhibins) and homodimeric combinations. (Lower panel) The structures of three of the major steroid hormones are shown. Each of the hormones is synthesized from cholesterol by the action of steroidogenic P450s and specific oxidoreductases.

LH and FSH. LH and FSH are heteromeric glycoprotein hormones that are structurally related and that likely evolved from a single ancestral precursor (Fig. 56-1). Both the common α-subunit and the unique β-subunits are processed from larger precursors that are cleaved by specific endoproteases to their mature forms. Glycosylation of both the α- and β-subunits occurs and has significant biologic effects, both in terms of the biologic activity and half-lives of these molecules. Because of the pulsatile nature of GnRH secretion, serum levels of FSH and LH also vary in a pulsatile fashion and protocols for the measurement of serum gonadotropin levels should take this moment-to-moment variation into account.
Figure 56-2 Reproductive receptors. Schematic representation of three major classes of receptor that transduce signals in the reproductive axes. (Above) GnRH , LH, and FSH receptors belong to a large family of transmembrane receptors that are coupled to G-protein-signaling pathways. The structures predicted for members of this large gene family include an extracellular domain that binds ligand, seven transmembrane-spanning segments, and cytoplasmic loops of varying lengths. The LH and FSH receptors are closely related to one another, whereas the GnRH receptor is more distant member of this gene family. (Middle) Activin receptors are composed of two non-identical subunits that have been designated as type I and II (based on their molecular sizes and by analogy to the type I and II transforming growth factor-β receptors). Each comprises an extracellular domain, membrane-spanning segment, and cytoplasmic domain. The intracellular domain encodes a protein kinase that phosphorylates specific serine and threonine residues of target proteins. Signal transduction occurs only when ligand is bound to both type I and II subunits forming an active heteromeric complex. (Below) Structure of a prototypic member of the steroid hormone–thyroid hormone–retinoic acid family of nuclear receptors. Essential features include a DNA-binding domain that recognizes specific sequences within regulated genes, a hormone-binding domain that binds ligand with high affinity, and an amino-terminal segment that is of variable length, but that is important for the maximal regulation of responsive genes. This same general structure is applicable to additional members of this gene family (termed "orphan receptors") for which a ligand has not been identified. Some orphan receptors (such as DAX and SF-1) have been shown to play critical roles in the development and function of the hypothalamic–pituitary–gonadal axis.

GONADS

Although the patterns of hormone secretion may differ substantially between men and women at the level of the pituitary and hypothalamus, many of the components of this axis are similar.

This is not true of the gonads themselves. Both the testes and ovary are complex organs comprising a number of specialized cell types (discussed in Chapters 61 and 62). The focus of this section is to provide a partial description of the factors and receptors that have been shown to participate in the regulation of the gonadal axis.

SITES OF ACTION OF LH AND FSH—TESTES LH is delivered to the testes via the blood and exerts its effects by binding to a high-affinity receptor expressed on the surface of Leydig cells. Characterization of cDNAs encoding this receptor predicts that the LH receptor is approximately 670–680 amino acids long (depending on the species) and is predicted to encode seven segments that span the plasma membrane. The activation of this G-protein-associated receptor has been correlated with increased intracellular levels of cAMP, which is viewed as an integral part of the second messenger pathway. Results from some investigators suggest that additional second messenger pathways, such as activation by phospholipase C, also contribute to gene regulation effected by LH receptor activation.

In the testes, the FSH receptor is localized exclusively to the Sertoli cells. The isolation of cDNAs encoding the FSH receptor revealed it to be highly related to the LH receptor, both in terms of size, predicted amino acid composition, and structural organization. As with the LH receptor, it is also believed to be coupled to G-protein-dependent signaling pathways. Stimulation of adenylate cyclase appears to be a critical signaling pathway and modulation of intracellular calcium levels may also be important. Via these mechanisms, FSH is believed to modulate processes important for both Sertoli cell growth and differentiation and for Sertoli cell function in the regulation of spermatogenesis.

SITES OF ACTIONS OF LH AND FSH—OVARY As in the testes, LH and FSH receptors are distributed in a cell-type-specific fashion in the ovary. The FSH receptor is localized exclusively to the surface of granulosa cells. Stimulation of this receptor in granulosa cells activates cyclic AMP-dependent signaling mechanisms. This activation promotes granulosa cell growth and differentiation and stimulates the gene encoding the aromatase P450, the rate-limiting step in estrogen biosynthesis.

In contrast to the FSH receptor, the LH receptor is not confined to a single cell type within the ovary, but instead is expressed in both theca and granulosa cells. The levels of LH receptor detected in these cell types varies, depending on the developmental stage of the follicle. LH receptors are present only on the theca cells in immature follicles, but are detected on both theca and granulosa cells of mature antral follicles. In theca cells, LH is believed to stimulate the level of androgen synthesis via cyclic AMP-dependent pathways.

STEROID HORMONE SYNTHESIS **Testes** The bulk of steroid hormone synthesis in the testes is confined to the Leydig cells, which in adult males synthesize approximately 5 mg of testosterone daily. As noted above (and depicted schematically in Fig. 56-3), substantial variations in serum testosterone occur moment to moment, owing to the pulsatility of LH secretion. Only small quantities of estradiol and 5α-dihydrotestosterone (5α-DHT) are secreted directly by the testes and the remainder of these hormones are derived from metabolic conversion in nongonadal tissues.

Ovary Steroidogenesis in the ovary is complex and changes markedly during the follicular and luteal phases of the ovarian cycle. During early follicular development, enzymes early in the steroidogenic pathway (side-chain cleavage, 17-hydroxylase) are
Figure 56-3 Integration of signals in the male reproductive axis. The pulses of GnRH secreted by neurons of the GnRH pulse generator are delivered via the long portal vessels to the cells of the anterior hypophysis. This signal leads to the pulsatile secretion of LH and FSH into the blood (shown at the upper right for LH). LH acts at the level of the Leydig cells within the interstitium of the testes to stimulate the pulsatile secretion of testosterone. The secreted testosterone acts within the testes to stimulate spermatogenesis and systemically to effect a number of physiological processes, including the feedback regulation of LH secretion. FSH binds to the membranes of Sertoli cells, where it acts to promote the process of spermatogenesis. Inhibin secretion by the Sertoli cell (particularly inhibin-B) acts as a component of the feedback loop that regulates the secretion of FSH.

localized to the thecal cells and aromatase is detected in the granulosa cells ("two compartment" model of ovarian steroidogenesis, *see* Chapter 62). Following ovulation, the cells of the corpus luteum continue to express high levels of side-chain cleavage P450 and 17-hydroxylase, but the levels of expression of aromatase drop.

INHIBINS, ACTIVINS, AND FOLLISTATIN The development of assays to measure pituitary gonadotropin levels led to the identification of nonsteroidal activities of gonadal origin that could suppress FSH release in castrate animals. This activity, termed inhibin, was ultimately purified and found to be composed of heterodimeric molecules composed of α- and β-subunits. Subsequent cloning studies revealed the existence of genes encoding a single α-subunit and two distinct β-subunits ($β_A$ and $β_B$), as shown in Fig. 56-1.

During studies to characterize the inhibins, it was noted that selected fractions of follicular fluid exhibited a distinctive activity. When used in appropriate bioassays, it was found that instead of inhibiting FSH release, these fractions led to a stimulation of FSH release. Purification of this activity, collectively termed activins, revealed that the active proteins were dimeric molecules composed of combinations of the same β-subunits that participate in the formation of inhibin heterodimers. Owing to its dimeric structure, three different activin molecules are possible: activin A, activin AB, and activin B, as shown in Fig. 56-1.

Studies by Ueno and coworkers established the existence of yet a third molecule capable of regulating FSH release in bioassays,

termed follistatin. Analysis of the structure of cDNAs encoding follistatin have demonstrated that this molecule is unrelated to either inhibin or activin. Current models suggest that a large portion of the biologic activity of this molecule is believed to derive from its ability to bind (and sequester) biologically active activins.

Testes   During embryonic development, the sites of α- and β-subunit expression vary, but become localized to the seminiferous tubule by the end of gestation. There is little question that Sertoli cells produce both inhibin and activin, although the mechanisms by which the production of these molecules by Sertoli cells are regulated is still unsettled. Available evidence suggests that the expression of inhibin subunits may vary in relation to the stage of development of the adjacent seminiferous tubule epithelium. Sertoli cells produce predominantly α-$β_B$ inhibin (inhibin-B), which appears to be regulated (directly or indirectly) by FSH, and likely by other paracrine factors as well. It is presumably through the production of inhibin-B that the testes effects a negative regulatory influence on FSH secretion by the pathway. The regulation of production of activin expression by Sertoli cells has been less completely defined.

Ovary   A number of studies have examined the identity of cell types that express α- and β-subunits in the ovary. Although some variation in the sites of subunit expression is evident in some studies, certain features are constant. First, it is clear that both α-subunit protein and α-subunit mRNA can be detected in the granulosa cells of growing follicles. Although patterns of β-subunit expression are more variable, it is detected in the thecal cells of dominant follicles in the human ovary.

Nongonadal Sites of Expression   A great surprise resulting from the development of assays for inhibin and activin was the recognition that many tissues outside the reproductive tract could be shown to express activin and inhibin subunits. The expression patterns reported for the different subunits suggests that activins are made in a variety of tissues and are likely to subserve a number of functions. The expression of inhibins, on the other hand, is more restricted and appears to play a central role in the modulation of FSH. Although the expression of follistatin often parallels the expression of inhibin and activin subunits, additional sites of expression have been described that imply functions beyond those related solely to the modulation of inhibin or activin.

Mechanisms of Action   The receptor that mediates the actions of activins is an area of active investigation. Specific proteins that bind activin have been identified and classified descriptively based on their physical properties. In crosslinking experiments, activin was shown to bind to two classes of membrane proteins (termed type I and type II receptors by analogy to the receptors for transforming growth factor [TGF]-β) having molecular weights of approximately ~50 and 70 kDa, respectively.

The detailed characterization of the activin receptors awaited the isolation of cDNAs encoding these proteins. The first such cDNA was isolated by expression cloning methods based on its capacity to confer on transfected cells the capacity to bind ^{125}I-labeled activin with high affinity. Analysis of the cDNA sequence predicted a transmembrane protein that contained motifs that suggested it employed a serine and threonine kinase as its intracellular signaling mechanism. The size of this receptor protein revealed it to be a type II activin receptor (Act RII). Subsequent studies revealed the existence of additional related members of the same gene family.

When antibodies directed at the type II activin receptors (such as Act RII) were used to precipitate the protein complexes crosslinked with ^{125}I-activin, the precipitates could be shown to contain proteins distinct from the type II receptors themselves. Screening strategies to isolate cDNAs encoding these proteins employed polymerase chain reaction (PCR)-based methods to identify cDNAs encoding novel transmembrane serine–threonine kinases. Subsequent crosslinking studies demonstrated that novel receptors isolated in this fashion (the activin type I receptors) could bind activin, but only in the presence of a type II activin receptor. The available evidence suggests that at least two distinct activin type I receptors exist. Thus, the combination of type I and type II receptors expressed in a given cell type is likely to afford an additional level at which differences in tissue responsiveness could be modulated.

To date, receptors have not been described that specifically bind either inhibin or follistatin. In the case of inhibin, owing to its distinct biologic properties, it is likely that such specific receptors exist. In the case of follistatin, however, it is believed that many, if not all, of its biologic properties can be accounted for on the basis of its capacity to bind and sequester activin with high affinity and the existence of a specific follistatin receptor seems less likely.

Insights From the Studies of Mice Carrying Targeted Disruptions of the Genes Encoding Inhibin, Follistatin, Activins, and the Activin Receptors   The study of the physiologic roles of inhibins, activins, and follistatin have been complicated by the intricacies of the systems being studied. Investigators have attempted to unravel these intricate systems by deleting the functional genes in living animals. Such studies have provided a number of interesting insights.

Inhibin   Matzuk and coworkers disrupted the functional α-subunit gene that is a component of both the inhibin-A and inhibin-B genes (*see* Fig. 56-1). As would be expected on the basis of the assays used to define the inhibins as regulators of pituitary FSH production, animals homozygous for the disrupted allele displayed elevated levels of serum FSH (*see* Chapter 10). Although the male and female homozygous mice were phenotypically normal, fertility was not normal in crosses with wild-type mice. Examination of the gonads revealed that the testes and ovaries of the homozygotes developed gonadal stromal tumor cells in a very high proportion of animals. These findings suggest that in addition to its role in the regulation of FSH, that in the cells of the gonadal stroma, inhibin—either directly or indirectly—also acts as a tumor suppressor. The basis for this capacity to antagonize the development of gonadal tumors remains to be elucidated. However, it is notable that gonadotropins are required for the development of activin-dependent tumors as crossbreeding with gonadotropin-deficient (hpg) mice prevents ovarian tumors. These findings indicate that gonadotropins are essential modifiers for tumor development in this model, perhaps reflecting their effects on follicle development.

Activins   Owing to the subunit composition of the activin molecules, testing the functional relevance of the different forms of activin via the generation of knockout mice was considerably more complex. The first information was from studies of mice in which the β-B subunit was disrupted. Mice homozygous for a β-B mutant allele demonstrated normal viability. The most marked abnormalities were abnormalities of eyelid development and female reproduction. Mesoderm formation and neurulation were normal.

Considerably different phenotypes were noted in mice in which the β-A subunit was disrupted. Although mice homozygous for the deleted β-A allele progressed to term normally, the mice died within 24 hours of birth. These mice also displayed several consistent phenotypic abnormalities, particularly defects in whisker and tooth development. A variable number displayed abnormalities of palatal development.

When mice carrying the β-B and β-A mutant alleles were bred to produce compound homozygotes, it was observed that the phenotype of the resulting animals was additive. That is, the defects that were present were those observed in the animals carrying either mutant allele. This observation permitted two important conclusions. The first is that the molecules composed of the individual activin subunits (i.e., β-A and β-B homodimers) are not functionally compensating for one another. Second, these studies suggest that β-A/β-B heterodimers do not have a unique function during embryogenesis.

Activin Receptor Type II The study of mice carrying targeted deletions of the activin receptor II provided a number of interesting contrasts to the results obtained in studies of mice carrying disruptions of the β-A or β-B genes. Male mice were delayed in reaching fertility and female mice were infertile. In male mice, these functional changes were traced to a decrease of seminiferous tubule diameter and total volume. In females, frequent follicular atresia was seen and corpora lutea were rare, consistent with abnormalities of the estrous cycle in the mutant mice. Investigations of mice homozygous for the deleted Act RII gene documented reduced FSH levels in both male and female animals, compared with wild-type animals, permitting the authors to conclude that the reproductive defects observed were a consequence of the reduced FSH levels caused by the absence of Act RII signaling.

Although many of the phenotypic abnormalities were consistent with the findings of the activin subunit gene disruptions (particularly the effects on the pituitary and gonadal function), other major effects were noted that were specific for the Act RII disruption. In particular, mice carrying a disruption of this gene demonstrated defects of the first brachial arch (reminiscent of Pierre-Robin syndrome). These defects suggested that the Act RII receptor is involved in the transduction of signals that are involved in the formation of the first brachial arch. The nature of this signal (apparently distinct from the activins themselves since these features were not observed in the activin "knockouts" themselves) remains to be identified.

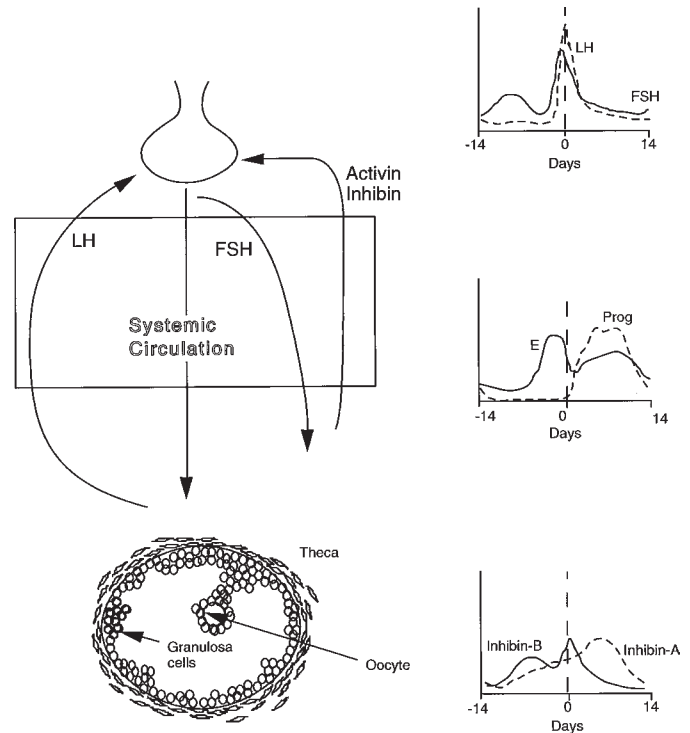
Follistatin Follistatin was originally defined on the basis of its capacity to antagonize the actions of activins. The targeted disruption of the murine follistatin gene permitted an examination of the physiologic impact of this molecule. Mice with the homozygous deletion died rapidly and displayed a number of defects, some of which suggested an alteration of activin function and many of which were specific for the follistatin gene disruption. Whisker development was abnormal, suggesting that follistatin may be an important modulator of the action of activin β-A. The shiny, taut skin resembled the skin of transgenic animals in which TGF-β overexpression had been directed using the keratin promoter. In addition, a number of additional defects were observed in the development of the musculoskeletal system, including changes in the number of ribs and vertebrae, as well as defects in the development of the palate. These results suggested that in addition to the role played in the modulation of activin function, follistatin may well play additional roles in the modulation of the


Figure 56-4 Integration of signals in the female reproductive axis. The pulsatile secretion of GnRH stimulates the pulsatile release of LH and FSH in to the blood by the gonadotropes (shown at upper right). Unlike the male, the levels of FSH and LH vary dramatically at different points in the menstrual cycle. FSH binds to the FSH receptor (localized to the plasma membranes of granulosa cells), where it acts to stimulate the growth of granulosa cells of the dominant follicle, as well as the levels of aromatase that they express. The sustained increased estradiol levels that result in the late follicular phase trigger the midcycle surge of LH and FSH that is required for ovulation. In the early portion of the menstrual cycle, LH acts principally at the levels of the ovarian stromal cells and stimulates the secretion of androstenedione, the substrate for granulosa cell estrogen synthesis (two-compartment model of ovarian hormonogenisis). After ovulation, the vascularization of the corpus luteum makes increased quantities of cholesterol—in the form of low-density lipoprotein—available for steroidogenesis, accounting for the increased progesterone secretion characteristic of the corpus luteum. If fertilization and implantation do not occur, the function of the corpus luteum declines, and progesterone and estradiol levels fall. As indicated (lower right), the regulation of serum inhibin-A and inhibin-B levels differ markedly at different points in the menstrual cycle.

function of other TGF-β related proteins or that it may possess functions that are independent of its role in the modulation of activins.

INTEGRATION OF THE SIGNALS

Each component of the hypothalamic–pituitary–gonadal axis is coordinated in a hierarchical fashion after puberty in men and women. In men, although levels of the gonadotropins and testosterone can be shown to vary minute by minute and to display some diurnal variation, large-scale changes do not occur (Fig. 56-3).

In women, interplay between the ovary, hypothalamus, and pituitary results in the cyclic changes that characterize the menstrual cycle. A schematic representing the hormonal changes that occur during the menstrual cycle are depicted in Fig. 56-4.

MODULATION OF THE HYPOTHALAMIC– PITUITARY–GONADAL AXIS

INHIBITION OF GONADAL FUNCTION   Female Contraception   The most common intervention affecting the function of the HPG axis is use of oral contraceptives. In the United States, these preparations include small doses of estrogen (ethinyl estradiol) and one of several progestational agents (norethindrone, norethindrone acetate, norethynodrel, norgestrel, ethynodiol diacetate, norgestimate, or desogestrel). The administration of these estrogen and progestogen combinations in low doses serves to inhibit the normal midcycle surge and to prevent ovulation. In addition to a large number of different combinations of these agents, contraceptives containing only progestational agents are available as oral agents and as depot preparations.

As would be expected from their mechanisms of action, the inhibition of ovulation that is achieved using such agents is readily reversible and normal ovulatory cycles resume within 6 months in more than 95% of women after cessation of contraceptive use.

Male Contraception   The success achieved in the development of oral contraceptives for women stimulated interest in developing similar methods for male contraception. These efforts have employed the parenteral administration of various androgen preparations. Protocols using weekly injections of testosterone enanthate have been the most widely studied and have been found to reproducibly induce a state of azoospermia or oligospermia. Using such protocols, contraception rates have been estimated at 0.8 pregnancies per 100 person-years in those patients whose sperm counts fall into the azoospermic range. Although this rate is comparable to other reversible methods of contraception, the failure to induce azoospermia in as many as 50% of subjects in some studies is unacceptable and is a major impediment to the broader application of such methods. The development of effective, reversible hormonal forms of male contraception have focused on the identification of regimens (e.g., the combination of testosterone injections and oral progestogens) that will lead to a higher frequency of azoospermia.

GnRH Analogs   Attempts to deliver GnRH chronically to stimulate gonadal function led to the recognition that the pulsatile delivery of GnRH to the gonadotrophs was essential for normal gonadotroph function. As noted above, the continuous delivery of GnRH to the pituitary leads to the induction of a form of reversible secondary hypogonadism. The mechanism of this tachyphylaxis has been traced to a downregulation of GnRH receptors on the gonadotroph and an uncoupling of postreceptor pathways.

These observations have led to the development and application of GnRH agonists to induce a state of reversible hypogonadism. These agents have been widely used to achieve a functionally castrate state by pharmacologic means. Such regimens are effective in both men and women and have been employed in the treatment of a wide range of conditions.

STIMULATION OF GONADAL FUNCTION   Female The techniques available to modulate the female reproductive tract and stimulate fertility have undergone explosive growth since the advent of successful in vitro fertilization (IVF) techniques in the late 1970s. Although the techniques and methodologies employed are quite varied, all rely on the use of agents to modulate the maturation of oocytes in a precise fashion, permitting the harvesting of ova for fertilization in vitro.

The simplest of such protocols employ the modulation of endogenous gonadotropin production using agents such as clomiphene citrate. This agent acts as an antiestrogen and acts to augment the secretion of endogenous gonadotropins. In some protocols, these effects are further augmented by the administration of exogenous gonadotropins.

Although somewhat more cost-effective, overall pregnancy rates using such stimulation protocols are lower than those using more conventional IVF treatment regimens. In these latter protocols, GnRH agonists are used to downregulate the production of endogenous gonadotropins so that ovarian follicular development can be regulated under circumstances in which the effect of endogenous gonadotropins are negligible. When suppression of ovarian function is achieved using these protocols, ovarian stimulation is achieved using exogenous gonadotropins for 9–10 days until follicular development is achieved. When follicular maturity is reached (assessed by ultrasonography and estradiol measurements), human chorionic gonadotrophin (hCG) is administered (to simulate the LH surge of a normal ovarian cycle), and oocytes are retrieved by a laparoscopic procedure.

Male   In men, primary and secondary hypogonadism is treated most frequently with transdermal or injectable depot preparations of testosterone, owing to the rapid metabolism and inactivation of unsubstituted forms of testosterone and the hepatotoxicity associated with the oral administration of the more stable 17-substituted androgens.

The systemic administration of testosterone—although providing hormone sufficient to support normal potency and secondary sexual characteristics—does not result in intratesticular concentrations of androgen that are capable of supporting normal spermatogenesis. For this reason, when fertility is desired by men with secondary forms of hypogonadism, different hormonal regimens must be employed that incorporate stimuli that mimic the trophic influences of gonadotropins on the testes. In men that have never undergone normal pubertal maturation (and as such have never established normal spermatogenesis), replacement regimens that supply stimuli that mimic the effects of both LH and FSH must be employed. By contrast, the administration of hCG may suffice to reestablish fertility in individuals that have developed an acquired form of secondary hypogonadism as adults.

SUMMARY

Increasingly detailed information has been amassed regarding the molecules, the receptors and the mechanisms by which the function of the gonads are controlled. In some instances, this knowledge has permitted the definition of the pathophysiology causing specific disease entities. In other instances (e.g., polycystic ovarian disease), the use of this knowledge has not yet permitted a complete understanding of the disease entity to emerge.

57 Disorders of Sex Determination and Differentiation

CHARMIAN A. QUIGLEY

THE BASIS OF NORMAL SEX DETERMINATION AND DIFFERENTIATION

Sex determination and differentiation are distinct, consecutive processes that follow the establishment of chromosomal sex at the time of fertilization. The term "sex determination" refers to the development of gonadal sex—a process that occurs at approximately 6–7 weeks' gestation in the human male fetus, and around 10–11 weeks' gestation in the female fetus. Male sex determination is synonymous with testis determination. This process (alternatively called primary sex differentiation) results from a coordinated series of exquisitely regulated, but as yet incompletely understood, events. As generally used, the term "sex differentiation," refers to the processes downstream of gonadal development—the processes that are regulated by gonadal secretions or lack thereof (also called secondary sex differentiation). In essence, the sex chromosome complement endowed at fertilization determines gonad type and the latter determines the pattern of differentiation seen in the genital ducts and external genitalia.

THE EMBRYOLOGY OF GONADAL AND GENITAL DEVELOPMENT In the first few weeks of gestation the primordial gonads develop from the condensation of a ridge of mesenchymal tissue located medial to the mesonephros (the forebear of the kidney), accompanied by thickening and proliferation of the coelomic epithelium, which penetrates the underlying mesenchyme. These primitive gonadal or genital ridges initially contain no germ cells. Between the 5th and 6th weeks of gestation (embryonic day 10.5–12 in the mouse) primordial germ cells migrate by ameboid movement from the endoderm of the yolk sac along the dorsal mesentery of the hindgut and into the indifferent gonad, where they invade the developing primary sex cords. Despite this, germ cells are not required for the processes of testis development to occur. At this stage the gonad comprises an outer cortex and inner medulla, and there is still no morphologic difference between the gonads of male and female fetuses. After the arrival of the germ cells, the gonad begins to differentiate: in the 46,XX fetus the cortex develops and the medulla regresses; in the 46,XY fetus the reverse occurs. The first discernible event in testis development is the appearance of primordial Sertoli cells, which differentiate from somatic cells of the coelomic epithelium. Soon after their appearance in the gonadal ridge, Sertoli cells proliferate, aggregate around the primitive germ cells, and align into cordlike structures, which subsequently become the seminiferous tubules. The seclusion of germ cells within the tubules prevents meiosis and commits the germ cells to spermatogenic development. This organizational process appears to be regulated by the Sertoli cells themselves. About 1 week later (around 8 weeks), steroidogenic Leydig cells differentiate from primitive interstitial cells of mesonephric origin. This process too may be controlled by paracrine influences from Sertoli cells, possibly anti-Müllerian hormone (AMH).

In contrast with the germ cell-independent development of the testes, the presence of germ cells is a prerequisite for normal ovarian differentiation. Without the germ cell seeding of the gonadal primordium, the tissue degenerates into a nonfunctional, mainly fibrous "streak." Before week 10 of gestation the only feature that distinguishes an ovary is the absence of testicular features. Thereafter, ovarian structure becomes distinguishable, with the development of the primary medullary sex cords. Secondary cortical sex cords provide the supporting structure for the arriving germ cells. These break up into clusters, becoming the primordial follicles at about week 16. The primordial follicles contain the diploid oocytes, which remain quiescent until puberty. Follicular cells arise from the same cell lineage as Sertoli cells. Theca cells represent the ovarian counterpart of Leydig cells.

There is a notable difference in the chronology of testicular versus ovarian development, the process of testis formation being completed by 8 weeks' gestation, at which time the process of ovarian development has not yet begun. In fact, morphologic ovarian development is not completed until after most of the processes of phenotypic sex differentiation, described in the following section, have occurred. This, and the fact that phenotypic development is normal even in complete absence of the ovary, highlights the lack of involvement of the ovary in this process. The embryologic development of the testis and ovary are summarized in Fig. 57-1.

The primitive internal genital tracts are also indistinguishable between the sexes until 7 weeks' gestation (Fig. 57-2). The fetus is endowed with two sets of internal duct structures: the paramesonephric (Müllerian) ducts, and the mesonephric (Wolffian) ducts. From the 8th week of gestation hormonal secretions from the fetal testes induce masculinization of the internal genital structures. Initially the Wolffian ducts are stabilized by the action (mainly local) of testosterone and thereafter undergo differentiation into the epididymides, vasa deferentia, and seminal vesicles; these pro-
Figure 57-1 Embryologic development of the gonads. **(A)** The primordial germ cells are located in the wall of the yolk sac in early embryogenesis. **(B)** At about the 5th–6th week of human gestation, germ cells migrate by ameboid movement from the coelomic epithelium, along the dorsal mesentery of the hindgut, to the genital ridge, the site of the future gonad. **(C)** During formation of the indifferent (bipotential) gonad, the primordial germ cells infiltrate the primary sex cords, which subsequently become the seminiferous tubules of the testis, or the primordial follicles of the ovary. **(D,E)** Formation of the testis continues after arrival of the germs cells, although these are not required for the process to occur. Probably under the direction of the newly differentiated Sertoli cells, the sex cords differentiate as the seminiferous tubules, in which germ cells are embedded. Morphologic development of the testis is complete by 8 weeks' gestation. **(F,G)** Formation of the ovary occurs later than that of the testis, at around week 10 of gestation, and does require the presence of germ cells. The primary sex cords develop into primordial follicles at about week 16 of gestation.

cesses occur between approximately 8 and 13 weeks' gestation. Dihydrotestosterone does not appear to mediate these processes, since the enzyme required for its production is not expressed in Wolffian tissues at the time of their differentiation. In parallel to the masculinization of the internal genitalia represented by Wolffian development, a process of "defeminization" of the genital ducts occurs as the Müllerian ducts regress under the influence of locally acting AMH secreted by testicular Sertoli cells, at around 8–10 weeks. The Müllerian ducts are obliterated by the 11th week of gestation, the only remnant of their existence in the 46,XY fetus being the prostatic utricle. Absence of one testis results in retention of the Müllerian structures and only limited Wolffian development on that side, indicating that the effects of AMH and testosterone are mediated to some extent in a paracrine fashion.

In the absence of testicular secretions, as in the normal 46,XX fetus, the inverse set of genital tract developmental processes occurs. Without local androgen action, the Wolffian ducts regress between about weeks 9 and 13. Similarly, in the absence of AMH the Müllerian ducts are permitted to develop. Their upper portions form the Fallopian tubes. The lower sections fuse and differentiate as the uterus and upper part of the vagina. The lower portion of the vagina derives from the urogenital sinus, which remains patent in the absence of androgen action.

Just as the gonads and internal genitalia are indistinguishable between the sexes for the first few weeks of life, so it is for the external genital primordia (Fig. 57-3). In the 4th week of gestation the external genitalia of both karyotypic sexes are represented simply by a midline protuberance—the genital tubercle. By week

Indifferent Stage

Female Development
Male Development

Figure 57-2 Embryologic development of the internal genitalia. **(Indifferent Stage)** The primitive internal genitalia at 7 weeks' gestation, showing the presence of both paramesonephric or Müllerian (female) and mesonephric or Wolffian (male) duct systems. **(Female Development)** In the female fetus between weeks 9 and 13 of gestation there is regression of the Wolffian ducts (shown with broken lines) with differentiation and development of the Müllerian ducts (shaded). The upper portions of the Müllerian ducts form the Fallopian tubes; the lower portions fuse to form the uterus, cervix, and upper part of the vagina. The urogenital sinus remains patent in the absence of androgen action, forming the lower part of the vagina. **(Male Development)** Differentiation of the Wolffian ducts in the male fetus occurs under the influence of testosterone between 9 and 13 weeks of gestation. These develop as the epididymis, vas deferens, and seminal vesicles (shaded). By week 11, the Müllerian ducts are obliterated by a process of apoptosis that occurs under the direction of AMH secreted by Sertoli cells (broken lines).

6 (still indifferent) two medial folds, the urethral folds, flank the urogenital groove, and two larger folds, the labioscrotal folds, are present laterally. Under the influence of androgen action (primarily dihydrotestosterone), the genital tubercle elongates to form the body of the penis, and the urethral folds fuse ventrally from behind forward, to form the penile urethra. The labioscrotal swellings or folds grow toward each other, fusing in the midline to form the scrotum. Dihydrotestosterone (DHT) also induces the urogenital sinus to differentiate as the prostate, and inhibits the formation of the vesicovaginal septum. These processes are completed by week 12 of gestation.

The testes migrate from their original lumbar location to the level of the internal inguinal ring above the scrotum, between 12 and 24 weeks' gestation. Descent of the testes through the inguinal ring and into the scrotum begins around week 28, and in most infants is completed by term.

In the absence of significant androgen action, such as in the normal female fetus, the genital tubercle elongates only slightly to form the clitoris (Fig. 57-3). The urogenital sinus remains open and the vesicovaginal septum forms between the genital and urinary portions of the urogenital sinus, so that the urethra opens anteriorly and the vagina posteriorly. The vestibule of the urogenital sinus is bordered laterally by the urethral folds, which fail to fuse and instead develop as the labia minora. Further laterally, the labioscrotal swellings enlarge somewhat but also remain unfused, forming the labia majora. There is minor fusion posteriorly, forming the posterior commissure, and anteriorly, producing the mons pubis. These events occur from about week 7 to week 12 of gestation. The timetable of gonadal and genital differentiation is shown in Fig. 57-4.

GENETIC AND HORMONAL CONTROL OF SEX DETERMINATION AND DIFFERENTIATION A complex interplay of genes, hormones, transcription factors, and receptors is required for normal sex determination and differentiation (Fig. 57-4; Table 57-1). The primary event governing the path down which morphologic sex differentiation proceeds is the development of
Figure 57-3   Differentiation of the external genitalia. **(Top)** At week 6 of gestation the external genitalia are undifferentiated, consisting of the midline genital tubercle, two medial urethral folds flanking the urogenital slit, and two larger labioscrotal swellings laterally. **(Left)** In the absence of androgen action the genital tubercle becomes the clitoris and the urogenital sinus remains patent. The vesicovaginal septum forms to separate the urethra from the vagina, located posteriorly. The urethral folds develop as the labia minora, whereas the labioscrotal folds enlarge slightly, remaining unfused, as the labia majora. **(Right)** In the male fetus in the presence of androgens (mainly DHT), the genital tubercle elongates to become the body of the penis, and the urethral folds fuse in the midline to form the penile urethra. The labioscrotal swellings fuse and enlarge to become the scrotum. These processes are completed approximately between weeks 8 and 12 of gestation.

the testis. In the 1930s the elegant experiments of Jost determined that maleness was a state imposed on the fetus that would otherwise develop as a female, because development of the ovary and female phenotype occur when the fetus is not exposed to the influences of specific "maleness-determining" genes.

SEX AND TESTIS DETERMINATION   The process of testis development appears to be controlled by a switchlike mechanism that involves the Y chromosomal *SRY* gene and its encoded protein, and, no doubt, other genes and proteins that either regulate or are regulated by SRY. However, for SRY to function, it must have a target—that is, there must first be development of the gonadal primordium. A candidate gene that may regulate the very earliest stages of gonadal development is the orphan nuclear receptor or transcription factor, steroidogenic factor 1 *(SF-1)*. Although its exact role is still being elucidated, SF-1 appears to be a key factor in development of the reproductive tract, at least in rodents. Analysis of studies in mice with deletions for the murine homolog of the *SF-1* gene reveals that *SF-1* is required in both sexes for develop-

ment of the bipotential primordial gonads and the embryologic adrenal glands, and for development and function of pituitary gonadotrophs. SF-1 appears to be one of the earliest-acting factors in the sex determination cascade and likely regulates genes encoding factors acting further down the pathway of gonadal development, such as AMH, WT1, DAX-1, LHb, P450scc, and perhaps even SRY itself, either directly or indirectly, via intermediate steps. Colonization of the bisexual gonad by germ cells is one of the earliest events in gonadal development, occurring before any morphologic distinction between the gonads of males and females is detectable. In mice, and probably in other mammals, the c-*Kit*/steel receptor–ligand system directs migration of germ cells from the yolk sac to the gonad and may also be responsible for their survival in their new milieu.

Once development of the primordial gonadal and genital structures has occurred, the next steps diverge between the sexes. In the karyotypic male a primary "switch" that initiates specific testicular development is the Y chromosome-encoded transcrip-

B

Male Development

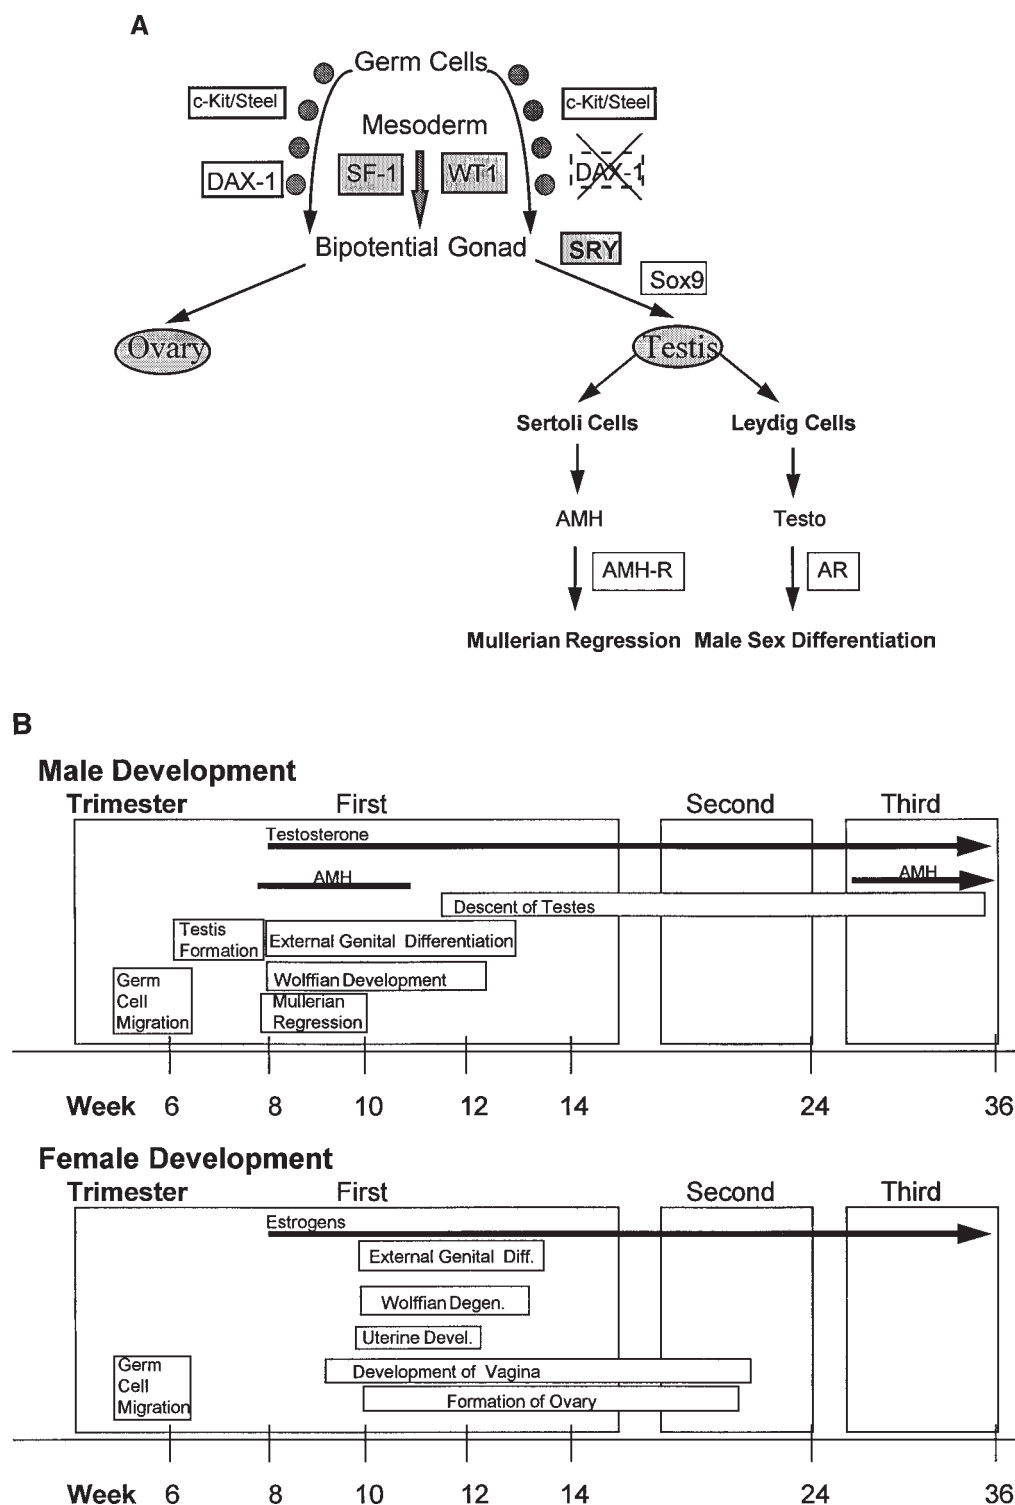
Female Development


Figure 57-4 Control and timing of gonadal and sexual differentiation. (**A**) Hypothetical scheme for genetic control of sex determination. The genetic determinants of gonadal and genital differentiation are shown in approximate sequence. c-Kit receptor and steel factor are involved in germ cell migration, one of the earliest events in gonad formation. SF-1 and WT-1 appear to be required for normal formation of the primordial bipotential gonad. SRY directs differentiation of the bipotential gonad as a testis, probably with interaction of other genes such as *SOX9*. It is presumed that *DAX-1* (or a nearby gene) is repressed in male development, since duplication of the locus suppresses testis development. After definitive testis formation has occurred, the testicular hormones AMH and testosterone direct the processes of Müllerian regression and masculinization of internal and external genitalia, each acting via a specific receptor (AMH receptor and androgen receptor). (**B**) Timetable. In both male and female development the first event of sex differentiation is the migration of germ cells, at around 5–6 weeks' gestation. This is followed by testicular development in the male. After onset of AMH and testosterone secretion at approximately 7–8 weeks' gestation, the Müllerian ducts regress and Wolffian ducts differentiate. The pattern of development is parallel, but essentially opposite, and somewhat delayed for female fetuses. In particular, there is a marked lag between testicular and ovarian development.

Table 57-1
Factors Involved in Sex Determination and Differentiation

Gene name	Locus	Protein name	Protein type	Action	Possible targets
SRY	Yp11.3	SRY	HMG box-type ligand-independent transcription factor	Bends DNA	AMH SOX9 $P450_{arom}$
SOX9	17q24–25	SOX9	HMG box-type ligand-independent transcription factor	Sertoli cell development Transcription regulation	DAX-1 Unknown
WT1	11p13	WT1	Ligand-independent transcription factor Tumor repressor	Transcription regulation	Unknown
DAX-1	Xp21	DAX-1	Orphan nuclear receptor	Inhibits SOX9 Regulation of gonadotropes Development of adrenals	SOX9
SF-1/Ftz-F1	9q33	SF1	Orphan nuclear receptor	Development of hypothalamic nucleus Development of gonads/adrenals Regulation of steroidogenesis	$P450_{scc}$ LHβ DAX-1 AMH
c-Kit	4q12	c-Kit	Transmembrane tyrosine kinase receptor	Migration/proliferation of stem cells ? Suppresses apoptosis	—
slf	12q22	Steel factor	Membrane-bound and soluble peptides Ligand for c-Kit receptor	As for c-Kit	c-Kit receptor
LH/CGR	2p21	LH/CG receptor	Seven transmembrane-spanning G protein-coupled peptide hormone receptor	Transduces LH signal Activates cAMP production	—
StAR	8p11.2	StAR	Mitochondrial protein transport factor	Mediates cholesterol transport to inner mitochondrial membrane	Unknown
AMH	19p13.2–13.3	AMH (MIS)	Glycoprotein homodimer, member of TGF-β family	Müllerian duct regression ? Regulates testicular descent	AMHR
AMHR	12q13	AMH Receptor	Transmembrane serine–threonine kinase receptor of TGF-β receptor type	Müllerian duct regression ? ? Regulates testicular descent	—
SRD51A	5p15	5α-Reductase 2	Microsomal enzyme	Converts testosterone → DHT	—
AR	Xq11–12	AR	Ligand-dependent nuclear transcription factor	Transcription regulation	AMHR ?P450arom

tion factor, SRY. SRY appears to direct the process of seminiferous tubule organization by Sertoli cells and to regulate transcription of the Sertoli cell glycoprotein AMH; AMH in turn may play a role in directing undifferentiated interstitial cells to develop as Leydig cells. Once testicular differentiation is established, other Y-encoded genes are required to maintain spermatogenesis. A number of other genes have been identified as having involvement in testis development; however, their exact positions in the path of testis development, their functions, and the factors that they regulate or by which they are regulated remain to be elucidated. These include the *SRY*-related gene *SOX9*, the Wilms tumor suppressor gene *WT1*, and the gene encoding the orphan nuclear receptor or transcription factor DAX-1. X-chromosomal sequences are also likely to affect testis development, since the presence of one or more additional X chromosomes (in Klinefelter syndrome and its variants) causes reduced testicular size.

At present, the factors directing ovarian development are poorly characterized; however, there is presumably an equally complex network of controls guiding this process. One such gene likely resides on the X chromosome and is probably a dosage-sensitive locus, as evidenced by girls and women with Turner syndrome, whose ovaries regress in the absence of two functional copies of the X chromosome. A candidate for this role is *DAX-1*. Duplication of the region of the X chromosome containing this gene results in development of streak ovaries in 46,XY individuals. In addition, the murine homolog of *DAX-1* is expressed in developing ovary at a time consistent with a regulatory role. Another ovarian determinant is likely autosomal, evidenced by the characterization of familial ovarian dysgenesis. The current hypothesis to explain the control of ovarian development is that it occurs when there is active function of as yet unidentified genes that repress testis-determining genes.

SEX DIFFERENTIATION Differentiation of the internal and external genitalia along male or female lines depends on the presence or absence of functional testicular tissue. Once function of the testis is established, at around 8 weeks of human gestation, development of the male sexual phenotype is under control of fetal hormones and the receptors that mediate their action. These include fetal luteinizing hormone (LH), the luteinizing hormone-chorionic gonadotropin (LH/CG) receptor, at least five steroidogenic enzymes involved in testosterone biosynthesis, steroid 5α-reductase 2 required for conversion of testosterone to dihydrotestosterone, the androgen receptor, AMH, and the AMH receptor.

Development of Wolffian structures requires testosterone, which is produced by testicular Leydig cells after activation of

their cell surface receptor, the LH/CG receptor, a member of the seven transmembrane domain G-protein coupled class of receptors. During the first trimester of gestation the ligand for this receptor is probably CG, produced in large quantity by the placenta. Subsequently, endogenous fetal LH is the primary ligand. The lack of dependence on fetal LH during genital morphogenesis is evidenced by the normal penile development of male infants with hypopituitarism; however, the subnormal penile size of these infants highlights the role of LH and testosterone action in the penile growth that occurs in the third trimester. Action of CG or LH at the Leydig cell LH/CG receptor stimulates testicular steroidogenesis. Sertoli cells may also help regulate Leydig cell secretion in a paracrine fashion. The biochemistry and molecular biology of the steroidogenic enzymes is described in further detail below. The outcome of this multistep process is a high local, and to a lesser extent systemic, concentration of testosterone.

Testosterone action is mediated by the androgen receptor (AR), a nuclear receptor-transcription factor found in high concentration in the tissues of the Wolffian ducts and external genitalia. Activation of AR by androgen binding results in interaction of the receptor–ligand complex as a dimer with the promoter regions of target genes, to regulate their transcription. The exact targets of the AR in genital development remain to be determined; however, the gene for the AMH receptor may be one of them. In external genital tissues testosterone (T) is converted by steroid 5α-reductase 2 to dihydrotestosterone, which has greater affinity for the AR. The same molecular events occur after interaction of either T or DHT with AR. In the absence of high androgen concentration, as in the female or androgen-deficient fetus, there is insufficient activated AR to induce transcription of target genes required for stabilization and development of the Wolffian system and for masculinization of the external genitalia. The female fetus bears the same AR as the male; thus, it is primarily the available concentration of androgens that is the major determinant of morphogenesis. AR function is described in further detail in Chapter 60.

Müllerian duct regression is induced by the Sertoli cell glycoprotein hormone, AMH, a member of the transforming growth factor β (TGF-β) class. The stimuli for AMH secretion by Sertoli cells are largely unknown, although there is evidence for regulation by both SRY and SF-1. The actions of AMH require a specific receptor, the AMH type II receptor (AMHR), a member of the serine–threonine kinase group of transmembrane proteins. Action of AMH at its receptor, which localizes in the mesenchyme surrounding the Müllerian ducts, results in involution of Müllerian structures by apoptosis. Expression of the AMH receptor may be regulated in part by AR.

Analysis of gene expression in wild-type and transgenic mice has led to the formation of a number of hypotheses to address the complex mechanisms of sex determination. Although these hypotheses are continually changing as more is learned about the timing and patterns of gene expression, and as new genes are discovered, the following represents a working hypothesis: *SF-1* and *WT1* are required to induce development of the primordial, bipotential gonad in both sexes; once this rudimentary structure is formed, specific sex-determining genes come into play; *SOX9* is required for Sertoli cell development and testis differentiation. However, in the female, *SOX9* is suppressed by *DSS/DAX-1*. In the male, *SRY* represses *DSS* (which is in single copy in the normal male), allowing expression of *SOX9* and subsequent testis differentiation (Fig. 57-4).

Estrogens and their receptor do not appear to play a significant role in mammalian sex determination and differentiation in either sex. This is evidenced by the fact that during normal fetal development males and females are exposed to equally high levels of maternal estrogens. Similarly, there is no phenotype associated with estrogen deficiency or inability to respond to estrogen *in utero*: transgenic mice with targeted disruption of the estrogen receptor, both males and females, are phenotypically normal at birth. Their fertility is, however, reduced.

DISORDERS OF SEX DETERMINATION AND DIFFERENTIATION

GENERAL BACKGROUND AND MOLECULAR PATHO-PHYSIOLOGY Abnormalities of sex determination and differentiation comprise two major clinical groups: disorders of gonadal development, with secondary effects on genital development, and defects of genital morphogenesis in the presence of normal gonads. The terminology is sometimes confusing: sex reversal refers to the condition in which the individual's genetic sex opposes the gonadal (and therefore generally the phenotypic) sex. These are individuals with 46,XY karyotype who have no testes (in their place usually are streak gonads) and have a female (or ambiguous) phenotype, and those with 46,XX karyotype who have testes and male (or ambiguous) phenotype. Pseudohermaphroditism (either male or female) refers to conditions in which karyotype and gonad are congruous; however, there is a discrepancy between the gonadal and the phenotypic sex: individuals with 46,XY karyotype and testes whose phenotype is female or ambiguous and those with 46,XX karyotype and ovaries whose phenotype is male or masculinized. Infants of either karyotypic sex with these latter disorders have phallic development that ranges from a completely formed penis to a diminutive clitoris; the labioscrotal region may be fully fused and rugose, or bifid and smooth; the internal structures may be mainly Müllerian (in the absence of AMH action), mainly Wolffian (in the presence of local androgen action), or a combination of the two. The genital morphology essentially reflects fetal production of, and response to, androgens and AMH during the critical period of gestation.

In contrast to disorders of testicular development and function, disturbance of ovarian development or function does not adversely affect fetal development of the normal female internal or external genital phenotype. However, exposure to supranormal androgen levels during gestation can induce masculinization of a female fetus, but has no detrimental effect on male fetal development. The disorders of sex determination and differentiation are summarized in Table 57-2. Approach to diagnosis and management is discussed at the conclusion of the chapter.

Because of the multiplicity of enzymes, hormones, receptors, and transcription factors involved, there are numerous opportunities for the usually well-coordinated processes of sex determination and differentiation to go awry. Hormones have no intrinsic action and must act via specific receptors. Thus hormone deficiencies are expressed by lack of function of the corresponding receptor. In general, steroid hormone deficiencies, resulting from defects of genes encoding biosynthetic enzymes, are manifest only in the presence of two defective gene alleles and are inherited as autosomal recessive traits. Compound heterozygosity occurs when the two alleles encoding an autosomal recessive trait each carry a different mutation. The functional outcome depends on the severity of the mutations independently, as well as on their interaction.

Table 57-2
Disorders of Sex Determination and Differentiation

Sex determination disorders
  46,XY sex reversal (46,XY karyotype with ovaries or streak gonads)
    SRY deletion/mutation
    SOX9 mutation
    DSS duplication
    WT1 deletion/mutation
  46,XX sex reversal (46,XX karyotype with testes)
    XX^{Y+}—*SRY* translocation
    XX^{Y-}—probable mutation of downstream regulator of testis development
  True hermaphroditism (various karyotypes with ovotestes)
  Chromosomal anomalies[a]
Sex differentiation disorders
  46,XY pseudohermaphroditism (46,XY karyotype with testes and female or ambiguous internal or external genitalia)
    Impaired testosterone production
      LH/CG receptor defect (Leydig cell hypoplasia)
      Defects of testosterone biosynthesis
        Defect of steroidogenic acute regulatory protein (StAR)
        3β-Hydroxysteroid dehydrogenase deficiency
        17α-Hydroxylase deficiency
        17,20-Lyase deficiency
        17β-Hydroxysteroid dehydrogenase deficiency
    Impaired androgen response
      5α-Reductase deficiency
      Androgen insensitivity syndromes
    Impaired anti-Müllerian hormone production or action
  46,XX pseudohermaphroditism (46,XX karyotype with ovaries and male or ambiguous internal or external genitalia)
    Fetal androgen excess
      Congenital adrenal hyperplasia
        21-hydroxylase deficiency
        11-β hydroxylase deficiency
        3-β hydroxysteroid dehydrogenase deficiency
      Aromatase deficiency
    Maternal androgen excess[a]
      Drugs
      Adrenal/ovarian tumors

---

[a]Not discussed in this chapter.

Receptors that mediate peptide hormone action, such as membrane-associated receptors like the LH/CG receptor, act as transducers of the hormone signal, setting off an intracellular signal cascade. Mutations of transducer-type receptors cause either an increase or a decrease in the activity of the system, depending on whether the mutation is an activating or an inhibitory one: this is illustrated by the contrasting effects of mutations in the LH/CG receptor, inhibitory mutations being associated with the syndrome of Leydig cell hypoplasia *(see below)*, whereas activating mutations are associated with the syndrome of familial male precocious puberty (*see* Chapter 59). Defects of these receptors are expressed only in the presence of two defective gene alleles.

Nuclear transcription factor receptors, such as those for steroid hormones, interact directly with target genes to modify their transcription, usually in a ligand-dependent fashion. Absence of ligand or defective ligand binding translates to absent or reduced activity of the ligand-dependent transcription factors; complete absence of a transcription factor (such as occurs when the encoding gene is deleted) not surprisingly results in lack of transcription of target genes. A second class of transcription factors appears to be ligand independent (e.g., SRY, WT1). Mutations that alter protein–DNA interactions between transcription factors and their target genes may result in decreased, increased, or sometimes promiscuous

transcriptional activation, the latter being caused by loss of DNA-binding specificity. In the case of a heterozygous mutation, the abnormal protein produced from the mutant gene may interfere with the action of the normal protein produced from the wild-type allele of the gene, a process referred to as the "dominant-negative" effect. In this situation, the mutant protein impairs the action of the normal one, either by blocking access of the normal factor to its target DNA, by forming inactive dimers that are unable to bind the target DNA sequence, or by sequestering other critical transcription factors because of disturbed protein–protein interactions. Defects in genes encoding intracellular receptors and transcription factors are usually considered dominant conditions, as generally only one mutant allele is required for detrimental effect. An exception is the AR, defects of which are inherited in an X-linked recessive fashion.

DISORDERS OF SEX DETERMINATION: SEX REVERSAL AND TRUE HERMAPHRODITISM   This section describes disorders of genes known or thought to be involved in development of the gonads. Syndromes associated with sex chromosome aneuploidy are detailed in Chapter 58. Two major classes of disorders will be discussed—those involving genes located on the sex chromosomes, and those involving autosomal genes. The general clinical features of sex reversal and true hermaphroditism are described

Table 57-3
Disorders of Sex Determination

Disorder	Frequency	Phenotype	Gonad type	Karyotype	SRY
XX male	1:20,000	Male Ambiguous (20%)	Testis	46,XX	SRY^+ (90%) SRY^-
True hermaphrodite	1:20,000	Ambiguous	Ovotestis	46,XX (70%) 46,XX/46,XY (20%) Other (46,XY rare)	SRY^- SRY^+ (few)
XY gonadal dysgenesis	1:100,000			46,XY	SRY normal (90%)
Partial		Ambiguous	Testis (dysgenetic)		SRY mutation
Complete (Swyer syndrome)		Female	Streak		SRY deletion

initially and are summarized in Table 57-3. Clinical features unique to specific gene defects are described in the relevant subsections.

General Clinical Features of Disorders of Sex Determination The archetypal and most common form of sex reversal is 46,XX maleness. Approximately 1:20,000 men has a 46,XX karyotype. The phenotype of most affected individuals with 46,XX maleness is similar to that seen in Klinefelter syndrome (47,XXY): structurally normal testes are present (sometimes cryptorchid) and the internal and external genitalia are male. Testicular size and histology are normal in infancy. Pubertal virilization occurs to a greater or lesser degree, but like those with Klinefelter syndrome, affected postpubertal individuals have small testes and are azoospermic, presumably because of the detrimental effect of the extra X chromosome. Histologically the testes have atrophic, hyalinized seminiferous tubules and Leydig cell hyperplasia. Up to 20% of 46,XX individuals with testes have subnormal masculinization, manifest by cryptorchidism, hypospadias, or frank genital ambiguity. 46,XX males are taller than average for females, but shorter than 46,XY males, presumably because of absence of stature-determining genes located on Yq.

True hermaphroditism defines the condition in which there is coexistence of ovarian and testicular tissue in the same individual, usually in the same gonad (ovotestis), less often in opposite gonads. Approximately 70% of affected individuals have a 46,XX karyotype and some cases may represent a variant form of 46,XX maleness. Without thorough histologic evaluation of the gonads it may be impossible to distinguish undervirilized 46,XX males from 46,XX true hermaphrodites. In addition, true hermaphroditism and complete sex reversal can coexist within the same family. Approximately 20% of individuals with true hermaphroditism have chromosomal mosaicism for 46,XX/46,XY or less commonly 46,XX/47XXY; a small number of cases have a pure 46,XY karyotype and a few with 47,XXY karyotype have been reported. Notably, the testicular portions of the gonads are dysgenetic, with interstitial fibrosis and rare or absent spermatogonia, although the ovarian portions are histologically normal. Malignant degeneration of the gonad is reported in approximately 5% of cases. Most affected individuals with true hermaphroditism have ambiguous genitalia; however, the phenotypic spectrum is broad: for example, one case of a fully masculinized boy with bilaterally descended ovotestes has been reported. A hallmark, although not universal feature is asymmetric genital development—Müllerian structures

(which may include a full or hemiuterus) on one side, and Wolffian structures on the other; a gonad-containing hemiscrotum on one side (more often the right) with a flat, empty labium majorum on the other. In general the pattern of development reflects the predominant functional nature of the gonad on the ipsilateral side. In association with an ovotestis, the internal genitalia may show elements of both Müllerian and Wolffian origin on the same side. The pattern of pubertal development reflects the function of the gonads, and fertility is not uncommon.

The disorder that represents the converse of 46,XX maleness is complete gonadal dysgenesis in a 46,XY female (Swyer syndrome; XY gonadal dysgenesis); however, it is much less common than the former condition, occurring in only 1:100,000 females. Affected individuals have streak gonads with female internal and external genitalia, although significant phenotypic variation is found within affected families. There is a high incidence of gonadal neoplasia (gonadoblastomas and germinomas) in the streak gonads. Because of deficient estrogen production, breast development is poor and these individuals often present with delayed puberty or primary amenorrhea; gonadotropin concentrations are in the castrate range. Pubic hair is usually present. Probably because of the presence of Y chromosomal stature-determining genes, affected women are of normal to tall stature compared with 46,XX females. They have no physical stigmata of Turner syndrome. However, individuals with deletion of the short arm of the Y chromosome (including the SRY locus), in addition to the general features described above, have certain features of Turner syndrome, such as lymphedema. The disturbances of testicular development (complete or partial gonadal dysgenesis) are associated with genital development that essentially reflects the functional state of the gonads at the critical period of sex differentiation.

In contrast to the numerous disorders of testicular development, clearly defined disorders of ovarian development (other than Turner Syndrome) are rare. One example of abnormal ovarian development likely resulting from a single gene defect is 46,XX gonadal dysgenesis. This disorder does not cause sex reversal, internal and external genitalia being those of a normal female. Affected young women present with failure of normal pubertal development, without phenotypic features of Turner syndrome; they are of normal height for females, and shorter than those with 46,XY gonadal dysgenesis, highlighting the role of Y chromosomal genes in stature determination. Their gonads are streaks;

however, in contrast to those with 46,XY gonadal dysgenesis, no increase in incidence of gonadal neoplasia has been found. Gonadotropins, particularly follicle-stimulating hormone (FSH), are markedly elevated. A familial form of 46,XX gonadal dysgenesis, in which affected individuals also have sensorineural deafness, is known as Perrault syndrome. In a large Finnish study of familial, apparently autosomal recessive, cases, the disorder is associated with mutations of the gene encoding the FSH receptor.

DISORDERS OF SEX DETERMINATION INVOLVING LOCI ON THE SEX CHROMOSOMES   Sex-Determining Region of the Y Chromosome—SRY Gene   The existence of a Y chromosomal "maleness-determining" gene was postulated in the 1930s, and in the 1960s was designated the "testis-determining factor" (TDF). Many candidates were proposed and rejected over the years. In 1990 the existence of such a gene was confirmed, with the discovery of the *SRY* gene (*Sry* in the mouse).

Genetic and Molecular Pathophysiology   The study of individuals with the syndromes of 46,XY gonadal dysgenesis and 46,XX maleness was the catalyst for the eventual localization and characterization of the *SRY* gene. The human *SRY* gene is a 1.0-kb intronless gene located just centromeric to the pseudoautosomal region of Yp (Yp11.3). The encoded protein acts as the dominant inducer of testis development in mammals. However, despite its preeminent role in testis determination, other Y-encoded sequences appear to regulate *SRY* expression.

Expression of *Sry* occurs in the gonadal tissue of fetal mice in the earliest period of specific testis formation, being first detected at embryonic day 10.5 in pre–Sertoli cells in the developing gonadal ridge. This finding suggests that these cells are integral to the process of testis development; indeed, one of the primary events in testis development appears to be induction of Sertoli cell differentiation. *Sry* expression peaks at day 11.5 and declines once testicular development is established, at day 12.5. Notably *Sry* expression is quite restricted to the urogenital ridge, with no evidence for expression in any other tissue at this critical time. *Sry* expression and Sertoli cell differentiation are followed by testis differentiation, most notably, Sertoli cell-regulated organization of seminiferous tubules and Leydig cell differentiation.

The human *SRY* gene comprises a single coding exon that predicts a 203-amino acid protein. Approximately the middle one-third of the protein represents the HMG (high-mobility group) domain, which endows SRY with its sequence-specific binding to a target nucleotide sequence—5'-AACAAAG-3'. The presence of the HMG box places SRY within a family of DNA-binding, transcription-regulating proteins, the HMG box proteins. The target genes of SRY are largely unknown, but may include those encoding AMH and the steroidogenic enzyme CYP11. Nuclear magnetic resonance spectroscopy analysis of the interaction between the SRY protein and the *AMH* gene promoter reveals that SRY binds in a sequence-specific manner in the minor groove of the DNA helix, intercalating the isoleucine residue at position 68 between the DNA strands, causing some unwinding of the strands and 70–80° bending of the DNA. In addition, SRY displays sequence-independent binding at four-way DNA junctions, which are intrinsically bent. Despite the absence of an activation domain, SRY–DNA interaction mediates transcriptional regulation, perhaps by bringing together distant DNA sequences or by facilitating access of other important transcription-regulating proteins to regulator sequences within specific testis-inducing target genes. It has been suggested that the spatial arrangement of the nucleopro-

tein complex organized by SRY is critical for the expression of these genes.

There are two main subtypes of 46,XX maleness and 46,XX true hermaphroditism—XX^{Y+} and XX^{Y-}. The majority of patients with complete 46,XX maleness are XX^{Y+}, resulting from translocation of all or part of the distal end of the Y chromosome, containing *SRY*, to the short arm of one X chromosome during paternal gamete meiosis (Fig. 57-6). In contrast, the majority of patients with 46,XX true hermaphroditism are XX^{Y-}. The molecular-phenotypic inference from these findings is that the presence of Y chromosome material results in a greater degree of masculinization. Two specific hot spots for Yp-Xp recombination within areas of high X-Y sequence homology have been reported to account for more than 50% of such recombination events. The presence of *SRY* in the genome of a 46,XX male can be confirmed by Southern blot or polymerase chain reaction (PCR) analysis. 46,XX males with unambiguous masculinization, more than 90% are *SRY* positive, whereas the converse holds for 46,XX males with genital ambiguity, approximately 5–10% of whom are positive for *SRY*. A small number of 46,XX true hermaphrodites have been found to be *SRY* positive. Nonrandom inactivation of the *SRY*-bearing X chromosome is the postulated explanation for the presence of ovarian and testicular tissue in the same gonad in individuals with *SRY*-positive true hermaphroditism. The coexistence of 46,XX complete maleness and 46,XX true hermaphroditism in a number of families is also postulated to reflect variations in the pattern of inactivation of the *SRY*-bearing X chromosome between affected individuals, affecting *SRY* expression. 46,XX maleness and true hermaphroditism are clearly genetically heterogeneous conditions. The finding that approximately 5–10% of 46,XX males with testes are completely negative for all Y-encoded sequences (XX^{Y-}) indicates that non-Y sequences must be responsible for testis determination in these cases, as discussed below. The absence of spermatogenesis in 46,XX males has been attributed to two factors, the presence of the extra X chromosome, and the absence of Y chromosomal genes involved in spermatogenesis.

In parallel to the finding of *SRY* sequences in the majority of 46,XX males, it would be predicted that most sex-reversed 46,XY females would have defects of the *SRY* gene. However, in general this has not proven to be the case; 85–90% of 46,XY females do not have demonstrable defects within the coding region of *SRY*. Suggested explanations for this finding include the theoretical presence of mutations located outside the HMG box-encoding region of the gene, such as in sequences important for regulation of *SRY* expression, of inactivating mutations in (as yet uncharacterized) upstream regulators of *SRY*, or of mutations that induce constitutive activity in genes usually negatively regulated by *SRY*.

SRY mutations are more common in 46,XY sex-reversed females with complete rather than partial gonadal dysgenesis. In the minority of individuals in whom an *SRY* defect can be detected, a variety of cytogenetic and molecular abnormalities have been reported. Phenotypic variation between individuals harboring the same mutation, both within and between kindreds, has been described. Variable penetrance is suggested as the explanation for the finding of the same *SRY* gene mutation in both affected and unaffected 46,XY individuals in certain families. Germline mosaicism for the *SRY* mutation may be associated with fertility in the fathers of affected individuals. Reported defects include deletion of Yp, isolated deletion of *SRY*, and at least 20 single-base mutations within the HMG box-encoding region of the *SRY* gene
Figure 57-5 Clinical examples of male pseudohermaphroditism. These infants all have 46,XY karyotype and show varying degrees of subnormal masculinization, more severe moving from left to right. **(A)** This baby has a mild androgen receptor defect. The defect of androgen action is manifest by failure of fusion of the urethra, resulting in penile hypospadias. There is also cryptorchidism with subnormal scrotal development. **(B)** This infant has a small penis with perineoscrotal hypospadias and a completely bifid scrotum. **(C)** This child has marked genital ambiguity: the phallic structure is intermediate between a clitoris and a penis, and the labioscrotal folds are smooth and unfused. Nevertheless, the testes are present in the labioscrotal folds. **(D)** The only evidence of androgen action in this 46,XY child is the mildly enlarged clitoris. **(E)** Complete lack of androgen action in a 46,XY individual (complete androgen-insensitivity syndrome; a patient with Leydig cell LH receptor defect would have a similar appearance).
Figure 57-6 The *SRY* gene. **(Upper)** Mechanism of translocation of the *SRY* gene onto the X chromosome. During paternal gamete meiosis there is pairing of the X and Y chromosomes in their pseudoautosomal regions (shaded) located on their short arms, with obligatory crossing over of homologous sequences. Genes in this region escape X inactivation. The *SRY* gene is located just proximal to the pseudoautosomal boundary; therefore, an unequal crossover between the Y and X chromosomes could result in translocation of Y chromosomal material (shown here as the whole of the pseudoautosomal region), including the *SRY* gene, to the distal X chromosome. These recombination events occur with increased frequency at two hot spots that contain areas of high X-Y sequence homology. **(Lower)** Mutations in the human *SRY* gene. There are many missense mutations in the *SRY* gene, all occurring within the region encoding the conserved HMG box. These are shown below the gene, using the single letter amino acid code designation (*see* Fig. 8B). Nonsense mutations introducing premature termination codons are boxed; frameshift mutations are underlined. Only one mutation has been reported outside the HMG box-encoding region. This was a nonsense mutation predicting truncation of the SRY protein by 42 amino acids.

(Fig. 57-6). Severe *SRY* gene mutations resulting in failed protein expression include a frameshift because of a 4-bp deletion, and a nonsense mutation introducing a premature termination codon into the message. Only one mutation has been reported outside the *SRY* HMG box-encoding region, this being a nonsense mutation in the 3' region of the gene resulting in loss of 42 amino acids from the carboxyl-terminus of the protein.

The majority of *SRY* mutations reported to date produce nonconservative amino acid substitutions at highly conserved sites within the HMG domain. In vitro analysis of mutant SRY proteins containing amino acid substitutions reveals abnormal DNA binding and bending: some mutant SRY proteins bind DNA less avidly but bend DNA normally, whereas others bind with near-normal affinity but bend the DNA to a different angle. The most severe defects appear to arise *de novo*, whereas the milder ones are compatible with fertility and thereby transmission to offspring. This is further evidenced by the fact that less dramatic missense mutations cause partial, rather than complete, gonadal dysgenesis, indicating that the mutant SRY protein likely retains some transcription-activating function. *SRY* gene mutations have also been reported in a few cases of 46,XY true hermaphroditism. One example was a postzygotic somatic mutation, because the affected individual had only the wild-type *SRY* sequence in leukocyte DNA but had both wild-type and mutant alleles in DNA derived from the gonads.

Although SRY is probably the key positive regulator of testis determination, there are clearly other upstream and downstream factors that must be activated or repressed to allow testis development to occur. This is implied by the following: (1) the majority of 46,XY females with gonadal dysgenesis have an intact *SRY* gene; and (2) some 46,XX males with testes are completely Y negative, indicating that non-Y sequences must be responsible for testis determination in these cases. Furthermore, the tight ontogeny of *Sry* expression during embryogenesis in the mouse suggests the presence of a "controller," that is, at least one upstream regulator of expression of the critical switch gene. In this regard, it is notable that a potential binding site for the early growth response-Wilms tumor 1 family of transcription factors has been reported upstream of the *SRY* open reading frame.

Dosage-Sensitive Sex Reversal–Adrenal Hypoplasia Congenita Critical Region on the X Chromosome, Gene 1—DAX-1 The *DAX-1* gene is implicated in development of the reproductive tract by its involvement in two unusual X-linked syndromes: dosage-sensitive sex reversal (DSS) and adrenal hypoplasia congenita-hypogonadotropic hypogonadism (AHC/HHG).

Clinical Features Karyotypic males with a duplication of the region of the X chromosome containing the *DAX-1* gene have typical features of 46,XY sex reversal, with streak gonads and a female phenotype. In contrast, individuals with deletion of this region have normal testes and normal male genitalia, although cryptorchidism has occasionally been reported. These males have congenital hypoplasia of the adrenal glands and many die unexpectedly in infancy or early childhood of undiagnosed adrenal failure, generally ascribed to "Addison disease." Those who, with replacement therapy, survive childhood also commonly have hypogonadotropic hypogonadism resulting in failure of pubertal virilization. This compound syndrome is known as adrenal hypoplasia congenita–hypogonadotropic hypogonadism (AHC/HHG) (*see* Chapter 59). One report also describes late development of high-frequency hearing loss in affected individuals. Female carriers

of AHC/HHG have no clear abnormality of either adrenal gland development or gonadotropin secretion; however, the author has received some reports of menstrual irregularity and early menopause.

Genetic and Molecular Pathophysiology The occurrence of sex reversal in the presence of two copies of sequences in the Xp21 region led to the designation of this locus as the dosage-sensitive sex reversal region (DSS). Subsequently it was determined that this same region was deleted in individuals with adrenal hypoplasia congenita (AHC). The *DAX-1* gene (DSS adrenal hypoplasia congenita locus on the X chromosome, gene 1) was cloned by analysis of this region in such patients. A well-described cytogenetic microdeletion syndrome encompassing the Xp21 region includes deletions of *DAX-1*, the dystrophin *(DYS)* gene (deletions of which cause Duchenne muscular dystrophy), and the gene encoding glycerol kinase (GK). The 5.0-kb *DAX-1* gene located at Xp21.3–21.2 encodes a new, although probably rather primitive, orphan member of the nuclear hormone receptor superfamily of transcription factors. The gene demonstrates evolutionary conservation, homologous sequences being detected in an X-linked pattern of distribution in many species. It comprises two exons and one intron that encode a 470-amino acid protein. The amino-terminal region of the protein, encoded by the first exon of the gene, contains a novel DNA-binding domain that has little homology with that of other members of the family. However, the ligand-binding domain, encoded in part by the first and in part by the second exon of the gene, has strong similarities with those of the retinoic acid and retinoid X receptors.

Expression of the homologous gene in the mouse occurs in the first stages of gonadal and adrenal differentiation and in the developing hypothalamus. In human studies, *DAX-1* is expressed in adult testis and adrenal cortex, in the hypothalamus and pituitary gland, and at low level in adult ovary and liver. The expression of *DAX-1* at all levels of the hypothalamic–pituitary–adrenal and gonadal axes supports its role in the coordinated development of the adrenal and reproductive systems and suggests that the DAX-1 protein may be directly or indirectly involved in gonadal regulation of hypothalamic–pituitary function. The promoter region of the *DAX-1* gene contains a binding site for SF-1, linking the two transcription factors in the control of development of steroidogenic tissues and suggesting that SF-1 may directly regulate *DAX-1*. Furthermore, the fact that disruption of *SF-1* inhibits development of gonads and adrenals *(see below)*, whereas deletion of *DAX-1* disturbs only adrenal development, suggests that *DAX-1* is downstream of *SF-1* in this cascade.

Duplication of the *DAX-1*-containing region of the X chromosome (DSS) results in classic sex reversal, with ovarian development in 46,XY individuals. Overexpression of this region impairs testis formation despite the presence of a functional *SRY* gene; suggesting a "toxic" effect on testicular development. In contrast, carrier females with duplication of this region may be fertile, indicating that double dosage of this locus does not impair normal ovarian differentiation. Whether the sex-reversing gene is *DAX-1* itself awaits analysis in transgenic animals. Recently, a cluster of potential candidates for the role of sex-reversal gene has been isolated from a region within 50 kb of *DAX1*, including *MAGE-Xp* or *MAGEL1* (melanoma associated antigen gene), *DAM6*, and *DAM10 (DSS/AHC* critical interval genes belonging to the *MAGE* superfamily). These genes are expressed in adult testis and the latter two are expressed in lung tumors. Their developmental roles remain to be characterized.

Although adrenal development does not proceed beyond the fetal stage, disruption of *DAX-1* does not prevent testicular development in males, indicating that this gene does not appear to play a role in normal testis differentiation. However, potential interactions between DAX-1 and the primary testicular switch, SRY in testis formation remain to be examined. Deletion of *DAX-1* has been reported in a number of patients with isolated AHC, whereas frameshift, premature termination, codon deletion, and missense mutations have been found in *DAX-1* genes of individuals with combined AHC/HHG, suggesting a possible dominant-negative effect of a retained but structurally abnormal protein on hypothalamic–pituitary function.

If *DAX-1* is indeed the sex-reversal gene, it may represent a link between normal ovarian and testicular differentiation pathways. Different genes must be activated or repressed to allow differentiation of ovary rather than testis or vice versa. It is conceivable that DAX-1 (or a related locus) may act as a repressor of a gene or genes involved in testis determination; thus, absence of the gene product is inconsequential for testis development, but excess is detrimental. Loss of one allele likely has minimal effect on ovarian function because there is an active locus on the other X chromosome. It has been suggested that this locus may be a remnant of an ancestral sex-determining system that operated by dosage before the process of X-chromosome inactivation evolved.

SEX DETERMINATION DISORDERS INVOLVING LOCI ON THE AUTOSOMES

Analysis of a number of informative families with 46,XX^{Y-} maleness, true hermaphroditism, or both reveals transmission patterns consistent with an autosomal dominant trait. One postulated mechanism to explain sex reversal in such cases is the presence of an upregulatory mutation in an as yet uncharacterized downstream regulator of testis determination.

SRY Homeobox-like Gene 9—*SOX9* After the discovery of the *SRY* gene, many related genes were soon identified. Those that encode proteins with more than 60% similarity to the *SRY* HMG box region have been termed *SOX* genes. One such gene, *SOX9*, is significantly involved in the process of testis formation.

Clinical Features The syndrome of campomelic dysplasia features a distinctive form of skeletal malformation that is present in 75% of 46,XY individuals affected by sex reversal (ovaries or streak gonads, and female internal and external genitalia). Affected 46,XX individuals have normal ovarian and external genital development. In most cases death occurs in infancy or early childhood because of respiratory compromise. The syndrome is uncommon, estimates of its frequency ranging from 1/5,000–1/200,000 live births.

Genetic and Molecular Pathophysiology *SOX9* was identified by cloning of a chromosomal translocation breakpoint from a sex-reversed patient with camptomelic dysplasia. The gene is located at 17q24–25, in a region termed sex-reversal autosomal 1 (SRA1); its cDNA is approximately 3.9 kb in size. The *SOX9* gene displays strong sequence conservation throughout mammalian evolution. Furthermore, the sequence similarity between *SOX9* and *SRY* suggests a possible evolutionary relationship between the two that may represent evolution from a dosage-dependent sex-determination system to a dominant system. Notably, dosage sensitivity is a feature of many regulatory genes.

In the human fetus, *SOX9* mRNA is detectable by Northern analysis in brain, liver, and kidney; by *in situ* hybridization, *SOX9* expression is detectable in the testis at week 18 of gestation in the area of the rete testis and seminiferous tubules. In the adult, *SOX9*

message is expressed most strongly in testis. It is also highly expressed in pancreas, prostate, kidney, brain, and the skeleton and at low level in most other adult tissues. In the mouse, the homologous *Sox9* gene is highly expressed in fetal skeletal tissues, as well as neural, cardiac, and other tissues. Its expression can be detected in mRNA isolated from whole embryos at day 8.5. Consistent with a role in testis determination, *Sox9* expression parallels Sertoli cell differentiation.

SOX9 encodes a 509-amino acid protein with features of a transcription regulator: it contains a putative DNA-binding HMG box domain and a proline- and glutamine-rich domain in its carboxy-terminal third, similar to activation domains of other transcription factors. In vitro deletion of this latter region destroys the transactivating function of the protein. SOX9 activates transcription via the nucleotide motif recognized by other HMG domain transcription factors, 5'-AACAAAG-3', and may represent another switchlike mechanism, because it appears to act in a dominant fashion, similar to SRY. SOX9 may be acting just downstream of SRY and may represent a target for SRY; however, this remains speculative, because the appropriate HMG box binding motif has not been identified within the *SOX9* gene promoter. One postulated relationship between the two transcription factors in testis determination is that *SOX9* expression in another cell type is required to complement *SRY* expression by Sertoli cells. Analysis of this hypothesis will require information regarding the comparative ontogeny of *SOX9* and *SRY* expression.

Inactivating mutations in one *SOX9* allele have been identified in a number of 46,XY individuals with camptomelic dysplasia and sex reversal. No patient has been reported with mutations in both *SOX9* alleles. In general *SOX9* mutations appear to occur *de novo*, providing further evidence of the autosomal dominant nature of the disorder. Mutations reported to date likely destroy protein function; these include frameshifts and nonsense mutations that lead to premature chain termination and loss of large portions of the protein. Thus the phenotype of individuals with these mutations appears to be caused by loss of function of the encoded transcription factor (haploinsufficiency), rather than resulting from a dominant-negative or gain-of-function effect. Missense mutations have not yet been reported. Affected sibling pairs with normal parents have been reported, likely as a result of gonadal mosaicism for the mutant gene.

Recently, a number of patients with autosomal sex reversal and campomelic dysplasia have been found to have chromosome 17 breakpoints at least 50–130 kb from the *SOX9* locus, suggesting the presence of other genes responsible for the same phenotype, or perhaps a disturbance of *SOX9* expression because of mutation of an upstream regulator. Positional cloning of the chromosome 17q breakpoint in one patient with sex reversal in the absence of campomelia (so-called acampomelic camptomelic dysplasia) identified a 3.5-kb cDNA that is expressed in testis but appears not to be translated. It was suggested by the authors that the mRNA itself has a functional role in sex determination.

Wilms Tumor 1—WT1 The Wilms tumor 1 *(WT1)* gene product, a member of the early growth response (EGR) family of transcription factors, is implicated in gonadal and genital development by analysis of human mutations and transgenic mice with a deletion of the gene.

Clinical Features Two clinical syndromes are associated with defects of the Wilms tumor 1 gene *(WT1)*. The Denys-Drash syndrome comprises a triad of gonadal dysgenesis, congenital

nephropathy, and subsequent development of Wilms tumor. Patients with Denys-Drash syndrome have heterogeneous disorders of gonadal and genital development. The gonads range from streak gonads or ovotestes in either 46,XX or 46,XY individuals, to rudimentary or dysgenetic testes in 46,XY patients, or normal ovaries (in a 46,XX patient). Perhaps because of an ascertainment bias, the majority of patients (about 90%) have 46,XY karyotype. Their external genitalia are usually ambiguous, sometimes female, occasionally male. The internal genitalia are often incongruous with respect to the external genital phenotype: Wolffian structures may be present in phenotypic females, Müllerian structures in phenotypic males. Even in 46,XX females, there may be anomalous internal genital development, and one 46,XY patient with dysgenetic testes had neither Müllerian nor Wolffian structures. Gonadoblastomas and granulosa cell tumors have been reported in some cases. The congenital nephropathy (caused by diffuse or focal mesangial sclerosis) generally presents with proteinuria and hypertension in the first year of life, with progression to renal insufficiency and death by 2 years of age. Wilms tumor is reported in more than 50% of cases, most presenting with an abdominal mass in the second year of life. The incidence would probably be higher if the patients survived longer, and in fact most are found to have persistent intralobar renal blastema, which may be the precursor of Wilms tumor. Of interest, the incidence of hypospadias and cryptorchidism is 10-fold higher in patients with bilateral Wilms tumor (distinct from the Denys-Drash syndrome) than in the general population.

In the WAGR syndrome, affected individuals, in addition to Wilms tumor and genitourinary abnormalities or gonadoblastoma, have aniridia and mental retardation. This disorder appears to be a contiguous gene defect, caused by heterozygous deletion of the 11p13 region that contains the *WT1* gene. Thus, other genes located in this region may also be involved in pathogenesis.

Genetic and Molecular Pathophysiology The *WT1* gene located in chromosomal region 11p13 is approximately 50 kb in size, contains 10 exons, encoding four distinct mRNA species (of approximately 3 kb), generated by the presence or absence of two alternative splice sites. The fact that all transcripts are expressed at a similar level suggests that each encoded protein makes a significant contribution to normal function. Interactions between the four proteins, each of which may have distinct targets and functions, may be important in the control of cellular proliferation and differentiation exerted by WT1. *WT1* expression occurs at a similar time to that of *SRY*, *WT1* mRNA being detectable in pronephric and mesonephric tissues on embryonic day 10.5 in the mouse, at which time *SRY* expression is detectable in pre–Sertoli cells. By embryonic day 11.5 the nephrogenic cord, condensing metanephric tissue, and urogenital ridge display high levels of *WT1* message. In the developing gonad *WT1* expression is localized to the stromal cell components, and in mature gonads it is confined to the Sertoli cells of the testis and granulosa and epithelial cells of the ovary. Expression also has been detected in abdominal and lung mesothelium.

The WT1 protein is a putative 45- to 49-kDa tumor suppressor with four contiguous Cys2-His2 zinc finger domains (encoded by exons 7–10) and an amino-terminus rich in proline and glutamine, consistent with a role as a transcription factor. WT1 has been shown to have separate domains that subserve transcriptional repression and transcription activation: residues 85–124 encompass the repressor domain, and 181–250 the activator domain. These regions are distinct from the DNA-binding domain and

their activities are probably mediated by protein–protein interaction. The WT1 protein shows homology to the early growth response-1 *(EGR-1)* gene product and has similar binding sites (5'-CGCCCCCGC-3'). These proteins are expressed early in the cell cycle, at G0 to G1 transition. The target genes for WT1 are at present unknown; however, it is suggested that the normal role of WT1 during embryologic development is to initiate a transcriptional program that controls differentiation of glomerular epithelial cells and gonadal primordium. The absence of both sets of internal genital duct anlagen in one patient would be compatible with a primary role of WT1 in early development of the bipotential internal duct systems. In renal tissue it acts as a tumor suppressor.

Examination of transgenic mice homozygous for a knockout mutation of *WT1* established a crucial role for WT1 in early urogenital development, with mutant embryos displaying failure of renal and gonadal development. Specifically, at day 11 of gestation, the cells of the metanephric blastema underwent apoptosis, the ureteric bud failed to grow out from the Wolffian duct, and the formation of the metanephric kidney did not occur. The mice were nonviable, probably because of abnormal development of the mesothelium, heart, and lungs.

The Denys-Drash syndrome in humans is associated with heterozygous germline mutations in *WT1* in approximately 95% of cases examined to date. The mutations cluster within or near the zinc finger (ZF) coding region (exons 7–10, particularly exon 9), most producing amino acid substitutions in ZF2 and ZF3. One mutation, encoding an arginine to tryptophan substitution at position 394 in the third zinc finger, has occurred recurrently, being present in approximately half of the cases reported to date. Other reported mutations include a variety of nonconservative missense, nonsense, frameshift, and splice-junction mutations, most of which appear *de novo*, since parental *WT1* genes are normal. In one case, however, the normal father of an affected child was found to be heterozygous for the mutant allele, a finding that suggested either mosaicism or reduced penetrance of the mutant gene. The disorder is genetically dominant, because no patients have been described with mutations in both alleles of the gene. The WAGR syndrome likely results from heterozygous loss of contiguous genes within the 11p13 region including the *WT1* gene, accounting for the aniridia and mental retardation that accompany the Wilms tumor and genitourinary abnormalities in WAGR cases. In patients in whom it has been examined, the mutant allele appears to have arisen in the paternally derived chromosome 11. The dominant phenotype associated with the null mutation indicates dosage sensitivity at this locus—that is, two functional copies of the gene are required to prevent the abnormalities associated with the syndrome.

The molecular pathophysiology of *WT1* mutations appears to be lack of normal DNA binding by the WT1 protein, because mutant WT1 proteins containing nonconservative amino acid substitutions within the zinc finger region do not bind to the EGR-1 consensus-binding sequence bound by wild-type WT1. Mutations that affect zinc-coordinating cysteine or histidine residues likely prohibit DNA binding by disrupting proper spatial organization of the zinc finger. WT1 appears to play a dominant-positive role in renal and gonadal development. Formation of inactive mutant–wild-type dimers could theoretically produce a dominant-negative effect, presumably via heterodimerization with wild-type WT1 protein. Interestingly, complete deletion of the *WT1* gene produces milder genital abnormalities (cryptorchidism and/or hypospadias), than does a mutation that encodes expression of an

abnormal WT1 protein, again suggesting a dominant-negative mechanism of action of mutant WT1. Although *WT1* mutations are heterozygous at the germ cell level, tissue from the Wilms tumors of these patients generally demonstrates loss of heterozygosity for *WT1*, indicating that two mutant *WT1* alleles may be required for loss of tumor suppressor function of WT1 ("two-hit" hypothesis). A role for interaction between WT1 and the ubiquitous tumor suppressor, p53, is suggested by an interaction between the two factors in transfected cells. The two may interact by direct protein–protein interaction or via an intermediate, and there is evidence that the tumor suppressor function of WT1 may be dependent on such an interaction, rather than be intrinsic to the protein itself.

Steroidogenic Factor 1—SF-1   Defects of steroidogenic factor 1 (SF-1) have not yet been reported in humans; however, the phenotype of transgenic mice with targeted disruption of the homologous gene (*fushi tarazu* factor-1 *[Ftz-F1]*) is well-characterized, and provides important insights into aspects of mammalian gonadal development.

SF-1 (also referred to as adrenal 4-binding protein [Ad4BP]), appears to hold a strategic position in inducing the development of the reproductive tract. Not only does SF-1 regulate gonadal and adrenal development, it also appears to control development of an important hypothalamic nucleus, and of pituitary gonadotropin-secreting cells. Furthermore, SF-1 regulates expression of the genes encoding three key steroidogenic enzymes: cholesterol side-chain cleavage enzyme, steroid 21-hydroxylase, and the aldosterone synthase isozyme of steroid 11β-hydroxylase.

The human gene encoding SF-1 is located at 9q33 and its murine homologue is on mouse chromosome 2. Two distinct proteins—SF-1 and ELP (embryonal long terminal repeat)—are produced by alternative promoter usage and splicing; however, the critical protein with respect to reproductive tract development is SF-1. SF-1 is an orphan nuclear receptor or transcription factor that contains the typical two central zinc fingers and a carboxy-terminal ligand-binding domain. *SF-1* is expressed in the urogenital ridge of male and female mice at embryonic day 9–9.5, the earliest stage of organogenesis of the gonads (still indifferent, and before *SRY* expression); it is subsequently expressed in fetal Sertoli cells and in the primordial cells of the adrenal glands. Consistent with its role in regulation of steroidogenesis, it is expressed before expression of the first enzyme of steroidogenesis, $P450_{scc}$. Expression in fetal ovaries is quite low, and disappears between embryonic days 13.5 and 16.5, in keeping with the lack of ovarian steroidogenic activity at that time. *SF-1* mRNA is detectable in the developing mouse pituitary at embryonic day 13.5–14.5 and can be specifically detected in gonadotrophs. In adult mice *SF-1* is expressed in all primary steroidogenic tissues, including all zones of the adrenal cortex, testicular Leydig and Sertoli cells, ovarian theca and granulosa cells, and corpus luteum. There is sexually dimorphic expression of *SF-1* postnatally. In male rats testicular *SF-1* mRNA levels decline markedly after the first week of life, whereas ovarian *SF-1* expression increases in females.

The expression of *SF-1* appears to be regulated by another factor, probably a helix-loop-helix protein similar to *c-Myc*, that binds to a region in the promoter of the rat *Ftz-F1* gene (homologous to *SF-1*), designated the *E box*. Expression of the binding factor precedes that of *SF-1*. This fact, and its tissue-specific pattern of expression, is consistent with a role as a regulator of *SF-1* expression. This factor may be the earliest member of the gonadal development cascade as yet identified.

SF-1 functions differently from most other members of the nuclear receptor family, because it appears to bind as a monomer, rather than as the more usual dimer, to a nonpalindromic DNA steroid response element half-site, 5'-AGGTCA-3'. Potential targets for SF-1 include the genes encoding $P450_{scc}$, DAX-1, LHβ, AMH, and oxytocin, because SF-1 binding sites have been located within the promoter regions of these genes.

The functional importance of *SF-1* and *Ftz-F1* is addressed by studies in transgenic animals. Both male and female mice lacking a functional *Ftz-F1* gene had phenotypically female internal and external genitalia and died in the neonatal period of adrenal insufficiency. They failed to develop steroidogenic tissues, having neither gonads nor adrenal glands (the steroidogenic components of adrenal glands and gonads likely have a common embryologic origin in the urogenital ridge). Interestingly, these mice did display mesenchymal thickening in the gonadal ridge area at the earliest stages of gonadal development (embryonic day 10.5), but thereafter the cells of this region underwent apoptosis (programmed cell death), suggesting that the role of SF-1 and Ftz-F1 may be in maintaining rather than initiating gonadal development. These mice also had abnormal development of the ventromedial hypothalamic nucleus, a region important in control of pituitary gonadotropin secretion. Expression of proteins specific to gonadotroph cells, LHβ, FSHβ (follicle-stimulating hormone), and gonadotropin-releasing hormone (GnRH) receptor was absent, implicating SF-1 in gonadotrope development and LH and FSH expression.

The presence of female internal genitalia in the null animals of both sexes indicates that the Müllerian ducts did not regress as expected in the males, reflecting lack of AMH action, because of absence of Sertoli cells. In females, expression of *SF-1* during the critical period of genital development would be detrimental to normal sex differentiation. SF-1 induction of *AMH* expression would likely induce Müllerian regression and failure of oviduct and uterine development. The fact that SF-1 expression in developing ovaries is low supports this hypothesis. Interestingly, although SF-1 binds to the promoter of the *AMH* gene, it is unable to regulate *AMH* gene expression in cotransfection assays using a heterologous cell line, unless its ligand-binding domain is deleted. This finding suggests a role for a possible ligand for SF-1 in its regulation of *AMH* expression in vivo, perhaps a Sertoli cell-specific factor. Such a factor could prove to be critical in the sex determination cascade.

In evaluating the role of SF-1 in reproductive tract development, a key question arises regarding the possible interactions between SRY and SF-1. The fact that the *Ftz-F1* null mice have no gonadal tissue at all, whereas individuals with *SRY* mutations develop gonads that more or less resemble ovaries suggests that normal *SF-1* or *Ftz-F1* expression must occur before *SRY* can be effective in inducing testis determination. Furthermore, expression of the two genes is temporally dissociated, *SF-1* being expressed in mouse testis at embryonic day 9–9.5, before transient gonadal *SRY* expression at day 10.5. However, in the older embryo expression of *SRY* correlates with sexually dimorphic expression of *SF-1*. In males SRY promotes upregulation of *SF-1*; absence of SRY in females results in reduced *SF-1* expression. In view of the discordant timing of expression of these proteins, this is likely an indirect effect. In this context it has been suggested that SRY could act by silencing a repressor of *SF-1*, thus facilitating *SF-1* expression.

In summary, SF-1 has multiple key roles in reproductive tract development, controlling development of the gonads and adrenal glands themselves, a hypothalamic center that regulates gonadal function, gonadotropin expression, and production of the two hormones essential for male sex differentiation—testosterone (by regulation of key steroidogenic enzymes) and AMH.

c-*kit* Receptor and Steel Factor   In the mouse, the steel factor *(Slf)* and its receptor, c-*kit*, represent a growth factor–receptor system that is involved in development of three major cell lineages: hemopoietic cells, melanocytes, and germ cells. Mice with mutations at either the *Slf* or c-*kit* locus have white coat color, sterility, and anemia, attributable to failure of stem-cell populations (melanoblasts, primordial germ cells, and pluripotent hemopoietic stem cells) to migrate and/or proliferate effectively during development.

The mouse c-*kit* gene is a proto-oncogene whose product is a 145- to 160-kDa transmembrane tyrosine kinase receptor of the same family as a number of growth factor receptors (such as insulin-like growth factor I and platelet-derived growth factor). The human c-*kit* gene is located at 4q12, spans more than 70 kb of DNA, and includes 21 exons, which are alternatively spliced. The longest transcript is approximately 5.2 kb. In mouse, Kit protein is expressed in primordial germ cells, spermatogonia, Leydig cells, and growing oocytes. Expression can be detected in primordial germ cells as early as mouse embryonic day 7.5, ceasing as germ cell proliferation is completed, after arrival at the gonadal ridge on day 13.5–15.5, and returning during the postnatal maturation of oocytes and spermatogonia.

The Kit receptor appears to be active in a homodimer form. Thus, mutations of a single allele at the c-*kit* locus may cause defective receptor activity by combination of mutant receptor with wild-type, inhibiting the action of the normal receptor (dominant-negative effect).

The ligand for the c-*kit* receptor, known as steel factor (Slf), stem cell factor (SCF), or Kit ligand (KL), is encoded by the Steel *(Slf)* locus. The gene maps to human chromosome 12q22. By alternative splicing the *Slf* gene codes for two different peptides, a membrane-bound form and a soluble form. In the testis, steel factor is produced primarily by the Sertoli cell. Deletion of the entire *Slf* gene is lethal in mice, whereas a mutation that allows production of only the soluble form of steel factor, while resulting in abnormal germ cell migration and spermatogenesis, is nevertheless compatible with life. These facts are interpreted as indicating that the membrane-bound form of Slf is crucial for differentiation of tissues. Slf and c-kit may in fact have their primary role as survival factors, because they appear to suppress apoptosis.

Although c-kit and Slf are crucial for the development and migration of primordial germ cells in rodents, understanding of their role in human testicular development is still evolving. In normal human testicular development Kit protein is detectable up to 15 weeks of gestation. However, in fetal testes of individuals with intersex conditions Kit was detectable at a later stage, suggesting disturbance of the timing of germ cell development. Notably, individuals with intersex conditions are at increased risk for development of germ cell tumors, and Kit is expressed at high level by seminomas, one type of germ cell tumor. In adult testicular tissue Kit protein is detectable in undifferentiated spermatogonia, whereas Slf/SCF is found on the membrane of the seminiferous tubules and on the surface of Sertoli cells, suggesting that the c-kit and Slf system may act in a paracrine fashion. SCF is also expressed in human ovary and cultured granulosa/luteal cells, in which it is downregulated by gonadotropins. Interestingly, both proteins are also expressed in the human central nervous system, particularly in the cerebellum, in addition to a wide variety of other fully differentiated tissues, suggesting that this system may have roles that extend well beyond fetal life. Despite the known role of c-kit in migration and proliferation of germ cells (in addition to hemopoietic stem cells and melanoblasts) in the mouse, human c-*kit* mutations have not been associated with reduced fertility in humans, but have been found only in association with piebaldism and in a human mast cell leukemia cell line.

In summary, in the mouse the c-kit–steel receptor–ligand system plays a crucial role in migration, differentiation, and survival of primordial cells destined to become germ cells, and there is evidence for a role for these factors in human testicular development and carcinogenesis. It has been hypothesized that c-kit and SCF may have a regulatory function in normal testicular tissue by providing environmental factors necessary for spermatogenesis. The relevance of this system to human fertility is yet to be addressed.

DISORDERS OF SEX DIFFERENTIATION: 46,XY AND 46,XX PSEUDOHERMAPHRODITISM   These disorders represent abnormalities of genital morphogenesis, in the presence of gonads that are appropriate for karyotype.

46,XY Pseudohermaphroditism   Male (46,XY) pseudohermaphroditism describes the condition in which an individual with male karyotype and normally formed testes has abnormal masculinization of the internal and/or external genitalia. The causes are numerous, but in essence there are two major classes—defects of production or response to testosterone, and defects of production or response to AMH. The causes of male pseudohermaphroditism are summarized in Table 57-2. Clinical examples are provided in Fig. 57-5.

Disorders of Testosterone Production or Action: General Clinical Features   The genital phenotype in these conditions generally reflects the severity of the defect at the functional level. 46,XY individuals with profound deficiency of androgen production or action have an entirely female phenotype. Those in whom some degree of androgen production and action is retained have a wide spectrum of genital phenotypes, including minor degrees of posterior labial fusion or clitoral enlargement; ambiguous genitalia characterized by incomplete labioscrotal fusion and a clitoris-like phallus; and more significant masculinization with reasonable penile size accompanied by urethral hypospadias, penile chordee, and cryptorchidism. The testes may be located anywhere from the abdomen to the inguinal canals or the labioscrotal region. Internal genital structures range from fully feminized, separate vaginal and urethral structures in cases in which there is minimal androgen action, to more masculinized structures, such as a urogenital sinus with ectopic vaginal orifice, in milder cases in which a moderate degree of androgen production and action has occurred. The development of Wolffian duct structures (epididymis and vas deferens) is also variable, depending on the degree of local testosterone secretion and action in early gestation. The vaginal pouch is blind and Müllerian duct structures are absent or diminutive because AMH is secreted normally by the Sertoli cells.

Disorders of Testosterone Production or Action: Specific Disorders—Leydig Cell Hypoplasia   *Clinical Features and Diagnosis.* Leydig cell hypoplasia (LCH) is a rare cause of male pseudohermaphroditism, in which Leydig cell differentiation and

testosterone production are impaired because of absence or defective function of LH/CG receptors on Leydig cell progenitors. This condition is generally inherited in a male-limited, autosomal recessive pattern. Inability to respond to CG or LH because of absence of the appropriate receptor results in inadequate testosterone production *in utero* and thereafter. The genital phenotype is generally female; however posterior labial fusion, a small vagina, or a urogenital sinus may be present, and occasional patients with small penis are reported, suggesting significant T production in the first trimester. Minimal development of either male or female secondary sexual characteristics occurs at puberty, a feature that distinguishes this condition from the androgen insensitivity syndromes, in which high estrogen production at puberty results in excellent breast development in most cases.

In postpubertal individuals the testes are slightly small. Although Sertoli cells are normal there is hyalinization of the seminiferous tubules and interrupted spermatogenesis and absent or reduced Leydig cells. The latter finding indicates that LH is required for development and survival of Leydig cells. Testicular membrane preparations do not bind labeled hCG, a fact that, until recently, has served as the primary evidence of a defect of the LH/CG receptor.

The diagnosis of Leydig cell hypoplasia would be suggested by low testosterone levels, despite high serum LH, in a 46,XY infant with female or ambiguous external genitalia; this hormonal profile should allow diagnostic differentiation from the androgen insensitivity syndromes, because in these latter conditions, at least theoretically, testosterone concentrations are high. Unlike infants with a testosterone biosynthetic defect, who may also have low serum testosterone and high LH, there is no elevation of testosterone precursors. In addition, there is no increase in testosterone or its precursors in response to hCG administration. Failure of pubertal development in a phenotypic female with high serum LH and no measurable sex steroids would also suggest this diagnosis.

Genetic and Molecular Pathophysiology. LCH is an apparently rare autosomal recessive disorder with an estimated prevalence of approximately 1:1,000,000, although this low prevalence may in part reflect lack of ascertainment. The 60-kb gene encoding the LH/CG receptor (CH/CG-R) is located at chromosomal position 2p21 and comprises 11 exons and 10 introns. The encoded receptor is a member of the seven transmembrane domain class of G-protein-coupled receptors in which ligand binding induces increased intracellular production of cyclic AMP, the principal mediator of hormone action in this system. Exons 1–10 encode the major portion of the amino-terminal extracellular domain, containing a leucine-rich repeat, whereas exon 11 codes for a small part of the extracellular domain, as well as all 7 transmembrane loops and the carboxy-terminal intracellular region. The LH/CG receptor has significant homology with the FSH and thyroid-stimulating hormone (TSH) receptors.

Testicular Leydig cells constitutively express LH/CG receptor in the absence of hormone. Interestingly, the receptor appears to be regulated by its ligand (LH or CG) via two processes: uncoupling (a fairly immediate process that results in reduced cAMP production in response to ligand, without reducing receptor number) and downregulation (a slower, biphasic process resulting in reduced receptor number because of internalization and degradation of already formed receptors, followed by reduced receptor mRNA transcription, via a cAMP-mediated process). These regulatory events are believed to contribute to the phenomenon of desensitization that occurs in the presence of continuous hormonal stimulation. In contrast to the constitutive receptor expression seen in Leydig cells, ovarian cells require hormonal stimulation for receptor expression: in the preovulatory follicle estrogen and FSH synergystically induce receptor mRNA expression in rat granulosa cells, also via cAMP-mediated events. Subsequently, the high levels of LH that occur at ovulation downregulate receptor expression. There appears to be some constitutive expression of LH/CG receptor in theca cells, in addition to hormonal regulation similar to, though less tight than, that seen in granulosa cells.

To date, reports of inactivating mutations in the *LH/CG-R* gene are scarce. In a pair of phenotypic female 46,XY siblings with Leydig cell hypoplasia a nonsense mutation was found in exon 11 of one allele of the *LH/CG-R* gene, introducing a premature termination codon that predicts truncation of the protein within the 5th transmembrane domain. Interestingly, the mutation was also present heterozygously in the phenotypically normal father and was absent in the mother. The affected siblings were therefore presumed to be compound heterozygotes, harboring a second undetected mutation on the other allele of the gene. In vitro studies of this mutant receptor revealed reduced cell surface expression of mutant receptor protein compared with the normal protein. In addition, hCG stimulation of cAMP production was impaired. In another family, three phenotypically female 46,XY siblings who had lack of breast development and primary amenorrhea, high serum LH, and absent Leydig cells on testicular histology, were found to be homozygous for a nonsense mutation that predicts protein termination in the third cytosolic loop of the receptor. Interestingly, their 46,XX sister, who had undergone menarche at 20 years of age, thereafter developing secondary amenorrhea, and who also had increased serum LH concentration, was homozygous for the same mutation. Another pair of affected siblings, born to consanguineous parents, were found to have a homozygous missense mutation resulting in an alanine to proline change at amino acid 593 in the 6th transmembrane domain of the receptor. In vitro studies revealed that although the receptor had normal affinity of binding for CG, the ligand-bound state did not induce cAMP production. The impaired cAMP production by Leydig cells harboring this mutant receptor explains the lack of hormonal action, since transduction of the hormonal signal requires cAMP-mediated events. The final patient whose mutation has been identified to date is a phenotypically male child with subnormal penile size, whose testes were normally descended. His serum LH was at the upper limit of normal for age during childhood. Analysis of genomic DNA revealed a missense mutation that converted the native serine to tyrosine at position 616 in the seventh transmembrane domain of the receptor. Surprisingly, in view of the normal masculinization of the affected child, in vitro studies of the mutant receptor revealed absent LH binding and cAMP production. This apparent paradox suggest either that testosterone secretion during the first trimester of gestation, when external genital morphogenesis occurs, is not LH or CG dependent, or that the in vitro finding of a nonfunctional LH/CG receptor does not reflect its activity in vivo. In contrast, penile growth during the third trimester is clearly dependent on function of the LH/CG receptor.

Defects of Testosterone Biosynthesis A defect in any of the enzymatic steps of testosterone biosynthesis can cause ambiguous genitalia because of insufficient testosterone production during male sexual differentiation. Depending on the location of the enzymatic defect in the steroidogenic pathway, these disor-

ders may also affect glucocorticoid and mineralocorticoid biosynthesis by the adrenal gland (Fig. 57-7). Five defects of testosterone biosynthesis have been described; however, they are relatively uncommon causes of male pseudohermaphroditism. Because all of the genes encoding these enzymes are located on autosomes, these disorders are inherited as autosomal recessive traits. Table 57-4 summarizes molecular information regarding enzymes of steroidogenesis.

The molecular and biochemical heterogeneity within each defect and the consequent variability of the testosterone biosynthetic defect makes it impossible to distinguish these enzyme disorders on clinical grounds. Internal and external genital development is variable, covering the full gamut of features described above. Wolffian derivatives also may be normal or hypoplastic, depending on the severity of the testosterone deficit.

Congenital Lipoid Adrenal Hyperplasia: Steroidogenic Acute Regulatory Protein—StAR; P450 Side-Chain Cleavage Enzyme—P450$_{scc}$ The first and rate-limiting step in gonadal and adrenal steroidogenesis (Fig. 57-7) is the transfer of cholesterol from the outer mitochondrial membrane to the inner membrane, mediated by a recently discovered protein, steroidogenic acute regulatory protein (StAR). Thereafter, conversion of cholesterol to pregnenolone involves three distinct biochemical reactions: 20α-hydroxylation, 22-hydroxylation, and side-chain cleavage (the C20—C22 bond). These reactions are mediated by a mitochondrial mixed function oxidase, cytochrome P450$_{scc}$ (previously known as 20,22-desmolase), located on the inner mitochondrial membrane. A defect in the conversion of cholesterol to pregnenolone causes congenital lipoid adrenal hyperplasia (CLAH), the rarest and most severe form of congenital adrenal hyperplasia. In this condition, neither the gonads nor the adrenals have steroidogenic capability.

Clinical Features and Diagnosis. Infants with this disorder usually present in the first few weeks of life with hyponatremia, hyperkalemia, and metabolic acidosis reflecting severe salt-wasting adrenal insufficiency, often resulting in neonatal death. Affected 46,XY infants usually have completely female external genitalia although minimal masculinization has been reported. Other features are typical for a defect of androgen production, as described above. 46,XX infants have normal female internal and external genital development. Computed tomography or magnetic resonance imaging scan of the abdomen reveals very large, lipid-laden adrenal glands as a result of the accumulation of cholesterol and cholesterol esters. Interestingly, the testes contain normal Leydig cells without lipid accumulation. Serum concentrations of adrenocorticotropic hormone (ACTH) are markedly increased (causing increased skin pigmentation in some cases), as is plasma renin activity, whereas serum and urinary concentrations of all adrenal and gonadal steroids and their metabolites, even after ACTH or hCG stimulation, are profoundly low. Adrenal and gonadal tissues from these patients are unable to convert cholesterol to pregnenolone in vitro. The disease has been said to be extremely rare in European populations; however, this may result in part from failure of ascertainment and early neonatal death precluding the diagnosis in many cases.

In contrast, it is thought to be the second most common form of adrenal hyperplasia in Japan and more than 50% of cases reported to date are of Japanese or Korean heritage. Unlike other forms of congenital adrenal hyperplasia (CAH), heterozotes display normal steroid responses to ACTH stimulation, since the defect is caused by absence or dysfunction of the StAR protein and not to a steroidogenic enzyme deficiency.

Genetic and Molecular Pathophysiology. The cholesterol transport protein *StAR* is encoded by an 8-kb gene located at 8p11.2 that comprises seven exons and six introns and contains an 855-bp open reading frame. A related pseudogene maps to chromosome 13. *StAR* mRNA expression is stimulated by trophic hormones, such as LH and ACTH, via cyclic AMP-mediated events. In addition, the promoter of the *StAR* gene contains binding sites for SF-1 and the estrogen receptor, implicating these important transcription factors in regulation of *StAR* expression. *StAR* mRNA expression in the human is limited to the ovary, testis, adrenal cortex, and kidney. Interestingly, although the placenta is an abundantly steroidogenic tissue, *StAR* is not expressed there, nor in brain, reflecting the fact that these tissues do not exhibit acute regulation of steroidogenesis. *StAR* is not expressed in any nonsteroidogenic tissues. The StAR protein comprises 285 amino acids and contains a hydrophobic amino-terminal region typical of a mitochondrial targeting sequence. It is produced as a 37-kDa cytosolic precursor that is imported to the mitochondria, where it is processed to four mature 30-kDa forms. The acute response of steroidogenic cells to stimulation is the transport of cholesterol to the inner mitochondrial membrane and the cholesterol side-chain cleavage enzyme. The mechanism of action of StAR in this process is thought to involve formation of contact sites between the inner and outer mitochondrial membranes.

In three apparently unrelated Asian patients, homozygous mutations have been detected in the gene encoding StAR: perhaps because of a founder effect, two individuals (one Japanese, one Korean) had the same mutation converting the codon for glutamine at position 258 to a termination codon. The third subject had a similar nonsense mutation, converting arginine 193 to a termination codon. One further patient with CLAH was found to have a mutation that disturbed mRNA splicing, resulting in deletion of the 185 bp of sequence corresponding to exon 5 of the gene. The deleterious effect of these mutations is presumably caused by absence of a functional protein and subsequent cellular damage because of the accumulation of cholesterol esters.

P450 Side-Chain Cleavage Enzyme—P450$_{scc}$ The first enzyme of steroidogenesis, P450$_{scc}$, is encoded by the 20-kb *CYP11A* gene localized to the q23–q24 region of chromosome 15. The gene is expressed in steroidogenic tissues, such as adrenal cortex, ovarian granulosa cells, testicular Leydig cells, and placenta. Expression of the P450$_{scc}$ gene is enhanced by ACTH, gonadotropins, cAMP, and SF-1, which may be acting via other factors. Expression patterns are tissue-specific and involve the use of alternate promoter sequences. The P450$_{scc}$ protein complex is located on the inner mitochondrial membrane. Electrons are transferred from NADPH to adrenodoxin reductase, a membrane-bound flavoprotein, then to adrenodoxin, a soluble iron-sulfur protein,

Figure 57-7 *(continued on next page)* Pathway of steroid biosynthesis and defects in steroidogenesis. The first step in steroidogenesis is the transport of cholesterol across the mitochondrial membrane, mediated by the transport protein StAR. The remaining steps in adrenal and gonadal steroidogenesis are accomplished by a number of enzymes. Most are of the P450 cytochrome family. However, 3β-hydroxysteroid dehydrogenase and 17β-hydroxysteroid dehydrogenase are of the short-chain alcohol dehydrogenase family.

Fig. 57-7 *(continued)*. Molecular defects that cause male pseudohermaphroditism are designated by triangles. Defects that cause female pseudohermaphroditism are designated with stars. 3β-Hydroxysteroid dehydrogenase deficiency can cause either male or female pseudohermaphroditism.
Table 57-4
Enzymes Involved in Steroidogenesis, Their Encoding Genes, and Chromosomal Loci

Gene name	Locus	Enzyme name	Enzyme type/location	Tissue	Action	Cofactors
CYP11A	15q23–24	P450scc	Cytochrome P450 mixed function oxidase Mitochondria	Adrenals, gonads	20α-Hydroxylation 22α-Hydroxylation 20–22 Side-chain cleavage	NADPH Adrenodoxin Adrenodoxin Reductase
HSD3B2	1p13–11	3βHSD	Dehydrogenase Membrane bound	Adrenals, gonads	Conversion of 3β-hydroxy-Δ^5-steroids to 3-keto-Δ^4-steroids	NAD$^+$
CYP21	6p21.3	P450C21	Ctyochrome P450 Mitochondria	Adrenals, gonads	21-Hydroxylation	NADPH
CYP11B1	8q22	P450C11	Cytochrome P450	Fascic, glomerulosa	11-Hydroxylation	NADPH
CYP11B2	8q22	P450cmo	Ctyochrome P450	Glomerulosa only	11 Hydroxylation, 18-Hydroxylation 18-Oxidation	
CYP17	10q24.3	P45017α	Cytochrome P450 Endoplasmic reticulum	Adrenals, gonads	17α-Hydroxylation 17-20 Side-chain cleavage (lyase)	NADPH
HSD17 (EDH17B1)	17q12–21	17βHSD	Dehydrogenase isozoymes	Gonads, placenta, other tissues	Interconversion androstenedione/ testosterone; esterone/estradiol	NADPH
HSD17B2 (EDH17B2)	16q24.1–24.2	17βHSD2	Membrane bound			
HSD17B3 (EDH17B2)	9q22	17βHSD3				
CYP19	15q21.1	P450arom	Cytochrome P450 Endoplasmic reticulum	Gonads, placenta	Conversion C19–C18 steroids	NADPH Reductase
SRD5A1	5p15	5α-reductase 1		Liver, skin	Reduction C19 and C21 steroids	NADPH
SDR5A2	2p23	5α-reductase 2	Microsomes	Liver, external genitalia		

and finally to the enzyme P450$_{scc}$ itself. No molecular defects in *CYP11A* have been found to date, despite extensive molecular studies; limited studies of adrenodoxin and adrenodoxin reductase mRNAs have also been normal in individuals with CLAH.

3β-Hydroxysteroid Dehydrogenase Deficiency The 3β-hydroxysteroid dehydrogenase/Δ^5–Δ^4 isomerases (3β-HSD1 and 3β-HSD2) are two highly homologous noncytochrome, membrane-bound short chain alcohol dehydrogenases that require NAD$^+$ as a cofactor. Both have two separate enzymatic activities: dehydrogenase activity and isomerase activity (conversion of Δ^5-steroids to Δ^4-steroids), the net result of which is the conversion of 3β-hydroxy-Δ^5-steroids (pregnenolone, 17-hydroxypregnenolone, and dehydroepiandrosterone) to the 3-keto-Δ^4-steroids (progesterone, 17-hydroxyprogesterone, and Δ^4-androstenedione, respectively). This is an essential step in the biosynthesis of all classes of steroid hormones; deficiency of 3β-HSD activity in steroidogenic tissues impairs both adrenal and gonadal (testicular and ovarian) steroidogenesis and is reported to be the second most common cause of congenital adrenal hyperplasia.

Clinical Features and Diagnosis. Affected 46,XY individuals have variable impairment of internal and external genital masculinization resulting from inadequate fetal testosterone biosynthesis because of defective function of the testicular isozyme, 3β-HSD2. In some cases there is also salt wasting adrenal insufficiency as a result of reduced synthesis of aldosterone and cortisol. Less severe "late-onset" forms of 3β-HSD present with more complete masculinization and without salt-wasting, reflecting genetic heterogeneity within this disorder. Because of lack of estrogen production, there is no breast enlargement at puberty, either in 46,XX or 46,XY individuals. The classic hormonal profile is a markedly increased concentration of the Δ^5-steroids (pregnenolone, 17-hydroxypregnenolone, and dehydroepiadrosterone) and their metabolites in the serum and urine. However, somewhat confusingly, Δ^4-steroids may also be increased, because of peripheral conversion of Δ^5-steroids to Δ^4-steroids resulting from 3β-HSD1 activity in peripheral tissues. Nevertheless, despite peripheral conversion, the ratio of Δ^5- to Δ^4-steroids and their metabolites is generally elevated. The peripheral Δ^5- to Δ^4- steroid conversion explains the paradoxical finding of ambiguous genitalia in conjunction with apparently normal Δ^4-steroid levels in some of these patients. Although Δ^4- steroid concentrations may be normal peripherally, it is probable that they were inadequate at the tissue level in the developing genitalia, and that specific activity of the testicular isoform, 3β-HSD2, is required to generate adequately high androgen levels during embryogenesis.

Genetic and Molecular Pathophysiology. There are two highly homologous human genes encoding isoenzymes responsible for 3β-HSD activity—*HSD3B1* and *HSD3B2*, encoding 3β-HSD1 and 3β-HSD2, respectively. The genes are approximately 7–8 kb in size and contain 4 exons and 3 introns. There is evidence for tight linkage between these genes, which are both located within band p13.1 on chromosome 1. Three pseudogenes containing stop codons or deletions have also been identified. The *HSD3B1* gene is the predominant form expressed in nonsteroidogenic tissues, such as liver and kidney, and encodes a 371-amino acid (42-kDa) protein. No mutations have yet been detected in the type I gene in individuals with 3β-HSD deficiency. The type II isoform of 3β-HSD has the same enzymatic activities but is expressed almost exclusively in the steroidogenic cells of the adrenals and gonads. In bovine adrenocortical cells the enzyme colocalizes with P450$_{scc}$

at the inner mitochondrial membrane, suggesting a possible functional association between the two enzymes in regulation of steroidogenesis. Studies in cultured human adrenal cells reveal regulation of 3β-HSD mRNA and protein levels by ACTH and angiotensin II. In Leydig cells there is some evidence from rodent studies that 3β-HSD activity is regulated by LH/CG.

More than 20 different mutations have been reported in the *HSD3B2* genes of individuals with 3β-HSD deficiency, including 14 different single-base mutations in one study. Other mutations include a single-base insertion resulting in a frameshift, an intronic mutation causing aberrant splicing, and single-base mutations causing either premature termination (nonsense mutations) or amino acid substitutions (missense mutations). Gene conversion events (transfer of deleterious mutations from associated pseudogenes) have been suggested to underlie some of the mutations in *HSD3B2*. In vitro studies using site-directed mutagenesis to recreate a number of mutant 3β-HSDs, reveal significantly reduced enzyme affinity and specific activity for the substrates pregnenolone and dehydroepiandrosterone, and in some cases for the enzyme cofactor NAD$^+$. The finding of a specific abnormality of NAD$^+$ binding associated with substitution of aspartic acid for glycine at position 15 raises the speculation that this region may contribute to the NAD-binding domain of the enzyme.

Although absence of salt losing in some patients with severe undermasculinization suggests that impairment of enzyme activity may differ between gonads and adrenals, molecular data indicate that the enzyme is similarly dysfunctional for either of its two main substrates, pregnenolone (adrenal) and dehydroepiandrosterone (gonad). These data suggest that the absence of salt wasting in some individuals results from weak residual enzyme activity sufficient to prevent salt loss, but insufficient to produce the testosterone levels required for male sex differentiation. The clinical heterogeneity of affected individuals (i.e., salt losing vs non–salt losing, varying degrees of masculinization) is at least in part explained by the genetic heterogeneity. Not surprisingly, mutations that completely destroy enzyme activity are associated with a more severe syndrome than are those that allow retention of some enzyme function. In general patients with non–salt wasting disease have up to 10% retained enzyme activity; however, there is no clear correlation between the molecular defect, enzyme activity, and clinical phenotype. The gene is located on an autosome and affected individuals are generally homozygous for the mutant allele; consanguinity has been reported in a number of pedigrees. Compound heterozygosity for two different mutations has been reported in a number of classically affected patients, and minor manifestations of simple heterozygosity have been described, including mild overproduction of Δ^5-steroids and mild ovarian dysfunction.

17α-Hydroxylase Deficiency and 17,20-Lyase Deficiency A single microsomal enzyme, cytochrome P450c17, catalyzes two consecutive oxidation reactions, the 17α-hydroxylase and 17,20-lyase (17,20-desmolase) reactions of adrenal and gonadal steroidogenesis. The 17α-hydroxylase reaction converts pregnenolone to 17-hydroxypregnenolone and progesterone to 17-hydroxyprogesterone, respectively (Fig. 57-7). This reaction is the rate-limiting step in androgen biosynthesis. The 17,20-lyase reaction cleaves the C17,20 bond to convert the C21 steroid 17-hydroxypregnenolone to the C19 steroid dehydroepiandrosterone (DHEA) and likely also catalyzes the equivalent conversion of 17OH-progesterone to Δ^4-androstenedione, although this

latter is somewhat controversial, with discrepant findings in various studies. DHEA and androstenedione are the major precursors of testosterone and estradiol.

Clinical Features and Diagnosis. 17α-Hydroxylase is required for cortisol, androgen, and estrogen synthesis and the enzyme is expressed in adrenal cortex and gonads. 17α-Hydroxylase deficiency may be characterized by deficiency of either or both of this enzyme's activities; however, the molecular basis for this differential expression of the defect is at present unclear. Because of fetal androgen deficiency, 46,XY individuals with 17α-hydroxylase deficiency in the adrenals and gonads have female external genitalia, although a few individuals with limited masculinization have been described. In 46,XX individuals the external genitalia are normal; however, there is failure of development of secondary sexual characteristics at puberty (breast development, pubic and axillary hair) because of deficiency of both adrenal androgens and ovarian estrogen (*see* Chapter 37).

Deficiency of 17α-hydroxylase activity also impairs adrenal cortisol production, and the resultant compensatory ACTH hypersecretion stimulates synthesis of progesterone, deoxycorticosterone (DOC), corticosterone, and 18-hydroxycorticosterone. The excess of the latter three compounds causes salt and water retention, hypertension, and hypokalemia because of their mineralocorticoid activity. Renin activity is therefore suppressed and aldosterone production reduced. Despite impaired cortisol production, evidence of glucocorticoid deficiency is unusual, perhaps because corticosterone has weak glucocorticoid activity.

In addition to catalyzing the 17α-hydroxylation reaction in the adrenals and gonads, $P450_{17\alpha}$ also catalyzes the 17,20-lyase reaction resulting in conversion of 17-hydroxypregnenolone to DHEA, and probably 17-hydroxyprogesterone to androstenedione (Fig. 57-7). Thus, deficiency of the lyase activity in the gonads prohibits synthesis of DHEA, Δ^4-androstenedione, testosterone, and estrogen. Glucocorticoid and mineralocorticoid production are retained because the enzymatic defect is distal to these pathways. hCG stimulation produces an increased ratio of 17-hydroxy-C21-steroids (17-hydroxyprogesterone and 17-hydroxypregnenolone) to C19-steroids (DHEA and Δ^4-androstenedione).

Genetic and Molecular Pathophysiology. *CYP17* is a single 6.6-kb, 8 exon, 7 intron gene located on chromosome 10 at band q24.3. The *CYP17* gene is very similar to *CYP21* (encoding the 21-hydroxylase enzyme), and the two may have originated from a common ancestral gene. $P450_{17\alpha}$ is expressed in human adrenal, testis, and ovarian theca cells, but not in ovarian granulosa cells or placenta. $P450_{17\alpha}$ mRNA is upregulated by ACTH via cAMP, and cAMP regulatory regions have been identified in the 5'-flanking region of the bovine $P450_{17\alpha}$ gene; expression is also regulated by the inhibin-activin system in the ovary. Gene transcription is inhibited by activators of protein kinase C. The *CYP17* gene encodes cytochrome $P450_{17\alpha}$ a 508-amino acid, 57-kDa protein that is part of the $P450_{17\alpha}$ complex anchored to the smooth endoplasmic reticulum of steroidogenic cells. The complex includes a 78-kDa flavoprotein reductase termed P450 reductase, containing binding domains for nicotinamide adenine dinucleotide phosphate (NADPH), flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD); and the cytochrome $P450_{17\alpha}$ enzyme itself, which contains heme-binding and steroid-binding regions, accepts electrons from NADPH via the P450 reductase, and catalyzes the overall oxidation reaction. The ratio of 17α-hydroxylase to 17,20-lyase activity differs between adrenal and testis and is

developmentally regulated at adrenarche, an increase in the ratio of lyase to hydroxylase activity occurring at this time. Site-directed mutagenesis has elucidated specific amino acid residues critical for either the 17α-hydroxylase or the 17,20-lyase activity; however, the basis for the time- and tissue-specific differential regulation of the enzyme's two main activities is not yet fully understood. There is evidence that serine phosphorylation of the enzyme increases lyase activity, whereas dephosphorylation eliminates this activity. Other regulatory features may include variation in the ratio of the NADPH P450 reductase to the $P450_{17\alpha}$ enzyme itself, resulting in alterations of electron transfer to the enzyme. The presence of specific endoplasmic reticulum membrane lipids in certain cell types has also been suggested as a factor involved in the differential activity of this enzyme's functions.

A variety of molecular defects has been described in the $P450_{17\alpha}$ genes of at least 15 individuals with 17α-hydroxylase deficiency. These include large deletions or insertions, small deletions and duplications, and single-base mutations causing frameshifts, premature termination, or amino acid substitutions. In vitro studies of a recreated mutant $P450_{17\alpha}$, in which histidine at position 373 was replaced by leucine, revealed that the mutant enzyme failed to bind the heme moiety critical for catalytic activity. Other mutations, however, are located distant from the critical heme-binding region or the active site, suggesting that the enzyme is sensitive to structural change. Interestingly, one specific mutation, a 4-base duplication that alters the reading frame of the *CYP17* gene, was found in six Dutch families and two families of Canadian Mennonites, suggesting that a founder mutation had presumably occurred in the Dutch antecedents of the Mennonites. Compound heterozygosity has been reported in this form of congenital adrenal hyperplasia, as well as in the more common forms. Individuals heterozygous for a single 17α-hydroxylase mutation are clinically normal; however, ACTH stimulation produces increased serum concentrations of DOC, corticosterone, and 18-hydroxycorticosterone.

A number of cases of 17,20-lyase deficiency have been reported in which 17α-hydroxylase activity was said to have been normal. Theoretically, different mutations in the $P450_{17\alpha}$ gene could result in either 17α-hydroxylase deficiency, 17,20 lyase deficiency, or both. However, in vitro protein expression of mutant genes of individuals with the clinical diagnosis of isolated 17α-hydroxylase deficiency has revealed the presence of combined enzyme deficiencies in all cases studied thus far and there is no clear molecular explanation for the apparently retained 17α-hydroxylase activity in vivo. In vitro analysis of mutant $P450_{17\alpha}$ enzymes predicted from the mutations detected in one compound heterozygote 46,XY patient with ambiguous genitalia reveals that retention of 20% of normal 17,20-lyase activity is adequate for some degree of masculinization.

17β-Hydroxysteroid Dehydrogenase 3 Deficiency The 17β-hydroxysteroid dehydrogenases (17β-HSDs, also known as 17β-ketosteroid reductases and as estradiol 17β-dehydrogenases) are NAD+/NADPH-dependent, membrane-bound enzymes not of the cytochrome P450 type, which catalyze the only reversible steps in the steroid biosynthetic pathway: interconversion of Δ^4-androstenedione↔testosterone, DHEA↔Δ^5-androstenediol and estrone↔estradiol) (Fig. 57-7) by oxidation or reduction of C-18 and C-19 steroids. There are at least three or four tissue-specific isozymes with differing specificity for either the oxidative or the reductive reaction. The isozymes are encoded by at least three distinct genes. 17β-HSD3 is the testicular isozyme, respon-

sible for the final step in testosterone synthesis, reduction of androstenedione to testosterone. Deficiency of this enzyme is the most common defect of androgen production.

Clinical Features and Diagnosis. Interestingly, although 46,XY individuals with deficiency of testicular 17β-HSD3 activity have female or mildly masculinized external genitalia, their internal genitalia are well-masculinized, with normally formed epididymis, vas deferens, and seminal vesicles. Reduced activity of testicular 17β-HSD3 is inferred by the finding of elevated ratios of androstenedione to testosterone and estrone to estradiol in spermatic venous samples. In addition, testicular tissues of affected individuals demonstrate impaired conversion of labeled Δ^4-androstenedione to testosterone in vitro. This defect is isolated to the gonads—the site of expression of 17β-HSD3. Other tissues have normal 17β-HSD activity because of normal function of the type 1 and 2 isozymes. The relatively normal masculinization of internal structures may result from activity of 17β-HSD isozymes other than 17β-HSD3 in the proximity of the Wolffian ducts producing adequate local testosterone by conversion of testis-derived androstenedione. In contrast there is insufficient testosterone at the level of the external genital primordia to act as substrate for 5α-reductase conversion to dihydrotestosterone.

A striking feature of this disorder is the marked virilization that occurs at puberty. Affected 46,XY individuals develop a male body habitus with abundant body and facial hair, enlargement of the penis and testes to normal adult size, and pigmentation and rugation of the labioscrotal folds. Gynecomastia is variably present. Many affected individuals spontaneously adopt the male gender role, with apparently adequate sexual function, but with infertility. These clinical observations correlate with normalization of peripheral and spermatic vein testosterone levels. Part of this effect appears likely to be related to increased LH secretion and Leydig cell hyperplasia, because Δ^4-androstenedione levels remain markedly elevated, indicating persistent enzyme dysfunction. Peripheral testosterone production as a result of retained extragonadal 17β-HSD activity may also contribute. The phenotype and clinical course of individuals with 17β-HSD deficiency is similar to that of individuals with 5α-reductase deficiency (described below).

The diagnosis of 17β-HSD3 deficiency is suggested by a 10- to 15-fold elevation of the ratios of Δ^4-androstenedione to testosterone and of estrone to estradiol in the perinatal period, after hCG stimulation in childhood, or after puberty. Because of a secondary increase in 3β-HSD activity, DHEA may be normal or only mildly elevated. Glucocorticoid and mineralocorticoid synthesis remain normal because the enzymatic defect is distal to these pathways.

Genetic and Molecular Pathophysiology. There are at least four HSD17B enzymes encoded by separate genes and expressed in a tissue-specific fashion, some being expressed predominantly in estrogenic or androgenic tissues and others more widely. The nomenclature of this group of genes and enzymes is quite daunting: the type 1 enzyme, 17β-HSD I, is also known as estradiol-17β dehydrogenase II. This isozyme is encoded by a gene located at 17q11–12, referred to as *HSD17B1* or *EDH17B2*. This locus in fact contains two genes in tandem: *h17b-HSDI* and *II*. The active gene is *h17b-HSDII*; *h17b-HSDI* is a pseudogene, also referred to as *EDH17BP1*, which is 89% homologous to the active gene. 17b-HSD I appears to be the isozyme responsible for ovarian 17β-HSD activity. The type 2 isoform, 17β-HSDII, is encoded by *HSD17B2*, located at 16q24. This isozyme, which is a 387-amino

acid, approximately 43-kDa progestin-regulated protein, is responsible for 17β-HSD activity in placenta and endometrium. Located predominantly in the endometrium, placenta, liver, and small intestine, this isozyme has a preference for NAD$^+$ as its cofactor in oxidation of estradiol and testosterone to estrone and androstenedione, respectively. The testicular isoform, 17β-HSD3 (III), which is the isozyme implicated in male pseudohermaphroditism as a result of 17β-HSD deficiency, is encoded by *HSD17B3 (EDH17B3)*, which shares 23% sequence homology with the *HSD17B1* and *2* genes. The gene spans 60 kb, contains 11 exons, and is located at 9q22. This isozyme preferentially uses NADPH as its cofactor in the reduction of androstendione to testosterone. In addition to being found in ovary, testis, and placenta, significant levels of various 17β-HSD mRNAs are found in peripheral sites, such as uterus, breast, prostate, and adipose tissue. In these peripheral locations 17β-HSD may play a major role in regulating the levels of active androgens and estrogens, by using either their oxidative or reductive functions. The 17β-HSDs are not expressed in the adrenals.

Mutations have been identified in the *HSD17B3* genes of approximately 20 individuals with 17β-HSD deficiency. These include single-base mutations causing amino acid substitutions, frameshift mutations, and splice junction mutations causing abnormal mRNA splicing and thereby disturbed protein structure and enzyme function. One 46,XY phenotypic female was found to have compound heterozygosity for two distinct amino acid substitutions and another had compound heterozygosity for a splice acceptor mutation and a missense mutation. When expressed in cultured mammalian cells in vitro the mutant enzymes displayed impaired enzyme activity. The unusual finding of normal Wolffian structures in these 46,XY phenotypic females is potentially explained by activity of 17β-HSD isozymes other than 17β-HSD3 converting testis-derived androstenedione to testosterone in the local area of the internal genital structures. Mutations have not been reported in the *HSD17B1* or *HSD17B2* genes to date. 17β-HSD deficiency is inherited in an autosomal recessive fashion and a number of extensive inbred Arab kindreds with numerous affected individuals have been reported.

Disorders of Androgen Action 5α-REDUCTASE DEFICIENCY The 5α-reductases are microsomal enzymes that catalyze the 5α-reduction of many C19 and C21 steroids, using NADPH as a cofactor. In the context of disorders of sexual differentiation, the most critical of these reactions is the conversion of testosterone to DHT, mediated by the isozyme 5α-reductase 2 (II). Deficiency of this enzyme results in a form of male pseudohermaphroditism previously referred to as pseudovaginal perineoscrotal hypospadias. This disorder is described in greater detail in Chapter 60.

Clinical Features and Diagnosis. Deficiency of 5α-reductase 2 in the tissues of the bipotential fetal external genitalia and urogenital sinus results in inadequate local DHT concentrations. As in other forms of defective androgen production or action, there is subnormal masculinization of these structures, generally presenting as ambiguous external genitalia. The genital phenotype varies widely between and even within affected kindreds, the most consistent findings being underdevelopment of the penis and prostate. It is on the basis of these clinical findings that the requirement for DHT in external genital masculinization has been inferred. Because differentiation of the gonads and Wolffian ducts is not dependent on DHT, the testes, epididymides, vasa deferentia, and seminal vesicles develop normally.

One of the most intriguing and well-documented features of this disorder is the striking virilization, including increased muscularity and deepening of the voice, that occurs at puberty in many affected individuals. In addition, the testes often enlarge and descend; however, spermatogenesis is absent or severely impaired. Whether this virilization is mediated by improved DHT levels or by supranormal T levels remains unclear. Acne, facial hair, temporal hair recession, and prostatic enlargement do not develop, presumably because these events require higher concentrations of DHT. In contrast to patients with androgen insensitivity syndromes, described below, gynecomastia does not develop because there is no increase in testicular estrogen production. Many affected individuals initially raised as females change their gender role to male around the time of puberty, for reasons that have not been fully elucidated, but likely include cultural as well as biologic factors.

Reduced conversion of T to DHT in the target tissues results in the marked increase in the ratio of T to DHT diagnostic of 5α-reductase 2 deficiency. In normal infants (2 weeks to 6 months of age), the hCG-stimulated T:DHT ratio is approximately 5 ± 2 (mean ±SD). Affected infants have markedly increased T:DHT ratios, in the 20–60 range or higher. Serum concentrations of LH may be mildly increased. 5α-Reductase 2 deficiency can be differentiated from 17β-HSD deficiency by the characteristic increase of serum androstenedione in the latter condition. A more direct, but more invasive diagnostic method is the in vitro demonstration of decreased 5α-reductase activity in genital skin fibroblasts; however, because post-hCG serum T:DHT concentrations are diagnostic, this procedure is not required to verify the diagnosis.

Genetic and Molecular Pathophysiology. There are two isozymes of 5α-reductase encoded by separate genes. 5α-Reductase 1 is encoded by the *SRD5A1* gene located at 5p15, and 5α-reductase 2, the enzyme defective in the clinical syndrome of 5α-reductase deficiency, is encoded by the *SRD5A2* gene located at 2p23. The genes are structurally similar, with five coding exons and four introns each. The two enzymes share approximately 50% amino acid identity. Androgen binding is mediated by the ends of the enzyme molecule and binding of NADPH, required as the cofactor for the reduction reaction, by the carboxy-terminal half. The 5α-reductase isozymes have differential expression patterns. The type 1 isozyme is not detectable in the fetus, but is transiently expressed in newborn skin and scalp, and permanently expressed in the liver, and in skin after puberty. The type 2 isozyme is expressed in the liver and in androgen target tissues, including the external genitalia, accessory sex organs, and prostate. The ontogeny of 5α-reductase 2 expression is incompletely characterized; however, the enzyme is not expressed in the Wolffian ducts at the time of their differentiation, a finding that supports the contention that T rather than DHT is the critical androgen involved in this process. Its expression is upregulated by androgens, as demonstrated by the marked increase in 5α-reductase 2 mRNA level in the prostate of castrate animals after testosterone administration. Expression appears to be regulated in the opposite fashion in the liver. Interestingly, 5α-reductase activity has also been detected in neurons.

5α-Reductase 2 deficiency is inherited in an autosomal recessive fashion, and there is a high frequency of consanguinity within affected kindreds. A wide variety of mutations has been identified in affected families from more than 20 different ethnic groups. Mutations range from complete deletion of the *SRD5A2* gene in a Papua New Guinea kindred, to single-base mutations distributed throughout the *SRD5A2* gene that result in gene-splicing defects, amino acid substitutions, or premature termination. A number of affected kindreds demonstrate compound heterozygosity for different mutations. In vitro expression of mutant proteins reveals a variety of causes of deficient enzyme activity: deletions, premature termination codons, and splice junction defects prevent expression of a functional enzyme; whereas amino acid substitutions impair binding of testosterone or produce an unstable enzyme. Alterations in both androgen and NADPH binding may be produced by such mutations. Differences in enzyme stability and affinity for testosterone and NADPH between kindreds reflect the genetic heterogeneity of the enzyme defect. There is no abnormality of the isozyme 5α-reductase 1 in individuals with the clinical syndrome of 5α-reductase deficiency, a fact that may in part explain the marked pubertal virilization of affected individuals.

Androgen Insensitivity Syndromes (Androgen Receptor Disorders) The androgen receptor (AR) is a nuclear transcription factor that is activated by binding of androgen to a conformation capable of binding to elements in the promoter regions of androgen regulated genes to regulate their transcription. Defective function of this transcription factor results in resistance to the effects of androgens—the well-characterized androgen insensitivity (or resistance) syndromes. These conditions are described in greater detail in Chapter 60.

Clinical Features and Diagnosis. The syndromes of androgen insensitivity (AIS), referred to by some authors as testicular feminization, are believed to comprise the most common definable cause of male pseudohermaphroditism. Affected individuals display variable degrees of defective masculinization. In the complete form of AIS not only is the genital phenotype unequivocally female, the labia minora and majora and clitoris in fact may be underdeveloped. Individuals with partial forms of AIS, who have some retained AR activity, have external genital phenotypes ranging from female with pubic hair at puberty, to almost completely masculinized. The complete form of AIS has a prevalence of approximately 1:20,000 male births. The prevalence of the partial forms of AIS is unknown.

Diagnosis of AIS in infancy currently relies on clinical features, because there have been no definitive hormonal studies in infants. Preliminary data in a few infants with complete AIS (CAIS) suggest absence of the typical postnatal LH and T surge seen at around 6–12 weeks of age in normal male infants. Diagnosis of CAIS is generally based on the classic clinical findings of 46,XY karyotype, testes, and absent uterus in an otherwise normal phenotypic female. The only condition with which complete AIS could be confused in infancy is Leydig cell hypoplasia (described above). However, the brisk T response to hCG in patients with CAIS should clearly differentiate these two conditions.

Diagnosis of partial forms of AIS in infancy is notoriously difficult, because there is no clear hormonal profile; however, a few case reports have noted increased concentrations of LH and T. Lack of suppression of sex hormone-binding globulin after androgen administration may aid in the diagnosis of these conditions; however, such studies have been undertaken in only a limited number of cases to date. The diagnosis of AIS should be suspected in a 46,XY infant with female or ambiguous genitalia if either the baseline or the hCG-stimulated concentrations of T and DHT are normal or exaggerated without disproportionate excess of T precursors. Demonstration of abnormal androgen binding in cultured genital skin fibroblasts or identification of a

mutation in the AR gene of an affected individual confirms the diagnosis, but is impractical outside of research institutions. Furthermore, measured receptor levels and androgen binding affinity often correlate poorly with the degree of masculinization. Depending on the severity of the androgen resistance, varying degrees of virilization and/or feminization occur at puberty. At and beyond puberty, LH, T, and DHT increase to supranormal levels and serum estrogen concentrations are also enhanced, because of testicular estrogen secretion (driven by LH) and peripheral aromatization of T.

Genetic and Molecular Pathophysiology. The approximately 90-kb gene encoding the AR contains eight coding exons and seven introns and is localized to the q11–12 region of the human X chromosome. AIS is thus inherited in an X-linked fashion. The AR is expressed in a wide array of genital and nongenital tissues, reflecting its role as a fairly ubiquitous transcription factor. The *AR* gene encodes a 110-kDa protein that is a member of the steroid receptor superfamily, comprising of three major functional domains: amino-terminal (transcription-regulating), central DNA-binding (zinc finger), and carboxy-terminal steroid-binding. After binding androgen, the AR, as a homodimer, interacts with androgen response element (ARE) DNA sequences in the promoter regions of target genes to regulate their transcription.

Molecular analysis of the *AR* genes of more than 100 hundred unrelated individuals with various forms of AIS has revealed a highly heterogeneous genetic basis for the spectrum of clinical disorders. Defects include rare complete and partial gene deletions, insertions and deletions of a few basepairs, and single-base mutations that disrupt splice junctions, introduce premature termination codons, or cause amino acid substitutions. Complete and subtotal deletions of the *AR* gene, as well as frameshift and nonsense mutations, result in absence of a functional AR protein. In contrast, missense mutations resulting in amino acid substitutions, of which at least 150 have now been described, allow production of a structurally normal protein. The majority of missense mutations (approximately 80%) are located in the five exons encoding the steroid-binding domain, with almost all of the remainder occurring in the two exons encoding the DNA-binding domain. The function of many mutant receptors has been analyzed in vitro: when the mutation affects the steroid-binding domain androgen binding may be absent, reduced (affinity or capacity or both), or qualitatively abnormal (thermolability of binding, increased ligand dissociation, or altered binding specificity). Mutations located within the zinc finger DNA-binding domain are generally associated with normal (occasionally increased) androgen binding; however, there is altered affinity, capacity, or specificity of receptor binding to appropriate DNA sequences. In vitro studies indicate that the underlying abnormality of defective ARs, whether the mutation affects DNA or androgen binding, is loss of transcriptional competence of the mutant receptor—reduced ability to regulate transcription of androgen-dependent target genes.

Disorders of Anti-Müllerian Hormone Production or Action—The Persistent Müllerian Duct Syndrome—Types I and II
DISORDERS OF ANTI-MÜLLERIAN HORMONE PRODUCTION Anti-Müllerian hormone ([AMH] or Müllerian inhibiting substance [MIS]) is a glycoprotein product of testicular Sertoli cells that mediates regression of the Müllerian duct structures during normal male embryogenesis. Deficiency of this hormone or abnormality of its receptor results in persistence of the Müllerian ducts, resulting in the mildest form of male pseudohermaphroditism.

Clinical Features and Diagnosis. Karyotypic males with deficiency of AMH have normal male external genitalia, normal testicular histology, and normal Wolffian duct differentiation. The two specific defects found in these individuals are persistence of the Müllerian ducts, and abnormalities of testicular descent (the persistent Müllerian duct syndrome—PMDS). The typical case is that of a phenotypically normal male infant with bilateral cryptorchidism (normal testicular histology) and inguinal hernias, who is found, at the time of hernia repair, to have a uterus, cervix, and fallopian tubes in the inguinal canal. Serum concentrations of AMH, which is readily measurable in the serum of normal males until puberty, are reduced in most affected individuals with PMDS, referred to as type I. In some, AMH concentrations are normal, suggesting either bioinactivity of the hormone (not yet reported), or an AMH receptor defect (discussed below), referred to as PMDS type II. A recent study determined that mutations of AMH and AMHR each account for approximately 50% of cases of PMDS.

Genetic and Molecular Pathophysiology. The human gene encoding AMH contains five exons and is located on chromosome 19, at position p13.3–13.2. Persistent Müllerian duct syndrome is therefore inherited in an autosomal recessive, male-limited, pattern. After *SRY*, *AMH* is the first molecular marker specific for testis differentiation. Its expression in developing mouse testis begins significantly later than that of *SRY*, at about day 13.5. In fact, *SRY* may regulate *AMH* production in males, because the *AMH* gene contains a regulatory element within its promoter that likely binds SRY. Notably however, the 48-h temporal dissociation between the expression of these two proteins suggests involvement of one or more intermediate factors. *AMH* expression is also regulated by SF-1, which binds to the *AMH* gene promoter, likely using a cofactor for optimal gene regulation. After puberty, AMH production is downregulated by androgens (a feature absent in individuals with AIS). *AMH* is not expressed prenatally in the ovary. However low amounts of AMH are released into the follicular fluid by mature granulosa cells in normal postpubertal females, who do not express SRY.

AMH, a member of the TGF-β family of growth factors, is a 560-amino acid, approximately 70-kDa glycoprotein that forms a 140-kDa homodimer. AMH is produced by Sertoli cells not only during the critical period, when it induces regression of the Müllerian ducts (weeks 9–11 of human gestation), but also in late gestation, after birth, and even in adulthood (at a reduced level), suggesting that AMH may have physiologic roles other than its control of Müllerian duct regression. In its role as the inducer of Müllerian duct regression in males during embryogenesis, AMH acts in a paracrine fashion, mediating only the regression of the ipsilateral Müllerian duct. Given the fact that the testes are invariably undescended in PMDS, one postulated role for AMH in the latter part of gestation is in the regulation of testicular descent. However, this speculation is tempered by the finding of variable AMH levels in boys with simple cryptorchidism. A postulated role of AMH in postpubertal females is to inhibit oocyte meiosis, allowing for enhanced oocyte maturation before selection for ovulation. AMH acts via the type II AMH receptor at target sites.

Mutations of the *AMH* gene have been identified in approximately 20 patients with the PMDS type I phenotype who have low or undetectable serum AMH. These include premature termination codons, frameshift mutations, and missense mutations present in the homozygous or compound heterozygous state. Surprisingly, the first exon of the *AMH* gene appears particularly mutation-

prone although it codes for an amino-terminal part of the AMH protein, which is not essential to bioactivity. The deleterious effect of *AMH* gene mutations reflects loss of function of the encoded peptide, presumably because of the markedly abnormal structure created by protein truncation, the predominant form of mutation reported to date.

DISORDERS OF ANTI-MÜLLERIAN HORMONE ACTION   The clinical features of this disorder are identical to those of the originally described PMDS. Since the availability of bioassay and radioimmunoassay and techniques for measurement of AMH, this group of patients has been identified by the finding of normal or increased serum concentrations of bioactive AMH (PMDS type II).

Genetic and Molecular Pathophysiology. The gene encoding human AMH receptor contains 11 exons and is located at 12q13. Surprisingly, the expression of *AMHR* is not detected until mouse embryonic day 15, substantially later than that of its ligand AMH (day 13.5). If this is a true biologic phenomenon, rather than a methodologic artifact, its basis remains to be explained. It is similarly enigmatic that expression of *AMHR* is regulated by androgens; however, androgens are not produced until after the onset of AMH secretion, in the hiatus between *AMH* and *AMHR* expression, suggesting that initial regulation of AMHR is not by androgens or AR. In mouse *AMHR* is expressed in mesenchymal cells adjacent to the Müllerian ducts, suggesting that AMH may alter some aspect of the mesenchyme surrounding the Müllerian ducts, which in turn induces duct regression. The receptor protein is a membrane-bound serine–threonine kinase similar to those for TGF-β and activin, containing a single transmembrane domain. Although it binds ligand directly, it requires the presence of a type I receptor for signal transduction.

Since its recent cloning, mutations in the human *AMHR* gene have been elucidated. The first reported case had a homozygous mutation at the splice donor site of intron 2, resulting in a downstream amino acid substitution and insertion of four new residues. In a study of 16 *AMHR* mutations, 10 patients had a 27-bp deletion in exon 10. Four patients were homozygous for this mutation, which predicts the loss of nine amino acids from the protein, and 6 patients were compound heterozygotes, having missense mutations on their other allele.

46,XX Pseudohermaphroditism   Essentially, disorders of female sex differentiation (female pseudohermaphroditism) represent the converse of male pseudohermaphroditism, in general resulting from excessive androgen exposure. Although intuitively likely, exaggerated response to normal androgen levels has not yet been described as a cause of female pseudohermaphroditism. There are far fewer causes of virilization of a female fetus than there are of undermasculinization of a male fetus. Abnormalities of Müllerian development, such as the Mayer-Rokitansky-Küster-Hauser syndrome, represent the mildest form of female pseudohermaphroditism. Lack of fetal estrogen effect does not affect gonadal or genital development, clearly evidenced by the fact that transgenic mice deleted for the estrogen receptor are phenotypically normal.

Disorders Producing Excessive Fetal Androgenization
The most common cause of excess fetal androgen production is congenital adrenal hyperplasia (of the 21-hydroxylase, 11β-hydroxylase, or 3β-hydroxysteroid dehydrogenase deficiency types). Molecular defects in these disorders are summarized in Figs. 57-8 and 57-9. A much rarer cause of female pseudohermaphroditism is aromatase deficiency in which fetal virilization results from high levels of testosterone and androstenedione because of the inability to convert these precursors to estrogens (Fig. 57-10). Female pseudohermaphroditism as a result of maternal androgen excess will not be discussed here.

Disorders Producing Excessive Fetal Androgenization: General Clinical Features   Virilization of a karyotypic female can produce variable genital phenotypes, depending primarily on the timing, duration, and degree of androgen excess. The phenotype ranges from limited clitoromegaly and posterior labial fusion in the milder cases, to intermediate degrees of virilization with labioscrotal fusion, a urogenital sinus, and significant clitoral enlargement, to severely virilized genitalia that are indistinguishable from those of a cryptorchid male infant. The gonads are normal ovaries and Müllerian duct derivatives develop normally, reflecting absence of AMH. Even in the most virilized infants, Wolffian development does not occur, perhaps because of differences in timing of adrenal versus gonadal androgen production or the presence of less significantly increased androgen concentrations in the vicinity of the Wolffian ducts.

Disorders Producing Excessive Fetal Androgenization: Specific Disorders—Congenital Adrenal Hyperplasia
21-HYDROXYLASE DEFICIENCY   Steroid 21-hydroxylase is a microsomal cytochrome P450 enzyme (P450c21), located on the smooth endoplasmic reticulum, that catalyzes the hydroxylation of progesterone to deoxycorticosterone and 17-hydroxyprogesterone to 11-deoxycortisol, using an NADPH-dependent cytochrome reductase as a cofactor. Deficiency of this enzyme is the most common cause of congenital adrenal hyperplasia in both sexes (*see* Chapter 52).

Clinical Features and Diagnosis. Hydroxylation is impaired in the zona fasciculata of the adrenal glands of those with 21-hydroxylase deficiency, so that 17-hydroxyprogesterone (17-OHP) is not converted to 11-deoxycortisol, the immediate precursor of cortisol. Cortisol deficiency leads to a compensatory increase in ACTH secretion that in turn drives the adrenal gland, resulting in overproduction of cortisol precursors, particularly 17-OHP. These steroids are shunted down the remaining functional steroidogenic pathway, producing a surfeit of androgens (mainly testosterone) that results in virilization of 46,XX fetuses but has no untoward effect on the male fetus. In more than half of cases, 21-hydroxylase is also deficient in the zona glomerulosa and there is failure of conversion of progesterone to 11-deoxycorticosterone, resulting in deficiency of aldosterone. Shock or death may result from severe salt wasting and resultant hypovolemia.

There are four major clinical forms of 21-hydroxylase deficiency: salt wasting (which accounts for approximately 75% of cases), simple virilizing, nonclassic "late onset" (also called attenuated or acquired), and cryptic (asymptomatic). Only the two most severe forms, which produce genital ambiguity, will be discussed. Female infants with the classic virilizing form of 21-hydroxylase deficiency have variable masculinization of the genitalia as described above.

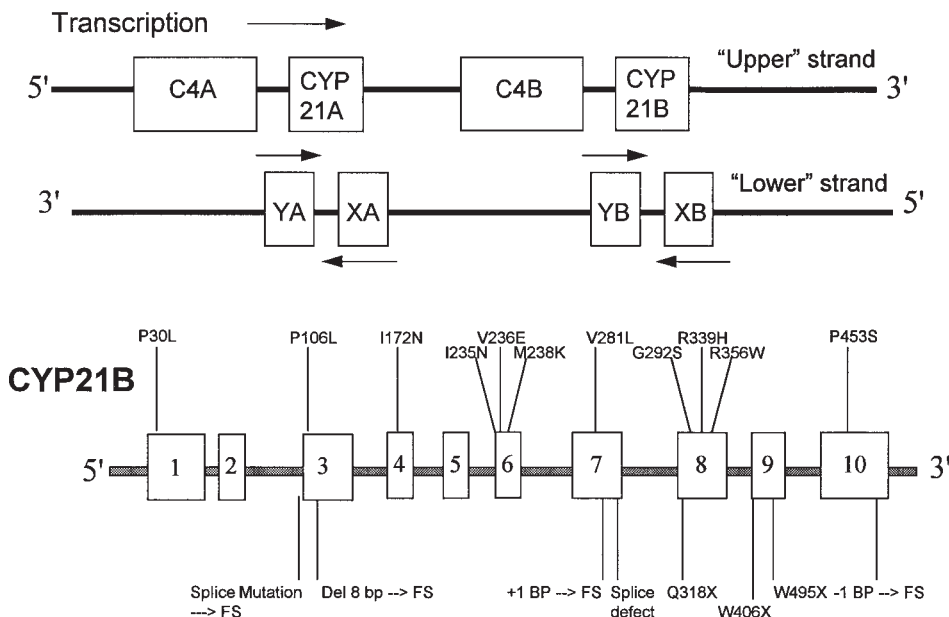
The virilizing form of 21-hydroxylase deficiency is the most likely diagnosis in an infant with genital ambiguity in the presence of 46,XX karyotype. This should be suspected in any partially virilized infant in whom gonads can not be located, either by palpation or by ultrasonography. The presence of a uterus enhances the likelihood of this diagnosis. Increased serum concentrations of 17-hydroxyprogesterone, often as high as 40,000–60,000 ng/dL, are invariably present in infants with enzyme deficiency severe enough to cause virilization; this is accompanied by hyponatre-


Figure 57-8 Genomic organization and molecular defects of *CYP21B* (encoding steroid 21-hydroxylase). **(A)** Genomic organization. *CYP21B*, the gene that encodes 21-hydroxylase, is located in complex a region of chromosome 6 that has undergone a duplication event. There are thus a number of pairs of tandemly arranged genes in this region. On the upper DNA strand, reading from the 5' direction, the arrangement is as follows: *C4A* (pseudogene for the 4th component of complement), *CYP21A* (the so-called pseudogene of *CYP21*), *C4B* (the active gene encoding the 4th component of complement), *CYP21B* (the gene encoding P450c21). On the lower strand the arrangement is even more complex: two genes (*XB* and *XA*) that overlap the 3' ends of *CYP21B* and *CYP21A*, respectively, are transcribed from the 5' to 3' direction. Two contiguous genes (*YB* and *YA*), which likely also arose by gene duplication, are transcribed in the opposite direction, using promoter sequences in the 5' region of *CYP21A*. The orientation of transcription is indicated by the arrows. **(B)** Molecular defects of *CYP21B*. Missense mutations, resulting in amino acid substitutions, are shown above the gene structure. The standard single letter amino acid code has been used. Other deleterious mutations, including nonsense mutations, splicing defects, and nucleotide deletions causing frameshifts, are shown below the gene. (Single letter amino acid code: A, alanine; C, cysteine; D, aspartic acid; E, glutamic acid; F, phenylalanine; G, glycine; H, histidine; I, isoleucine; K, lysine; L, leucine; M, methionine; N, asparagine; P, proline; Q, glutamine; R, arginine; S, serine; T, threonine; V, valine; W, tryptophan; Y, tyrosine. X denotes a nonsense mutation introducing a termination codon.)

mia, hyperkalemia, and hyperreninemia in those with the salt-wasting form. An ACTH stimulation test is not necessary to make the diagnosis of CAH in a virilized female infant.

Genetic and Molecular Pathophysiology. P450c21 is encoded by the *CYP21* gene *(CYP21B)* located on chromosome 6 at position p21.3, within about 2 centiMorgans of the HLA complex, with which it has tight linkage. *CYP21* and *CYP17* (encoding P450$_{17\alpha}$) are thought to have arisen from a common ancestor gene. *CYP21* contains 10 exons and its 2.0-kb cDNA encodes a 55-kDa protein. There is a homologous gene, generally considered a pseudogene, designated *CYP21P* (or *CYP21A*), located 30-kb upstream. This gene contains three deleterious mutations: an 8-bp deletion in exon 3, a T insertion in exon 7, and a stop codon in exon 8, such that it does not encode P450c21. However, the finding that sequences within this gene are transcribed has led to speculation that it may not in fact be a pseudogene. The gene encoding the fourth component of complement *(C4B)*, is located centromeric to *CYP21* and it too has a homologous pseudogene *(C4A)* near the *CYP21* pseudogene. These two gene-pseudogene pairs are believed to have arisen through a duplication event. The genetic arrangement is further complicated by the presence of two additional genes, termed *XB*, and *YB*, that overlap *CYP21* on the complementary DNA strand. *XB* is transcribed in the opposite direction to produce an extracellular matrix protein termed tenascin-X; the product of

YB is unclear. A homologous pair of genes, *XA* and *YA*, overlap *CYP21A* on the complementary DNA strand. *CYP21* expression is regulated by ACTH via cAMP, using a specific cAMP-responsive sequence in the 5'-flanking region of the gene that binds a putative adrenal-specific nuclear protein (ASP). In addition, SF-1 activates the P450c21 promoter, as does another homologous orphan nuclear receptor nerve growth factor-induced gene-B (NGFI-B). Expression of this latter transcription factor increases dramatically in the adrenal cortex in response to stress. Interestingly, expression of P450c21 has recently been demonstrated in skin.

Inheritance of 21-hydroxylase deficiency is autosomal recessive and the incidence of the disorder ranges from 1:15,000 (some white populations) to 1:700 (Yupik Eskimo tribe), the general incidence being reported as approximately 1:5,000. Molecular defects in *CYP21* have been elucidated in approximately 100 patients with 21-hydroxylase deficiency. These almost all appear to have arisen as a result of recombination events between *CYP21* and its homologous pseudogene, *CYP21P*, and result in either deletion of *CYP21*, or transfer of mutations from the pseudogene to the functional gene (a process termed "gene conversion"). This phenomenon has been suggested to account for the predominance of 21-hydroxylase deficiency over other forms of CAH. Complete deletion of *CYP21* occurs in about 20% of cases of the classic salt-wasting form. In a few cases the deletion has included the neigh-
CYP11B1

Figure 57-9   Molecular defects of *CYP11B1*. Mutations in *CYP11B1* causing 11β-hydroxylase deficiency and female pseudohermaphroditism have been reported in a number of individuals. Missense mutations are shown above the gene; frameshift (FS) and nonsense mutations are shown below the gene. Mutation R448H is found commonly in Moroccan Jews. This residue is probably required for heme binding. The majority of mutations have been found in exons 6–8.
CYP19

Figure 57-10   Molecular defects of *CYP19* gene. The *CYP19* gene (encoding the aromatase enzyme, P450arom) has a complex structure in its 5' region: there are six untranslated exons (shaded boxes, locations not clearly known) and six alternate promoters used in different tissues (designated "P"); translation begins within exon 2. Rare mutations causing female pseudohermaphroditism have been reported. The two missense mutations shown above the gene denoted with asterisks were present in the same patient, who was therefore a compound heterozygote. Because of its role in heme binding, cysteine 437 is highly conserved. A splice junction mutation resulting in an 87-bp insertion is depicted below the gene. The patient was homozygous for this mutation.

boring *C4* gene. However, as in most other genetic disorders, single-base mutations are common, and cause truncation, aberrant splicing, or amino acid substitutions. In a comprehensive study of 88 families, Speiser et al. determined that the most common mutation was an A-G change in the second intron affecting mRNA splicing (26%); large deletions had occurred in about 21% of affected individuals; substitution of isoleucine 172 by asparagine was found in 16%; and replacement of valine 281 by leucine in 11%. Homozygosity for severe mutations is present in about 50% of those with classic salt-wasting 21-hydroxylase deficiency. Correlations between enzyme activity (phenotype) and mutation (genotype) were noted, although some patients' enzymatic phenotypes were not as predicted from their genotype. Compound heterozygosity for different *CYP21* mutations is common. The clinical and enzymatic findings of such patients results from the combined effect of different mutations in each allele.

In vitro analysis of mutant 21-hydroxylase enzymes has been performed in a number of cases. A mutant containing threonine at position 428 in place of cysteine has complete loss of enzymatic activity and heme binding. Of note, cysteine 428 is invariant among all P450 enzymes and is believed to be the heme-binding site. Other amino acid substitutions depress enzyme activity to varying degrees.

11β-HYDROXYLASE DEFICIENCY   11β-Hydroxylase is a cytochrome P450 enzyme that catalyzes the final step in cortisol synthesis, 11β-hydroxylation of 11-deoxycortisol to cortisol in the zona fasciculata of the adrenal gland. A related isozyme in the zona glomerulosa, aldosterone synthase, catalyzes the final three

steps in aldosterone synthesis, hydroxylation and dehydrogenation (oxidation) of 11-deoxycorticosterone to aldosterone (these latter activities are also referred to as corticosterone methyl oxidase types I and II [CMO I; CMO II]). Deficiency of 11β-hydroxylase results in a relatively common form of congenital adrenal hyperplasia, accounting for approximately 5% of cases, depending on ethnic background. This enzyme is not involved in gonadal steroidogenesis.

Clinical Features and Diagnosis. There is a relatively high frequency of 11β-hydroxylase deficiency in Saudi Arabia and in Moroccan and Iranian Jews because consanguinity in these families is common. Affected female (46,XX) infants present with variable genital virilization, similar to those with 21-hydroxylase deficiency. In a number of kindreds, affected females have been so severely virilized that they have been reared as males, the diagnosis delayed until puberty, when breast development and menses occurred. 11-Deoxycortisol is massively elevated and serum concentrations of 11-deoxycorticosterone, adrenal androgens, testosterone (by conversion from androstenedione), and ACTH are also increased. The distinguishing clinical feature of this condition is the presence of hypertension, induced by increased secretion of 11-deoxycorticosterone, the mineralocorticoid activity of which causes sodium retention and suppression of plasma renin activity. Hypokalemia resulting from the mineralocorticoid excess is variably present. There is minimal correlation between the severity of the virilization and the hypertension. Precocious pseudopuberty and advanced skeletal maturation occurs in untreated cases of both sexes.

Genetic and Molecular Pathophysiology. There are two genes encoding 11β-hydroxylase isozymes. The 6.5-kb, 9-exon *CYP11B1* gene encoding P450C11*(P450XIB1)* is localized to 8q21. A contiguous gene, *CYP11B2*, located approximately 40 kb away within the same chromosomal locus, encodes a second 11β-hydroxylase isozyme (P450cmo) that displays 93% amino acid homology with the first. *CYP11B1* and *CYP11B2* are structurally homologous to *CYP11A*, the gene that encodes P450$_{scc}$, and the trio represent a subfamily within the P450 superfamily.

CYP11B is expressed in the zona fasciculata of the adrenal cortex, under regulation by ACTH via cAMP. Like genes encoding other steroidogenic enzymes, the *CYP11B* promoter also contains a binding site for SF-1. P450C11 is a mitochondrial protein predicted to contain 479–503 amino acids, including an amino-terminal mitochondrial signal sequence. P450C11 catalyzes 11β-hydroxylation of 11-dexoxycortisol to cortisol in the zona fasciculata of the adrenal gland. It also has limited 18-hydroxylase activity. *CYP11B2*, the gene expressed in the zona glomerulosa, encodes the isozyme P450cmo (P450aldo; P450XIB2), which catalyzes the three-step conversion of 11-deoxycorticosterone to aldosterone (11-hydroxylation, 18-hydroxylation, and 18-oxidation). Its expression is regulated by angiotensin II.

Mutations in *CYP11B1* have been reported in at least 12 individuals with 11β-hydroxylase deficiency. Reported mutations include a 2-bp insertion and a 1-bp deletion (both of which cause a frameshift, deleting the enzyme's heme-binding domain); single-base mutations introducing termination codons (nonsense mutations), and a number of missense mutations causing amino acid substitutions. Substitution of arginine by histidine at position 448 is the predominant defect in P450C11 in Moroccan Jews, suggesting a founder effect. This amino acid is highly conserved and believed to be required for heme binding. Transient transfection studies reveal that this mutation abolishes enzymatic activity. Despite this, individuals heterozygous for this mutation have no demonstrable hormonal abnormalities, indicating that approximately 50% of enzyme activity is adequate for normal steroidogenesis. Hydroxylase activity is also abolished in other mutant enzymes containing different amino acid substitutions. The majority of mutations cluster in exons 6–8 of the *CYP11B1* gene, suggesting that this region encodes residues critical for enzymatic activity. Notably, clinical variation has been observed between individuals with the same mutation.

The mutations reported to date are *de novo* point mutations. The relatively high frequency of mutations in this gene is suggested to result from its high frequency of CpG dinucleotides, a well-recognized mutational hot spot in the human genome, rather than from recombination between *CYP11B1* and *CYP11B2* (as occurs between *CYP21* and its adjacent pseudogene *CYP21A*). Mutations in *CYP11B2* cause aldosterone synthase deficiency, which can present in infancy with hyponatremic, hypovolemic shock, but does not affect sexual differentiation in either sex.

3β-Hydroxysteroid Dehydrogenase Deficiency   3β-Hydroxysteroid dehydrogenase (3β-HSD) is a noncytochrome, membrane-bound enzyme that requires NAD$^+$ as a cofactor to catalyze the conversion of 3β-hydroxy-Δ^5-steroids (pregnenolone, 17-hydroxypregnenolone, and dehydroepiandrosterone) to the 3-keto-Δ^4-steroids (progesterone, 17-hydroxyprogesterone, and Δ^4-androstenedione; Fig. 57-7). Deficiency of 3β-HSD, which is less common than 21-hydroxylase deficiency, impairs steroidogenesis in the adrenals and gonads, resulting in reduced synthesis of cortisol, aldosterone, and gonadal steroids.

Clinical Features and Diagnosis. Deficiency of 3β-HSD produces significant genital ambiguity in males, as described in detail above. However, in karyotypic females 3β-HSD deficiency is associated with only mild genital virilization (mild clitoromegaly or posterior labial fusion) not of sufficient severity to suggest genital ambiguity. Further clitoral enlargement and premature development of pubic and axillary hair may occur during childhood in untreated patients. The androgenization in females results from exaggerated levels of the relatively weak androgen dehydroepiandrosterone. Some cases have associated salt wasting because of reduced synthesis of aldosterone and cortisol.

Genetic and Molecular Pathophysiology. Details of the genetics and molecular biology of this gene are provided in the preceding section on 3β-HSD deficiency as a cause of male pseudohermaphroditism and will not be reviewed here. One affected female without genital ambiguity was found to be homozygous for a nonsense mutation that produced a truncated protein of 169 amino acids, compared with the usual 371 amino acids. Compound heterozygosity for a missense mutation and an intronic mutation likely causing a splicing defect was found in another female with normal genitalia, whose affected brother had ambiguous genitalia. Other mutations in affected females will likely be similar to those found in affected males and their effect on genital development will probably reflect the nature and severity of the mutation.

Aromatase Deficiency   The conversion of androgens to estrogens is controlled by aromatase (P450arom), a cytochrome P450 enzyme located in the endoplasmic reticulum of estrogen-producing cells. Using NADPH-cytochrome P450 reductase as a cofactor, this microsomal enzyme catalyzes conversion of C19 steroids (androstenedione and testosterone) to C18 estrogens (estradiol, estrone, estriol), by modification of the steroid A ring to a phenolic ring.

Clinical Features and Diagnosis. Androgens produced by the fetal adrenal gland and then desulfated and aromatized by the placenta are the major source of circulating estrogens during pregnancy. An apparently rare cause of female pseudohermaphroditism is the inability to convert fetal androgens to estrogens because of lack of placental aromatase activity. Three cases of aromatase deficiency have been described. In two cases, the mothers developed progressive virilization in the latter part of pregnancy, which resolved after delivery; serum androgens were high and estrogens low. Despite this, growth and development of the fetuses and placentas throughout gestation were normal. In the first case in vitro assays of the placenta after delivery revealed negligible aromatase activity. Absence of maternal virilization in the third case suggested that some aromatase activity was retained.

The 46,XX affected infants in each case had male-appearing or ambiguous external genitalia with marked clitoral enlargement, rugation and fusion of labioscrotal folds, and a single meatus at the base of the phallic structure. The virilization results from conversion of dehydroepriandrosterone sulfate (DHEAS) to androstenedione and testosterone by the placenta; its inability to aromatize these steroids to estrogens results in massive elevations of these compounds. Most recently, a pair of affected 46,XX and 46,XY siblings have been reported. The female had ambiguous genitalia, similar to those described above; the male was normally masculinized.

The two affected 46,XX subjects who are now postpubertal exhibited features of androgen excess from puberty onwards. Clitoral enlargement and development of facial acne were noted, in

addition to absence of breast development, attributed to deficiency of ovarian aromatase. Gonadotropins were modestly elevated, accompanied by high adrenal androgen concentrations, high plasma testosterone, low estradiol concentrations, and ovarian cysts on pelvic ultrasound. Because estrogens are the hormones primarily responsible for skeletal maturation, this was delayed, resulting in tall stature. There was also significant osteoporosis in the affected adult male.

These cases, as well as the single reported case of an estrogen receptor (ER) mutation and the evidence from ER-deleted transgenic mice, indicate that contrary to long-standing beliefs, estrogens are not required for fetal survival.

Genetic and Molecular Pathophysiology. Aromatase (P450arom) is a cytochrome P450 enzyme encoded by a 9-exon, 70-kb gene designated *CYP19*, whose chromosomal locus is 15q21.1. P450arom is expressed in a wide variety of human tissues, including the granulosa and luteal cells of the ovary, testicular Sertoli and Leydig cells, the placenta, adipose tissue, brain, muscle, and liver and in the preimplantation blastocyst. Expression levels and transcript sizes are quite different in these various tissues and expression is regulated in part by the use of tissue-specific alternative promoters, in ovary, placenta, brain, and adipose tissue. However, because the translational start site is conserved in the various mRNA species, the same protein is expressed in all tissues. Like that of other steroidogenic enzymes, the aromatase gene promoter contains a binding site for SF-1, and it appears that this site is involved in the cAMP-mediated regulation of gene expression. The expressed protein is similar to other P450 enzymes, containing a carboxy-terminal heme-binding region encoded by the 9th exon.

The defects in the above cases were inherited in an autosomal recessive pattern and there was known parental consanguinity in one case. In the first case described, the affected girl was homozygous for a splice junction point mutation that resulted in translation of an abnormal peptide containing an extra 29 amino acids. In vitro analysis revealed that the mutant enzyme retained only a minimal level of activity. In the second case, the affected individual was found be a compound heterozygote for two single-base mutations that introduced two separate amino acid substitutions into the enzyme: arginine to cysteine at position 435 and cysteine to tyrosine two residues downstream, at amino acid 437. In vitro analyses of the mutant enzymes revealed extremely low activity in the presence of the R435C substitution, and complete absence of activity with the C437Y defect. Cysteine 437 is very highly conserved, and is apparently involved in heme binding, hence the destructive effect of the mutation on enzyme function. In the final case, the mutation replaces a highly conserved arginine residue with cysteine at position 375 of the peptide. The mutant protein expressed in vitro had only 0.2% of the activity of wild-type P450arom. The region of the protein in which arginine 375 is located is postulated to be involved in anchoring the enzyme to the cell membrane. Molecular defects in *CYP19* are summarized in Fig. 57-10.

Disorders of Müllerian Development Mayer-Rokitansky-Küster-Hauser (MRKH) Syndrome Although individuals with this disorder clearly are phenotypic females, the condition technically represents the mildest form of female pseudohermaphroditism, in parallel with PMDS in the male. This developmental abnormality appears to result from defective Müllerian duct fusion in early gestation; however, the exact nature of the defect remains unclear. Affected girls usually present in their teens with primary amenorrhea in the presence of otherwise normal secondary sexual development. Examination reveals absence or severe hypoplasia of the vagina; uterine agenesis is usual; however, some uterine development (uni- or bicornuate uterus), or occasionally a normal uterus, may be present. The ovaries are normally developed. There appear to be two subtypes of the disorder—the typical (isolated) and atypical forms, frequency of each being approximately equal. The typical form is characterized by the laparoscopy or laparotomy findings of symmetric muscular buds (the Müllerian remnants) and normal Fallopian tubes. The atypical form has asymmetric hypoplasia of one or both buds, with or without dysplasia of the Fallopian tubes. The atypical form has associated anomalies including renal defects (agenesis or ectopia in about 30–50% of patients) and skeletal abnormalities (vertebral malformations; Klippel-Feil anomaly) of varying severity. The MURCS association comprises Müllerian duct aplasia, renal agenesis or ectopia, and cervical somite dysplasia (Klippel-Feil). This represents the most severe form of the disorder and may represent a mesodermal malformation spectrum. Laparoscopy is required to distinguish the typical from the atypical form of the MRKH syndrome. Because of these associated anomalies, all patients with vaginal atresia should have skeletal radiographs and renal and pelvic ultrasound performed.

The MRKH syndrome occurs in 1 in 4000–5000 females. Most cases are sporadic; however, a genetic defect likely underlies familial cases (approximately 5%), which have been reported in patterns consistent with sex-limited autosomal dominant or autosomal recessive inheritance. Galactose-1-phosphate uridyl transferase activity is reduced in some patients and may represent a candidate gene for MRKH syndrome.

DIAGNOSIS AND MANAGEMENT OF DISORDERS OF SEX DETERMINATION AND SEX DIFFERENTIATION

DIAGNOSIS Abnormalities of sexual development require evaluation by an experienced team, including a pediatric endocrinologist, urologist, and geneticist. In the newborn period, rapid but careful diagnosis and early, appropriate sex assignment are essential to optimize parental adjustment to the child's apparently incongruous genital appearance and to minimize subsequent psychosocial problems for the child. The principal aims of the diagnostic evaluation are to determine (1) presence of potentially life-threatening adrenal steroid deficiencies and electrolyte derangements; (2) chromosomal sex; (3) type and functional status of the gonads; (4) internal genital anatomy; and (5) most appropriate sex-of-rearing.

Consanguinity between parents is suggestive of autosomal recessive conditions, such as CAH and 5α-reductase deficiency. Likewise, the presence of similarly affected siblings or a family history of ambiguous genitalia, infertility, amenorrhea, lack of pubertal development, or sudden death in infancy is suggestive of a genetically determined defect. A history of genital abnormalities, severe gynecomastia, or infertility in maternal relatives suggests an X-linked condition, such as androgen insensitivity. A history of maternal virilization during pregnancy could suggest aromatase deficiency.

Clinical, ultrasound, and radiographic examination should define the following features:

1. External genital anatomy. Specifically, the size of the phallic structure (stretched penile length, excluding foreskin,

and diameter at midshaft), location of the urethral meatus, presence of a separate vaginal orifice, size, and fusion and rugation of labioscrotal folds provide information regarding the degree of fetal androgenization. Hyperpigmentation of the genitalia represents evidence of ACTH excess as a result of some form of CAH.

2. Location of gonads. Gonads in the inguinal region are highly likely to be testes (ovarian herniation occurs exceptionally rarely), suggesting that the infant is probably a genotypic male (or much less likely, another karyotype with presence of *SRY*). If no gonads are palpable in a partially masculinized infant, ultrasound examination is required to locate the gonads (which may be anywhere from the inguinal ring to the abdomen) and to examine for associated developmental abnormalities of the renal tract.

3. Presence or absence of a uterus. Because of exposure to maternal estrogens, the uterus is enlarged and readily detectable by rectal examination or ultrasonography in newborn females. Presence of a uterus reflects absence of AMH effect during gestation, generally indicating that the gonads are not testes (or, if testes are present, that AMH action was absent during gestation).

4. Internal genital anatomy. Cystoscopy or voiding cystourethrogram is required to define the anatomy of the lower urogenital structures, including type of urethra (long, male-type vs short, female-type), presence of a vagina or more rudimentary structure such as a prostatic utricle, and presence and location of the vaginal orifice (perineal vs urethral). The longer the urethra, smaller the vaginal structure, and higher its entry to the urethra, the greater the degree of androgenization that occurred *in utero*.

5. Presence of other dysmorphic features or intrauterine growth retardation. These findings may suggest that the genital defect is part of a more generalized disturbance of morphogenesis.

Despite careful examination, it is almost impossible to differentiate between many of the disorders of sex determination and differentiation on clinical grounds alone. Detailed laboratory evaluation is urgent if dealing with an infant with ambiguous genitalia in whom the sex of rearing is yet to be determined. Hormone secretion in the immediate postnatal period is dynamic, with hormone concentrations changing rapidly over the first few days of life. Therefore, optimally, blood should be drawn within the first 36 h of life for hormone analysis. Primary care institutions should be instructed that for any infant with a concern regarding genital development, 10 mL of blood should be drawn immediately and the serum frozen for later use. The following studies should be undertaken urgently on fresh blood:

1. Karyotype. In all cases a formal karyotype is required. A buccal smear is inadequate because of frequent false-negative results.

2. Electrolytes and adrenal steroids for evidence of congenital adrenal hyperplasia. 17-Hydroxyprogesterone (for 21-hydroxylase deficiency); 11-deoxycortisol (for 11-hydroxylase deficiency); 17-hydroxypregnenolone and dehydroepiandrosterone (for 3β-hydroxysteroid dehydrogenase deficiency); pregnenolone; progesterone; 17-hydroxypregnenolone; and 17-hydroxyprogesterone (for 17-hydroxylase deficiency); and in most cases, plasma renin activity should be measured on the initial blood sample. Other more discriminating steroids can be measured on the stored, frozen serum once the karyotype and initial critical values are obtained. Normal electrolytes in the immediate postnatal period do not exclude congenital adrenal hyperplasia, and until definitive results are obtained, these should be monitored for development of hyponatremia and hyperkalemia.

3. Testosterone (T), dihydrotestosterone (DHT), and T precursors to determine the presence of a defect of T biosynthesis or 5α-reductase deficiency in karyotypic males (Table 57-5). Serum T is high (>200 ng/dL) in cord blood, but plummets to become almost undetectable at the end of the first week of life, rising from about 2–3 weeks, to peak at >200 ng/dL at around 8–12 weeks of age. Serum T falls

again from 12 to 16 weeks, finally becoming essentially unmeasurable by 6 months of age. Steroid analysis should therefore be performed during periods of maximal testicular activity, or, if this is not possible, after testicular stimulation with hCG (gonadal steroids and DHT are measured before, and 24 h after, administration of 1500 IU hCG every other day for three doses). Normal infants respond with T values >200 ng/dL, often much higher. An increased ratio of T to DHT (>20:1) during periods of active testicular steroidogenesis or after hCG is found in 5α-reductase deficiency. Hormonal profiles found in defects of T biosynthesis are summarized in Table 57-5. T and DHT concentrations are probably within normal limits in AIS; however, increased concentrations have been reported in a few infants with partial AIS. Minimal data are available for infants with complete AIS.

4. LH and FSH. LH concentration should be markedly increased in infants with Leydig cell hypoplasia and may also be increased in infants with partial AIS. FSH is increased in those with gonadal dysgenesis, but may not be elevated in early infancy.

5. ACTH stimulation test. This is required to characterize steroidogenic defects that affect the adrenals as well as the gonads (CLAH, 3β-hydroxysteroid dehydrogenase deficiency, and 17-hydroxylase deficiency). In virilized karyotypic females, an ACTH stimulation test is not required for diagnosis of 21-hydroxylase deficiency, but may aid diagnosis of other forms of CAH by exaggerating precursor steroid levels.

6. Gonadal biopsy. This may be required in cases of suspected gonadal dysgenesis.

If concentrations of testosterone, DHT, and steroid precursors are normal in a karyotypic male with abnormal masculinization, the differential diagnosis then likely rests between a partial form of AIS and the perplexing "black box" of undiagnosable forms of male pseudohermaphroditism.

MANAGEMENT   Sex of Rearing   Although an accurate diagnosis is important, sex assignment is based primarily on gonadal and genital morphology rather than diagnosis. It has been usual practice to assign female sex-of-rearing to any infant with ovaries, no matter how virilized, since she is potentially fertile. The converse principle has not generally been applied for infants with testes, since it has been argued that successful functional outcome after reconstruction of severely undermasculinized genitalia is unlikely. This is clearly a vital area of management, and one that is currently undergoing re-examination. Unfortunately, a detailed discussion of the principles, practice, and outcome of sex assignment of infants with disorders of sex determination and differentiation is beyond the scope of this chapter.

Gonadectomy   Gonadectomy is required for all individuals reared as females who have testes or gonadal dysgenesis and a Y-bearing cell line. However, opinion regarding the optimal timing of this procedure varies. For individuals with 46,XY or mosaic forms of gonadal dysgenesis, gonadectomy is advisable at the time of diagnosis, because of the high risk of malignancy. In those reared as females who have retained production of and responsiveness to testosterone, gonadectomy should be undertaken at the time of initial genital reconstructive surgery to prevent potential virilization at puberty. In those with complete AIS (therefore no

response to T), the timing of gonadectomy is the subject of debate. Some physicians recommend early gonadectomy for psychological reasons; others prefer to defer this until after puberty to take advantage of the excellent spontaneous feminization that results from endogenous testicular estrogen secretion. In following the latter course it is important that the young woman be made aware in early adolescence that the gonads will need to be removed at the completion of puberty because of the risk of malignancy. If inguinal hernia repair is required in early childhood, simultaneous gonadectomy is considered advisable, to obviate the need for a second surgical procedure.

Hormone Replacement Therapy   Gonadectomized individuals and females with CLAH or aromatase deficiency require estrogen supplementation at the appropriate time for puberty and thereafter, to induce and maintain feminization. The addition of cyclic progesterone is generally recommended once feminization is established, and is mandatory for those with a uterus. For partially virilized infants reared as male, testosterone therapy is usually required in infancy to enhance penile size before surgery, and may be beneficial at puberty to optimize virilization. Certain individuals with partial forms of AIS may require and respond to high-dose testosterone therapy. Despite the enzymatic defect in conversion of testosterone to DHT, this therapy may also normalize serum DHT concentrations and improve virilization in some men with 5α-reductase deficiency.

Affected individuals of either sex with any form of congenital adrenal hyperplasia require standard replacement therapy with glucocorticoids and mineralocorticoids. Treatment with physiologic doses of glucocorticoids suppresses ACTH production, thus reducing levels of precursor steroids that otherwise produce detrimental effects, such as virilization, advanced skeletal maturation, and, in the 17-hydroxylase and 11-hydroxylase deficiency forms of CAH, hypertension. The addition of antiandrogens to the standard therapy for CAH is currently under investigation.

Prenatal Diagnosis and Treatment of CAH   Prenatal diagnosis and treatment of female fetuses affected by virilizing 21-hydroxylase deficiency has been undertaken successfully in a number of cases. This procedure requires that the molecular defect has been characterized in a prior affected sibling. Dexamethasone treatment is initiated as soon as pregnancy is confirmed. At 10 weeks' gestation, a chorionic villus biopsy is performed and karyotype determined. If the karyotype is 46,XY, dexamethasone is suspended because masculinization is normal in affected males. If the karyotype is 46,XX, dexamethasone is continued until the status of the fetus is determined by molecular analysis of *CYP21*. If the 46,XX fetus is determined to be unaffected, dexamethasone treatment is suspended; if affected, the treatment is continued until term. Although not yet reported, this procedure would also be applicable in other forms of CAH, provided the molecular defect has been determined in an older sibling. Maternal complications of dexamethasone treatment are not insignificant (often quite severe Cushingoid changes), and such management should be undertaken only under the guidance of a team experienced with this therapy.

58   Sex Chromosome Disorders

Andrew R. Zinn

INTRODUCTION

Because sex chromosome disorders frequently result in abnormalities of sexual differentiation, the two subjects are usually discussed together in medical texts. The biology of human sexual differentiation and the pathophysiology of associated defects were discussed in the previous chapter. This chapter examines sex chromosome disorders from a genetic perspective, emphasizing unique features, such as X inactivation and dosage compensation, X-Y recombination, and male-specific functions of the Y chromosome. Table 58-1 summarizes karyotype, genotype, and phenotype data for selected disorders included in this chapter. The reader should consult an endocrinology textbook for more information about the clinical features of the various disorders.

STRUCTURE AND FUNCTION OF HUMAN SEX CHROMOSOMES

The structures of the human X and Y chromosomes and the approximate positions of some genes of interest are depicted in Fig. 58-1. The X chromosome is about 160 Mb in length. It contains probably thousands of genes, encoding a variety of enzymes and structural and regulatory proteins. A distinguishing feature of most of these genes is that males have only one copy, accounting for X-linked recessive inheritance of many genetic diseases (*see* Transmission of Human Genetic Diseases, Chapter 4). By contrast, the much smaller Y chromosome is believed to contain a paucity of genes. The Y chromosome is divided into two parts. The euchromatic portion is about 30 Mb in length and contains all known Y-linked genes. The heterochromatic portion on the long arm can vary in length among normal men, averaging approximately 20 Mb. This region is composed of simple repetitive sequences and probably does not contain any genes. Because females do not require any Y-specific gene products, the Y chromosome has generally been regarded as functioning only in sexually dimorphic processes, such as testis formation and male gametogenesis. This notion is incorrect. As the discussion of Turner's syndrome will show, the Y chromosome also contains genes involved in general viability, growth, and morphogenesis.

Normally there is no recombination between the X and Y chromosomes except in the most distal regions, where the chromosomes pair and recombine during male meiosis. This pairing may be important for proper chromosome segregation. It is important to note that the X and Y chromosomes bear identical copies of these recombining regions, and therefore genetic markers in these "pseudoautosomal" regions do not show strictly sex-linked inheritance. The short arm (p) pseudoautosomal region spans about 2.6 Mb and appears to be gene-rich. The region is known to contain genes for two cytokine receptor α-subunits (*CSF2RA*, *IL3RA*), an adenine nucleotide translocase *(ANT3)*, two lymphocyte cell surface antigens (*CD39*, *MIC2*), the enzyme acetylserotonin methyltransferase *(ASMT)*, a nuclear protein of unknown function *(XE7)*, and the 5' part of the gene for a red blood cell antigen *(Xg)*. Thus far, the only gene assigned to the 0.4-Mb long arm (q) pseudoautosomal region is *IL9R*, which encodes another cytokine receptor.

Only a handful of genes have been discovered in the strictly sex-linked portion of the Y chromosome. Known Y-specific genes encode the testis-determining factor *(SRY)*, a zinc-finger protein of unknown function *(ZFY)*, a ribosomal protein *(RPS4Y)*, a homolog of the tooth-bud protein amelogenin *(AMELY)*, the male transplantation antigen H-Y *(SMCY)*, and several testis-specific proteins that may function in spermatogenesis (*TSPY*, *RBM*, and *DAZ*). Interestingly, the *ZFY*, *RPS4Y*, *AMELY*, and *SMCY* genes all have closely related X homologs, perhaps reflecting divergence of the sex chromosomes from an ancestral autosome pair. Alternatively, these X-Y homologous genes may be the result of subsequent transposition events. Data on the origin of X-Y genes from evolutionary comparisons of other species are equivocal.

X INACTIVATION AND DOSAGE COMPENSATION

Unlike the genes just mentioned, the vast majority of X-linked genes do not have Y homologs. Thus males have only one copy of most X-linked genes, whereas females have two. This gender difference in the dosage of X-linked genes is balanced at the level of expression by the inactivation of one X chromosome in females during early embryogenesis, first postulated in the early 1960s by Mary Lyon. The choice of which X chromosome undergoes inactivation in each embryonic cell is normally random, but the pattern of inactivation propagates to daughter cells. Thus normal women are mosaic with regard to which X chromosome is active. The inactive X chromosome becomes hypermethylated and late-replicating, and in most tissues it condenses into the Barr body or sex chromatin. This process is irreversible except in oocytes, in which the inactive X is reactivated just before meiosis.

Cytogenetic studies of X deletions and translocations indicate that a *cis*-acting region of the proximal long arm must be present for a chromosome to undergo X inactivation. The process appar-

Features of Selected Sex Chromosome Disorders

Disorder	Karyotype	Molecular cytogenetics	Sexual phenotype	Gonads	Extragonadal features	Molecular defect
XY gonadal dysgenesis (Swyer syndrome, XY female, MIM 306100)	46,XY	Usually normal	Female	Streak gonads; risk of gonadoblastoma	Tall stature	*SRY* mutation in some cases
XYp– Turner female	46,XY; 46,XYp–	Small Yp deletion, often with Xp;Yp translocation	Female	Streak gonads; risk of gonadoblastoma	Turner-like, especially lymphedema	Deletion of *SRY* and nearby gene(s)
XX male (MIM 278850) gene	46,XX	Y;X or Y;autosome translocation in most cases	Male	Testes with azoospermia	Klinefelter-like	Presence of *SRY* in most cases
Dosage-sensitive sex reversal (MIM 600191)	46,XY; 46,XY,dup(X); unbalanced X translocation	Xp21.2 disomy	Female	Streak gonads	No specific features	Overexpression of *DAX1* gene?
Camptomelic dysplasia with sex reversal (MIM 211970)	46,XY, sometimes abnormality involving 17q24.3-q25.1		Female	Streak gonads	Severe skeletal abnormalities, extraskeletal defects	Haploinsufficiency of *SOX9* gene
Klinefelter's syndrome	47,XXY and variants		Male	Hyalinized testes; azoospermia	Poor to normal virilization; gynecomastia; long legs	Not known
Turner's syndrome	45,X and variants		Female	Streak gonads	Short stature, webbed neck, aortic coarctation, cubitus valgus, others	Not known
45,X/46,XY mosaicism (including mixed gonadal dysgenesis)	45,X/46,XY mosaic		Male, female, or ambiguous genitalia	Streak gonads or dysgenetic testis with risk of gonadoblastoma; normal testes in some cases	Turner-like (variable)	
Gonadoblastoma (MIM 424500)	46,XY, 46,XYp–, 45,X/46,X,+mar	Presence of Y material	Female	Dysgenetic gonad	Variable	Not known
Syndrome associated with small ring X chromosomes	45,X/46,X,r(X) mosaic	Ring X lacking X inactivation center in Xq13.2	Female	Streak ovaries	Mental retardation, multiple congenital anomalies	Functional disomy of unknown X-linked genes
46,XY$_{Xq}$ syndrome	46,XYq–	Yq;Xq translocation	Male	Not reported	Mental retardation, microcephaly, other anomalies	Functional disomy of unknown X-linked genes
Azoospermia (MIM 415000)	46,XY or 46,XYq-	Yq11.23 deletion	Male	Azoospermia; variable histology	Sometimes short stature	Deletion of *DAZ* gene?

MIM numbers from Online Mendelian Inheritance in Man, OMIM™, January 1996.

ently initiates within this region, termed the X inactivation center *(XIC)*, and then spreads to the rest of the chromosome. A gene discovered fortuitously in the *XIC* region termed *XIST* (X-inactive specific transcript) has been implicated in the initiation of X inactivation. The *XIST* expression pattern is unique: the gene is transcribed only from the inactive X chromosome. Expression of *XIST* precedes chromatin condensation and transcriptional inactivation of other X-linked genes. The gene is transcribed as a >15-kb polyadenylated, alternatively spliced RNA that does not appear to encode any protein. The RNA is localized within the nucleus to the Barr body, where it may serve a structural function. Once *XIST* is expressed and X inactivation has occurred, the inactive state of the chromosome is maintained by DNA methylation and chromatin condensation.

Although X inactivation is a chromosome-wide phenomenon, some specific genes escape X inactivation, i.e., they are transcribed from both the active and inactive X chromosomes. These genes are not dosage compensated. In some instances, Y-linked copies may serve instead to equalize the levels of gene products in males and females. For example, it appears that all short arm pseudoautosomal genes escape X inactivation. The X-linked homologs of the Y-linked genes *ZFY*, *RPS4Y*, and *SMCY* also escape X inactivation. However, some genes that escape X inactivation have no functional Y-linked homologs. Why such X-specific genes should escape inactivation is unclear (indeed, in most cases mouse orthologs undergo X inactivation). The signals that determine whether a gene is subject to X inactivation are unknown. Some genes that escape X inactivation are clustered, and local chromatin structure is likely to be important.

DISORDERS OF SEX DETERMINATION

Classic studies indicated that phenotypic sex in the fruit fly *Drosophila melanogaster* is determined by the numerical ratio of X chromosomes to autosomes; the *Drosophila* Y chromosome is genetically inert with regard to sex determination. It was once thought that the same mechanism of sex determination would be true for mammals. However, karyotyping studies in the late 1950s showed that XO and XX humans are female, whereas XY and XXY individuals are male. These data established the Y chromosome's primacy in human testis determination. Further cytogenetic and molecular genetic studies of rare "sex reversed" XX males and XY females culminated with the report in 1990 by Peter Goodfellow and colleagues of the single Y-linked gene, *SRY* (sex-determining region Y), that directs the differentiation of the bipotential gonad into testes. The human *SRY* gene encodes a protein of 204 amino acids that belongs to the high-mobility group (HMG) family of DNA-binding proteins. The gene is expressed in adult testis (where its function is unknown) and transiently in the gonadal ridge during embryogenesis. In all likelihood *SRY* acts by regulating transcription of other genes. The SRY protein binds to the minor groove of the double helix at specific sequences, and its binding induces a bend in the target DNA. It is not yet known which genes are regulated by *SRY*, nor is it certain whether SRY binding activates or inhibits transcription. One gene that might be activated by SRY binding is *MIS*, which encodes the Müllerian inhibiting substance that causes regression of the presumptive female reproductive tract.

The discovery of *SRY* has clarified the etiology of most cases of XX sex reversal. The *SRY* gene and adjacent Y chromosome

Figure 58-2   Aberrant Xp-Yp interchange.

Figure 58-3   Sexual phenotype of XY individuals with various Xp duplications.
sequences can be detected in most XX males by DNA hybridization or polymerase chain reaction (PCR) assays. The most frequent location of *SRY* sequences in these males is the short arm of the X chromosome. *SRY*'s propensity to be translocated from Yp to Xp can be explained by the gene's proximity to the pseudoautosomal region. The mechanism of transposition involves aberrant X-Y interchange during male meiosis (Fig. 58-2).

The translocated *SRY* gene is probably subject to X inactivation. Some cases of incomplete sex reversal, e.g., XX true hermaphroditism (presence of both testicular and ovarian tissue), may be due to mosaic *SRY* expression as a result of stochastic X inactivation.

Mutations that eliminate *SRY* or affect the region of the protein involved in DNA binding cause XY sex reversal. However, only about 10% of XY females have detectable *SRY* mutations. The remaining 90% remain unexplained and are presumably caused by environmental factors or mutations in other genes required for testis determination.

One such gene has already been identified because of its similarity to *SRY*. This gene, denoted *SOX9* (SRY box), was cloned as a member of the *SRY* subfamily of HMG proteins. Lesions in one copy of the *SOX9* gene, which maps to chromosome 17, have been discovered in several patients with camptomelic dysplasia, a rare skeletal disorder associated with XY sex reversal. The other copy of the gene in these patients is apparently normal. The mechanism by which half-normal dosage, or haploinsufficiency, of *SOX9* causes both skeletal malformations and sex reversal is not yet known. Expression studies of the mouse homolog are consistent with the direct involvement of *SOX9* in both abnormalities.

Still another gene has been implicated in sex determination by studies of sex chromosome disorders. A number of XY females have been reported with partial X chromosome duplications that include band Xp21.1 of the short arm (Fig. 58-3). Because, in the absence of a second X chromosome, the duplicated X is not inactivated, sex reversal is thought to be caused by twofold increase in expression of a gene or genes within the duplication.

Using molecular markers to study these subjects and 27 other unexplained 46,XY females, Bardoni et al. identified a submicroscopic Xp duplication in one subject and delimited the critical region of Xp21.1 associated with sex reversal to just 160 kb. They
designated the Xp locus causing sex reversal *DSS* (dosage-sensitive sex reversal). An attractive candidate gene for *DSS* known to lie within the critical region is *DAX1*, a member of the nuclear hormone receptor gene superfamily. Loss of function mutations in *DAX1* cause congenital adrenal hypoplasia and hypogonadotropic hypogonadism but do not prevent testis determination. An interesting notion is that *DSS* may represent an ovary determining gene. Whether the *DAX1* gene is indeed *DSS* should become clear from experiments using transgenic mice.

SEX CHROMOSOME ANEUPLOIDIES

XY sex reversal associated with *SOX9* haploinsufficiency or *DSS* duplication illustrates the critical importance of proper gene dosage. Abnormal gene dosage also plays a role in the phenotypes of numerical sex chromosome disorders, or aneuploidies. The most common sex chromosome aneuploidy is Klinefelter's syndrome (47,XXY; 46,XY/47,XXY; and variants), with an incidence of about 1 in 500 male births. The extra X chromosome is usually the result of meiotic nondisjunction during paternal or maternal gametogenesis. The phenotype is variable but is characterized by small, firm testes, azoospermia, tall stature, eunuchoid habitus, gynecomastia, and elevated gonadotropin levels (Fig. 58-4). Azoospermia is caused by loss of spermatogenic cells. Animal studies suggest that this loss is somehow caused by the presence of an unpaired X chromosome at the pachytene stage of meiosis. Hyalinization of seminiferous tubules and impaired Leydig cell testosterone production follows loss of germ cells. Exogenous androgen is the treatment of choice for testosterone deficiency, whereas treatment of severe gynecomastia is surgical.

The phenotype of Klinefelter's syndrome is mild compared to disorders involving an extra autosome, for example trisomy 21 (Down's syndrome). The reason for the milder phenotype in XXY men is that the additional X chromosome undergoes inactivation, whereas extra autosomes in other aneuploidy syndromes remain active. For this same reason, XXX females are usually normal, although they may be subfertile. Individuals with greater degrees of X aneuploidy (e.g., 48,XXYY; 48,XXXX; 49,XXXXY; or 49,XXXXX karyotypes) often show more severe abnormalities, even though all the supernumerary chromosomes undergo X inactivation. These abnormalities, which include mental retardation and skeletal malformations, are presumably caused by increased dosage of genes that escape X inactivation. Interestingly, some
Figure 58-4 Klinefelter's syndrome. (Used with permission from Blackwell Science.)

Figure 58-5 Turner's syndrome. (Used with permission from Blackwell Science.)

similar features have been noted in men with severe Y aneuploidy, such as 48,XYYY or 49,XYYYY karyotypes, suggesting that the culprit genes may be X-Y homologous or pseudoautosomal.

By contrast to Klinefelter's syndrome, the loss of one sex chromosome, or monosomy X, causes the more severe disorder known as Turner's syndrome. Partial or complete monosomy X (45,X karyotype) is found in about 1 in every 3000 liveborn girls. The prenatal incidence is much greater: as many as 2% of all human conceptuses are estimated to be 45,X, but fewer than 1% survive to term. Paradoxically, liveborns with monosomy X have only modestly reduced life expectancy. An adult woman with Turner's syndrome is shown in Fig. 58-5. As with Klinefelter's syndrome, the phenotype is variable. Characteristic features include growth retardation, ovarian failure, and specific physical abnormalities,

such as webbed neck, aortic coarctation, increased carrying angle of the elbows (cubitus valgus), lymphedema, horseshoe kidney, and others. Metabolic and endocrine abnormalities are also frequent, including hypertension, glucose intolerance, and autoimmune thyroid disease. Girls with Turner's syndrome are not typically mentally retarded, although as a group they show selective impairment of nonverbal cognitive skills such as visual-spatial abilities.

The pathophysiology of Turner's syndrome is poorly understood. Growth retardation is not caused by growth hormone deficiency, although administration of pharmacologic doses during childhood accelerates growth and may increase final stature. Ovarian failure reflects rapid oocyte loss beginning around 6 months of gestation. Usually by early infancy there are few or no remain-

ing oocytes, and the ovaries become fibrous streaks. Infertility is the rule, with rare exceptions. Ovarian sex steroid production is usually deficient, and most girls with Turner's syndrome require hormonal replacement therapy to induce puberty and to maintain cyclic menses. Some extragonadal manifestations, such as webbed neck, lymphedema of the extremities, and perhaps aortic coarctation, may be caused by delayed or defective lymphatic vessel development.

The mechanism of chromosome loss in Turner's syndrome is not known. Meiotic nondisjunction probably accounts for only a minority of cases. The single X chromosome is maternal in about three-fourths and paternal in about one-fourth of 45,X patients. There are no imprinting effects, i.e., the parental origin of the X does not appear to influence the phenotype. Many patients with Turner's syndrome have karyotypic variants of monosomy X, most commonly mosaicism, the presence of two or more cell lines with different karyotypes (e.g., 45,X/46,XX). Mosaicism results from mitotic errors after conception. The second cell line often contains a structurally aberrant X chromosome. Mosaicism for a cell line with two or more copies of the X chromosome long arm enhances viability as compared with the nonmosaic 45,X constitution.

Mosaicism for a Y-bearing cell line, most often 45,X/46,XY karyotype, deserves particular mention. The phenotype varies depending upon the proportion of XY cells and their tissue distribution. Bilateral testes may be present, or there may be unilateral testicular tissue with a contralateral streak gonad, a condition termed mixed gonadal dysgenesis (*see* Chapter 57). Regardless of the sexual phenotype, the presence of a Y chromosome confers a high risk of gonadoblastoma, a malignant tumor arising in the dysgenetic gonad. Prophylactic removal of streak gonads or histologically abnormal testes is recommended in any patient whose karyotype includes Y material. The Y-linked gene(s) predisposing to gonadoblastoma appears to be distinct from *SRY*, because XY females with *SRY* deletions or mutations are still at risk. Some studies using sensitive PCR assays have reported an alarmingly high prevalence of cryptic Y sequences in Turner's syndrome patients. However, in the absence of testes or virilization, the clinical significance of low levels of Y material detected by PCR but not by karyotype is uncertain.

Several genetic mechanisms underlie the phenotype of Turner's syndrome. Oocyte loss may be caused in part by the effects of an unpaired X chromosome during meiosis, analogous to spermatogonia loss in Klinefelter's syndrome. Haploinsufficiency, or half-normal dosage of X-linked genes, may also contribute to ovarian failure. As previously noted, the inactive X chromosome is reactivated in oocytes; diploid expression of certain X-linked genes may be required for normal oocyte function. Consistent with this hypothesis, small deletions of Xq have been observed in some otherwise normal women with premature menopause.

Anatomic abnormalities, such as lymphedema associated with Turner's syndrome, suggest that diploid dosage of certain X-linked genes is important not only for ovarian function, but also for extragonadal development. Yet, after early embryogenesis, only one X chromosome is active in somatic tissues of normal women. This apparent contradiction can be explained if the genes responsible for extragonadal Turner features escape X inactivation. How then do we explain normal development in males, who have only one X chromosome? One possibility is male-specific upregulation of X-linked gene expression, the mechanism of dosage compensation in *Drosophila*. However, there is no evidence for such upregulation in mammals. Another possibility is that in addition to its role in sex determination, the Y chromosome supplies a second copy of certain genes whose dosage is critical for normal somatic development.

Present data, although not definitive, favor the latter hypothesis. Deletions of either the Xp or Yp pseudoautosomal region are associated with short stature, suggesting that at least part of the growth retardation in Turner's syndrome is caused by haploinsufficiency of one or more pseudoautosomal genes. A strong candidate called *SHOX* (short stature homeobox-containing gene) was discovered by Rao and colleagues. Other evidence that X-Y homologous genes play a role in Turner's syndrome comes from studies of Y deletions associated with sex reversal. Rare XY females with *SRY* deletions can arise by the same mechanism of aberrant Xp-Yp interchange that causes XX males (Fig. 58-2). In addition to streak gonads, these XYp– females almost invariably display extragonadal Turner's syndrome features, most commonly lymphedema. By contrast, XY females with *SRY* point mutations or intragenic deletions have streak ovaries but no extragonadal manifestations of Turner's syndrome. These data imply that there is at least one Y-linked Turner's syndrome gene near *SRY*. David Page and colleagues have identified two candidate genes in this region, *ZFY* and *RPS4Y*. Both genes have X-linked homologs that escape X inactivation, as predicted for Turner's syndrome genes. The *ZFX* and *ZFY* genes encode highly similar zinc finger proteins of unknown function that may be transcription factors. The *RPS4X* and *RPS4Y* genes encode isoforms of S4, a ubiquitous ribosomal small subunit protein. The S4X and S4Y proteins have been shown to function interchangeably in ribosomes, consistent with the hypothesis that *RPS4Y* serves to provide a second dose of S4 in males. However, the amount of S4Y in ribosomes is only about 10% that of S4X, and no biochemical consequences of S4 haploinsufficiency have been demonstrated. Thus the role of either *RPS4X/RPS4Y* or *ZFX/ZFY* in Turner's syndrome is speculative. Interestingly, the mouse *Zfx* and *Rps4* genes are both subject to X inactivation. Moreover, there do not appear to be functionally interchangeably mouse Y homologs. Even though the overall complement of X-linked genes in humans and mice is very similar, the XO mouse has good viability, is fertile, and is anatomically normal. Species differences in X inactivation and X-Y homology may explain the striking contrast in the phenotype of monosomy X in mice versus humans.

OTHER SEX CHROMOSOME DISORDERS

One variant of Turner's syndrome that has received much attention involves mosaicism for a ring X chromosome, or 45,X/46,X,r(X) karyotype. The associated phenotype varies dramatically. Some individuals have typical Turner's syndrome, whereas others show more severe abnormalities such as mental retardation and multiple congenital anomalies. The severity of the phenotype correlates inversely with the size of the ring; larger rings tend to be associated with a milder phenotype.

It is remarkable that a partial deletion, e.g., a ring, can be more deleterious (at least in liveborns) than the complete absence of one X chromosome. The explanation may lie with X inactivation and dosage compensation. Some small ring X chromosomes lack the *XIC* region; others retain *XIC* but fail to express the *XIST* gene (Fig. 58-6).

The absence of *XIST* expression correlates with the severity of the phenotype. Barbara Migeon and coworkers have shown that
Figure 58-6 Two types of ring X chromosomes.
Figure 58-7 Aberrant Xq-Yq interchange.

Figure 58-8 Deletion mapping a Yq azoospermia locus. (*YRRM* genes have been renamed *RBM*.)

rings that fail to express *XIST* express some genes that are normally X inactivated. Thus the severe phenotype associated with mosaicism for a small ring X chromosome is probably caused by overexpression of one or more X-linked genes, as yet unidentified.

The importance of dosage compensation is also illustrated by another sex chromosome disorder. About one in every 1000 males lacks a portion of Yq, including the heterochromatic region. Men with the 46,XYq– karyotype are often normal, consistent with the absence of genes in this region. Deletions extending into the Yq euchromatic region are sometimes associated with short stature or infertility. In rare cases there are severe abnormalities, such as mental retardation, microcephaly, and other dysmorphic features. The severity of the phenotype does not generally correlate with the extent of the deletion.

After the discovery of long arm pseudoautosomal region, David Page and colleagues speculated that aberrant Xq-Yq interchange might be one cause of Yq deletions, just as aberrant Xp-Yp recombination causes Yp deletions (Fig. 58-2). To test this hypothesis, they studied ten 46,XYq– males and found evidence of aberrant Xq-Yq recombination in three subjects. All three had severe phenotypes. The other seven subjects in whom there was no evidence of abnormal X-Y recombination showed only mild or moderate abnormalities. In the three severely affected subjects, portions of distal Xq as large as 10 Mb were translocated to the Y chromosome, resulting in partial X disomy (Fig. 58-7).

One X-linked gene within the translocated portion, *G6PD* (glucose-6-phosphate dehydrogenase), was shown to be expressed from both the normal X and the translocated portion, leading to a twofold increase in enzyme activity. Page et al. concluded that diploid dosage of one or more genes in distal Xq caused the severe phenotypes of the three severely affected subjects. They termed this disorder the "XY$_{Xq}$ syndrome."

Molecular characterization of Yq deletions has also yielded insight into the function of the Y chromosome in male reproduction. As noted above, some men with cytogenetically visible Yq deletions have azoospermia (the absence of sperm in semen), suggesting that the euchromatic portion of Yq contains one or more genes important in spermatogenesis. This Yq locus is denoted *AZF* (azoospermia factor) (Fig. 58-8).

Several groups have found using DNA assays that up to 10% of men with unexplained azoospermia bear *de novo* Yq microdeletions. Two candidates for *AZF* have been identified by positional cloning. The first is a family of Y-specific genes originally called *YRRM* (Y RNA recognition motifs), discovered by Ann Chandley, Howard Cooke, and colleagues. These genes, now designated *RBM,* are members of a larger family of RNA-binding proteins. There are at least three functional genes and numerous Y-linked pseudogenes. Most *RBM* sequences are clustered near the *AZF* region of distal Yq, but related sequences are also present near the centromere on both Yp and Yq. One of the functional genes is absent in most normal Japanese men and thus appears to

represent a normal polymorphism. The *RBM* genes are expressed specifically in germ cells, where they may play a role in RNA splicing or packaging during spermatogenesis. The presence of multiple *RBM* genes, at least some of which are polymorphic, makes it difficult to infer their importance from naturally occurring deletions.

The second *AZF* candidate, termed *DAZ* (deleted in azoospermia), was discovered by Rene Reijo, David Page, and colleagues. Like the *RBM* genes, *DAZ* encodes an RNA recognition motif and shows testis-specific expression. Reijo et al. found that *DAZ* but not *RBM* was deleted in 12 of 89 azoospermic men with *de novo* Yq deletions. Interestingly, testicular biopsies from some of these men showed variable defects, even among adjacent seminiferous tubules in some instances. The defects ranged from the complete absence of germ cells (Sertoli-cell-only syndrome) to meiotic arrest with occasional mature condensed spermatids. *DAZ* is a strong candidate for *AZF*, the locus whose frequent deletion is associated with azoospermia, but this does not rule out a role for the *RBM* genes as well in spermatogenesis. Understanding the precise functions of these male-specific genes is the subject of active investigation.

SUMMARY

The study of human sex chromosome disorders has been richly rewarding. Classic chromosome studies of Klinefelter's syndrome, Turner's syndrome, and mixed gonadal dysgenesis revealed the mechanism of mammalian testis determination. Genetic studies are now yielding molecular explanations for disorders of sex determination. Identification of genes responsible for other phenotypes associated with sex chromosome disorders, such as the ring X syndrome, the XY_{Xq} syndrome, and Turner's syndrome, should be forthcoming. Molecular studies of these "experiments of nature" will also provide further insight into the unique biology of the mammalian sex chromosomes.

59 Disorders of Pubertal Development

Karen D. Bradshaw and Charmian A. Quigley

INTRODUCTION

Puberty is a complex developmental process that culminates in sexual-maturity. This transitional period begins in late childhood and is characterized by maturation of the hypothalamic–pituitary–gonadal axis, the appearance of secondary sexual characteristics, acceleration of growth, and ultimately the capacity for fertility. Significant endocrinologic changes accompany these developmental events. This chapter reviews the physiologic changes of normal puberty and examines the causes of precocious and delayed sexual maturation.

NORMAL PUBERTAL DEVELOPMENT

The age at which the somatic changes of puberty begins is variable. In industrialized countries, pubertal changes usually begin between 8 and 13 years of age in girls, and between 9 and 14 years of age in boys. This variability in the time of onset is likely a reflection of the number of distinct influences that can affect the time at which it begins, both genetic and environmental. Approximately 5% of a given population will have the onset of puberty at an age outside of this range and will be considered to have either precocious or delayed puberty.

In girls, the first somatic change that occurs is usually the beginning of breast development (thelarche), although in a minority of instances, pubic hair growth (pubarche) is the initial event. Thelarche and pubarche occur at mean ages of 10.9 and 11.2 years, respectively. Although the process of pubertal development is in fact a continuum, for descriptive purposes it is usually described in terms of a series of distinct stages, the five stages of breast and pubic hair development outlined by Marshall and Tanner being the most commonly employed scheme (Table 59-1). In parallel with the somatic changes of puberty, the volume of the ovaries and uterus enlarges, and the mucosa of the vagina thickens and becomes keratinized, evidenced clinically by lightening of the color of the mucosa from a deep red to a pale pink. After a variable period, averaging a little less than 2 years from the onset of breast development, most of the processes of pubertal maturation are complete, and menarche (the first menstrual period) occurs. Although most girls achieve menarche a little before their 13th birthday, the timing of this event is variable, and may occur as late as 14½ years in normal girls.

As in girls, puberty in boys is often described as a series of five distinct stages, based on testicular size, penile development, and distribution and character of pubic hair. In boys, the first physical evidence of puberty is an increase in testicular size. Measurement of the testes (length and width) or estimation of testicular volume using a Prader orchidiometer allows for early detection of pubertal onset. Testicular volume of 4.0 mL (or length of 2.5 cm), representing the onset of puberty, is noted at an average age of about 11½ years. Testicular enlargement is followed by scrotal thinning, development of pubic hair, and penile enlargement. Adult testicular volumes and penile dimensions are generally achieved by about 16 years of age; however, there is quite marked individual variation, with young men completing their sexual maturation anywhere between the ages of 14 and 18 years.

In addition to the appearance and development of secondary sexual characteristics in both boys and girls, puberty represents a period during which marked changes in body size and composition occur. Before the onset of puberty, the bodies of boys and girls are composed of similar proportions of adipose tissue and muscle. By the end of puberty, boys have a higher percentage of muscle and a lower percentage of fat relative to girls. It is during this period that the most rapid increases in bone mineralization occur.

PHYSIOLOGY OF PUBERTY

HORMONES AND PUBERTY Puberty is a period during which many dramatic hormonal changes occur. Of these, it is clear that changes in the axes controlling the secretion of growth hormone and gonadal steroids play central roles in this process.

Growth hormone (GH) is produced by the somatotrophs of the anterior pituitary gland. Although its control is complex, its synthesis and release is under the principal control of growth hormone releasing hormone (GHRH), which is released by the nerve endings of the hypothalamic GHRH neurons into the hypophyseal portal circulation. In response to pulses of GHRH, the pituitary releases pulses of GH into the systemic circulation. GH exerts its effects by binding to high-affinity receptors on the surfaces of responsive cells.

Although GH certainly modulates some biologic processes directly, in many tissues the actions of GH are modulated indirectly through the action of growth factors that are produced in response to the action of GH, specifically insulin-like growth factor-1 (IGF-I, previously known as somatomedin C) and its complex series of binding proteins. Serum levels of IGF-I rise with age in concert with age-related increases in mean GH levels.

Table 59-1
Stages of Development of Secondary Sexual Characteristics

Boys: genital (penis) development
Stage 1   Prepubertal: testes, scrotum, and penis of about same size and proportion as in early childhood.
Stage 2   Enlargement of scrotum and testes. Skin of scrotum reddens and changes in texture.
Stage 3   Enlargement of penis, at first mainly in length. Further growth of testes and scrotum.
Stage 4   Increased size of penis with growth in breadth and development of glans. Testes and scrotum larger; scrotal skin darkened.
Stage 5   Genitalia adult in size and shape.
Girls: breast development
Stage 1   Prepubertal: elevation of papilla only.
Stage 2   Breast bud stage: elevation of breast and papilla as small mound. Enlargement of areola diameter.
Stage 3   Further enlargement and elevation of breast and areola, with no separation of their contours.
Stage 4   Projection of areola and papilla to form a secondary mound above level of breast.
Stage 5   Mature stage: projection of papilla only, related to recession of areola to general contour of breast.
Both sexes: pubic hair
Stage 1   Prepubertal: vellus over pubes is not further developed than over abdominal wall.
Stage 2   Sparse growth of long, slightly pigmented, downy hair, straight or slightly curled, chiefly at base of penis or along labia.
Stage 3   Considerably darker, coarser, and more curled hair. Hair spreads sparsely over junction of pubes.
Stage 4   Hair now adult in type, but area covered is still considerably smaller than in adult. No spread to medial surface of thighs.
Stage 5   Adult in quantity and type with distribution of horizontal (or classically "feminine") pattern.
Stage 6   Spread up linea alba (male-type pattern).

At the onset of puberty, increased activity of the gonadotropin releasing hormone (GnRH) pulse generator causes a progressive rise in mean concentrations of gonadotropins, resulting from an increase in the frequency and amplitude of GnRH pulses *(see below)*. These increases are first detected as nocturnal gonadotropin pulses, but as puberty progresses gonadotropin pulses also increase during daytime, until adult mean gonadotropin levels are achieved.

More recently, a role for leptin, the recently described hormone produced by adipose tissue, in the onset of puberty has been described. In leptin-deficient ob/ob mice, treatment with leptin restores puberty and fertility. Subsequent studies have demonstrated that treatment of normal prepubertal mice with leptin accelerates maturation of the reproductive tract and results in earlier reproduction. Similarly, in prepubertal boys, leptin levels increase several months before the onset of puberty, as determined by the initial rise in testosterone.

Concentrations of a variety of other hormones also change with onset and progression of puberty. As a result of increased sex steroid concentrations, sex hormone-binding globulin is lower during puberty than in childhood. The gonadal peptide inhibin, structurally related to transforming growth factor-β (TGF-β), is regulated by and involved in regulation of follicle-stimulating hormone (FSH). This product of Sertoli and granulosa cells shows a progressive increase in mean concentration with advancing puberty in both sexes. Concentrations of the glycoprotein anti-Müllerian hormone (AMH) show quite marked sexual dimorphism. AMH is produced in Sertoli cells and is relatively high in newborn boys, but undetectable in girls. In contrast, the hormone becomes very low in boys during puberty, at which time AMH concentrations increase in girls.

The role of estrogens in the process of skeletal maturation in both boys and girls had been postulated for some time. As an example, effective suppression of the rapid skeletal maturation seen in boys with gonadotropin-independent forms of precocious puberty requires inhibition of aromatase activity to reduce serum estradiol concentrations, in addition to antiandrogens to interfere with androgen action. Furthermore, a female patient with a genetic deficiency of aromatase activity had no pubertal growth spurt and exhibited delayed skeletal maturation, indicating that estrogens are required for these events.

Inferences drawn from such cases regarding the importance of estrogen in promoting skeletal maturation in both sexes are reinforced by contrasting the patterns of pubertal development in syndromes of androgen and estrogen resistance. Studies of patients with complete testicular feminization (complete androgen insensitivity) have documented that a normal pubertal growth spurt is observed with the onset of pubertal gonadal function. Such findings suggest that the effects of gonadal steroids in male pubertal development are not mediated via the androgen receptor, but are instead exerted indirectly after the conversion of testosterone to estrogen.

The study of a male patient with estrogen resistance, in whom estrogens are unable to exert their effects at the tissue level, confirms these deductions. In this patient with estrogen resistance, an inactivating mutation of the estrogen receptor was shown to have several discernible physiologic consequences. First, the epiphyseal growth plates of this man demonstrated no evidence of epiphyseal fusion. Consequently, at the time of diagnosis (age 28) the patient was still growing. In addition to these effects on bone maturation, skeletal mineralization was also abnormal. At age 28, the patient's mineral bone density was markedly decreased, even when corrected for his retarded bone age of 15 years.

These considerations emphasize the complex hormonal interactions that characterize the process of normal puberty. It is clear that the normal functioning of each of these components is necessary for normal pubertal development to occur. As described below, abnormalities at many levels can disrupt normal pubertal growth, development and maturation.

MATURATION OF THE HYPOTHALAMIC–PITUITARY–GONADAL AXIS Maturation of the reproductive system occurs in a phasic manner in humans and in higher primates, and can be viewed as occurring in several distinct stages.

The first stage, which begins during fetal life and lasts until late infancy, is characterized by development of the neuroendocrine systems responsible for regulation of the reproductive system. The area in the arcuate nucleus of the hypothalamus destined to

become the GnRH pulse generator develops intrinsic and unregulated pulsatile activity by about 11 weeks of gestation. During this stage the reproductive system appears to be fully active, with gonadotropin and sex steroid hormone concentrations being measurable in fetal plasma. Concentrations of luteinizing hormone (LH) and FSH peak at about 4–5 months' gestational age. Later in gestation, negative feedback from gonadal steroids begins to regulate the unrestrained pulsatile activity of the hypothalamic pulse generator and by term, gonadotropin levels (and by inference the activity of the GnRH pulse generator) are low.

At the time of delivery the infant is separated from the dominant source of sex steroids, the placenta, and owing to the withdrawal of this negative feedback, the levels of gonadotropins rise. This increase is responsible for a transient secondary stimulation of the infant's gonads occurring in the first months after birth. Although occurring in both boys and girls, this is observed most readily in female infants in whom there may be prolonged neonatal breast budding.

By 6 months of postnatal age, gonadotropin and sex steroids concentrations in plasma have again declined to low levels and the third stage of maturation begins. This stage lasts throughout childhood, and is characterized by low plasma concentrations of LH, FSH, and sex steroids.

From a physiologic perspective, the prepubertal stage of development presents apparent contradictions. Measurements of gonadotropins and sex steroids during fetal development suggest that the hypothalamic–gonadal axis has completely developed *in utero* and that it is regulated by steroid hormones during the latter stages of pregnancy. Despite this, during the prepubertal period, gonadotropins remain low even when sex steroid concentrations are extremely low, such as in patients with Turner's syndrome or in castrate children. That serum gonadotropin concentrations remain low under such conditions suggests that additional inhibitory mechanisms in the central nervous system or hypothalamus have developed. Early studies to explain these different regulatory behaviors focused on examining the sensitivity of the hypothalamus and pituitary to feedback inhibition by gonadal steroids. Such investigations demonstrated that the levels of estrogen and androgen required to inhibit LH and FSH secretion in young prepubertal animals and in humans are consistently lower than those required to suppress gonadotropin levels to an equivalent extent in adult castrate animals. Such differences in the sensitivity of regulation of gonadotropin secretion in young prepubertal and adult animals have been described in a number of different species. Although such observations have substantial power in explaining the prepubertal quiescence of gonadotropin secretion, other observations suggest that additional mechanisms might also be operative. Although mean serum concentrations of gonadotropins are low during the prepubertal period, the reproductive system is not completely inhibited during this stage, because small spontaneous LH pulses occur at a low frequency in normal children.

The fourth stage, puberty itself, occurs as the result of reactivation of the reproductive axis. Although a great deal of effort has been expended to identify the signals that control the onset of puberty, it appears that the mechanisms responsible for the initiation of pubertal events are extremely complex and likely involve the integration of numerous different signals, including attainment of a certain body mass or composition and perhaps neural signals derived from centers within the central nervous system that serve as a biologic clock.

The onset of puberty is heralded by striking increases in nocturnal LH secretion, manifest by an increase in amplitude and frequency of LH pulses. These increases of LH precede rises of sex steroid concentrations and the development of secondary sex characteristics. As pubertal maturation progresses, the amplitude and frequency of gonadotropin pulses also increase during the day, in a pattern similar to that seen at night, until the final stage of sexual maturation, adulthood, is reached. In this period, regular pulses of GnRH establish the mature pattern of gonadal steroid secretion. In females, this results in the regular cyclical variations of gonadotropins, estrogen, and progesterone characteristic of the menstrual cycle. In males, the same regular pulses of GnRH establish a pattern characterized by relatively constant levels of testosterone and gonadotropins, with minimal diurnal variation.

VARIATIONS OF NORMAL PUBERTY

EARLY Fairly common forms of partial premature pubertal development are the isolated development of pubic hair (premature pubarche) and the isolated development of breasts (premature thelarche). Although these are benign conditions, such patients must be followed closely to monitor for progression to constitutional precocious puberty (CPP).

Precocious pubarche is most often a benign condition secondary to early adrenarche. Balducci et al. studied 171 subjects with isolated precocious pubarche. Mild abnormalities of steroidogenesis (nonclassic forms of 21-hydroxylase or 3-β hydroxysteroid deficiency) were present in 12% of patients as diagnosed by adrenocorticotropic hormone (ACTH) stimulation tests. In the majority of those, basal 17α-hydroxyprogesterone (17α-OHP) levels were higher than in pubertal norms and were thought to be a good screening test to determine which patients should undergo ACTH stimulation testing. In some patients premature pubarche may predict the development of functional hyperandrogenism in the mid-teenage years associated with polycystic ovarian syndrome in girls.

Premature thelarche is typically associated with a degree of FSH secretion, antral follicular development, and ovarian function that is greater than that measured in age-matched prepubertal control subjects. The prevalence of ovarian microcysts detected by ultrasonography is increased in these girls; however, plasma estradiol is commonly unmeasurable despite genitourinary cytology that shows evidence of estrogenization. Premature thelarche usually occurs in the first 2 years of life and regresses before puberty. Children who present with breast development later are more likely to have some degree of continued breast development, representing an early stage of precocious puberty. Once breast development is stimulated much beyond the breast-bud stage and reaches early adolescent proportions, breast contour generally does not regress. Occasionally (approximately 10–15%) girls go on to develop complete precocious puberty, but in the majority of patients the breast bud is a transient event that warrants only close follow-up for the appearance of other pubertal signs.

PRECOCIOUS PUBERTAL DEVELOPMENT

The development of isosexual secondary sexual characteristics before the age of 8 years in girls and before the age of 9 years in boys is termed precocious puberty. Precocious puberty is characterized by early and progressive sexual development accompanied by advancement of skeletal maturation as measured by bone age. The rapid linear growth that characterizes precocious puberty is

*[a]*An overview of the causes of gonadotropin-independent precocious puberty. This term is used interchangeably with the term peripheral precocious puberty.

associated with premature and rapid skeletal maturation and fusion of the epiphyses, in most cases resulting in short adult stature compared with genetic height potential.

There are two major classes of precocious puberty: disorders that result from early reactivation of the hypothalamic–pituitary–gonadal axis (generally referred to as gonadotropin-dependent or central precocious puberty, Table 59-2) and those that do not (referred to as gonadotropin-independent precocious puberty, Table 59-3). Most girls and approximately half of boys who present with precocious puberty have central, gonadotropin-dependent precocious puberty which results from the secretion of GnRH from the hypothalamus. Although central precocious puberty is much more common among females than males, boys with this form of precocious puberty are more likely to be found to have an underlying central nervous system (CNS) abnormality. By contrast, the majority of girls have no discernible structural CNS lesion and are thus said to have an "idiopathic" form of the disorder. The overall incidence of gonadotropin-dependent precocious puberty has increased in both sexes because of the survival of children who have received CNS irradiation for brain tumors or leukemia.

GENERAL EVALUATION   Evaluation of patients with early pubertal development should begin with a detailed history focused on the occurrence of prior CNS trauma, radiation, or seizure activity, exposure to exogenous sex steroids in cosmetics or food, or a positive family history. In girls, physical examination should focus on determining whether the development reflects androgen action, estrogen action, or both. Girls with isolated androgenization most likely have premature adrenarche or congenital adrenal hyperplasia, whereas those with estrogenization or evidence of both androgen and estrogen action are more likely to have precocious puberty. In boys, the presence of isolated androgenization most likely represents premature adrenarche, whereas the finding of testicular volumes of more than 4.0 mL is diagnostic of precocious puberty. Diagnostic evaluation should begin with an X-ray to assess bone age as a marker for sex steroid hormone action. In general establishing that skeletal age is concordant with chronological age allows for continued observation.

When secondary sexual characteristics are associated with an advanced bone age, measurements of estradiol, testosterone, and thyroid hormone should be obtained, and a GnRH stimulation test

is indicated to differentiate between central (gonadotropin-dependent) and peripheral (gonadotropin-independent) causes of precocious puberty. In most cases, the diagnosis of gonadotropin-dependent precocious puberty, particularly in younger children, warrants obtaining a magnetic resonance imaging (MRI) or computerized tomography head scan.

GONADOTROPIN-DEPENDENT PRECOCIOUS PUBERTY

IDIOPATHIC PRECOCIOUS PUBERTY   In girls, most cases of precocious puberty are central (gonadotropin-dependent) in origin, and are believed to be caused by premature maturation of the hypothalamic–pituitary–ovarian axis. In perhaps two-thirds of cases, no recognizable cause of the disorder can be found. In these cases, the pattern of development and progression parallels that of normal pubertal development, although the onset is at an early age.

CNS DISORDERS   Lesions of the CNS are well-recognized as causing central precocious puberty. Common causes include static encephalopathy as a result of infection, hypoxia, trauma, or irradiation during infancy or early childhood. A less common, but nonetheless important, cause of central precocious puberty is a CNS tumor. These tumors can be viewed as causing precocious puberty by one of two distinct mechanisms. Hypothalamic hamartomas are benign tumors that have been shown to contain measurable GnRH. As such, they may be considered to be acting as ectopic GnRH pulse generators that have escaped from the normal inhibitory influences exerted in the prepubertal period on the centers that normally secrete GnRH. These small tumors are more frequently diagnosed in boys than in girls and are most easily visualized using MRI, as some may be only 2 or 3 mm in size. These tumors tend to grow slowly—if at all—and rarely cause neurologic symptoms.

The chance of finding CNS pathology in either sex is inversely proportional to the age of the child, with the greatest yield in children younger than 4 years old. Kappy found that in girls whose pubertal development began after 6 years of age, any CNS pathology was already known or clinically evident, suggesting that routine MRI in these children will less likely have positive findings. In contrast, Pescovitz and coworkers reported that in a series of 4000 children referred to the National Institutes of Health, about one-third of the girls and more than 90% of the boys had an identifiable lesion of the

CNS visible on computed tomography or MRI scans. This high prevalence of CNS lesions reflects the referral population.

Cranial irradiation has dose-dependent effects on many hypothalamic–pituitary functions. Although doses of cranial irradiation exceeding 50 g to the hypothalamic–pituitary axis may render a child gonadotropin deficient, lesser doses of irradiation have been associated with early puberty in both sexes. Low-dose cranial irradiation (18–24 g) used in the CNS prophylactic treatment of acute lymphoblastic leukemia is associated with a downward shift in the distribution of ages at pubertal onset and menarche in girls. Central precocious puberty is rare in boys treated in this manner.

The pathophysiology of central precocious puberty in non-hamartomatous lesions of the CNS is not yet established. It is possible that neural defects located near the hypothalamus cause precocious puberty by interfering with tonic central nervous system inhibition of the hypothalamic–pituitary–gonadal axis. It is also possible that focal derangements of the cellular environment in the vicinity of GnRH neurons may be causally related to the premature activation of GnRH secretion. Junier and Ojeda have speculated that neurotrophic or mitogenic activities produced locally in response to brain injury may be involved in the process. They suggest that the response of GnRH neurons to hypothalamic injury comprises three phases: an initial stage during which some of the neurons lose mature morphologic characteristics, reverting to a presumably more immature condition; an intermediate phase in which morphologic differentiation is reestablished and an increased synthesis of TGF-β by reactive astrocytes enhances GnRH release without affecting GnRH gene expression through a process that may involve glial release of prostaglandins; and a third phase in which the rise in sex steroids caused by the GnRH-dependent increase in basal LH release activates GnRH neurons to secrete gonadotropins in an episodic nature.

TREATMENT OF GONADOTROPIN DEPENDENT PRE-COCIOUS PUBERTY Historically, medroxyprogesterone and cyproterone acetate were used to attempt to suppress activation of the hypothalamic–pituitary–gonadal axis. Neither of these agents was satisfactory, because they were not fully effective in inhibiting pubertal or skeletal maturation or in improving adult height.

The recognition that the continuous, nonpulsatile presentation of GnRH to the pituitary gonadotrophs induced a state of secondary hypogonadism led to the development and use of potent GnRH agonists in the therapy of precocious puberty. These gonadotropin-releasing hormone analogs (GnRHa; *see also* Chapter 34) represent the first truly effective treatment for central precocious puberty. Significant reductions in basal and peak (GnRH-stimulated) serum FSH and LH concentrations occur within the first month of GnRHa therapy. In parallel with these changes, a reduction in plasma concentrations of estradiol (in girls) and testosterone (in boys) occurs after the first month and persists while the drug is administered. Importantly, the effects of these drugs are reversible. After withdrawal of GnRHa therapy, gonadotropin and gonadal steroid concentrations return to their pretreatment levels.

Institution of GnRHa therapy results in a decrease in growth velocity, usually within a range that is appropriate for the child's skeletal maturation. The slowing of linear growth is accompanied in most cases by slowing of skeletal maturation—one of the primary aims of such treatment. Preservation of, or an increase in, adult height can be achieved in some children with gonadotropin-dependent precocious puberty treated with GnRHa. Most investigators, using the tables of Bayley and Pinneau, reported increases

in the predicted final height of patients during the course of GnRHa therapy with a mean increase of 5 cm. Most studies suggest that the greatest improvement in predicted adult height is obtained in children whose bone ages are relatively young at the onset of treatment, indicating the need for early diagnosis and intervention. The length of time that such therapy is continued depends on bone age and estimates of final height in individual cases. Although concern has been raised regarding the possible effect of pubertal suppression on skeletal mineralization, an important feature of normal puberty, evidence available to date indicates no significant problem. Baens et al. evaluated the bone mineral density (BMD) in female patients treated with GnRHa for gonadotropin-dependent precocious puberty who had completed therapy and had subsequently attained a bone age of greater than 14 years. They found that BMDs were not different from those of a control population of girls with the same bone ages.

The physical effects of pubertal suppression are not limited to the effects on bone development. The majority of girls experience no increase in breast development, and a third show regression to an earlier Tanner stage, correlating with a reduction in ovarian and uterine size. Some girls experience transient vaginal bleeding approximately 2–4 weeks after initiation of GnRHa therapy because of estrogen withdrawal. Effects on pubic hair are less predictable, although most children show either no progression or a minor degree of regression. Some children show an increase in pubic hair that correlates with normal adrenarche.

GONADOTROPIN-INDEPENDENT PRECOCIOUS PUBERTY

Gonadotropin-independent forms of precocious puberty are about one-fifth as common as gonadotropin-dependent forms of precocious puberty. Gonadotropin-independent precocious puberty is characterized by increased production of gonadal steroids, causing the typical physical changes of puberty, in the absence of reactivation of the hypothalamic–pituitary axis (Fig. 59-1). This form of precocious puberty includes conditions that mimic the effect of pituitary gonadotropins on gonadal function, such as those in which there is secretion of gonadotropins from nonpituitary sources. Table 59-3 lists conditions associated with gonadotropin-independent precocious puberty. Molecular mechanisms underlying two forms of gonadotropin-independent precocious puberty, familial Leydig-cell hyperplasia and McCune-Albright syndrome, have recently been described.

McCUNE-ALBRIGHT SYNDROME McCune-Albright syndrome (MAS) is characterized classically by the clinical triad of cutaneous hyperpigmentation, polyostotic fibrous dysplasia, and endocrine dysfunction. Although it is stated that at least two of the features of the triad must be present to make the diagnosis, this guideline should be interpreted with caution, since the features may develop over time. The condition occurs distinctly less frequently in boys than in girls, who comprise 90% of affected patients. In contrast to those with central precocious puberty, these girls not uncommonly present with vaginal bleeding as the first sign of their sexual development. A pattern of variable involvement of hormone-secreting cells occurs in subjects with MAS, and the endocrine abnormalities are characterized by excessive function of these cells. The most common endocrine manifestation of MAS is precocious puberty, often associated with ovarian cysts. A waxing and waning course of the precocious puberty is not uncommon. Depending on the specific cell types affected, a variety of
Figure 59-1 A schematic representation of the hypothalamic–pituitary–gonadal axis indicating the levels disturbed in selected forms of precocious puberty. Testitoxicosis (familial male precocious puberty, FMPP) is caused by amino acid substitution mutations in the membrane receptor for luteinizing hormone (LH) that result in its constitutive, ligand-independent activation. The gonadotropin-independent gonadal function that is observed in individuals with McCune-Albright syndrome is caused by mutations in a component of the FSH-regulated signaling cascade in granulosa cells of the ovary. In these individuals, replacement of one of two critical amino acid residues in a G protein subunit (Gsα) results in the constitutive activation of adenylate cyclase, mimicking the effect of FSH receptor activation in stimulating steroidogenesis in granulosa cells.

epidermis; the number and size of melanocytes is normal, but the melanosomes are enlarged. The skeletal and cutaneous involvement in MAS is commonly asymmetrical and the skin lesions often stop abruptly at the midline.

The diverse clinical abnormalities of MAS have in common the involvement of cells that respond to extracellular signals through activation of the hormone-sensitive adenylate cyclase system, the membrane-bound enzyme that catalyzes the formation of the intracellular second messenger cyclic adenosine monophosphate (cAMP). However, these endocrine disturbances are not accompanied by increased plasma concentrations of the relevant trophic or stimulatory hormones. Thus, girls with precocious puberty caused by MAS have ovarian enlargement and follicular hyperplasia but have low serum levels of LH and FSH and a prepubertal response of LH to administration of GnRH.

The basis of the gonadotropin-independent nature of the precocious sexual development in MAS was elucidated by the identification of mutations that activate the intracellular second messenger pathways by which the trophic hormones such as gonadotropins and thyrotropin signal. The activity of the hormone-sensitive adenylate cyclase system is primarily regulated by two guanine-nucleotide binding proteins (G proteins)—one inhibitory and the other stimulatory (*see* Chapter 46). Schwindinger et al. identified a mutation in the gene encoding the α-subunit of the stimulatory G protein that regulates adenylate cyclase activity. A heterozygous guanine to adenine transition was found in exon 8 of the gene encoding the α-subunit of Gs, predicting the replacement of arginine by histidine at position 201 of the mature protein. This amino acid is located within a critical region of the Gsα protein and the substitution causes a marked decrease in the intrinsic GTPase activity of Gsα, prolonging the survival of the active conformation of the enzyme and resulting in constitutive activation of adenylate cyclase activity. The consequent increased production of cAMP explains the increases in endocrine organ function typical of this disease, since this system mediates the stimulatory effects of many hormones (gonadotropins, thyrotropin, adrenocorticotropin, and GH-releasing hormone). In addition, cAMP modulates cellular proliferation in certain tissues, providing a basis for the hyperplasia seen in some tissues in MAS. Subsequent work by Weinstein and coworkers confirmed and extended these findings. Using PCR and allele-specific hybridization, these investigators identified two types of mutation at the same position implicated by Schwindinger (the codon encoding amino acid residue 201), resulting in substitution of either a histidine or a cysteine residue for the native arginine at this position. In the pathologic specimens from each of four patients with MAS studied by Weinstein, the mutant allele was found to be present in greatest abundance, relative to the normal allele, in the tissues histologically most affected, but in low levels in most of the tissues examined. The mutation has been found within the dysplastic bone lesions of affected patients, and may produce these lesions by inducing proliferation of mesenchymal progenitor cells. The mutation has also been detected in the hyperpigmented skin lesions, which commonly colocalize with the bone lesions, but its role in their pathogenesis remains unclear. Inactivating mutations of Gsα are associated with pseudohypoparathyroidism.

The findings reported above are consistent with the hypothesis that a spontaneous mutation early in gestation produced an abnormal monoclonal cell population and that the variable clinical presentation of MAS is caused by the varying degrees of somatic

other endocrine disturbances may occur, including hyperthyroidism (caused by nodular or follicular thyroid hyperplasia) in 20–40% of patients, hypercortisolism (caused by nodular adrenal hyperplasia), and growth hormone- or prolactin-secreting pituitary adenomas.

The peculiar bone lesion of MAS (polyostotic fibrous dysplasia) may occur in any bone, including long bones, the skull, and pelvis, and result in pathologic fracture or severe disfigurement. Malignant degeneration occurs in up to 4% of lesions. The usually large, pigmented cutaneous lesions (*café-au-lait* patches) have irregular, "serrated" outlines. Their distribution, like the variable involvement of endocrine tissues, reflects an underlying genetic mosaicism that results from a postzygotic somatic cell mutation occurring after a number of cell divisions have taken place. Common sites of occurrence of the *café-au-lait* patches include the forehead, the neck or upper back, the shoulder and upper arm, the lumbosacral region, and the buttocks. They often follow a distribution that is not dermatomal, but in fact relates to the lines of Blaschko, which are thought to represent the patterns of dorsal and ventral outgrowth of two different cell populations during early embryogenesis. The hyperpigmentation is present in the basal

mosaicism of this genetic alteration that would otherwise represent an autosomal dominant lethal defect. Because of this mosaicism, MAS is not inherited.

FAMILIAL MALE PRECOCIOUS PUBERTY Although the endocrine disturbances are confined to the testes, a similar mechanism characterizes another GnRH-independent form of precocious puberty, familial male precocious puberty (FMPP, familial testotoxicosis). This disorder is inherited in an autosomal dominant, male-limited pattern and is characterized by the onset of puberty (testicular enlargement) before 4 years of age. Testosterone production and Leydig cell hyperplasia occur autonomously, in the context of low, prepubertal levels of LH. The clinical hallmark of this disorder is the relatively modest enlargement of the testes for the degree of virilization. Affected adult men are often short because of early epiphyseal fusion; however, they are otherwise healthy and have normal fertility. Although LH concentrations are low in childhood, they are normal in adulthood, indicating that normal maturation of the hypothalamic–pituitary–gonadal axis occurs. The disorder is not expressed in heterozygous females, since estrogen production by ovarian follicles requires coordinated stimulation by both LH and FSH; thus, activation of the LH pathway alone has no significant effect.

The pathogenesis of this gonadotropin-independent form of precocious puberty has been traced to heterozygous mutations within specific segments of the gene encoding the receptor for luteinizing hormone and chorionic gonadotropin (the LH/CG receptor). The LH/CG receptor is a member of the seven transmembrane domain family of G-protein coupled receptors. Unlike the inactivating mutations of the LH receptor, which can occur in many parts of the molecule, most of the activating mutations of the LH receptor have resulted in amino acid substitutions within the fifth and sixth transmembrane helices and the cytoplasmic loop that connects them. Shenker et al. found a mutation that resulted in replacement of the native aspartate with glycine, at position 578, in the sixth transmembrane helix of the protein. In vitro studies of the mutant receptor containing the Asp 578 to Gly substitution demonstrated marked increase in cyclic AMP production in the absence of ligand. It is presumed that the structural changes induced in the LH receptor by these amino acid substitutions shift these portions of the receptor to a conformation that mimics the conformation of the normal LH receptor activated by LH. This conformation of the mutant LH receptor leads to the agonist-independent production of cAMP, and thereby to autonomous testosterone production by the Leydig cells of affected boys. The presence of the Asp 578 to Gly mutation in most affected kindreds studied to date is believed likely to reflect a common genetic ancestry in many cases. However the finding of this same mutation in a number of ethnically diverse individuals suggests the occurrence of fresh mutations in some cases. Other less common mutations include replacement of alanine 572 by valine, threonine 577 by isoleucine, aspartate 582 by glycine, and methionine 575 by isoleucine. This latter amino acid is located in the sixth transmembrane domain of the receptor, close to a region important for binding of G proteins. Recently, a mutation that converts methionine 398 to threonine has been reported. In contrast with the majority of mutations in this disorder, this amino acid is located in the second transmembrane domain of the receptor. Notably, there was phenotypic heterogeneity associated with this mutation, since one boy carrying the mutant allele had no evidence of precocious puberty.

ECTOPIC HORMONE PRODUCTION Human chorionic gonadotropin (hCG)-secreting germ cell tumors have been thought to cause precocious puberty exclusively in boys. Because of the extensive structural homology of the β-subunits of hCG and LH, the excess hCG acting through the LH receptor stimulates Leydig cell production of testosterone.

Non-CNS tumors causing gonadotropin-independent precocious puberty in females have also been described. In such instances, the pubertal development is most often traced to the presence of a granulosa cell ovarian tumor or an adrenal tumor that produces excess estrogen.

Although the cell types and hormones differ in the different tumors described above, they do share a common characteristic. That is, in each instance a hormone that is normally produced by specific cell types and regulated in a very precise fashion is expressed by the neoplastic cells in an inappropriate or unregulated fashion. Although not well-studied, it appears that the genetic events leading to the genesis of the neoplasms in some way mimic the signals controlling hormonogenesis.

Although not strictly a cause of precocious puberty, congenital adrenal hyperplasia, most commonly because of deficiency of 21-hydroxylase, is another cause of early virilization. It is distinguished by absence of testicular enlargement in boys (hence the designation "pseudopuberty"), and virilization without feminization in girls.

TREATMENT OF GONADOTROPIN-INDEPENDENT FORMS OF PRECOCIOUS PUBERTY Because patients with these forms of precocious puberty demonstrate pubertal development that is independent of pituitary gonadotropin secretion, GnRH agonist therapy is ineffective, at least as part of initial management. As such, even though the molecular lesions are different, treatments for FMPP and MAS are instead focused on directly inhibiting the synthesis or action of sex steroids.

In boys with FMPP, this has been approached through administration of inhibitors of steroidogensis, such as the antifungal agent ketoconazole. This compound inhibits the enzyme that catalyzes the cleavage of the 20,22 bond of the cholesterol molecule, and thus inhibits the synthesis of both androgens and estrogens. An alternative approach has been to employ drugs that block the actions of androgen at the level of the androgen receptor itself. Although more potent drugs are now available, published reports have used spironolactone, a drug that has demonstrated modest activity as a competitive inhibitor of androgen receptor function. Results using this drug have been somewhat disappointing, but have been more encouraging when coupled with testolactone. This compound is an aromatase inhibitor that blocks the enzyme (P450 aromatase) that catalyzes aromatization of testosterone, the rate-limiting step in estrogen biosynthesis, thereby reducing the high estrogen concentrations responsible for the accelerated skeletal maturation typical of this condition. Of note, the early maturation of the hypothalamus induced by exposure to high levels of sex steroids may result in the activation of the endogenous GnRH pulse generator, leading to the development of central, gonadotropin-dependent precocious puberty, secondary to the preexisting gonadotropin-independent precocious puberty. In such instances, the addition of GnRHa therapy is required to prevent progression of pubertal development and skeletal maturation.

Treatment of girls with precocious puberty because of MAS uses drugs that inhibit the synthesis of estrogen (aromatase inhibitors). The longest-term studies of this type have used testolactone.

Although demonstrating some efficacy, the benefits were minimal and were likely caused by imperfect patient compliance (because of side effects of the drug) and the relatively low potency of testolactone itself in inhibiting aromatase activity. The availability of more potent aromatase inhibitors (e.g., arimidex) may improve the effectiveness of such approaches in the future. The approach to inhibition of testosterone synthesis in boys with precocious puberty caused by MAS is similar to that employed in the treatment of patients with FMPP. Addition of a GnRH analog is required for those patients with MAS who develop secondary central precocious puberty.

CONTRASEXUAL DEVELOPMENT

Contrasexual (or heterosexual) development refers to feminization in males or virilization in females, and can occur at any age, either prepubertally or postpubertally. These disorders are not forms of puberty. Evaluation consists of careful history and physical examination followed by measurement of gonadal and adrenal steroids, and in more subtle cases, ACTH stimulation testing to identify cryptic or atypical forms of congenital adrenal hyperplasia. Depending on the pattern of steroid hormone excess detected, imaging of the adrenals, gonads, or liver may be required. Gynecomastia is the most common manifestation of feminization and in pubertal boys is usually a benign self-limited condition; however, gynecomastia in a prepubertal boy is clearly pathologic. When associated with hypogonadism, Klinefelter's syndrome should be considered and a karyotype obtained. In most cases, estrogen concentrations are not increased. However, in those patients in whom there is measurably high estrogen concentration, the source of excess estrogen may be a neoplasm (e.g., adrenal, hepatic, or testicular), an abnormality of steroid metabolism, or increased extraglandular conversion of C-19 steroids to C-18 estrogens, such as occurs in the presence of significant obesity (gynecomastia is more common in obese boys). Exposure to exogenous estrogens is another uncommon cause of feminization in males.

Females with virilization may have adrenal or gonadal sources of androgen excess, causing development of sexual hair, clitoromegaly, acne, and hirsutism. The most common cause of virilization in prepubertal girls is congenital adrenal hyperplasia (CAH) because of deficiency of 21-hydroxylase activity ("late-onset" or "attenuated" CAH). Other virilizing forms of CAH include 3β-hydroxysteroid dehydrogenase and 11-hydroxylase deficiency. Severely advanced skeletal maturation is a common accompaniment of the virilization in affected girls, and these conditions can be further complicated by the development of secondary central precocious puberty. A variety of molecular defects underlie these enzyme deficiencies, as described in Chapter 57. Virilizing adrenal adenoma or ovarian neoplasms are associated with elevated levels of dehydroepiandrosterone sulfate, androstenedione, or testosterone. β-hCG and α-fetoprotein may also be increased and should be measured as markers for ovarian, testicular, and hepatic tumors in virilized girls and feminized boys.

DELAYED PUBERTAL DEVELOPMENT

Delayed puberty is defined by lack of physical changes of sexual maturation at a chronological age that is two standard deviations above the mean age of onset of puberty. In the United States, the ages of 12 years in girls and 14 years in boys serve as practical guidelines to determine the need for evaluation. Diagnostic evaluation should differentiate between constitutional

Table 59-4
Causes of Delayed Pubertal Development

Constitutional delay
Hypogonadotropic hypogonadism
  Isolated gonadotropin deficiency
  Kallmann's syndrome and variants
  Functional gonadotropin deficiency
    Chronic systemic disease and malnutrition
    Anorexia nervosa
    Exercise-induced amenorrhea
  CNS disorders
    Tumors
    Radiation therapy
    Anatomic defects (e.g., septo-optic dysplasia)
  Miscellaneous disorders
    CHARGE association
    Noonan's syndrome
    Aarskog syndrome
    Prader-Willi syndrome
    Laurence-Moon-Biedl or
    Bardet-Biedl syndromes
Hypergonadotropic hypogonadism
  Klinefelter's syndrome
  Primary testicular failure
  Gonadal dysgenesis and variants
  Primary ovarian failure

delay, hypogonadotropic hypogonadism, and hypergonadotropic hypogonadism. Causes of delayed puberty are listed in Table 59-4.

VARIATIONS OF NORMAL PUBERTY—DELAYED (CONSTITUTIONAL DELAY)   Constitutional delay of puberty is a common, benign condition that represents a variant of normal puberty. The pattern of pubertal progress in affected children is quite normal; however, its time of onset is delayed with respect to the population as a whole. Boys are referred for evaluation of this condition significantly more often than are girls. In conjunction with their delayed pubertal development, these children generally have mildly short stature, approximately two to three standard deviations below the mean for age throughout childhood. Their short stature is accompanied by delayed skeletal maturation (2–4 years behind chronological age) and these children generally demonstrate sexual maturation that is more commensurate with their bone age than their chronological ages. Adult height and sexual maturation are achieved significantly later, many young men reporting continued linear growth in their late teens or early 20s. Final height is generally appropriate for the genetic background, but is commonly in the low normal range. The family history often reveals other affected individuals in the family, most often males.

HYPOGONADOTROPIC HYPOGONADISM

Hypogonadotropic hypogonadism describes the deficiency of pulsatile release of gonadotropins, which may result from a variety of hypothalamic or pituitary disorders. In the presence of a hypothalamic defect, or absence of GnRH-secreting neurons, failure of GnRH secretion results in lack of stimulation of pituitary gonadotropin secretion. In contrast, pituitary disorders, such as tumors or hypophysitis, cause direct failure of pituitary gonadotropin secretion.

During embryogenesis, the olfactory nerves and terminal nerve develop from the olfactory placode in the nose. The olfactory sensory neurons have short dendrites that terminate at the olfactory

epithelium in dendritic knobs with cilia that contain G-protein coupled, seven transmembrane domain, odorant receptors. The olfactory nerves associate with the terminal nerve and vomeronasal nerve to produce a bridge between the olfactory epithelium and the forebrain. The cells that will become GnRH-synthesizing neurons arise within the region of the olfactory placodes and migrate from the nasal epithelium, through the cribriform plate of the nose and then along the olfactory tract–forebrain axis to reach the preoptic and hypothalamic areas, where they differentiate to become the GnRH-secreting neurons. The exact cellular origin of the GnRH neurons has yet to be established; however, there is evidence in studies of embryonic chicks that they in fact derive from an embryonic precursor in the region that will become the nasal epithelium, rather than the olfactory placode itself. These GnRH-secreting neurons, which are dispersed through the medial basal hypothalamus rather than being located in a discrete nucleus, transduce neural signals into a hormonal signal—the periodic secretion of GnRH. Given the developmental connection between olfactory and GnRH neurons, it is of particular interest to note the relationship between olfactory acuity and reproduction in animals, evidenced by the importance of pheromones in sexual attraction.

KALLMANN'S SYNDROME AND VARIANTS Isolated gonadotropin deficiency may occur sporadically or in a familial pattern. In contrast to patients with delayed puberty because of CNS tumors or constitutional delay, those with gonadotropin deficiency usually have appropriate or tall stature for their age. Untreated adults and individuals of pubertal age commonly have eunuchoid proportions.

Kallmann's syndrome was first described in 1856. It is uncommon, occurring with approximately one-tenth the frequency of Klinefelter's syndrome (approximately 1:10,000 in males and 1:50,000 in females). As originally described, it comprised the association of hypogonadotropic hypogonadism with anosmia or hyposmia resulting from agenesis or hypoplasia of the olfactory bulbs and tracts. The disorder results from failure of fetal GnRH secretory neurons to migrate from the olfactory placode, where they arise, to the medial basal hypothalamus. Three modes of transmission have been described: X-linked, autosomal recessive, and autosomal dominant.

Typical clinical features of Kallmann's syndrome include delayed puberty, eunuchoid habitus, gynecomastia, and reduced sense of smell (often unknown to the patient). Cryptorchidism and a small penis are present in infancy in some affected individuals. Carrier females may display partial defects, such as reduced sense of smell, delayed menarche, or irregular menses, but are normally fertile. Other clinical features of Kallmann's syndrome include unilateral renal agenesis in up to 40% of patients; midline facial anomalies, such as cleft lip, high-arched or cleft palate, or other forms of imperfect facial fusion; short metacarpals; talipes cavus; cerebellar ataxia; sensorineural deafness; epilepsy; and synkinesia (mirror movements of the hands). Variant forms of Kallmann's syndrome manifest varying combinations of these features. MRI scans may demonstrate hypoplasia of the olfactory gyri and absent olfactory bulbs and tracts. When analyzed histologically, the olfactory epithelium of a patient with Kallmann's syndrome was thinner than normal and contained fewer neurons. Those that were present lacked cilia, were immature, or showed signs of degeneration.

The X-linked form of Kallmann's syndrome has been most extensively studied. Positional cloning studies by Legouis et al. led to the isolation and characterization of the gene defective in this form of Kallmann's syndrome. The Kallmann gene *(KAL1* or *KALIG1)*, which is located at Xp22.3, and (at least partially) escapes X inactivation, encodes a 680-amino acid protein that is apparently extracellular in location. An inactive homologous pseudogene *(KALP)* is located on the Y chromosome at Yq11. The derived amino acid sequence of KAL1 predicts a protein that contains a leader peptide and no transmembrane or anchoring regions are present. The protein contains four fibronectin type III motifs (FNIII), suggesting a role in cell adhesion. Its general structure is similar to that of known neural-cell adhesion molecules (NCAMs) that mediate neurite outgrowth or axon–axon interactions. Such a function would be consistent with the well-characterized defect of embryonic neuronal migration in patients with Kallmann's syndrome. In addition to these motifs, the protein sequence also contains a region (the WAPS domain, or whey acidic protein core domain) that has been associated with proteinase inhibitor activity in a number of proteins. This association of domains in the predicted amino acid sequence of the *KAL1* gene suggests that this protein may also play a role in the tissue remodeling that accompanies this neuronal migration. Examination of the pattern of expression of the gene during embryogenesis demonstrates that it can be detected in various neuronal populations of the central nervous system, including cells of the olfactory bulbs. These findings have suggested that the KAL1 protein might be involved both in directing neuronal migration, as well as influencing the differentiation of specific cell types. KAL is conserved in other mammals, including monkey, cow, rabbit, and sheep, and in xenopus, zebra fish, and chicken, in which it is expressed in a wide range of tissues. Of note, it is not conserved in mice or rats, a fact that has hampered its characterization.

Studies of patients with the X-linked form of Kallmann's syndrome indicate heterogeneity at the genetic level, although all but one of the mutations reported to date predict the absence or marked truncation of the encoded protein. In a study of 21 male patients with the X-linked form of the disorder, Hardelin and coworkers detected a range of abnormalities within the *KAL1* gene, including large deletions in two families, and nine different point mutations in other affected individuals, resulting in introduction of premature termination codons into the sequence. These findings support the involvement of the *KAL1* gene in the pathogenesis of Kallmann's syndrome. It is suggested that defects of *KAL1* gene expression may underlie the varied clinical findings in Kallmann's syndrome. The relationship of KAL1 to disorders such as epilepsy or synkinesia is suggested by knowledge of its role in neuronal migration. The role of KAL1 in events such as kidney formation and migration is more obscure; however, KAL is expressed in the Wolffian duct, which is involved in renal development by interaction with the metanephric mesenchyme.

To date, the genetic causes of the other forms of Kallmann's syndrome (i.e., non-X-linked) have not been defined. However, studies of individuals with Kallmann's syndrome associated with cytogenetic abnormalities have suggested possible loci for genes responsible for the autosomal dominant form of Kallmann's syndrome *(KAL2)* at 1q, 7q, and 12q. It is likely that the genetic defects will be traced to other genes that participate in the pathways affecting migration of the GnRH-secreting neurons.

Treatment of individuals with Kallmann's syndrome with supplemental testosterone will induce virilization, whereas intranasal GnRH or intramuscular chorionic gonadotropin can stimulate endogenous sex steroid production and even reproductive capability.

ISOLATED GONADOTROPIN DEFICIENCY A number of families have been reported in which affected individuals have isolated gonadotropin deficiency without the features of Kallmann's syndrome. The inheritance pattern is autosomal recessive. Although not yet reported in humans, it is likely that this defect results from GnRH deficiency as a result of mutations in the gene encoding GnRH, as has been observed in the hypogonadal (Hpg) mouse.

ISOLATED FSH DEFICIENCY A small number of patients have been reported to have isolated deficiency of FSH. A woman with isolated deficiency of FSH who presented with primary amenorrhea and infertility was found to have a mutation in the gene encoding the β-subunit of FSH. The 2-bp sdeletion caused a frameshift in the coding sequence, predicting the formation of a truncated protein that lacks regions required for association with the α-subunit of FSH and for binding to the FSH receptor.

FUNCTIONAL GONADOTROPIN DEFICIENCIES Severe systemic and chronic disorders and malnutrition are associated with delayed puberty or failure to progress through the stages of puberty. In general, when body weight is less than 80% of ideal weight for height a functional gonadotropin deficiency may occur. Examples include the functional gonadotropin deficiencies associated with anorexia nervosa and exercise-induced amenorrhea. In such instances, normal hypothalamic–pituitary–gonadal function accompanies restoration of normal body mass.

CNS DISORDERS

Mass lesions, such as sellar or suprasellar tumors (e.g., craniopharyngioma), commonly disturb the processes of pubertal development, causing either precocious puberty (as described *above*) or pubertal delay. Such tumors cause pubertal delay by impairing hypothalamic or pituitary function. In addition to abnormalities of pubertal development, growth failure, polydipsia, polyuria, and visual disturbances may also be part of the presentation of children with craniopharyngioma.

HYPERGONADOTROPIC HYPOGONADISM

Primary gonadal failure is associated with elevated gonadotropins because of the absence of negative feedback effects of gonadal sex steroids. The most common causes of hypergonadotropic hypogonadism are associated with karyotypic and somatic abnormalities, but isolated gonadal failure can also present with delayed puberty without other abnormal physical findings.

MUTATIONS OF THE LH AND FSH RECEPTORS The receptors for the gonadotropins LH/CG and FSH are both members of the seven transmembrane domain family of G-protein coupled receptors. Selective defects in the gonadal response to gonadotropins have been traced in several pedigrees to mutations of the genes encoding the FSH and LH/CG receptors. In males, rather than being associated with delayed puberty, mutations in the gene encoding the LH/CG receptor are classically associated with a form of male pseudohermaphroditism termed Leydig-cell hypoplasia (LCH). This disorder is characterized by female phenotype in the presence of a 46,XY karyotype, low serum testosterone, increased serum LH, and lack of testosterone secretion in response to hCG administration. Mutations in the LH/CG gene, particularly in the transmembrane regions of the receptor protein, causing this phenotype include those that result in premature termination or amino acid replacement.

The discovery of inactivating mutations in the LH receptor in patients with LCH and defective fetal masculinization is to be expected. Several interesting aspects of LH receptor mutations deserve comment. First is that a 46,XX sibling of two patients with LCH was a phenotypically normal adult female with amenorrhea and cystic ovaries, suggesting that such a defect was consistent with normal pubertal development, but impairment in the normal ovarian cycle. Second, the identification of a missense mutation of the LH receptor in a phenotypic male infant evaluated for a small but normally formed penis suggests that the range of altered phenotypes associated with abnormalities of the LH receptor may be broader than those initially identified.

An uncommon form of hypergonadotropic hypogonadism is 46,XX gonadal dysgenesis. Affected girls, who typically present with pubertal failure, are of normal stature and have no phenotypic features of Turner's syndrome. The condition appears to be genetically heterogeneous and both sporadic and familial cases have been reported. One familial variant—Perrault syndrome—has sensorineural hearing loss associated with the hypogonadism. A candidate recessive gene on chromosome 2, the *ODG1* gene (ovarian dysgenesis 1) was identified by analysis of a large cohort of affected Finnish patients. The disorder is common in this population (1: 8300 females) and is inherited in an autosomal recessive manner. Aittomaki et al. have recently discovered a missense mutation in the gene encoding the FSH receptor in affected families. The FSH receptor gene is located at 2p21, coinciding with the *ODG1* locus. A limited number of families with such defects have been described to date. The mutation in the FSHR gene in this group is an arginine to valine substitution at amino acid 189, located in the extracellular ligand-binding domain of the receptor. The mutation segregated with the affected phenotype and had a dramatic effect on the binding of ligand and the stimulation of cAMP production. Of interest, the affected males in the pedigrees were phenotypically normal and half were fertile, suggesting that variable defects in spermatogenesis might be the only discernible effect in males with the disorder.

KLINEFELTER SYNDROME The most common form of primary testicular failure is Klinefelter's syndrome (47,XXY karyotype), which occurs with an incidence of 1:1000 males. Male sexual differentiation is normal; testicular function remains relatively normal until about the age of puberty, declining thereafter. Patients with Klinefelter's syndrome do not usually present with delayed puberty, although affected patients may demonstrate a slowing or arrest of pubertal development as testicular function declines. Supplemental testosterone is then required. Klinefelter's syndrome and its variants are described in Chapters 57 and 58.

TURNER'S SYNDROME Turner's syndrome, 45,X gonadal dysgenesis, is associated with short stature, female phenotype, and delayed or absent pubertal development. Patients have "streak" gonads consisting of fibrous tissue without germ cells (germ cells may be present in infancy). Other classic but variable phenotypic features include ptosis, low-set ears, micrognathia, a short "webbed" neck, a broad shieldlike chest, hypoplastic areolae, short fourth or fifth metacarpals, cubitus valgus, structural anomalies of the kidney, extensive pigmented nevi, hypolastic, hyperconvex fingernails and toenails, and left-sided cardiovascular anomalies, coarctation of the aorta being the most common.

Disordered growth is a major clinical feature of this syndrome, beginning *in utero* and worsening progressively from early childhood

onward. Patients have no pubertal growth spurt and reach a mean final height approximately 20 cm shorter than that of the reference population. Although short stature is a classic feature of Turner's syndrome, it is not a feature of other forms of hypergonadotropic hypogonadism that occur without karyotypic abnormalities. Because growth hormone secretion is usually normal in Turner's syndrome, it is likely that the short stature is related to a subtle form of skeletal dysplasia, reflecting imbalances of gene expression caused by the absent X chromosome segments. Growth hormone treatment improves growth rates and the adult height of many affected patients.

Pubic hair may appear late and is usually sparse in distribution. Serum gonadotropin concentrations in Turner syndrome are high between birth and 4 years of age. They decrease toward the normal range in prepubertal patients and then rise to castrate levels after 9 or 10 years of age.

Variant forms of gonadal dysgenesis are associated with a variety of mosaic phenotypes, usually including a 45,X line, in addition to more complex X chromosomal rearrangements. Girls and women with these karyotypes may have phenotypic features typical of those with the classic syndrome of 45,X gonadal dysgenesis, or may have fewer manifestations. Patients with Swyer syndrome (46,XY complete gonadal dysgenesis) have streak gonads and pubertal delay similar to those with Turner's syndrome. They do not, however, have the short stature typical of Turner's syndrome and, in most cases, do not have the other phenotypic features. Gonadal dysgenesis and other sex chromosome defects are outlined in Chapters 57 and 58.

Other causes of primary ovarian failure include radiation therapy, chemotherapy, and premature menopause. Patients with Addison's disease may have autoimmune oophoritis and other features of autoimmune disease, in addition to their adrenal failure. Primary amenorrhea is a common presenting feature of women with androgen-insensitivity syndrome (phenotypic females with 46, XY genotype and androgen resistance). A sex steroid biosynthetic defect as a result of 17α-hydroxylase deficiency will be manifested by delayed puberty and primary amenorrhea in a phenotypic female (regardless of genotype) with hypokalemia and hypertension.

Breast development in female patients with pubertal delay may be induced by estrogen replacement therapy using either a conjugated equine estrogen (such as Premarin) or synthetic estrogen (such as ethinyl estradiol) at slowly increasing doses until feminization is achieved. Thereafter, a progestin is required to induce uterine endometrial cycling, and for convenience, an appropriate relatively low-dose combined oral contraceptive pill may be used. Estrogen replacement therapy in Turner's syndrome is more complex, requiring coordination of timing with respect to growth hormone therapy to optimize adult height achievement.

60 Defects of Androgen Action

Michael J. McPhaul

INTRODUCTION

Since 1935 it has been recognized that the principal androgen secreted by the testes is testosterone. The seminal observations of Bruchovsky and Wilson and of Anderson and Liao, however, led to the recognition that although testosterone is the most abundant circulating androgen, 5α-dihydrotestosterone is the predominant hormone found complexed to the androgen receptor (AR) in the nuclei of target cells, such as the prostate. This finding opened a new perspective on androgen physiology and focused attention on the enzyme that mediated this conversion, 5α-reductase, as a potential modulator of androgen action in selected tissues. As described below, this inference has been confirmed by the later recognition that in selected patients abnormalities in male development are caused by defects in the conversion of testosterone to 5α-dihydrotestosterone.

STRUCTURE AND MECHANISM OF ACTION OF THE ANDROGEN RECEPTOR

Abundant biochemical and genetic data demonstrated that the actions of androgen were mediated by a single receptor that was encoded on the X-chromosome, and that defects in this receptor protein, the AR, could present as a range of abnormalities of male phenotypic sexual development. The isolation of cDNAs encoding the AR revealed it to be a member of a large group of related transcription factors, the steroid-thyroid hormone-retinoid family of nuclear receptors. This family includes members that are ligand responsive and others that are believed to be constitutively active or modulated by other influences, such as phosphorylation. All exhibit a modular structure (displayed for the AR in Fig. 60-1) comprising a highly conserved DNA-binding domain, a less highly conserved carboxy-terminal hormone-binding domain, and an amino-terminal segment that is poorly conserved between individual family members, both in terms of primary amino acid sequence and length. The DNA-binding domain is composed of two elements (termed "zinc fingers") that mediate the sequence-specific DNA binding of the AR. This segment is the most highly conserved region between members of this gene family. The carboxy-terminus is approximately 250 amino acids long and encodes the portion of the protein that binds androgens with high affinity. Of note, the amino-terminus of the AR is somewhat atypical in that it contains three segments composed of repeated amino acids (one of repeated glutamine residues, one of repeated proline

residues, and one of repeated glycine residues). Polymorphisms of these regions appear to have little effect on AR function in normal individuals, but expansions of the glutamine repeat have been implicated in the pathogenesis of spinal and bulbar muscular atrophy (Kennedy's syndrome, *see below*).

The non–ligand-bound AR is believed to exist in the cell in association with a number of ancillary proteins, particularly members of the heat shock protein family. After the binding of hormone, the receptor dissociates from these proteins and binds to specific DNA sequences within or adjacent to androgen-responsive genes. This ligand-activated receptor is believed to interact with components of the transcriptional apparatus to stimulate formation of active transcription complexes. In some models, the AR appears to modulate genes in a negative fashion or to alter mRNA stability, but these phenomena have been less-well-characterized.

ANDROGEN RECEPTOR DEFECTS

CLINICAL FEATURES   A spectrum of phenotypes can result from defects of AR function (Table 60-1). Patients completely unresponsive to the actions of androgen (referred to as complete testicular feminization or complete androgen insensitivity) have a 46,XY karyotype, but an external phenotype that is completely female in appearance, despite normal or elevated levels of circulating androgens. Owing to the secretion and action of Müllerian-inhibiting substance (MIS) by the functional testes present in these patients, the uterus and fallopian tubes are absent. Such individuals are usually raised as females and may first seek attention for evaluation of primary amenorrhea. Gonadectomy is often performed, because the intra-abdominal testes show an increased rate of malignant tumor development. With estrogen replacement, these individuals often lead completely normal lives as women, although they are infertile.

The term incomplete testicular feminization has been applied to individuals with nearly complete forms of androgen resistance who demonstrate only slight evidence of virilization (such as clitoromegaly). These patients are usually managed in a fashion similar to that of patients with complete testicular feminization.

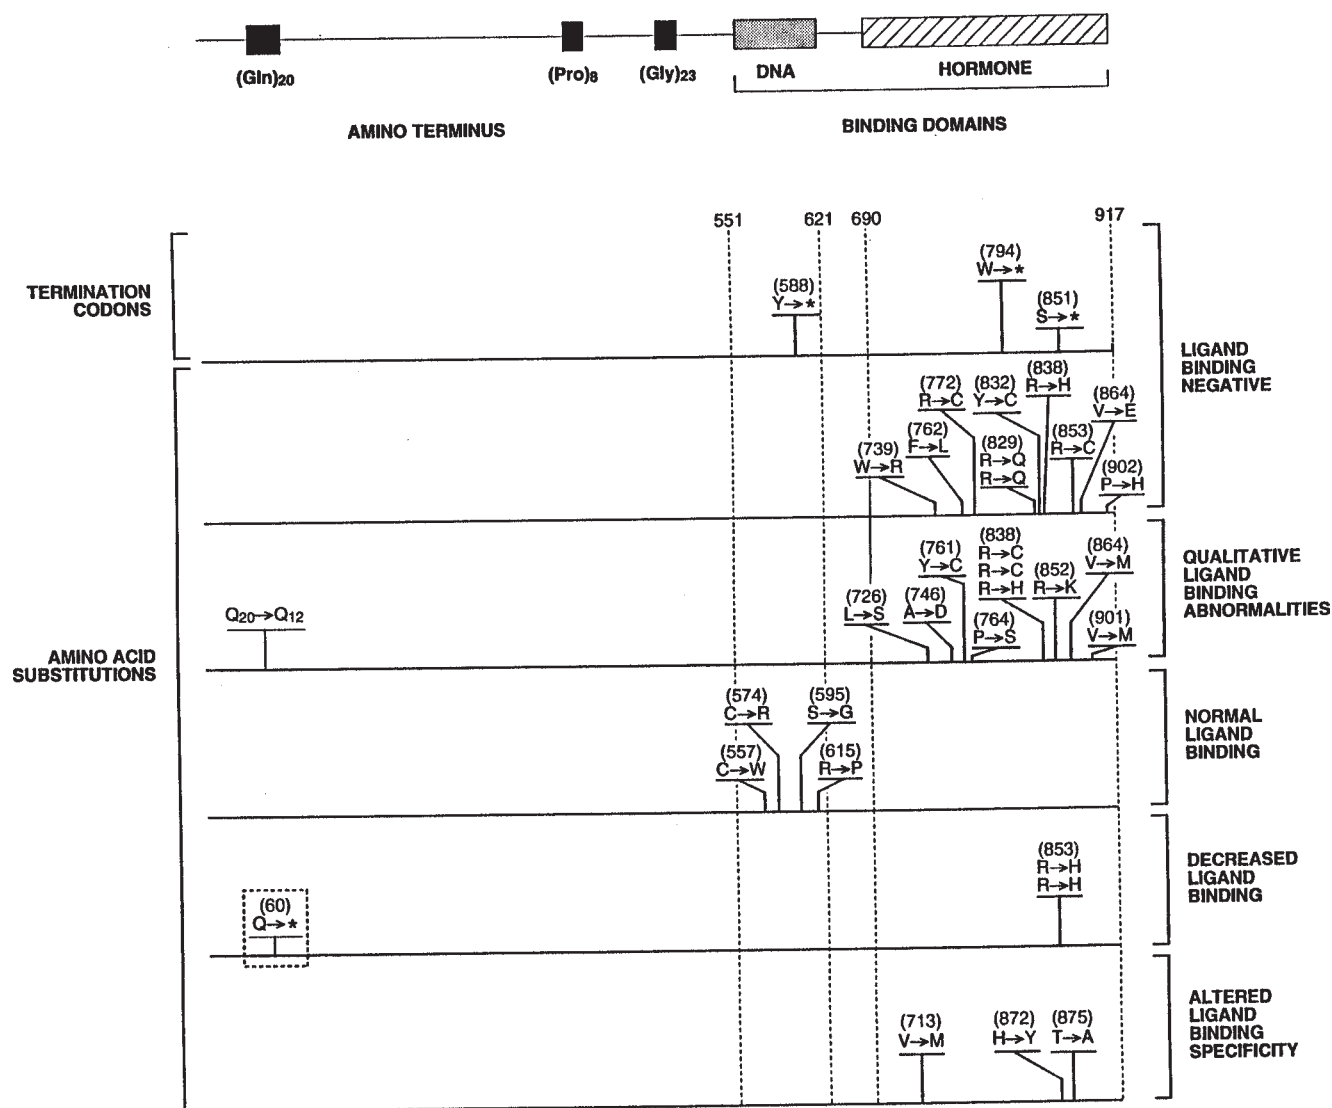
Partial androgen resistance or Reifenstein's syndrome is a constellation of features that includes severe defects of male urogenital development (perineal or penoscrotal hypospadias) and gynecomastia. Reifenstein's syndrome represents a far more difficult clinical problem. As noted, the developmental abnormalities are substantial and the surgical correction of these defects often requires multiple separate surgical sprocedures. Such efforts are hampered by the small size of the genitalia of affected children. After


Figure 60-1   Mutations of the human androgen receptor that cause abnormalities of androgen receptor function. A schematic representation of the human androgen receptor (AR) is shown. The approximate boundaries of the DNA- and hormone-binding domains are indicated, as are the locations of the repeated stretches of glutamine, proline, and glycine residues within the amino terminus. (Below) The mutations causing androgen resistance are grouped according to the type of genetic lesion (amino acid substitution or premature termination codon, left margin) or the effect that mutation has on receptor function (right margin). Also included in this figure are three mutations reported in the literature detected in prostate cancer specimens that appear to alter the binding characteristics and activities of the mutant ARs. Not depicted in this summary are deletions and insertions of AR gene segments that account for 5–10% of AR mutations. Expansions of the glutamine repeat that causes spinal and bulbar muscular atrophy are also not represented. (Adapted from McPhaul et al, J Clin Endocrinol Metab 1993;76:17–23.)

surgical correction, most individuals with this phenotype are raised as males, although many exhibit difficulty with gender identity.

At the mildly affected end of the spectrum, a small number of individuals have been described in which normal development of the external genitalia has occurred, but in which some degree of undervirilization is clinically evident. In some, this phenotype has been associated with azoospermia and infertility without undervirilization, whereas in others normal sperm density and fertility occur in undervirilized men. Patients with these phenotypes have been identified as having AR defects on the basis of a family history and abnormalities of in vitro ligand-binding assays of the androgen receptor. Although specific AR defects have now been reported in association with these syndromes, it is not clear how frequently such phenotypes are caused by AR defects in the general population.

An unusual variation of the undervirilized phenotype is that presented by patients with spinal and bulbar muscular atrophy (SBMA, Kennedy's syndrome) (*see* Chapter 100). Patients with this syndrome have normal male development and normal male secondary sexual characteristics throughout much of their lives but develop signs of clinical androgen resistance beginning in middle age. Although these signs of androgen resistance that they display are unmistakable (usually gynecomastia), the difficulties presented by the symptoms of anterior motor neuron degeneration pose a far more serious threat to the health of such patients and represent the usual cause of death in affected individuals.

ANDROGEN RECEPTOR MUTATIONS AND DEFECTIVE AR FUNCTION   Molecular defects of the AR that cause the syndromes of androgen resistance have been studied by a number

Table 60-1
Phenotypes Associated with Defects in the Genes Encoding the Androgen Receptor and 5α-Reductase II

Gene	Syndrome	External genitalia	Wolffian duct derivatives	Müllerian duct derivatives
AR	Complete testicular feminization	Completely female	Not virilized	Absent
	Complete androgen insensitivity			
	Incomplete testicular feminization	Predominantly female; some clitoromegaly, closure of the posterior fourchette	Usually partially virilized	Absent
	Reifenstein syndrome	Substantial phallic development, but with severe forms of hypospadias	Variable defects	Absent
	Under-virilized, fertile male	Male phenotype with small phallus	Male	Absent
	Infertile male	Male phenotype	Male	Absent
5α-Reductase II	5α-Reductase deficiency	Can be variable: ranging from female external genitalia at birth to a predominantly male phenotype with hypospadias	Normal male	Absent

of groups. The causative mutations have been identified in more than 100 pedigrees and now include all of the major clinical syndromes. A database listing the mutations causing androgen resistance is accessible via the Internet.

Deletions or insertions of the AR gene have been found to occur with a frequency of approximately 5–10% of patients with androgen resistance and range in size from single or multiple nucleotides to deletions of the entire gene. Because such mutations disturb the open reading frame of the AR, patients with this type of mutation do not express an intact receptor protein and, with few exceptions, lack detectable androgen binding in their cells and tissues. In addition, because the intact AR is not present in the tissues of such patients, AR function is absent and affected individuals always demonstrate the phenotype of complete testicular femininization.

In contrast to the frequency of deletions and insertions in the AR gene, single nucleotide substitutions are much more frequent and account for the bulk of patients with androgen resistance as a result of AR mutations. In some cases, such substitutions result in large changes of receptor structure, as when they result in alterations of AR mRNA splicing or introduction of premature termination codons within the AR open reading frame. These instances, as with gene deletion or insertion mutations that interrupt the primary sequence of intact AR protein, are usually associated with a lack of detectable androgen binding in tissues and a phenotype of complete testicular feminization.

Single nucleotide substitutions that result in single amino acid changes within the AR protein are the most frequent type of mutation in the AR. To this point, these defects have been found to fall into two large categories: those within the DNA-binding domain and those that have been localized to the hormone-binding domain of the receptor. Unlike the other mutation categories described above (deletions, insertions, premature termination), the effect of these substitutions on AR function can be quite variable, and thus the entire spectrum of androgen-resistant phenotypes has been traced to single amino acid substitutions within the AR protein. In most instances, the principal effect of the amino acid substitution is on AR function, whereas major effects on the level of AR abundance, as measured in patient fibroblasts, are uncommon.

Amino acid substitutions in the DNA-binding domain have little effect on the binding of ligand by the mutant receptor. Despite the capacity of these mutant ARs to bind ligand normally, receptor function is reduced after ligand stimulation, compared with the activity of the normal AR. This reduced function can be shown to be caused by a decreased capacity of the mutant AR to bind to target sequences within responsive genes. In this category of mutation, the degree of impairment of receptor binding to DNA appears to have a direct relationship to the degree that receptor function is reduced. Similar conclusions hold true for larger alterations of receptor structure occurring within the DNA-binding domain that maintains the reading frame of the receptor (e.g., deletions of single amino acid residues within the DNA-binding domain or the single reported instance caused by in-frame deletion of exon 3).

Amino acid substitutions in the hormone-binding domain (HBD) can result in a variety of changes in the capacity of the AR to bind its ligand. In a surprisingly small proportion of cases, the amino acid replacement renders the receptor completely unable to bind ligand. Under these circumstances, it is presumed that the alteration of the HBD structure is distorted. This conformational change blocks the capacity of the AR to bind its ligand and the mutant receptor is thus "locked" into an inactive conformation. This type of mutant AR is functionally equivalent to mutations that result in the synthesis of truncated forms of the AR, because even pharmacologic doses of potent synthetic androgens are unable to restore receptor function in vivo or in functional assays performed in vitro.

More frequently, however, amino acid substitutions in the HBD lead to the synthesis of mutant ARs that exhibit ligand-binding properties that are abnormal compared with the binding properties of the normal AR (e.g., bind ligand with a reduced affinity or stability). Although the exact type of ligand-binding abnormality differs depending on the nature and location of the amino acid substitution within the hormone-binding domain, it appears that the formation and stability of the hormone–receptor complex is the final determinant of the degree of impairment of mutant AR function. In vitro studies of such mutant receptors demonstrate that the use of multiple high doses of physiologic ligands

(testosterone or dihydrotestosterone) or the use of potent nonmetabolizable androgen agonists can overcome the defective function of many mutant ARs of this type. In addition to its mechanistic implications, this finding may have substantial clinical implications as well, since it suggests that the pharmacologic manipulation of many mutant ARs may be possible.

Studies have now been performed to study the levels of expression and the function of normal and mutant ARs. It seems clear that the major effect of most mutations in the AR is not at the level of AR abundance, but at the level of AR function. This is not true in all cases, however, with the most obvious exceptions being mutations that result in truncation of the receptor protein (e.g., termination codons or alterations of mRNA splicing). There also appears to be a relationship between the level of mutant AR function and the phenotype observed in the patient: mutant ARs devoid of function being associated with complete testicular feminization, those with partial activity associated with incomplete forms of androgen resistance. This relationship is most clearly seen using assays that measure the level of AR function in fibroblasts established from the patient under study (e.g., delivery of an androgen-responsive reporter gene directly into the cultured fibroblasts).

ANDROGEN RECEPTOR MUTATIONS—SPECIAL CASES The androgen-resistance syndrome described above is caused by mutations that impair receptor function to various degrees. Two additional types of AR mutation have been identified that result in an alteration of AR responsiveness or an apparent "gain" of function.

The first example of a "gain of function" mutation in the androgen receptor is the genetic defect causing Kennedy's syndrome. The pathogenesis of this extraordinary disease was traced to the expansion of a triplet nucleotide repeat (CAG) encoding a repeated sequence of glutamine residues within the amino-terminus of the receptor (*see* Fig. 60-1). The expansion of this glutamine repeat, the first of an increasing number of similar diseases that have also traced to the expansion of trinucleotide repeats (*see* Chapter 100), is believed to have two different effects on AR function. First, it is clear that the expansion of this segment of the AR diminishes the capacity of the AR to activate responsive genes after androgen stimulation. This diminished AR function can be demonstrated using a variety of functional assays and is presumably the cause of the subtle signs of androgen resistance observed in affected individuals. It is clear from the study of rare patients with complete deletions of the AR that the SBMA phenotype (progressive death of motor neurons in bulbar nuclei and in the spinal cord) is not caused by a simple lack of functional AR. Instead, this disease appears to be caused by some type of toxic "gain of function" that is caused by the expression of androgen receptors containing the expanded glutamine repeats in specific cell types. Analogy to results obtained from the study of the Huntington disease gene (also caused by a glutamine repeat expansion) would suggest that the glutamine expansion may permit interaction of the mutant AR with intracellular targets in spinal motor neurons that somehow mediate the observed cell-type-specific toxicity. Studies have also raised the possibility that a lower number of CAG repeats may correlate with the age of onset of prostate cancer.

The second type of AR mutation that causes a gain or alteration of receptor function are the mutations that have been identified in human prostate cancer specimens. First identified in a prostate tumor cell line, LNCaP, amino acid substitutions have been identified in a number of clinical prostate cancer specimens. Although a number of these mutations have been identified, fewer have been

completely studied as to the effect that they have on the ligand responsiveness of the mutated AR. In those instances in which detailed studies have been performed, tests of receptor function using androgen-responsive reporter genes demonstrate that the mutant ARs can be stimulated by ligands that cannot ordinarily activate the normal unmutated AR. Such ligands include adrenal androgens and even compounds (such as hydroxyflutamide) that normally act to antagonize the function of the unmutated AR. It is not yet possible to conclude how important these mutant receptors are in the progression of prostate cancers toward the androgen-independent phenotype.

5α-REDUCTASE DEFICIENCY

PHYSIOLOGIC AND CLINICAL STUDIES The observation that 5α-dihydrotestosterone was the principal hormone bound to the AR in the nuclei of target cells suggested the potential importance of 5α-reductase in androgen physiology. The subsequent identification of rare patients with specific defects of virilization who formed reduced quantities of 5α-reduced androgen metabolites served to emphasize the importance of this metabolic step. The normal virilization of other tissues, such as the epididymis in patients with clinical 5α-reductase deficiency, led to the concept that the action of testosterone was sufficient to effect the actions of androgen in selected tissues, but that the formation of 5α-dihydrotestosterone was crucial in others, such as the prostate, a dichotomy that as yet is still unexplained mechanistically.

CLINICAL PHENOTYPE The clinical features of infants with a deficiency of 5α-reductase are consistent with a marked defect of androgen action (Table 60-1). The external genitalia are characterized by a microphallus, severe hypospadias, and a bifid scrotum. A blind vaginal pouch is present and opens either directly onto the perineum or onto a urogenital sinus. Owing to the production of MIS by the functional testes, no Müllerian structures are present. It is of interest that at puberty, several changes take place in the phenotype of affected individuals. The phallus enlarges and some male secondary sexual characteristics appear, such as changes in voice and muscle mass. Notably, this increase in testosterone has not been reported to result in acne, prostate growth, or male pattern baldness. It has also been reported that in such individuals, raised initially as females, gender identity may change after the pubertal rise in androgen levels.

5α-REDUCTASE STRUCTURE AND MECHANISM OF ACTION Attempts to purify 5α-reductase using classic techniques of protein purification failed and its structure remained elusive until Anderson and colleagues employed expression cloning in *Xenopus* oocytes to isolate a cDNA encoding a steroid 5α-reductase from rat prostate in 1992. This advance permitted a number of studies by this same group and resulted in the isolation of cDNAs encoding two related isozymes (Fig. 60-2) encoded by two distinct, related genes from humans and from all vertebrate species examined to date. Inspection of the structures of the cDNAs indicate substantial sequence divergence between the two isozymes, both within and between different species (Fig. 60-2). Both enzymes are extremely hydrophobic and are believed to be imbedded in the nuclear membrane of cells, accounting for the failure of extensive efforts to purify the enzyme in an active form. Structural differences between the two isozymes confer substantial differences in their physical properties that have been exploited to develop compounds that inhibit one or the other isozyme preferentially.
Figure 60-2 Comparison of the structures of human steroid 5α-reductase I and II and mutations that alter the binding of testosterone and NADPH. (Above) Alignment of the predicted protein sequences for steroid 5α-reductase I (259 amino acids) and steroid 5α-reductase II (254 amino acids). The degree of sequence identity is shown for each of the five coding exons (boxed percentages). (Below) Mutations identified within the coding sequence of steroid 5α-reductase deficiency. Although mutations have been detected in each coding exon that result in 5α-reductase II deficiency, only mutations that cause alterations in the binding of testosterone or NADPH are indicated. (Drawn after Russell et al, Annu Rev Biochem 1994;63:25–61.)

Studies of the distribution of the two isozymes (Table 60-2) have demonstrated that the patterns of expression of these two proteins differ, both in terms of tissue, cell type, and stage of development. These differences suggest substantially different physiologic roles for the two enzymes.

GENETIC DEFECTS OF STEROID 5α-REDUCTASE II The genetic lesions causing clinical 5α-reductase deficiency have now been identified in a number of families from around the world. In all instances, when a genetic defect has been detected, it has been traced to a mutation within the 5α-reductase II gene. Unlike the AR gene, the gene encoding 5α-reductase II is autosomal and each individual possesses two copies of the 5α-reductase II gene. For this reason, mutations causing clinical 5α-reductase deficiency are recessive and the inheritance of two defective 5α-reductase II gene alleles is required for the defects to be manifest. 5α-Reductase II deficiency is infrequently caused by deletions or insertions in the gene. More often, defects in the gene are caused by mutations that result in premature termination of the protein or single amino acid substitutions within the open reading frame. Identification of the locations of these substitutions and determination of the physical properties of the mutant enzymes have permitted the identification of amino acid residues important for binding of steroid substrates and for the binding of nicotinamide adenine dinucleotide phosphate (NADPH), a cofactor required for the reduction reaction. Of interest, these studies have also identified sites that have been mutated repeated in apparently unrelated pedigrees. These sites are apparently more susceptible to mutation.

As a consequence of the recessive nature of clinical 5α-reductase II deficiency, it would be expected that the genetic basis of this rare trait would be traced most frequently to homozygosity for a single defective allele (e.g., consanguinity). Surprisingly, a high proportion of patients (40%) have been found to be compound heterozygotes, suggesting either an unexpectedly high mutation rate of the 5α-reductase II gene or a high frequency of individuals in the general population that carry single defective alleles.

GENETIC DEFECTS OF STEROID 5α-REDUCTASE I An abnormal phenotype caused by a deficiency of 5α-reductase I has not yet been described in humans. The differential expression of steroid 5α-reductase I in selected tissues (*see* Table 60-2) suggests that specific phenotypes in humans that result from lesions in this gene may well be identified in the future.

Table 60-2
Distribution of 5α-Reductase I and II Expression in Rat and Human Tissues

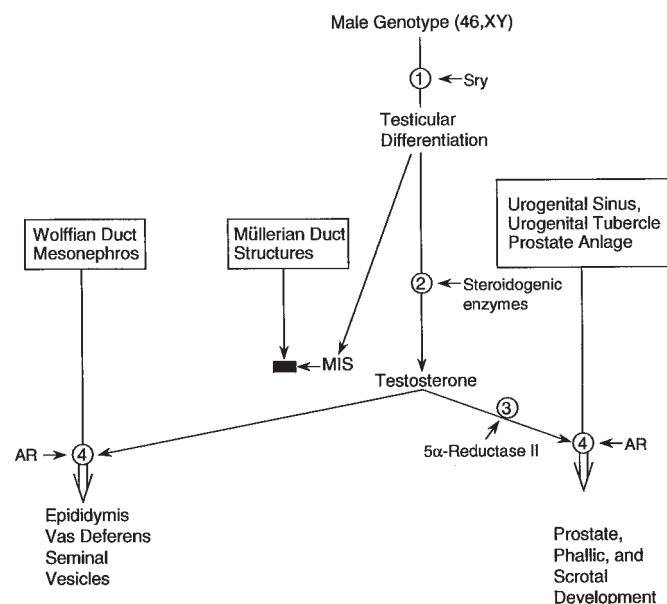
Summary of studies measuring 5α-reductase I and II expression using measurements of the corresponding RNA (*) or protein (†) are derived from published studies of Russell and coworkers. The rating scales (1+ least, 5+ highest) used in this summary are designed to convey a sense of the relative abundance of the 5α-reductase isozymes in the two species—rat and human—that have been studied most carefully. Because the rat and human measurements have been conducted separately, they can only be compared with one another in a qualitative fashion. D is detectable (i.e., at the limits of detection). ND, is not detected; —, values not reported. In addition to the results tabulated here, the studies of Thigpen et al. clearly indicate that in the human substantial changes in abundance can be demonstrated in the expression of the type I and type II isoenzymes in a tissue at different times in development.
[a]Histochemical studies indicate that the expression of 5α-reductase II is localized to the cells of the dermal papilla.
[b]Staining localized to epithelial cells in histochemical studies.
[c]Staining localized to basal epithelial and stroma cells.
[d]Type I is detected in basal epithelial cells and type II in stroma cells in *in situ* hybridization studies of the regenerating rat central prostate.
[e]Type I and II are localized to the epithelial cells using *in situ* hybridization.


Figure 60-3   Schematic the pathways controlling the development of the normal male phenotype. Male sexual development is a complex cascade of events that can be affected by lesions in a number of genes. Some, such as lesions in the *AR* or *SRY*, can cause disturbances of virilization of all androgen-responsive tissues. The effects of defects in other genes, however (such as mutations of 5α-reductase II), are manifest only in selected tissues. It is likely that defects in other genes can contribute to defects in virilization, as a large proportion of the subjects with abnormalities of male phenotypic development cannot be accounted for by defects in the genes most carefully studied to date, such as the AR and steroid 5α-reductase II.

Owing to the lack of mutations in the human population, the first insights into the nature of defects that may be expected in humans have come from experiments in mice in which steroid 5α-reductase I gene has been disrupted by homologous recombination. Male mice homozygous for this targeted null allele develop normally, both prenatally and postnatally. Unexpectedly, although female mice homozygous for this same null allele develop normally into adulthood, when pregnant, such mice fail to initiate parturition normally. Experiments in which different steroids were administered to these steroid 5α-reductase I-deficient mice suggested that the synthesis and actions of 5α-reduced androgens were important elements of the normal parturition process in mice. Although the mechanisms and generality of these findings remain to be determined, such results suggest that 5α-reductase I may play important—and even unexpected—roles in human physiology as well.

SUMMARY

The development of the male phenotype is a complicated process that involves the active participation of genes involved at many levels, from gonadal differentiation to the androgen receptor itself. Defective virilization can be caused at defects anywhere along the pathway displayed schematically in Fig. 60-3. Taking into account the clinical syndromes caused by known defects of genes such as steroid 5α-reductase II and the androgen receptor, the pathogenesis of a large proportion of defects in virilization remains unexplained. It is conceivable that some may represent defects in genes required for normal AR function or at steps beyond the site of action of the AR itself (e.g., coactivators, or defects in genes activated by the AR).

TESTICULAR EMBRYOGENESIS

Between 1947 and 1952 Alfred Jost formulated the concept that sexual differentiation is an ordered process in which chromosomal sex determines gonadal sex, and gonadal sex in turn directs the development of phenotypic sex. Since 1959 it has been known that in humans and other mammals the Y chromosome determines maleness. These insights led to the postulate of a gene or genes on the Y chromosome that would act as a "master switch" to set in motion the cascade of events that leads to the development of the male gonads. The discovery and the roles played by the genes involved in testicular embryogenesis and their involvement in human diseases and experimental models characterized by abnormal testicular development are discussed in Chapter 57.

BASIC ENDOCRINOLOGY OF THE TESTIS

MICROSCOPIC ORGANIZATION From a functional point of view, the microscopic architecture of the testis consists of two regions, the interstitial and tubular compartments, which are separated by the basal lamina. The interstitial compartment contains loose connective tissue with interspersed epithelial cells, the Leydig cells, which are specialized for the synthesis and secretion of testosterone. The tubular compartment consists of cylindrical structures, the seminiferous tubules, which are lined with Sertoli and germinal cells. Sertoli cells create support for the germ cells by resting on the basal membrane of the tubule and extending apically, and are believed to produce several growth factors affecting the process of testicular development and sperm maturation. In addition, they offer a critical contribution to the process of male sexual differentiation through the production of anti-Müllerian hormone (AMH), which causes regression of the Müllerian ducts. The growth and maturation of the germinal epithelium into mature spermatozoa is a highly synchronized process. According to the degree of maturation, germ cells can broadly be classified as spermatogonia, primary spermatocytes, secondary spermatocytes, spermatids, and spermatozoa. However, in post pubertal individuals more than a dozen different stages of germinal cell maturation have been described on the basis of subtle histologic differences.

Cytoplasmic projections originating from the Sertoli cells between spermatogonia and primary spermatocytes are connected by tight junctions, and divide the tubule into the basal compartment (containing the Leydig cells, the basal lamina, the myoid cells, and the spermatogonia) and the adluminal compartment (containing primary and secondary spermatocytes, spermatids, and mature spermatozoa). Diffusion of protein, ions, or steroid hormones between the adluminal and basal compartments is impossible, since, similar to the blood–brain barrier, the tight junctions between these two compartments of the testis create an environment that is impermeable to macromolecules.

PHASES OF SPERMATOGENESIS The germinal epithelium undergoes continuous replication to regenerate multipotent stem cells, as well as to produce cells that can proceed through subsequent maturative changes that result in the formation of mature spermatozoa. The mechanisms regulating sperm maturation are largely unknown; however, it is well-established that spermatogenesis occurs only in the presence of androgens and a functional androgen receptor, and that Sertoli cells have a dual role of providing physical support for the maturing germinal cells and of producing, under the stimulation of follicle-stimulating hormone (FSH) and testosterone, factors important for the stimulation of germ-cell maturation. Two human conditions, congenital hypogonadotropic hypogonadism (HH) and men after hypophysectomy, have been very instructive in understanding the role played by the two gonadotropins in inducing sperm maturation. In congenital HH, the administration of human chorionic gonadotropin (hCG), a luteinizing hormone (LH)-like molecule that induces high intratesticular level of testosterone, is followed by the induction of germ-cell maturation from spermatogonia to spermatids. To obtain the full maturation of spermatids to spermatozoa, however, the simultaneous administration of FSH is required. Similarly, replacement with both gonadotropins is necessary to restore spermatogenesis after hypophysectomy, although once spermatogenesis is restored, it can be maintained by injecting hCG alone. Hence, the actions of both gonadotropins are necessary for normal spermatogenesis to occur. Three main events are necessary for the completion of spermatogenesis: (1) stem-cell renewal by mitosis, (2) reduction of chromosomal number by meiosis, and (3) transformation of conventional cells into specialized elements that can reach and fertilize the egg.

Spermatogonial Stem-Cell Renewal The most primordial cells of the germinal lineage are called spermatogonia, of which three types are usually recognizable morphologically. The type A dark spermatogonium, which is thought to be the most primordial, is characterized by a densely stained chromatin containing a centrally located pale area, known as the nuclear vacuole. The type A pale spermatogonium, has a palely staining chromatin and one or two nucleoli. The type B spermatogonium is smaller, has coarse granules of heavily stained chromatin, and is believed to represent a more advanced level of maturation when compared with the type A cells.

Meiotic Maturation   A minority of type B spermatogonia commit themselves to further differentiation, and, by responding to unknown stimuli, divide and detach from the basement membrane of the tubule to form the primary spermatocytes. These cells undergo a complex maturation process involving two meiotic divisions: the first from primary spermatocytes into secondary spermatocytes and the second from secondary spermatocytes to spermatids. When primary spermatocytes reach the time of the first meiotic division, they have already engaged in DNA synthesis, and each of their chromosome pair consists of four chromatids. Hence, when the first meiotic division occurs, the resulting secondary spermatocytes contain a haploid number of chromosomes, but each is composed of a pair of chromatids (haploid number of chromosomes and diploid DNA content). Only after the second meiotic division do the developing germ cells (at this level of maturation termed spermatids) have both haploid chromosomal number and haploid DNA content.

Spermiogenesis   In the final phase of germ-cell maturation spermatids undergo a number of morphologic changes, and are transformed into specialized cells that can reach and fertilize the ovum. These can be conveniently followed in five phases, consisting of (1) nuclear changes, (2) acrosome formation, (3) flagellum development, (4) redistribution of cytoplasm, and (5) spermiation. During the final phases of sperm maturation the nuclear chromatin condenses, the nucleus becomes progressively smaller and more peripheral, and is positioned in close contact with the cell membrane (nuclear changes), from which it is separated by the acrosomal cap. The latter is formed from large vacuoles produced by the Golgi complex, and contains enzymatic activities important for the penetration of the ovum during fertilization (acrosomal formation). The next most important change observed during this phase consists in the development of the sperm tail (flagellar development), the structure capable of generating the motion of mature spermatozoa. Its architecture is highly conserved among species, and consists of nine peripheral doublet microtubules (known as subfibers A and B), surrounding an additional central pair of microtubules, and is arranged in pattern termed the "9 + 9 + 2" structure. Connections between each peripheral doublet are provided by dynein arms, which project from subfibers A toward subfibers B, and by nexin links. Dynein arms are made of dynein, a protein with ATPase activity that is vital to the generation of flagellar motility. Other connections between each peripheral doublet and the two central microtubules are provided by radial spikes. The intimate connections between the central and peripheral tubular structures of the sperm tail are critical for the achievement of the typical wavelike motion necessary for the propulsion of the mature spermatozoa. Diseases associated with absence of the dynein arms, and with sperm immotility, have been described, and are discussed in Table 61-1.

The eccentric migration of the nucleus toward the acrosomal cap occurs simultaneously with the caudal migration of the cytoplasm toward the developing tail (redistribution of the cytoplasm). The latter is facilitated by a system of cytoplasmic filaments, which extend from the nuclear membrane close to the acrosome to the caudal end of the developing sperm. The seminiferous tubules empty into a network of ducts called the rete testis. By the time the spermatids reach the rete testis, they have been shed of almost the entire cytoplasm, which at this stage is termed the residual body, and is phagocytosed and degraded by the surrounding Sertoli cells (spermiation).

FINAL PHASES OF SPERM MATURATION   The interval from the beginning of spermatogenesis to the delivery of sperm into the rete testis is approximately 74 days. During the next 12 days, spermatozoa transit through the epididymis and vas deferens, undergo a number of final morphologic and functional changes, and acquire motility and full capacity to fertilize an ovum.

PHYSIOLOGY OF TESTICULAR FUNCTION   A discussion of the hormonal regulation of testicular function, of the synthesis and mechanism of action of testicular steroids, and of the feedback mechanisms regulating the hypothalamic–pituitary–testicular axis is presented in Chapter 56.

MALE HYPOGONADISM

Disorders of testicular function result from abnormalities involving the endocrine (Leydig cells) or reproductive (germ-cell maturation) compartments of the testis. If low testosterone production is present, it is usually accompanied by infertility, because normal spermatogenesis requires normal production of testicular androgens (hypogonadism with undervirilization and infertility). However, there are situations in which hypogonadism is restricted to the germinal compartment (hypogonadism with infertility and normal virilization).

The serum levels of gonadotropins indicate at what site within the hypothalamic–pituitary–gonadal (HPG) axis the defect is localized. In those instances in which gonadal function is abnormal (hypergonadotropic or primary hypogonadism), gonadotropin levels are elevated. In those instances in which the hypothalamopituitary structures are defective (hypogonadotropic or secondary hypogonadism), gonadotropin levels are inappropriately normal or low. Depending on the serum level of gonadotropins, hypogonadism can be classified as hypergonadotropic or hypogonadotropic (if caused by testicular or hypothalamic-pituitary disorders, respectively) and eugonadotropic (if the abnormality lies only in the germinal cells) (Tables 61-1 through 61-3).

Both congenital and acquired forms of Leydig cell dysfunction have been described, and the clinical picture that results when testosterone synthesis is impaired is different depending on whether androgen deficiency developed prenatally, before puberty, or after puberty (Table 61-4). If the developing fetus was not exposed to adequate level of androgen as a result of testicular failure during fetal development, the infant will be affected with pseudohermaphroditism, characterized by a large spectrum of potential abnormalities, including ambiguous genitalia, micropenis, and rudimentary testes (Table 61-4). If reduced testosterone production developed before puberty, but testicular function was normal during embryogenesis, androgen-related somatic changes that are observed at puberty are absent or incomplete and the patient develops an eunuchoid habitus because of failure of closure of the epiphyses and poor development of the skeletal muscles and body hair (Table 61-4). If reduced testosterone production developed after puberty, the first symptom of the patient is impotence, whereas loss of secondary sexual characteristics may take 5–10 years to become complete (Table 61-4).

Hypogonadism manifested by abnormal sperm production (Table 61-1 and 61-3) can be associated with normal virilization, since many infertile men produce normal or only minimally abnormal amounts of testosterone. However, in other cases infertility is associated with a reduced production of testosterone and clinical signs of androgen deficiency (infertility from hypergonadotropic or hypogonadotropic disorders [Table 61-2]). In such cases, infertility is a direct consequence of the reduced testosterone production.

Table 61-1
Eugonadotropic Germinal Cell Failure

	Clinical features and causes	Treatment
Ductal obstruction	See text.	See text.
Varicocele	Most frequently recognized cause of infertility; however, infertility is not always associated with its presence. It is still debated why varicocele causes infertility.	Surgical removal is indicated in adult with infertility of unknown cause, and in adolescent with testicular growth failure. Whether surgical removal improves sperm quality or not is still controversial.
CAH (congenital adzenal hyperplasia)	Suppression of LH and FSH by supraphysiologic production of androgens.	Exogenous glucocorticoid.
Infections	The microorganisms most frequently detected are *Ureaplasma urealyticum* and *Chlamydia trachomatis*. They are thought to induce infertility by impairment of germ-cell maturation, inflammatory occlusion of the ejaculatory ducts, induction of autoimmune phenomenon, and dysfunction of ejaculated sperm.	Doxycycline.
Immotile cilia syndrome	Sperm of normal number and morphology, but with no motility. Associated with bronchiectasis and sinopulmonary infections because of immotility of respiratory cilia. Kartagener's syndrome is the association of immotile cilia syndrome and situs inversus. Immotile cilia syndrome is caused by deletion or shortening of dynein arms and absence of central microtubules.	Microinjection in the perivitelline space or into the oocyte of the recovered sperm.
Autoimmunity	Autoantibodies can be detected against the basement membrane of the seminiferous tubule or against the sperm in 5–10% of men evaluated for infertility.	Steroids (however not always useful to improve sperm quality).
Environmental factors	Lead, mercury, cadmium, dibromochlorpropane (DBCP), 1,1,12-trichloro-2,2-*bis*(*p*-chlorophenyl-ethane) (DTT), *p*,*p*'-DDE	Remove toxin.
Drugs and radiation	Chemotherapeutic agents, anabolic steroids, cocaine, marijuana, ethanol, radiation >1.0 gy, ^{131}I treatment >100 mCi, high scrotal temperature.	Remove toxin.
Retrograde ejaculation	Associated with diabetes, transurethral prostatectomy. Typically with an ejaculate of <1.3 mL.	α-Adrenergic agonists or intraoperative recovery of sperm from vas deferens or epididymis.
Failure of emission	Associated with spinal cord injury, multiple sclerosis, diabetes.	Electroejaculation, recovery of sperm from vas deferens or epididymis.

HYPERGONADOTROPIC DISORDERS

Hypergonadotropic disorders of the testes are caused by primary testicular failure, and, as shown in Table 61-2, they can be grouped in two main categories, congenital and acquired abnormalities. Some congenital syndromes lead to primary hypogonadism as a result of chromosomal abnormalities, enzymatic defects, or receptor defects. Others are congenital multiorgan diseases with associated hypogonadism. Acquired diseases causing primary hypogonadism result from the direct exposure of the testis to a large variety of exogenous toxic agents. The typical endocrine abnormalities found in these patients consist of decreased to undetectable serum levels of testosterone and an elevation of the two gonadotropins above the normal range owing to the absence of the negative feedback inhibition exerted by testosterone.

HYPERGONADOTROPIC HYPOGONADISM CAUSED BY CHROMOSOMAL ABNORMALITIES

KLINEFELTER'S SYNDROME Background This syndrome was initially described in 1942, at a time when no techniques to study hormone levels or chromosomal banding were available. Its frequency is about 1/500 males at conception, but only 1/1000 live male newborns. Therefore, even if the Klinefelter phenotype is perceived as benign, half of all 47,XXY fetuses are lost before birth.

In the large majority of cases this syndrome is associated with a 47,XXY chromosomal pattern; however 46,XY/47,XXY mosaicism is detected in approximately 10% of patients. Less frequently it is found in 46,XX males, or in individuals with Xq trisomy, X-autosome translocations, or poly-X (48XXXY, 49XXXXY).

Clinical Features Prepubertal diagnosis of this disorder is possible in the cases in which microphallus or cryptorchidism are part of the prepubertal phenotype, or when a determination of the karyotype is requested if mental retardation or multiple congenital anomalies are detected by the physician.

The features of undervirilization are most often detected in the postpubertal patient and include bilateral gynecomastia, small testes, azoospermia, decreased muscular mass, and abnormal skeletal proportions suggestive of eunuchoid habitus. Small testicular size because of the absence of germ cells is a consistent clinical abnormality. In addition, progressive hyalinization and fibrosis of the seminiferous tubules results in increased testicular consistency.

Mild mental retardation and personality disorders are identified more frequently in patients with Klinefelter's syndrome than in the general population, and these abnormalities are usually more evident in the group of patients with polysomic-X conditions. Other conditions that have been detected with increased frequency in patients with Klinefelter's syndrome include thyroid abnormalities, diabetes mellitus, and breast and other types of cancer.

Table 61-2
Hypogonadotropic and Hypergonadotropic Disorders

Hypergonadotropic disorders	*Hypogonadotropic disorders*
Congenital	**Congenital**
Chromosomal abnormalities	**Associated with gonadotropin deficiency**
Klinefelter's syndrome	Kallmann's syndrome
46,XX males	Fertile eunuch syndrome
46,XY pure gonadal dysgenesis (Swyer syndrome)	Associated with biologically inactive LH
Multiorgan diseases	**Mutations of the LH gene**
Myotonic dystrophy	
Alströmis syndrome	**Associated with central nervous system disorders**
Ullrich Noonan syndrome	Prader-Lahart-Willi syndrome
Bilateral anorchia	Laurence-Moon-Biedl syndrome
Down's syndrome	Möbius's syndrome
Niemann Pick disease	Börjeson-Forssman-Lehman syndrome
Receptor defects	LEOPARD syndrome
LH-resistant testis	Rud's syndrome
Syndromes of androgen resistance	Lowe's syndrome
Defects of steroidogenesis	Carpenter's syndrome
Lipoid CAH	**Associated with adrenal insufficiency**
3β-Hydroxysteroid	Adrenal hypoplasia congenita
Dehydrogenase/Δ^5-Δ^4-isomerase (3β-HSD) deficiency	
17α-Hydroxylase/17,20-lyase deficiency	**Acquired**
17β-Hydroxysteroid dehydrogenase (17β-HSD) deficiency	**Associated with anatomic disorders**
Type 2 5α-reductase deficiency	Pituitary apoplexy
Acquired	Primary or metastatic tumors of pituitary or adjacent structures
Viral	Infection
Medications	Infiltrative disorders (hemochromatosis, sarcoidosis, histiocytosis,
Trauma	lymphocytic hypophysitis)
Environmental	Empty sella
Autoimmunity	**Functional**
Ionizing radiation	Secondary to Cushing's syndrome
	to ethanol
	to exercise
	to empty sella
	to hyperprolactinemia
	Associated with systemic diseases
	AIDS
	Liver diseases
	Renal diseases
	Hemochromatosis
	Neurologic diseases

From a clinical standpoint, patients affected by 46,XY/47,XXY mosaicism manifest less serious phenotypic abnormalities, and can be fertile. However, other variants of this disease, including 48,XXXY, 48,XXYY, and 49,XXXXY individuals, are associated more frequently with cryptorchidism, growth retardation, mental deficiency, antisocial behavior, facial dysmorphism, and skeletal abnormalities.

The endocrine features of these patients show a typical evolution that becomes evident when they are examined for a period of years. Usually basal FSH, LH, and testosterone are normal in virtually all subjects studied before age 12; however, by age 14 LH and FSH are elevated. At these early states, the secretion of testosterone is kept within the normal range by the increased production of gonadotropins. By the time the patient has reached his middle 20s, however, primary gonadal failure is evident and testosterone levels will be low or in the low range of normal, despite elevated gonadotropins.

Diagnosis   Final diagnostic confirmation of this syndrome is obtained by analyzing the karyotype and by detecting one of the many chromosomal abnormalities described above.

Genetic Basis of Disease   The most common cause of Klinefelter's syndrome is nondisjunction during the first or second meiotic division. The extra X chromosome can be of paternal or maternal origin with approximately the same frequency. Most of the maternal cases are associated with impaired disjunction during the first meiotic division, and maternal age is a factor in these cases. A second possible mechanism, occurring in 3% of the cases, is nondisjunction after the first postzygotic mitosis. A third potential mechanism was described in an Italian family, in which the mother had a 46,XX/47,XXX mosaicism, possibly because of a nondisjunctional event during her zygotic development, and three of her children were affected by the classic Klinefelter karyotype 47,XXY.

The origin of the 46,XY/47,XXY mosaicism derives from nondisjunctional events in mitosis during zygotic development.

Table 61-3
Causes of Hypergonadotropic and Eugonadotropic Germinal Cell Failure

Hypergonadotropic	*Eugonadotropic*
Undescended testis (cryptorchidism)	Ductal obstruction
Germinal cell aplasia (Sertoli cells only syndrome)	Varicocele
Idiopathic seminiferous tubular failure with hyalinization	Congenital adrenal hyperplasia
Androgen resistance	Heat
	Infections
	Radiation
	Drugs
	Autoimmunity
	Impairment of sperm transport
	Immotile cilia syndrome

Table 61-4
Manifestations of Leydig Cell Dysfunction

Prenatal Leydig cell dysfunction
  External genitalia: female, ambiguous; male, hypoplastic
  Wolffian duct derivatives: absent; rudimentary
  Müllerian duct derivatives: absent
  Gonads: small; rudimentary testes, which can be located intra-abdominally, inside the inguinal canal, or in the scrotum
Prepubertal Leydig cell dysfunction
  External genitalia: small penis <3–4 cm, small testis <5 mL, lack of rugal folds, and pigmentation in the scrotum
  Accessory sex organs: small prostate and seminal vesicles
  Hair growth: no development of terminal facial hair, no recession of scalp line, decreased body hair, female escutcheon
  Linear growth: eunuchoidal skeletal proportions
  Bone development: delayed bone age, predisposition to osteoporosis
  Voice: voice remains high-pitched
  Muscle mass: absent; reduced development of muscle mass
  Psyche: decreased libido
Postpubertal Leydig cell dysfunction
  External genitalia: softening and decreased volume of the testes
  Psyche: decreased libido, sexual potency, and aggressivity
  Bone: predisposition to osteoporosis
  Hair growth: decreased growth and amount of facial, pubic, and axillary hair
  Spermatogenesis: impaired
  Muscle mass: decreased

Patients with mosaicism have a lesser degree of gynecomastia and androgen deficiency. Normal testicular size has been described in these patients, and this is particularly true when the normal stem cell line 46,XY is present in the testis.

The additional sex chromosomes in patients with 48,XXYY karyotype derive from successive nondisjunctional events in the first and second meiotic division in the father. In contrast, the additional X chromosomes in 49,XXXXY patients are maternally derived, and originate from sequential nondisjunctional events in both the first and second meiotic divisions.

Whether development of the Klinefelter phenotype requires the entire extra X chromosome remains an open question. One study looking at phenotype–karyotype correlations has associated the development of the Klinefelter phenotype with genes mapping to region Xq11–Xq22. However this observation was not confirmed by other investigators in a patient with a 47,X,del(X)(pter–p11),Y karyotype.

Therapy The main complaints of these patients are the symptoms of hypogonadism, particularly gynecomastia, infertility, and reduced libido, and several psychosocial problems. Standard treatment for these problems is replacement with tes-tosterone, which should be started immediately after puberty. Gynecomastia is usually unresponsive to treatment with testosterone, and many of these patients will require surgical removal of the enlarged breasts. Infertility is not improved by the treatment with testosterone, and in most cases a further reduction in the sperm count will be observed. Because this disease is associated with an increased risk of developing breast cancer that may approach 20 times that for normal men, some authors have advocated yearly screening mammography, but it is not clear whether this is a useful measure.

46,XX MALES Background and Clinical Features This is a variant of Klinefelter's syndrome, occurring in approximately 1/20,000 male births. The phenotype resembles that of patients with Klinefelter's syndrome, with the major difference being short stature, because of the absence of Y sequences that are important for normal somatic growth, and normal intellectual development. The testes are small and firm, androgen production is compromised, and gynecomastia is a frequent abnormality present in adolescent patients. Germ cells are absent, and serum levels of gonadotropins elevated. Affected individuals have male psychosexual identification.

Diagnosis   These patients are usually referred to a physician to investigate the typical phenotypic abnormalities that become evident after puberty. Some of these patients are referred at an earlier stage of their life, since at times this entity is associated with hypospadias, particularly in the subgroup of patients in whom no Y sequences are detected. The identification of a 46,XX karyotype associated with a male phenotype and endocrine studies showing hypogonadism and infertility permit the successful diagnosis of this condition.

Genetic Basis of Disease   The presence of Y material containing *SRY* can be demonstrated in the X chromosome of approximately 80% of these patients. This event is caused by X-Y recombination occurring outside the pseudoautosomal segments in which X-Y pairing normally occurs, resulting in the transfer of *SRY* from the Y to the X chromosome. The consensus is that *SRY* translocated to the X chromosome is sufficient to trigger testicular differentiation and the development of a male phenotype. The remainder of these patients (approximately 20%) do not carry any identifiable Y sequence and have larger incidence of ambiguous genitalia. As yet, no mechanism has been identified to account for the male phenotypic development observed in these patients. One possibility could be an activating mutation of a factor normally induced by *SRY* in the cascade of events leading to the differentiation of the male gonad.

The pathogenesis of infertility in these patients is probably caused, as in Klinefelter's syndrome, by the presence of two X chromosomes in the germ cells and the lack of regions of the Y chromosome that are essential for spermatogenesis. Management of these patients is the same as that for patients with Klinefelter's syndrome.

46,XY PURE GONADAL DYSGENESIS (SWYER SYN-DROME)   Background and Clinical Features   46,XY pure gonadal dysgenesis, of which a complete and an incomplete form have been described, occurs both in sporadic and familial forms.

The complete form of this disease is associated with an impairment of testosterone and AMH production that begins in the initial phase of fetal development, and results in a female phenotype characterized by sexual infantilism with bilateral streak gonads, Müllerian duct development, and female internal organs.

In the incomplete form of the disease the virilization of the phenotype depends on the degree of differentiation achieved by the gonads, which varies from streak gonads to dysgenetic testes, and on their residual capacity to produce testosterone and AMH. In the incomplete form of the disease virilization is never normal. Therefore the characteristics of the internal and external genitalia of these patients are more ambiguous than in the complete form. The presence of spontaneous gynecomastia is associated with an estrogen-secreting neoplasm, which in these patients can frequently be a gonadoblastoma. Unlike 46,XX males, this entity is associated with normal stature because of the presence of most of the Y chromosome.

Diagnosis   46,XY pure gonadal dysgenesis is a form of primary hypogonadism that is typically associated with increased levels of gonadotropins. Testosterone levels are almost undetectable in patients with the complete form, and decreased but detectable in patients with the incomplete form. The diagnosis should be suspected in individuals presenting with primary hypogonadism, a 46,XY karyotype, and with the phenotype and pattern of inheritance discussed above.

Genetic Basis of Disease   This disease is associated with a remarkable degree of genetic heterogeneity. It has been associated with abnormalities occurring in the Y-linked *SRY* gene, with an X-linked pattern of inheritance, and with a sex-limited autosomal dominant inheritance. Defects of *SRY* (deletions of the *SRY* gene and most frequently point mutations) have been detected in approximately 10–15% of the sporadic cases and in three kindreds with the familial form. Other X-linked and autosomal genes that could be involved with this syndrome, including *AMH*, *SF-1*, *WT1*, *DSS*, and *SOX-9*, are discussed in Chapter 57.

Molecular Pathophysiology of Disease   The association of this disease with alterations in the sequence of *SRY*, and potentially with other autosomal or X-linked genes, is leading to a more sophisticated understanding of the complex cascade of events required for normal testicular differentiation. The sequence of events, and the precise mechanism of interaction among these factors is not completely clear and currently is under investigation.

Treatment   The sex of rearing should be based on the degree of genital ambiguity. When this critical dilemma has been properly addressed and skeletal growth is complete, the rudimentary gonads should be prophylactically removed, since they may undergo malignant degeneration. At this point testosterone or estrogen replacement should be started to ensure the development of the secondary sexual characteristics and the prevention of osteopenia.

HYPERGONADOTROPIC HYPOGONADISM FROM MULTIORGAN DISEASES

ALSTRÖM SYNDROME   Clinical Features   This rare entity, described in 1959 by Alström, is characterized by autosomal recessive inheritance, and by multifactorial disorders including retinal pigment degeneration, obesity, diabetes mellitus, acanthosis nigricans, sensorineural deafness, chronic nephropathy, and metabolic abnormalities such as hyperuricemia and hypertriglyceridemia. Hypogonadism is typically a clinical feature of affected men, but not women. It is a primary form of hypogonadism, associated with low testosterone and high gonadotropin levels. Alström's syndrome is usually associated with normal secondary sexual characteristics; however, the small testes demonstrate hyalinized tubules and thickening of the lamina propria.

Genetic Basis of Disease   The pathophysiology of Alström's syndrome is unknown. Because it is expressed only in the homozygous state, a single-gene abnormality, as yet undefined, is responsible for this multisystem involvement. Recently, the disease gene was localized to chromosome 2p.

NOONAN SYNDROME (MALE TURNER'S SYNDROME) Background and Clinical Features   This disease was once classified as the male Turner's syndrome, because of the association of primary testicular failure with many of the clinical stigmata of Turner's syndrome. The incidence is estimated to be between 1:1000 and 1:5000 live male births. Approximately half of the cases are familial and the pattern of inheritance is autosomal dominant with variable penetrance. The typical clinical picture includes webbed neck, ptosis, hypertelorism, down-slanting palpebral fissures, low set of posteriorly rotated ears, congenital heart disease, short stature, low hairline, shield chest, cubitus valgus, and hypogonadism because of primary testicular failure. The most frequently occurring cardiac malformation is pulmonic stenosis, followed by atrial septal defect. The testes are frequently hypoplastic and intra-abdominal. The endocrine function of the testes

can be normal, or consistent with primary Leydig cells dysfunction (high gonadotropins and low testosterone). Although some affected individuals are fertile, infertility is present in the majority of patients and is associated with germinal cell aplasia.

Diagnosis The diagnosis is suspected in 46,XY individuals presenting with the clinical features described above and with a normal karyotype.

Genetic Basis of Disease The genetic abnormality accounting for this rare disorder has recently been localized on chromosome 12q22–qter by genome linkage analysis of a three-generation Dutch family with the disease, and 20 smaller two-generation families from Great Britain. The biologic and biochemical characteristics of the gene product are currently unknown.

Treatment The treatment is directed toward the cardiac complications of the disease. At puberty, affected males can require replacement with testosterone.

MYOTONIC DYSTROPHY Background and Clinical Features Myotonic dystrophy (MD) is an autosomal dominant disorder that expresses remarkable variability in its clinical manifestations. It becomes apparent in adulthood, and is characterized by progressive weakness and atrophy of the facial, neck, hand, and lower extremities muscles. Myotonia can manifest in several muscles and is characterized by prolonged muscle contraction with inability to relax. Other features include cataracts, cardiac arrhythmias, baldness, primary hypothyroidism, mental retardation, and, in as many as 80% of these patients, primary testicular failure.

Diagnosis Hypogonadism in MD is a primary testicular disease, as suggested by the presence of testosterone levels ranging from modestly decreased to low normal and slightly elevated gonadotropins that hyperrespond to LH-releasing hormone (LHRH) stimulation. Testicular atrophy is usually noted during adulthood. There is good correlation between the circulating levels of testosterone and the clinical signs of androgen deficiency, which usually are mild. Most patients maintain normal facial and body hair growth and normal libido. The histology of the testes varies from normal to marked tubular atrophy or peritubular hyalinization, with or without loss of the interstitial cells. Testicular size is frequently decreased in association with complete germinal cell destruction. Infertility is reported in as many as 44% of the cases in a recent series.

Genetic Basis of Disease This disease has been associated with expansion of a highly polymorphic GCT repeat located in the sequence of the myotonin-protein kinase gene, which has been mapped on chromosome 19q13.2–13.3. In the normal population, the GCT tract length ranges from 5 to 30 repeats. In patients affected by MD the size of the GCT tract expands dramatically, up to 2000–3000 copies. The mechanism responsible for the association between the expansion of the GCT repeat located in the myotonin-protein kinase gene and hypogonadism has not yet been defined.

Therapy Replacement therapy with testosterone has been advocated for patient with low testosterone not only to correct the hypogonadism, but also to increase and maintain muscular size and strength.

BILATERAL ANORCHIA (VANISHING TESTES SYNDROME) Background This syndrome is also known as "congenital anorchia" or "testicular agenesis." Bilateral anorchia is found in approximately 1% of boys receiving surgery for bilateral cryptorchidism. It is found in approximately 1 of every 20,000 male newborns.

Clinical Features The phenotype detected in these patients correlates with the time of embryologic development at which testicular function became deficient. Individuals in which testicular function became abnormal before 8 weeks of gestation have female internal and external genitalia. Individuals developing abnormal testicular function between 8 and 10 weeks of gestation exhibit an intermediate phenotype, with ambiguous genitalia and variable masculinization of the internal structures. Loss of testicular function after 10 weeks of gestation is associated with the development of a normal male phenotype. In each instance, no histologic or hormonal evidence for the presence of a functioning testis is available. Hormonal studies are compatible with primary gonadal failure, with high gonadotropin and low testosterone level.

Diagnosis The diagnosis of this disorder should be suspected in patients with anorchia in whom intra-abdominal gonads cannot be demonstrated by provocative testing or during explorative surgery.

Genetic Basis of Disease The pathogenesis for the degeneration and disappearance of the testes is controversial because it could potentially result from trauma, vascular insufficiency, or infection. Several sibships with multiple affected individuals have been reported. In one case there was parental consanguinity, suggesting a possible autosomal recessive transmission of the disease.

HYPERGONADOTROPIC HYPOGONADISM FROM RECEPTOR DEFECTS

LH-RESISTANT TESTIS (LEYDIG CELL HYPOPLASIA) Clinical Features Leydig cell hypoplasia is a rare condition. In 46,XY individuals it is associated with primary testicular failure and a spectrum of phenotypic abnormalities of the internal and external genitalia. It is inherited as an autosomal recessive disorder.

In male patients the main clinical features of this syndrome consist of ambiguous external genitalia, ranging from extreme forms that present as 46,XY females to milder forms in which normal phallic development is observed. The internal genitalia consist of a blind-ending, rudimentary vagina, owing to the absence of Müllerian derivatives and the presence of Wolffian duct-derived structures. The histologic features of the testis consist of a drastic reduction in the number of Leydig cells, which in some instances are completely absent, and in limited germ-cell maturation.

Although virilization of the external genitalia is very limited in these patients, Wolffian duct-derived structures, such as the vas deferens and the epididymis, undergo normal embryologic development. This implies that during fetal development the Leydig cells of these patients are able to produce androgens despite the inactivating mutations of the LH receptor, suggesting that during early fetal development Leydig cell maturation and androgen production may be independent of LH stimulation.

Diagnosis These patients manifest a resistance to LH, as shown by the elevated level of LH and low level of testosterone. FSH has been reported to be normal in most cases, and abnormally elevated in a minority of patients. Testosterone precursors such as dihydroepiandrosterone (DHEA), 17α-progesterone, progesterone, and androstenedione are low compared with normal males. As would be anticipated, the LHRH stimulation test is associated with an LH hyperresponse.

A clinical picture of abnormal virilization associated with low testosterone and testosterone precursors in the presence of high LH is virtually diagnostic of this syndrome. Alternatives to consider in the differential diagnosis are androgen resistance because of defects in the androgen receptor, type 2 5α-reductase deficiency,

Table 61-5
46,XY Patients with Inactivating Mutations of the LH Receptor Gene Causing LH Resistance

	Ethnic background	Familial consanguinity	Clinical phenotype	Mutation	Functional characterization of the receptor
Family 1	Brazilian	+	Development of testis, epididymis, and vas deferens. External phenotype: female	Ala593→Pro	Lack of hCG-dependent cAMP production
Family 2	Brazilian	–	Testicular development. External phenotype: female	Arg554→Stop	Presumed completely inactive
Family 3	Puerto Rican	+ (four generations earlier)	Micropenis, otherwise normal male phenotype	Ser616→Tyr	Lack of ligand binding

and defects of testosterone biosynthesis. Each defect can be differentiated on the basis of the clinical phenotype and hormonal data.

Genetic Basis of Disorder The association of Leydig cell hypoplasia with an abnormal binding activity of the LH receptor and with the endocrine features described above led to the identification of the LH receptor as the culprit in this syndrome. Although the cDNA encoding this molecule has been available since 1990, this hypothesis has only recently been confirmed by the molecular analysis of the LH receptor gene in three unrelated families with the disorder. The clinical features, LH-receptor mutations and functional abnormalities of the LH-receptor gene in these families, are described in Table 61-5.

Molecular Pathophysiology of Disease Mutations in the coding sequence of the LH receptor have the potential to affect any of the functions performed by this molecule, including LH binding, G-protein activation with subsequent production of cyclic adenosine monophosphate (cAMP), posttranslational modifications or postsynthesis transport. The Ala593Pro mutation is localized to the sixth transmembrane domain of the LH receptor gene. Binding analysis of this mutant receptor using ^{125}I-hCG has shown only minor changes in ligand binding (normal kDa, and decreased B_{max} caused largely by decreased transfection efficiency of the mutated receptor in HEK293 cells). When compared with the wild-type receptor, however, it is clear that this mutation completely prevents cAMP production, indicating that the region of the gene containing residue 593 is important for normal intracellular signal transduction. The molecular analysis of the missense mutation Ser616Tyr causes a total loss of ligand binding, and consequently of cAMP production, indicating that this amino acid, which is located in the seventh transmembrane domain of the receptor, is critical for normal ligand binding. The third mutation identified, Arg554→Stop, causes premature interruption of the translation process of the LH receptor mRNA, eliminates a large part of the receptor, and presumably prevents transduction of the hormonal signal. The molecular analysis of more patients affected by this disorder will be useful in dissecting the structure–function correlation of the LH receptor gene.

Treatment Androgen or estrogen replacement therapy is indicated depending on gender selection. The final choice as to how these patients should be raised depends on the same criteria established for patients with other forms of male pseudohermaphroditism. The intra-abdominal gonads should be surgically removed at the time of the diagnosis to prevent neoplastic degeneration. In most instances it is recommended that pediatric patients affected by micropenis should receive a course of testosterone treatment to normalize the size of the phallus.

SYNDROMES OF ANDROGEN RESISTANCE Hypogonadism because of androgen receptor defects is associated with a wide spectrum of clinical phenotypes, ranging from 46,XY women with the syndrome of complete testicular feminization to phenotypically normal men affected by infertility. The clinical features, endocrinology, biochemistry, and molecular biology of these syndromes are discussed in Chapter 60.

HYPERGONADOTROPIC HYPOGONADISM CAUSED BY DEFECTS IN THE SYNTHESIS OF TESTOSTERONE IN 46,XY INDIVIDUALS

(20,22-DESMOLASE, 3β-HYDROXYSTEROID DEHYDROGENASE, 17α-HYDROXYLASE/17,20-DESMOLASE, 17β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY) The pathway for steroid biosynthesis shown in Table 61-6 is responsible for the conversion of cholesterol to testosterone, and consists of five well-characterized enzymatic steps.

Genetic diseases associated with impaired activity of each of these enzymes have been described. Because normal production of testosterone by the developing testis is critical for the development of a normal male sexual phenotype, abnormalities of these enzymes in 46,XY individuals are associated with different degrees of male pseudohermaphroditism. Three of these enzymes (20,22-desmolase, 3β-Hydroxysteroid dehydrogenase, and 17α-hydroxylase) are involved in both cortisol and testosterone biosynthesis; hence, individuals with abnormalities of these enzymes are affected by a combination of male pseudohermaphroditism and hypoadrenalism. Some of these congenital abnormalities can be partial, and may become clinically evident only at puberty.

CONGENITAL LIPOID ADRENAL HYPERPLASIA (CHOLESTEROL SIDE-CHAIN CLEAVAGE DEFICIENCY, P450$_{scc}$ DEFICIENCY) Background Congenital lipoid adrenal hyperplasia (lipoid CAH) is a rare autosomal recessive defect in which the synthesis of all steroid hormones (estrogens, glucocorticoids, mineralocorticoids, and androgens) is impaired. This syndrome has recently been associated with genetic abnormalities of the StAR (steroidogenic acute regulatory) protein, the factor that mobilizes cholesterol from the outer mitochondrial membrane into the inner mitochondrial membrane.

Clinical Features Newborn patients with this disease have female external genitalia irrespective of karyotype, exhibit a severe form of salt-losing congenital adrenal hyperplasia (CAH), and accumulate lipids in the gonads and adrenals, which are grossly enlarged. Male infants with this syndrome present with male pseudohermaphroditism, characterized by female external genitalia with a blind-ending hypoplastic vagina, absent uterus and fal-

lopian tubes, hypoplastic Wolffian derivatives, and cryptorchid testes. Heterozygous parents of affected siblings develop normally. Their condition is not unmasked by provocative testing.

Diagnosis This disease should be suspected at birth in patients with a salt-losing crisis and the phenotype discussed above. Further aid to a correct diagnosis is obtained by showing the typical enlargement of the adrenals and testes, which is visible using magnetic resonance imaging (MRI) or computed tomographic scanning. Typically the serum levels of cortisol, aldosterone, and testosterone are undetectable adrenocorticotropic hormone (ACTH), FSH, and LH are elevated, and no response is evident after stimulation with ACTH or β-hCG. At puberty a minimal degree of virilization can occur in 46,XY individuals.

Genetic Basis of Disease For a long time this disease has been ascribed to defects of the P450$_{scc}$ system, which consists of the cholesterol side-chain cleavage enzyme and two electron transfer proteins, termed adrenodoxin reductase (AR) and adrenodoxin (AD). This conclusion was based on hormonal studies of affected patients who were unable to produce adrenal and gonadal steroids, and on the inability of mitochondria from affected tissues to convert cholesterol to pregnenolone. However, a role for P450$_{scc}$ has been ruled out in molecular studies of affected individuals, in which abnormalities in the coding sequence of this gene have never been detected. In addition, P450$_{scc}$, AR, and AD are normally transcribed and translated in the steroidogenic tissue of affected individuals, suggesting that the lesion responsible for lipoid CAH is located elsewhere. When the role of the StAR protein became clear, this factor appeared immediately to be the candidate gene responsible for lipoid CAH. Molecular analysis of the StAR protein, now performed in at least 22 families, has confirmed that this factor has a central role in the etiology of lipoid CAH. Mutations affecting both alleles of the *StAR* gene have been detected in 95% of the patients. Most families have homozygous mutations, and a minority appear to be compound heterozygotes. The importance of these mutations in the etiology of lipoid CAH has also been demonstrated by showing that *StAR* cDNAs carrying these mutations lack the ability to promote pregnenolone synthesis in transfected cells.

Therapy Glucocorticoid and mineralocorticoid replacement is the first therapeutic step for these patients. Given the sexual phenotype, most patients are raised as females. Prophylactic orchidectomy followed by estrogen replacement should be performed to prevent the neoplastic degeneration of the retained gonads and to avoid any possible virilization at the time of puberty.

3β-HYDROXYSTEROID DEHYDROGENASE (3β-HSD) Δ^5, Δ^4-ISOMERASE DEFICIENCY Background 3β-HSD regulates the conversion of Δ^5-3β-hydroxysteroids (pregnenolone, 17-OH pregnenolone, dehydroepiandrosterone, and androstenediol) into the corresponding Δ^4-3-ketosteroids (progesterone, 17-OH-progesterone, androstenedione, and testosterone, respectively). Absent or reduced activity of this enzyme is potentially associated with impaired formation of all steroid hormone classes, including progesterone, mineralocorticoids, glucocorticoids, androgens, and estrogens.

Clinical Features There is a remarkable heterogeneity in the clinical presentation of 46,XY individuals affected by this disease. The two major clinical features of these patients are incomplete virilization and salt-wasting. The degree of salt-wasting is heterogeneous, and ranges from life threatening to clinically inapparent syndromes. In a similar fashion, the defects of virilization can range from the development of various genital ambiguities (including hypospadias, micropenis, and presence of a blind-ending vagina) to, in rare cases, the development of normal external genitalia. In most instances, the Wolffian duct derivatives develop normally, suggesting that although the prenatal testes were capable of some androgen production, these quantities were insufficient to permit normal development of the sexual phenotype. The Müllerian duct derivatives involute normally indicating normal production of AMH by the Sertoli cells. At puberty these patients have typical hypergonadotropic hypogonadism with high gonadotropin and low testosterone. These endocrine abnormalities are associated with gynecomastia, spermatogenic arrest, and phenotypic features of undervirilization. Interestingly, no correlation has been made between the degree of salt-wasting and of impairment of male sexual differentiation, suggesting that 3β-HSD mutations can affect the different steroidogenic pathways differently.

Diagnosis The diagnosis of this disorder should be suspected in patients presenting with adrenal and gonadal insufficiency. An elevated ratio of Δ^5- to Δ^4-steroids is characteristic of this disorder; however, the interpretation of the endocrine data can be complicated by the increased level of some Δ^4-steroids, including serum 17-OH-progesterone and Δ^4-androstenedione, and urinary pregnanetriol. This is caused by the presence of two 3β-HSD enzymes, of which only one is mutated (*see* Genetic Basis of Disease).

Genetic Basis of Disease This disease is transmitted as an autosomal recessive character, and the gene is located in the region

p11–p13 of chromosome 1. Two isoenzymes with 3β-HSD activity have been cloned, and have been designated type I and type II 3β-HSD. Their structural organization consists of four exons and three introns, which are included in a genomic DNA fragment of about 7.8 kb. The type I 3β-HSD mRNA is transcribed in the breast, placenta, and skin, and to a much lower degree in the gonads. The type II isoenzyme is transcribed exclusively in the adrenals, testis, and ovary. The identification of two isoenzymes with the same activity and with a different pattern of expression has the potential of explaining the presence of normal to elevated serum levels of some Δ^4-3-ketosteroids in the patient population with 3β-HSD deficiency. Since the disease causes salt-wasting and ambiguous genitalia, it would be expected that the type II isoenzyme (which is exclusively transcribed in the adrenals and gonads) is the mutated gene and the type I isoenzyme (which is transcribed in the periphery) would maintain its activity and would be responsible for the residual conversion of Δ^5-3β-hydroxysteroids to Δ^4-3-ketosteroids. In agreement with this expectation, the molecular abnormalities causing clinical 3β-HSD deficiency have so far been localized exclusively to the type II isoenzyme. Numerous mutations in the coding region of the 3β-HSD gene have been identified by sequence analysis of SSCP (single-strand conformational polymorphism) variants detected in genomic DNA obtained from these patients. They include missense, nonsense, and frameshift mutations, and have been detected in homozygous or compound heterozygous patients. Their functional characterization has been very useful in defining the functionally important regions of the 3β-HSD gene.

Molecular Pathophysiology   There is a reproducible correlation between the impairment of the enzymatic activity caused by each mutation and the clinical abnormalities of the patients. This is particularly true with regard to the presence of salt-wasting forms of the disease in which no residual enzymatic activity is detected. Molecular analysis of the 3β-HSD gene of these patients has shown the presence of nonsense mutations (causing the synthesis of prematurely truncated proteins) and missense mutations (causing the replacement of critical amino acids) (Table 61-7). The only identified patient of this group with minimal residual enzymatic activity (0.1–0.3%) is a compound heterozygote carrying two missense mutations (Leu108Trp and Pro186Leu). The presence of such low level of activity is most likely inadequate to prevent the development of salt-wasting.

In patients with non–salt-wasting forms of the disease, there is residual 3β-HSD activity that ranges from 1 to 10%, a level that appears to permit sufficient mineralocorticoid synthesis to prevent salt-wasting. Interestingly, in patients with this milder form of the disease premature stop codons have not been described, which completely abolish 3β-HSD activity, rather only missense or splicing mutations have been found (Table 61-8).

Of note is the observation that the amino acid residues that are mutated are conserved in all members of the vertebrate 3β-HSD isoenzymes described to date.

It is not yet clear why the clinical abnormalities of genital development and salt-wasting do not correlate. A potential explanation for this phenomenon is that different mutations affect C_{21} and C_{19} steroidogenesis in different ways. Future molecular investigations of more patients with 3β-HSD deficiency should help to clarify this point.

Therapy   Therapy involves replacement with glucocorticoids and, if required, mineralocorticoids. Sufficient androgens should be given early in life to correct the microphallus and allow surgical

treatment of hypospadias. Normal replacement doses should be given at the time of puberty.

17α-HYDROXYLASE/17,20-LYASE DEFICIENCY   Background   Two important steps of the steroidogenic pathway are regulated by the enzyme 17α-hydroxylase/17,20-lyase (P450$_{c17}$). The first reaction consists of the 17α-hydroxylation of pregnenolone and progesterone into 17-hydroxypregnenolone and 17-hydroxyprogesterone. These C_{21} steroids undergo cleavage of the C-17,20 carbon bond via the 17,20-lyase reaction to yield the C_{19} steroids dehydroepiandrosterone and androstenedione.

To date, more than 120 cases with P450$_{c17}$ deficiency have been described in the worlds literature. The large majority of these patients are affected by complete 17α-hydroxylase deficiency; however, about 20 cases with a partial form of this disease have been described. There is clear evidence that P450$_{c17}$ catalyzes both the 17α-hydroxylase and 17,20-lyase reactions, but the description of 14 patients with only 17,20-lyase deficiency indicates that a complete understanding of this disorder has not yet been achieved.

Clinical Features   Of the enzymatic activities catalyzed by P450$_{c17}$, 17α-hydroxylase is critical for the production of both glucocorticoid and sex steroids, whereas 17,20-lyase, which is located one step downstream in the steroidogenic pathway, is critical for the

production of sex steroids only. In theory, defects of $P450_{c17}$ activity could occur as isolated deficiencies of 17α-hydroxylase or 17,20-lyase or as combined 17α-hydroxylase/17,20-lyase deficiency. In practice it is almost impossible to differentiate between combined 17α-hydroxylase/17,20-lyase and isolated 17α-hydroxylase deficiencies on clinical and biochemical grounds. However, isolated 17,20-lyase deficiency has been described as an independent entity in 14 patients, and two types of enzymatic defects have been proposed for this syndrome. In the first one there is an incomplete defect of the Δ^4 and Δ^5 pathways, whereas in the second type, associated with normal serum levels of DHEA, there is a complete defect only in the Δ^4 pathway.

The deficient production of cortisol observed in these patients is associated with a compensatory overproduction of ACTH, which stimulates the production of large amounts of corticosterone, usually found at concentrations 50- to 100-fold higher than normal. Although corticosterone has a lower affinity for the glucocorticoid receptor (GR) than does cortisol, its activity is sufficient to prevent the development of overt adrenal insufficiency. As a result of the increased production of deoxycorticosterone (DOC), corticosterone, and 18-hydroxycorticosterone, affected patients develop retention of water and salt, hypokalemic alkalosis, and hypertension. Suppression of renin and aldosterone production is a feature of most patients; however, a few individuals with normal or elevated aldosterone have been reported in the Japanese literature, and this finding has still not been adequately explained.

Deficient production of sex steroids is associated in these patients with hypogonadism and a compensatory overproduction of gonadotropins. Since normal levels of testosterone synthesis are necessary during fetal life for the development of the normal male sexual phenotype, affected patients manifest different abnormalities of the external genitalia, ranging from an apparent female phenotype with a blind-ending vagina to hypospadias and male-appearing genitalia with micropenis. The Wolffian derivatives can be hypoplastic or normal, the Müllerian derivatives are normally involuted, and the hypoplastic testes may be located intra-abdominally, in the inguinal canal, or in the scrotum. There is lack of correlation between the severity of hypertension and hypokalemia and that of hypogonadism, again suggesting that the various mutations of $P450_{c17}$ can affect the C_{21} and C_{19} steroidogenic pathways in different ways.

Diagnosis 17α-Hydroxylase/17,20-lyase deficiency should be considered in every 46,XY patient with a family history of pseudohermaphroditism that suggests an autosomal recessive inheritance. It is usually recognized in young adults with hypertension, hypokalemia, and ambiguous genitalia. The diagnosis of 17α-hydroxylase deficiency can be confirmed by demonstrating increased serum concentrations of pregnenolone, progesterone, corticosterone, 18-hydroxy-DOC, and DOC, associated with increased urinary excretion of their respective glucoronidate metabolites. Plasma renin activity, serum cortisol, and aldosterone are usually suppressed and ACTH is elevated. Affected males have low testosterone and elevated gonadotropins. The response to hGC and ACTH stimulation tests are impaired. This steroid pattern applies to patients with combined 17α-hydroxylase/17,20-lyase deficiency. In patients with 17,20-lyase deficiency the clinical symptoms are usually limited to the sexual phenotype. An important feature of this latter group of patients is the presence of normal serum level of cortisol and DOC and of their urinary metabolites. However, because of the presence of 17,20-lyase deficiency, these patients have been found to have increased serum level of progesterone, 17OH-progesterone, and OH-pregnenolone, increased urinary level of pregnanetriolone, and decreased serum level of testosterone and its precursors.

Genetic Basis of Disease The human $P450_{c17}$ gene *(CYP17)* is a single copy gene, located on chromosome 10q24–25. It consists of eight exons and seven introns spanning 6569 bases. Full-length cDNA clones have been isolated from adrenal and testicular sources and have the same nucleotide sequence. When the cDNA clones encoding this enzyme are expressed in cultured cells, the expressed protein displays both 17α-hydroxylase and 17,20-lyase activities. The molecular and functional analyses of 20 mutations of the *CYP17* gene have been published (Table 61-9). They show that the genetic lesions of 17α-hydroxylase deficiency are random events, and that there are no structural features of the gene predisposing to specific abnormalities. The functional analyses of these mutations have shown that they impair both 17α-hydroxylase and 17,20-lyase activities, giving further demonstration that this gene encodes a protein possessing both enzymatic activities. Only a limited number of mutations have been reported more than once and were detected in unrelated individuals from Guam and of German-Dutch descent, indicating that this disorder is genetically heterogeneous, unless associated with a specific ethnic group.

Molecular Pathophysiology *Introduction* The description of the molecular defects and functional abnormalities affecting patients with the complete and incomplete forms of 17α-hydroxylase deficiency and with isolated 17,20-lyase deficiency have elucidated several new aspects of this disease. The biochemical events associated with 17α-hydroxylase activity consist of a chain of events involving proper anchorage of the enzyme into the microsomal membrane, heme binding, substrate binding, transfer of electrons from NADPH to cytochrome P450 reductase, and O_2 binding. Mutations specifically affecting heme and substrate binding have been identified. Targeted site-directed mutations of the rat *CYP17* have been very informative in dissecting the amino acids of this protein that contribute to the 17α-hydroxylase and 17,20-lyase activities and showed the importance of residues Arg346 and Arg363 in inducing 17,20-lyase and 17α-hydroxylase activities, respectively.

Complete Combined 17α-Hydroxylase and 17,20-Lyase Deficiency Fifteen mutations resulting in loss of 17α-hydroxylase and 17,20-lyase activity have been identified in the *CYP17* gene. They include insertion of premature termination codons, amino acid replacements, or small deletions. Premature termination codons resulting from nonsense mutations or from other abnormalities of the open reading frame (including deletions or insertions of DNA) lead to truncated forms of the P450c17 protein, which, by being deprived of the C-terminal heme-binding domain, become functionally inactive. Complete loss of enzymatic function in three patients with missense mutations has identified residues Ser106, His373, and Arg440 as critical for both 17α-hydroxylase and 17,20-lyase activities. Of note is the speculation that the mutation occurring in amino acid residue 106 may affect substrate binding, whereas the two other mutations (His373 and Arg440) affect heme binding.

Partial Combined 17α-Hydroxylase and 17,20-Lyase Deficiency Partial deficiency of 17α-hydroxylase and 17,20-lyase has been studied in two patients. One of these two patients was a boy with ambiguous genitalia, carrying two different *CYP17* mutant alleles: one resulting in an Arg239Stop nonsense mutation

Table 61-9
Mutations of the CYP17 Gene in 46,XY Patients with 17α-Hydroxylase/17,20-Lyase Deficiency

Origin	Karyotype	Sex of Rearing	Mutation
Canada[a] Netherlands[a]	46,XY	F	4 bp duplication

			Duplication of Ile112
Canada	46,XY	M	Arg239→Stop
			Pro342→Thr

[a]This mutation was described in two unrelated Canadians of German origin and in 6 unrelated families residing in the Friesland region of the Netherlands.
[b]This mutation was described in two unrelated individuals from Guam.
Modified from Yanase T. J Steroid Biochem Mol Biol. 1995;53:153–157.

and the other causing a Pro342Thr missense mutation. The residual activity of these two alleles was respectively 0 and 20% of normal. These data, together with the functional analysis of a 46,XY female with homozygous premature termination codons (with residual functional activity of 0%) and of her normally virilized heterozygous father (thought to have a residual functional activity of 50%), have been very useful in understanding the amount of 17α-hydroxylase activity that is necessary for the development of the male sexual phenotype. Because the boy with ambiguous genitalia had a residual activity of 20% and the normally virilized individual described above was thought to have a residual activity of 50%, it would appear that the threshold activity necessary to change the sexual phenotype from female to ambiguous male is between 0 and 20%, and to change from ambiguous to normal is between 20 and 50%.

Isolated 17,20-Lyase Deficiency   Only one patient with this form of the disorder has been analyzed at the molecular level. This patient was found to be a compound heterozygote, with one allele containing an Arg496Cys missense mutation and the other allele containing a Glu461Stop nonsense mutation. In contrast to the clinical study, both alleles of this patient showed a dramatically reduced activity of both 17α-hydroxylase and 17,20-lyase. This finding prompted a clinical reevaluation of the patient, who was found to have deficient activity of both 17α-hydroxylase and 17,20-lyase when reexamined at age 25 years. These results led to speculation that the levels of P450$_{c17}$ activity expressed in vivo were affected by unknown age-dependent factors or that a modifying effect had been exerted by the estrogen replacement that had been initiated in the interim.

Treatment   Treatment consists of replacement with cortisol, which accomplishes suppression of ACTH followed by the normalization of DOC, corticosterone, and 18-hydroxycorticosterone, and by the normalization of renin and aldosterone levels. Adult 46,XY individuals reared as females require estrogen replacement and removal of the abdominal gonads to prevent their malignant degeneration. Adult 46,XY individuals raised as males require androgen replacement, surgical correction of their external genitalia, and, if necessary, orchiopexy.

17β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY (17β-HSD DEFICIENCY)   Background   The enzyme 17β-hydroxysteroid dehydrogenase (17β-HSD) catalyzes the conversion of androstenedione and estrone into testosterone and estradiol, respectively. As such, it converts two weak precursors,

androstenedione and estrone, into two potent hormones, testosterone and estradiol, that, on interacting with high affinity with their receptors, induce their biologic effects. The reaction catalyzed by 17β-HSD is reversible. The reduction of the 17-keto group is believed to occur mainly in the testis and ovary, where it is required for the synthesis of testosterone and estradiol. The oxidation reaction, which is believed to occur in several peripheral tissues, is important for the inactivation of these two hormones.

Five different isoenzymes with 17β-HSD activity have been isolated and designated 1 through 5 according to the chronological order of their identification. These isoenzymes have different biochemical features, and are expressed in different tissues (Table 61-10). Interestingly, the isoenzymes 1 and 3 favor the reduction reaction, whereas the type 2 and 4 isoenzymes favor the oxidation reaction. The isoenzymes 2 and 4 have ubiquitous tissue distribution, whereas the isoenzymes 1 and 3 are expressed in a more selective way. The mRNA of the type 1 isoenzyme is present in the ovary and placenta, whereas the type 3 mRNA has been detected almost exclusively in the testis. Information concerning the type 5 isoenzyme is at present less detailed. Mutations of the type 3 isoenzyme have recently been associated with 17β-HSD deficiency.

Clinical Features   Approximately 42 patients from 23 families with classic 17β-HSD deficiency have been reported. This number probably does not reflect the high incidence of this syndrome in the Gaza strip, where it is estimated that 1 in 100–150 individuals is affected by this disorder. The pattern of inheritance is autosomal recessive. At birth these patients present with female external genitalia, absent Müllerian and normal Wolffian duct derivatives, and undescended testes. Based on this phenotype, gender assignment is female in almost every case. At puberty, both virilization (developing a deep voice, large phallus, and various degree of body and facial hair) and feminization (developing variable degree of gynecomastia) occur. Some of these individuals have undergone a change in gender role behavior in parallel with the virilization occurring at the time of puberty. Impaired 17β-HSD activity explains the abnormal virilization of the external genitalia at birth, the elevated serum level of androstenedione and decreased testosterone, and the enhancement of pituitary gonadotropin production. A milder form of late-onset 17β-HSD deficiency has recently been identified in 3 adult patients with gynecomastia and hypogonadism in a study of 48 subjects with idiopathic pubertal gynecomastia. The frequency of this syndrome is unknown. It is

Table 61-10
Features of Five Isoenzymes with 17β-HSD Activity

17β-HSD deficiency	Amino acid size	Exons	Chromosome localization	Tissue localization	Cellular localization	Preferred substrate	Preferred cofactor	Catalytic preference

equally unclear whether these patients are heterozygous for an inactivating mutation of type 3 17β-HSD or whether they are homozygous for a mutation of type 3 17β-HSD causing a milder enzymatic defect.

Endocrine Features and Diagnosis   The diagnosis should be considered in 46,XY patients presenting with pseudohermaphroditism inherited with an autosomal recessive pattern. Plasma androstenedione, estrone, and gonadotropin levels are elevated, whereas testosterone and dihydrotestosterone are decreased or in the low normal range. Steroid hormone metabolism has been studied in the testes of several affected subjects. In these tissues it was found that the conversion of androstenedione to testosterone was consistently abnormal. However, other authors have found that the oxidative reaction catalyzed by 17β-HSD was normal in cultured fibroblasts obtained from one patient.

Most of these patients are diagnosed at puberty, when they are referred for failure to menstruate, or because they develop a mixed pattern of virilization and feminization. The diagnosis of 17β-HSD deficiency is more challenging in the newborn. However, the correct interpretation of the endocrine tests should permit the diagnosis of this disorder in any age group.

Genetic Basis of Disease   Because of its biochemical characteristics and tissue distribution, type 3 17β-HSD was considered to be a good candidate to cause the clinical abnormalities of 17β-HSD deficiency. Subsequent analysis has identified 14 mutations of this gene in 17 families with the typical phenotypic, endocrine, and genetic features of the syndrome. The mutations detected include 10 missense mutations, 3 splice junction abnormalities and 1 small deletion resulting in a frameshift. Patients with the syndrome were most frequently homozygous (12), but heterozygotes (1) and compound heterozygotes (4) have been described as well (Table 61-11). The mutation Arg80Gln has been detected in three unrelated families, including a member of the large kindred from the Gaza strip and two Brazilian families. Considering the high incidence of 17β-HSD deficiency in the Gaza strip, screening programs for this mutation may be worthwhile in that part of the world to detect heterozygosity or for prenatal diagnosis. The real frequency of this mutation in the entire Arab population of the Gaza strip could be very high, if one considers that homozygous females are asymptomatic, have normal internal and external genitalia, undergo normal sexual development, and have unimpaired fertility.

The frequency of compound heterozygosity underscores the possible high frequency of heterozygous carriers, a potentially important fact, considering the recent identification of individuals with partial deficiency of testicular 17β-HSD activity that was reported in a group of patients with gynecomastia.

Molecular Pathophysiology of Disease   Nine of the ten substitution mutations described in Table 61-11 have been recreated in vitro, and the activity of the mutated enzyme was studied in transfected cells. Eight of the nine mutations are completely inactivating. However, in agreement with biochemical studies performed in cultured genital skin fibroblasts, the ninth mutation (Arg80Gln) retains a small amount of activity. Detailed analysis of the enzymatic activity of this mutant has revealed a 100-fold decreased affinity for the cofactor NADPH, localizing at least a portion of the NADPH-binding domain to the region surrounding residue 80.

These recent developments in the molecular biology of 17β-HSD deficiency have permitted understanding of why these patients undergo virilization at the time of puberty. The consensus is that androstenedione, which is produced by the testes in supraphysiologic concentrations at the time of puberty, provides the substrate for the extraglandular production of testosterone by one of the four 17β-HSD isoenzymes that are not impaired in this disorder. However, two clinical features of 17β-HSD deficiency await adequate explanation. It is not clear why inadequate virilization is more complete during embryonic development, when the external genitalia do not virilize at all, than at the time of puberty, when a substantial masculinization of the phenotype occurs. In addition, it is not clear why the embryonic structures of the developing male genitalia respond to the hormonal abnormalities created by 17β-HSD deficiency in a different way. In this disorder the Wolffian derivatives undergo almost normal virilization during embryogenesis, whereas the external genitalia do not virilize at all. Further studies of subjects affected by 17β-HSD deficiency should help to answer these important biologic questions.

Treatment   Patients are usually raised as females and treatment consists of gonadectomy followed by estrogen replacement at the time of expected puberty. When the diagnosis is correctly identified in early infancy and gender reassignment is possible, the patients should receive testosterone treatment at pediatric doses and genitoplasty early in infancy and be replaced with adult doses of testosterone at the time of expected puberty. The basic enzymatic defect persists, and impaired spermatogenesis is present during adulthood.

TYPE 2 5α-REDUCTASE DEFICIENCY   The enzyme 5α-reductase is involved in the conversion of testosterone into the powerful 5α-reduced metabolite dihydrotestosterone (DHT). Two isoenzymes have been isolated that share this enzymatic activity, and have been designated types 1 and 2 5α-reductase. The clinical syndrome is associated with mutations of the type 2 isoenzyme.

Table 61-11
Summary of the Mutations Detected in Type 3 17β-HSD

Ethnic background	Family history	Mutation	Comment
Homozygous patients			
Lebanese	Yes	Arg80Gln	Residual enzymatic activity
Brazilian	Yes	Arg80Gln	Residual enzymatic activity
Syrian	No	655-1, G-A	Disrupt splice acceptor
Greek	Yes	655-1, G-A	Disrupt splice acceptor
American	No	325+4, A-T	Disrupt splice donor
American	No	325+4, A-T	Disrupt splice donor
German	No	325+4, A-T	Disrupt splice donor
German	No	Phe208Ile	Inactivates enzyme
Iranian	No	Ser65Leu	Inactivates enzyme
Polish	No	Δ 777–783	Frame shift truncates protein
Brazilian	No	Ala203Val	Inactivates enzyme
Brazilian	Yes	Glu215Asp	Inactivates enzyme
Compound heterozygous patients			
American	No	Ser232Leu	Both inactivate enzyme
		Met235Val	
American	Yes	325+4, A-T	Disruption of splice donor; inactivates enzyme
		Pro282Leu	
Brazilian	Yes	Arg80Gln	Residual enzyme activity; disrupts splice acceptor
		326-1, G-T	
Italian	No	325+4, A-T	Disrupt splice donor

ACQUIRED CASES OF HYPERGONADOTROPIC HYPOGONADISM

None of these conditions of primary hypogonadism has a genetic basis. They are listed according to their etiology in Table 61-12.

HYPOGONADOTROPIC DISORDERS

Several congenital and acquired disorders (listed in Table 61-2) account for HH. Their common denominator consists of the impaired production of LHRH or of gonadotropins by the hypothalamus or pituitary gland. This in turn results in failure to stimulate the correct production of gonadal steroids and in a spectrum of clinical manifestations that vary depending on whether the abnormality developed before birth, before puberty, or after puberty (Table 61-4).

HYPOGONADOTROPIC DISORDERS ASSOCIATED WITH ISOLATED GONADOTROPIN DEFICIENCY

KALLMANN'S SYNDROME **Background** The first description of Kallmann's syndrome (KS) dates back to 1856 by Maestre de San Juan, but it was not until the original description by Kallmann in 1944 that the disease was recognized as an inherited entity.

It is found in 1 of every 10,000 newborn males, and in 1 of every 50,000 newborn females, and occurs in both sporadic (in up to 50% of the cases) and familial forms. Because of its predominance in the male sex, it was initially thought that KS is an X-linked disorder. However, there is now convincing evidence that additional forms exist that demonstrate autosomal recessive and autosomal dominant forms of transmission. In agreement with this heterogeneous inheritance, chromosomal abnormalities have been detected both in the X chromosome and, in patients with the autosomally inherited form, in autosomes. Within the X chromosome, the KS gene has been located in the Xp22.3 region. At least five different syndromes are caused by abnormalities involving this region of the X chromosome, including short stature, chondrodysplasia punctata, mental retardation, ichthyosis, and KS. The location of the gene(s) responsible for the autosomally transmitted KS is not yet known.

Embryology of the LH-RH Neurons The molecular events associated with the migration of the LHRH-secreting neurons during embryogenesis are intimately connected with the pathogenesis of KS. These neurons originate in the epithelium of the olfactory placode, from which they migrate into the brain by the 12th week of gestation along the pathway of the developing olfactory tract, represented by the olfactory, terminalis, and vomeronasal nerves. The LHRH neurons enter the brain through the nervus terminalis and vomeronasal, and thence into the septal-preoptic area and the hypothalamus. The normal migration of the LHRH neurons depends on genes located in Xp22.3, the same area of the X chromosome that is deleted in patients with KS. This was demonstrated by Schwanzel-Fukuda in a fetus with KS and a deletion of Xp22.3, in whom LHRH-expressing neurons were not found in the hypothalamus, but were instead identified beneath the forebrain, within the dural layers of the meninges and on the cribriform plate. When the migration is completed, there are fewer LHRH neurons in the brain (approximately 1500), than there were in the nose at the beginning of this process, probably because during the migration many cells die or differentiate into other cell types. Only after reaching their final destination in the brain do the LHRH-containing neurons acquire the capacity to secrete LHRH.

Radiation
  15 rads: transient germinal epithelium damage causing ↑ FSH
  >600 rads: permanent germinal damage
  2000–3000 rads: permanent germinal and interstitial damage
Autoimmunity
  As part of the autoimmune polyglandular syndrome type II
Trauma
  Frequent acquired cause of hypogonadotropic hypergonadism because of the relatively unprotected intrascrotal position of the testes

Clinical Features   Individuals affected by KS can sometimes be recognized before puberty because of the presence of microphallus or cryptorchidism. Most patients, however, are recognized at puberty when they present with delayed appearance of the secondary sex characteristics or for the development of eunuchoid features. Abnormalities observed in KS other than those related to hypogonadism include hyposmia, anosmia, cleft lip, or cleft palate. Other symptoms occasionally described with the disease are sensory neural deafness, ocular motor abnormalities, abnormal spatial visual attention, cerebellar dysfunctions, talipes cavus deformity, and unilateral renal aplasia. It should be kept in mind that anosmia, which is considered one of the cardinal symptoms of KS, is not present in every patient, and that in some large series this feature is absent in up to 50–60% of the cases. In addition, some KS patients also manifest other diseases, like chondrodysplasia punctata, mental retardation, ichthyosis, short stature, and ocular albinism, which are associated with the deletion of the distal short arm of the X chromosome.

The hypogonadism of KS is caused by reduced secretion of LHRH by the hypothalamus, as shown by the observation that in almost every KS individual there is adequate response of LH and FSH after sufficient priming of the pituitary with exogenous LHRH. The decreased secretion of LHRH results in an abnormal secretory pattern of LH pulses, ranging from decreased or absent amplitude to diminished frequency. In the complete form of LHRH deficiency, LH and FSH deficiency is severe, and no evidence of sexual maturation is evident. In the incomplete form (known as the fertile eunuch syndrome), there is either normal FSH and low LH, or partial defects in both, with some degree of germ cell maturation. Although it is widely believed that this syndrome represents a continuum with the complete form of KS, the genetic studies to establish whether the fertile eunuch syndrome is a variable manifestation of KS or a separate genetic entity have not been performed. Microphallus and olfactory disturbances appear to be less common in this variant. Another variant form of isolated gonadotropin deficiency has been described in men with isolated FSH deficiency.

Laboratory tests reveal low serum FSH and LH levels and low testosterone. However, a large degree of heterogeneity in the serum levels of FSH and LH can be observed.

Diagnosis   The diagnosis is suggested by the typical clinical picture and laboratory tests that demonstrate hypogonadotropic hypogonadism. The most challenging differential diagnosis is with delayed puberty. Important criteria are the ability to show the presence of anosmia or hyposmia, any other associated congenital defect or positive family history for KS. However, the separation of these two entities may require a prolonged period of observation.

Genetic Basis of Disease   Using positional cloning techniques, two independent groups have isolated a candidate gene for KS *(KAL)* that is located at the Xp22.3 interval. Evidence that this gene is responsible for KS comes from the observation that in some affected patients it contains extensive deletions, or point mutations. The presence of a highly conserved *KAL* homolog in the Y chromosome has somehow delayed the development of mutation scanning strategies; however, point mutations within the 14 exons of the gene have been detected in at least 14 patients.

Molecular Pathophysiology   Sequence analysis of the *KAL* cDNA has provided interesting insights into the pathogenesis of Kallmann's syndrome. The predicted protein is 680 amino acids long. Owing to the lack of a transmembrane domain or a phosphatidyl inositol anchorage site, it is believed to be an extracellular matrix molecule. Search for homologies has shown the presence of two important motifs. The first is a 4-disulfide core domain, found in a number of proteins with protease inhibitory activity, that is located in the N-terminal part of the molecule. The second is a region of similarity with the fibronectin type III repeat, found in numerous adhesion molecules involved in axon to axon interaction or in neuronal migration. Based on these sequence homologies, the KAL protein may represent an extracellular matrix factor that possesses both antiprotease and adhesion (or antiadhesion) functions. This protein may play a critical role in the migration process involving the olfactory and LHRH neurons during embryogenesis. Its absence or abnormal function in Kallmann's syndrome may help to explain the double clinical defect (hypogonadism, anosmia) observed in many of these patients. In addition, abnormalities of the KAL protein could also explain some of the other, less frequent, manifestations of the disease. RNA *in situ* hybridization studies have demonstrated *KAL* mRNA expression in the Purkinje cells of the cerebellum, the nucleus of the oculomotor nerve, the mesonephros, and the facial mesenchyme, which correlates with the presence in some KS patients of cerebellar dysfunctions, eye movement defects, unilateral renal aplasia, and cleft palate.

Despite these important new developments, there are still a number of unanswered questions. The *KAL* gene does not explain the autosomal types of KS, which is probably caused by abnormalities of autosomal genes that influence the migration of the LHRH neurons to the hypothalamus. In addition, it is not clear what the defect is in patients with hypogonadotropic hypogonadism without anosmia or in patients affected by the sporadic form of KS. If the sense of smell of patients without anosmia is normally developed, one can hypothesize that their olfactory bulb has developed normally and that their *KAL* gene may be normal, or that they represent a group with variable penetrance of the LHRH migratory defect, with mutations that do not completely impair function of the *KAL* gene product. In patients affected by the sporadic form of KS there is no supportive family history of an X-linked trait. Initial reports in abstract form suggest that the *KAL*

gene is mutated only in a minority of these patients. Therefore the sporadic form of KS seems to be a heterogeneous disorder, arising in part from *de novo* mutations of the *KAL* gene, and in part from mutations of an unidentified autosome.

HYPOGONADOTROPIC HYPOGONADISM FROM BIOLOGICALLY INACTIVE LH

HYPOGONADISM CAUSED BY MUTATIONS IN THE GENES OF THE HPG AXIS   Abnormalities occurring in the sequences of the genes encoding LHRH, the LHRH receptor, LH, or FSH have the potential of explaining some cases of idiopathic hypogonadotropic hypogonadism (HH) or infertility in males. However only a few such patients have been identified. It is likely that heterozygous patients with these mutations are subfertile; therefore, one can speculate that patients carrying homozygous mutations in the genes of the HPG axis are very rare because they would be the product of two subfertile individuals.

Evidence supporting the possibility that mutations of the LHRH gene are associated with hypogonadotropic hypogonadism is illustrated by the hpg mouse, an animal model with hypogonadism and infertility as a result of a deletion of the LHRH gene. Two studies have investigated the sequence of gonadotropin-releasing hormone (GnRH) in patients with idiopathic HH. Weiss et al. studied the coding region, the promoter, and the 3' untranslated tract of the GnRH gene in three male patients. No mutations were detected in this study. In another investigation reported in abstract form, Layman and collaborators identified a homozygous A-to-G transition 85 bp downstream from the splice donor site of intron 2 in 1 of 117 patients with HH. These authors speculated that this mutation could create a potential alternate donor splice site or affect transcription of the GnRH gene; however, no data have been presented in this regard.

Mutations of the FSH gene have not been reported in men, but are known to account for hereditary hypergonadotropic ovarian failure in women. Individuals of male sex with mutations of the FSH receptor have been identified in these pedigrees. These individuals are predicted to have a spectrum of abnormalities ranging from azoospermia to normospermia; however, the characteristics of their sexual phenotype have not yet been described in detail. The FSH receptor can also undergo activating mutations, as recently described by Gromoll and collaborators in a man who was able to sustain spermatogenesis despite being hypophysectomized.

HYPOGONADOTROPIC HYPOGONADISM CAUSED BY MUTATIONS OF THE LH GENE   In males, only one case of hypogonadism with infertility has been associated with mutations of the LH gene. The propositus of this study was a 17-year-old patient with a hormonal profile showing low testosterone, high immunoreactive LH, and normal FSH. A testicular biopsy specimen revealed arrest of spermatogenesis and the absence of Leydig cells. When this patient was treated with exogenous hCG, a normal increase in testosterone secretion occurred, which was in contrast with the initial diagnosis of primary hypogonadism. Subsequently, the LH of this patient was found to be devoid of biologic activity using a dispersed Leydig cell bioassay, suggesting the production of an immunologically active but biologically inactive LH molecule. Sequence analysis of the coding sequence of the LH β gene revealed the patient to be homozygous for a missense mutation, Gln to Arg at amino acid residue 54. Functional experiments have shown that this mutation impairs the ability of the resulting LH to bind and activate its receptor. This study was extended to other

Table 61-13
Syndromes Associated With Central Nervous System Disorders

	Clinical and genetic features
Prader-Willi syndrome	*See text*
Möbious syndrome	*See text*
Laurence-Moon-Biedl syndrome	*See text*
Börjeson-Forssman-Lehman syndrome	X-linked mental retardation (XLMR) syndrome, mapped to Xq26–27. Associated with supraorbital ridges, ptosis, hypotonia, mental retardation, hypogonadism
LEOPARD syndrome	Lentigenes, ECG conduction defects, ocular hypertelorism, pulmonic stenosis, retarded growth, deafness, hypogonadism
Rud's syndrome	Mental retardation, epilepsy, hypogonadism, ichthyosis
Lowe's syndrome	XLMR syndrome mapped to Xq26. Associated with cataracts, renal tubular acidosis, hypogonadism, hypotonia, mental retardation
Carpenter's syndrome	Obesity, acrocephaly, craniosynostosis, agenesis of the hands and feet

members of the family, including three maternal uncles and the mother of the propositus, and has elucidated how heterozygous carriers of both sexes manifest clinically. The mother of the patient, an obligate heterozygote, underwent normal puberty and was fertile. The three heterozygous maternal uncles underwent normal puberty, reported normal libido and sexual performance, and had a normal physical examination. However, their serum testosterone concentration was low in several measurements, and at the time of the study they were childless. Therefore, given the limited nature of the pedigree, it would appear that heterozygous mutations of the LH gene do not manifest with important clinical abnormalities in the female sex, but may be associated with infertility in males.

Although mutations of the LH gene causing hypogonadism and infertility have only been detected in one male patient, the description of this case report has permitted a better understanding of the physiologic role played by LH during the embryologic development of the male sexual phenotype. The proband of this study was born with normal masculinization of his genitalia and with descended testes. Thus one can argue that LH is not critical for normal male sexual development, and that during embryogenesis adequate amounts of androgens from the adrenals or the testes are produced, probably under the stimulation of placental hCG.

HYPOGONADOTROPIC HYPOGONADISM ASSOCIATED WITH CENTRAL NERVOUS SYSTEM DISORDERS

Several congenital syndromes have been described in which central nervous system (CNS) disorders are associated with hypogonadotropic hypogonadism (Table 61-13). One hypothesis is that these disorders may be the consequence of a spectrum of congenital abnormalities disrupting at the same time the neuronal pathways leading the LHRH neurons into the hypothalamus and the normal development of the CNS. The identities and function of the gene(s) responsible for this group of syndromes are unknown.

PRADER-WILLI SYNDROME (PWS) Introduction PWS is an unusual condition occurring in 1 of every 25,000 newborns that is associated in about 50% of the cases with an interstitial deletion of chromosome 15, involving 15q11–q13. It is generally sporadic, although 10 families with more than one case have been described. The origin of the deleted chromosome 15 is paternal in almost all the individuals investigated by cytogenetic and DNA studies, making PWS one of the best examples for parental imprinting in humans.

Clinical Features The PWS phenotype is characterized by childhood obesity, carbohydrate intolerance, short stature, mental deficiency, infantile hypotonia, small hands and feet, a characteristic face, and hypogonadism. The latter is present in 95% of the cases, is mostly caused by GnRH deficiency, and is associated with cryptorchidism, micropenis, and scrotal hypoplasia. The response of serum gonadotropin concentrations to a single GnRH bolus is usually attenuated; however, long-term treatment with clomiphene or GnRH may stimulate gonadotropin secretion.

Genetic Basis of Disease The large size of the 15q11–q13 deletion has hampered the identification of candidate PWS genes in this region; however, the identification of two atypical PWS deletions, which greatly reduces the common region of deletion, has helped in focusing the quest for candidate genes to a smaller portion of 15q11–q13. As a result, three genes displaying paternal allele-specific expression have been recently identified in the area commonly deleted in PWS. One of these genes is the small nuclear ribonucleoprotein-associated polypeptide N gene *(SNRPN)*, a molecule involved in mRNA splicing, that is transcribed only from the paternal allele. The two other candidate genes are *PAR-5* and *PAR-1*, which were isolated from a YAC contig of the region deleted in PWS, and cluster together with *SNRPN* to a roughly 250-kb subregion of 15q11–q13.

Molecular Pathophysiology of Disease Whether any of these three genes is directly involved in the phenotype of PWS is currently under investigation. Considering the role played by *SNRPN* in mRNA splicing and the complex phenotype of PWS, one is tempted to speculate that a malfunctioning *SNRPN* contributes to PWS by altering the expression of several different and unrelated genes. This theory awaits confirmation in the years to come.

LAURENCE-MOON-BIEDL SYNDROME This entity has traditionally been considered as the association of retinitis pigmentosa, obesity, mental retardation, polydactyly, spastic paraparesis and hypogonadism. Currently two syndromes with slightly different manifestations are recognized: the Laurence-Moon syndrome, in which spastic paraparesis dominates and polydactyly is very rare; and the Bardet-Biedl syndrome, with very rare neurologic complications and frequent occurrence of dystrophic extremities and renal disease. Hypogonadism is present in both entities, and it manifests with microphallus, hypospadias, and undescended testes in prepubertal boys. There is disagreement on the origin of testicular failure as cases of both primary and secondary hypogonadism have been reported in the literature. The dis-

Table 61-14
Functional Causes and Systemic Diseases Associated with Hypogonadotropic Hypogonadism

Functional causes
  Hyperprolactinemia: Patients affected by hyperprolactinemia can develop HH because of either the direct effect of hyperprolactinemia, which impairs the hypothalamic release of LHRH, or the mass effect of the adenoma.
  Cushing's syndrome: Increased cortisol impairs normal production of LHRH.
  Exercise: In men strenuous exercise can associate with decreased testosterone levels, without any change in LH and Testesterone Binding Globulin (TeBG) production. Usually without clinical signs.
  Melatonin: One case of HH with increased melatonin production has been described, in which spontaneous normalization of melatonin hypersecretion was associated with reversal of HH.
Systemic diseases
  AIDS: Frequent association between AIDS and HH (observed in 30% of HIV-positive patients in one study). In addition, preliminary data suggest that hypogonadism is probably associated with the wasting syndrome frequently observed in these patients.
  Obesity: associated with ↓ TeBG, ↓ total testosterone, normal free testosterone, and ↑ estradiol (the latter because of increased peripheral conversion of aromatizable compounds).
  Liver diseases: Multifactorial hypogonadism, with primary and secondary components, characterized by ↓ testosterone, ↑ estradiol, and gonadotropin levels from normal to moderately elevated.
  Renal failure: Multifactorial hypogonadism with primary and secondary components. Hyperprolactinemia, a cause of HH, is present in 25% of men with chronic renal insufficiency undergoing dialysis.
  Hemochromatosis: Multifactorial hypogonadism, with primary and secondary components. The secondary form of hypogonadism is predominant and it is caused by accumulation of iron in the pituitary gland. It is associated with diabetes, liver cirrhosis, and congestive heart failure.

ease is transmitted in an autosomal recessive manner, as indicated by a consanguinity rate of 48% among parents of affected patients in one series, and by a male to female ratio of 47:41 by combining two large studies.

MÖBIOUS SYNDROME   This entity is also known as congenital oculofacial paralysis and is associated with multiple cranial nerve paralyses involving the 3rd, 4th, 5th, 9th, 10th, and 12th nerves, mental retardation, gait disturbances, peripheral neuropathy, and hypogonadism. Gonadotropin deficiency has been documented in several patients; however, considering the normal gonadotropin response to GnRH, GnRH deficiency is likely to constitute the primary defect. It is transmitted as an autosomal dominant trait, although sporadic cases have also been described. The clinical characteristics of the remaining syndromes belonging to this group of diseases are summarized in Table 61-13.

HYPOGONADOTROPIC HYPOGONADISM ASSOCIATED WITH ADRENAL INSUFFICIENCY

ADRENAL HYPOPLASIA CONGENITA   Background Adrenal hypoplasia congenita (AHC) is a rare congenital disorder in which hypogonadotropic hypogonadism is associated with adrenal insufficiency. Two forms of this disorder have been described, the miniature adult form, secondary to ACTH deficiency transmitted as an autosomal recessive character, and the X-linked primary, or cytomegalic form.

Clinical Features   ACH usually manifests with symptoms of adrenal insufficiency early in infancy. Gonadotropin deficiency is commonly associated with the X-linked primary form of AHC, and is noted at the expected time of pubertal maturation. The nature of the hypogonadotropic hypogonadism reported in these patients may be caused by pituitary gland dysfunction, based on lack of gonadotropin responses to prolonged pulsatile stimulation with synthetic GnRH.

Genetic Basis of Disease   The gene for AHC has been mapped to chromosome Xp21 based on the deletion of this region in patients with a contiguous gene syndrome that includes AHC, glycerol kinase deficiency, and Duchenne muscular dystrophy.

The gene responsible for this syndrome, designated *DAX-1*, has recently been isolated. It is a new member of the nuclear hormone receptor superfamily, and has been found to be deleted in some AHC patients or to have point mutations in patients with AHC, but no evidence of a deletion. The exact role played by this gene in the pathogenesis of the hypogonadotropic hypogonadism observed in AHC is currently under investigation.

ACQUIRED FORMS OF GONADOTROPIN DEFICIENCY FROM FUNCTIONAL CAUSES OR SYSTEMIC DISEASES

A brief discussion of these diseases, none of which has a genetic etiology, is presented in Table 61-14.

ANATOMIC DISORDERS ASSOCIATED WITH HYPOGONADOTROPIC HYPOGONADISM

A large number of anatomic disorders are associated with HH (Table 61-2). Infiltrations of the pituitary by inflammatory lesions, as in the case of lymphocytic hypophysitis, or by granulomatous diseases, such as in sarcoidosis, tuberculosis, and histiocytosis X, are well-described causes of gonadotropin deficiency. Other disorders consist of tumors developing in the hypothalamic–pituitary region. They act by the local compression and destruction of the gonadotroph. They include nonsecretory or secretory pituitary adenomas, craniopharyngiomas, dysgerminomas, metastases, meningiomas, hamartomas, or hypothalamic tumors.

Panhypopituitarism can also be the consequence of pituitary apoplexy. This condition has been described in patients affected by pituitary tumors or diabetes mellitus, in patients harboring lesions producing increased intracranial pressure, and in the setting of radiotherapy and anticoagulation. Residual LH and FSH deficiency after pituitary apoplexy has been described in 76 and 58% of the patients, respectively, and diminished testosterone secretion in 85% of the subjects investigated in a large study. The mechanism is believed to reflect the direct destruction of the adenohypophysis by the apoplexy.

Table 61-15
Systemic Disorders Associated With Infertility

Diseases impairing fertility	*Mechanism*
Infections	
Gonorrhea	Obstruction of the seminal pathway
Syphilis	Orchitis
Tuberculosis	Obstruction of the seminal pathway
Infectious parotitis	Orchitis
Chlamydial epididymitis	Obstruction of the seminal pathway
Brucellosis	Orchitis
Filariasis	Obstruction of the seminal pathway
Typhoid	Orchitis
Endocrine Disorders (other than hypogonadism)	
Thyrotoxicosis	Increased estrogen level
Diabetes	Impotence and ejaculatory disturbances
Systemic illnesses	
Renal failure	Hypogonadism
Hepatic failure	Hypogonadism
Sickle cell anemia	Impaired sexual maturation
Neurologic diseases	
Paraplegia	Impotence, ejaculatory dysfunctions, decreased testosterone level
Chronic respiratory tract diseases	
Bronchiectasis	Associated with immotile cilia syndrome or with Young's syndrome
Chronic sinusitis	
Chronic bronchitis	

GERMINAL CELL FAILURE

INTRODUCTION Infertility is usually defined as lack of conception after 1 year of adequate and unprotected intercourse. In many Western countries, approximately 15% of couples are unable to conceive within 12 months. Female and male factor disorders are equally distributed, and each are present in about 50% of the cases. Significant abnormalities are found in the male alone in one-third of the cases, while in an additional 20% of cases abnormalities are found in both members of the couple. Therefore, given the high incidence of concomitant disease in both partners, basic evaluation is warranted in both the man and the woman.

In the male partner it is useful to proceed in a stepwise way, starting with (1) a careful medical history, which is then followed by (2) a physical exam, (3) a semen analysis, and, if useful, (4) a testicular biopsy.

By questioning the patient, one should always keep in mind that a group of treatable causes of infertility are associated with decreased testosterone production as a result of a hypothalamic or pituitary cause. To ascertain this the patient should be asked whether he underwent normal puberty, and whether he is affected by symptoms of impotence or decreased libido. If this is the case, an appropriate work-up, including measurement of LH, FSH, testosterone, and prolactin and imaging of the pituitary, is warranted. In addition to hypogonadotropic disorders, numerous systemic disorders should be considered a possible secondary cause of male infertility (Table 61-15).

Another possible cause of infertility is caused by a direct anatomic damage to the testis or seminal pathways. Consequently it is important to investigate whether the patient has a history of testicular trauma or torsion or of genitourinary or testicular infections, and whether he underwent genitourinary surgery. Finally, it is important to ascertain whether the patient has been taking medications or illicit drugs or has been exposed to environmental factors known to affect normal gonadal function (Table 61-1).

It is useful to classify disorders of the germinal compartment of the testes according to the serum FSH level. Based on this, male infertility can be of the hypogonadotropic, hypergonadotropic, or eugonadotropic type. Hypogonadotropic disorders fall in the group of diseases discussed in Table 61-2. Patients with a hypogonadotropic disorder are affected by the simultaneous failure of the interstitial and germinal cells and belong to a group of infertile patients for which successful treatments are available.

Hypergonadotropic and eugonadotropic disorders represent categories of infertility that are characterized by increased or normal levels, respectively, of FSH (Table 61-3). In such states, the interstitial compartment is usually not affected by the disease, and therefore infertility will be the only symptom. Although a large number of conditions have been associated with male infertility, specific etiologies have been defined for only a small percentage of the conditions recognized. In many series, 60–80% of the infertile population consists of individuals with varicocele or idiopathic disease (Table 61-16). Since the exact mechanism causing infertility in men with varicocele is not understood, one can conclude that the etiology of infertility has not been defined in as many as 80% of patients. It is reasonable to assume that a better understanding of the basic biology of male infertility will permit a more successful treatment of these patients in the future.

EUGONADOTROPIC GERMINAL CELL DYSFUNCTION

OBSTRUCTION OF THE SEMINAL PATHWAY *Introduction* Acquired or congenital obstruction of the epididymis, vas deferens, or ejaculatory duct leads to azoospermia in up to 6% of infertile men. Up to 40% of men with azoospermia are eventually found to have an obstruction at some level of the seminal pathways, which is typically associated with normal testicular development, normal FSH, and normal histology of the testicular biopsy specimen. A classification based on the findings at explor-

Modified from Baker HGW, et al. Relative incidence of etiological disorders in male infertility. In: Santen RJ, Swerdloff RS, eds. Male Reproductive Dysfunction: Diagnosis and Management of Hypogonadism, Infertility and Impotence. New York: Marcel Dekker, 1986; pp. 341–372.

atory scrototomy in 365 patients with azoospermia and normal serum FSH levels is shown in Table 61-17. Of these entities, only those with a genetic etiology will be discussed in detail. The others are grouped in Table 61-18.

CONGENITAL BILATERAL ABSENCE OF THE VAS DEFER-ENS (CBAVD) Background The most frequent genetic abnormality causing ductal obstruction is known as congenital bilateral absence of the vas deferens, or CBAVD, an autosomal recessive condition associated with azoospermia, which accounts for at least 1–2% of infertility cases in men. A similar abnormality, known as congenital unilateral absence of the vas deferens (CUAVD) has also been described, and it is believed to be an incomplete form of CBAVD. Recently, both these entities have been shown to be a genital form of cystic fibrosis (CF).

Clinical Features The typical patients with CBAVD presents with infertility as a result of absence of the vas deferens, and with a low-volume (<1 mL), acidic (pH <7.0) ejaculate, which consists predominantly of prostatic fluid. The seminal vesicles of these patients are often anatomically and functionally abnormal, as shown by the fact that only a small percentage of men with CBAVD have completely normal seminal vesicles on transrectal ultrasonography, and by the observation that CBAVD is associated with agenesis or dysplasia of the seminal vesicles in up to 75% of patients. Testicular anatomy and function are otherwise normal, as shown by their normal size and consistency on physical exam, the normal level of testosterone and FSH, and the normal histology of the biopsy specimen. Therefore, apart from azoospermia, the typical patient with CBAVD is healthy, and, unlike patients with CF, is not affected by disease of the respiratory system and pancreas.

Diagnosis On physical exam, the scrotal vasa are frequently not palpable, and the epididymal remnants are firm and enlarged. As stated above, further support for the diagnosis of CBAVD comes from the association of azoospermia with a low-volume ejaculate and normal testicular size and function.

Genetic Basis of Disease Absent or rudimentary vasa deferentia are not unique to CBAVD, but are noted also in 95% of males with CF. Since the ductal abnormalities of these two entities are very similar, it was postulated that CF and CBAVD could be related disorders. This possibility was confirmed once the gene responsible for cystic fibrosis was isolated and identified as the cystic fibrosis transmembrane-conductance regulator *(CFTR)* gene, and mutations of this molecule were detected both in CF and CBAVD. As a consequence, the general consensus is that CBAVD is a primarily genital form of cystic fibrosis, and that CF and CBAVD are extremes of a clinical spectrum. Studies performed on patients representing the entire clinical spectrum of CF have shown that the minimal amount of residual normal *CFTR* mRNA that is compatible with a normal phenotype is between 8 and 12% of normal. In patients with severe cystic fibrosis this amount is reduced to less than 1–3% of normal, whereas in those with an intermediate level of normal *CFTR* mRNA, a phenotype of mild cystic fibrosis develops. Hence, since CBAVD patients have an even milder form of CF that is uniquely localized in the vas deferens, the level of normal *CFTR* mRNA transcribed in this syndrome should be only slightly below the minimal amount necessary for a normal phenotype.

Molecular Pathophysiology of Disease A recent study, analyzing a large number of patients with CBAVD and CUAVD, has permitted a better understanding of the genetic lesions responsible for this condition (Table 61-15). In this series, mutations in the open reading frame (ORF) of both *CFTR* alleles were present in 19% of patients (group A); 33% of patients had the combination of one *CFTR* allele mutated in the ORF and one *CFTR* allele carrying the 5T variant (group B). The latter is a form of *CFTR* associated with 5 thymidines in the sequence known as "polyT sequence," which is located in intron 8 and is associated with reduced levels of *CFTR* mRNA. Thus, when the 5T allele is present together with an ORF mutation in the other allele, the amount of correctly transcribed *CFTR* is minimal, and the patient exhibits CBAVD. Mutations in the ORF of only one *CFTR* allele were present in 19% of patients (group C), suggesting that in this group other, but still undetected, *CFTR* abnormalities must be present in the second allele outside the ORF. The 5T allele and a normal second allele were present in 7% of patients (group D), also suggesting that the second allele must carry other still undetected abnormalities. Finally, 22% of patients did not carry ORF mutations or the 5T allele of *CFTR* (group E), suggesting either that CBAVD is a heterogeneous syndrome caused by genes other than *CFTR*, or that other undetected mutations are present in both alleles outside the ORF.

CUAVD and the *CFTR* Gene The presence of ORF mutations of the *CFTR* gene in patients with CUAVD is well established. In addition 25% of such patients were found to carry a 5T allele in the study by Chillón et al., suggesting that CUAVD could very well be an incomplete form of CBAVD.

Therapy Until recently patients with CBAVD were considered untreatable. However, the combination of in vitro fertilization with direct microsurgical aspiration of sperm (MESA) from the proximal ductal system has been successful in achieving pregnancies.

OTHER EUGONADOTROPIC DISORDERS CAUSING GERMINAL CELL FAILURE These disorders are discussed in Table 61-1.

HYPERGONADOTROPIC GERM-CELL FAILURE

IDIOPATHIC GERMINAL CELL FAILURE Background and Clinical Features This is a heterogeneous and large group, accounting for 60–80% of all patients with infertility. In the large majority of cases these patients are normally virilized, and the only clinical finding may be the presence of atrophic gonads. Some of

Table 6-17
Relative Frequency of Conditions Associated With Obstructive Azoospermia

Abnormality	Percentage of patients	Cause	Other features
Empty epididymis	13	Defective spermatogenesis, immune orchitis	Associated with abnormal testicular biopsy and abnormal spermatogenesis
Capital epididymal blocks	29	Young's syndrome, caused by inspissated secretion	Obstruction between ductuli efferentes and ductuli epididymis
Caudal epididymal blocks	19	Postinfective (epididymitis, after tuberculosis or gonorrhea)	
Blocked vas	11	Postinfective or postsurgery	Vasectomy is the most frequent cause of vasal obstruction
CBAVD *See text*	18	Associated with mutations of CFTR	
CUAVD *See text*	5	Associated with mutations of CFTR	
Ejaculatory duct blocks	14	Congenital, traumatic, or neoplastic (local extension of prostate cancer)	Diagnosed preoperatively, based on features of ejaculate

Table 61-18
CBAVD Patients Classified According to Genetic Abnormalities of CFTR

Mutation in ORF of both alleles (19%)
Mutation in ORF of one allele, and 5T variants in second allele (33%)
Mutation in ORF of one allele (19%)
5T variant in one allele (7%)
No detectable abnormalities of CFTR (22%)

Modified from Chillon M, et al. N Engl J Med 1995;332:1475–1480.

these patients may have normal FSH levels, and therefore are classified as eugonadotropic, whereas others have increased FSH levels and, consequently, are classified as hypergonadotropic. The histologic abnormalities detected in the testes of these patients are heterogeneous and consist of germinal cell aplasia (also known as Sertoli-cell-only syndrome [SCOS] of which two types have been described depending on whether germinal cell aplasia is present in each [type I] or most [type II] testicular tubules), arrest of germinal cell maturation at the spermatogonia or spermatocyte stage, or hyalinization of the seminiferous tubules with hypospermatogenesis. In these patients semen analysis may encompass the entire spectrum of sperm abnormalities, ranging from azoospermia to oligospermia, astenospermia, and presence of a stress pattern of sperm morphology. A careful medical history can help in detecting the minority of cases caused by infection, cytotoxic drugs, immunologic factors, or cryptorchidism; however, the mechanism leading to most of the cases is unknown. A genetic component has long been suspected, and autosomal or X-linked inheritance has been detected in a number of pedigrees. In addition, a genetic abnormality arising as a *de novo* mutation of an elusive "azoospermia factor" in the Y chromosome has been theorized since 1976.

Identification of a Putative Azoospermia Factor of the Y Chromosome   A systematic approach to the identification of the azoospermia factor (AZF) has recently produced some important developments. Using genomic DNA extracted from 89 men in whom semen analysis had revealed azoospermia and testicular biopsy specimens showed a range of abnormalities ranging from SCOS to maturation arrest, Reijo and colleagues have performed a detailed deletion map of a 30-Mb fragment of the Y chromosome, which included proximal Yq, the centromere, and Yp. A deletion of an area called the AZF region was detected in 12 of 89 azoospermic men in a portion of Yq, which appeared to be a new event, since no such deletion was present in the genomic DNA of 7 male relatives that was tested as a control. By using exon trapping, these investigators were able to identify a novel gene within the AZF region. This molecule, named *DAZ* (deleted in azoospermia), is a single-copy gene that is transcribed only in the testes and bears an RNA recognition motif, suggesting that it is an RNA-binding protein. The frequency by which the AZF region is deleted is high. According to the study of Reijo et al., 1 of every 8 men with azoospermia has a deletion of the AZF region. Thus, since approximately 1 in 1000 men is azoospermic because of severe spermatogenic defects, it appears that the AZF region is deleted at the rate of 1 in every 10,000 newborn males.

Absence of Correlation Between *DAZ* Deletion and Biopsy Findings   The histology of the testes that was available in 9 of the 12 men carrying a deletion of the AZF region was very heterogeneous. Five patients were affected by SCOS and four by maturation arrest at the level of spermatogonia or premeiotic spermatogenic cells. In addition, in two of the patients with maturation arrest, the biopsy specimen revealed the presence of occasional mature, condensed spermatids. This finding was quite unexpected, since the general consensus has always been that the azoospermia factor regulates some specific step in the process of sperm maturation, and therefore its absence should have been associated with a specific histologic abnormality.

Current Status of Knowledge   The information generated by these new findings can be condensed in four major points. First, germ cells can persist, at least in some men, even when an intact AZF region is not present. Second, the AZF region is not absolutely required for the production of mature, condensed spermatids, and it is not essential for progression of male germ cells through meiosis. Third, SCOS and testicular maturation arrest are not distinct disorders, at least when associated with Yq deletions,

but appear to represent different manifestations of the same underlying defect. Finally, despite these considerations, the AZF region contains a gene, *DAZ*, which may represent the elusive azoospermia factor. As an RNA-binding protein, DAZ has all of the features of a potentially important regulatory molecule and could regulate some basic phenomenon required for sperm maturation. In addition, *DAZ* was found to be deleted in 12 azoospermic patients, and because it is transcribed only in the testes, it is expressed in a location that seems directly tied to spermatogenesis. Further evidence supporting an important role for the AZF region in spermatogenesis comes from the observation that this segment of the Y chromosome is also deleted in a minority of patients (2 of 35) affected by oligospermia (i.e., <15–10,000,000 sperm/mL). In addition, loss of the *Drosophila* gene *boule*, which has remarkable similarity to *DAZ*, results in azoospermia in fruit flies.

Even if the evidence provided to date is convincing, more concrete proof, for example in the form of inactivating point mutations in nondeleted azoospermic and oligospermic patients, will be necessary to establish that the *DAZ* transcript is critical for spermatogenesis.

Unsolved Issues   The identification of *DAZ* does not exclude that other genes within AZF may be important for gametogenesis, or that genes essential for spermatogenesis may be present elsewhere in the human Y chromosome. One such factor could belong to the *RBM* (RNA-binding-motif) family of genes, which were previously reported by Ma and collaborators as putative AZF candidates, and do not map within the AZF region identified by Reijo et al. Further evidence for the presence of other Y-derived factors important for spermatogenesis comes from two recent deletion studies of the Y chromosome in azoospermic and oligospermic patients. In the study of Najmabadi et al., microdeletions were detected in 11 of 60 patients. In 4 of these 11 patients the deletion did not correspond to the AZF region. In the study of Vogt and collaborators, microdeletions were found in 13 of 370 patients. Interestingly, this study has identified two additional segments of Yq, besides the AZF region of Reijo et al., that are deleted in azoospermic patients. These regions of the Y chromosome have been named AZF-a, -b, and -c. According to the data of Vogt et al., and in contrast to the finding of Reijo et al., the deletion of each of the three potential AZF regions is associated with a specific histologic abnormality of the testis. Deletion of AZF-c, which coincides with the segment defined as the AZF region by Rejio et al., is associated with type II SCOS. Deletions of AZF-a and -b are associated with type I SCOS and spermatogenic arrest at the spermatocyte stage, respectively. A candidate spermatogenesis gene for segment AZF-b is *RBM1*, which is absent in patients lacking this fragment of chromosome Y. Candidate spermatogenesis genes for segment AZF-c are *DAZ* and *SPGY* (the latter is a new gene, isolated by Vogt's group, which is localized in this area of chromosome Y and has 85% sequence similarity to *DAZ*). No candidate spermatogenesis genes for segment AZF-a have yet been identified.

Extension of these studies to a larger number of patients should help to understand more details on the role played by Yq in controlling spermatogenesis.

Therapy   Since the understanding of the basic mechanisms causing idiopathic germinal cell failure is poor, the medical treatments available are mostly empirical or based on uncontrolled trials. The rationale is to use hormonal therapy with the aim to stimulate sperm production. Treatments include administration of clomiphene citrate, tamoxifene, testolactone, testosterone, bromo-

criptine, gonadotropins, and gonadotropin-releasing factor. There is no clear data indicating whether these treatments result in increased pregnancy rate or improved semen quality.

New hope for some of these patients is offered by the development of new techniques in assisted reproduction, including subzonal sperm microinjection and intracytoplasmic injection of spermatozoa retrieved from the epididymis. Some of these techniques are becoming increasingly more effective in improving the prognosis of severe male factor infertility.

CRYPTORCHIDISM   Background and Clinical Features
Cryptorchidism is a common anomaly detected in humans and many animal species, consisting of the failure of one or both testes to reach their final destination inside the scrotum at the end of the process of testicular migration from the abdominal cavity. It is a condition occurring with increasing frequency, found in 3–5% of newborn males. Many undescended testes will spontaneously reach the scrotal cavity during the initial 3 months of life, and consequently the incidence of cryptorchidism will drop to 0.8% at 1 year of age. Spontaneous testicular descent is unlikely to occur after the 12 month of age. Bilateral cryptorchidism is observed in 15% of the cases.

The clinician should be aware of other conditions mimicking cryptorchidism, such as pseudocryptorchidism, in which the gonad at times occupies a scrotal position and at times retracts in the inguinal canal, and the ectopic testes, in which the testes migrate through an ectopic pathway and eventually will occupy a pubic, femoral, perineal, or superficial inguinal position.

Etiology   Many cryptorchid testes will eventually be unable to fulfill their reproductive role because of abnormalities occurring in their germinal compartment. In this regard, it is controversial whether the failure to descend into the scrotum is the cause or the consequence of the abnormalities present in a cryptorchid testis. Although there is not a unifying theory for all cases of cryptorchidism, failure to migrate inside the scrotum could be, at least in some cases, the consequence of blunted gonadotropin production during the third trimester of gestation. Migration of the testes inside the scrotum is thought to be regulated by the shortening of the gubernaculum, an androgen-dependent process requiring both maternal hCG and fetal LH, which stimulate the fetal testes to produce testosterone. The importance of testosterone in this process is also indirectly underscored by the observation that antiandrogen treatment of pregnant dams blocks testicular descent in rat pups. There is still considerable disagreement as to whether cryptorchidism should be considered a genetic disease or not, and evidence in favor of and against such a possibility has been presented. However, many genetic diseases associated with impairment of androgen synthesis or action, and with conditions predisposing to inadequate intraabdominal pressure, like the prune belly syndrome, cause bilateral cryptorchidism. Additional information on the genes responsible for the intrascrotal migration of the testes during sexual differentiation is offered with increasing frequency by the study of mice models carrying targeted deletion of factors thought to be active during urogenital embryogenesis. One such factors is the *Hoxa10* gene, a member of the *HOX* gene family of transcription factors, whose absence is associated with developmental abnormalities, including bilateral cryptorchidism resulting in severe defects in spermatogenesis and increasing sterility with age. Progress in the identification of the network of genes involved in regulating testicular descent during embryogenesis should help in understanding the cause, and in directing a proper treatment of cryptorchidism.

Treatment   The first step in the treatment of these boys is using hCG or LHRH alone or in combination. hCG should be given at a total dose of 10,000 IU for 2–3 weeks, after 6 months of age. LHRH can be given as a nasal spray at the dose of 20 μg/d. The success of this treatment, which can be inflated if the treated patient population includes boys with retractile testis, varies and ranges between 10 and 35% among the different studies. Subjects who do not respond to medical treatment should undergo orchiopexy and should be operated on between ages 6 and 18 months. Another important consideration in favor of early surgery is that intra-abdominal positioning of a testis is associated with an increased risk of malignant degeneration. Despite this, there is no clear-cut evidence that demonstrates that placing the retained testis inside the scrotum reduces the risk of neoplastic degeneration.

ANDROGEN RESISTANCE   The infertile man syndrome is one of the phenotypes described in patients with androgen resistance. A study published in 1982 suggested that at least 40% of patients with idiopathic azoospermia were affected by a form of androgen resistance causing decreased ^{3}H-DHT binding of the receptor, as assessed by monolayer binding assay of genital skin fibroblasts cultured from these patients. No abnormalities of the pituitary–testicular axis were detected in these individuals. Although an interesting possibility, there is significant controversy as to whether 40% of infertile patients are indeed affected by androgen resistance as this study implies. Molecular analysis of the androgen receptor in this group of patients has not been performed in a systematic way; however, a partial gene deletion in one of seven azoospermic men was detected by PCR and Southern analysis in one study.

62 Ovarian Diseases

Elizabeth A. McGee and Nicholas A. Cataldo

INTRODUCTION

The primary function of the human ovary, the production of fertilizable gametes, is essential to the survival of the human species. Traditionally, ovarian gametogenesis has been viewed as intricate and delicately balanced, but recent information suggests that, although intricate, this process may be governed by multiple parallel, redundant systems, which evolved by enhancing reproductive success. Knowledge of ovarian physiology derived from disciplined studies at the molecular level is just beginning to be applied clinically, and the application of molecular biology to the prevention and treatment of ovarian disease is still in its infancy. This chapter will outline some aspects of current research on the molecular physiology of both the normal and abnormal ovary.

OVARIAN FUNCTION

OVARIAN ONTOGENY In the third week after fertilization, germ cells arise in the yolk sac endoderm at the caudal aspect of the embryo and begin to migrate to the gonadal ridge, which at this stage consists of coelomic epithelial mesenchyme and elements of the mesonephros. At this stage presumptive ovaries are indistinguishable from presumptive testes. The factors that govern formation of the gonadal ridge are not known, but the expression of the orphan nuclear receptor SF1, the *DAX* gene product (which may be regulated by SF1), and the nuclear receptor WT1, that is the product of the Wilms' tumor gene, are all required early in this process. Although *SRY* plays a key role in testicular differentiation in the male, genes that play a similar role in directing ovarian development have not been identified. Differentiation of the ovary is generally believed to begin approximately 2 weeks later than testes become identifiable in males and to proceed by default when testis-determining factors are absent. Unlike the testis, which can form in the absence of germ cells, formation of a functional ovary requires the interaction of germ cells with the gonadal ridge and mesonephros; if germ cells do not reach the presumptive ovary, it degenerates into a fibrous streak.

The regulation of germ cell migration to the gonadal ridge is not clearly defined, but adhesion molecules, including fibronectin, laminin, and the integrins, likely play a role. However, a more clearly understood pair of molecules in this process, extensively studied in the mouse, is the receptor c-kit and its ligand. A transmembrane protein with tyrosine kinase activity encoded by the dominant white spotting (W) locus, c-kit is expressed by primordial germ cells. The kit ligand, called stem cell factor (SCF) or mast cell growth factor, is encoded by the steel (Sl) locus and is expressed by cells along the germ cell migration pathway from the yolk sac to the genital ridge. There are two splice variants of the transmembrane form of SCF, one of which can be cleaved to form a soluble form (Fig. 62-1). Mutations in cell surface SCF, such as Steel-dickie and Steel-panda, result in the decreased ability of germ cells to migrate to the genital ridge and decreased survival of the cells that do arrive. Many W mutations result in female sterility or decreased numbers of primordial follicles, but some mice with these mutations are fertile, even in the face of reduced receptor kinase activity or reduced c-kit mRNA expression. Though c-kit and its ligand are thought to have a critical role in germ cell migration and proliferation, the lack of a uniform phenotype in these mutants suggests a more complex system with other modulating factors involved. Transforming growth factor-β (TGF-β) has been suggested to be a chemotactic factor released by the genital ridge, whereas tumor necrosis factor (TNF)-α has been suggested as an early germ cell mitogen that along with leukemia inhibitory factor (LIF) could prevent premature differentiation during migration. Future investigations will likely clarify the roles of growth and chemotactic factors and adhesion molecules in the process of germ cell migration.

After reaching the genital ridge, the primordial germ cells, now called oogonia, must continue to both proliferate and survive. Oogonia become invested by a single layer of flat, pregranulosa cells derived from the rete ovarii to form primordial follicles. If they fail to be surrounded by these pregranulosa cells, oogonia die spontaneously, apparently by apoptosis. The receptor c-kit and its ligand, SCF, may play a role in oogonial survival, since apoptosis can be blocked in vitro by added SCF. Other factors implicated in the regulation of oogonial apoptosis include LIF and related molecules oncostatin M and ciliary neurotropic factor, as well as interleukin (IL)-4 and basic fibroblast growth factor (bFGF). The role of these factors in human germ cell migration, proliferation, and survival has not been defined. Few studies have been performed on human embryonic tissue, but in one such study c-kit was localized to human oogonia.

In the human embryo, germ cells reach the gonadal ridge by the 7th week of gestation. Oogonia increase their number by mitosis from approximately 10,000 by the 6th week to 6 million by 20 weeks' gestation, at which time their number peaks and mitosis ceases. By 11–12 weeks, some oogonia have begun their transformation into oocytes by entering meiosis; they remain arrested at
Figure 62-1 **(Left)** The c-kit receptor is a member of the PDGF branch of the tyrosine kinase family of receptors, with a large extracellular domain containing five IgG-like domains. Its intracellular tyrosine kinase region is separated by a kinase insert. **(Right)** SCF, the c-kit ligand, has two forms (KL-M1 and KL-M2) that can be generated by alternate splicing of the same gene. The KL-M1 form can be proteolytically cleaved to form a soluble KL-S. (Modified from Donovan, 1994.)

the dictyotene stage of the first meiotic prophase until they are ovulated. Oocytes that do not enter meiosis are lost by the time of birth. Formation of primordial follicles (Fig. 62-2A) begins at about 16 weeks' gestation and is complete by 6 months after birth.

Factors other than those mentioned may also play a role in follicle formation. Involvement of gonadotropins or other pituitary factors in the process of follicle formation is suggested by one study showing that this process occurs inefficiently and to variable degrees, with a poorly organized rete ovarii, in monkeys that were hypophysectomized *in utero*. Other genetically but not physiologically defined factors regulate follicle formation in the fetal sheep ovary: the Booroola Merino and Inverdale strains, studied because of their tendency to have large litters, have also been noted to have delayed or defective follicle formation. Homozygotes for the Booroola mutation $FecB^B$ show delayed follicular formation and growth, whereas homozygotes for the Inverdale mutation $FecX^I$ show a total failure of development past the primary stage. Genes in humans homologous to the sheep $FecB^B$ and $FecX^I$ have not yet been identified.

Some germ cell tumors in women are believed to arise from germ cells that failed to migrate successfully to the gonad. These tumors can be found at many sites near the normal germ cell migration path, including the mediastinum, adrenal, and both the small and large intestinal mesenteries, as well as in more remote sites such as the pineal gland. The incidence of germ cell tumors has been increasing, leading some investigators to conclude that environmental and intrauterine toxic exposures may affect germ cell migration. Further study of these tumors, as well as of the migration of germ cells in animal models, may give additional insight into the processes of germ cell migration, proliferation, survival, and tumorigenesis.

FOLLICULAR DEVELOPMENT   Primordial follicles (Fig. 62-2A) can begin further development at any time after their formation, or they may remain dormant for more than 50 years. As a primordial follicle begins to mature, the granulosa cells become cuboidal and divide to form several layers around the oocyte (Fig. 62-2B). The zona pellucida, a mucoid glycoprotein layer around the oocyte that is formed by both granulosa cells and the oocyte, appears as the granulosa cells differentiate. A distinct theca layer begins to condense around the follicle and becomes vascularized. Since the theca is separated from the avascular granulosa by a basement membrane, access of serum proteins to the granulosa and oocyte is functionally limited. As both the granulosa and theca cells continue to divide and the oocyte increases in size, an antrum develops within the granulosa layer, filled with fluid that is a transudate from the thecal vasculature (Fig. 62-2C). Follicular fluid also contains proteins secreted by granulosa cells, many of which are paracrine factors important for continued follicular development.

How primordial follicles are maintained in a relatively static condition for decades and then induced to grow and differentiate is still poorly understood. Static primordial follicles do not demonstrate differentiated function, suggesting that they either express suppressors, or fail to express activators, of the genes that induce follicular differentiation. One candidate suppressor of granulosa cell differentiated function is the product of the Wilms' tumor gene WT1, a zinc-finger transcription factor. In rodents, high levels of WT1 are expressed in the gonadal ridge and in the granulosa cells of primordial follicles and lower levels in primary and early secondary follicles, but minimal levels in more developed follicles. WT1 represses the expression of inhibin-α, insulin-like growth factor (IGF)-II, IGF-I receptor, early growth response gene *(EGR)*-1, *PAX-2*, platelet-derived growth factor (PDGF)-A, colony-stimulating factor (CSF)-1, and TGF-α. It has been hypothesized that by suppressing the expression of growth and differentiation genes, WT1 can act on early follicles as a "stasis factor," and as the level of WT1 falls, the rate of follicular development increases. Further studies should elucidate the regulation of WT1 expression, as well as the interaction of WT1 with other genes involved in follicular development.

A second factor that may play a role as an activator of human folliculogenesis is growth and differentiation factor (GDF)-9, a member of the TGF-β superfamily. In the mouse, GDF-9 is expressed in oocytes at the primary through preovulatory follicle stages, and it is necessary for follicular development past the early secondary stage. Female mice deficient in GDF-9 are infertile and resistant to gonadotropin stimulation, despite the expression of gonadotropin receptors in their ovaries.

Early follicular growth can occur in the absence of gonadotropin stimulation, as evidenced by the presence of preantral follicles in the ovaries of anencephalic infants as well as in gonadotropin-deficient patients. Although larger antral follicles are clearly dependent on gonadotropin for further mitosis and differentiation as well as protection from apoptosis, several in vitro studies of rodent follicles have suggested a role for follicle-stimulating hormone (FSH) in earlier follicle development as well, perhaps in conjunction with activin or other factors. The initial stimulus to follicular growth and the exact role of FSH in preantral follicle development are still not clearly understood, nor is the molecular basis of the induction of granulosa cell FSH receptors. An interaction of granulosa and oocyte factors is likely to regulate early follicle growth and development.
Figure 62-2 **(A)** Primordial follicles just below the epithelium of the ovary (dark arrows) with clusters of transitional and primary follicles (open arrow). **(B)** Primary follicles (P) and a secondary follicle with an oocyte (O) surrounded by granulosa cells (G) with an external theca layer (T). **(C)** A slightly larger follicle that is beginning to develop an antrum (A). **(D)** A maturing Graafian follicle, with a large antrum (A), a cumulus (C) surrounding the oocyte (O), with well-developed granulosa and theca layers. **(E)** Higher magnification of the follicular wall of a preovulatory follicle. The granulosa layer is separated from the thickened theca layer by the basement membrane (B). Just beneath the basement membrane, a rich vascular network (dark arrows) is developing. **(F)** An atretic follicle, with cellular debris or apoptotic bodies (dark arrows) visible in the antrum.

THE OVARIAN CYCLE Cyclic ovarian function, which leads to the maturation of usually a single dominant follicle per ovulatory cycle, its transformation into a corpus luteum, and then the regression of the corpus luteum in the absence of pregnancy, is dependent on the pulsatile secretion of FSH and luteinizing hormone (LH), which begins at puberty. The ovarian cycle is normally 26–30 days in length and has been classically divided into a follicular phase and a luteal phase, each of roughly 14 days, separated by ovulation at midcycle (Fig. 62-3). For reference, the first day of menstrual bleeding is designated Cycle Day 1. The follicular phase, which begins with the onset of menses, is characterized by the selection of one member of a cohort of developing follicles as the dominant follicle. This follicle becomes the largest follicle in either ovary, reaching a diameter of 20 mm or more before ovulation, and secretes increasing amounts of estrogen, principally 17-β-estradiol. The dominant follicle can be identified by vaginal sonography by cycle day 6 and it has established an estrogen-dominant follicular microenvironment by cycle day 8.
Figure 62-3   The serum levels of estrogen (E), progesterone (P), FSH, and LH throughout the follicular and luteal phases of the ovarian cycle. (Modified from Carr BR The ovary, in Textbook of Reproductive Medicine.)

The luteal phase, which begins at the time of ovulation, is characterized by the organization of the corpus luteum from the remaining granulosa and theca cells of the dominant follicle. The corpus luteum produces the large quantities of progesterone necessary to sustain an early pregnancy.

FOLLICULAR STEROIDOGENESIS   Only healthy, dominant follicles produce significant quantities of estrogen. Follicular steroidogenesis requires the cooperation of both granulosa and theca cells and the stimulation of these cells by FSH and LH, respectively. FSH and LH are heterodimeric glycoprotein hormones produced by the pituitary, which share a similar α-subunit but contain distinct but related β-subunits. The receptors for FSH and LH are also distinct but homologous proteins, each of which is a member of a family of receptors that have seven membrane-spanning regions and transmits its signal by activating a guanosine triphosphatase (GTPase) designated G_s (Fig. 62-4). Binding of gonadotropin to its receptor thereby activates adenylate cyclase and increases generation of cyclic adenosine monophosphate (cAMP), an activator of the protein kinase A pathway of signal transduction. Although the role of FSH and LH receptors in steroidogenesis is well established, LH has been suggested to have additional functions resulting from the activation of the phosphoinositol or protein kinase C pathways.

Because all of the enzymes required for estrogen synthesis from cholesterol are not present in significant quantities in either the granulosa or theca alone, both cell types must participate in this process. Theca cells, which have receptors for LH but not FSH, respond to LH stimulation by producing the enzymes P450 cholesterol side-chain cleavage ($P450_{scc}$) and 17α-hydroxylase/17,20-lyase ($P450_{c17}$), as well as cholesterol transport proteins. Cholesterol is metabolized to pregnenolone by $P450_{scc}$ and then to dehydroepiandrosterone (DHEA) by $P450_{c17}$ (Fig. 62-4). DHEA is converted to androstenedione by the action of 3β-hydroxysteroid dehydrogenase (3β-HSD). Androstenedione diffuses out of the theca cell, across the follicular basement membrane, and into granulosa cells, where it is converted into estradiol through the action of the enzymes P450 aromatase ($P450_{arom}$) and 17β-hydroxysteroid dehydrogenase, both stimulated by FSH. This cooperation in estrogen biosynthesis between theca and granulosa cells has been termed the two-cell model of ovarian steroidogenesis.

FOLLICULAR SELECTION AND DOMINANCE   In a spontaneous cycle, usually only one follicle is selected to become dominant and eventually ovulate, while the remaining antral follicles undergo atresia. How a follicle escapes the fate of atresia and assumes dominance is not well-understood. Our understanding of this process has been considerably enhanced in the last few decades by observing the results of ovulation-induction treatment in infertile women. Such therapies work by increasing circulating FSH, of either exogenous or endogenous origin, and thereby often result in multiple dominant follicles in a single cycle. Greater than
Figure 62-4 The cooperation of the granulosa and the theca cells in the production of estrogen from cholesterol.

normal FSH levels appear to "rescue" follicles in a developing cohort that might otherwise have undergone atresia, lending credence to the concept that FSH plays a critical role in this process. In a natural ovulatory cycle, circulating FSH begins to rise at the end of the luteal phase, in association with decreasing serum levels of estrogen and inhibin, a granulosa-derived protein that inhibits pituitary FSH release. This FSH increase advances the growth of the leading cohort of follicles. By cycle day 6, the estrogen and inhibin secreted by these growing follicles lead in turn to a decrease in serum FSH (Fig. 62-4), which coincides with a slowing of growth and the eventual atresia of the nondominant follicles. The role of FSH in preventing follicular atresia is supported by studies of granulosa cell apoptosis in vitro.

FSH stimulates granulosa cell expression of several proteins that could function in a positive feedback loop to promote development of the dominant follicle. Foremost of these is the LH receptor. The induction of LH responsiveness in the granulosa is critical to allow the dominant follicle to ovulate in response to the midcycle LH surge and subsequently to develop into a corpus luteum. It also may allow intracellular cAMP levels to be maintained in the face of declining FSH stimulation. FSH also induces granulosa cells to increase production of other proteins that modulate follicular function. Among these are inhibin, which acts on the theca to augment androstenedione biosynthesis as well as on the

pituitary to decrease FSH output, thereby slowing the development of nondominant cohort follicles; and IGFs, which augment FSH-induced growth and steroidogenesis in granulosa cells as well as LH-induced steroidogenesis in the theca.

How the dominant follicle is selected from among its cohort of recruited follicles is still a mystery. Current research into this question has focused on the regulation of LH receptors, the process of angiogenesis in growing follicles, the role of cytokines and growth factors in the synergistic regulation of follicle growth and steroidogenesis, and the regulation of aromatase by steroid metabolites. The role of the balance in intracellular second messenger pathways and receptor crosstalk is also being investigated.

Numerous putative autocrine and paracrine ovarian regulatory factors have been investigated extensively in the last few years. Much information has accumulated on the action of such factors on ovarian tissues in vitro (Table 62-1), and clearly such proteins have a role in modulating gametogenesis and steroidogenesis. The ability of a factor to elicit a response in an isolated in vitro system does not necessarily imply that it can elicit the same response in a dynamic organism with multiple modulatory influences. The role of individual factors in vivo has been technically more difficult to establish, because many of these factors exist in families of multiple receptors and ligands that can potentially compensate for another factor rendered inactive, for instance with genetic knockout techniques. Such genetic knockouts can also produce systemic effects that prevent the demonstration of a clear ovarian role of the nonfunctional gene. Targeted transgenic studies in which the alteration of gene expression can be limited both developmentally and anatomically will likely aid in clarifying the intraovarian role of many substances. The difficulties encountered in identifying the roles of each ovarian paracrine factor suggest that the redundancy in the reproductive system has evolutionary significance in that it reduces the dependence of the reproductive process on any single gene product.

FOLLICULAR ATRESIA Atresia is a fate that can befall a follicle at any stage of development, from primordial to antral. Once a primordial follicle leaves the quiescent state and enters the growth phase, it must progress inevitably to either ovulation or loss through atresia. The majority of ovarian follicles are lost through atresia. Atresia of antral follicles has been well-studied in several animal models and has been shown to involve granulosa cell apoptosis. Apoptosis thus plays a major role during folliculogenesis and dominant follicle selection, in addition to its role in the reduction of oocyte number in the fetal ovary. Apoptosis is usually associated with degradation of chromosomal DNA into oligonucleosomal fragments by the activation of a Ca^{2+}/Mg^{2+}-dependent endonuclease. This degradation of granulosa cell DNA thus serves as a biochemical marker of follicular atresia and has allowed the study of this process in some detail. Studies have identified endonuclease activity and DNA fragmentation in the granulosa cells of rat follicles induced to become atretic by gonadotropin withdrawal. DNA fragmentation has been found in granulosa cells from atretic follicles in a number of species, including primates.

The regulation of antral follicular apoptosis has been extensively studied in an immature, pregnant mare serum gonadotropin (PMSG)-treated rat model. PMSG stimulates the development of numerous healthy antral follicles, which can be dissected from the ovary and either cultured intact or punctured to obtain granulosa cells for monolayer culture. In both models, apoptosis is induced by culture in serum-free medium, and can be prevented by adding

Table 62-1
Growth Factor Actions

Growth factor	Action
Tyrosine kinase receptors	
Insulin/IGF-I/IGF-II	Possibly increase early follicle growth; enhance gonadotropin-stimulated steroidogenesis; enhance LHR expression
EGF/TGF-α	Stimulate GC proliferation; inhibit FSHR(GC) and LHR(TC) expression; inhibit steroidogenesis and inhibin secretion
FGF	Stimulate GC proliferation; inhibit TC steroidogenesis; stimulate angiogenesis
SCF	Germ cell migration, proliferation, and survival; oocyte growth?; meiosis inhibition?
PDGF	Enhance TC proliferation; inhibit TC steroidogenesis
VEGF	Stimulate angiogenesis
NGF	Possible role in early follicle development
KGF	GC mitogen; suppress apoptosis
HGF	GC mitogen
Serine–threonine kinase receptors	
inhibin[a]	Augment thecal steroidogenesis
activin	Augment progesterone production; enhance FSH action
MIS	Promote meiosis, follicle growth
TGF-β	Follicle growth; inhibit thecal $P450_{c17}$; inhibit differentiation
GDF-9[a]	Initiation of follicle development?
7-TM G-protein linked receptors	
GnRH	Promote meiosis; promote apoptosis
VIP	Early follicle growth and differentiation
PACAP	Early follicle growth and differentiation
Cytokines	
IFN-γ	Decrease granulosa steroidogenesis; promote apoptosis
TNF-α	Decrease granulosa steroidogenesis; induce LIF/IL-1 expression
IL-1	Increase prostaglandins; decrease progesterone; prevent premature follicle rupture?
IL-2	Suppress ovulation; augment progesterone production
IL-6/IL-11/OSM/LIF	Promote germ cell survival; suppress FSH action

[a]Inhibin and GDF-9 are included with the serine–threonine kinases because of homology. Their receptors have not yet been described.
GC, granulosa cell; TC, theca cell.

to this medium FSH, LH/human chorionic gonadotropin (hCG), epidermal growth factor (EGF), or bFGF. IGF-I prevented granulosa cell apoptosis only in intact follicles, not in dispersed granulosa cells, suggesting that it acts on the theca. Growth hormone-induced IGF-I secretion also blocks apoptosis in preovulatory follicles. IL-1 also decreases apoptosis in intact follicles, apparently through nitric oxide acting as a mediator to raise intracellular cyclic guanosine monophosphate.

Other work has suggested a role for activin in follicular atresia and hence granulosa cell apoptosis. Activin is a protein product of granulosa cells, originally identified for its pituitary FSH-stimulatory action, that also affects steroidogenesis and other differentiated functions of granulosa and theca cells. In primates, systemic activin-A administration in the early follicular phase appears to cause the demise of the dominant follicle despite a rise in serum FSH. In vitro activin treatment of primate mature granulosa and luteal cells inhibits steroidogenesis and decreases the number of steroidogenic cells, but the role of cell death in these effects is uncertain. In an immature, PMSG-primed rat model, activin-A injected into the ovarian bursa promoted the atresia of antral follicles. Another study in which activin was subcutaneously administered to immature rats resulted in enhanced growth of smaller follicles, but increased atresia of granulosa cells within larger follicles. Also, an in vitro study of early antral follicles in culture demonstrated modest activin inhibition of apoptosis. Activin may

have different roles in small secondary and early antral than in large antral and preovulatory follicles. Further studies are needed to clarify the role of activin in follicle growth and apoptosis.

A number of molecules have been implicated as intracellular mediators of apoptosis in granulosa cells. Members of the Bcl-2 family of apoptosis regulatory proteins, which includes Bcl-2, Bax, Bcl-x-long, and Bcl-x-short, are expressed by granulosa cells of humans and other species. In the immature rat model described above, Bax mRNA expression by granulosa cells was decreased by in vivo PMSG treatment and increased in serum-free follicle culture, but Bcl-2 expression was unaffected. The tumor suppressor p53, which can promote apoptosis, was localized to granulosa cells only in atretic follicles, and its expression was decreased by PMSG and increased in serum-free follicle culture.

Another mediator of apoptosis is a cell-surface protein homologous to the TNF-α receptor, known as Fas, APO-1, and CD95. Fas can be activated to transduce an apoptotic signal by either a natural ligand (Fas ligand, a TNF-α homolog) or anti-Fas antibody. In women, Fas is expressed by luteinizing granulosa cells, with stimulation by interferon-γ (IFN-γ), and anti-Fas antibody triggers apoptosis. The intracellular events resulting from activation of Fas appear to involve activation of an acidic sphingomyelinase that can generate ceramide, an intracellular second messenger known to be capable of transducing an apoptotic signal. The action of Fas may be mediated in part through the Bcl-2 system.

Apoptosis may occur because of the presence of specific signals leading to cell death or may occur by default if positively regulating systems are not activated. The exact role of atresia in the dynamics of follicle growth and dominant follicle selection has not been clearly determined.

OVULATION   As the dominant follicle matures, it produces increasing amounts of estrogen, thereby effecting positive feedback on the pituitary gonadotrophs to produce the midcycle gonadotropin surge. The LH surge begins about 36 h and peaks about 10 h before ovulation; it triggers the major events of ovulation, including resumption of meiosis, cumulus expansion, cumulus-oocyte expulsion, and luteinization. The underlying regulation of these seemingly independent events has been studied intensively by those interested in both fertility control and infertility treatment. The duration of the LH surge has been found to be critical in triggering the events of ovulation: in primates, LH levels must be maintained for 18–24 h for oocyte maturation to occur, but for 34–48 h for optimal granulosa luteinization and corpus luteum function. Surge levels of LH are also necessary for the expression of prostaglandin-related genes in the rodent ovary.

In the developing follicle, resumption of meiosis is apparently inhibited by a signal to the oocyte originating in cumulus cells. In vitro, meiosis resumes in oocytes from antral follicles if the cumulus is removed or in response to cAMP. Atretic follicles of some species may exhibit meiosis briefly, as the granulosa cells lose function. Follicular fluid and granulosa cell-conditioned media both can inhibit meiosis of oocytes in vitro. These findings have led to the suggestion that granulosa cells produce an oocyte maturation inhibitor (OMI) under gonadotropin regulation. The identity of OMI has remained elusive. Hypoxanthine, a purine derivative, can inhibit meiosis in vitro and has been suggested to be the physiologic OMI. Other candidate OMIs have included inhibin and Müllerian inhibitory substance (MIS). Alternatively, the inhibition of meiosis may be a result of the functional relationship between the granulosa and the oocyte, and maturation may follow its physical disruption. This issue has not been resolved.

During the process of ovulation, the cumulus-oocyte complex loses its connection to the mural granulosa cells and probably briefly floats freely in the follicular fluid. At this time the follicular circumference is expanding, but the intrafollicular pressure does not increase. For the oocyte to be ovulated and reach the fallopian tube, it must pass through the mural granulosa layer, the follicular basement membrane, the theca layer, the ovarian stroma, and the surface epithelium of the ovary. This process is simplified because the enlarging follicle migrates (or expands) to the periphery of the ovary, adjacent to the surface epithelium.

Prostaglandins of the E and F series are elevated in follicular fluid before ovulation; and in rats prostaglandin synthetase is regulated by LH. The exact function of prostaglandins in ovulation is not known, but high doses of prostaglandin synthetase inhibitors have been reported to interfere with ovulation in humans.

The process of ovulation has been compared to the inflammatory response of wound healing. As in wound healing, plasminogen activators (PA) have been shown to play a role in the tissue remodeling that occurs during ovulation and formation of the corpus luteum. The regulation of the PA system at the time of ovulation has been recently characterized in the rat. Tissue plasminogen activator (tPA) is secreted by rat granulosa cells and produced but not secreted by the theca. Production of both tPA and an inhibitor, called plasminogen activator inhibitor (PAI), are stimulated by the gonadotropin surge; but PAI mRNA expression peaks about 6 h after rats are given hCG as a surrogate LH surge, while tPA expression does not peak until 12 h after hCG; thus the inhibitor is likely present before the production of the activator. Before ovulation, tPA mRNA and protein are expressed at high levels by the granulosa, while PAI is expressed strongly by the preovulatory theca and surrounding interstitium. After hCG, follicles enlarge rapidly and protrude from the ovarian surface. At 12 h after hCG, thecal expression of PAI in the portion of the follicle closest to the ovarian surface is lower than in the rest of the follicle. Granulosa expression of tPA in this region is greater than in the rest of the follicle. This temporal and spatial differential expression of tPA and its inhibitor could allow plasmin, which is generated from plasminogen from both serum and follicular fluid, to thereby activate collagenases only at the site of the stigma, where the cumulus-oocyte complex escapes from the follicle. The localized follicular expression of interstitial and Type IV collagenases and their inhibitors also appears to be regulated by LH.

Experimental disruption of the components of the PA system by several methods decreases the efficiency of ovulation, but seldom results in complete ovulatory suppression. Transgenic mice lacking either tPA or urokinase (uPA) gene function are fertile and have no obvious reproductive phenotype. Animals derived from these lines and lacking both functional genes have impaired wound healing. Although they are still fertile, early studies suggest that they ovulate at a decreased rate. The lack of clear inhibition of ovulation in the absence of plasminogen activators suggests that, as with follicle growth, the process of ovulation is also governed by redundant regulatory systems.

THE LUTEAL TRANSITION   After the release of the oocyte, the follicle begins its transition to the corpus luteum, the endocrine organ of pregnancy. The factors regulating this metamorphosis are not entirely understood, but the quality of luteal function is correlated with the adequacy of the follicular phase of the cycle. Studies of human granulosa and luteal cells cultured in vitro implicate the absolute level of intracellular cAMP in driving the cellular events of luteinization. The relatively lower levels of cAMP generated by FSH induce cell growth and replication, but the higher levels generated in response to LH lead to cessation of cell division and increased steroidogenesis. This cAMP effect may be augmented by other second messenger pathways activated by LH. Recently, a 43-kDa cAMP response-element binding protein (CREB) was shown to be expressed in growing primate follicles, but not in corpora lutea, and was correlated with expression of proliferating cell nuclear antigen. Differential expression of CREB may be another mechanism by which cAMP can exert different responses in the same tissue at different times.

Another key step in the formation of the corpus luteum is angiogenesis, the growth of numerous small vessels into the previously avascular granulosa. Vascular endothelial growth factor (VEGF), which stimulates proliferation of capillary endothelial cells, is expressed by human granulosa-luteal cells under positive regulation by LH. Other angiogenic factors, including bFGF and PDGF, may also be involved in this process. Vascularization allows the granulosa direct access to serum-derived growth factors and hormones, as well as to LDL-cholesterol used as a precursor for progesterone synthesis.

Progesterone, the principal product of the corpus luteum, is necessary both to prepare the endometrium for implantation and to maintain early gestation. The LH surge induces large increases in

granulosa cell steroid acute regulatory protein (StAR), P450$_{scc}$, and 3β-HSD expression, which lead to more efficient synthesis of progesterone. The human corpus luteum, unlike that of some other mammals, continues to secrete estrogen in addition to progesterone, particularly during the mid-luteal phase (Fig. 62-3). The human corpus luteum is also distinctive, in that 17-hydroxy-progesterone is not a substrate for the lyase function of P450$_{c17}$, as it is in many other species. Therefore the metabolism of pregnenolone either to progesterone by 3β-HSD or to androstenedione (an estrogen precursor) by P450$_{c17}$ is a key branch point in luteal steroid production and the regulation of these enzymes could be a critical determinant of luteal steroid products.

LUTEAL REGRESSION   In the absence of pregnancy, the corpus luteum begins to degenerate spontaneously after 2 weeks. This process, like follicular atresia, involves apoptosis, since both spontaneous and experimentally induced luteal regression are associated with morphologic apoptosis or oligonucleosomal DNA fragmentation. DNA fragmentation also occurs in luteinized human granulosa cells obtained during oocyte retrieval for in vitro fertilization.

Although prostaglandins have been implicated in spontaneous luteal regression in nonprimate species, the mediators of luteolysis in primates have not been definitively identified. A role for macrophages, lymphocytes, and their secretory products (cytokines), as well as prostaglandins, has been proposed. Macrophages and lymphocytes invade the corpus luteum and become more numerous as the corpus luteum ages. Cytokines, including IFN-γ of lymphocyte origin and TNF-α of macrophage origin, decrease steroidogenesis by luteal cells from human, rat, and cow. Fas antigen has been localized to the human corpus luteum, suggesting its involvement in luteal regression. The possible role of locally produced IFN-γ and lymphocyte-derived Fas ligand in mediating apoptosis during luteolysis is being investigated further.

OVARIAN SENESCENCE   Menopause refers to the permanent cessation of menses. Ovarian function generally follows a gradual decline, with cyclical bleeding becoming increasingly irregular; only about 10% of women experience an abrupt natural cessation of menses. Women may ovulate during the menopausal transition, but bleeding during this interval is often the result of fluctuations in estrogen levels not related to ovulation and luteal demise. Therefore, a patient's memory of the timing of her last menstrual period may not be an accurate estimation of the cessation of ovulatory function. Several prospective studies of ovarian function during the menopausal transition are currently under way.

Primordial follicles are believed to enter the growth phase at a relatively constant rate and are subject to loss through atresia at any stage of their development. There is excellent evidence, however, that their rate of loss increases as menopause approaches. This accelerated loss, predicted to begin on the average at age 38 years, is associated with a decrease in inhibin and an increase in FSH serum levels. It is not understood why the rate of follicular loss increases at this age, but it may be dependent on the mass of the declining primordial follicle pool. Ongoing studies of unilaterally ovariectomized women, who have a decreased follicle pool, may shed light on this question.

SUMMARY   Human ovarian tissue has been difficult to obtain for regulatory studies of folliculogenesis, luteinization, and luteolysis, and significant differences exist between humans and nonprimate animal models. Primate models will continue to be important in the study of these processes. However, the use of new technologies, which allow the evaluation of smaller amounts of tissue, as well as the development of cell lines and long-term tissue culture techniques, are allowing more in-depth studies of human tissues involving the regulation of follicular growth and atresia, ovulation, luteinization, and steroidogenesis.

OVARIAN DYSFUNCTION

DISORDERS OF INCREASED OVARIAN FUNCTION
McCune-Albright syndrome   McCune-Albright Syndrome (MAS), or polyostotic fibrous dysplasia, is caused by a postzygotic mutation in the *GNAS1* gene encoding the α-subunit of G$_{sα}$, a G protein that stimulates adenylate cyclase. The resulting sporadic activation of G-protein-linked processes throughout the body leads to diverse manifestations, including bony lesions, *café-au-lait* skin lesions, and endocrine dysfunction. In the ovary, the activating mutation of the adenylate cyclase system leads to the premature development of relatively normal-appearing follicles, which include a thecal component and can secrete estrogen, independent of gonadotropin stimulation. As a result, approximately half of girls affected with MAS will exhibit signs of isosexual precocity, often presenting with vaginal bleeding. Follicles grow and regress, causing relapsing and remitting manifestations of precocity. Normal pregnancies have been reported in women with MAS who had developed isosexual precocity, but infertility and subfertility have also been noted. Long-term evaluation of larger numbers of these patients will be needed to accurately evaluate their fertility potential. It is possible that some cases of idiopathic gonadotropin-independent sexual precocity may be localized manifestations of mutations similar to that in MAS, but this has not yet been demonstrated.

Granulosa Cell Tumors   Granulosa cell tumors represent 5–10% of all ovarian neoplasms and can be divided into two types, juvenile and adult, on the basis of histology and age of occurrence. Juvenile tumors are diagnosed in the first three decades of life, whereas adult-type tumors often present after menopause. About 5% of all granulosa cell tumors are diagnosed before the normal age of puberty. These tumors are generally multicystic and only rarely malignant. When these tumors occur prepubertally, about 80% produce sufficient estrogen to result in isosexual precocity; they account for about 10% of isosexual precocity in girls. Some of these tumors also produce inhibin, indicative of differentiated granulosa cell function; serum inhibin levels have been measured as a marker of tumor recurrence. Currently being sought are possible mutations in the genes encoding the inhibin subunits and gonadotropin and growth factor receptors that might promote granulosa cell replication and tumorigenesis.

In the adult-type granulosa cell tumor, mutations have been identified in the G$_i$ subunit of regulatory G proteins, although the physiologic significance of these mutations has not been established. It is uncertain why the inability to turn off a normally transcribed stimulatory signal, as with the G$_i$ mutation described above, should be manifested as tumor in later life, whereas the uncontrolled activation of the same signal, in MAS, is manifested as a relatively normal-appearing follicle earlier in life. Further studies will be necessary to elucidate the regulatory events involved in the stimulation of follicular growth by cAMP.

Multifollicular Ovulation   Twin and higher-order multiple gestations have long been a source of general curiosity and scientific interest. Monozygotic twinning results from the division of a single zygote after fertilization and is believed to be primarily related to zygote factors, with possible contributions from uterine and implantation factors. The incidence of monozygotic twinning

has been relatively constant over time and among diverse ethnic groups. By contrast, the incidence of dizygotic twinning, which results from the separate fertilization of two ovulated eggs, varies among ethnic groups and has fluctuated over time. Although the study of genetically identical monozygotic twins has been of great interest to both psychiatrists and geneticists because of the ability to examine the effect of different environments on the same genetic background, ovarian physiologists are understandably more interested in dizygotic twinning as a resource to evaluate the mechanisms determining the ovulatory quota. In every species there is a relatively constant number of oocytes released each cycle, the ovulatory quota, and hence an average litter size. In humans, usually only a single fertilizable egg is produced per cycle, though this control can be overridden by agents that increase gonadotropin stimulation of the ovary.

Variations in the incidence of dizygotic twinning has fueled discussion of the possibility of the underlying molecular mechanisms involved. Dizygotic twins have been noted to occur with a frequency as high as 1 in 8 pregnancies in some African populations and as low as 1 in 400 in some Pacific Rim countries. The incidence of twinning varies over the reproductive life span, with a higher frequency noted in the later reproductive years. Twinning also occurs with a high frequency within some families. Pharmaceutical agents to induce and augment spontaneous ovulation are associated with increased rates of multifollicular ovulation and multifetal pregnancy. One of these, clomiphene citrate, acts as a partial estrogen antagonist, thereby decreasing the negative feedback of estrogen on pituitary FSH secretion. This increase in FSH secretion presumably promotes ovulation by rescuing some recruited follicles that would otherwise have undergone atresia. Injections of FSH, as either human menopausal gonadotropins or purified or recombinant FSH, similarly stimulate development of increased numbers of follicles. The ability to induce superovulation pharmacologically and produce large numbers of mature oocytes in a single cycle has been critical in the development of in vitro fertilization and other assisted reproductive technologies. The introduction of these therapies for the infertile couple has fueled the study of the control of follicular growth, selection, dominance, and atresia.

Is there a molecular explanation for the increased ovulatory quota in families or population clusters with high rates of twinning? Mothers of twins have been studied in search of hormonal differences that could result from a genetic mutation and would be reflected in increased FSH action on the ovary. Some studies have shown higher levels of both estrogen and FSH in the follicular phase in mothers of twins, while inhibin levels may be either normal or elevated. Examination of familial twin clusters has revealed no mutations in the FSH-β, GnRH, LH-β, and FSH receptor genes. No other mutation has yet been found in humans which could account for the apparent increased gonadotropin activity and enhanced follicular survival, although studies of the GnRH receptor, inhibin-α, and the IGF system are ongoing.

More intriguing in understanding the molecular basis of the ovulatory quota have been genetic studies of two strains of sheep with large litter size, the Booroola Merino and the Inverdale. The Booroola gene mutation, designated $FecB^B$, is autosomal and is associated with an increased number of ovulations in the heterozygous state and a further increase in the homozygote. The altered physiology is not well-understood, but appears to result in maturation of larger numbers of follicles of a smaller size, with no net difference in total granulosa cell mass compared with wild-type Booroolas. Serum FSH is slightly elevated, but no other abnormalities in the hypothalamic–pituitary–ovarian axis are detectable. The Inverdale mutation, $FecX^I$, is X-linked. $FecX^I$ heterozygotes, like $FecB^B$ heterozygotes and homozygotes, show increased number of antral follicles, but homozygotes display failure of ovarian development and have streak gonads. Several groups are currently studying fecundity-related genes in sheep, but the relationship of these genes to twinning in humans has not yet been established.

DISORDERS OF DIMINISHED OVARIAN FUNCTION A number of disorders lead to diminished ovarian function. The spectrum of ovarian phenotypes of these disorders, which can include lack of estrogen production, menstrual acyclicity, and infertility, often overlaps, leading to confusion both in classifying these disorders and in determining their molecular basis. Diminished ovarian function is traditionally classified by its time of onset relative to menarche, but many disorders may have their origin in fetal life or childhood and remain unrecognized until clinical presentation when a girl fails to exhibit estrogen-induced secondary sexual characteristics at the time of expected puberty. A developmental approach to the classification of diminished ovarian function may be more helpful in understanding and recognizing these naturally occurring functional ovarian defects.

Ovarian Dysgenesis Absolute ovarian failure can result from improper ovarian development during embryogenesis. As discussed above, ovarian development depends on complex interactions between germ cells and components of the gonadal ridge, and interference with either component will result in ovarian dysgenesis, with fibrous streaks devoid of germ cells replacing the ovaries. Patients with streak ovaries are sexually infantile and generally have elevated serum gonadotropins by the time of expected puberty, because they lack normal negative feedback from ovarian estrogen and inhibin.

The most common cause of gonadal dysgenesis is Turner's syndrome, or monosomy X. The lack of a second X chromosome results in streak gonads and numerous characteristic somatic features, including shield chest, widely spaced nipples, and lymphatic abnormalities. In Turner's syndrome, germ cells apparently migrate normally to the ovaries, but primordial follicles are not formed efficiently and germ cells are lost. Gonadal dysgenesis in girls with Turner's syndrome could potentially result from a defect at any of the stages of follicle formation, including the entry of oocytes into meiosis and the association of oocytes with granulosa cells.

Gonadal dysgenesis also occurs in women with two apparently normal X chromosomes. Several disorders that include craniofacial abnormalities are associated with ovarian dysgenesis, including an interstitial deletion of chromosome 2q found in a girl with ovarian dysgenesis, mental retardation, craniofacial abnormalities, and cardiac defects. Deletions of chromosome 3q have also been associated with gonadal dysgenesis and ovarian failure. It is possible that large chromosomal deletions interfere with the process of pairing in meiosis, resulting in early germ cell loss. However, gonadal dysgenesis also occurs with apparently normal karyotypes. In Denys-Drash syndrome, a mutation in the *WT1* gene is associated with renal malformations, Wilms' tumor, and gonadal dysgenesis. Most cases of this syndrome are in genetic males, but a few have been reported in genetic females. Sensorineural deafness and blepharophimosis have also been associated with lack of ovarian function. Further study of the cause of the

associated disorders, many of which occur in midline structures, is likely to reveal common systemic molecular defects that have consequences for both the ovary and other organs during early development.

Failure of Ovarian Function In another group of disorders, the ovaries may be formed normally but still not function adequately. This might result from deficiency of specific factors regulating the initiation of follicle growth, such as GDF-9. Alternatively, normally formed but unresponsive ovaries have been shown to result from mutations affecting gonadotropin function.

An FSH receptor mutation was recently found among a group of Finnish women selected because of primary or early secondary amenorrhea. Initial study of these women suggested a recessive pattern of inheritance, and linkage analysis of multiplex families mapped the trait to chromosome 2p, the known location of the FSH receptor (FSHR) gene. Sequencing the FSHR gene in affected individuals revealed a mutation in exon 7, which encodes a portion of the extracellular domain of the receptor. In expression studies, this mutant receptor was unable to stimulate cAMP production in response to FSH. Further analysis of the receptor in the expression system demonstrated apparently normal ligand binding affinity but extremely low levels of receptor expression. The authors concluded that the recessive disorder leading to amenorrhea resulted from either abnormal FSH receptor trafficking or increased receptor degradation.

Though LH receptor (LHR) defects have long been recognized as a cause of testicular Leydig cell hypoplasia, recently an inactivating mutation of LHR was associated with anovulation in a woman who apparently exhibited secondary sexual characteristics at puberty but had a small uterus and never had regular cyclic menses. Three of her sisters were XY pseudohermaphrodites with normal female external genitalia and absent Leydig cells on gonadal histology. The LHR in all four of these patients contained a homozygous mutation that created a stop codon in the third intracellular loop, resulting in a nonfunctional receptor. The index patient's history demonstrates that LHR function is not essential for estrogen production in quantities sufficient for breast development, despite being necessary for ovulation and luteinization.

There are also isolated reports of mutations associated with gonadotropin subunit defects. Hypergonadotropic hypogonadism has been reported in a woman with a homozygous mutation in the FSH-β gene that results in an FSH molecule unable to bind to its receptor. Her fertility was restored with exogenous FSH treatment. In contrast to female heterozygotes with the FSHR mutation described above, who often have large families, this patient's mother, an obligate heterozygote, was subfertile and had ovulatory dysfunction. It is possible that the presence of a defective FSH molecule interfered with the function of the normal protein, thereby reducing the efficiency of follicle growth and ovulation.

Defects in the enzymes necessary for estrogen biosynthesis can also result in sexual infantilism, but ovarian stimulation and in vitro fertilization have been performed successfully in some patients with estrogen deficiency, indicating that estrogen is not necessary for human preovulatory follicle development.

Premature Ovarian Failure Premature ovarian failure (POF), also called premature menopause, is clinically defined as the loss of ovarian function before the age of 35 years despite adequate gonadotropin stimulation. Generally this term is applied to women who have undergone normal pubertal sexual maturation and have experienced some degree of cyclic ovarian function.

Premature ovarian senescence can result from either an abnormally small endowment of primordial germ cells or increased germ cell loss with time.

A number of X-linked conditions are associated with POF. Although Turner's syndrome usually results in severe early germ cell loss and gonadal dysgenesis, some germ cell survival can occur in ovaries of women with X-chromosome mosaicism or partial deletions, allowing for short-lived ovarian function including normal puberty and even, rarely, fertility. Two X-chromosome loci have been linked to POF by the study of translocations in affected families: POF1, at Xq26–q28, and POF2, at Xq13.3–q21.1. The specific genes at these loci responsible for this phenotype have not yet been identified.

Another X-chromosome locus that may be associated with ovarian senescence is the fragile X gene, *FMR-P*, which maps to Xq28. The fragile X syndrome is caused by a lack of FMR-P protein resulting from an amplification of CCG triplet nucleotide repeats within the promoter region of this gene. Males with fragile X syndrome exhibit mental retardation, facial dysmorphism, and macroorchidism. Female fragile X carriers show an increased rate of premature menopause and an increased rate of dizygotic twinning, which may be an epiphenomenon of the increase in gonadotropins as ovarian senescence approaches. It is presently unclear how these observations are related to the fragile X genotype. Although it has been suggested that FMR-P plays a role in germ cell proliferation in the testis, its role in the ovary has not been demonstrated. If it affects the efficiency of primordial follicle formation, a mutation at this locus might lead to a decrease in the overall follicular complement and thus an earlier cessation of cyclic ovarian function.

Any defect that decreases the efficiency of formation of primary follicles, resulting in a smaller starting pool of follicles, could potentially lead to POF, even if follicles were depleted at a normal rate. Increased atresia of oocytes in primordial follicles in the fetus or of small follicles at a later time could also lead to POF. Dysregulation of the complex mechanisms that regulate ovarian apoptosis could be a factor, although no such defects have been demonstrated in women to date. Further studies of familial POF clusters may reveal defects in factors regulating cell–cell interaction, cell growth, or apoptosis.

Progressive Ovarian Damage Galactosemia is an autosomal recessive metabolic disorder characterized by a deficiency of galactose-1-phosphate uridylyltransferase, leading to an inability to metabolize galactose and the accumulation of potentially toxic galactose-1-phosphate in tissues. Treatment with dietary galactose restriction improves or prevents the development of abnormalities of the liver, kidney, eye, and central nervous system. Women with this disorder develop ovarian failure nearly without exception. The time of its onset is variable and appears to depend on the age of institution of dietary treatment. Both primary amenorrhea and rare pregnancies have been observed. Ovarian failure develops over several years in association with follicular depletion, and once established is irreversible. The gonadotropins produced by these women are biologically active, despite the fact that galactose is present in the carbohydrate moiety of normal gonadotropins; gonadotropin receptors are probably also normal, since ovulation can occur and testicular function in males with galactosemia is normal. The molecular basis for the accelerated depletion of ovarian follicles in galactosemia is unknown. It is hoped that dietary intervention begun early enough, perhaps *in utero*

after prenatal diagnosis in offspring of known carriers, will be successful in reversing this process.

Autoimmune disorders may also cause progressive ovarian damage and lead to POF. POF may occur as an isolated autoimmune endocrinopathy, or it may be associated with other known autoimmune diseases of the endocrine system, including Hashimoto's thyroiditis, insulin-deficient diabetes, and Addison's disease. Histologic examination of the ovaries in women with autoimmune POF often reveals a lymphoplasmacytic infiltrate involving growing but not primordial follicles. Abnormal ovarian monocytes and fibroblasts have been reported, as well as altered serum cytokine profiles. Although antiovarian antibodies have been described in some cases of POF, they are not consistently directed against any single antigen. Ovarian failure often follows a relapsing and remitting course and pregnancies can occur, occasionally after prolonged absence of ovarian function. Further investigation will define the relative roles of cell-mediated and humoral immunity in this form of ovarian failure.

POLYCYSTIC OVARY SYNDROME Polycystic ovary syndrome (PCOS) was first described by Stein and Leventhal in 1935 as the association of enlarged, cystic ovaries with amenorrhea and hirsutism. Since then, PCOS has been the subject of much study leading to few definitive answers. Central to the frustration involved in the study of PCOS is the lack of agreement on a definition of the syndrome, along with probable variations in phenotypes among patient populations. These differences lead to difficulties in comparing studies of PCOS.

The definition of PCOS most often accepted in the United States is that of ovulatory dysfunction associated with ovarian hyperandrogenism. Other features that have been used in various combinations as inclusion criteria are the sonographic appearance of many small subcapsular ovarian cysts and increased stroma, an elevated LH/FSH ratio, elevated androstenedione or testosterone, hirsutism, and truncal obesity. Generally excluded or considered as a distinct subset of PCOS is hyperthecosis, a severe form of progressive androgenization beginning just after puberty and resulting from a proliferation of ovarian theca.

Though the lesions responsible for PCOS have not been established, the interaction of inappropriate signals from the central nervous system and the ovary is thought to perpetuate what has been called a vicious cycle (Fig. 62-5). Excess androgen is aromatized to estrogen in the periphery, a process more pronounced in obesity. Tonic estrogen levels enhance pituitary LH secretion, while suppressing FSH secretion. Elevated LH continues the cycle by stimulating excessive thecal androgen production. What initiates this cycle in PCOS is not known, but other disease processes can also result in tonic estrogen levels, anovulation, and hirsutism, including Cushing's syndrome, thyroid dysfunction, adult-onset adrenal hyperplasia, and steroid-producing ovarian tumors. PCOS may therefore be viewed as a final common pathway resulting from any of a number of metabolic derangements.

According to one theory, PCOS results from exaggerated adrenarche in obese girls, leading to increased peripheral conversion of adrenal androgens to estrogens. Prospective studies of young girls are underway to test this hypothesis.

Another possible cause of the PCOS phenotype is an abnormality of the hypothalamic gonadotropin-releasing hormone (GnRH) pulse generator. Increased LH pulse frequency and amplitude have been found in some PCOS patients, suggesting an underlying increased GnRH pulse frequency. As shown in Fig. 62-5, possible causes of abnormal GnRH pulse generation include alteration of central dopaminergic tone, central progesterone resistance, and alterations in the feedback response to steroids.

At the ovarian level, abnormalities in the response to gonadotropins have been suggested. Follicles from PCOS ovaries have decreased numbers of granulosa cells with low aromatase activity in vivo, yet they can respond to FSH in culture by increasing aromatase activity. Furthermore, follicle growth and ovulation can be stimulated with low doses of exogenous FSH in these patients. Also suggested, but not yet conclusively demonstrated, as intraovarian abnormalities responsible for PCOS are the presence of an intrafollicular FSH antagonist, such as an IGF-binding protein; dysfunctional regulation of paracrine growth factors; and alterations in the regulation of steroidogenic enzyme activity.

It has also been hypothesized that PCOS results from an overproduction of inhibin by granulosa cells. Inhibin is a dimeric protein product of granulosa cells, which acts both to decrease pituitary FSH release and to increase thecal androgen production. However, inhibin α- and β-subunit expression in PCOS ovaries does not differ from that in normal ovaries.

In summary, it is uncertain whether the events that initiate the pathophysiology of the hypothalamic–pituitary–ovarian axis in PCOS originate centrally or within the ovary, or indeed if the same abnormality is responsible in all women with this syndrome.

Hyperinsulinemia and PCOS Many women with PCOS, both obese and lean, show peripheral insulin resistance and compensatory hyperinsulinemia. The ovary in PCOS escapes insulin resistance, and hyperandrogenism may thus result from excessive insulin-stimulated thecal androgen production. In addition to a direct action on androgen production, high serum levels of insulin inhibit hepatic production of IGF-binding protein-1, resulting in increased bioavailability of IGF-I to the theca.

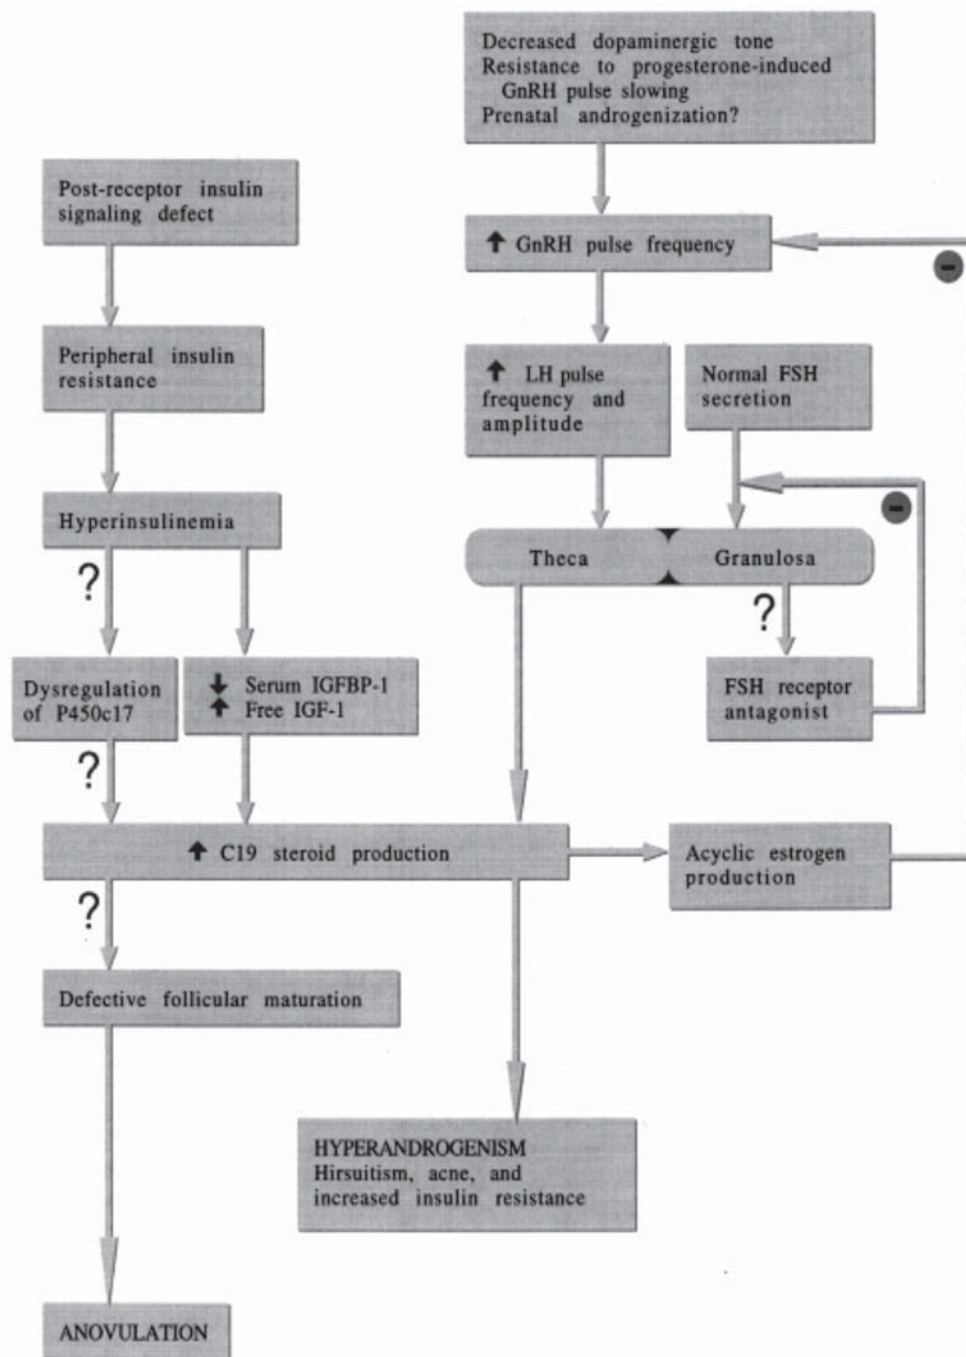
Although the role of insulin resistance in the pathogenesis of PCOS has not been established, its molecular basis has been studied, and treatments that ameliorate insulin resistance are showing promise in correcting the reproductive abnormalities. Though the association of polycystic ovaries and hyperandrogenism was first described in syndromes associated with insulin receptor (IR) mutations, such structural mutations have generally not been identified in PCOS, but rather insulin resistance appears to result from postreceptor defects in signal transduction. On binding insulin, the IR activates protein kinase cascades which mediate both the metabolic (e.g., glucose and amino acid uptake, lipogenesis) and endocrine (e.g., stimulation of gonadal steroidogenesis) actions of insulin. Studies of adipocytes from both obese and lean women with PCOS demonstrate a postreceptor defect in insulin-stimulated glucose uptake that appears intrinsic rather than acquired, in that it is associated with decreased content of the insulin-dependent glucose transporter GLUT4. Compared with normal cycling women, PCOS subjects show a greater degree of serine phosphorylation of the IR on adipocytes, a mechanism postulated to inhibit tyrosine phosphorylation and thereby retard signal transduction. Functionally significant genetic polymorphisms in proteins of the insulin signaling system have been demonstrated in insulin resistance associated with non–insulin-dependent diabetes, and similar polymorphisms might be anticipated in women with insulin resistance and PCOS. In support of a functional rather than direct genetic origin of insulin resistance, insulin sensitivity is improved by metformin and troglitazone, drugs that act by facilitating postreceptor events.


Figure 62-5   The pathophysiology of the polycystic ovary syndrome. Shown are the influences on the hypothalamic–pituitary–ovarian axis that have been postulated to result in the phenotypic abnormalities shown in the shaded boxes at the bottom. Uncertain relationships are also noted, including the stimulation of LH secretion by insulin and the impact of dysregulation of $P450_{c17}$ activity on androgen production by the theca.

Genetic Studies   Although no single molecular abnormality is common to all women with PCOS, pedigree studies have suggested either polygenic inheritance or incomplete penetrance of a dominant mutation. Several associated genetic markers have been found; they include genes encoding a dopamine receptor expressed in the hypothalamus, enzymes involved in steroid biosynthesis, and major histocompatibility complex (HLA) antigens. A mutation in the D3 dopamine receptor was found with increased frequency in hyperandrogenic, dysovulatory Hispanic women and

was associated with resistance to ovulation induction with clomiphene; a deficiency of dopamine action has been postulated to elevate circulating LH in PCOS. A potentially activating point mutation in the promoter of the gene encoding the androgen synthetic enzyme $P450_{c17}$ was associated with PCOS in women and with premature male-pattern baldness in men. This mutation did not cosegregate with either of these disorders, however, excluding a causal relationship. Mutations in the steroid biosynthetic enzymes 21-hydroxylase, $P450_{arom}$, 17β-HSD, and 3β-HSD have

all been associated with hyperandrogenic anovulatory syndromes resembling PCOS, but steroidogenesis in ovarian tissue from women with PCOS is not defective in vitro. Association of PCOS with HLA DR and DQ, but not A, B, or C, alleles has also been reported in women with negative screens for 21-hydroxylase deficiency, which is closely linked to HLA. More recently, an association of the VNTR (variable number of tandem repeats) locus, which is present in the 5'-flanking region of the insulin gene, with an increased risk of PCOS was demonstrated. Interestingly, the genotype associated with PCOS is also associated with decreased insulin gene expression in the process.

PCOS: Summary In summary, PCOS exhibits many common but not universal features, including disordered folliculogenesis, ovarian hyperandrogenism, pituitary hypersensitivity to GnRH and exaggerated LH release, and peripheral insulin resistance. Despite these common features, molecular and genetic evidence does not point to a single defect in the majority of affected women. The PCOS phenotype is likely the final common expression of a number of other defects, perhaps of single gene origin, that have yet to be elucidated. Ongoing studies using animal models with PCOS-like syndromes, as well as prospective human studies, may increase our understanding of the pathogenesis of this complex syndrome.

SUMMARY

The mechanisms that direct germ cells in the yolk sac to migrate to the gonadal ridge and become enclosed in a follicular apparatus, and then direct these follicles to begin to grow in controlled cohorts during 50 or more years, are far from being completely identified. More is known about the effects of gonadotropins and growth factors on cohorts of follicles recruited to the final steps of preovulatory development, but the exact molecular mechanisms governing dominance, ovulation, and luteinization also remain to be clarified. Tissue remodeling is clearly of prime importance in the cycling ovary, but it is apparently regulated by multiple redundant systems. As knowledge of these processes advances, a more precise picture of the myriad causes of ovarian dysfunction will become apparent.

INTRODUCTION

Breast cancer is the second leading cause of cancer death affecting women in the United States, with more than 180,000 new cases each year. Even with recent advances in breast cancer treatment, approximately one-half of breast cancer patients will eventually die of this disorder. The high mortality of breast cancer has focused attention on prevention and on identifying breast cancer precursors. Invasive breast cancer may develop gradually from specific microscopically defined precursor lesions. However, these lesions are relatively common and only a small proportion of the proposed precursor lesions appear to progress to invasive breast cancer, emphasizing that progression is nonobligatory. Identifying biologic and genetic abnormalities that herald progression to invasive breast cancer may enable us to intervene before progression occurs.

BREAST CANCER EVOLUTION

Invasive breast cancer probably evolves from normal epithelium of the terminal duct or lobular unit through a series of increasingly abnormal proliferative lesions including typical and atypical hyperplasia and noninvasive *(in situ)* carcinoma. Typical hyperplasia, or proliferative disease without atypia (PDWA), is composed of myoepithelial and epithelial cells growing in an irregular pattern of slitlike lumina and papillations. Atypical ductal hyperplasia (ADH) is composed primarily of epithelial cells and has a more regular growth pattern. Both typical and atypical "hyperplasias" are misnomers in the sense that recent genetic evidence demonstrates that they are really benign neoplasms. Ductal carcinoma *in situ* (DCIS) is a malignant neoplasm with low-grade and high-grade types. The low-grade "noncomedo" type of DCIS is composed of relatively small regular epithelial cells that typically grow in a perforated microglandular pattern. The high-grade "comedo" variant of DCIS is characterized by large irregular epithelial cells usually growing in solid sheets with prominent central necrosis. Examples of each of these lesions are shown in Fig. 63-1. There are also lobular, as opposed to ductal, variants of atypical hyperplasia and *in situ* carcinoma, but so little is known about their biologic characteristics that they will not be emphasized in this chapter.

Epidemiologic studies support this model of breast cancer evolution (Table 63-1). Studies of previously excised breast lesions show progressively increasing relative risks (RR) of later developing invasive breast cancer in women with typical hyperplasia (RR = 1.5–2), atypical hyperplasia (RR = 4–6), and noninvasive carcinoma (RR = 10–12). These results are consistent with the notion that incomplete excision and residual disease progresses to invasive breast cancer, or alternatively, with the notion that these lesions are markers for other abnormalities left behind with the capacity to progress. Similar evidence is provided by studies of *in situ* carcinoma treated by lumpectomy, which show local recurrence

rates of 10–75%, with half the recurrences being invasive cancer. Postmortem studies of women dying of causes other than breast cancer show that typical hyperplasia, atypical hyperplasia, and *in situ* carcinoma are present in about 30, 2, and 2% of random breasts, respectively. The precursor-product concept is supported by histopathologic studies that find these same lesions in a very high proportion (50–90%) of breasts containing invasive breast cancer, consistent with the idea that they may be precursors.

This model represents a reasonable working hypothesis in the design of studies to investigate the biologic mechanisms underlying the development and progression of human breast cancer. Table 63-2 summarizes biologic abnormalities known to be associated with these putative precursor lesions when they are not accompanied by invasive breast cancer. Table 63-3 summarizes abnormalities in morphologically similar lesions when they are found in breasts already containing invasive cancer. Nearly all the biologic characteristics studied so far were first described in invasive breast cancer, and have only recently been reevaluated in premalignant and preinvasive breast disease. Tables 63-2 and 63-3 summarize many of the findings discussed in this chapter. Several interesting studies have not been included because they used ambiguous terminology for premalignant disease, or their results were descriptive rather than quantitative and difficult to tabulate.

GENETIC FACTORS PARTICIPATING IN THE PROGRESSION TO CANCER

Whatever mechanisms are behind the overall growth imbalance in breast cancer evolution, measurement of biologic parameters governing proliferation itself may eventually prove to be useful prognostic factors in the clinical management of this disease. In the next section, genetic factors that potentially participate in the progression from premalignant lesions to breast cancer will be reviewed. These include genes involved in signal transduction, such as hormone receptors, oncogenes, growth factors, and their receptors, which are frequently upregulated in malignancies. Also covered are overall parameters of cell growth, such as proliferation rate and DNA content. Finally, we review genes that are specifically inactivated in malignancies, the tumor suppressor genes, which have been implicated in studies of breast cancers and hereditary breast cancer families. Development of an understanding of the genes that control cell proliferation, either alone or in combination with other factors, may be found to enhance our ability to more appropriately match treatment to risk in patients who already have breast cancer or its antecedents.

HORMONE RECEPTORS

ESTROGEN RECEPTOR (ER) Estrogen is an important hormone involved in regulating the differentiation and proliferation of normal breast epithelial cells. Its effects are manifold and incompletely understood. It influences cells by interacting with the estrogen receptor (often referred to as ER) in the nucleus, eliciting a cascade of transcriptional regulatory activity. Prolonged estrogen exposure has been demonstrated to be the most significant risk factor for developing invasive breast cancer. This increased
Figure 63-1   Representative photomicrographs of putative precursor lesions and malignant invasive breast cancers. (**A**) Normal terminal duct lobular unit (TLDU), where many breast cancers are thought to arise. (**B**) Proliferative disease without atypia (PDWA, or typical hyperplasia) is composed of myoepithelium and epithelium growing in an irregular pattern of slitlike lumina and papillations. (**C**) Atypical ductal hyperplasia (ADH) is composed primarily of epithelial cells and has a more regular growth pattern. (**D**) Ductal carcinoma *in situ* (DCIS) is an unequivocal malignant neoplasm with two particularly common morphologic phenotypes. The low-grade or "noncomedo" type of DCIS (ncDCIS) is composed of relatively small regular epithelial cells that typically grow in a perforated microglandular pattern (shown here). The high-grade "comedo" variant of DCIS (cDCIS) is characterized by large irregular epithelial cells growing in solid sheets with prominent central necrosis (not shown). (**E**) Invasive breast cancers break down and escape from the duct. Note the lighter staining stromal elements. (**F**) Breast cancer metastasis in a lymph node. The metastasis is the lighter staining tissue at the bottom of the picture growing inside the darker staining lymphoid tissue.

risk may be partially caused by the mitogenic effect of estrogen on breast epithelium, which may permit the accumulation of random genetic damage taking place in replicating cells. The ER gene maps to chromosome 6q25.1, and is overexpressed in 60–70% of invasive breast cancers. Overexpression of ER is associated with lower risk of relapse, prolonged overall survival, and enhanced response to endocrine therapy relative to ER-negative tumors.

ER expression appears to be generally low in normal breast epithelium, with the exception of a small peak during the first week of the menstrual cycle. Immunohistochemical (IHC) studies show that expression is usually restricted to 1–2% of normal cells, but that nearly all breasts contain at least a few ER-positive cells. There are only a few small IHC studies of ER in hyperplastic breast disease, and they show that ER is significantly overexpressed relative to normal epithelium in these lesions. About a third of typical hyperplasias, and all atypical hyperplasias, contained a significant proportion (>20%) of ER-positive cells, and virtually all hyperplastic lesions contained at least a few positive cells. A relatively large number of studies have evaluated ER expression in noninvasive carcinomas. On average, about 20% of comedo DCIS express ER, compared with about 70% of noncomedo DCIS. The rate of ER overexpression for *in situ* carcinomas reported as mixed or not-otherwise-specified (NOS) ranges from 40 to 90%. ER expression of noninvasive cancer appears to be about the same whether or not they are associated with invasive breast cancer. The data regarding this issue for hyperplastic lesions is too sparse to evaluate.

PROGESTERONE RECEPTOR (PR)   PR expression in normal breast epithelium is regulated by ER. Similar to ER, PR is overexpressed in a significant proportion of invasive breast cancers (50–60%), and such tumors have a relatively better prognosis and response to antihormonal therapy than PR-negative tumors. The PR gene is mapped to chromosome 11q22–23, but PR expression has not yet been studied in hyperplastic breast disease. There is a single study reporting very low (0%) and high (80%) rates of ER-positive comedo and noncomedo DCIS, respectively.

PROLIFERATION RATE

Cell-cycle kinetics provides a very strong prognostic factor in invasive breast cancer. Proliferation has been measured by light microscopic mitotic index, S-phase fraction (SPF), by flow cytometry, thymidine-labeling index (TLI), and IHC for cell-cycle related proteins such as Ki67. Regardless of the methodology used, rapidly proliferating tumors are consistently associated with significantly shorter disease-free and overall survival.

The proliferation of normal breast epithelium is regulated by the menstrual cycle, with maximum rates seen during the follicular phase. Absolute proliferation rates of normal cells are usually quite low—1 to 2% or less. The little information available regarding proliferation in hyperplastic breast disease suggests that rates are relatively higher in atypical than typical hyperplasia, but still very low in absolute terms in both types of lesions. For noninvasive carcinomas median TLIs of 5.2 and 1.8 have been measured in comedo and noncomedo DCIS, respectively. The trend was similar in a small study measuring median SPF in comedo (SPF = 12.3) and noncomedo (SPF = 6.5) lesions. The proliferation rates of hyperplasias and *in situ* carcinomas from breasts containing invasive cancer may be substantially higher than morphologically similar lesions unassociated with invasive disease.

DNA CONTENT

DNA content is diploid in normal breast epithelium. Although ploidy has apparently not been evaluated in typical hyperplasia of the breast, two small studies of atypical hyperplasia report that 30% of these lesions are aneuploid. DNA content has been more thoroughly investigated in noninvasive carcinomas. Several studies have shown that 60–85% of comedo DCIS are aneuploid, compared with 30–50% for noncomedo DCIS. DNA content has not been evaluated in premalignant or preinvasive lesions in breasts containing invasive cancer.

The majority of invasive cancers (60–70%) contain abnormal amounts of DNA (aneuploidy), which is thought to be a crude reflection of major clonally selected chromosomal gains or losses. Aneuploidy in invasive breast cancer is modestly associated with reduced disease-free and overall survival in patients with invasive breast cancer.

ONCOGENES AND GROWTH FACTOR RECEPTORS

Many oncogenes and/or growth factors have been shown to be activated or inappropriately expressed in invasive breast cancer (*see* Chapter 7). A few of these have also been evaluated in premalignant and preinvasive breast disease.

ERBB2   The most thoroughly studied gene in breast cancers is *ERBB2* (also known as c-*erbB2 HER2*, or c-*neu*). The *ERBB2* gene resides on chromosome 17q11.2–12 and codes for a 185-kDa transmembrane glycoprotein with tyrosine kinase activity. It is a member of the type 1 growth factor receptor family, and its ligand is unknown. The gene is amplified or overexpressed in 20–30% of invasive breast carcinomas,

Table 61-1
Morphologic Model of Breast Cancer Evolution and Epidemiologic Evidence Supporting It

Model	Relative risk of developing invasive breast cancer	Incidence in random breasts	Rate of concurrence with invasive breast cancer
Normal epithelium	1	—	—
Typical hyperplasia	2[a]	30%	50–90%
Atypical hyperplasia	4–6[a]	1–2%	50–90%
In situ carcinoma	10–12[b]	1–2%	50–90%
Invasive carcinoma	—	1–2%	—

[a]Bilateral relative risk; [b]Ipsilateral relative risk.

and this activation is associated with many unfavorable prognostic factors and poor clinical outcome.

IHC has been used to detect overexpression of *ERBB2* in premalignant or preinvasive breast disease relative to normal epithelium. A small number of typical and atypical hyperplasias have been evaluated for *ERBB2* and, with rare exception, no overexpression has been detected. Several studies have addressed *in situ* carcinomas. In studies involving more than 100 combined cases, very high rates of overexpression (60–100%) were found in comedo DCIS. Equally comprehensive studies of noncomedo DCIS found much lower rates (0–50%). Additional studies of mixed or NOS DCIS reported intermediate rates of c-*erbB2* overexpression ranging from 30 to 80%. No overexpression was observed in the less than 50 cases of *in situ* lobular carcinoma that have been evaluated. Studies evaluating *ERBB2* in premalignant and preinvasive lesions from breasts containing invasive cancer find about the same rates of overexpression and amplification as when invasive cancer is not present.

The weight of evidence suggests that activation of *ERBB2* is an important early event in malignant transformation leading to *in situ* carcinoma. Given the overall high rates of *ERBB2* activation associated with *in situ* carcinomas, contrasted with the much lower rates observed in invasive cancer, many cases of *in situ* carcinoma stop overexpressing this oncogene as they evolve to invasive disease; alternatively, a significant proportion of invasive lesions must arise *de novo* by mechanisms independent of *ERBB2*.

EPIDERMAL GROWTH FACTOR RECEPTOR (EGFR) EGFR (c-*erbB1*) is a 170-kDa transmembrane glycoprotein encoded by a gene on chromosome 7p12. It is a type 1 growth factor receptor with tyrosine kinase activity that binds several known ligands, including epidermal growth factor and transforming growth factor-α. This gene is rarely amplified, but is overexpressed in about 40–50% of invasive breast cancers. This expression is associated with many unfavorable biologic characteristics and relatively poor clinical outcome. EGFR appears to be present at low levels in most normal breast epithelial cells. In one small report, expression was observed in 25% of DCIS. Otherwise, EGFR has not been evaluated in premalignant or preinvasive breast disease.

***ras* GENE FAMILY** The *ras* family of oncogenes (designated N-*ras*, H-*ras*, and K-*ras*) encodes highly similar proteins with molecular weights of about 21 kDa. The *ras* genes map to chromosomes 1p13, 11p15, and 12p12.1, respectively. They are involved in the intracellular transduction of external stimulation of growth factor receptors coupled to the GTPase-activator proteins RASA, NF1, and others. The RAS proteins become activated on stimulation, and transduce these signals to other effector molecules, and subsequently are inactivated. Mutated RAS proteins are expressed but appear to have lost the ability to be inactivated. Mutations of *ras* genes are common in some types of cancer, but the incidence and significance of mutations in breast cancer is unclear. Expression rates varying from 30 to 80% have been reported in invasive breast cancer, depending on the assay.

Using IHC, rates of *ras* expression in normal breast epithelium have been reported to range from 0 to 100%, suggesting that there are significant technical inconsistencies between studies. A handful of studies have evaluated *ras* expression in precursor lesions of invasive breast cancer, but, to date, have made no definitive attempt to correlate expression and mutation. One study of typical hyperplasias reported variable rates of RNA expression for H-*ras* (4.5%), K-*ras* (22%), and N-*ras* (30%). IHC studies of *ras* expression in typical hyperplasias report rates of 80–100%. A single small IHC study observed *ras* expression in 100% of atypical hyperplasias and noninvasive carcinomas. These results, while incomplete, suggest that *ras* expression may gradually increase during the transition from hyperplastic to malignant breast disease. The issue of comparing levels of *ras* activation in premalignant disease from breasts with and without cancer is unexplored. However, a provocative preliminary study found a relatively elevated rate of *ras* expression in hyperplasias from women who later developed invasive breast cancer (15 years follow-up), compared with hyperplasias from women who did not (40 vs 20%, respectively).

***Myc* GENE FAMILY** The *myc* family of cellular oncogenes encode nuclear DNA-binding phosphoproteins, which play important but as yet incompletely understood roles in the regulation of cell growth and differentiation. MYC proteins form heterodimeric complexes with basic helix-loop-helix-leucine zipper transcription factors whose activity is regulated by a number of positive (MAX) and negative (MAD, MXI1) regulators. The best characterized members of this multigene family, *myc*, *mycn*, and *mycl*, map to chromosomes 8q24, 2p22–24, and 1p32, respectively. The prototypical member of this family, *myc*, is activated by gene rearrangement, amplification, or overexpression. Estimates of the frequency of *myc* activation range from 1 to 56% of invasive breast cancers studied, and such activation is modestly associated with an aggressive biologic phenotype and poor clinical outcome.

IHC studies show *myc* expression in the epithelium of 0–60% of normal breasts, again suggesting that technical inconsistencies may be confounding this issue. A single study measuring RNA expression found *myc* in 18% of typical hyperplasias. A few studies evaluating mixed or NOS DCIS found a 100% incidence of MYC protein expression by IHC, and an 11% rate of *myc* amplification by Southern blotting. In an interesting preliminary report, the rate of *myc* expression was higher in patients with "benign" biopsies who later exhibited invasive breast cancer than in patients who did not (53 vs 17%, respectively).

GROWTH FACTORS

Growth factors regulate cellular proliferation through receptor mediated autocrine or paracrine mechanisms. Disruption of these peptide–receptor interactions may be involved in the development and progression of many types of cancer. A few have been evaluated in precursors of invasive breast cancer.

TRANSFORMING GROWTH FACTOR-α (TGF-α) TGF-α maps to chromosome 2p13. TGF-α, and its receptor EGFR, are reported to be overexpressed in up to 50% of invasive breast cancers, and in most studies both are associated with increased proliferation, other aggressive biologic features, and relatively poor clinical outcome. Preliminary IHC studies find low rates (0–8%) of TFG-α expression in normal breasts. In the few cases examined, the majority (87–100%) of both hyperplastic lesions and noninvasive carcinomas overexpress TGF-α; other studies noted increased immunostaining for TFG-α in normal epithelium adjacent to rapidly proliferating epithelium, suggesting a possible juxtacrine effect.

Table 63-2
Biomarker Phenotypes of Precursor Lesions From Breasts Without Invasive Cancer

Biomarker assay	Normal	Ductal hyperplasia		Ductal carcinoma in situ

TRANSFORMING GROWTH FACTOR-β (TGF-β) TGF-α is a member of a family of closely related peptides with growth inhibitory properties. The prototypical member of this family, TGF-β1, maps to 19q13. In the normal breast, the subtypes of TGF-β are expressed in both epithelial and stromal cells. By IHC, the patterns of TGF-β expression suggest that it participates in the regulation of differentiation and growth inhibition by both autocrine and paracrine mechanisms. Paradoxically, TGF-β appears to be expressed in the majority of invasive breast cancers, suggesting that malignant cells may have lost the ability to respond to its inhibitory effects. Very little information is available regarding TGF-β expression in precursor lesions of invasive breast cancer. One study found no evidence of expression by IHC in a few noninvasive carcinomas. In contrast, another small descriptive IHC study reported appreciable expression in normal, premalignant, and invasive malignant lesions.

INSULIN-LIKE GROWTH FACTOR 1 (IGF-I) IGF-I (formerly called somatomedin C) is a member of a family of growth factors homologous to insulin, but has distinct receptor binding and biologic effects. This gene maps to chromosome 12q22–24. It is a physiologic mediator and stimulator of normal cell growth. Most invasive breast cancers appear to express receptors for IGF-I, and are stimulated to grow in vitro in response to exogenous IGF-I and IGF-II. Preferential expression of IGF-I and -II by stromal cells suggests that they may function in a paracrine fashion. As with most growth factors, very little is known about IGF-I or -II expression in premalignant breast disease. There is a single report involving a handful of cases finding no expression of IGF-II in DCIS. Descriptive studies of "fibrocystic disease," which may harbor hyperplastic lesions, have observed expression of IGF-I in 50% of cases.

TUMOR SUPPRESSOR GENES AND HEREDITARY BREAST CANCER GENES

In contrast to the genes discussed in the previous sections, which increased gene expression stimulates neoplastic transformation, the tumor suppressor genes (TSG) lead to malignant transformation primarily by loss of function. Genetic studies of rare families predisposed to specific cancers or patterns of cancers have lead to the identification of a number of TSGs (*see* Table 63-4) by positional cloning techniques. Hereditary cancer families are rare, and the function of many of the TSGs are unknown. However, loss of heterozygosity (LOH) events at these loci are frequently seen in many cancer

types, including sporadic breast cancers. These observations suggest that both inherited and somatic mutations are targeting the same genes.

RB The *RB* gene is perhaps the archetypal TSG, and was originally characterized as a cancer predisposition gene in a childhood ocular tumor, retinoblastoma. Statistical analysis of retinoblastoma epidemiology suggested two forms of this disorder, a unilateral, unifocal presentation with no clear hereditary basis, and a bilateral, multifocal, hereditary form. These data led Knudson, on the basis of studies of the kinetics of tumor formation in the hereditary versus sporadic forms of retinoblastoma, to propose the "two-hit" model of genetic predisposition to cancer. Knudson proposed that the RB phenotype segregated in families as an apparent autosomal dominant trait, with affected individuals inheriting only a single functional copy of the *RB* gene. The tumors appearing in affected individuals resulted from the loss of the remaining functional allele of the *RB* gene in retinal cells. The unifocal development of retinoblastoma in sporadic cases is also caused by loss of both functional *RB* alleles, but in this circumstance reflected the low statistical probability of damage to both copies of the same gene during retinal development. The *RB* gene has proved to be a nuclear phosphoprotein of 110 kDa. RB undergoes cyclic phosphorylation and dephosphorylation during the cell cycle. Current models suggest that the unphosphorylated form of RB complexes with RB-associated proteins that are essential for cell division, and that on phosphorylation, RB releases these factors, permitting entry into the cell cycle. LOH of the *RB* locus is found at relatively high frequency in breast cancers, but interpretation of these deletion events are complicated by the discovery of the nearby *BRCA2* gene. Interestingly, carriers of inherited *RB* gene mutations are not at greatly increased risk of breast cancer, suggesting that although *RB* gene mutations may promote breast cancer evolution, these mutations are not themselves sufficient to cause breast cancer.

TP53 *TP53 (p53)* is a tumor suppressor gene located on chromosome 17p13. It encodes a 53-kDa nuclear phosphoprotein that functions as a transcription factor and is involved in the regulation of cell proliferation. Mutated *TP53* is very common in many types of cancer. Although wild-type *TP53* is undetectable by IHC, many *TP53* mutations are missense point mutations resulting in an inactive protein with a prolonged half-life, which accumulates to very high concentrations in the cell nucleus. For this reason, measuring TP53 protein expression is a relatively easy and accurate

surrogate assay for detecting mutations. Up to 50% of invasive breast cancers contain mutated or overexpressed *TP53*, which is associated with many other aggressive biologic factors and poor clinical outcome.

There are very few studies regarding *TP53* alterations in normal and hyperplastic breast epithelium. In IHC studies involving less than 50 samples of normal breast epithelium, no expression of *p53* was observed, consistent with wild-type gene structure and function. The "normal" epithelium of patients with Li-Fraumeni syndrome, who have inherited *p53* mutations, often overexpress *TP53*. One study has evaluated nine cases of atypical hyperplasia, and found no evidence of expression. Noninvasive carcinomas have been evaluated more thoroughly. Investigations involving more than 100 cases of comedo DCIS observed rates of *TP53* overexpression ranging from 33 to 67%, approaching that of invasive breast cancer. These same studies also examined an appreciable number of noncomedo DCIS, and found much lower rates ranging from 0 to 25%. Other studies evaluating mixed or NOS DCIS report intermediate rates of overexpression or mutation ranging from 16 to 33%. Currently, there is no substantial information regarding the *TP53* status of premalignant or pre-invasive diseases in breasts also containing cancer.

OTHER POTENTIAL BREAST CANCER TSG Other TSGs that have been identified are involved in diverse functions, including check point control, such as *MTS1* (p16), transcriptional repression *(WT1)*, signal transduction modulation *(RASA, NF1)*, and DNA repair *(MSH2, MLH1, ATM)*, suggesting that mutations in genes regulating cell proliferation, genetic stability, and cell death could all drive the process of clonal evolution.

GENES MUTATED IN HEREDITARY FORMS OF BREAST CANCER Because of the high prevalence of breast cancer in the population, clustering of breast cancer in families is not unusual. Therefore, the etiology of families with multiple cases of breast cancer may reflect chance and environmental factors, as well as heredity. Approximately 5–10% of breast cancer is now thought to have a hereditary basis. Hereditary breast cancers are inherited in an autosomal dominant fashion, and, as in *RB* and other inherited cancers, breast cancer gene heterozygotes only form tumors in breast epithelial cells that lose the remaining, normal copy of the gene. Germ line mutations in three genes, *TP53 (see above)*, *BRCA1*, and *BRCA2*, have been detected in hereditary breast cancer families.

Table 63-4
Cloned TSGs with LOH in Breast Cancers

Gene (HGM symbol)	Location	Gene product
Bacterial mutS homolog (MSH2)	2p22–21	DNA mismatch repair mutant in HNPCC
Bacterial mutL homolog (MLH1)	3p23–22	DNA mismatch repair mutant in HNPCC
Von-Hippel Lindau (VHL)	3p25–26	Cell membrane protein
ras p21 GTPase activator (RASA)	5q13	ras-GTPase activator protein
Adenomatous polyposis coli (APC)	5q21	Cytoplasmic protein (unknown function)
p16 (MTS1)	9p21	Inhibitor of cyclin-dependent kinase 4
Ataxia telangiectasia (ATM)	11q23	DNA repair
Breast cancer 2 (BRCA2)	13q13	Unknown function
Retinoblastoma (RB)	13q14	Nuclear phosphoprotein regulating entry into cell cycle
p53 (TP53)	17p13	Transcription factor regulating entry into cell cycle
Neurofibromatosis 1 (NF1)	17q11.2	ras-GTPase activator protein
Breast cancer 1 (BRCA1)	17q21	Nuclear protein of unknown function—transcription factor?

LI-FRAUMENI SYNDROME   Inherited *TP53* mutations result in the Li-Fraumeni syndrome, a very rare, familial association of childhood sarcomas, early onset breast cancer in females, and other malignant neoplasms. The high frequency of somatic mutations of *TP53* in sporadic cancers and mutations of *TP53* in Li-Fraumeni syndrome is evidence supporting the common genetic pathways in the evolution of inherited and acquired breast cancer.

BRCA1   In contrast, the relationship of between mutations of *BRCA1*, the most common hereditary breast cancer predisposition gene, and sporadic breast cancer is less clear. The *BRCA1* gene was first mapped by genetic linkage studies of breast cancer families, and the gene was eventually identified by positional cloning studies. This gene encodes a 220-kDa protein. Its nuclear localization and the identification of two zinc-finger DNA domains near the amino-terminus of the protein have led to speculation that BRCA1 may function as a transcription factor. Mutant *BRCA1* gene carriers are at a very high risk of exhibiting breast cancer at a young age and also show increased risk of having ovarian cancer. Germ line mutations in *BRCA1* account for 50% of all hereditary breast cancers, and may account for 2% of all breast cancers. Although LOH of the 17q21 region is frequently seen in sporadic breast cancers, somatic mutations of *BRCA1* are absent in sporadic breast cancers. The LOH of the *BRCA1* region may be associated with downregulation of this gene in developing breast cancers, and gene transfer experiments indicate that expression of wild-type *BRCA1* protein inhibits the growth of breast cancers in vitro and in vivo. Other recent studies of indicate that the BRCA1 protein is aberrantly localized to the cytoplasm in breast cancer cell lines. Thus, in sporadic breast cancers, faulty BRCA1 localization because of mutation of a putative chaperone protein might have the same effect as mutation of *BRCA1* itself.

BRCA2   A third breast cancer susceptibility locus, designated *BRCA2*, was also mapped by genetic linkage studies of breast cancer families. Positional cloning studies recently isolated *BRCA2*, and characterization of this gene is in progress. Gene carriers are at high risk of developing breast cancer, breast cancer of the male breast, and potentially, other cancers. No clues to the apparent function of *BRCA2* have yet emerged from DNA sequence analysis, except for reports of distant homology to part of the *BRCA1* gene. Germline mutations have been detected in *BRCA2*, and the LOH events found in breast and other cancers from *BRCA2* gene carriers always delete the normal *BRCA2* allele. Studies of the relationship of *BRCA2* to sporadic breast cancers are complicated by the nearby *RB* gene because most tumors studied lose both genes within the LOH region, it is unclear which gene is involved in the clonal evolution process. One report indicates that a breast cancer cell with chromosome 13q LOH maintained heterozygosity for *RB*, but was homozygous for markers around *BRCA2*, suggesting that *BRCA2* is responsible for the putative LOH event.

OTHER POTENTIAL INHERITED BREAST CANCER GENES   Epidemiologic studies have suggested that other genes are asso-

ciated with increased risks of breast cancer, albeit at a much smaller magnitude than the genes discussed above. Studies of a highly polymorphic markers in the *HRAS* gene on chromosome 11p15 have associated particular alleles of *HRAS* with elevated risk of breast cancer and other cancers.

It is well established that homozygotes for mutations in the ataxia-telangiectasia *(ATM)* gene are at extremely high risk of cancer, particularly lymphoma and leukemia. Studies linking excess cancer risk in *ATM* mutation heterozygotes are more controversial. These studies suggest that female relatives of patients with ATM have excess risk of breast cancer; with the estimated relative risk of breast cancer to ATM heterozygotes of 3.9-fold. These results suggest that *ATM* heterozygotes could account for 3.8% of breast cancer cases.

Two new genes involved in DNA repair, designated *MSH2* and *MLH1*, have been identified at chromosome 2p22–21, and 3p23–22, respectively. Mutations in these genes lead to hereditary nonpolyposis colon cancer (HNPCC). A consequence of mutations in genes is microsatellite instability, or destabilization of the polymorphic alleles found at simple sequence repeat polymorphisms (microsatellites). This phenomenon is thought to result from impaired DNA repair, and is characteristic of the colon cancers found in HNPCC patients. DCIS, lobular carcinoma *in situ* (LCIS), invasive, and metastatic breast cancers have been evaluated for microsatellite instability. Microsatellite instability is observed in about 20% of invasive breast cancers, and was observed at moderate frequency *in situ* breast cancers. All chromosomal loci investigated demonstrated low levels of microsatellite instability. Microsatellite instability was significantly correlated with the lobular histotype, and with lymph node involvement. A trend was also observed associating microsatellite instability and large tumor size, implying that tumors with microsatellite instability may be more aggressive.

ALLELIC IMBALANCE OR LOSS-OF-HETEROZYGOSITY (LOH)   Loss-of-heterozygosity (LOH) refers to the disappearance of polymorphic marker alleles when constitutional DNA and tumor DNA from a cancer patient are genotyped. The LOH events are genomic deletions that discard the normal copies of TSGs, or uncover existing TSG mutations. Breast cancers have been extensively studied for LOH events, which have been detected on almost every chromosome arm. Breast cancer LOH regions coincide with known TSG loci. However, it remains to be determined whether the LOHs are related to mutations in the known TSGs or in as yet unknown genes in the vicinity. The availability of large numbers of highly polymorphic segments of the human genome that can be easily amplified in formalin-fixed, paraffin-embedded archival breast tumors by polymerase chain reaction (PCR) should allow breast cancer researchers to precisely map the LOH loci, and either implicate known TSGs or identify new ones.

The concept that invasive breast cancer arises from certain precursor lesions has been based primarily on epidemiologic and histopathologic evidence. More recent studies provide genetic evidence supporting this model of breast cancer evolution. For instance, LOH analysis in a series of hyperplasias, noninvasive, invasive, and metastatic carcinomas were carried

out. LOH was evaluated by PCR amplification of 13 highly polymorphic gene loci that had shown high rates of loss (>25%) in previous studies of invasive breast cancer. DNA was extracted from precursor or cancer lesions microdissected from formalin-fixed, paraffin-embedded tissue from breasts with and without invasive cancer. Hyperplasias and *in situ* carcinomas from breasts without invasive cancer showed at least 1 LOH (for the 13 loci tested) in 29 and 66% of lesions, respectively. Such accumulation or selection of allelic losses is unequivocal evidence that most (probably all) of these lesions are true neoplasms. The incidence of LOH in hyperplasias and *in situ* carcinomas from breasts with invasive cancer was even higher (52 and 80%, respectively). At least 1 LOH was also found in 95% of invasive cancers and 97% of metastatic cancers evaluated. The majority of LOH-positive hyperplasias (53%) and *in situ* carcinomas (79%) from breasts containing invasive cancer shared their LOH phenotypes with a more "advanced" lesion present in the same breast, consistent with the idea that there are precursor–product relationships between them. Invasive cancer shared its LOH phenotype with metastatic cancer from the same patient 85% of the time.

PROPERTIES OF ESTABLISHED MALIGNANCIES

INVASION AND METASTATIC SPREAD OF BREAST CANCER Dysregulation of genes involved in the control of cell growth results in the establishment of an *in situ* malignancy; however, alterations in the expression of new classes of genes fuel the processes of invasion and metastasis that result in evolution of breast cancer towards systemic disease. This novel gene expression changes the binding relationships of the breast cancer cells to extracellular matrix (ECM) components of the basement membrane, such as fibronectin, laminin, and collagen. In the case of breast cancers, particular attention has been focused on the expression of the laminin receptors, because the interactions of breast cancer cells to basement membrane laminin are much greater than those of normal breast tissue. Another class of cell adhesion proteins under scrutiny in breast cancer invasion are the integrins, which comprise a large family of transmembrane glycoproteins involved in cell–matrix and cell–cell interactions by functioning as receptors to extracellular matrix proteins, and also as adhesion molecules.

This change in binding relationships between breast cancer cells and the ECM components are a prelude to release of proteolytic enzymes that lead to the destruction of the basement membrane and subsequent invasion of the breast cancer into the surrounding tissue. These include serine proteinases, collagenases, and cysteine proteinases that specifically degrade ECM components. In breast cancers, capthepsin B, a lyzosomal cysteine proteinase with a broad spectrum of action against many proteins, including all the ECM components mentioned above, has been extensively studied. Results from these studies indicate that breast tumors that expressed high levels of capthepsin D had a negative prognostic impact for ultimate tumor spread or recurrence.

After invasion, malignant cells may spread to distant sites through the process of metastasis. Malignant cells penetrate lymphatic or vascular channels and ultimately arrest in small lymphatics or capillaries, although less than 0.01% survive in the circulation. Most cancers seem to respond to the local environment in response to growth factors produced by the host tissue. In a permissive environment, cancers can reverse the process of escape from the primary tumor and invade back across the basement membrane into the surrounding tissue. Ultimately, these micrometastases must release growth factors to stimulate the production of new blood vessels. This process, referred to as angiogenesis, must take place to continue growth at the new site. Invasive breast cancers usually spread to local and regional lymph nodes, particularly to the axillary, mammary, and superclavicular nodes. Distant sites of breast cancer metastasis include bone, lung, liver, pleura, adrenals, skin, and brain.

BREAST CANCER PROGNOSTIC FACTORS By far the most important prognostic factor for breast cancer is the stage at the time of diagnosis. Breast cancers are categorized as stage I–IV on the basis of tumor size and evidence of metastatic spread. Stage I refers to tumors 2 cm or less without direct extension or nodal metastases. Stage II refers to tumors 2–5 cm without nodal metastases, or with homolateral axillary metastases with no evidence of fixation to surrounding structures. Stage III refers to tumors larger than 5 cm with or without nodal metastases, or any tumor with axillary metastases sufficiently extensive to cause fixation of the affected nodes to adjacent structures, or any tumor with fixation to adjacent muscle or fascia that does not include the chest wall. Stage IV refers to any tumor with fixation to the chest wall or skin of the breast; any tumor with metastasis to regional nodes outside the axillary region, or other more distant metastases.

The histologic grade of the primary tumor is another useful prognostic indicator. The degree of glandular differentiation (the extent to which the tumor still resembles normal breast structures) and the extent of nuclear atypia in terms of size, irregularity of shape, and prominence of nucleoli are noted. Poor levels of differentiation and cells with large, irregularly shaped nuclei with prominent nucleoli are indicators of poor prognosis.

The level of proliferation is another useful prognostic factor. Proliferation can be assessed histologically by the mitotic index; or by immunohistochemical evaluation of proteins associated with proliferation, such as Ki-67 or PCNA; or by measurement of the number of cells in the S phase of the cell cycle by flow cytometry. High levels of cell division are associated with poor prognosis.

ESTROGEN RECEPTORS AND BREAST CANCER Estrogen and progesterone are implicated in the development of breast cancer by a number of epidemiologic observations, including increased risk for breast cancer with either early menarche or delayed menopause, and by exogenous administration of estrogens after menopause. In contrast, ovariectomy confers a protective effect against developing breast cancer. Taken together, these observations suggest that breast cancers are dependent on these hormones for their growth and evolution. Estrogen is a powerful mitogen for both normal breast epithelium and breast cancer cells; endogenous estrogen stimulates cell proliferation and tumor progression. This mitogenic signal is mediated by the estrogen receptor, a member of the nuclear receptor family. Stimulation of the ER upregulates expression of the PR. Therefore, measurement of the status of both ER and PR by ligand-binding analysis has become an important tumor marker. In general, ER-positive tumors are better differentiated, show lower mitotic activity, and are less aneuploid than ER-negative tumors, although ER-negative DCIS may have progressed beyond hormonal dependence, but these popular speculations may be an oversimplification. For example, in one recent study, proliferation was measured in DCIS and normal terminal duct lobular units (TDLUs) in the same breasts from a large number of patients dichotomized on the basis of menopausal status. Proliferation rates in TDLUs were much lower in postmenopausal compared with premenopausal women, consistent with the well-known mitogenic effect of estrogen on normal breast epithelium. In contrast, there was no difference in proliferation between the two groups in DCIS, suggesting that replication may be relatively independent of hormonal control, regardless of ER status. However, much remains to be studied in this important area of breast cancer research.

The "good" histopathologic features of ER-positive tumors translate into improved disease-free survival and better overall survival for patients with ER-positive tumors. ER status may eventually be shown to be useful as a prognostic factor in the clinical management of patients who already have DCIS or cancer, either alone or in combination with other factors such as histology and proliferation rate. However, its most promising role relates to its ability to mediate the effects of antihormonal drugs, such as tamoxifen, that might be used in future chemoprevention trials. These agents inhibit the recruitment of cells into the cell cycle by estrogen, resulting in diminished proliferation of breast cancer cells.

Overall, about 70% of primary breast cancers are ER-positive, and approximately 60% of these patients respond to antiestrogen therapy. Several studies have shown that tamoxifen can prolong disease-free survival in patients with ER-positive invasive breast cancer, probably by binding ER and suppressing cell division. Other studies have shown that the relative risk of developing a second breast cancer in patients initially treated with tamoxifen may be reduced by as much as half. These favorable effects may be as biologically relevant to premalignant lesions and carcinoma *in situ* (CIS) as they are to invasive breast cancer, and this type of reasoning has already provided theoretical support for a few ongoing chemoprevention trials in patients at high risk for developing invasive breast cancer. Unfortunately, prolonged tamoxifen therapy fails in most patients because of acquired resistance to its antiestrogenic effects. Tamoxifen resistance probably arises as a result of tumor-specific alterations ER gene structure or expression.

BREAST CANCER TREATMENT   With increased public awareness of breast cancer, combined with expanded use of screening mammography, 70% of breast cancers now present with stage I disease. Approximately 70% of these patients will be cured by surgery, with about 30% recurring within 5 years. Primary breast cancer surgery ranges from total mastectomy to more breast-conserving approaches such as lumpectomy. Although the chances of surviving breast cancer are approximately the same with either mastectomy or lumpectomy with radiation therapy, local failure rates remain higher after the latter procedure, ranging from 2 to 40%. This wide range of local recurrence is probably caused by differences in surgical or radiotherapeutic techniques, such as definition of surgical margins and doses of radiation delivered. The 30% of patients presenting with stage II or greater disease, and those patients with stage I disease who recur, derive significant benefit from adjuvant chemotherapy, such as systemic chemotherapy with cyclophosphamide, methotrexate, and fluorouracil. So far, the benefit of adjuvant chemotherapy for women with stage I breast cancers is marginal, and not without morbidity. Much of current breast cancer research is dedicated to identifying tumor biologic factors that predict recurrence in order to tailor specific treatments to the patient's needs.

SUMMARY

The majority of invasive breast cancers most likely evolve from precursor lesions. However, the putative precursor lesions are common relative to invasive breast cancer, emphasizing that progression is not obligatory, and that many biologic abnormalities underlying tumor progression are morphologically silent at the light microscopic level. Identifying these abnormalities may provide the ability to diagnose premalignant lesions at high risk for progression to invasive breast cancer, and allow for some type of intervention before progression occurs. Many studies are beginning to investigate the biologic characteristics of putative precursor lesions, such as hyperplasias and *in situ* carcinoma. Most such studies have retrospectively looked at features first described in invasive breast cancer. To date, very little is known with certainty about the biology of hyperplastic breast disease. *In situ* carcinomas have been more thoroughly studied, and there is considerable but still incomplete information regarding ER, proliferation rate, ploidy, *ERBB2*, and *TP53* status in such lesions. With the exception of these few biomarkers, however, very little else is known with certainty about the biology of preinvasive breast cancer. Based on recent genetic evidence supporting a precursor–product relationship between precursor lesions and invasive cancer in the same breast, future studies might benefit from evaluating the biologic phenotypes of putative precursors taken from breasts with and without invasive cancer. Comparison of phenotypes in these contrasting settings may emphasize biologic events that are critical in breast cancer evolution.

VIKAS P. SUKHATME

INTRODUCTION

This overview begins with a review of key concepts in developmental biology as they apply to the kidney. Molecules of demonstrated importance in nephrogenesis are then discussed. Finally, the focus is on implications of this work for basic science and clinical nephrology.

DESCRIPTION OF KIDNEY DEVELOPMENT

In mammals, the urogenital system develops sequentially in three stages: the first two stages, that is, formation of the pronephros and mesonephros, are transient. The last stage, development of the metanephros, represents the final kidney in reptiles, birds, and mammals; whereas, in fish and amphibians, the mesonephros is the final kidney. Importantly, all three steps in kidney development are characterized by induction of mesenchyme to epithelium. Here we shall focus only on metanephric development. Ureteric bud epithelium, an out-pouching of the Wolffian duct, invades metanephric mesenchyme, initiating "induction" of mesenchyme at its tip. Based on histologic features, the subsequent process has been divided into various steps: condensation, vesicle formation, comma and S-shaped body formation, glomerular cleft formation with angiogenesis, and then nephron formation (proximal and distal segments). In turn, as part of a reciprocal interaction, mesenchyme causes ureteric bud to branch sequentially, with mesenchymal condensates surrounding each new tip, thereby leading to differentiation in a centrifugal manner. The bifurcating ureteric bud structures ultimately form the collecting duct. Though this description of embryonic kidney development owes much to the classic work of Grobstein and Saxen, only recently have there been substantial advances in defining some of the critical underlying regulatory molecules.

CONCEPTS AND METHODOLOGIES IN STUDYING DEVELOPMENT AND THEIR APPLICATION TO THE KIDNEY
Developmental biologists of the past were embryologists and anatomists. Their primary work consisted initially of detailed observations. Later, many effectively utilized a "cut-and-paste" approach. These ablation and/or transposition experiments—for example, those of Spemann—led to many key developmental principles, especially the concept of induction. The next wave of developmental biologists were geneticists, who generated a host of developmental mutants in lower organisms such as

Drosophila. Finally, molecular genetics invaded the field, and descriptions at the level of molecules—transcription factors, matrix proteins, extracellular and intracellular signals—have emerged. This fusion of embryology, classical genetics, and molecular and cell biology has invigorated the field.

We begin with some general concepts in developmental biology. The first notion is that of mosaic vs regulative development. Vertebrate embryos display regulative development: removal of a blastomere or even an entire half of an embryo still leads to the formation of a normal embryo. In contrast, development in Caenorhabditis elegans is mosaic, that is, cell fate is more rigidly determined. Regulative development is largely a result of morphogens, molecules influencing various processes; for example, cell movement, polarization, or differentiation. These morphogens may be diffusible or cell-surface-bound. The effect of these morphogens is to set up (an) inductive event(s), a process whereby one cell influences another cell's development. In turn, a cascade of events can occur, the key mediators being transcription factors, growth and differentiating factors, cell adhesion molecules, and extracellular matrix.

Several approaches can be utilized to identify these molecules. Two broad schemes emerge: the phenotype-to-genotype approach and vice versa. The former is best exemplified by the use of positional cloning. Advantages are that the cloned gene is obviously of developmental importance and no prior knowledge of the protein is required for its identification. The disadvantage is that this methodology is demanding (albeit getting easier) and only a few mouse and human models exist; that is, the underlying genes may represent a small subset of developmentally critical genes. To circumvent this difficulty, zebrafish may be a suitable organism in which to perform a saturation mutagenesis analysis. In the phenotype to genotype approach, the initial goal is to identify candidate genes of developmental importance. A useful starting point is homology screening, either through low-stringency nucleic acid hybridization or through polymerase chain reaction (PCR)-based methodologies, or consider homologs of genes with demonstrated importance in lower organisms. A focus on growth factors or their receptors, adhesion molecules, proto-oncogenes, transcription factors, or intracellular signaling molecules is likely to yield the most useful information. Moreover, ± screening from cells at different developmental stages could be intersected with the above approaches. A narrowed list of clones could then be analyzed by *in situ* hybridization and/or Northern analysis to check for tissue-restricted and stage-specific expression. Ultimately, one could use

either forced ectopic expression in transgenic mice or in lower organisms (of the wild-type gene or a dominant negative construct) or knockout studies including conditional knockouts in cell culture or animals to analyze the function of the candidate gene. Less definitive results, but at considerably less cost, could be obtained utilizing antisense oligonucleotides or antibodies in kidney organ culture.

A useful framework for thinking about development is to divide events into three sequential categories: those involving patterning, those relating to cell differentiation and commitment, and those concerning morphogenesis. Patterning refers to regional specification, that is, the establishment of a body plan. It usually has to precede cell differentiation, in which cells start from a pluripotent or multipotent state and progressively assume specific differentiated fates that bring them closer to their final function in the developed organism. It is important to distinguish cell differentiation from commitment or determination. Commitment is the narrowing of the phenotypic possibilities open to a cell; differentiation is the actual enactment of that limited capability. As a result, commitment usually precedes differentiation. Morphogenesis refers to the creation of form—that is, the shaping of new structures—and therefore usually occurs after some differentiation has begun. Thus, these three, often sequential events—patterning, cell differentiation and commitment, and morphogenesis—form a logical paradigm in which to view development.

It is important to recognize that diverse molecular and cellular processes underlie these three steps. These processes include: cell growth and death (usually apoptosis rather than necrosis), cell motion, cell adhesion, imprinting, and cytoplasmic segregation. To delineate these processes, what they are and where and when they occur during a given developmental process is the challenge to the cell and molecular biologist.

How Does This Developmental Paradigm Relate to Kidney Development?   With regard to patterning, it is noteworthy that the formation of the metanephric kidney occurs only after the two earlier kidneys (the pronephros and the mesonephros) have formed. Nothing is known about the critical morphogen(s) that govern(s) the timing, location, or orientation of these structures. Regarding cell commitment and differentiation, cell lineages in the kidney have been delineated for many cell types with the exception of mesangial cells and endothelial cells of the glomerular capillary tuft: metanephric mesenchyme gives rise to the epithelial glomerular components, as well as to proximal and distal nephron. Ureteric bud epithelium develops into the mature collecting duct. These fate-mapping data arise from chimeric embryos and through the use of β-galactosidase transducing retroviruses to mark cells. Some of the more interesting questions relating to cell differentiation are the nature of the inducing signal from the ureter that leads to conversion of mesenchyme to polarized epithelium, the nature of the reciprocal interaction (mesenchyme to ureteric bud signaling), the development of the mesangial cell, the formation of the basement membrane, and the process of angiogenesis. Many excellent reviews are available that cite the changes in gene expression of various molecules during these steps. Additional candidates may be identified by educated guesswork from other tissues showing mesenchyme to epithelium conversion or through methodologies mentioned above, such as homology screening. Moreover, the availability of better cell culture systems (for example, cells arrested at different stages of differentiation, which can

be differentiated in culture by change in matrix or serum components) will also serve as useful starting reagents. Below, we only cite data that provide definitive proof of the importance of a select subset of potential critical molecules. Finally, with regard to morphogenesis in the kidney, diverse questions arise: What causes the formation of the cleft in the glomerulus? What is responsible for the complex branching that occurs in the nephron? How does the collecting system reshape after its initial formation? Few answers are currently available to these problems.

GENETIC CASCADES   Based on studies in lower organisms, a particularly fruitful approach to defining the elaborate genetic program that regulates kidney development is to focus on transcription factor genes expressed in the embryonic kidney, perhaps identified initially by homology screening. That a candidate gene is critical for nephrogenesis can then be established by the generation of a knockout mouse. Subsequently, efforts to identify downstream targets as well as upstream events—that is, *cis* elements and transfactors regulating expression of these transcription factor genes—can be utilized to start building a database of gene–protein interactions. Another useful starting point to identify potential critical transcription factors is to focus on the regulation of genes whose products play physiologic roles in the adult kidney. After ascertaining that transcriptional control plays a role in their expression, a search for factors regulating their expression will undoubtedly provide clues to tissue-specific regulation and define critical events occurring earlier in developmental time. Alternatively, genes essential for nephrogenesis, whether transcription factors or not, as ascertained by knockout or ectopic expression studies in transgenic mice, can form the starting point for such "upstream" studies.

CLONED GENES CRITICAL FOR NEPHROGENESIS   We shall not discuss here many candidate genes—based on their stage-specific expression—of possible importance in kidney development. Rather we cite only data from in vivo "experiments" (in mouse or man) that clearly establish the importance of a candidate gene for nephrogenesis.

WT-1 (Wilms' tumor gene-1) is a tumor suppressor gene involved in the genesis of Wilms' tumor. The protein functions as a transcription factor with a DNA binding domain consisting of four zinc fingers, three of which are similar to those of the EGR gene family. Human mutations in the DNA binding region of WT1 have been characterized and are present in 10–20% of Wilms' tumors. Importantly, the best correlation of these mutations is in the rare Denys-Drash syndrome. During embryogenesis, WT1 expression is tissue-restricted. It is most strikingly expressed in induced metanephric mesenchyme and subsequently in podocytes. Persistent expression is noted in mesothelial tissues: pericardium, pleural, and peritoneal cells. WT1 knockout mice display no metanephric kidney, no gonads, and an abnormal mesothelium, leading to hypoplastic lungs and heart. The homozygotes die at embryonic day 13–15. Curiously, formation of the mesonephric kidney is largely unaffected, though the number of nephrons is decreased two- to threefold and ureteric bud fails to grow. The latter result was unexpected since WT1 is minimally expressed in uninduced mesenchyme and is not detectable in ureteric bud or Wolffian duct. Blastemal cells in the knockout mouse undergo apoptosis. Pax 2 *(see below)* is expressed on the ureteric bud side in WT1 (–/–) embryos but not in blastema, suggesting that WT1 expression is a prerequisite for Pax 2 expression in blastema.

Of the Pax gene family, Pax 2 and Pax 8 are expressed in developing kidney. These genes encode transcription factors and are related to the Drosophila segmentation genes in a region referred to as the paired box. Pax 2 expression occurs in the collecting system and in condensed mesenchyme, comma and S-shaped structures, but not in mature glomeruli, whereas Pax 8 expression differs from that of Pax 2 in that it is absent in the ureteric bud. Little Pax expression is seen in the adult. Increased Pax 2 expression has been formed in the hyperproliferative dysplatic epithelia of tubuler of children with dysplastic kidneys. When Pax 2 expression was constituently expressed in a transgenic mouse, including epithelial cells of the glomerulus, marked developmental anomalies resulted, reminiscent of those seen in the Finnish congenital nephrotic syndrome. Also, in Danforth's short tail mouse, Pax 2 expression is absent in mesenchyme. These mice show renal agenesis. Pax 2 stimulates the WT-1 promoter, and it may play a role in tissue-specific expression of WT-1.

The N-myc proto-oncogene belongs to the myc family of basic helix-loop-helix/leucine-zipper transcription factors. N-myc expression during nephrogenesis is similar to that of Pax 2 except that no expression is seen in the ureteric bud. N-myc knockout mice die at 11.5 days of gestation, precluding study of metanephric development. The mesonephros shows a decreased number of tubules and hypoplasia.

OP-1, also known as BMP-7, is a member of the TGF-β family, which shows striking expression in induced mesenchyme and early epithelial structures of the glomerulus with lesser expression in the ureteric duct. OP-1 knockouts display severe defects in the developing kidney. Though some comma and S-shaped bodies are present, the extensive formation of tight condensates is markedly reduced, resulting in a highly disorganized structure with much loose interstitial tissue. These data indicate a critical role for OP-1 in the survival and growth of both epithelium and mesenchymal components of the developing kidney. However, it is possible that even earlier defects in nephrogenesis might be noted if effects of maternal transfer of OP-1 to the embryo could be negated.

Wnt-4, a secreted glycoprotein, is part of the Wnt gene family, whose members play diverse developmental roles. During nephrogenesis, Wnt-4 expression is detected in condensing mesenchyme, comma and S-shaped bodies, and later restricted transiently to the region of epithelial fusion between the S-shaped bodies and collecting duct. Mice deficient in Wnt-4 activity fail to form pretubular aggregates, thus exhibiting a block in epithelial transformation of metanephric mesenchyme. Initial expression of WT1 in Wnt-4 knockout mice is normal. N-myc and Pax 2 expression is also normal except none is present in tubules. Pax 8 expression is, however, completely absent. These findings indicate that Wnt-4 activity plays no role in the development of ureteric epithelium.

Bcl-2, an oncogene described first in a B-cell lymphoma, functions by blocking programmed cell death or apoptosis. Apoptotic cells have been noted in the corticonephrogenic zone as well as in the papilla and may account for 3% of the cells in the developing kidney. As a first approximation, Bcl-2 expression is widespread in the developing kidney: in branching ureteric bud, metanephric cap tissue, and early tubular structures, and persists at lower levels in glomeruli, tubules, and collecting duct. Bcl-2 knockout mice develop polycystic kidneys with dilated tubules and hyperproliferative glomerular epithelial cells. The interstitium also contains immature cells.

The mouse limb deformity (ld) locus was identified as a result of transgene insertion. Several proteins (termed formins), the result of alternative splicing of the ld transcript, have been identified; they encode nuclear proteins expressed in the apical ectodermal ridge, a structure critical for limb development, as well as in epithelial cells of the pronephros and mesonephros (in the chicken). The human kidney is the major site of expression among several fetal tissues analyzed. Insertional mutagenesis at the ld locus in the mouse gives rise to a recessively inherited characteristic limb deformity (reduction and fusion of the distal bones and digits) and a renal aplasia phenotype, findings consistent with the pattern of expression of the ld transcript.

Defects in the PKD1 gene, identified recently by positional cloning, account for approximately 85% of mutations in autosomal dominant polycystic kidney disease (ADPKD). The gene product is a transmembrane protein expressed primarily on the ureteric bud side. It is most prominent in mature tubules, with lower levels in Bowman's capsule and the proximal ureteric bud. PKD1 is also expressed in hepatic bile ductules and pancreatic ducts (sites of cystic changes in ADPKD) and in skin (not known to be affected ADPKD). Based on the characterized human mutations in the PKD1 gene, it is clear that this gene product is of obvious import in nephrogenesis, though little mechanistic insight is currently available to account for the complex phenotypic changes noted in cells from PKD patients. A second gene (PKD2) for ADPKD has been identified by positional cloning. The PDK2 gene shares homology with PKD1 and appears to be a member of the family of voltage-activated calcium channels.

The PDGF family consists of three homo/heterodimeric members: AA, AB, and BB. The PDGF-α receptor binds both A and B chains, whereas the PDGF-β receptor only binds the B chain. The PDGF-α receptor is expressed in mesangial structures in early glomeruli, but it declines as glomeruli mature. Since PDGFs mediate chemotaxis, differentiation, and growth, and affect production of extracellular matrix, they are prime candidates to be key developmentally important molecules. Mice deficient for PDGF B chain activity show renal, cardiovascular, and hematologic abnormalities and die perinatally. Importantly, no glomerular tuft forms, perhaps because of the absence of mesangial cells. A single or a few widened capillary loops are present. In addition, PDGF-β receptor knockout mice exhibit a similar glomerular defect. These findings are consistent with earlier data that mesangial cells respond mitogenically to PDGF (BB and AB more than AA) primarily through the PDGF-β receptor. Furthermore, they also suggest that mesangial cell development depends on a well-developed capillary network or vice versa.

c-Ret, a receptor protein tyrosine kinase, is normally expressed at the advancing tip of the ureteric bud, in the Wolffian duct, as well as in the developing central and peripheral nervous systems. Mice lacking c-Ret activity die postnatally because of complete or partial failure of renal development, with histology of rudimentary kidneys showing marked disorganization and decrease in tubules (proximal and distal), glomeruli, and vessels, as well as reduced ureteric bud branching. Moreover, large regions of undifferentiated mesenchyme are also present. These findings suggest that the c-Ret receptor transduces a critical signal presumably derived from metanephric mesenchyme involved in ureteric bud branching and growth.

FUTURE PROSPECTS

Though the pace of developmental biology research, as it pertains to the kidney, has clearly accelerated in recent years, many gaps remain in our understanding. What implications might this new knowledge have? From the basic science standpoint, nephrogenesis shares many features with other developmental systems such as the mammary gland, lung, and pancreas: inductive interactions, angiogenesis, branching morphogenesis, and so on. Thus, insights gained in one system will aid in the other. New families of growth factors or receptors may be identified, or novel members of pre-existing families might emerge. From a clinical standpoint, there is the emerging belief that mechanisms involved in development play a role, not only in primary renal genetic disorders, but also in the response of the kidney to injury, both acute and chronic. Introduction of growth factors such as HGF or IGF-I or blockade of ICAM-1 may prevent acute renal failure. Chronic injury caused by overexuberant production of TGF-β1, PDGF, or FGF might be amenable to therapy, either by preventing action of these molecules or, potentially, by transdifferentiating the resident cells that produce them. Both protein-based and gene therapy approaches could be envisioned. In this vein, one might be able to differentiate blastemal cells in a Wilms' tumor, thereby decreasing production of IGF-II, a factor that likely functions in an autocrine fashion to promote blastemal cell growth. Such differentiating agents might include peptide factors or other molecules by analogy with the use of all *trans*-retinoic acid in the treatment of acute promyelocytic leukemia. Finally, though it is hard to envision because of the complex architecture of the kidney, introduction of a suitable stem-cell population might lead to new nephron formation. Interestingly, adult fish, for example, do generate new functioning nephrons in response to toxic injury. Thus, many and varied opportunities for novel interventions will undoubtedly present themselves in the years ahead, fueled by a better understanding of kidney development.

65 Mechanisms of Leukocyte Extravasation

M. Amin Arnaout

INTRODUCTION

The recruitment of leukocytes from the blood stream into tissues is a key step in immune surveillance and host defense against pathogens. It is also an essential factor in acute and chronic inflammation. Therefore, elucidation of the molecular events that underlie leukocyte emigration into tissues in physiologic and pathologic states is important in understanding mechanisms of disease and in devising new therapies. In this concise review, current understanding of the molecular basis of leukocyte emigration into tissues is presented.

ANATOMIC FEATURES OF LEUKOCYTE EXTRAVASATION

STAGES IN TRANSENDOTHELIAL MIGRATION OF PHAGOCYTES   The transition of leukocytes from the blood into tissues involves a series of interactions between leukocytes and the vascular endothelium. Some of these interactions were elegantly described in the late 19th century by Cohnheim. In classic ex vivo studies using the mesentery and the tongue of frogs, Cohnheim found that as these tissues became irritated by manipulation under the microscope, the vessels dilated, and the blood flow increased transiently, then slowed down. Polymorphonuclear leukocytes (largely neutrophils) began to contact the vessel wall and to roll, with some adhering firmly, and then slowly crept across the endothelium into the extravascular space (Fig. 65-1). Refinements to the technique of intravital video microscopy has since allowed better monitoring and quantitative analysis of these interactions. As leukocytes enter postcapillary venules, they are pushed toward the endothelium by the faster moving (at 1–3 mm/s) red blood cells. In tissues continuously exposed to mechanical and/or chemical stress (such as the skin and gut), a significant proportion of polymorphonuclear leukocytes establish unstable interactions (contact) with endothelium, which, under flow conditions (shear stresses varying between 3 and 20 dyne/cm^2), force a rotational motion of the leukocyte (rolling). The slower speed of rolling leukocytes (approx. 20–60 µm/s) permits some to stick or firmly adhere to endothelium (i.e., become stationary for several seconds) as a prelude to emigration, a process that takes few minutes to complete. Whereas rolling appears to be a necessary precursor to neutrophil extravasation in mesenteric and skin postcapillary

venules, it may not be a prerequisite for emigration in other vascular beds. In rabbit lung, for example, neutrophil extravasation occurs in capillaries, not postcapillary venules. The geometric dimensions of such capillaries give little room for neutrophils to roll prior to adhesion and emigration.

The earliest leukocytes present at an inflammatory site tend to be neutrophils. This can be shown experimentally by the intradermal injection of the bacterial-derived product lipopolysaccharide (LPS). This elicits rapid influx of neutrophils peaking within approximately 4 h and soon followed by a mononuclear cell infiltration, which becomes predominant by 48 h. Other types of inflammation are accompanied by the predominance of other leukocyte cell types. For example, parasitic diseases are associated with an inflammatory influx where eosinophils predominate, whereas chronic inflammation is usually accompanied by a predominance of mononuclear cells.

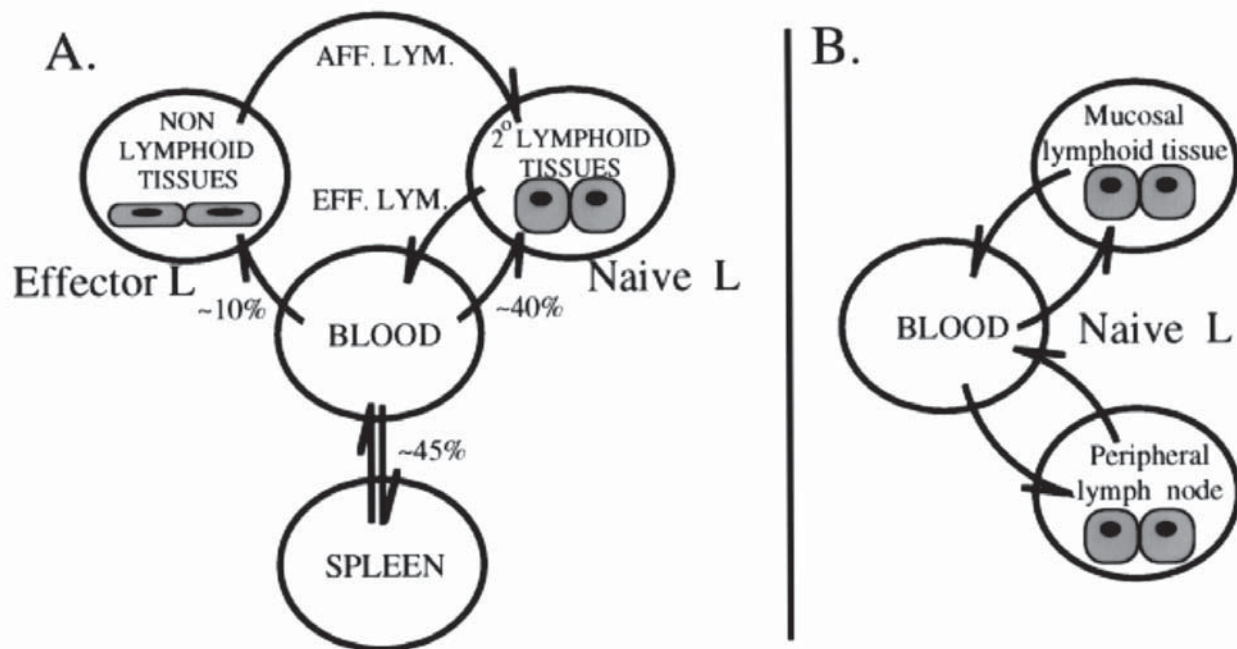
PATTERNS OF LYMPHOCYTE EMIGRATION (HOMING) INTO TISSUES   Homing of Naive Lymphocytes   In contrast to phagocytic cells, most lymphocytes (with the exception of some terminally differentiated cells, such as γδ intraepithelial cells and plasma cells) that cross the endothelial cell barrier into tissues, migrate back to the blood and then again into tissues (i.e., they recirculate). Less than 1:100,000 lymphocytes is specific for a certain antigen, and hence the need for these cells to continuously circulate through the potential ports of "foreign" antigen entry (lungs, skin, and gastrointestinal tract [GI], and their draining lymph nodes) for efficient immune surveillance. Blood to lymph recirculation can be demonstrated experimentally by injecting labeled lymphocytes intravenously and monitoring their appearance in the cannulated thoracic duct and in the spleen, for example. Approximately 40% of injected lymphocytes are recovered from spleen after 1 h, making it the predominant organ through which lymphocytes circulate. An additional 10% of lymphocytes circulate through the rest of secondary lymphoid organs in humans. Under normal conditions, recirculation of naive lymphocytes (those that have not encountered antigen) through secondary lymphoid organs takes place through histologically distinct postcapillary venules called high endothelial venules (HEV), with no significant migration across normal "flat" venular endothelium (Fig. 65-2A). Recirculation through the spleen takes place through blood sinusoids. Extravasated lymphocytes then leave the lymph nodes through the efferent lymphatic vessels. Recirculation of lymphocytes through peripheral and mucosal secondary lymphoid organs is not random: distinct subpopulations target either one or the other
Figure 65-1 Stages in the extravasation of a leukocyte into the extravascular interstitium. Activated endothelial cells are shaded. (*See text* for details.)


Figure 65-2 Recirculation routes of naive and effector lymphocytes. **(A)** Approximately 40% of naive lymphocytes move between the blood and secondary lymphoid tissues—mucosal lymphoid tissues and peripheral lymph nodes—with subpopulations migrating through either one or the other **(B)**. Naive cells migrate across cuboidal specialized venular endothelium (HEV). Effector lymphocytes extravasate through flat endothelium in nonlymphoid tissues and reach back to mucosal or lymph nodes through afferent lymphatics. (*See text* for details.)

(Fig. 65-2B). Important features of the cuboidal-shaped HEV that may be important in facilitating large-scale migration of lymphocytes include discontinuous intercellular junctions; synthesis of sulfated glycotopes that are unique to this endothelium; and a prominent glycocalyx, which facilitates retention of normally secreted growth factors and adhesion molecules, and of matrix proteins including laminin and fibronectin. HEV endothelium is normally restricted to secondary lymphoid tissues, with the exception of the spleen.

Homing of Activated Lymphocytes   Once a naive lymphocyte encounters its antigen, usually on the surface of a dendritic antigen-presenting cell (APC), the lymphocyte is held at this site for several days, in close contact with APC, during which time it is activated by ligation of its antigen receptor in the presence of costimulatory signals, and begins to divide. Its progeny then re-enter the circulation via the efferent lymphatics and through the thoracic duct into the blood. These effector/memory cells, in

contrast to their predecessors, acquire the ability to selectively home in on the organs where they first encountered antigen. For example, lymphocytes activated in mucosal intestinal lymphoid tissues (which include organized structures such as Peyer's patches and tonsils) or in the peripheral lymph nodes (PLN) preferentially home back to the gut and PLN, respectively. Their migration into these sites, however, does not normally follow the same path that their predecessors followed: The activated cells preferentially migrate across "flat" endothelium of the nonlymphoid tissues and not through HEV endothelium—their access to the secondary lymphoid organs takes place through the afferent lymphatics draining into this organ (Fig. 65-2A). These distinct migration routes ensure the continuous delivery of naive lymphocytes to sites of antigen exposure, of activated cells to nonlymphoid tissues for antigen elimination, and contribute to the rapid recall and faster responses characteristic of secondary immune reactions.

These "normal" leukocyte migratory patterns can be altered in pathologic states: Effector lymphocytes can extravasate across "flat" and HEV endothelium in acute inflammation. In addition, chronically inflamed extra lymphoid tissues (such as rheumatoid synovium, pancreas in diabetes mellitus, and the thyroid gland in autoimmune thyroiditis), can acquire HEV-like properties, thus facilitating large-scale migration of lymphocytes into these sites.

MOLECULAR BASIS OF LEUKOCYTE EXTRAVASATION

Genetic and molecular cloning studies unraveled the major receptor/ligand systems involved in leukocyte extravasation (Table 65-1). These belong to five cell adhesion molecule families, the integrins, selectins, immunoglobulin-like, proteoglycans, and mucins.

The first indication that leukocyte recruitment into tissues is mediated by specific surface receptors came from understanding the pathophysiology of a genetic deficiency in leukocyte-adhesion-dependent functions called leukocyte adhesion molecule (Leu-CAM) deficiency (LAD). In this disease, leukocyte contact and rolling on vascular endothelium are intact, but the sticking and diapedesis components of extravasation are defective. Biochemical and immunochemical studies identified the defective leukocyte proteins as CD11/CD18 (β2 integrins), members of the integrin family.

ADHESION MOLECULES MEDIATING EXTRAVASATION OF PHAGOCYTIC CELLS   Contribution of Selectins to Neutrophil Influx   In neutrophils, selectins expressed on leukocytes (L-selectin) and on vascular endothelium (P- and E-selectin) mediate the initial neutrophil contact and rolling on mesenteric venular endothelium. The slower speed of rolling enables leukocytes to sense and react to the local microenvironment. Many inflammatory mediators (presented by endothelia in free or proteoglycan-bound forms) are recognized by G-protein-coupled leukocyte surface receptors belonging to the seven-membrane spanner family, members of which include the IL-8-, C5a-, MCP-1-, and PAF receptors. Ligation of these receptors triggers leukocyte activation. This leads to rapid switching of leukocyte integrins from inactive to active states, that are able to mediate firm adhesion and cell migration (Fig. 65-3). This activation-dependency, which is sensitive to pertussis toxin, a G-protein αi inhibitor, distinguishes firm adhesion from contact and rolling activities. Rolling followed by firm adhesion and neutrophil emigration may proceed in an integrin-dependent but selectin-independent manner when blood flow is reduced or stopped, conditions that prevail in many inflammatory states such as ischemia-reperfusion injury, sepsis, and occlusive vascular diseases.

Each of the three selectins can mediate early contact and neutrophil rolling. Studies in selectin knockout mice reveal complementary roles for P- and L- selectin but overlapping roles for P- and E-selectins in neutrophil contact and rolling. Early contact and rolling caused by surgical exposure of venules is P-selectin-mediated, whereas rolling on cytokine-activated endothelium is L-selectin-dependent. Neutrophil extravasation into the peritoneal cavity of P- or L-selectin-deficient mice is significantly reduced but is normal in E-selectin-deficient mice. Thioglycolate-induced neutrophil accumulation in the peritoneal cavity of E-selectin deficient mice is significantly reduced by anti–P-selectin monoclonal antibodies (MAbs), although this treatment is ineffective in reducing influx in normal mice. Thus, optimal neutrophil extravasation, at least in the peritoneum, is mediated by P- and E-selectin working in concert, in combination with L-selectin. While neutrophil accumulation into the peritoneal cavity is reduced in P-selectin knockout mice, it is unaffected in the lung, emphasizing the important role of vascular hemodynamics as well as tissue-specific endothelial-cell adhesion profiles in recruitment of inflammatory cells in different vascular beds.

Structural and Physical Factors Contributing to Selectin-Mediated Neutrophil Adhesion   Selectins project a significant distance from the cell surface (approximately 15–43 nm depending on the number of short concensus complement repeats (SCR) (Fig. 65-3). This provides one likely explanation for their utility in mediating the initial contact between leukocytes and endothelium. The shorter length of L-selectin (only two SCRs) is compensated for by its preferential expression on membrane microvilli. Selectins bind to several ligands in a calcium-dependent manner.

Table 65-1
Leukocyte and Endothelial Cell Adhesion Molecules Involved in Leukocyte Extravasation

Leukocyte receptor	Endothelial ligand
CD62L (L-selectin)	GlyCAM-1; CD34; MadCAM-1; ?[a]
PSGL-1	CD62P (P-selectin); ?
PSGL-1; ESL-1; ?	CD62E (E-selectin)
CD49d/β7 (α4β7)	MadCAM-1; VCAM-1 (CD106); Fibronectin
CD49d/CD29 (α4β1)	CD106; Fibronectin
CD51/CD61 (αVβ3)	CD31 (PECAM-1)
CD11a/CD18 (αLβ2)	ICAM-1 (CD54) ICAM-2 (CD102)
CD11b/CD18 (αMβ2)	CD54; CD102; Fibrinogen; ?
CD11c/CD18 (αXβ2)	Fibrinogen, ?
CD44	?; Hyaluronate; Fibronectin
?	VAP-1[b]
?	VAP-2
?	CD49f/CD29[c] (α6β1, EA-1)

[a]? indicates ligands or receptors that remain to be identified.
[b]VAP-1, VAP-2, vascular adhesion proteins 1 and 2. Their functional significance in vivo is not established.
[c]CD49f/CD29, a laminin receptor that may be involved in lymphocyte adhesion to endothelium and in targeting thymocyte progenitors to the thymus, an area not further discussed in this concise review.

Figure 65-3 Adhesion molecules mediating neutrophil extravasation. Selectins act early in mediating contact and rolling, with integrins mediating sticking and emigration. P-selectin consists of an N-terminal globular lectin domain ($\sim4 \times 2.5 \times 2.5$ nm), followed by an EGF-like region (small rectangle in figure), and nine SCRs arranged as rod-shaped structures, with each SCR aligned as a bead fitted into the proposed triple loop structure. The homologous E- and L-selectins contain six and two SCRs, respectively. Alternative spliced forms of selectins have been reported. PSGL-1 is a disulfide-linked dimeric transmembrane glycoprotein having a large mucin ectodomain depicted as a rod-like structure with arbitrary-based carbohydrate branches. ESL-1 contains multiple cysteine-rich repeats with an N-terminal putative ligand binding region. The vascular ligand(s) for neutrophil L-selectin remains to be identified. Integrins, heterodimers of an α-subunit noncovalently associated with a β-subunit, are drawn to accommodate the head and tail morphology revealed by EM studies. Dimensions of the combined head and each tail are 8×10 nm and 15 nm, respectively, with the N-terminal halves drawn as squares (low-affinity forms) or as circles (high-affinity forms). Inflammatory mediators are shown as small white boxes, released from the subendothelium and/or surface expressed (as in the case of platelet activating factor, PAF, and others). Integrin ligands CD54, CD102, and CD31 (a ligand for $\alpha v\beta3$) are transmembrane glycoproteins and members of the immunoglobulin (Ig) family (characterized by the presence of the Ig domain with dimensions 4×2.5 nm, depicted here as ellipsoidal). CD54, CD102, and CD31 contain five, two, and six Ig domains respectively.

SELECTIN LIGANDS   Most selectin ligands carry sialylated or sulfated fucosylated structures, normally expressed on the termini of O- or N-linked oligosaccharides or glycolipids. A common prototype of a selectin ligand is Lewis X (Le^x), a lactosamine (Galβ1-3GlcNAc or Galβ1-4GlcNAc) backbone in an α1-3 linkage to a fucose, and an α2-3 linkage to a sialic acid (sialylated Le^x) or to sulfate (sulfo-Le^x). The affinity of monovalent sLe^x to selectins is low (micromolar to millimolar range). Proper presentation of such monovalent carbohydrates is therefore essential for promoting contact and rolling in vivo. The dense patches of O-linked oligosaccharides, presented by cell surface mucins, may explain why many physiologic selectin ligands belong to this class of glycoproteins. Mucins also assume rigid extended structures (Fig. 65-3), projecting several nanometers from the cell surface, thus providing ample opportunity for the Ca^{2+}-dependent high on-rate, high off-rate interaction that characterizes selectin-ligand interactions.

Neutrophil L-selectin and vascular P-selectin bind to mucin-type ligands. None of the three cloned L-selectin ligands, GlyCAM-1, CD34, or MadCAM-1 (Table 65-1) appear to be involved in promoting neutrophil contact and rolling in post-capillary venules: expression of GlyCAM-1 is limited to HEV endothelium. Although CD34 is expressed by nonlymphoid "flat"

endothelium, it does not contain the sulfated oligosaccharides required for recognition by L-selectin. Furthermore, its expression is downregulated by inflammatory cytokines such as IL-1 and tumor necrosis factor-α (TNF-α), which normally promote neutrophil extravasation. MadCAM-1 expressed on "flat" endothelium also lacks L-selectin-binding carbohydrates. These observations suggest that L-selectin-mediated neutrophil contact and rolling in postcapillary venules is mediated by yet to be characterized carbohydrate-based ligands.

The P-selectin ligand on neutrophils is a cell surface mucin dimer called PSGL-1 (Table 65-1, Fig. 65-3). PSGL-1 is expressed on neutrophils, monocytes, NK cells, and lymphocyte subsets. PSGL-1 can also be recognized by E-selectin, accounting perhaps for the functional overlap between P- and E-selectins. Another P-selectin ligand was recently isolated from mouse neutrophils and HL60 cells, and appears to be a sialylated glycoprotein of 160 kDa (80 kDa reduced). Its structure is unknown at present. E-selectin also binds to ESL-1, a nonmucin leukocyte glycoprotein that is identical to fibroblast growth factor receptor (FGFR) type 3. ESL-1 is ubiquitous, but is only sialylated and fucosylated in myeloid cells, and therefore serves as an E-selectin ligand in these cell types. The contribution of ESL-1 to neutrophil contact and rolling in vivo remains to be established.

Regulated Expression of Selectins   L-selectin is constitutively expressed in leukocytes, but is rapidly shed when cells are activated. P-selectin is expressed within few minutes on the endothelial cell surface as a result of mobilization of intracellular vesicles (Weibel-Pallade bodies) by thrombin or histamine. Other stimuli such as oxygen-free radicals and TNF-α can maintain this expression for longer periods by preventing the normal endocytosis of expressed P-selectin and through increased synthesis, respectively. E-selectin is newly synthesized and expressed within 1–4 h in response to lipopolysaccharides or cytokines such as interleukin-1 (IL-1) and TNF-α, with the level of expression returning to baseline by 24–48 h in vitro. The rapid expression of P-selectin makes it an ideal candidate for rapid neutrophil contact and rolling observed on venular endothelium. Expression of both P- and E-selectin at later time points may explain the observations that P-selectin can compensate for E-selectin deficiency, and that loss of contact and rolling is incomplete in P-selectin knockout mice.

Mechanisms of Integrin-Mediated Neutrophil Adhesion   Integrin-mediated firm adhesion occurs through β2 integrins, the predominant integrins expressed in neutrophils. β2 integrins bind to ligands expressed on vascular endothelium such as CD54 (ICAM-1) and CD102 (ICAM-2) and others that remain to be identified (Fig. 65-3). Transendothelial migration (across tight junctions) is also integrin-mediated. Both firm adhesion and transendothelial migration are energy-dependent processes requiring cell activation and the transformation of integrins from low- to high-avidity states. Although integrins are essential in emigration, the counter receptors involved and the events that facilitate this transition are not clearly defined at present. CD31, a heavily glycosylated Ig member, which is preferentially expressed at endothelial tight junctions, can serve as a counter-receptor for integrin αVβ3. The migrating neutrophil induces endothelial cell retraction through an increase in endothelial cell intracellular Ca^{2+}, thus transiently loosening the tight junctions while squeezing through. A homophilic interaction between neutrophil and endothelial CD31 may be involved in this process. Migration through the basement membrane and subendothelial tissues, rich in matrix proteins and hyaluronate, may involve CD44, an abundant neutrophil proteoglycan, in addition to leukocyte integrins.

Factors Contributing to the Influx of Other Phagocytic Cells   In contrast to neutrophils, where β2 integrins predominate, eosinophils and monocytes express additional members of the integrin family, including β1, β3, and β7, which may play complementary or overlapping roles in the emigration of these cells. Thus, the nature and kinetics of appearance of leukocyte subpopulations at an inflammatory site (for example, the early appearance of neutrophils in infected regions, or the accumulation of eosinophils at allergic sites) are determined in part by the intrinsic adhesion profile of leukocytes. In addition, the type of inflammatory mediators present and the nature and kinetics of the endothelial and leukocyte adhesion responses to these mediators are crucial. Some mediators are cell-specific (e.g., monocyte chemotactic protein 1 [MCP-1] and IL-5 for monocytes and eosinophils, respectively); IL-4 selectively upregulates expression of CD106 (VCAM-1) on endothelial cells, thus facilitating the influx of eosinophils and mononuclear cells that express α4 integrins (the receptors for CD106). Other mediators induce the influx of leukocyte subtypes by increasing expression of a number of endothelial CAMs (e.g., the monokines IL-1 and TNF-α induce expression of CD54, CD106, E-, and P-selectins) and/or by activating

leukocytes (e.g., C5a, IL-8, platelet activating factor, GM-CSF, and TNF-α activate neutrophils and monocytes). Inflammatory mediators may act additively, synergistically, or antagonistically. For example, interferon-γ (INF-γ), together with LPS or TNF-α (but not IL-1), prolongs expression of E-selectin. TGF-β and IL-4, either alone or in combination, inhibit cytokine-induced E-selectin expression. Finally, differences exist in the adhesive phenotype of endothelium from different vascular beds, and in its response to mediators. IL-1 and TNF-α are poor inducers of CD54 on cultured synovial-derived endothelium, in contrast to umbilical-vein-derived endothelium. TNF-α can upregulate expression of CD54 and E-selectin on both arterial and venous-derived endothelium, but the inducible expression of CD106 by TNF-α is restricted to venular endothelium. Other agonists, such as oxidized LDL or lysophosphocholine (that are associated with atherogenesis), can induce CD106 (and CD54) expression on cultured arterial endothelium and likely contribute to the inflammatory origins of atherosclerosis.

ADHESION MOLECULES MEDIATING LYMPHOCYTE EXTRAVASATION   As in the case of transendothelial emigration of phagocytes, endothelial- and leukocyte-adhesion molecules and mediators orchestrate the trafficking of lymphocyte subpopulations into lymphoid and nonlymphoid organs.

Migration of Naive Lymphocytes   Recirculation of naive cells through HEV in PLN and in mucosal lymphoid tissues, such as Peyer's patches (PP), is largely mediated by L-selectin and by L-selectin and α4β7 integrin, respectively (Fig. 65-4). P-selectin is not involved, since most lymphocytes lack P-selectin ligands. Migration into both tissues requires β2 integrins. Supporting evidence comes from knockout mice, in which L-selectin deficiency leads to loss of naive cell recirculation through PLN nodes but only to a 50% reduction in recirculation through PP. Expression of the sulfated L-selectin ligands CD34 and GlyCAM-1, but not MadCAM-1 on PLN HEV, is in large part responsible for the fact that lymphocyte recruitment to PLN is L-selectin-mediated. Although GlyCAM-1 is not an integral membrane protein, it may still be involved in adhesion through an association with the thick glycocalyx of HEV. MadCAM-1 expression on PP and the lack of GlyCAM-1 expression in this tissue are important determinants in directing lymphocyte trafficking to PP. MadCAM-1 binds L-selectin through its mucin domain and integrin α4β7 through its N-terminal Ig-domain, thus accounting for the limited dependency of lymphocyte trafficking to PP on L-selectin (Fig. 65-4), and for the fact that mucosal lymphoid tissues in L-selectin knockout mice are populated by lymphocytes. Lymphocyte contact and rolling on PP HEV can be mediated by L-selectin or by α4β7, with the latter also contributing to firm adhesion. The selective expression of α4β7 on microvilli (as in the case of selectins) may in part explain its ability to mediate lymphocyte contact and rolling. β2 integrins also contribute to the pertussis-sensitive firm adhesion and emigration (Fig. 65-4). Their partial role in lymphocytes is predicted by the nearly normal lymphocyte extravasation and functions in Leu-CAM deficiency (LAD). The nature of the "physiologic" mediators involved in integrin activation during lymphocyte recirculation is undetermined at present.

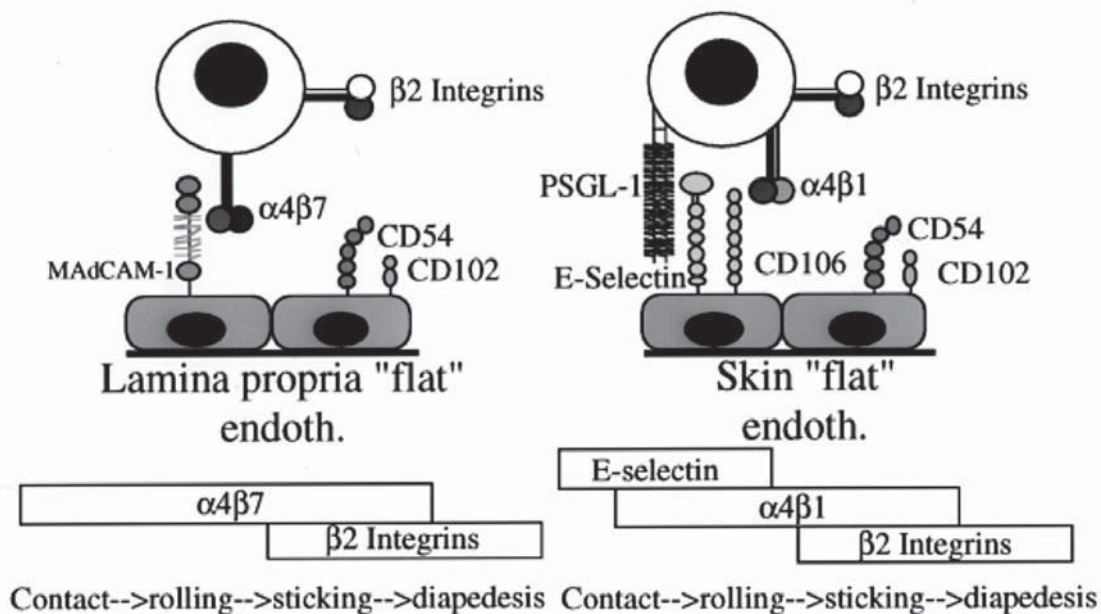
Emigration of Effector/Memory Cells   The phenotype of the leukocyte and receptive endothelium are also largely responsible for the predominant migration of effector lymphocytes through "flat" endothelium. Effector lymphocytes are largely L-selectin-negative but display preactivated integrins (Fig. 65-5). In addition,
Figure 65-4   Major adhesion molecules mediating recirculation of naive lymphocytes. The L-selectin ligands CD34 and GlyCAM-1 on PLN HEV have mucin domains, as well as sulfated moieties (shown as black branches). MadCAM-1 is also sulfated on PP HEV (but not on "flat" endothelium) and is composed of a mucin domain as well as three Ig domains. (*See text* for details.)


Figure 65-5   Major adhesion receptors mediating recirculation of effector lymphocytes. CD106, an Ig member with seven Ig domains (and alternatively spliced forms) serves as a ligand for α4 integrins in inflamed endothelium. (*See text* for details.)

MadCAM-1 is expressed in lesser amounts on flat endothelium compared to HEV, and is not properly sulfated, ensuring a predominance of α4β7 and α4β1 integrins in mediating contact, rolling, and firm adhesion in nonlymphoid tissues of the gut and inflamed organs, respectively. Effector lymphocytes (with preactivated integrins) also tend to arrest rapidly after very brief (or no) rolling. β2 integrins also contribute to firm adhesion and emigration (Fig. 65-5). High expression of CD44 on effector/

memory cells may facilitate lymphocyte migration through the subendothelium.

Lymphocyte Homing to Other Nonlymphoid Tissues
L-selectin plays minimal roles in targeting lymphocyte subsets to the skin, since venular endothelium generally lacks the glycotopes required for recognition by L-selectin. This, together with the fact that most lymphocytes do not express functional P-selectin ligands, may explain why contact and rolling are mediated by the vascular
Figure 65-6 Schematic diagram showing the primary structural features of integrin α- and β-subunits. Three or four of the seven repeats in the ectodomain of the α chains (generally repeats 4–7 and 5–7 in integrins lacking and containing the α A-domain, respectively) contain consensus metal binding sites (indicated by closed circles). The position of the A-domain, present in the α chains of all four β2 integrins, as well as those of α1β1, α2β1, and αEβ7, is shown. The β chain contains a C-terminal, four cysteine-rich repeats (CRR), and a putative A-like domain. Both the α and β chains span the plasma membrane once and contain, with the exception of β4, short cytoplasmic tails.

E-selectin, which is constitutively expressed in this tissue (Fig. 65-5). Vascular E-selectin binds to a cutaneous lymphocyte antigen (CLA) that is identical to a modified form of PSGL-1. Lymphocytes targeted to skin are α4β1-positive but α4β7-negative, and are therefore likely to utilize α4β1 integrin to mediate contact and rolling in an analogous manner to mucosal-targeted lymphocytes. As in most other tissues, β2 integrins contribute to lymphocyte firm adhesion and emigration. It remains unclear if novel organ-specific receptor/ligands or combinations of already known adhesion molecules are responsible for selective lymphocyte emigration to other organs such as lung, central nervous system, joints, or pancreas in disease states. The acquisition of the HEV phenotype in chronic inflammatory disorders affecting these organs (e.g., rheumatoid arthritis, multiple sclerosis, diabetes mellitus) and the anti-inflammatory effects of MAbs directed against selectins and/or integrins in animal models of these diseases, argue that already known receptors/ligand pairs are involved in lymphocyte emigration in these pathologic states.

STRUCTURAL ANALYSIS OF THE SELECTIN AND INTEGRIN LIGAND-BINDING SITES

SELECTIN LIGAND-BINDING DOMAIN The crystal structure of the C-type lectin-EGF domains of human E-selectin was recently solved. The lectin domain, which contains the ligand-binding site, is ovoid in shape, consisting of five β strands, two α-helices, and an extended number of loops. It contains a Ca^{2+} ion, well-coordinated by the side chains of E80, N82, N105, D106, the main chain carbonyl of D106, and two water molecules, forming the typical pentagonal bipyramid coordination sphere. The side chains of the conserved amino acids essential for ligand binding (Y48, N82, N83, E92, Y94, K11, and K113) lie on the same face as the bound Ca^{2+}, forming a single binding site, which can coordinate a monovalent carbohydrate ligand such as sLe^x. How such an arrangement allows selectin–ligand interactions with rapid on/off rates and of sufficient affinities to withstand the forces applied by the blood flow is unclear at present. One hypothesis proposes that affinity of a selectin-monovalent saccharide pair may be significantly enhanced by receptor clustering, as in other receptor-ligand interactions. Another view contends that side-chains from separate but clustered saccharide units (displayed by a mucin or a proteoglycan) would bind with higher affinity to an individual receptor lectin domain.

INTEGRIN LIGAND-BINDING DOMAINS Integrins bind to structurally unrelated ligands, including immunoglobulins, proteoglycans, cadherins, complement proteins, coagulation factors, and a large number of matrix proteins. Despite the structural complexity and diversity of these ligands, one common feature that is essential for recognition by integrins is a short and surface-accessible sequence containing a negatively charged aspartic acid or glutamic acid residue. Integrin binding to most ligands is also dependent on divalent cations and requires rapid switching of integrins from a low- to a high-avidity state in response to cell activation signals. Increased affinity appears to be a result of activation-dependent conformational changes in integrins. Such changes are suggested by certain MAbs that react with integrins after, but not before, cellular activation. The best candidates for integrin activation in the vasculature are chemokines acting through their G-protein-coupled receptors. The nature of the conformational changes that lead to a change in integrin affinity is not known.

Chemical crosslinking, mutagenesis, peptide inhibition and/or direct ligand binding studies using isolated integrin domains have identified three potential ligand binding regions (Fig. 65-6). One major site is located in a von Willebrand factor (vWF) A-type

domain present in the extracellular region of the α-subunit of seven integrins. This domain undergoes conformational changes in response to activation in whole cells and binds directly to several integrin ligands in a divalent-cation–dependent manner. A second metal-dependent ligand binding site is located in a proposed A-like domain present in all integrin β-subunits. Identification of this site was based on chemical crosslinking, peptide inhibition studies, and mutagenesis of single amino acids that block integrin ligand binding. No direct binding studies have so far been carried out using the isolated A-like β domain. It is important to recognize that this domain is also involved in the noncovalent association of the integrin β-subunits to their α-subunit counterparts. A third putative ligand binding region has been mapped to the EF-hand-like calcium binding domains 5 and 6 of the α-subunits (Fig. 65-6).

Crystal structure of the A-domain from integrin CD11b revealed that it adopts the common "dinucleotide-binding" α/β fold, with seven amphipathic α-helices surrounding a mostly parallel centrally located hydrophobic β-sheet. A single divalent cation binding site—metal ion-dependent adhesion site (MIDAS)—is located in a crevice at the top of the β-sheet, explaining the divalent-cation-dependent binding of this domain to several ligands. The MIDAS motif comprises a DxSxS sequence (residues 140–144 in CD11b, D, aspartic acid, S, serine x = any amino acid) from the βA-α1 loop, threonine (T)209 from the α3-α4 loop, and D242 from the βD-α5 loop. The two serines and the threonine make strong bonds to the metal via their sidechain hydroxyl oxygen atoms; two water molecules also bind directly to the metal, and the two aspartates make indirect contacts via water molecules. In the crystal, the side chain of a glutamate residue from a neighboring molecule completes the metal coordination. This arrangement may be a mimic of a natural integrin–ligand interaction and may explain the essential role of acidic residues in integrin ligands. The DxSxS motif is present in the β conserved region, which also assumes a similar hydropathy profile, forming the basis for the proposal that a modified A-like domain is also present in all integrin β-subunits. Recent studies show that the integrin A-domain also exists in a second conformation, suggesting a structural basis for the conformational changes observed at integrin activation.

LEUKOCYTE ADHESION AS A TARGET OF ANTI-INFLAMMATORY THERAPEUTICS

Since excessive accumulation of activated leukocytes in extravascular tissues contributes to several acute and chronic inflammatory disorders, targeting the responsible receptors to prevent injury has been a major therapeutic goal. Blocking MAbs to selectins, β2 and α4 integrins, and some of their ligands (e.g., CD54, CD31) have been found to markedly attenuate the parenchymal and microvascular dysfunctions observed in several animal models of inflammation, including ischemia-reperfusion injury, allograft rejection, antigen-induced arthritis, diabetes mellitus, immune complex-induced alveolitis, and glomerulonephritis. The inhibitory effects of anti-β2 integrin/ligand MAbs in these models is understandably incomplete, as patients with β2 integrin deficiency display near-normal functions of mononuclear cells. As discussed above, mononuclear leukocytes display and use multiple integrins in mediating cell adhesion, in contrast to neutrophils, which predominantly express β2 integrins. In these, as well as other models of immunologic injury, use of anti-α4 MAbs has significant anti-inflammatory effects. As expected *(see above)*, a

combination of anti-β2 and α4 integrin antibodies was found to almost completely inhibit mononuclear leukocyte recruitment in the majority of the inflammation models tested. Since integrins not only mediate extravasation but also several potentially harmful functions in the extravascular interstitium (e.g., bystander damage to healthy tissues, associated with phagocytosis, exocytosis of toxic compounds, and target cell killing), some of the beneficial effects of anti-β2 and anti-α4 integrin MAbs can also alleviate injury despite little or no inhibitory effects on extravasation.

Blocking MAbs directed against L-, P- or E-selectins also reduce inflammation in several models of ischemia-reperfusion injury, immune-complex diseases, and acute inflammation. The protective effects observed using single anti-selectin MAbs have been partial, and may require targeting all three selectins simultaneously, as suggested by the gene knockout studies described above.

SUMMARY

Significant progress has been made in understanding the molecular basis of the migration of various leukocytes from the blood stream into tissues under physiologic and pathologic states. Specific adhesion molecules on leukocytes and the vascular endothelium intertwine in response to locally released inflammatory signals to generate selective migration patterns, which ensure efficient surveillance of the body compartments by immune and inflammatory cells. While the identity of some adhesion and signaling molecules involved in leukocyte extravasation remains to be defined (Table 65-1), the therapeutic potential of targeting some of the already known key receptors has been amply documented in animal models of inflammatory diseases, and more recently in phase II and III clinical trials. Structural and biochemical studies are beginning to unravel the fine details of receptor–ligand interactions and should help in reconstructing the structural basis for the dynamic interaction between receptors and ligands during leukocyte emigration. These approaches will likely lead to more specific small molecule-based therapeutics.

66 Ischemic Acute Renal Failure

Joseph V. Bonventre

INTRODUCTION

Acute renal failure (ARF) is a clinical syndrome characterized by a deterioration of renal function over hours to days, with associated failure of the kidney to excrete nitrogenous waste products and to maintain fluid and electrolyte homeostasis. This clinical entity was defined in the seminal works of Bywaters, who characterized it in victims of aerial bombings during World War II. Bywaters described tubular cell necrosis and intratubular pigmented casts in the kidneys of these patients.

ARF can result from decreased delivery of oxygen and nutrients to renal tubular cells, a toxic or obstructive insult to the renal tubule, a tubulointerstitial process with inflammation and edema, or a glomerular disease resulting in a primary reduction in glomerular filtration. If the defect in clearance is related to obstruction of urinary outflow, the ARF is termed "postrenal." ARF is "prerenal" if the kidney itself is functionally normal or near-normal, so that kidney function is abnormal because of decreased renal blood flow. If the reduction in total organ or local blood flow becomes severe enough to cause tubular cell injury, prerenal ARF has progressed to "ischemic" ARF with tubular necrosis, loss of concentrating ability, and loss of ability of the kidney to conserve sodium. Prerenal azotemia and ischemic ARF are responsible for most episodes of ARF. Nephrotoxins are responsible for the next largest category of causes of ARF. Radiocontrast agents and various drugs including aminoglycosides are the most common toxic causes of ARF.

Since ischemia is the primary cause of ARF, most of what we know about the cellular and molecular features of ARF have been established using ischemia as the model insult in animals and as the focus of studies in humans. We will devote this chapter primarily to ischemic ARF. One should recognize, however, that many of the features of postischemic ARF are likely to be applicable to toxic ARF, where the pathological features of tubular injury are quite similar to those seen in the postischemic state.

The pathophysiology of ischemic renal injury is relevant not only to the acute setting associated with reduction in total renal perfusion but also to diseases such as hemolytic uremic syndrome, thrombotic thrombocytopenic purpura (TTP), acute vasculitis, and acute atheroembolic disease. In addition, many chronic diseases of the kidney result in ischemic injury to this organ. These include renal vascular disease, diabetic and hypertensive nephropathy, collagen vascular diseases, and chronic tubulointerstitial diseases.

There are vascular and tubular components to the pathophysiology of ischemic ARF. In this chapter, we will review the vascular, cellular, and molecular features of the pathophysiology of tubular cell injury. We will then discuss the molecular response of cells to hypoxia and relate this to gene induction in the kidney in response to ischemia. Finally, the important features of the repair process of the kidney after an ischemic insult will be presented.

VASCULAR COMPONENT OF ARF

The pathophysiology of ischemic acute renal failure is complex. There is clearly an important vascular component to the injury, not only at the level of total renal perfusion but also at the microvascular level where heterogeneity of blood flow, arteriolar vasoconstriction, and capillary obstruction limit oxygen delivery to renal tubular cells, whose oxygen needs are quite high. At a systemic level, inadequate blood flow to the kidney may result from hypotension, decreased cardiac function, renal artery stenosis, or occlusion. Within the kidney, small vessel disease secondary to atherosclerosis, atheroemboli, or vasculitis can result in ischemia. In addition, ischemia may result from local vasoconstriction due to an imbalance between vasoconstrictive and vasodilatory factors. These changes in vasoconstrictive forces may result from systemic vasoactive agents that are active locally on the small vessels of the kidney. Alternatively, damage to the endothelium, or alteration in endothelial function, may result in decreased production of vasodilatory substances, such as nitric oxide. With ischemia and reperfusion, there is preglomerular vasoconstriction that results in a primary reduction in glomerular filtration rate (GFR). Vasodilatory responses to agents such as acetylcholine are decreased in the postischemic tissue. There also is loss of autoregulation, with ischemic renal failure interfering with the normal vasodilatation that occurs in response to lowering of intraluminal pressure at the microvascular level.

There have been therapeutic attempts in animals as well as in humans to counter the vasoconstriction that occurs with ischemic acute renal failure. The renal vasculature is quite sensitive to endothelin, which reduces renal blood flow and glomerular filtration rate (GFR). Intraarterial injection of antibodies into a branch of the rat renal artery results in preservation of postischemic glomerular blood flow and single-nephron GFR in the region of the kidney supplied by the branch artery. Dopamine has been administered for both prevention and treatment of ARF in critically ill

patients. Clinical studies, however, do not support the routine use of dopamine for either prophylaxis or established ARF. Furthermore, the benefit of dopamine may be outweighed by its potential side effects, such as tachyarrhythmias, pulmonary shunting, and gut or digital necrosis.

Because calcium within vascular smooth muscle cells increases vascular tone and contributes to vasoconstriction, calcium channel blockers have been used as renovascular vasodilators. Their utility in ARF has been demonstrated in renal allografts, where calcium antagonists reduce the incidence of tubular necrosis and delayed graft function. Furthermore, in other conditions in which vasoconstriction is prominent, such as cyclosporine therapy and radiocontrast-induced ARF, calcium channel blocking agents have been reported to be effective in prevention of ARF. The use of these agents is limited, however, by their potential to cause systemic hypotension and therefore worsen ARF.

In animals, atrial natriuretic peptides (ANPs) attenuate the severity and potentiate the recovery of renal function even when administered after the ischemic insult in experimental ARF. This effect is presumed to be a result of the vasodilatory actions of ANPs, although these agents are also natriuretic and diuretic. Preliminary results from a multicenter prospective study indicate that these agents do not have a beneficial role in patients with ARF.

Heterogeneity of blood flow plays an important role in the pathophysiology of ischemic renal failure. Differences in the distribution of blood flow contributes to the heterogeneous nature of the tubule lesions seen with ischemia. Vascular congestion in the outer medulla and decreased blood flow to this region are features of experimental ischemic acute renal failure in rats. This vascular congestion may result in part from swelling of endothelial or tubular epithelial cells, resulting in interference with flow through the vasa recta.

The vulnerability of the tubules in the outer medulla is also enhanced by the vasa recta countercurrent exchange of oxygen, which results in a marked drop-off in oxygen tension, with increasing distance into the medulla from the cortex. The S3 segment, pars recta, of the proximal tubule, traverses this region and is more sensitive to ischemic injury than is the S1 or S2 segment. This vulnerability results from the imbalance between metabolic demand and oxygen delivery in this nephron segment. While many medullary cells increase their rates of glycolysis in an anaerobic environment, S3 proximal tubule cells in the outer medulla are not able to preserve their ATP levels using the glycolytic pathway, despite their ability to utilize glucose as an energy source to a greater extent than can S1 and S2 proximal cells.

Ischemia also results in primary changes in the glomeruli. The major morphological change in glomeruli of postischemic kidneys is capillary loop collapse, which is probably secondary to mesangial and vascular smooth muscle cell contraction. There is also flattening of the visceral epithelial cell bodies with increased permeability.

TUBULAR COMPONENT OF ARF

A pathological hallmark of ischemic and toxic ARF is tubular necrosis. With ischemia and reperfusion there are structural, biochemical, and vascular changes in the kidney that result in desquamation of viable and nonviable tubular cells, intraluminal tubular obstruction, and transtubular backleak of the glomerular filtrate.

STRUCTURAL CHANGES   Early morphological changes observed with ischemia include disruption of the microtubular and

actin cytoskeletal networks and blebbing of proximal tubule cell apical membranes with loss of the brush border. Proximal tubule cells lose their polarity and the integrity of their tight junctions, perhaps as a consequence of alterations in the actin cytoskeleton. Within 15 min of ischemia, Na^+-K^+-ATPase redistributes from the basolateral to the apical membrane, interfering with Na^+ and Na^+-coupled vectorial transport in the proximal tubule. There is loss of adhesion of viable epithelial cells, perhaps because of redistribution of integrins to the apical surface. Live and dead cells slough into the tubular lumen, contributing to cast formation. Tubular obstruction results in increased intratubular pressure and a reduction in GFR. Arg-Gly-Asp (RGD) peptides are partially protective against ischemic injury in animals. These peptides are proposed to act by interfering with cell–cell adhesion in the tubular lumen, thus preventing the increase in proximal tubular pressure normally observed in ischemic acute renal failure in animals. Loss of the epithelial cell barrier and the tight junctions between viable cells results in backleak of the glomerular filtrate, further reducing effective GFR. RGD peptide binding sites have also been identified along the intimal surface of blood vessels in ischemic kidneys.

Given the importance of intratubular obstruction to the pathophysiology of ARF, a potential approach to therapy would be to increase intratubular flow rate in an attempt to decrease the formation of obstructing casts. Furosemide and bumetanide have been used with this rationale. While these diuretics have been shown in experimental animal models to partially protect the kidney against ischemic injury, many studies in humans have failed to demonstrate effectiveness of these agents to prevent or treat postischemic ARF.

VOLUME REGULATION   With energy store depletion and cell injury, cell swelling occurs. This may be of particular significance in the outer medulla, where endothelial cell swelling into the lumen of the capillary, together with extrinsic pressure resulting from tubular cell swelling, may compromise capillary patency. Mannitol has been administered to animals and patients with the rationale that prevention of cell swelling and increase in intratubular flow might decrease intratubular obstruction and mitigate renal dysfunction. Mannitol and other osmotic agents have been demonstrated to have a protective effect in the preservation of transplanted kidneys and prevention of delayed graft function, which is most often ischemic in etiology. Mannitol is also likely effective in the prevention of myoglobinuric ARF and is recommended, along with vigorous fluid replacement and $NaHCO_3$, for the prevention and treatment of early myoglobinuric ARF.

CALCIUM   In addition to the role that calcium plays in vasoconstriction mediated by the vascular smooth muscle cell, calcium may have a primary toxic intracellular action in the renal tubular cell as a consequence of ischemia. Under normal conditions, extracellular $[Ca^{2+}]$ is 10,000-fold greater than cytosolic $[Ca^{2+}]$. ATP-dependent mechanisms are responsible for maintenance of this large gradient. ATP depletion leads to an increase in $[Ca^{2+}]$ in tubular epithelial cells. This increase in $[Ca^{2+}]$ results in part from an increase in intracellular $[Na^+]$, which occurs secondary to energy depletion and consequent inhibition of the Na^+/K^+ ATPase. The decrease in the transmembrane $[Na^+]$ gradient potentiates Ca^{2+} entry into the cell via the Na^+/Ca^{2+} exchanger. There is inhibition of Ca^{2+} extrusion by Ca^{2+} ATPases because of decreased ATP. Thus, Ca^{2+} accumulates within ischemic cells. There are a number of Ca^{2+}-activated enzymes, such as proteases and phospholipases, which can be toxic to cells. In addition, uptake into mitochondria may interfere with ATP generation and ultimately lead to mito-

chondrial destruction. In addition, increased levels of cytosolic $[Ca^{2+}]$ can lead to disruption of the cytoskeleton. While increases in cytosolic $[Ca^{2+}]$ occur soon after hypoxia in experimental systems, there remains some controversy as to the extent to which increased cytosolic $[Ca^{2+}]$ causes the ischemic tubular cell injury.

ACIDOSIS Kidney ischemia stimulates glycolysis, thus increasing the generation of protons and leading to a decrease in cellular pH. Although severe acidosis has been proposed to be detrimental to the kidney, mild acidosis (pH 6.9) protects cells and the isolated perfused kidney against hypoxia and substrate deprivation in vitro. The mechanism of protection by mild degrees of acidosis is not known. The protection is not dependent on preservation of cellular ATP levels. Reduction in pH protects tubules exposed to ionomycin or mitochondrial inhibitors despite the fact that the tubules have increases in $[Ca^{2+}]_i$ equivalent to those changes observed in unprotected tubules. Acidosis has been reported to stabilize cell membranes and may decrease transmembrane calcium flux.

It is possible that the protection afforded by reduced pH results from inhibition of an enzymatic process that would otherwise be detrimental to the cells, such as phospholipase A_2 activity. When blood flow and oxygen delivery are re-established, the extracellular pH rapidly returns to normal. With the increase in intracellular pH upon reperfusion, activation of phospholipase A_2 would be enhanced. This might lead to further alteration in membrane structure and secondarily to enhanced Ca^{2+} permeability, which in turn will further enhance phospholipase A_2 activation. The increase in pH that occurs as a consequence of reperfusion may contribute in an important way to "reperfusion injury."

REACTIVE OXYGEN SPECIES Reactive oxygen species are partially reduced species of oxygen that can cause marked tissue injury. With restoration of oxygen after a period of ischemia, there is a rapid burst of oxidant formation. Reactive oxygen species react with cell membranes to form lipid peroxides, which are generated at high levels during reperfusion. Sources of these oxidants in the kidney include mitochondrial electron transport, endoplasmic reticulum mixed function oxidases, cyclooxygenases, lipoxygenases, the xanthine oxidase system, autooxidation of catecholamines, and neutrophil NADPH oxidase. Reactive oxygen species are toxic to cells in vitro via complex mechanisms involving lipid peroxidation of plasma and mitochondrial membranes, increases in cytosolic calcium concentration, reduction in cellular ATP levels, and activation of phospholipases and endonucleases. The fact that some animal studies show protection against functional tissue damage with antioxidants or reactive oxygen species scavengers, while other studies show no such protection, has resulted in disagreement regarding the extent to which reactive oxygen species contribute to the functional deficits associated with ARF.

By their action to increase phospholipase A_2 activity and enhance arachidonic acid availability, reactive oxygen species increase the production of vasoactive eicosanoids. In the glomerulus, the net effect of production of these eicosanoids is an increase in arteriolar resistance and a decrease in glomerular ultrafiltration coefficient. Another way in which reactive oxygen species may cause local vasoconstriction in the microvasculature of the kidney is by the degradation of the vasodilator nitric oxide.

PURINE DEPLETION With ischemia and reperfusion, there is ATP utilization, without the normal savage mechanisms that are responsible for the regeneration of ATP from ADP, AMP, and

their nucleoside and base breakdown products. As a result, these purine breakdown products accumulate in cells. Unlike nucleotides (ATP, ADP, AMP, IMP), adenosine and hypoxanthine leak out of cells. Adenosine can constrict both afferent and efferent arterioles. Hypoxanthine is converted by xanthine oxidase to uric acid, a process that generates reactive oxygen species. Whereas some animal experiments have indicated that intravenous administration of ATP and magnesium protected against ischemic injury, other investigators have found that ATP can cause direct injury to oxygenated proximal tubules and is vasoconstrictive. The loss of adenine nucleotide precursors during the ischemic period limits the ability of the postischemic kidney to regenerate ATP upon reoxygenation.

PHOSPHOLIPASES The phospholipase A_2 (PLA$_2$) family of enzymes hydrolyze phospholipids to generate free fatty acids and lysophospholipids. Membrane lipid peroxidation associated with ischemia/reperfusion enhances the susceptibility of membranes to PLA$_2$. PLA$_2$ activation may adversely affect cell viability by direct actions on membranes or indirectly because of metabolic products. PLA$_2$ can cause membrane degradation and changes in plasma and mitochondrial membrane bioenergetics and permeability. PLA$_2$ acts synergistically with reactive oxygen species to confer these toxicities. In addition, the PLA$_2$-induced production of lysophospholipids, arachidonic acid, eicosanoids, and platelet activating factor, results in destructive cellular processes in the kidney. The toxic products of PLA$_2$-induced phospholipid degradation alter cell and mitochondrial membrane permeability, resulting in an alteration of the bioenergetic capacity of the cell. In addition, eicosanoids are vasoconstrictive and chemotactic for neutrophils.

INFLAMMATION, LEUKOCYTES, AND ADHESION MOLECULES

Leukocytes have been implicated in the pathophysiology of ischemic ARF. Adherence of the leukocyte to the vascular endothelium is an essential step for extravasation of the cell into ischemic tissue. Complement activation, a consequence of ischemia/reperfusion, is chemotactic for neutrophils. Adherent and activated leukocytes release reactive oxygen species, proteases, elastases, myeloperoxidase, leukotrienes, and other enzymes that damage the ischemic tissue directly, enhance additional inflammatory cell infiltration, and increase vasoconstriction. These mediators, together with leukotriene B4 and platelet activating factor, generated by the infiltrating cells, increase vascular permeability and upregulate adhesion molecule expression promoting further inflammation. In addition, interactions of neutrophils by endothelium may cause capillary plugging that can interfere with restitution of blood flow to areas of the kidney upon reperfusion, even though total renal blood flow is restored.

Neutrophil CD11/CD18 adhesion molecules play important roles in neutrophil-endothelial interactions. These heterodimeric molecules are composed of a common β chain (CD18) and distinct α chains: CD11a (lymphocyte function-associated antigen-1, LFA-1), CD11b (Mac-1 or Mo1), and CD11c (p150,95). LFA-1 and Mac-1 bind to intercellular adhesion molecule 1 (ICAM-1) on endothelial cells. ICAM-1 is a member of the immunoglobulin supergene family. Postischemic kidneys sustain increased injury when perfused with activated neutrophils. The administration of a monoclonal antibody directed against ICAM-1 protects animals from ischemic ARF, even when this antibody is administered 2 h after the

ischemic period. Furthermore, ICAM-1-deficient mice are protected against acute renal failure.

APOPTOSIS

It has generally been considered that the cell death that accompanies ischemia/reperfusion represents a passive response of the cell to a depletion of energy stores in the setting of high metabolic demand with pathobiological consequences as described above. It may be, however, that there are certain circumstances postischemia when the cell contributes to its own demise actively, perhaps programmed to commit suicide so that the organ is better positioned to repair itself, an "altruistic cell death." There is a great deal of evidence that a form of programmed cell death or "apoptosis" occurs in the postischemic animal brain and some evidence that it also occurs in postischemic heart and kidney. When the kidney is made chronically ischemic by partially occluding the renal artery, both necrosis and apoptosis of renal epithelial cells is observed over the next 2–8 days. From 10–28 days after clip placement, during the time when there is marked reduction in renal mass, there is continued cell death, but only apoptosis is observed. In studies where the renal artery is completely occluded and the kidney is then reperfused, there is morphological and biochemical evidence for apoptosis, including DNA fragmentation and endonuclease activation. Apoptosis has also been described in clinical ARF in man, particularly in post-transplant ARF, where it coexists with necrosis.

Cell death and cell survival genes have been identified in the nematode, *Caenorhabditis elegans*, and mammalian homologs have recently been identified. The *bcl-2* gene product inhibits apoptosis in many mammalian systems. Increased Bcl-2 protein levels have been found in viable neurons after ischemia/reperfusion. Overproduction of Bcl-2 in transgenic mice resulted in a reduction in brain infarction volume in response to ischemia and reperfusion. After renal injury, Bcl-2 expression is increased in regenerating proximal tubule cells; Bcl-2 knockout mice manifest congenital renal hypoplasia and develop multicystic kidney disease.

GENES WHOSE EXPRESSIONS ARE ALTERED BY HYPOXIA

Oxygen deprivation is common in biology. Prokaryotes are well-adapted to this "stress" and have developed special defense mechanisms to deal with it. Some vertebrate species, for example, the Western painted turtle, can survive long periods of anoxia with minimal adverse consequences. These vertebrates are exceptions, however, since compromised oxygen delivery with resultant hypoxia is highly detrimental to brain, cardiac, kidney, and liver function in most vertebrates. Nevertheless, mammals may have evolved mechanisms to respond to hypoxia, to limit injury and to potentiate recovery of damaged tissue.

Hypoxia in tissue culture increases expression of a number of genes resulting in increased production of various types of proteins (Table 66-1). Some of these proteins may prevent or mitigate injury, although if and how this might occur remains speculative at the present time. Probably the most well-studied mammalian gene in which oxygen exerts control of expression is the erythropoietin gene, which responds to hypoxia with increased gene transcription. This hypoxic response appears to be mediated by two *cis* elements, the dominant of which is the 3' enhancer. A 5' element works in combination with this 3' element to give a maximal

response. A hypoxia-inducible factor (HIF) has been identified which specifically binds to the 3' enhancer element.

A number of other genes have been found to be induced with hypoxia in tissue culture. Genes encoding the glycolytic enzymes, lactic dehydrogenase and phophoglycerate kinase-1, are upregulated. Although the control of glycolysis is primarily at the level of posttranslational modifications of glycolytic enzymes, upregulation of these genes might enhance energy production from glycolysis in the hypoxic cell.

Hypoxia also results in upregulation of other genes which may serve in the injury or repair process or induce vasodilatation. These include genes encoding growth factors such as PDGF-A and B, TGF-β1, vascular endothelial growth factor (VEGF), and endothelin. These proteins have been implicated in regulation of vascular tone, wound healing, angiogenesis, proliferation, antiproliferation, and embryonic development. Interleukin 1α, tyrosine hydrolase, and HSP70 are also upregulated. By contrast, hypoxia results in a decrease in placental growth factor mRNA levels. It has been reported that hypoxia responsive transcription-activating cis elements are present in the 5' flanking region of the VEGF, LDH, and phosphoglycerate kinase-1 genes. Hypoxia increases the mRNA levels of VEGF, as it does tyrosine hydrolase, by increased transcription as well as increased RNA stability.

Another mechanism by which an organism can protect itself against hypoxia and reoxygenation or potentiate cell death is to increase or decrease its defense against reactive oxygen species. Catalase and superoxide dismutase are induced in procaryotes during shifts from anaerobic to aerobic environments. By contrast, in the postischemic kidney, there are reduced mRNA levels of superoxide dismutase. In neuronal cells, it has been shown that down-regulation of superoxide dismutase causes apoptotic cell death.

Exposure of eukaryotic cells to a variety of stresses, including ischemia and reperfusion, thermal and oxidative stress, viruses, calcium ionophores, and heavy metals induces a remarkably conserved "heat shock response." This response is highly conserved in evolution and is seen with hypoxia and reoxygenation in *Drosophila* larvae. The "heat-shock response" includes the preferential synthesis of "heat-shock proteins" (HSPs), while generalized cellular protein synthesis is suppressed. With ischemia and reperfusion, there is activation of heat-shock transcription factor and increase in mRNA levels of members of the HSP-70 gene family. The postischemic early localization of HSP-72 to the apical part of the proximal cell positions this protein at the site of the cell undergoing rapid changes during the early period of ischemia.

It has been reported that the postischemic kidney becomes relatively resistant to a subsequent ischemic insult. It has been proposed that the heat-shock response may confer this protection. The heat-shock response protects cultured neurons against amino acid excitotoxicity, which is believed to be the effector mechanism of ischemic injury to the brain in vivo. It remains controversial, however, whether the heat-shock response confers protection of the kidney against tubular cell injury.

RECOVERY FROM ACUTE RENAL FAILURE

In contrast to the heart and brain, where ischemia results in permanent cell loss, the kidney, severely damaged by ischemia or toxins, has the ability to completely restore structure and function. The tubular epithelium can completely regenerate and differentiate. Active mitotic activity is characteristic of ischemic ARF in humans, and epithelial cell regeneration has been recognized as a hallmark of tubular necrosis since the descriptions by Bywaters. Postischemic recovery recapitulates certain aspects of renal development. Proteins normally expressed only in early nephron development are expressed in the recovering kidney epithelium. Likewise, other proteins, which are normally expressed in the adult kidney but at low levels or not at all in the embryonic kidney, such as Kid-1, preproEGF, and Tamm Horsfall protein, are downregulated in the postischemic kidney.

Epithelial morphogenesis in renal development depends on soluble and nonsoluble factors including growth factors and matrix components. It is possible that the developmental hierarchy of gene expression is repeated in the repair process postischemia. After ischemia proliferating cell nuclear antigen (PCNA), a marker, albeit not specific, for the G_1-S transition in the cell cycle and hence mitogenesis, was detected primarily in the S3 segment of the proximal tubule. PCNA was maximally expressed at 2 days postischemia. Most, if not all, of the surviving epithelial cells in the damaged tubule have the capacity to undergo a mitogenic response. Thus, restoration of the epithelium does not rely on a small population of "stem cells." This participation of a large percentage of parenchymal cells in the tissue repair process is similar to what is seen in liver regeneration after partial hepatectomy, where more than 95% of remaining hepatocytes of the young rat progress through the cell cycle. In the liver, the hepatocytes do not dedifferentiate, either morphologically or functionally, during this process of regeneration. More than 70 immediate-early genes have been identified to be induced after partial hepatectomy. Many of these genes do not have known functions.

Vimentin, normally present in mesenchymal cells but not in epithelial cells, and hence a marker for the state of differentiation, is prominently expressed in the S3 segment 2–5 days postischemia, whereas it is undetectable in epithelial cells from either sham-operated control kidneys or contralateral kidneys from experimental animals. Cells in the S3 segments in the outer stripe of the medulla that stain positively for PCNA also stain positively for vimentin. Vimentin staining is also positive in kidneys that are chronically ischemic as a result of imposed renal artery stenosis.

IMMEDIATE-EARLY GENES AND PROTO-ONCOGENES A number of immediate-early genes and protooncogenes are induced in the postischemic period (Table 66-2). Since many of these same genes are induced when cells are exposed to growth factors, it becomes of interest to know whether the induction of these genes is involved in the proliferative response postischemia. Some of the encoded proteins are transcription factors. Transcription factors play critical roles in the regulation of cell growth and

differentiation and the processes by which embryonic cells become spatially organized to form differentiated tissues in the process termed "pattern formation." Genes induced with ischemia and reperfusion include c-*fos*, *Egr-1* (*zif-268*), c-*jun*, c-*myc*, *KC*, and *JE*. The signals for induction of these genes have not been clearly defined. In some cases, hypoxia itself may play a role, but other genes are likely induced in response to injury or in response to cytokines, oxidant stress, or other mediators that are present in the postischemic tissue. It is clear that expression of these genes is not equivalent to mitogenesis, since many of the cells in which these genes are expressed, for example, the thick ascending limbs, are not the cells undergoing proliferation. Thus the induction of these genes may play a role in protection of cells against ischemic injury or in mounting a response that will help regenerate other cells in the kidney. Since the products of these genes are localized to cells that do not undergo necrosis or apoptosis, they are not marking cell death. Immediate-early gene expression may reflect a cellular response to the dedifferentiating influences of ischemic injury. If the damage is not severe enough to kill the cell, the cell may respond to the insult with a "differentiation" response that is mediated in part by the expression of these immediate-early or protooncogenes.

In evaluating the potential consequences of increased production of a protein such as c-Jun in the postischemic kidney it is also necessary to understand what regulates the function of the protein. *Trans*-acting activity of c-Jun is positively regulated by phosphorylation of two serine residues in the amino-terminus. The stress-

activated protein kinases (SAPKs), also called p54 MAP and JNK kinases, are a subfamily of the extracellular signal-regulated kinase (ERK) family of serine/threonine kinases, which are upregulated in response to the inflammatory cytokine, tumor necrosis factor α (TNF-α), UV irradiation, and cellular stresses, including heat shock and inhibitors of protein synthesis. The SAPKs are markedly activated in response to renal ischemia and reperfusion. This activation of SAPKs, resulting in increased transactivation of c-Jun, may function in cytoprotection, differentiation, apoptosis, and/or repair.

Another important implication of the above described pattern of immediate early gene response is that two of these genes, *JC* and *KE*, encode proteins that are chemotactic. Thus the generation of these proteins may recruit neutrophils and other inflammatory cells to the site of injury with consequent adverse effects as described previously. In addition to these adverse effects, however, it is possible that the infiltrating inflammatory cells may produce factors that act in a paracrine manner to enhance survival, increase regeneration, and/or increase apoptosis in an effort to eliminate cells irreversibly injured. Ischemia also alters the antigenic characteristics of the tubular epithelial cell. These modifications may cause a cell-mediated immune response which, if prolonged, can lead to chronic tubulitis and interstitial inflammation.

The proto-oncogene, c-*myc*, is induced during regeneration after folic-acid-induced injury to the kidney. Members of the myc family are also expressed in the developing kidney and have been implicated in both the control of mitogenesis as well as differentiation.

OTHER GENES WHOSE EXPRESSIONS ARE MODIFIED WITH ISCHEMIA   In addition to the above genes there are a number of other genes whose expressions are modified with ischemia/reperfusion. These include clusterin, a gene that is also upregulated in the prostate when testosterone withdrawal induces apoptosis. Kidney lipocortin 1 (annexin 1) levels are also increased in the postischemic kidney. Since this protein binds to phospholipids, it may act to protect lipids against phospholipase attack. E-selectin expression is upregulated with ischemia. This may enhance leukocyte-endothelial adhesion. Other genes whose expression is primarily in the kidney, such as *renin* and *Kid-1*, are downregulated in the postischemic organ.

GROWTH FACTORS

An important component of the repair process in the kidney may involve the local induction of genes encoding growth factors, which then act in a paracrine or autocrine manner to enhance epithelial cell regeneration. mRNA levels of the gene that encodes the platelet-derived growth factor-B (PDGF-B) increase in response to hypoxic exposure of endothelial cells. While PDGF likely does not directly enhance the growth of kidney epithelial cells, this growth factor may induce fibroblasts to release factors that may act on the epithelial cell to enhance proliferation and potentiate tubulogenesis.

Another growth factor that may be important for the recovery of the kidney after an ischemic insult is epidermal growth factor (EGF). EGF is a potent mitogen for kidney epithelial cells. Infusion of EGF into the rat enhances mitogenesis and potentiates recovery from ischemic acute renal failure. With ischemia, however, there is a marked reduction in levels of preproEGF mRNA along with reduced urinary excretion of EGF, although binding of EGF increases in both cortical and medullary tissue. By contrast to the fall in EGF levels postischemia, there is marked induction of heparin-binding EGF-like growth factor (HB-EGF) mRNA in

the kidney after ischemia and reperfusion. HB-EGF, like EGF, is mitogenic for kidney epithelial cells. The mRNA of HB-EGF is localized to the distal nephron, suggesting it may exert a paracrine function on the proximal nephron where mitogenesis predominates postischemia.

Transforming growth factor-α (TGF-α) is a 50-amino acid peptide that exerts its biological effects via the EGF receptor. Developing mesonephric tubules, renal cell carcinomas and other human tumors produce TGF-α. TGF-α may derive from infiltrating macrophages in the postischemic tissue and then act on epithelial cells to promote mitogenesis. TGF-α is more important than EGF in the fetus, where mRNA for EGF is not detectable prenatally. It is possible that TGF-α may play an important role in the kidney undergoing repair. TGF-β is also increased in regenerating tubules following ischemic injury and is localized primarily to tubules of the outer medulla.

There are increased amounts of insulin-like growth factor I (IGF-1) receptors after renal ischemia. There is also a decrease in IGF-1 binding protein mRNA. Thus IGF-1 bioavailability is increased in the postischemic kidney. Administration of IGF-1 accelerates recovery of rat serum creatinine levels after an ischemic insult, and its effects are being evaluated in human trials. IGF-I is produced in the mesonephros and promotes organogenesis of the kidney. These effects on renal development support the view that factors important for repair of the kidney are recapitulating roles played during renal development. IGF-1 likely has effects other than its action as a growth factor, which may contribute to its protective effect in the postischemic kidney. It increases GFR in normal and postischemic kidneys and is anabolic, decreasing protein breakdown. IGF-1 has been shown to prevent apoptosis in differentiated cells, acting as a survival factor, without stimulating proliferation. In addition, IGF-1 is a potent inducer of nitric oxide release from endothelial cells and through this action may decrease neutrophil adherence to the postischemic endothelium. PDGF and TGF-β, present in increased amounts in the postischemic kidney, are also chemoattractants and may contribute to the inflammatory response.

Hepatocyte growth factor has also been shown to enhance recovery of the kidney after ischemic and mercuric chloride-induced renal injury. mRNA levels of HGF and its receptor for this growth factor, c-met, are markedly increased, particularly in the outer medulla, in the postischemic period.

CONCLUSIONS AND SPECULATION

It is clear that, while we have come a long way in the last 15 years in our understanding of the biochemical and pathophysiological determinants of renal cell injury postischemia, much remains unknown. In addition, while we have come to recognize the important parallels between renal development and postischemic repair, we know little about the factors responsible for the remarkable ability of the kidney to regenerate and restore morphological and functional integrity. We do not understand why this process of repair is delayed in many of our patients.

In order to understand the recovery process from ischemic ARF it will be necessary to understand how cell cycle signals and effectors are integrated. How do growth factors and cell-matrix interactions influence the process? Are novel growth factors involved, factors that remain to be discovered? Perhaps a better understanding of the hierarchy of gene activation that occurs in renal development will provide critical insight into the normal repair process and how to best influence it therapeutically. A better understand-

ing of how tubulogenesis is controlled ex vivo in artificial matrices may provide important insight into the role played by matrix factors and may further our progress in an ultimate quest to "create" a functional tubule in vivo.

67 Potassium Secretory Channels in the Kidney

STEVEN C. HEBERT

INTRODUCTION

The regulation of urinary potassium excretion depends on the coordinated function of potassium transporters (cotransporters and exchangers), ion pumps, and specialized channels in apical and basolateral membranes of distinct cell types along the distal nephron of the mammalian kidney. This chapter focuses on recent molecular and functional information about these potassium secretory channels in the thick ascending limb of Henle (TAL) cells and principal cells in the cortical collecting duct (CCD).

Ion channels are integral membrane proteins that span the lipid bilayer to form narrow hydrophilic (water-like) pores through which ions move passively in accord with electrochemical driving forces. Fluxes of ions as high as 1 million per second can be achieved through these pores. Channels open or close rapidly in response to biological signals by switching between conducting and nonconducting conformations of the protein subunits forming a single ion channel. This mechanism of control of the channel by biological stimuli is referred as "gating." Ion channels can also distinguish or discriminate among ions, an important characteristic called "selectivity": e.g., potassium may permeate a channel pore at a rate 10^4-fold higher than that for Na^+, despite being smaller than the K^+.

Based on these properties, K^+ channels can be classified into five broad groups:

1. Voltage-gated K^+ channels can open or close in response to changes in membrane potential.
2. Calcium-activated K^+ channels are modulated by changes in the intracellular calcium concentration.
3. Ligand-gated K^+ channels are controlled by neurotransmitters (serotonin), hormones (norepinephrine and acetylcholine), cyclic nucleotides (cyclic GMP), or extracellular nucleotides (purinogenic or purinoceptors).
4. ATP-sensitive K^+ (KATP) channels are regulated by the intracellular concentration of ATP.
5. Stretch-regulated channels are modulated by mechanical forces (e.g., stretch).

Ion channels can vary considerably in their electrophysiological and pharmacological properties, even within a single class. Thus, K^+ channels can also be categorized, based on the character-

istics of their ionic current profile, as delayed or outward rectifiers and inward rectifiers (Fig. 67-1).

RENAL K^+ SECRETORY CHANNELS

Potassium channels involved in K^+ secretion by distal segments of the nephron belong to the class of channels referred to as inward rectifiers. Inwardly rectifying K^+ (IRK) channels are characterized by a lack of significant voltage-gating and by their ability to transport potassium more readily in the inward (absorptive) than outward (secretory) direction. This ability to conduct better in one than the opposite direction is called *rectification* and is defined by plotting channel current against holding potential (called an I-V or current-voltage curve) and observing the slope (conductance) of the I-V curve (Fig. 67-1). Inward rectifiers exhibit a higher conductance at hyperpolarized membrane potential, where the K^+ current is in the influx direction, than during depolarization, where the current becomes outward. IRK channels exhibit either a "strong" or a "weak" type of inwardly rectification. The strongly rectifying channels exhibit little or no conductance above a certain threshold potential (usually at or near the resting membrane potential of the cell), making them well-suited to function in maintaining the resting membrane potential and in regulating cell excitability (e.g., in muscle cells). On the other hand, the weakly rectifying channels show a reduced, but significant, conductance at depolarizing potentials. Moreover, these latter channels open and close in response to cellular metabolic events (via nucleotide [or ATP]-mediated inhibition of channel activity), and thereby may serve important roles in some cells during ischemia (e.g., in heart and brain). This latter characteristic of nucleotide sensitivity has given these channels the name *ATP-sensitive* or K_{ATP} channel.

Renal K^+ Secretory Channels in TAL and Principal Cells are K_{ATP} Channels In the kidney, secretory K_{ATP} channels have been characterized in apical membranes of thick ascending limb (TAL) cells and principal cells of the cortical collecting duct (CCD). In both medullary (MTAL) and cortical (CTAL) segments of the TAL, K_{ATP} channels are the dominant conductance in apical plasma membranes and provide the crucial K^+ efflux pathway for potassium entering cells via the apical Na^+:K^+:$2Cl^-$ cotransporter (Fig. 67-2). This apical recycling of potassium ensures that an adequate supply of luminal potassium is provided for efficient function of the Na^+:K^+:$2Cl^-$ cotransporter. In addition, this channel mediates the apical component of a transcellular (basolateral-
Figure 67-1 Differences in strong and weak inward rectifying channels. The dashed lines represent current-voltage (I-V) plots for both types of rectifiers. Positive current (the upper half of the I-V plot) represents potassium efflux from cells (secretion), while negative current is potassium influx into cells. The slope (arrows) of the I-V curve is the conductance. Note that the conductance for strong rectifiers goes to zero for positive currents. In contrast, the weak rectifiers exhibit significance conductance at positive currents.

to-apical) current flow that returns to the basolateral side via the paracellular pathway predominantly as a cation current carrying Na^+, Ca^{2+}, and Mg^{2+}. This paracellular current is sufficient to account for one-half of the net transepithelial movement of sodium, making this system of Na^+ absorption about twice as efficient (moles Na^+ absorbed/mole Ox_2 consumed) as cells utilizing sodium channels, where all of the Na^+ absorbed traverses the transcellular pathway (e.g., the principal cell). In fact, the apical K^+ channels are so important for net transepithelial Na^+ transport in the TAL that blockade of these channels virtually abolishes salt absorption in this nephron segment.

The conductive properties of the apical membranes of TAL cells are almost entirely because of potassium. Two types of inwardly rectifying and ATP-sensitive K^+ channels have been identified on apical membranes of TAL segments by patch clamp: a *low-conductance* (20–35 pS) channel and an *intermediate-conductance* (70 pS) channel. Both channels exhibit a high open probability (P_o), are inhibited by mM MgATP ($K_{1/2} \approx 0.6$–1 mM), and are exquisitely sensitive to reductions in cytosolic pH (~50% reduction in P_o by a 0.2-pH unit decrease). The activity of the intermediate conductance K_{ATP} channel can be significantly reduced by tetraethylammonium (TEA) or quinine, whereas these agents have no effect on the low-conductance channel. In contrast, the low, but not intermediate, conductance channel is inhibited by high concentrations (~250 μM) of gliburide. In the rat TAL, the intermediate conductance K_{ATP} channel makes up about 65–70% of the total apical K^+ conductance. A low conductance K_{ATP} channel with nearly identical properties has been identified in apical membranes of principal cells in the CCD where it mediates K^+ secretion into urine (Fig. 67-2).

The K_{ATP} channel in rat TAL and principal cells is highly regulated by hormones, metabolism, and changes in acid-base state (Fig. 67-3). Metabolic-related changes in ATP dually modulated channel activity: high MgATP concentrations (within the normal range of ATP; 2–3 mM) reversibly block channel activity ($K_{1/2} \approx 0.6$–1.0 nM) while lower concentrations of MgATP (50–100 μM) are required to maintain channel activity. The stimulatory effect of low ATP concentration, however, clearly relates to regulation of channel activity by phosphorylation-dephosphorylation processes (Fig. 67-3):

1. Channel activity rapidly diminishes (called channel "run-down") on patch excision unless the cytosolic face is exposed to low concentrations of MgATP.
2. Generally, the catalytic subunit of cAMP-dependent protein kinase, PKA, is also required for channel maintenance, and PKA, together with MgATP, can restore channel activity after run-down.
3. Nonhydrolyzable ATP analogs cannot maintain or restore channel activity.
4. In patches in which channel activity is maintained by MgATP alone, the PKA inhibitor (PKI) reversible reduces channel activity, providing evidence for an important role for endogenous PKA.
5. PKC reversibly inhibits channel activity and antagonizes the stimulatory effect of PKA, a process that is Ca^{2+}-dependent.

The ratio of cellular ATP:ADP may be more important than ATP concentration, since low concentration of ADP can reverse the MgATP-mediated inhibition of these channels. Cytosolic pH is also an important regulator of the low-conductance K_{ATP} channel in the apical membranes of principal cells; cellular acidification within the physiologically achievable range leads to channel inhibition. Finally, K_{ATP} channel activity in rat principal cells is also inhibited by activation of protein kinase C or calcium-calmodulin-dependent kinase II, arachidonic acid (or its metabolites), and by actin cytoskeleton.

What is the evidence that these K_{ATP} channels mediate K^+ secretion into tubular urine? Large-conductance (maxi-K) channels (a type of voltage-gated channel) and K_{ATP} channels are the only potassium channels observed on patch clamping apical membranes from TAL and principal cells. Whereas either channel could, in principle, mediate potassium secretion, maxi-K channels are normally quiescent at normal resting cell voltages (but can be activated by μM cytosolic Ca^{2+} or cell swelling), making them a less likely candidate for K^+ secretion. Moreover, maxi-K channels are inhibited by TEA while $K^+(Rb^+)$ secretion and the transepithelial voltage in the CCD are not blocked by luminal TEA. This provides strong evidence that the low-conductance K_{ATP}, and not the maxi-K^+ channel, is involved in K^+ secretion by principal (and TAL) cells.
Figure 67-2 Schematic representation of the apical secretory potassium channels in thick ascending limb (TAL) cells and in principal cell from the cortical collecting duct (CCD). In CCD, Na$^+$ passively enters principal cells through apical membranes via the amiloride-sensitive channel and is actively extruded across basolateral membranes via the Na$^+$-K$^+$-ATPase. The K$^+$ entering cells via this latter pump is either secreted across apical membranes by the low-conductance secretory K$_{ATP}$ channel or recycles across basolateral membranes by one of several potassium channels. In TAL, two types of K^{ATP} channels (the **low** conductance –30 pS and the **intermediate** conductance –70 pS channels) mediate apical recycling of potassium entering cells via the Na$^+$-K$^+$-Cl$^-$ cotransporter. (*See text* for discussion.)
Figure 67-3 The activity of the apical, potassium secretory K$_{ATP}$ channels in TAL and principal cells are regulated by hormones, acid-base status, and metabolic state of the cell. (*See text* for discussion and further details.)

Finally, it is somewhat curious that inward rectifiers should be used at all in renal cells for potassium secretion since the outward (and in this case the lower) conductance is what determines the magnitude of potassium secretion at any given electrochemical driving force (Fig. 67-1). While the answer to this question may never be known with certainty, the intrinsic high open probability of these channels, together with its sensitivities to pH and the metabolic state of the cell (Fig. 67-3), do provide for a level of regulation that may offer distinct advantages for a channel involved in modulation of K$^+$ secretion.

A MOLECULAR MODEL FOR INWARD-RECTIFYING CHANNELS

A candidate for the renal secretory inward-rectifier potassium channel was recently cloned from rat kidney (ROMK1). ROMK1 encodes a ~45-kDa protein having only two potential membrane-spanning helices (M1 and M2); (Fig. 67-4) bracketing an H5-like region (thought to form part of the pore in voltage-gated channel). This predicted topology makes ROMK1 quite distinct from voltage-gated (*Shaker* family) potassium or ligand-gated ion channels (Fig. 67-4). Subsequent to the cloning of ROMK1, other inwardly

rectifying K^+ channels have been isolated from kidney and a number of other tissues, and all exhibited a similar general topology. These genes and their channel protein products form a new family of potassium channels called the inwardly rectifying K^+ (IRK) family. More recently, other cation channels have been cloned that exhibit the two-membrane spanning domain type of topology: a novel channel found in *Saccharomyces cerevisiae*, in which this domain is in a tandem combination with a six-membrane-spanning

domain typical of the *Shaker* family; P_{2x}-type purinoceptor channels activated by binding extracellular ATP and expressed in nerve cells; and the amiloride-sensitive Na^+ channel expressed in kidney principal cells. Whether there is a common evolutionary thread among these distinctive channel families remains to be elucidated.

Molecular diversity in ROMK is achieved by alternative splicing (the isoforms are designated ROMK1, ROMK2a, ROMK2b,

Table 67-1
Characteristics of ROMK and K_{ATP} Channels in Kidney

	ROMK	*Intermediate conductance*	*Low conductance*
Single channel conductance, γ(pS)	30–45	70	25–35
Inward rectifier	Yes	Yes	Yes
Open probability, P_o	High	High	High
ATP inhibits	Yes	Yes	Yes
$\downarrow P_o$ by $\uparrow$ ATP or $\uparrow$ (ADP/ATP)	$K_i \approx 2.5$ nM	At (mM)	$K_i \approx 0.5$–1 mM
Inhibited by glyburide	No	No	Yes High υM
Ion selectivity	$K^+ \gg Na^+$	$K^+ = Rb^+ =$ $NH_4 = Cs^+ \gg Na^+$	$K^+ \gg Na^+$ (20:1)
pH$_i$-dependence ($\uparrow$ pH$_i$ reduces P_o)	Yes	Yes	Yes

and ROMK3); these spliced isoforms are both functional as channels and alternatively expressed along the mammalian nephron. The finding that the ROMK gene contains introns within the coding region is an unusual feature for a mammalian K^+ channel, suggesting that these splicing events may serve some important role in altering channel function or regulation (or both). ROMK1–ROMK3 isoforms are produced by alternative splicing at the 5' end of the transcripts, which alters both the length and amino acid sequence of the encoded channel at initial segment of the NH_2-terminus. The role of the NH_2-terminal variations on the ROMK isoforms in altering channel function and regulation by phosphorylation-dephosphorylation processes is currently under active investigation.

As shown in Fig. 67-5, ROMK isoforms are differentially expressed along the nephron, with the overall distribution of ROMK being consistent with this IRK, representing the low-conductance secretary K_{ATP} channel observed in TAL and principal cells. ROMK2, which encodes the channel with the shortest NH_2-terminus, is the most widely distributed of the ROMK transcripts. In contrast, the ROMK1 transcript is only expressed in collecting ducts (CCD, OMCD, and initial IMCD), whereas ROMK3 is expressed only in the earlier nephron segments (MTAL, CTAL, and DCT). Thus, all of these nephron segments, except the OMCD, apparently express at least two different ROMK isoforms: ROMK2 and one of the isoforms (ROMK1 or ROMK3) encoding a channel protein with a longer NH_2-terminus. Do ROMK isoforms associate to form heteromultimeric complexes in some of these nephron segments? Would such heteromultimeric channels exhibit distinctive functional and regulatory properties? While these important questions are being actively pursued in several laboratories, other inward-rectifying K^+ channels have recently been shown to heteromultimeric complexes: the G-proteingated cardiac atrial K^+ channel formed from two IRK subunits and the pancreatic β-cell K_{ATP} formed from an IRK and the sulfonylurea receptor, which is a member of the P-glycoprotein family. The latter is quite interesting, since ROMK lacks significant sensitivity to glyburide, while the native low-conductance K_{ATP} in TAL or principal cells is inhibited by high micromolar concentrations of this potent sulfonylurea (Table 67-1). Could ROMK associate with a p-glycoprotein which would, like the β-cell K_{ATP}, impart sulfonylurea sensitivity? Mutations in ROMK1 cause the antenatal variant of Bartter syndrome.

FUNCTION OF ROMK CHANNELS AND CORRELATION WITH STRUCTURE ROMK K+ channels expressed in *Xenopus laevis* oocytes have been shown to exhibit many of the ion permeation and regulatory properties of the native low-conductance K_{ATP} channels observed on patch clamping of apical membranes of thick ascending limb and principal cells. These ROMK channels have the following basic properties: a unitary conductance of 30–45 pS in symmetrical 140–150 mM KCl; high $K^+:Na^+$ selectivity ($K^+ > Rb^+ > NH4^+ > Na^+$, Li$^+$); weak inward rectification resulting from block by internal Mg^{2+} and/or a polyamine such as spermine or spermidine; marked sensitivity to "cytosolic" side reductions in pH; modulation by arachidonic acid; run-down or loss of channel activity in excised patches in the absence of MgATP that involves dephosphorylation by a protein phosphatase; reactivation of channels after run-down by re-exposure to MgATP and the catalytic subunit of protein kinase A; and sensitivity (inhibition) by higher concentrations of MgATP.

Importantly, ROMK channels exhibit no reduction in channel activity with addition of millimolar concentrations of TEA$^+$ to extracellular media. This lack of sensitivity to TEA$^+$ is in K^+ secretion in kidney since both K^+ secretion by the CCD and the low-conductance K_{ATP} channel found in principal cells are characteristically unaffected by TEA$^+$. The aromatic amino acid, phenylalanine, at position 148 within the H5 region on ROMK1, could impart significant sensitivity to external TEA$^+$ in ROMK channels, since site-directed mutagenesis studies in *Shaker* channels have shown that aromatic amino acids at a similar position confers a high sensitivity to external TEA$^+$. It is plausible that the positively charged arginine, at position 147 in ROMK1, might interfere with TEA$^+$ binding, and explain the lack of high TEA$^+$ sensitivity in the ROMK1 channel. In this regard, recall that the intermediate conductance K_{ATP} channel found in rat TAL is sensitive to block by external TEA$^+$. This pharmacological difference, together with the differences in single channel conductance and sensitivities to glyburide, provide strong evidence that ROMK does not, by itself, encode the –70 pS K_{ATP} channel. However, the similarity in many of the properties of the low- and intermediate-conductance channels suggest that these IRKs may be structurally similar. The possibility remains, however, that the intermediate conductance channel could be a heteromultimer of ROMK and some other IRK.

As discussed earlier in this chapter, inward rectification is also a characteristic of the apical secretary K_{ATP} channels in kidney as well as other members of the IRK family of channels. Recent studies have begun to identify important amino acid residues or segments critical for both types of rectification. The COOH-, but not NH_{2-}, terminus appears to be important in determining inward rectification. Moreover, a single negatively charged amino acid residue (aspartic acid) in the second membrane-spanning helix of the strong inward rectifiers like IRK1 appears to be important in imparting this type of rectification. Importantly, ROMK lacks this charged amino acid residue, consistent with its weak type of inward rectification.

As discussed above, the secretory K^+ channels in distal nephron segments are ATP-sensitive or K_{ATP} channels. A segment following the second membrane-spanning region contains a Walker A site motif (GXG[H in ROMK]XXGK) within a so-called $P0_4$-binding or P loop that has been linked to ATP binding in many other proteins. In fact, a 27-amino acid region containing the Walker type A site exhibits significant similarity to the catalytic subdomain I of ERBB3, a member of the epidermal growth factor (EGF) receptor tyrosine kinase family. Based on this potential ATP-binding segment and the presence of several potential protein kinase A and protein kinase C phosphorylation sites in the COOH-terminus of ROMK channel proteins, we have suggested that this region forms a regulatory domain. Recent studies are consistent with the role of this COOH-terminal domain in regulation by nucleotides and protein serine-threonine kinases.

In summary, molecular cloning has begun to identify important ion channels in the mammalian kidney. One of these, ROMK, appears to form the ion permeation pore of the ATP-sensitive inwardly rectifying K^+ channel that mediates potassium secretion into tubular urine of TAL and CCD. Future studies will clearly provide new information on the function and regulation of this channel and provide new insights into renal potassium handling.

68 Alport Syndrome

KARL TRYGGVASON AND PIRKKO HEIKKILÄ

BACKGROUND

Alport syndome, also termed hereditary nephritis, was initially described in 1927 by AC Alport as an inherited kidney disease characterized by hematuria and sensorineural deafness. Later, ocular lesions were also associated with the syndrome and, with the introduction of the electron microscope, irregularities and disruptions in the glomerular basement membrane (GBM) were shown to be typical for this disorder as well. The disease is progressive, usually leading to renal failure during adolescence or before middle age.

Alport syndrome is primarily inherited as an X-chromosome-linked dominant trait with an estimated gene frequency of 1:5000, but autosomal forms also exist. The defective gene in X-linked Alport syndrome was located in 1988 and 1989 to the long arm of the X chromosome. In 1990, a gene encoding a novel basement membrane (type IV) collagen α5 chain was discovered and localized to the Alport gene region on chromosome X, and this was soon followed by identification of mutations in this gene in Alport patients. More recently, mutations have also been reported in the genes for the α3 and α4 type IV collagen chains in the rarer autosomal forms of Alport syndrome. Presently, well over 100 different mutations are now identified in type IV collagen genes in Alport patients. These mutations can be considered responsible for abnormalities in the structural framework of the GBM, resulting in kidney manifestations. In this chapter we review clinical features of the disease, the molecular properties of the GBM and type IV collagen, which are the prime targets of the disease, as well as recent advances in the molecular genetics and therapy.

CLINICAL FEATURES AND DIAGNOSIS

Characteristically, Alport patients have recurrent microscopic or gross hematuria in childhood, earlier in males than in females. It usually leads to end-stage renal disease in affected males and in rare cases also in females. The hearing loss is sensorineural and primarily affects high tones. Electron microscopy usually reveals thinning and thickening of the GBM with longitudinal splits into thin layers with a basket-weave pattern (Fig. 68-1). These changes are most evident in male patients, except in boys of very young age. Lenticonus, a peculiar change of lens shape, is also frequently observed in Alport patients. Recurrent corneal erosion has also been reported. The disease is inherited and family history is present

in 85% of cases. The remaining 15% may represent new mutations. Recent work has revealed a large proportion of patients with renal failure and mutations in type IV collagen without hearing loss or eye lesions. Thus, the classical clinical definition for the Alport syndrome, i.e., hereditary nephritis with hearing loss, does not apply to all patients with type IV collagen defects. Clinicians should, therefore, consider Alport syndrome as a possible diagnosis for patients with hematuria and/or renal failure, even though they lack symptoms such as hearing loss, ocular lesions or family history.

STRUCTURE AND MOLECULAR BIOLOGY OF THE GLOMERULAR FILTRATION BARRIER

FILTRATION BARRIER   The glomerulus is a specialized vascular organ that functions as the filtration unit of plasma. Glomerular filtration is distinguished from transcapillary exchange in other organs by two characteristics: First, the glomerulus almost completely excludes plasma proteins of the size of albumin (mol wt approximately 70,000, radius 3.6 nm) and larger from the filtrate. Second, the glomerulus exhibits an extraordinary high permeability to water and small solutes. The filtration effect across the glomerulus depends on the size of the molecules; radius, which is called a size-dependent permeability barrier in the glomerulus. The filtration decreases with increasing effective molecular radius. In addition to the size, the glomerulus discriminates between molecules according to their charge, allowing greater penetration of neutral and cationic molecules than of anionic molecules of the same size.

The actual filtration barrier consists of the fenestrated capillary endothelium, the GBM of 300–350 nm in thickness, and the epithelial podocytes that are separated by the slit and connected by a thin diaphragm. Similar to basement membranes elsewhere in the body, the GBM consists of type IV collagen, laminin, proteoglycan, and nidogen/entactin. Type IV collagen forms the structural framework of the GBM together with laminin, which also plays a role in cell adhesion. Nidogen interconnects the type IV collagen and laminin networks, and proteoglycans are believed to serve as an anionic filtration barrier.

TYPE IV COLLAGEN   Type IV collagen is a basement membrane specific protein that belongs to the large family of collagens that are the main extracellular structural proteins in all multicellular organisms. Collagen molecule is composed of three α chains, characterized by the repeating Gly-X-Y sequence, where X and Y can be any amino acid. The glycine residue, as every third amino acid enables the assembly of three chains into a triple-helical struc-

The interruptions, which are not shown in the figure give flexibility to the molecule and the type IV collagen network. **(B)** Three α chains form a triple-helical molecule. **(C)** Individual molecules assemble by end-to-end associations into a network-like structure into which other basement membrane proteins are bound in a largely unknown fashion. In reality, the type IV collagen network structure also contains more complex laterally aligned molecules.

ture. All collagens consist of three α chains that form the triple-helical molecule inside the cell. Once secreted from the cells, the triple-helical molecules assemble by end-to-end aggregation and lateral alignment into a tightly crosslinked network structure (Fig. 68-2). Presently, six genetically distinct type IV collagen

Table 68-1
Diseases with Linkage to Type IV Collagen Chains

Disease	*Type IV collagen α chain involved*

X-linked Alport syndrome	α5
X-linked Alport syndrome associated with diffuse esophageal lyomyomatosis	α5 + α6
Autosomal Alport syndrome	α3 and/or α4
Acquired	
Goodpasture syndrome	α3

α chains are known. Of those, the α1 and α2 chains are ubiquitous and can be found in all basement membranes. In contrast, the α3, α4, α5, and α6 chains are minor component chains with a more restricted tissue distribution and thus probably specialized functions. For example, molecules containing α3, α4, and α5 chains are particularly abundant in the GBM. Basement membranes containing these chains are believed to be stronger as a result of the presence of a high content of cysteine residues and, thus, disulfide crosslinks. The strength of the structural network is considered to be particularly important in basement membranes, such as those of renal glomeruli and the lens capsule, which do not have supportive collagen fibers. Molecules containing the α3–α6 chains have been shown to be involved in the pathogenesis of diseases such as Goodpasture syndrome, Alport syndrome, and/or diffuse esophageal leiomyomatosis (Table 68-1). Isoform switching (α4, α5) of type IV collagen is developmentally arrested in Alport syndrome, leading to increased susceptibility of renal basement membranes to endoproteolysis.

TYPE IV COLLAGEN GENES   The mammalian type IV collagen genes are located pairwise in an unique head-to-head fashion on three different chromosomes: chromosomes 13, 2, and X (Fig. 68-3). This implies that the six genes have evolved through duplication and inversion of an ancestral gene. Subsequently, the duplicated genes have undergone two further rounds of duplication, resulting in the three head-to-head located gene pairs on different chromosomes. The type IV collagen genes are large, over 100 kb, and complex, containing 46–52 exons. The genes are termed COL4A1, COL4A2, COL4A3, COL4A4, COL4A5, and COL4A6, respectively, for the type IV collagen α1, α2, α3, α4, α5, and α6 chains.

MOLECULAR PATHOLOGY OF THE DISEASE

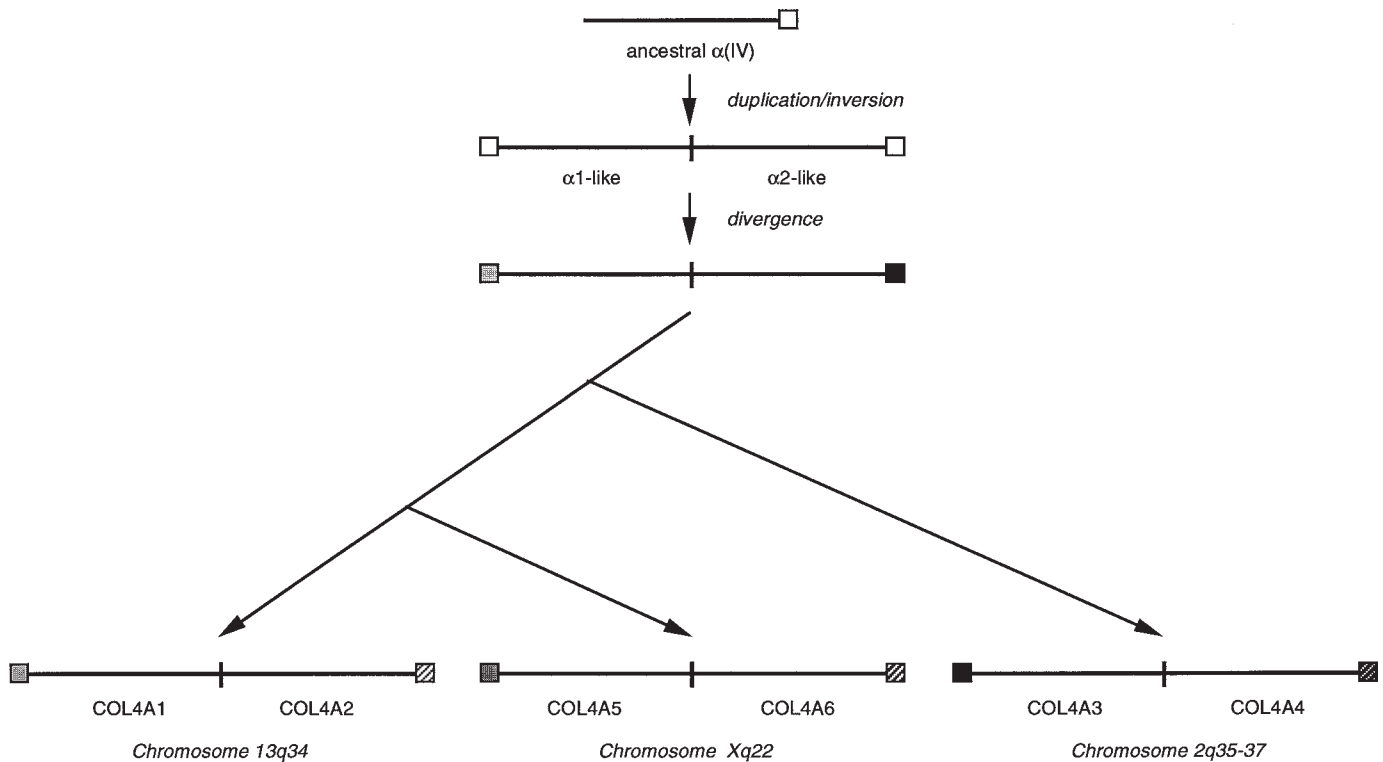
Mutations have been described in the COL4A5 gene in more than 100 cases of X-linked Alport syndrome. Furthermore, mutations have been identified in the COL4A3 and COL4A4 genes in autosomal recessive forms of the disease. Almost all of the mutations identified to date differ among familial groups. This, together with the complexity of the collagen genes, makes DNA-based diagnosis of Alport syndrome particularly difficult. About 15% of the mutations are large gene rearrangements, such as deletions, insertions, inversions, or duplications. The rest are small mutations, mainly large proportion of single base changes, in addition to small deletions, insertions, or duplications. The mutations can result in a complete absence of the protein (α chain) in question, a truncated protein, or a malfunctional protein. A loss of the carboxyterminal noncollagenous domain would prohibit the formation of heterotrimers. Several mutations in Alport syndrome involve replacement of a glycine residue in the collagenous domain


Figure 68-3 Evolution of type IV collagen genes. Analysis of the gene and protein sequences indicate that an ancestor type IV collagen α chain gene was first duplicated and inversed, followed by divergence of the genes to α1- and α2-like genes. This gene pair was later duplicated to two other chromosomes so that the α3(IV) and α4(IV) genes were formed prior to those of α5(IV) and α6(IV).

by another amino acid. Glycines at every third position are required for the formation of collagen triple helices, since this amino acid is the only amino acid small enough to fit into the interior of the tightly wound triple helix. Glycine mutations are also frequently the cause of other collagen disorders such as osteogenesis imperfecta. Based on the knowledge obtained from studies on osteogenesis imperfecta, it has been suggested that the abnormally folded triple helices are very susceptible to degradative enzymes, leading to the partial or total absence of all the α3, α4, and α5 chains. As a result, the structural framework of the GBM, which requires type IV molecules containing these polypeptide chains, becomes structurally weak and disrupted. The use of monoclonal antibodies against the α3, α4, or α5 chains in immunofluorescence microscopy of kidney biopsies may become a method to confirm the diagnosis of Alport syndrome in some cases, as an absence of these antigens can sometimes be seen in the skin basement membrane. A mouse model for the autosomal form of Alport syndrome has been produced by a collagen COL4A3 knockout. The mice develop progressive glomerulonephritis.

An interesting fact is that a clear correlation cannot be found between the nature of a mutation and the respective phenotype. A small single amino acid substitution can cause as severe symptoms as a large deletion of almost the entire collagen gene.

THERAPY

GENERAL   Although the onset of hematuria occurs during early childhood, the disease usually progresses slowly. A large number of male patients enter terminal renal failure during adolescence (juvenile form), but the onset also occurs beyond 25 years of age (adult type). Usually affected males and homozygous
Figure 68-4   Expression of β-galactosidase in porcine kidneys following in vivo perfusion with an adenovirus containing the β-galactosidase reporter gene under the cytomegalovirus promoter. Intense expression (dark color) can be observed in almost all glomeruli, whereas little, if any, is observed in the tubular cells.

females develop end-stage renal disease before the fifth decade of life, while heterozygous females rarely develop renal failure. There is no satisfactory and curative conservative treatment available. Patients developing end-stage renal disease are treated by hemodialysis and also by kidney transplantation whenever possible. About 5% of transplanted patients develop anti-GBM nephritis and reject the allografted kidneys.

PROSPECTS FOR GENE THERAPY   As a result of this advances in molecular genetics and biology research, gene therapy may be developing into a real possibility for the treatment of hereditary diseases in the future. Although gene therapy has not yet come of age as a real therapeutic alternative, extensive research efforts are being made in that direction. Hereditary kidney diseases such as Alport syndrome, primarily affecting the renal glomeruli, could potentially be treated by somatic gene therapy, which involves the introduction of normal cDNAs or complete genes for the α3, α4, or α5 chains into glomerular cells. Recent work has already shown it to be possible to transfer foreign genes into over 85% of the glomeruli in vivo (Fig. 68-4). Thus, the stage has been set for actual gene therapy experiments in animal models of Alport syndrome. There are, however, many obstacles to overcome before we can expect the disease to be cured in humans by gene therapy. But if gene therapy is going to become a viable alternative for the treatment of genetic diseases in general, it is likely to become an option for Alport syndrome.

69 Nephrogenic Diabetes Insipidus

DENNIS BROWN AND DENNIS A. AUSIELLO

INTRODUCTION

The neurohypophyseal antidiuretic hormone, arginine vasopressin (AVP), stimulates urinary concentration in mammals by increasing the water permeability of renal collecting ducts and by stimulating NaCl reabsorption by thick ascending limbs of Henle into the medullary interstitium. In the collecting duct, AVP binds to specific V2 receptors (V2R) on the basolateral plasma membrane of principal cells and stimulates adenylyl cyclase, which increases cytosolic cAMP levels. The increase in cAMP activates protein kinase A (PKA) and protein phosphorylation ensues. While the nature and role of the PKA substrates remains generally obscure, one phosphorylated protein is the vasopressin-sensitive water channel, aquaporin 2 (AQP2), which relocates from a pool of intracellular vesicles to the apical plasma membrane of principal cells upon vasopressin stimulation. This exocytotic insertion of water channels, illustrated in Fig. 69-1, greatly increases the water permeability of the principal cell apical membrane. Because the basolateral membrane of principal cells has a constitutively high water permeability because of the presence of two other water channels, AQP3 and AQP4, this vasopressin-induced apical exocytotic process is the rate-limiting step for increasing collecting duct epithelial cell water permeability. The urine in the tubule lumen equilibrates osmotically with the hypertonic interstitium by the bulk flow of water across the collecting duct principal cells, and the urine is concentrated.

Defective urinary concentration has long been recognized in man and in animal models such as the Brattleboro DI rat and the nephrogenic diabetes insipidus (NDI) mouse. The molecular basis for many of these related disorders has been examined and elucidated, thanks to the cloning and sequencing of two of the key proteins involved, the V2R and the vasopressin-sensitive collecting duct water channel, AQP2. This brief review will discuss cell and molecular biological evidence showing that mutations resulting in defective targeting and/or function of the V2R and the AQP2 water channel can both lead to distinct forms of NDI. Type I congenital nephrogenic DI (CNDI), the more frequent X-linked form, is caused by mutations in the vasopressin receptor, whereas type II CNDI is an autosomal recessive disease resulting from mutations in the AQP2 water channel.

CONGENITAL NDI—LOCATION OF THE VASOPRESSIN V2 RECEPTOR (V2R) GENE

CNDI was first described over 50 years ago, and genetic linkage studies in several families established that it is an X-linked trait. In CNDI, arginine vasopressin production is normal, but the target cells in the kidney do not respond to the presence of circulating hormone. Thus, the transepithelial water permeability of the collecting duct remains in its low basal state, and a large volume of hypotonic urine is produced. Clinically, this condition is recognizable soon after birth and if not corrected can result in severe dehydration, hypernatremia, and damage to the central nervous system. Linkage studies showed that the gene responsible is located in the subtelomeric region of the long arm of the X chromosome in region 28 (Xq28), where the V2R gene is also located.

STRUCTURE OF THE V2R

The V2R is a 371-amino acid protein that is a member of the family of seven membrane-spanning domain receptors that couple to heterotrimeric G proteins. Other members of this large family include rhodopsin and the β_2-adrenergic receptor. Homologs of the V2R have been cloned from human, pig, and rat, and the receptor sequences are more than 90% identical. The membrane topology of the receptor, as well as several functionally important features, are illustrated in Fig.69- 2. These include: (1) an extracellular N-terminus with a consensus site for N-linked glycosylation; (2) a cytoplasmic carboxy-terminus and large intracellular loop that contain several sites for serine and threonine kinase phosphorylation, and which probably play a role in receptor internalization and sequestration; (3) conserved sites for fatty acylation, which may serve as an additional membrane anchor in the C-terminal tail; and (4) two highly conserved cysteine residues in the second and third extracellular loops, which may form a disulfide bridge that is important for correct folding of the molecule and stabilization of the ligand-binding site.

CNDI AND MUTATIONS IN THE V2R

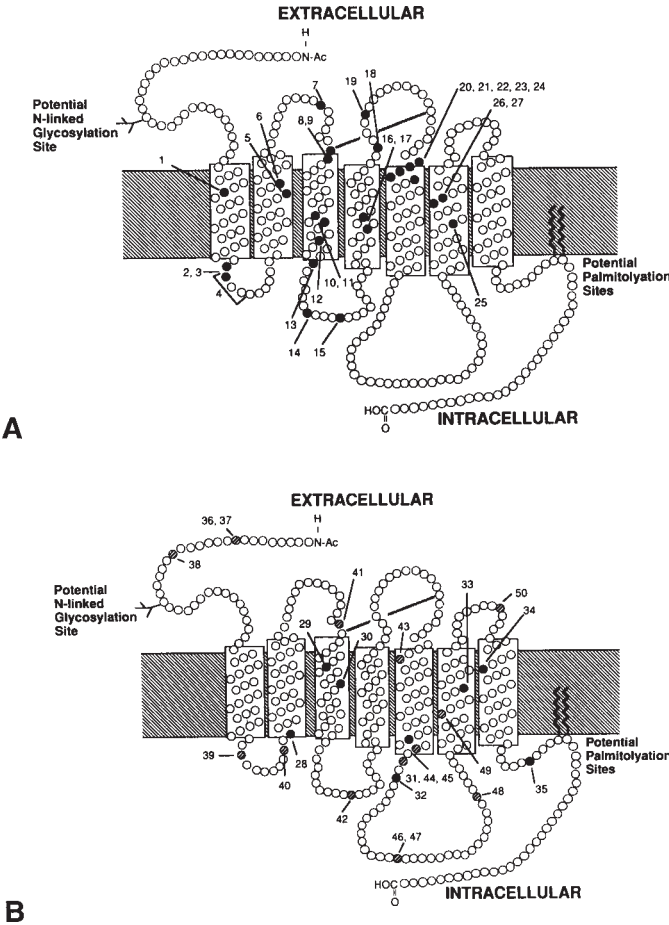
A series of reports have now identified mutations in the coding sequence of the V2R gene that can account for the production of a nonfunctional receptor by target cells in the kidney. A vast array of missense, nonsense, and frameshift mutations in various domains of the receptor coding sequence have been reviewed in detail previously, and some are illustrated in Fig. 69-3. Some result in the appearance of premature stop codons, which produce an effective null mutation by causing early truncation of the growing
Figure 69-1   Proposed pathway of AQP2 recycling in collecting duct principal cells. AQP2 is located on intracellular vesicles that move to and fuse with the apical plasma membrane following vasopressin stimulation and a subsequent rise in intracellular cAMP levels. The water channel is then internalized via clathrin-coated pits and eventually recycles back to the apical membrane in a complex trafficking pathway that has not yet been fully elucidated. In the same cell type, two other aquaporins, AQP3 and AQP4 (also referred to as the mercurial insensitive water channel [MIWC]), are located on the basolateral plasma membrane. The membrane localization of these two proteins is not regulated by vasopressin. They are constitutively present in this membrane domain, and they are assumed to be responsible for its permanently high water permeability.
Figure 69-2   Membrane topology of the vasopressin receptor (V2R) molecule. The 371-amino acid protein has seven membrane-spanning domains, an extracellular N-terminus, and a cytoplasmic C-terminus. Several features of the molecule are illustrated, with some key residues and potential phosphorylation sites shown in black. One mutation (R113W), close to the disulfide bridge, is shown. In work from our laboratory, a FLAG epitope added to the N-terminus allows efficient immunolocalization studies to be performed and was used to demonstrate retention of the R113W mutation in the RER.


Figure 69-3   Reported mutations in the V2R, showing the diversity of affected sites and types of mutations. **(A)** Missense mutations. **(B)** Nonsense and frameshift mutations. (Taken from Holtzman et al.)

polypeptide chain. Others are single-point mutations that cause a single amino acid replacement at a functionally critical site in the receptor molecule. One such example is an arginine (R) 113 to tryptophan (W) mutation caused by a C -> T base transition. This point mutation at the end of the first extracellular loop is one amino acid toward the carboxyl-terminus from a critical cysteine residue and may interfere with the formation of an important disulfide bond within the vasopressin receptor. Interestingly, an analysis of other G-protein coupled receptors has shown that tryptophan is never found at position 113 in any functional receptor, indicating that its presence is incompatible with normal receptor function.

Mutations in the V2R sequence that still allow the production of a full-length or near full-length protein could result in CNDI by interfering with different aspects of the receptor-ligand signal transduction cascade. For example: (1) the receptor could be expressed normally at the plasma membrane, but fail to bind vasopressin; (2) the receptor could be expressed normally at the membrane, bind its ligand normally, but fail to couple to its stimulatory GTP-binding protein, so that adenylyl cyclase is not activated;(3) the mutated receptor may be incorrectly folded and might be retained for degradation in the rough endoplasmic reticulum (RER), and may never reach the cell surface; (4) changes in the ability of the receptor to be phosphorylated may affect several aspects of function, including trafficking and desensitization. So far, functional analyses of the potential cell biological mecha-

nisms that result in CNDI have lagged behind the rapid rate at which various V2R mutants have been identified at the molecular level.

THE R133W MUTATION MODIFIES INTRACELLULAR TRAFFICKING OF THE V2R

The experiment in nature provided by the R113W V2R mutation has provided a model for the study of structural elements within receptors that permit proper folding and/or movement through the intracellular biosynthetic pathway. It has been repeatedly shown that misfolded proteins are triaged by a rigorous quality-control mechanism within the RER, and in most cases abnormally folded or assembled proteins are targeted for intracellular degradation without leaving the RER. When expressed at normal levels in vivo, the R113W V2R probably never reaches the plasma membrane in detectable amounts. Experimental overexpression of the R113W V2R in transfected LLC-PK1 cells appears to "saturate" the quality-control process, allowing at least some mutated V2R to escape degradation and reach the cell surface. Once at the cell surface, the R113W V2R can bind vasopressin, albeit at lower affinity than the wild type receptor, and can stimulate intracellular cAMP accumulation. However, even in transfected cells, the bulk of the mutated receptor is located within the RER by immunocytochemistry (Ausiello et al., unpublished results). An R337V2R mutation provides another example of receptor dysfunction because of arrested maturation and degradation before expression on the cell surface.

Thus, this particular mutation disables the V2R and the urinary concentrating mechanism, not by preventing receptor-ligand binding (although there is a shift in binding affinity), but by modifying the intracellular trafficking of the abnormal protein, such that it never reaches the plasma membrane and never comes into contact with its stimulatory ligand. A similar situation occurs in cystic fibrosis. The most common mutation in the CFTR gene product is the so-called ΔF508 mutation, again a single-point mutation. This mutation also leads to the trapping of a misfolded CFTR protein in the RER and prevents its delivery to the cell surface where it normally functions as a PKA-regulated chloride channel. Under experimental conditions that allow delivery of the ΔF508 CFTR to the cell surface, it functions normally and is regulated normally by PKA. Functional rescue of mutant V2 receptors has been demonstrated in transfected COS-7 cells by coexpression of the normal receptor sequences. Thus, it may be possible to devise therapeutic strategies that result in the correct delivery of misfolded, but otherwise functionally active, proteins to their correct location at the cell surface in vivo.

AUTOSOMAL RECESSIVE NDI—MUTATIONS IN AQUAPORIN 2

Some cases of NDI are not of the typical X-linked type, but are autosomal-recessive in nature. Alterations in the vasopressin receptor have not been found in these individuals, but instead, the defect lies within the vasopressin-regulated water channel, aquaporin 2 (AQP2). Based on two decades of studies, it was postulated that vasopressin exerts its antidiuretic effect by causing the exocytotic insertion of water channels into the apical plasma membrane of collecting duct principal cells (Fig. 69-1). The resulting increase in membrane water permeability allows osmotic equilibration to occur between the luminal fluid (urine) and the hypertonic medullary interstitium of the inner medulla.
Figure 69-4   Membrane topology of the aquaporin 2 (AQP2) water channel. This 271-amino acid protein spans the lipid bilayer six times. Both N- and C-termini are in the cytoplasm. There is a consensus site for N-glycosylation in the second extracellular loop, and phosphorylation sites for PKC (Pc) and PKA (Pa) are located in the C-terminal tail. Two point mutations (R187C and S216P) that were found in NDI patients are indicated with arrows. (Taken from Deen et al.)

AQP2 was cloned and sequenced based on its homology to AQP1, and a series of studies showed that AQP2 is the vasopressin-sensitive water channel in collecting duct principal cells. In collecting duct principal cells, the membrane localization of AQP2 is tightly regulated by the antidiuretic hormone, vasopressin. In Brattleboro homozygous rats, which lack vasopressin and which have hypothalamic diabetes insipidus, AQP2 is located primarily on intracellular vesicles but is delivered to the apical plasma membrane by exocytosis following vasopressin treatment in vivo. A similar translocation was seen in isolated perfused tubules from normal rat. More recently, translocation of AQP2 from intracellular vesicles to the plasma membrane has been demonstrated in transfected renal epithelial cells in culture. This latter result shows that the AQP2 protein contains sorting information that allows it to be incorporated into a regulated pathway of exocytosis. Together, these data directly support the shuttle hypothesis of vasopressin action, which invokes a cycle of exo- and endocytosis of water channels to explain the stimulatory effect of vasopressin on collecting duct water permeability.

In contrast, the proximal tubule and thin limb water channel, AQP1, is delivered to the plasma membrane in a constitutive, nonregulated pathway that results in a permanently high membrane water permeability in these renal epithelial cells. When expressed in epithelial cells in culture, AQP1 is also delivered to the cell surface without the need for hormonal stimulation. Thus, AQP1 and AQP2 contain distinct targeting motifs that direct them to different and physiologically important intracellular transport pathways. These distinct pathways can be maintained in vitro in transfected epithelial cells, providing powerful new model systems for the investigation of aquaporin cell biology.

Important data on the role of AQP2 in non–X-linked NDI was obtained by examining the AQP2 molecule in human disease. A few examples of AQP2 mutations have now been described (Fig. 69-4), but in most cases the cause of the AQP2 inactivity is not clear. In the first patient studied, two distinct point mutations were found that resulted in a substitution of Cys for Arg[187], and Pro

for Ser[216]. The R187C mutation occurs in a region of the third extracellular loop that is strongly conserved in members of the aquaporin family. The S216P mutation is located in the last transmembrane domain of AQP2. When mRNAs coding for these mutated proteins (which had the predicted size of 29 kDa) were expressed in Xenopus oocytes, no increase in membrane osmotic water permeability was detected above that seen in water-injected controls. However, whether the mutated proteins actually reached the cell surface of oocytes is unknown.

Mutations in the AQP2 gene that result in production of a full-length protein could have at least two consequences that would result in a loss of principal cell vasopressin-sensitivity: (1) the production of an AQP2 channel that is still vasopressin-sensitive, and is inserted into the plasma membrane after vasopressin action, but which has lost the capacity to function as a water channel; (2) the production of a water channel that is still functional, but that is no longer targeted to the plasma membrane after vasopressin action.

Other mutations could, of course, be null mutations that result in an absent or severely truncated protein. In support of the second possibility, oocyte expression studies have shown that the missense mutations R187C and S216P are impaired in their delivery to the cell surface. The trapped form of these AQP2 mutants is a 32-kDa high mannose form, indicating that the protein is blocked in the RER, in much the same way as the ΔF508 CFTR mutation is trapped inside the RER. However, it could not be determined whether these mutants were also functionally inactive water channels. That the water permeability of AQP2 can be modified by mutagenesis was shown by recent data indicating that some point mutations, including mutations in asparagine residue 123, significantly affect channel water permeability. The plasma membrane expression of this mutation was only slightly decreased from that shown by the wild type protein in oocytes.

ACQUIRED NDI

Several pathological conditions or drugs result in the syndrome of acquired NDI. Among these are lithium-induced NDI and hypokalemia (which occurs in 40% of all patients receiving lithium, polyuria in up to 35%, and NDI in 12–20%). Many studies have shown that a major cellular effect of lithium is an impairment of cAMP production that would, in principal cells, normally occur after vasopressin stimulation. While the basis for this inhibition is likely to be complex, acute lithium loading in renal epithelial cells directly inhibits adenylyl cyclase activation by competing for activation of the stimulatory GTP-binding protein subunit, Gs. The effect appears to be at the magnesium-sensitive rate limiting step in the generation of dissociated and GTP-activated Gαs-subunit, which normally activates adenylyl cyclase.

How might this modify collecting duct water permeability? Acutely, the effect would be to inhibit vasopressin-induced insertion of the AQP2 water channel into the plasma membrane of principal cells, which is a cAMP-dependent process. However, lithium also has chronic effects, and it has recently been shown that the cellular content of AQP2 protein is decreased in lithium-treated rats. This effect probably results from decreased transcription of the AQP2 gene, which is known to have a cAMP-responsive element in its 5' flanking region. Other studies have shown that dehydration of normal rats, or AVP treatment of Brattleboro rats, increases cellular AQP2 levels, implying that increased cellular cAMP "switches on" AQP2 production in principal cells. In lithium intoxication, the cellular cAMP levels would be chronically reduced, thus lowering AQP2 production at the transcriptional level.

Hypokalemia also results in NDI, and experimental hypokalemia in rats also reduces the cellular content of AQP2. Again, the precise cause is unknown, but hypokalemia causes cellular resistance to AVP, as well as directly stimulating thirst. At the cell biological level, it is known that lowering cellular potassium inhibits clathrin-mediated endocytosis and thus may interfere with the exo- and endocytosis of key proteins involved in the antidiuretic response. In particular, AQP2 is probably internalized and recycled by a process involving clathrin-coated pits, and most receptors, including the vasopressin receptor, is also dependent on clathrin-mediated endocytosis as part of its recycling pathway. Thus, interference with the correct recycling of either or both of these proteins could result in an NDI-like syndrome. Studies on tissues from potassium-depleted animals have shown a significant reduction in AVP-induced cAMP generation, which would, as in the case of lithium toxicity, result in lower transcription on the AQP2 gene and lower AQP2 levels in principal cells.

SUMMARY

With the cloning and sequencing of key proteins that are involved in the renal medullary concentrating mechanism, cell biological explanations for nephrogenic diabetes insipidus are now emerging. In congenital X-linked NDI, many mutations in the vasopressin receptor result in varying degrees of receptor inactivation, either by altering the function of the receptor itself or by preventing its proper targeting and trafficking to the plasma membrane of principal cells in the collecting duct. The rarer cases of non–X-linked NDI can, in some cases, be attributed to defects in the AQP2 water channel. Again, it is likely that functional as well as trafficking mutations will explain the NDI phenotype in cases where vasopressin-receptor activation and cAMP generation are normal. Finally, two examples of acquired NDI were presented, and potential causes of the defect based on the cellular actions of lithium and hypokalemia on AQP2 production and trafficking have been proposed.

70 Polycystic Kidney Disease

GREGORY G. GERMINO AND LUIZ F. ONUCHIC

BACKGROUND

Renal cysts are common clinical findings, often incidentally discovered in the course of evaluating other problems. They may be either acquired or seen in association with a number of inherited and congenital disorders. The most common disorder, autosomal dominant polycystic kidney disease (ADPKD), is an important cause of end-stage renal disease (ESRD), accounting for 5–8% of the entire ESRD population. At the time of Dalgaard's sentinel description of polycystic kidney disease (PKD), death from renal failure was a frequent outcome for affected individuals. While transplantation and dialysis have improved the prognosis for those suffering from PKD, no therapies have yet been discovered that prevent or inhibit cystogenesis. Hindering their development has been an incomplete knowledge of the pathogenesis of this process. Although most types of renal cysts share some common features (cell proliferation, basement membrane abnormalities, fluid secretion), the broad range of disorders associated with renal cysts suggests that defects in multiple, possibly intersecting, pathways are responsible for cyst formation and expansion. Recent molecular genetic studies have yielded important breakthroughs that are likely to lead to the unraveling of this mystery. In this chapter, we will review these data and how they have improved our understanding of renal cystic disease.

CLINICAL FEATURES

The hallmark of this group of disorders is the replacement of normal renal parenchyma by cysts in a process that frequently results in renal impairment. The cysts vary greatly in number and size, ranging from microscopic lesions of several millimeters in diameter to very large, macroscopic structures >10 cm in width. In general, larger cysts are seen in ADPKD, tuberous sclerosis (TS), and von Hippel Lindau disease (VHL), whereas smaller cysts are more often associated with autosomal recessive polycystic kidney disease (ARPKD) and medullary cystic disease/nephronophthisis (MCDNP). The cysts increase in both number and volume in most of the disorders as the individual ages. Table 70-1 summarizes the features associated with each disorder.

The nephron segment from which cysts are derived varies among the disorders and can, on occasion, be used to help establish a diagnosis. In ARPKD, the principal renal histopathologic abnormality is cystic expansion of all generations of the collecting ducts.

In the neonatal form of the disease, up to 90% of the collecting ducts are involved with cysts found in both the cortex and medulla. The kidneys tend to be massively but symmetrically enlarged and are usually palpable on exam. Ultrasonography typically reveals increased echogenicity with loss of corticomedullary differentiation. The cysts often are not detectable using radiologic imaging techniques. These severely affected children typically die within the first year of life. Children affected with a less severe form have a 10–60% involvement of their collecting ducts. Their kidneys are usually less enlarged and may develop macroscropic cysts. Hypertension, progressive renal insufficiency, and liver disease (portal tract fibrosis) are the primary manifestations of the disease in this older group.

The cysts in MCDNP arise from the distal convoluted tubules and are found in the medulla and the cortico-medullary junction. Tubulo-interstitial inflammation and fibrosis are universal features and may be present even in the absence of renal cysts. The kidneys typically are small and hyperechoic on ultrasound. The cysts, which are small and heterogeneous in size, may be difficult to visualize without special methods that maximize resolution of the abdominal ultrasound or CT scan. Affected individuals often present with polyuria, polydypsia, and hyposthenuria, and develop progressive renal impairment. Autosomal recessive forms of the disease present in childhood and are important causes of ESRD in this age group. Rare families have been reported with a later onset of disease and an autosomal dominant pattern of inheritance.

Renal cysts develop from all nephron segments in ADPKD. The cysts begin to form *in utero* and slowly increase in size and number during the lifetime of the individual. In early stages of the disorder, the kidney may be either normal in size or slightly enlarged. Progressive cystic disease typically distorts the structure of the kidney and results in chronic renal insufficiency in approximately 50% of affected individuals. Hypertension is a common problem and is associated with a greater likelihood of developing ESRD. There is considerable intra- and interfamilial variation in the severity of disease, with a number of families displaying progressive severity in successive generations. ADPKD occasionally presents with severe manifestations in childhood. These cases tend to have inherited the disease from an affected mother and often cluster within families.

It is important to note that most of the diseases discussed above have associated extrarenal manifestations that may be major causes of morbidity or premature death (Table 70-1). Congenital hepatic fibrosis is an important cause of morbidity in children with ARPKD

Table 70-1
Genetic Renal Cystic Disorders—Clinical Features

Disease	Inheritance	Kidney pathology	Renal manifestations	Extrarenal manifestations	Clinical onset	Clinical course
ADPKD	AD	All nephron segments cyst size variable, often >1 cm	Recurrent infections, hematuria, nephrolithiasis, renal failure	Liver cysts (40%), occasional cysts in other organs (pancreas, spleen), intracranial aneurysms, aortic aneurysms, cardiac valvular abnormalities, (mitral valve) prolapse) colonic diverticiculi	3rd and 4th decades (occasionally earlier)	50% evolve to ESRD by age 60
ARPKD	AR	All portions of the collecting duct 90% involvement, infantile form 10–60% involvement, later forms cysts usually <0.5 cm	Abdominal mass, hematuria, concentrating defect renal failure	Hepatic fibrosis, portal hypertension, hypertension, pulmonary hypoplasia	Infants and children (occasionally in early adulthood)	~20% die of respiratory failure within 1st month; ESRD, hypertension, portal hypertension, infection
Bardet-Biedl Syndrome	AR	Calyceal cysts Tubulointerstial nephritis cysts usually < 0.5 cm	Polyuria, isothenuria, renal failure	Mental retardation, pigmentary retinopathy, polydactyly, obesity, hypogonadism, polydipsia	Infancy	ESRD in childhood
MCDNP	AR	Corticomedullary cysts, tubulointerstial nephritis cysts usually <0.5 cm	Polyuria, isothenuria renal failure	Growth retardation	1st and 2nd decades	ESRD common in childhood
Senior-Loken	AR	Same	Same	Pigmentary retinopathy	Same	Same
	AD	Same	Same	Normal	3rd and 4th decade	ESRD in 4th decade
Tuberous sclerosis	AD	All nephron segments, cysts range from microscopic to >1 cm	Renal tumors, occasional massive cystic disease that mimics ADPKD, occasional renal impairment	Cortical tubers, retinal hamartoma, angiofibroma, astrocytomas, cardiac rhabdomyoma, renal angiomyolipoma, renal cell carcinoma	Childhood and adulthood	Neurological complications predominate but complications of renal disease are 2nd most common cause of death
Von Hippel-Lindau Syndrome	AD	Cortical predominance cysts range from 0.5 to 3 cm	Renal carcinoma, occasional ESRD	Hemangioblastoma, cystadenocarcinoma, pheocromocytoma, occasional cysts in other organs (liver, pancreas)	3rd and 4th decades	Neurological complications and cancers are important causes of morbidity and death, renal failure uncommon

Table 70-2
Genetic Renal Cystic Disorders — Chromosome Localization

Disorder	Prevalence	MIM no.	Chromosomal assignment	Protein product
ARPKD	1/1000			
PKD1	85–95%	173900	16p13.3	Polycystin
PKD2	5–15%	173910	4q21-q23	Polycystin 2
PKD3	Rare	600666	?	?
ARPKD	1/6000–1/40,000	263200	6p21.1-p12	?
Bardet-Biedl syndrome	Rare			
BB1		209901	11q13	?
BB2		209900	16q21	?
BB3		600151	3q13	?
BB4		600374	15q22.3	?
MCDNP				
Autosomal recessive				
NPH1	85%	256100	2q13	NPHP1
NPH2	15%	?	?	?
Senior-Loken	Rare	266900	?	?
Autosomal dominant	Rare	174000	?	?
Tuberous sclerosis	1/10,000			
TSC1	~50%	191100	9q34	Hamartin
TSC2	~50%	191092	16p13.3	Tuberin
TSC/PKD	Rare	600273	16p13.3	Tuberin and polycystin
TSC3	Rare	191091	12q23-q24 (unconfirmed)	?
TSC4	Rare	191090	11q22-q23 (unconfirmed)	?
Von Hippel-Lindau Syndrome	1/40,000–1/100,000	193300	3p25-p26	G7 (elongin A homolog)

who have milder forms of renal disease, for example. These features may be helpful in establishing a specific diagnosis.

DIAGNOSIS

The diagnosis of renal cystic disease is usually established by imaging studies such as ultrasound, CT scan, or MRI. Renal size, the number and location of cysts, and the age of the individual are important parameters that help establish a diagnosis. Multiple macroscopic renal cysts are the most common presentation of ADPKD, but renal enlargement without visible cysts is more typical of ARPKD and early stages of ADPKD. Distinguishing the disorders on the basis of their radiologic appearance is not always possible, so other clinical features are usually important in establishing a specific diagnosis. The pattern of inheritance of the disease within a family is one very helpful diagnostic criterion. Massive renal enlargement in an infant whose parents do not have renal cystic disease is most likely to have ARPKD, whereas an identical presentation in a child whose parent has renal cysts almost certainly has an autosomal dominant form of PKD. Other clinical features, such as congenital hepatic fibrosis, angiomyolipomas, or cerebellar and spinal hemangioblastomas suggest ARPKD, tuberous sclerosis, VLH disease, respectively. There is considerable overlap in the clinical presentation of the various disorders, however, and an exact diagnosis based solely on clinical findings is not always possible. Genetic studies may be required to distinguish the subgroups.

GENETIC BASIS OF DISEASE

Linkage studies have yielded a number of surprising results. Many of the disorders that had been previously thought to be genetically homogeneous were found linked to more than one gene, whereas ARPKD, which had been thought to have up to four genetically distinct forms, is associated with only one locus (Table 70-2). Studies of ARPKD families with both noninfantile

and severe perinatal presentations found linkage to identical markers on chromosome 6p21-cen. These studies suggest that ARPKD is genetically homogeneous and have important implications for genetic counselors. Prenatal DNA testing can now be offered to families who have previously had an affected child, if DNA material from the affected individual is available for analysis (blood, parafin-embedded specimens, and so on). Although the gene for ARPKD has not yet been isolated, it has been localized to a YAC contig of less than <3.1 Mb.

Recessive MCDNP, when present without significant extrarenal abnormalities, is a clinically homogenous disorder, yet genetic linkage studies have recently determined that it actually is comprised of at least two genetically distinct diseases. The major locus, NPH1, which accounts for ~85% of recessive MCDNP, has been mapped to chromosome 2q13. Cloning the interval in a yeast artificial chromosome contig revealed that several markers mapped to more than one locus within the NPH1 region. Further analysis determined that large-scale rearrangements were present in 80% of individuals from multiplex families and 65% of the sporadic cases. Sequence-tagged sites mapping into the interval were found to be absent in the DNA of affected individuals. Most of the individuals had large, homozygous deletions of approximately 250 kb involving a 100-kb inverted duplication. These data suggest that large rearrangements of a gene(s) at 2q13 is a common mechanism of disease in this disorder, making it the highest frequency of large rearrangements reported for any autosomal recessive trait. The recent discovery of the *NPHP1* gene will allow direct gene testing as a diagnostic test in the future. *NPHP1* was discovered to encode a 4.5-kb mRNA that is predicted to produce a novel protein of 732 amino acids whose function is presently unknown. Its only recognizable feature is a single SH3 domain. A curious and unanticipated feature is the gene's unusual pattern of expression. There is barely detectable expression in any adult organ other than muscle.

These findings are of immediate clinical use, as they permit the diagnosis of NPH1 in the majority of sporadic cases without the need for renal biopsy.

The chromosome location of NPH2 is presently unknown. It is perhaps not surprising that the clinically heterogeneous group of recessive forms of MCDNP that present with extrarenal manifestations is also genetically heterogeneous. Senior-Loken syndrome (MCDNP with retinitis pigmentosa) is not linked to chromosome 2 markers and is likely to represent yet another genetically distinct disorder. Bardet-Biedl syndrome, a group of disorders that has renal pathology similar to that of MCDNP but with mental retardation, obesity, retinitis pigmentosa, polydactyly and/or syndactyly, and hypogonadism maps to at least four loci, none of which are on chromosome 2 (Table 70-2). The chromosomal location of the gene for the autosomal dominant form of MCDNP has not yet been determined.

ADPKD has been found to be a genetically heterogenous disorder with at least three unique loci implicated in its pathogenesis. PKD1 is the most common, accounting for 85–95% of all ADPKD, and maps to chromosome 16p13.3. PKD2 is responsible for 5–15% of all ADPKD, and maps to chromosome 4. This form of ADPKD presents with an identical profile of extrarenal manifestations (liver cysts, aneurysms, and so on) but is thought to be less severe. It has recently been discovered that non-PKD1 patients live longer than PKD1 patients (median survival 71.5 vs 56.0 years), have a lower risk of progressing to renal failure, are less likely to have hypertension, tend to be diagnosed at an older age (median 69.1 vs 44.8 years), and have fewer renal cysts at the time of diagnosis. A small number of families have been discovered in which the disease does not segregate with either chromosome 16 or chromosome 4 markers (PKD3). The number of families is very small but apparently the disease is equal in severity to that seen in PKD1. This form of ADPKD has not yet been mapped, and it is possible that this subgroup also is genetically heterogeneous.

The 10-year search for *PKD1* illustrates both the challenges and opportunities offered by positional cloning. While a combination of molecular and genetic techniques rapidly localized the gene to a 500-kb gene-rich segment on 16p13.3, the large number of potential candidate genes greatly complicated the search. Two clues ultimately led to its identification. The first was the discovery that a major form of tuberous sclerosis (TSC2) mapped to the *PKD1* region. The other major "breakthrough" was provided by a family that had a child with tuberous sclerosis and renal cystic disease, whose mother and sibling only had ADPKD. Cytogenetic analysis revealed that the mother and sibling with ADPKD had balanced translocations between chromosome 16 and 22 [46XX t(16;22)(p13.3;q11.21)], whereas the child with TSC2 had an unbalanced karyotype [45XY/-16-22+der(16)(16qter-16p13.3::22q11.21-22qter)]. Since other studies had previously found loss of heterozygosity for 16p13.3 markers in TSC-associated lesions, TSC2 was hypothesized to lie within the deleted telomeric segment whereas *PKD1* was likely to be bisected by the translocation.

Further study proved both hypotheses to be true. A group of individuals with TSC2 were found to have an overlapping set of DNA deletions disrupting a gene that mapped just distal to the breakpoint (Fig. 70-1). The gene has been called tuberin and has a region of homology to a GTPase activating protein. The PKD1-associated translocation was found to bisect the adjacent gene, which encoded a 14-kb transcript. Affected individuals in the family with the translocation were discovered to have a novel mRNA

of 9-kb. A small number of intragenic mutations (deletions, splice site disruption) were subsequently identified in other pedigrees that had PKD1, proving that the gene disrupted by the translocation was indeed *PKD1*.

The *PKD2* gene was discovered much more quickly. The predicted protein product of a candidate gene isolated from the minimal genetic interval on 4q22 was found to have modest homology to PKD1. A subsequent search for mutations uncovered a handful of pathogenic variants which are likely to truncate the normal protein.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

Another gene (PKD2) structurally similar to PKD1 is located on chromosome 4q22 and also causes ADPKD. This chapter will focus primarily on PKD1, including its role in the pathogenesis of cyst formation.

PKD1 GENE STRUCTURE Several features of *PKD1* and it gene product, polycystin, make it one of the most complicated disease genes yet discovered:

Size The gene encodes a 14-kb mRNA that is derived from 46 exons that extend over ~53 kb of genomic DNA. Its protein product, polycystin, is 4302 amino acids in length and likely to be a membrane-associated glycoprotein with multiple membrane-spanning segments. Both the size of the *PKD1* mRNA and its gene product are among the largest reported to date.

Unusual DNA Sequence Repeats An intron within the middle of the gene contains a ~2.5-kb segment that is 96% composed of polypyrimidines on its coding strand. Similar but much shorter elements discovered in other genes have been reported to form triple helical structures that can regulate DNA replication and RNA transcription and processing. The extreme length of this element in *PKD1* may play a role in the pathogenesis of PKD1.

Family of Homologous Sequences Greatly complicating the isolation and characterization of the gene was the discovery that ~70% of the gene was replicated in at least three copies clustered together on 16p13.1. The other loci, which also are transcribed, differ from *PKD1* by less than 5% in their shared segments. Only the last ~3.9 kb of the *PKD1* mRNA is unique and can be used to distinguish *PKD1* from its homologs. PKD2 encodes a protien called polycystin. The PKD2 gene is expressed ubiquitously, including the kidney.

POLYCYSTIN, THE PKD1 GENE PRODUCT The peptide sequence of polycystin suggests that it is likely to be a membrane glycoprotein that mediates cell–cell and/or cell–matrix interaction with a carboxy-terminal portion communicating with intracellular signaling pathways (Fig. 70-2 and 70-3). It is a novel protein with multiple domains that have homology to those of other known proteins. It is predicted to have between 7 and 11 transmembrane domains that follow its extracellular N-terminal segment of either 2500 or 3000 amino acids. Most models of the protein structure place its amino- and carboxy-terminal segments on opposite sides of the cell membrane, with the latter positioned within the cytoplasm.

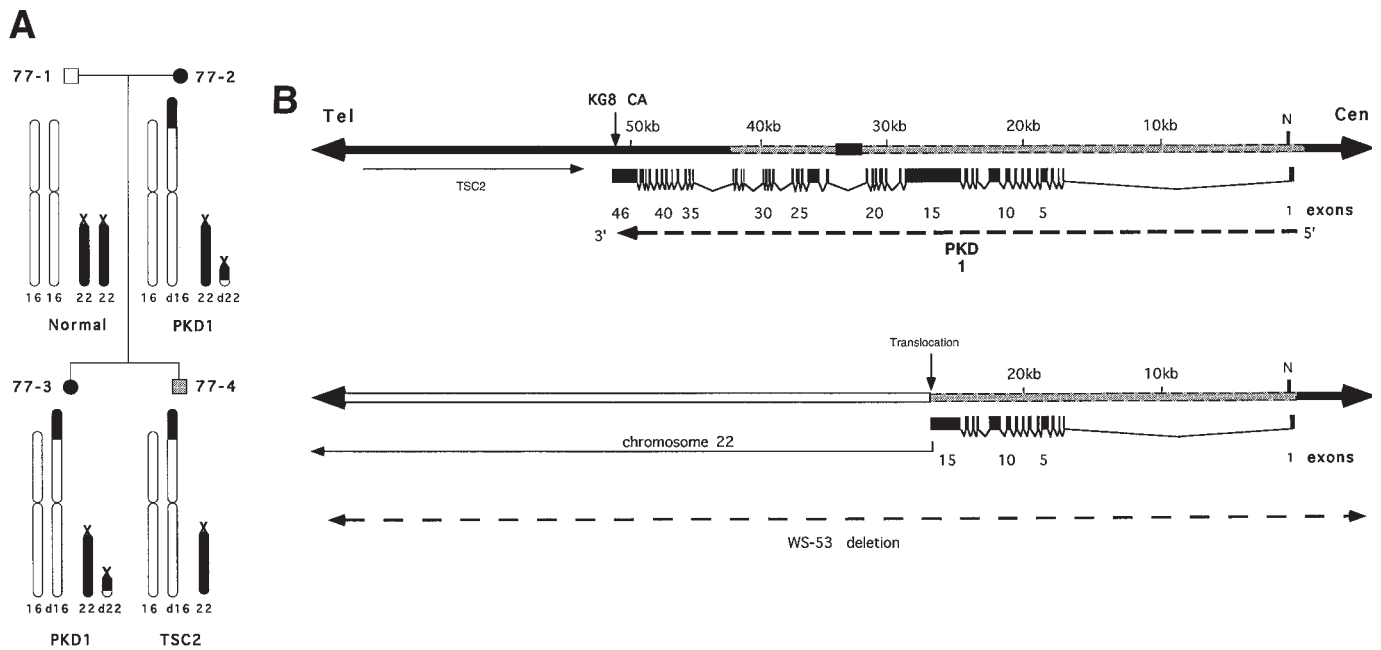
The amino end of the predicted protein begins with an amino-terminal hydrophic signal sequence, which is soon followed by a pair of leucine-rich repeats (LRR). Flanking the LRRs on their amino and carboxy ends are distinctive cysteine-rich segments that are similarly found in a number of other LRR-containing proteins. The combination of both an amino and carboxy cluster with the LRRs has been previously reported for only three other protein


Figure 70-1 **(A)** The PKD1 Breakthrough: a pedigree with chromosomal abnormalities segregating with ADPKD and tuberous sclerosis. Unfilled box is the unaffected father (77-1). Filled symbols identify individuals affected with ADPKD (77-2, 77-3). The shaded box (77-4) identifies an individual with tuberous sclerosis and cystic disease of the kidney. The homologous pairs of chromosome 16 and 22 for each individual are schematically illustrated beneath each symbol. Individuals 77-2 and 77-3 have ADPKD and a balanced translocation [t(16;22)(p13.3;q11.21)] whereas individual 77-4 has an unbalanced translocation with loss of der22 [-16-22+der(16)(16qter→ 16p13.3:22q11.21 → 22qter)]. *16* and *22* identify normal chromosomes whereas *d16* and *d22* define the derivative chromosomes. **(B)** Genomic structure of *PKD1*. The top line represents the chromosome segment with its orientation as listed (tel, telomere; cen, centromere). The segment is marked in kilobases (kb). *N* identifies a *Not*I restriction site that maps to the 5' end of the gene. The location of an intragenic, polymorphic microsatellite (KG8 CA) is shown. The shaded portion of the chromosome indicates the segment of the gene found replicated elsewhere on chromosome 16. The darkly stippled box within the replicated region indicates the position of the polypyrimidine tract described in the text. The numbered, linked vertical bars and boxes beneath the chromosome represent *PKD1* exons. The direction of transcription for *PKD1* and *TSC2* is indicated by the arrow above each gene name. The segment immediately below the normal chromosome illustrates the impact of the [t(16;22)(p13.3;q11.21)] translocation on the *PKD1* gene structure. The dashed line at the bottom indicates the approximate extent of a deletion that was discovered in individuals with tuberous sclerosis and severe polycystic kidney disease at any early age. (Adapted with permission from Watnick T, Germino GG. Genetic mechanisms of renal disease. Diseases of the Kidney, Schrier and Gottschalk eds. Boston: Little Brown, 1996.)

families: the trk proto-oncogenes and two developmental proteins, slit and Toll. These elements are located in the extracellular portion of each protein and are thought to mediate protein–protein interactions in cell–cell and cell–matrix recognition. The domains also may form part of the ligand-binding region of the receptors.

Another important feature of the protein sequence is a peptide module ~80 amino acids in length that is replicated 16 times. The first repeat is positioned between the LRRs and a C-lectin domain with the rest tandemly grouped after LDL-A module (Fig. 70-2). The basic unit is similar in structure to the I set of immunoglobulin (Ig) domains, being comprised of a b strand followed by a turn that links the modules but lacks the consensus cysteines. The Ig-like cluster is followed by an ~700-amino acid segment that has significant homology to the receptor for egg-jelly (REJ) in the sperm of the sea urchin. The receptor binds to matrix surrounding sea urchin eggs, and the interaction results in ion-channel activation and initiation of the fertilization process. The recent discovery that PKD2 has high homology to a family of voltage-activated ion channels has prompted some to speculate that the sea urchin sperm–egg matrix interaction may serve as a model of PKD1-PKD2 function. Finally, the short cytoplasmic tail of polycystin has an α-helical coiled-coil structure made of five heptad repeats that has been shown to interact with the cytoplasmic C-terminus

of PKD2. Both naturally occuring and engineered mutations of either gene have been shown to disrupt this interaction. These data suggest that the gene products of *PKD1* and *PKD2* may function as partners in a common signaling cascade involved in tubular morphogenesis. The data also suggest that an important role of PKD1 may be to regulate the activity of PKD2.

It is interesting to note that the possible functions of polycystin as predicted by its sequence are consistent with many of the earlier hypotheses regarding the pathogenesis of ADPKD. Coordinated cell growth and morphogenesis are regulated in part by cell–matrix and cell–cell interactions. The abnormalities in extracellular matrix, regulation of tubular cell growth, epithelial cell polarity, expression profile of developmental genes, and the vectorial transport of tubular fluid observed in ADPKD cysts may be downstream effects of mutations that disrupt the function of polycystin.

MUTATION STUDIES Mutation analyses have been greatly hindered by the high sequence similarity of *PKD1* to its homologs. It has been estimated that 80–90% of all pathogenic mutations are located within the replicated portion of the gene. Only a small number of mutations have been discovered, and most have been clustered in the 3' locus-specific segment (Fig. 70-3; Table 70-3). Nonetheless, a few patterns appear to be emerging. Most of the mutations have been unique. Most of the mutant alleles have been
Figure 70-2 Predicted structure of polycystin, the *PKD1* gene product. Different computer analyses identify variable numbers of transmembrane (TM) spanning segments, but most models predict a final product with multiple TM elements and amino- and carboxy-termini located on opposite ends of the cell membrane. (Adapted from Burn TJ et al: Hum Mol Genet 1995;4:575–582; Hughes J et al: Nat Genet 1995;10:151–160; International Polycystic Kidney Disease Consortium. Cell 1995;81:289–298. Reprinted with permission from Watnick T, Germino GG. Molecular mechanism of renal disease. Diseases of the Kidney, Schrier and Gottschalk, eds. Boston: Little Brown, 1996.)

expressed and thought likely to produce mutant proteins lacking the final membrane-spanning regions and/or the cytoplasmic component of the protein. The model of the protein structure predicts that such abnormalities would affect membrane localization of the gene product, disrupt intracellular signaling pathways, or result in a secreted form of the protein. The mutant proteins might be able to bind their extracellular partners (some of which may be other polycystin molecules) but be unable to transmit this information across the membrane. Finally, one recent study suggests that gene conversion events between *PKD1* and its homologs may be an important mechanism causing mutations to occur.

One important goal of performing genotype/phenotype correlations is to determine genetic variants that predict more severe disease. This information can be clinically very useful as well as provide important clues to a protein's function. In the case of *PKD1*, only one pattern has been discovered that reproducibly

correlates with disease severity. A small group of children has been described that is affected with a severe form of polycystic kidney disease and tuberous sclerosis (TS). They have been discovered to have deletions which remove the entire *PKD1* gene and disrupt the adjacent *TSC2* gene.

It is important to note that the children with TS and massive cystic disease had *de novo* mutations and were not members of families with documented ADPKD. Similar deletions have not been found in severely affected children born into families with classic ADPKD. In the only report of a child with early onset ADPKD in which the defect has been defined, the variant was a nonsense mutation that changed Tyr3818 to a stop codon. It is not presently known whether there is a subset of mutations associated with any of the extrarenal manifestations of ADPKD.

PKD1 GENE AND PROTEIN EXPRESSION   Studies of *PKD1* gene expression have determined that it is widely expressed in both fetal and adult organs, though at variable levels (*see* Chapter 64). The highest level of gene expression appears to be in the brain. Fetal kidney and liver and cystic kidney and liver have higher levels of expression than their normal adult counterparts. The level of expression in normal adult kidney is variable, most likely reflecting differences in regional expression within the kidney.

Conflicting reports have been published describing the tissue and developmental profile of polycystin expression. Reports have differed with respect to which nephron segments have significant levels of expression, when expression is highest, and which extraepithelial cell types express polycystin. For example, one study reports that polycystin is present in the smooth muscle cells lining vessels while several other studies explicitly note its absence in these structures. There is a broad consensus, however, on several points. First, it appears likely that polycystin is widely expressed in adult tissues, though often at very low levels. For example, most investigators have detected polycystin in normal pancreatic and biliary ductules, two other cell types subject to cystic change. Second, most investigators agree that the protein is present in fetal kidney and in lesser amounts in adult kidney. One study of murine polycystin expression determined that it is highest in late fetal and early neonatal life, and drops 20-fold by the third postnatal week. These data have been cited as evidence that PKD1 plays an important role in kidney tubule differentiation and maturation. Third, most investigators agree that the protein is membrane-associated, with the majority favoring a reporting basolateral localization. Finally, all investigators agree that the protein appears to be more abundant in cystic kidney.

The biologic significance of the transcripts encoded by the homologous loci remains unknown. It has not yet been determined whether the 21-kb, 17-kb, or 8.5-kb mRNA encoded by these loci are translated into proteins or are derived from nonfunctional pseudogenes. If the mRNA of the PKD1 homologs are translated, their protein products would include most of the important functional domains contained in the 5' end of *PKD1* and could be involved in modulating disease severity.

PKD2 GENE   The gene for the second most common form of ADPKD, *PKD2*, is located on chromosome 4 and encodes a 5.4-kb mRNA. Analysis of the translated sequence predicts an integral membrane protein of ~110 kDa with 6 TM domains nested between amino- and carboxyl-termini that are likely to be intracellular. The cytoplasmic C-terminus contains an EF-Hand motif that has been shown in vitro to bind calcium. The protein sequence of PKD2 has significant homology to the voltage-activated Ca^{2+} channel a_{1E} protein and part of polycystin. An ion-channel activity
Figure 70-3 PKD1 mutations. This figure illustrates the relative location of *PKD1* exons, protein domains, and mutations. Most of the mutations reported to date have been clustered in the *PKD1*-specific portion of the gene (solid bar). The table below the figure lists the position of each mutation and describes its likely impact on the final gene product. Ig, immunoglobulin-like repeat; REJ, receptor for egg-jelly domain; TM, transmembrane segment.

Table 70-3
PKD1 Mutations

Variant name	Type of mutation	Position	Predicted effect on protein
77-2	Translocation	Exon 15	Truncation
JHU 273	Transversion, T→G	Exon 23	No change
	Transition, T→C	Exon 23	Missense, Met2760Thr
	Transversion, G→C	Exon 23	Missense, Arg2761Pro
	Transition, T→C	Exon 23	Missense, Met2764Thr
	Transition, T→C	Exon 23	Missense, Ileu2826Thr
JHU 086	Transversion, T→G	Exon 23	No change
	Transition, T→C	Exon 23	Missense, Met2760Thr
	Transversion, G→C	Exon 23	Missense, Arg2761Pro
	Transversion, C→G	Exon 23	Missense, Leu2763Val
	Transition, T→C	Exon 23	Missense, Met2764Thr
OX 114	Deletion, 2 kb	Intron 30–Intron 34	Frameshift deletion, 446 bp
OX 875	Deletion, 5.5 kb	Intron 34–Exon 46	Truncation
OX 29 (P35)	Deletion, 15 bp	Exon 39	In-frame deletion, 5 aa
OX 1095 (P167)	Deletion, 72 bp	Intron 39–Exon 40	In-frame deletion, 17 aa
III 2 (P117)	Transversion, C→A	Exon 41	Nonsense, Tyr3818Stop
OX 1175 (P198)	Transition, C→T	Exon 41	Nonsense, Glu3037Stop
OX 1054	Deletion, 20 bp	Intron 43	Splicing defect
			+ intron, causes frameshift
			– intron, causes in-frame deletion, 22 aa
OX 461	Deletion, 18 bp	Intron 43	Splicing defect
			+ intron causes in-frame insertion, 19 aa
			– intron causes in-frame deletion, 22 aa
OX 32	Transition, G→C	Intron 44	Splicing defect: in-frame deletion of exon 44
VR 4001	Transition, C→T	Exon 44	Nonsense, Gln4041Stop
OX 42	Transition, C→T	Exon 46	Nonsense, Arg4227Stop

has been proposed, though not yet demonstrated, for the *PKD2* gene product. The results of Northern blot analysis suggest that the mRNA is expressed ubiquitously. Preliminary studies have reported that the protein is likely to be membrane-associated and widely expressed in both fetal and adult tissues. In the kidney, it appears to be present in the renal tubule epithelia at the basolateral

membrane. Because the protein is predicted to have only six TM-spanning regions, one model proposes that it forms either homo- or heteromultimers to create a functional channel or pore. In vitro studies, which have shown that the protein can self-associate, support this hypothesis. Whether PKD1-PKD2 heteromultimers may also be components of a functional channel remains to be determined.

ADPKD CLINICAL VARIABILITY One of the interesting features of this disease is the variability with which it presents in related members of a family. It is easy to understand how the disease may differ in severity in different pedigrees, where the mutation may differ. It is less clear why the same mutation causes different clinical presentations in genetically related individuals. The child with early onset PKD1 described above had a fraternal twin who had inherited the same *PKD1* mutation but was clinically unaffected in childhood. Variants of other modifying genes could account for some of the difference. Modifying genes have been shown to have significant effects on the clinical expression of cystic disease in murine models of PKD, for example. However, other factors are also likely to significantly alter the course of disease. The strongest evidence in support of this claim is provided by pathologic examination of human PKD kidneys. One is struck by the focality of disease—not all nephrons undergo cystic change despite all cells in each nephron sharing the same mutation of *PKD1*. Why, if every tubular cell within an affected individual's kidney or biliary tract inherits the same germline mutation and the same genetic modifiers, do only a small fraction become cystic? These observations suggest that a second, possibly rate-limiting, step must be required for cysts fo form.

Recent studies have provided a partial answer to this question for PKD1. Using a novel method for isolating DNA from the epithelial cells lining single renal cysts, it has been shown that renal cysts in ADPKD are monoclonal. Moreover, a significant fraction of cysts was found to have loss of heterozygosity (LOH) for two closely linked, polymorphic markers located within *PKD1*. Genetic analysis determined that is was the normal haplotype that was lost or mutated in cyst-lining epithelia.

An obvious challenge is reconciling the results of immunolocalization studies which suggest increased abundance of polycystin in cyst-wall lining cells with the results of the LOH study. Some have suggested that the latter phenomenon may be a consequence of the cystic state rather than an important step in its pathogenesis. While more data will be required to resolve the matter, several lines of evidence support the "two-hit" genetic model for PKD1. First, a similar process has also been recently described for hepatic cysts in ADPKD. Second, small single or oligo-basepair insertions, deletions or nonsense mutations can be detected in many cysts lacking LOH. Finally, the results of gene targeting studies in mice suggest that loss of function of both alleles is necessary for cyst formation. A *PKD1* mutation that mimics one found in human ADPKD was introduced into mice by homologous recombination. Heterozygotes had no discernible phenotype, whereas homozygotes died during the perinatal period with massively enlarged cystic kidneys, pancreatic ductal cysts, and pulmonary hypoplasia.

An important consideration is the extraordinary number of somatic mutations that must apparently occur to account for the number of cysts observed (10^2–10^4). The data suggest that *PKD1* is likely to be highly mutable. Unique genomic structural features, including unusual polypyrimidine tracts within introns 21 and 22

of the gene, might be responsible for both the high frequency of the disease within the population as well as the large number of "second hits" observed in cystic epithelia. The indistinguishable clinical presentation of all forms of ADPKD suggests that a similar two-step process occurs in each. The pattern of mutations described for PKD2 is consistent with a loss-of-function model. However, in contrast to PKD1, the relative infrequency of PKD2 and PKD3 in the population suggests that their respective genes are not highly mutable. How then, can one account for the number of second hits that must occur to account for the extraordinary number of cyts that are observed? Two models have been proposed: (1) the second hit rates of *PKD1*, *PKD2*, and *PKD3* reflect the average rate of somatic mutation in the genome rather than an unusually high rate of somatic mutation resulting from a locally mutable structure within each gene; or (2) somatic inactivation of *PKD1* may be the second step that leads to clonal expansion in the other forms of ADPKD. The second model predicts that the relative frequency of the respective forms of the disease in the population is determined by the rate of germline mutation at each genetic locus while the frequency with which cysts form is determined by the rate of somatic mutation of *PKD1*. Further study is required to determine whether either model is correct.

Regardless of whether somatic mutation of PKD1 is necessary for all forms of ADPKD, the data suggest that functional inactivation of PKD gene products is an essential step in cyst formation. These findings have important implications for investigators seeking to define polycystin's function. For example, the two-hit model suggests that PKD1 mutations are likely to result in gene products with decreased function. While one may easily imagine how mutations that result in truncated proteins with loss of essential domains impair activity, the impact of missense mutations is often more difficult to predict. The model challenges investigators to explain how these changes result in compromise of the protein's function. One must determine whether missense changes disrupt critical domains or affect the way the protein is processed and sorted through the cell (e.g., Δ508 and CFTR). The two-hit model also has important implications for investigators seeking to create suitable model systems and to develop effective therapies. Approaches that result in inactivation of the gene may be necessary to reproduce the disease state, while strategies directed at replacement of PKD gene function may reverse it.

TREATMENT/FUTURE DIRECTIONS

There presently is no cure (except for transplantation) for any of the forms of PKD, and all currently available therapies are directly available therapies are limited to managing complications associated with the diseases (hypertension, infection, pain, and so on). ADPKD offers unique opportunities for intervention, since the most severe complications of the disease typically do not develop until the fifth or sixth decade. It also poses significant challenges, however, since the therapy must be very safe. For example, we do not want to offer a treatment now to a child, with the hope of preventing ESRD in 50 years, and instead give him/her a higher likelihood of developing a cancer at age 30. Moreover, not everyone who inherits the same mutation will go on to suffer the most severe complications. One must understand the mechanism of disease if we are to offer safe and effective therapies (e.g., definition of the intersecting pathways that result in renal cystic disease may allow investigators to detour around possible blocks in signaling pathways). Alternatively, a gene product (e.g.,

polycystin) may function as a receptor, and competitive agonists or antagonists may be effective. One must have suitable models for testing possible therapeutic compounds or other interventions. Human cell culture systems are easily manipulated and useful for characterizing a number of aspects (transport, signaling pathways, proliferation, and so on) but have significant limitations. Genetically faithful animal models of human disease can be extremely useful when available. An exciting consequence of discovering human disease genes is that one can now use molecular genetic techniques (e.g., gene targeting) to create mice that develop human forms of PKD. These are likely to offer many new opportunities for better understanding the pathophysiology of the disease and testing therapeutic interventions.

In the short run, the discovery of genes for the various forms of PKD will have the greatest impact on our diagnostic capabilities. DNA testing can be used to evaluate relatives of an affected individual as possible donors for living related transplants in ADPKD. Genetic testing may soon be able to establish a diagnosis when individuals present with atypical features (kidneys not enlarged and only a few cysts) or an overlap syndrome (early severe cystic disease in a child, parents unaffected; ?VHL or TS). Studies correlating genotype with phenotype may identify those who would benefit most from interventions and close observation (severe early childhood forms, massive cystic disease, subarachnoid aneurysms, and so on). DNA testing may preclude renal biopsy as a diagnostic test for children with clinical features suggestive of NPH1.

An additional benefit resulting from the identification of one of the major "cystogenes" is that it is very likely to aid the discovery of others. The three types of ADPKD are virtually indistinguishable and are likely to develop as a consequence of defects in interactive factors involved in a common pathway. The protein-binding partners of polycystin are obvious candidates for PKD2 and PKD3 (and so on). Identification and characterization of the interacting proteins by means of biochemical (purification) or genetic (yeast two hybrid) techniques will likely help to define the pathways that regulate tubular morphogenesis. Finally, discovery of the *NPHP1* gene is likely to improve our understanding of the pathogenesis of another important clinical problem, chronic interstitial nephritis.

71 Renal Neoplasms
Wilms' Tumor and Renal-Cell Carcinoma

KIM E. NICHOLS AND DANIEL A. HABER

INTRODUCTION

Identification of disease-related genes has been greatly facilitated by the use of positional cloning strategies. These molecular approaches, based on genetic localization rather than biologic function, have led to the isolation of genes responsible for the development of several human cancers. Among these are *WT-1*, a tumor suppressor gene implicated in the pediatric kidney cancer Wilms' tumor, and *VHL*, the gene for the Von Hippel Lindau syndrome, a disease associated with the development of renal cysts and renal-cell carcinoma. The identification of specific genes involved in the development of renal tumors may lead to a better understanding of both normal kidney development and tumor formation. For instance, *WT-1* has been shown to be required for normal formation of the kidney and gonads. Its role in the survival of renal blastemal cells and the formation of glomeruli is under active investigation. Additional insight into kidney development may follow the identification of other Wilms' tumor genes and the further characterization of the *VHL* gene.

WILMS' TUMOR

Wilms' tumor or nephroblastoma is the most common abdominal solid tumor of childhood, accounting for 5–6% of all pediatric cancers and affecting 1 in 10,000 children. The tumor was first characterized in 1899 by the surgeon Max Wilms', after whom it was named. Wilms' tumors are thought to arise from primitive renal stem cells (blastemal cells) that maintain a limited capacity to differentiate. Classical Wilms' tumors are characterized by their "triphasic" histology consisting of varying degrees of blastemal, epithelial, and stromal components. However, elements of neural or skeletal muscle differentiation may also be present. This complex histologic pattern suggests a recapitulation of early events in kidney development, consistent with the malignant transformation of a pluripotent renal stem cell.

THE KNUDSON "TWO-HIT" MODEL OF TUMORIGENESIS Although the majority of Wilms' tumors are unilateral, approximately 10% are bilateral. Bilateral cases occur at a younger age than unilateral tumors (on average 2 years earlier) and may be associated with a positive family history. These observations, analogous to those made in two other pediatric tumors, retinoblastoma and neuroblastoma, led to the "two-hit" model of

tumorigenesis proposed by Knudson and Strong in the early 1970s. Based on statistical analysis of the age of incidence of unilateral versus bilateral tumors, Knudson predicted that two "rate-limiting hits" are required to initiate tumor formation. Most unilateral tumors represent sporadic cases in which these two rare genetic events have arisen in the same cell. However, children who already harbor one genetic lesion in their germline, either inherited from a parent or occuring *de novo*, require only one additional "hit" in somatic cells. The high probability of sustaining a single genetic event explains the early onset of tumors in these children and their frequent multifocal or bilateral incidence. The Knudson model has been confirmed by the demonstration of allelic losses in tumor specimens involving specific chromosomal loci and eventually by the identification of individual genes targeted by the mutational events. The two rate-limiting hits that were predicted are now understood to represent the inactivation of both alleles of a tumor suppressor gene.

While isolation of the *RB* gene involved in retinoblastoma has fulfilled all of the predictions of the Knudson model, Wilms' tumor has proved more genetically heterogeneous. Only 1% of Wilms' tumor cases show evidence of familial transmission, indicating that most bilateral tumors result from *de novo* germline mutations. This may reflect reduced fertility in individuals who carry a mutation in one allele of a gene that is involved in genito-urinary development *(see below)*. In addition, multiple genetic loci have been implicated in Wilms' tumor. *WT1*, the Wilms' tumor gene residing at the chromosome 11p13 locus, has been identified, and its properties are the subject of intensive study. Studies are currently underway to isolate the second Wilms' tumor gene localized to the chromosome 11p15 locus and a potential third Wilms' tumor gene implicated in rare familial cases.

ISOLATION OF THE WT1 TUMOR SUPPRESOR GENE AT 11p13 The development of Wilms' tumor may be associated with congenital malformation syndromes, whose characterization has proved critical to the definition of the different genetic loci contributing to Wilms' tumorigenesis. In 1964, Miller and associates described an association between the incidence of Wilms' tumor and aniridia, a malformation of the iris. The incidence of aniridia is 1 in 70 among children with Wilms' tumor, an approximately 1000-fold increase over that in the general population. Conversely, one-third of children with aniridia eventually develop Wilms' tumor. In 1978, Riccardi and coworkers discovered that children affected with the rare Wilms' tumor, aniridia, genito-
Figure 71-1 Genetic mechanisms underlying predisposition to Wilms' tumor. As predicted by the Knudson model, sporadic tumors are initiated by two rare genetic events, leading to the inactivation of both alleles of a tumor suppressor gene in a renal precursor cell. In WAGR Syndrome, genetic predisposition results from the presence of an interstitial deletion at chromosome 11p13, resulting in the loss of one *WT-1* allele in the germline. Only one subsequent genetic event in somatic cells is required for complete inactivation of *WT-1*. In Beckwith-Wiedemann Syndrome, predisposition to Wilms' tumor and other embryonic cancers is derived from the presence of an additional copy of the paternally derived chromosome 11p15 locus. This may result from partial trisomy at 11p15 or from inheritance of two chromosomes 11 from the father and none from the mother (uniparental isodisomy). These unusual genetic events presumably result in overexpression of an imprinted gene, expressed only from the paternally derived allele. The additional events leading to tumorigenesis have not been well-defined.

urinary malformations, and mental retardation (WAGR) syndrome had a constitutional deletion in one copy of chromosome 11, at band p13 (Fig. 71-1). This finding, supported by the presence of allelic losses in sporadic Wilms' tumor specimens, led to the identification of the first genetic locus involved in etiology of Wilms' tumor.

The *WT-1* gene, mapping to the smallest region of overlap between naturally-occuring deletions at chromosome 11p13, was isolated by two groups in 1990. The presence of point mutations within the gene, both in sporadic Wilms' tumor specimens and in the germline of children with genetic predisposition, confirmed its

identity as the Wilms' tumor suppressor gene at the 11p13 chromosomal locus. *WT-1* encodes a transcription factor with a critical role in kidney development *(see below)*. Genito-urinary defects that are observed in children with WAGR syndrome have therefore been attributed to the reduced expression of *WT-1* during development, resulting from the loss of one germline WT1 allele (Table 71-1). Another 11p13 gene contributing to the WAGR phenotype has also been identified: the *Pax 6* gene is contiguous with *WT-1*, and constitutional loss of one germline allele results in aniridia. *Pax 6* has recently been shown to be the master gene responsible for eye development in *Drosophila*. The genetic cause of the other major defect in WAGR syndrome, mental retardation, has not been explained.

The *WT-1* gene is encoded by 10 exons, spanning 50 kb of genomic DNA. WT-1 protein migrates with a size of ~55 kDa on SDS-PAGE and contains two apparent functional domains: the carboxy-terminus (exons 7–10) contains four zinc fingers of the cysteine-histidine type, mediating specific DNA binding, while the amino-terminus contains a glutamine and proline-rich domain involved in the regulation of transcription (so-called transactivation) (Fig. 71-2). *WT-1* therefore encodes a transcription factor, predicted to regulate the expression of other genes that are important for kidney and urogenital development. WT-1 protein exists as four isoforms resulting from the presence or absence of two alternative splices in the mRNA transcript. Alternative splice I results from the insertion of 17 amino acids (exon 5) between the transactivation and DNA binding domains, and its exact function has not been determined. Alternative splice II results from the use of an alternative splice donor site in exon 9, leading to the insertion of three amino acids (lysine, threonine, serine or "KTS") between zinc fingers 3 and 4. Presence of this KTS insertion greatly reduces the DNA binding affinity of *WT-1* and has recently been shown to alter its subnuclear localization to structures that may be associated with the mRNA splicing machinery. The four isoforms are present in constant proportion in all WT-1 expressing tissues and, while WT-1 has recently been shown to dimerize in vivo, the functional consequences of the interaction between these isoforms remains unknown.

WT-1 MEDIATED TRANSCRIPTIONAL REGULATION AND GROWTH SUPPRESSION The mechanism of action of *WT-1* is not well-understood. WT-1 zinc fingers 2–4 have extensive amino acid homology to the three zinc fingers of the early growth response gene *EGR1* (also known as *NGF1-A*, *Krox 24*, and *Zif 268*), a gene induced by mitogenic stimuli and implicated in signaling pathways involved in cell proliferation. In DNA binding assays, the four zinc fingers of WT-1 bind to the GC-rich consensus sequence (5'-GCGGGGGCG-3') recognized by EGR1, although with much reduced affinity. However, other potential WT-1 DNA-binding sites have recently been proposed, including a higher affinity GC-rich site (5'-GAGTGCGTGG GAGTAGAA-3') identified from genomic DNA fragments and a TC-repeat sequence (5'-TCCTCCTCC-3') present in WT-1 responsive promoters. Definition of the optimal WT-1 DNA target site awaits a better characterization of promoter sequences that are physiologically regulated by WT-1.

Binding of WT-1 to target promoter sequences generally results in repression of transcription. WT-1 has thus been defined as a transcriptional repressor, although it is also capable of activating transcription, depending on the nature of the target promoter sequence, the presence of potential cofactors such as p53 *(see*

Table 71-1
Genetic and Phenotypic Characteristics of Congenital Syndromes Associated
with Wilms' Tumor and Adult Renal-Cell Carcinoma

Locus	Gene	Syndrome	Tumor	Phenotype	Mechanism
Embryonal renal cancers					
11p13	WT1	WAGR	Wilms'	GU anomolies	Reduced gene dosage
11p13	WT1	Denys-Drash	Wilms' gonadoblastoma	Mesangial sclerosis pseudohermaphroditism	Gain of function (dominant negative)
11p15	?	Beckwith-Wiedemann	Wilms' hepatoblastoma adrenocortical ca	Organomegaly	Increased gene dosage
?	?	Familial cancer	Wilms'	—	—
Adult renal cancers					
3p13-14	?	Familial cancer	Renal cell ca	—	—

7q31.1-34	Met	Familial cancer	Renal cell ca	Papillary	Tyrosine kinase activation
Figure 71-2 Functional domains of the *WT-1* tumor suppressor gene. WT-1 encodes a transcription factor divided into two functional domains. The carboxy-terminus comprises 4 zinc finger domains that mediate binding to specific DNA sequences, while the amino-terminus contains a transactivation domain that represses transcription from target promoters. The presence or absence of two alternative splices in the *WT-1* transcript results in four different isoforms with potentially distinct functions.

below), and mutations within *WT-1* itself. In transfection assays, *WT-1* has been shown to repress transcription from a large number of promoters containing a GC-rich sequence, including those of EGR1, insulin-like growth factor 2 (IGF-2), platelet-derived growth factor α chain (PDGF-α), Pax 2, colony stimulating factor 1, insulin-like growth factor 1 receptor (IGF1-R), transforming growth factor-β (TGF-β), epidermal growth factor receptor (EGFR), and WT-1 itself, among others. This has led to the model that *WT-1* may be a negative regulator of growth-inducing genes. However, regulation of promoter constructs by *WT-1* has proved to be a poor predictor of its effect on endogenous genes. The development of cell lines expressing *WT-1* under the control of a tightly regulated inducible promoter has shown that most of these potential *WT-1* target genes are unaffected by induction of *WT-1*. However, expression of one of these genes, EGFR, is repressed following induction of *WT-1* expression in vivo. WT-1-mediated apoptosis is preceded by induction of the cyclin-dependent kinase inhibitor, p21. The increase in p21 occurs in a p53-independent manner.

One of the critical properties of tumor suppressor genes is their ability to arrest the growth of malignant cells or repress their tumorigenic phenotype. The retinoblastoma susceptibility gene, *RB*,

mediates cell-cycle arrest in G1, while p53 can either induce a G1 block or trigger programmed cell death (apoptosis), depending on the cellular context. Reintroduction of wild-type *WT-1* into a Wilms' tumor cell line, expressing an aberrant endogenous *WT-1* transcript, results in suppression of colony formation in vitro. The few cells that emerge, expressing low levels of wild-type *WT-1*, demonstrate reduced clonogenicity in soft agar and delayed tumorigenicity in nude mice. In a model osteosarcoma cell line expressing an inducible *WT-1* gene, WT-1 isoforms lacking the KTS alternative splice trigger programmed cell death. The onset of apoptosis in these cells follows the suppression of EGFR synthesis and is prevented by constitutive expression of this growth factor receptor. *WT-1*–induced cell death in these cells may therefore result from the withdrawal of growth-factor-mediated signals required for cell survival. Although these observations have interesting implications for a role of *WT-1* in growth factor/cell death pathways in vivo, the exact function of *WT-1* during kidney development and tumorigenesis remain uncertain.

ROLE OF WT-1 IN KIDNEY AND UROGENITAL DEVELOPMENT The developmental role of *WT-1* has been closely linked with its expression pattern. By RNA *in situ* hybridization, *WT-1* transcript is detectable in cells of the developing kidney (condensed mesenchyme, renal vesicle, and glomerular epithelium), Sertoli cells of the testis, granulosa cells of the ovary, and mesothelial cells comprising the pericardial, pleural, and peritoneal surfaces. WT1 expression is also seen in stromal cells of the spleen and in the capsule of the thymus. Although normal hematopoietic cells expressing WT-1 have not been identified, high levels of mRNA expression have been found in a subset of lymphoid and myeloid leukemias. In contrast to other *WT-1* expressing tissues, presence of the *WT-1* transcript in the developing kidney is transient and associated with specific developmental structures. In the mouse, peak *WT-1* expression occurs around the time of birth, with minimal levels detected in the adult kidney. Histological analysis shows low levels of expression in the primitive blastemal stem cells, and high levels as these cells differentiate into the podocytes of glomeruli.

The critical role of *WT-1* in genito-urinary development is best demonstrated by the generation of WT1-null mice. These mice, lacking both *WT-1* alleles, fail to develop either kidneys or gonads; their vestigial renal buds lack blastemal cells and fail to differen-

tiate following inductive stimuli. Homozygous deletion of *WT-1* in the mouse is lethal during embryonic development, possibly resulting from cardiac and diaphragmatic malformations that might be caused by the absence of *WT-1* expression in the mesothelial cells lining these organs. However, in contrast to the human WAGR syndrome, mice lacking one *WT-1* allele have no evidence of genito-urinary malformation and do not develop renal tumors.

The role of *WT-1* in genito-urinary development has also been demonstrated in humans, most prominently in Denys-Drash Syndrome (DDS). While children who have a deletion of one *WT-1* germline allele (e.g., WAGR syndrome) may have genito-urinary defects of varying severity, those with DDS display renal mesangial sclerosis progressing to renal failure and intersex disorders characterized by pseudohermaphroditism and streak gonads (Table 71-1). Virtually all patients with DDS harbor a point mutation in one *WT-1* germline allele, most commonly affecting zinc finger 3 or 4. The severe developmental defects observed in children expressing a WT-1 protein with a disrupted DNA binding domain, in contrast to those with a deleted allele, suggest that specific *WT-1* mutations may encode a dysfunctional protein. Although functionally inactive, such mutants would act in a dominant or "gain of function" manner, presumably disrupting the properties of the wild-type protein. Potential mechanisms for these so-called "dominant negative" *WT-1* mutations are discussed below.

INACTIVATION OF WT-1 IN RENAL AND MESOTHE-LIAL TUMORS Gross deletions affecting *WT-1* are rare, but approximately 10% of sporadic Wilms' tumors contain point mutations within the coding region, including missense, nonsense, and frameshift mutations. Missense mutations or small deletions within the zinc finger domain have been shown to disrupt DNA binding activity, whereas mutations within the amino terminus result in altered transactivational properties. Unlike other tumor suppressor genes in which both alleles must be inactivated to initiate tumor formation, a significant fraction of *WT-1* mutations observed in Wilms' tumors are heterozygous. This observation suggests that some mutations encode dysfunctional or dominant negative WT-1 proteins *(see above)*, capable of disrupting *WT-1* function despite the expression of the residual wild-type allele. One such mutant, encoding a disrupted zinc finger domain with reduced DNA binding affinity, demonstrates oncogenic effects on primary kidney cultures, consistent with a dominant transforming effect. A potential mechanism for dominant-negative *WT-1* mutations has recently been proposed, based on the observation that the amino-terminus mediates dimerization of WT-1 as well as its localization to distinct subnuclear structures. Co-expression of wild-type *WT-1* and a mutant with a disrupted DNA-binding domain results in the relocation of the wild-type protein within subnuclear structures. Dominant-negative *WT-1* mutants may therefore exert their effect by sequestering and functionally inactivating wild-type *WT-1*.

In addition to mutations disrupting *WT-1* function, other mechanisms have been reported to alter the properties of this tumor suppressor gene. RNA editing, the insertion of a nucleotide in the mRNA transcript that differs from that present within the gene itself, has been observed in rodent *WT-1*, resulting in subtle alterations in the functional properties of the encoded protein. Aberrant mRNA splicing appears to be a relatively frequent occurrence in Wilms' tumor specimens, with approximately 10% of tumors expressing a transcript with an in-frame deletion of *WT-1* exon 2.

This truncated protein, which is not detected in normal *WT-1* expressing tissues, appears to result from altered splicing, rather than from a mutation within the *WT-1* gene itself. The encoded protein lacks a critical portion of the *WT-1* transactivational domain, resulting in potent activation, rather than repression, of transcription from target promoters.

The potential consequences of transcriptional activation by *WT-1* variants, in contrast to transcriptional repression by wild-type *WT-1*, are best demonstrated in desmoplastic small round cell tumor (DSRT), a rare mesothelial cell-derived pediatric malignancy. DSRT exhibits a characteristic chromosomal abnormality, consisting of a translocation between chromosomes 11p13 and 22q12. Molecular characterization of this tumor has revealed a chimeric fusion of one *WT-1* allele with the Ewing's sarcoma gene *EWS*. The translocation, analogous to that between *EWS* and other transcription factors in Ewings sarcoma and related tumors, results in the expression of a chimeric protein, containing the potent transactivation domain of EWS and zinc fingers 2–4 of WT-1. The initial genetic lesion underlying DSRT may therefore result in transcriptional activation of a subset of *WT-1* target genes.

NEPHROGENIC RESTS AND THE TIMING OF WT-1 INACTIVATION Nephrogenic rests, also termed "nephroblastomatosis" or "nodular renal blastema," represent persistent foci of primitive but nonneoplastic blastemal cells, within the otherwise normal renal tissue. Nephrogenic rests are usually microscopic, although they may measure up to several centimeters, and are not normally seen in the kidneys of children over 1 year of age. However, 30–40% of kidneys from children with unilateral Wilms' tumor, and virtually all kidneys from children with genetic predisposition, contain one or more nephrogenic rests. Untreated, nephrogenic rests may either regress spontaneously, persist, or evolve into Wilms' tumor. A potential link between the distinct histological subtypes of nephrogenic rests and the different Wilms' tumor genetic loci has been suggested: "intralobar rests," arising within the kidney lobule, are typically found in patients with aniridia and genetic abnormalities at 11p13, whereas "perilobar rests," present at the periphery of the kidney lobule, are associated with Beckwith-Wiedemann syndrome (BWS), a Wilms' tumor-associated syndrome linked to chromosome 11p15 *(see below)*. However, this correlation between histologic features and genetic loci remains to be confirmed by molecular studies.

Mutational analysis of nephrogenic rests arising within the normal kidney of sporadic Wilms' tumor cases has demonstrated that these lesions are clonally related to the associated Wilms' tumor. In two cases in which a sporadic Wilms' tumor contained a point mutation within *WT-1*, nephrogenic rests present within the uninvolved portion of the affected kidney demonstrated the identical *WT-1* mutation. Thus, nephrogenic rests may arise from renal precursor cells harboring a *WT-1* mutation, in effect constituting genetic precursors of Wilms' tumors. Inactivation of *WT-1* is therefore an early genetic event, potentially leading to the immortalization of blastemal cells and increasing the target cell population susceptible to additional genetic hits, leading to the development of Wilms' tumor.

INTERACTION BETWEEN WT-1 AND p53 In contrast to most human malignancies, p53 mutations are extremely rare in Wilms' tumor, observed in <1% of cases. Mutations in p53 appear to be specifically associated with the anaplastic variant of Wilms' tumor, a rare subtype characterized by gross chromosomal instability, resistance to chemotherapeutic agents, and having a poor

clinical prognosis. The majority of p53 mutations observed in human tumors lead to amino acid substitutions that disrupt protein function while enhancing its stability, resulting in elevated levels of expression. However, most Wilms' tumors express high levels of p53 protein, despite the absence of p53 mutations. Recent observations have shown that WT-1 protein is capable of binding and stabilizing p53. In a series of eight primary Wilms' tumors, in which both *WT-1* and p53 were wild-type, the level of p53 protein was well correlated with that of WT-1. In cultured cells, binding of WT-1 to p53 alters the properties of p53, specifically blocking its ability to induce apoptosis. Thus, *WT-1* may have properties in addition to those of a classical tumor suppressor gene. In the 90% of sporadic Wilms' tumors that express low levels of wild-type *WT-1*, it may effectively disrupt p53 function, obviating the need to inactivate p53 by mutational mechanisms.

WT-1 also interacts with par-4 (prostate apoptosis response). Par-4 appears to augment WT-1-mediated repression and blocks activation by WT-1.

THE SECOND WILMS' TUMOR LOCUS: CHROMOSOME 11p15 A second genetic locus on chromosome 11, at band 11p15, has been implicated in the development of Wilms' tumor. Like 11p13, this locus has been identified both by germline abnormalities in children with genetic predisposition and by somatic allelic losses in Wilms' tumor specimens. BWS, an overgrowth syndrome characterized by visceromegaly, hemihypertrophy, macroglossia, umbilical hernia, and hypoglycemia, is notable for the increased incidence of embryonal malignancies, including adrenal carcinoma, hepatoblastoma, and Wilms' tumor (Table 71-1). In BWS cases that show familial transmission, linkage has been established to chromosome 11p15. Further, in children presenting with *de novo* BWS, striking karyotype abnormalities have been observed affecting 11p15. In contrast to the chromosomal deletions seen in WAGR syndrome, BWS has been associated with chromosomal duplication events. Partial trisomy at 11p15 has been observed, with the duplicated 11p15 locus invariably derived from the paternally inherited allele (Fig. 71-1). In BWS children without gross karyotype abnormalities at chromosome 11p15, molecular studies have revealed uniparental isodisomy, i.e., inheritance of two paternally derived chromosomes 11 and absence of any maternally derived chromosome 11.

The chromosome duplication events and the unequal parental inheritance are consistent with genomic imprinting, the differential expression of genes between maternally and paternally inherited chromosomes. Thus, an imprinted gene, whose maternal allele is silent and whose paternal allele is expressed, would be overexpressed in a child carrying two copies of the paternally inherited chromosome 11p15. Such a dosage effect would be consistent with the overgrowth features that are characteristic of BWS. One candidate gene for BWS is insulin-like growth factor 2 (*IGF-2*), a growth-inducing gene localized to 11p15 known to undergo genomic imprinting, with expression restricted to the paternal allele. Although no direct evidence has proven that overexpression of *IGF-2* is responsible for BWS, loss or "relaxation" of *IGF-2* imprinting, resulting in expression of *IGF-2* by both maternal and paternal alleles, has been observed in the germline of children with this syndrome. In addition, Wilms' tumors frequently show loss of imprinting and increased *IGF-2* expression, suggesting that this gene may contribute to tumor growth, possibly through direct activation of this growth factor receptor pathway. However, an alternative possibility has been proposed, based on the observa-

tion that *IGF-2* expression is associated with reduced expression of a contiguous putative tumor suppressor gene *H19*. *H19* is imprinted in the opposite direction to *IGF-2*, with expression restricted to the maternally derived allele. Since *H19* encodes an untranslated RNA species capable of suppressing tumorigenicity in cultured cell lines, loss of *H19* expression, with or without overexpression of *IGF-2*, may contribute to Wilms' tumorigenesis.

IGF-2 and *H19* may contribute to the etiology of BWS and potentially to the growth properties of Wilms' tumors. However, molecular mapping studies have defined a genetic locus that is distinct from these genes, and that is the specific target of allelic losses in Wilms' tumor specimens. This locus, WT2, has properties that are more characteristic of a classical tumor suppressor gene and may prove to be inactivated by point mutations and deletions, rather than by alterations in genomic imprinting. A number of other tumors, including breast cancer, cervical cancer, and leukemias, demonstrate loss of heterozygosity at 11p15, suggesting that this new tumor suppressor gene may prove to be involved in a number of different malignancies.

FAMILIAL WILMS' TUMOR AND OTHER GENETIC LOCI Although familial transmission of susceptibility to Wilms' tumor is rare, three large pedigrees have been reported, with cancer predisposition showing an autosomal dominant inheritance pattern. Linkage studies in all three families have excluded either of the chromosome 11 loci in transmission of disease susceptibility. The chromosomal location of this familial Wilms' tumor gene is currently unknown. In addition to the major genetic loci capable of initiating Wilms' tumorigenesis, other loci have been implicated in tumor progression. The contribution of the p53 gene to the anaplastic phenotype has been discussed above. In addition, 10–20% of Wilms' tumors show loss of heterozygosity at chromosomes 16q or 1p, which may be associated with a somewhat worse clinical prognosis. Finally, even the primary Wilms' tumor genetic loci on chromosome 11 may act in concert to promote tumor growth, as demonstrated by a number of tumors showing both mutations within *WT-1* and allelic losses affecting the 11p15 locus. Thus, the genetic etiology of Wilms' tumor is complex, involving potential contributions from several genes, which may play different roles during normal kidney development and tumor formation.

RENAL-CELL CARCINOMA

THE 3p13-14 RCC LOCUS Renal-cell carcinoma (RCC) is the most common malignancy of the adult kidney. In contrast to Wilms' tumor, the malignant cells are thought to originate from the tubular epithelium of the kidney, rather than from glomerular precursors, and RCC does not share the embryonic histological features of nephroblastoma. Whereas the great majority of RCCs are sporadic, they can occur in the setting of familial predisposition, demonstrating an autosomal dominant inheritance pattern. Like Wilms' tumor, RCCs arising in genetically predisposed individuals develop at an earlier age and show bilateral or multifocal involvement, although genetic susceptibility to RCC does not appear to be associated with defects in genito-urinary development. The chromosome 3p13-14 locus has been implicated in the formation of RCC, by the presence of allelic losses in tumor specimens, as well as by the transmission of translocated chromosomes involving 3p13-14 in rare familial cases. Efforts to isolate the 3p13-14 RCC gene by positional cloning techniques have been complicated by genetic events involving the von Hippel Lindau gene (*VHL*), located at a neighboring locus, 3p25-26.

VON HIPPEL LINDAU SYNDROME Hereditary RCC may occur in the setting of von Hippel Lindau (VHL) syndrome. VHL carriers develop multiple renal cysts that have the potential for malignant degeneration, tumors of the adrenal glands and pancreas, and hemangiomas of the retina and central nervous system. Cytogenetic and molecular analyses of kidney tumors from patients with VHL have demonstrated allelic losses affecting chromosome 3p25-26, culminating in the recent identification of the *VHL* gene by positional cloning techniques. Unlike WT-1, the absence of clear amino acid homology between VHL and other known proteins has made it difficult to predict the function of this potential tumor suppressor gene. *VHL* encodes a 30-kDa cytoplasmic protein, whose amino terminus contains eight copies of an acidic tandemly repeated pentamer (Gly-X-Glu-Glu-X) of uncertain significance. VHL protein has recently been found to associate with transcriptional elongation factors known as elongins, suggesting that this tumor suppressor gene may be directly involved in mRNA processing. *VHL* mRNA is expressed in a broad range of tissues, including adult brain, kidney, adrenal gland, prostate, and lung. Alternative splicing has also been observed in the *VHL* transcript, reflecting presence or absence of exon 2. While the splicing variant encoding exon 2 is the more prevalent in most normal tissues, an inverted ratio has been observed in some RCCs, suggesting a functional significance.

MUTATIONS IN THE VHL TUMOR SUPPRESSOR GENE Of patients with VHL syndrome, 39–75% have germline mutations in one *VHL* allele, with their renal cell cancers showing loss of the remaining wild-type allele. However, *VHL* mutations are not limited to RCC arising within this familial syndrome: 30–60% of sporadic nonpapillary renal-cell carcinomas contain mutations in the *VHL* gene and 80–90% show loss of heterozygosity at the VHL locus. Thus, *VHL* appears to play a major role in the development of adult renal cancers. Mutations are evenly spaced over the three exons of the gene and include insertions, deletions, splice-site abnormalities (primarily affecting exon 2), and missense and nonsense mutations. While deletions affecting the short arm of chromosome 3 have been reported in many different cancers, including sporadic pheochromocytoma, small-cell lung cancer, mesothelioma, and cancers of the breast, ovaries, colon, thyroid, prostate, and bladder, no mutations in the *VHL* gene have been identified in these tumors. Chromosome 3p may therefore contain a number of important tumor suppressor genes, with *VHL* playing a specific role in kidney tumorigenesis. The relationship between *VHL* and the familial *RCC* gene at 3p14-15 remains unclear. Like the two Wilms' tumor genes on the short arm of chromosome 11, the presence of two adult kidney cancer loci at chromosome 3p has complicated molecular and cytogenetic analyses. Sporadic RCCs may show loss of the entire chromosome region from 3p13 to the telomere, resulting in deletion of both of these loci. Rare patients with familial RCC have been reported to have both a germline translocation affecting the RCC locus at chromosome 3p13-14, as well as a mutation in the *VHL* gene in their renal cancers. These observations suggest potential functional interactions between the two chromosome 3p tumor suppressor genes involved in renal cell carcinoma.

Hereditary papillary renal carcinoma (HPRC) is histologically and genetically distinct from VHL. The HPRC gene has been localized to 7q31.1-34. Mutations have been identified in the tyrosine kinase domain of the *met* gene in HPRC families. These mutations may cause constitutive activation of the MET protein.

CONCLUSIONS

The application of molecular genetics to the study of pediatric and adult renal tumors has led to the definition of genetic loci that play critical roles in the initiation of tumorigenesis. Positional cloning strategies have led to the identification of specific tumor suppressor genes, *WT-1* and *VHL*, and may yield additional genes in the near future. Identification of these disease genes is only the first step; biochemical and functional characterization of the gene products will provide a better understanding of the abnormalities in growth and developmental pathways that result in tumor formation. *WT-1* has proved to be a paradigm for studying the critical steps in early kidney development, involving transcriptional regulation of growth inducing genes, induction of programmed cell death, and a potential role in the survival of renal blastema and the differentiation of glomeruli. The isolation of other Wilms' tumor genes that may contribute to nephroblast development and studies of *VHL* and the genetic loci involved in adult renal cancers will undoubtedly enhance our understanding of the genetic lesions that lead to cancer of the kidney.

72 Introduction to Selected Epidermal Gene Mutations

ANGELA M. CHRISTIANO, DANIEL B. DUBIN, AND THOMAS S. KUPPER

INTRODUCTION

Genodermatoses, or genetic disorders that primarily involve the skin, have been the subject of many monographs and reviews, and an exhaustive review of these is well beyond the scope of this section. The accessibility of skin, and the ease with which it can be observed, has allowed for the identification of well over a hundred diseases that qualify as genodermatoses, and the mode inheritance of many has been well-documented. Many of these diseases have a clear pattern of inheritance with complete penetrance (e.g., epidermolysis bullosa dystrophica), while others can arise spontaneously and are incompletely penetrant (e.g., tuberous sclerosis). More recently, an explosion of novel molecular genetic approaches and techniques have led to a series of important breakthroughs in the identification of specific gene defects underlying certain of these diseases (Table 72-1). The rate at which this is occurring ensures that any treatise that attempts to be exhaustive and current is doomed to failure. Rather than being encyclopedic and all-inclusive, we have tried to focus on several selected genodermatoses for which there has been significant experimental work performed around identifying the genetic defect. Even this is not inclusive; for example, we have not discussed in details the very elegant work that has been done by Deitz and colleagues in the identification of fibrillin as the defective gene in Marfan's syndrome, and by

Hohl's group on the identification of transglutaminase as the defective enzyme in lamellar ichthyosis. The reader is referred to the primary references for more information, and several representative texts and reviews are listed below.

Most of the genodermatoses for which the gene and its protein product have been identified are listed in Table 72-2, and several are discussed at some length in the ensuing chapters. When possible, diseases in which (1) the gene has been identified, and (2) a plausible mechanism has been advanced by which the defective genotype results in the observed phenotype, have been selected for expanded discussion.

Familial Melanoma/multiple mole syndrome (*see* Chapter 85)	Melanoma, pancreatic carcinoma?

73 Epidermolysis Bullosa Simplex

Yiu-mo Chan and Elaine Fuchs

BACKGROUND

The term "epidermolysis bullosa" (EB) was first introduced by Koebner in the late 19th century to describe a nonscarring, blistering skin disease. The name was subsequently adopted for a group of heterogenous congenital disorders that are all characterized by trauma-induced blistering of skin. The blisters may be formed intraepidermally, junctionally, or intradermally. When the blisters are formed within the basal epidermal layer of the skin, it is given the name "simplex." Today, epidermolysis bullosa simplex (EBS) constitutes a group of autosomal-dominant genetic skin diseases affecting 1 in 40,000 in the population. It is further divided into different subtypes according to the clinical severity. The penetrance in families with EBS is high, and in its most severe form, the disorder is apparent at birth.

We begin this chapter by describing the clinical and ultrastructural features of EBS and the common criteria for diagnosis. We then present the lines of evidence that led to the discovery that EBS is frequently, if not always, a result of a mutation in either of two keratin genes whose products form an extensive cytoskeletal array of 10-nm filaments in basal epidermal cells. After exploring the structural implications for the mutant keratins and their effects on keratin-filament assembly, we discuss the functional significance of the keratin network in the epidermis. Finally, we consider the impact on management and treatment of the disease.

CLINICAL FEATURES AND DIAGNOSIS

There are three major types of EBS: Dowling-Meara (D-M), Koebner (K), and Weber-Cockayne (W-C) (Table 73-1). D-M EBS is the most severe form in which blistering occurs over the entire body (Fig. 73-1). The nails may be lost, but usually regrow without dystrophy. K-EBS is intermediate in severity. Although blistering still remains generalized, it is considerably less severe and less painful. Like D-M EBS, the nails may shed and regrow without dystrophy. W-C EBS is the least severe form in which blistering is very mild and restricted mostly to the hands and feet. Unlike the other two generalized forms of EBS, symptoms in W-C EBS can be so mild that in some patients, it is not manifested until adult life, where it is detected as a result of unusually stressful exercise. Other, less-common subtypes of EBS, which are often associated with extra features such as mottled pigmentation or serous blistering and bruising, have also been reported. In all cases, blistering

in EBS arises from mild mechanical trauma. In a number of cases, high temperatures seem to exacerbate the symptoms. Since blister cleavage is within the epidermis, the patient generally heals without scarring. Although blistering in some EBS cases can be very severe, the disease is rarely a threat to life. The primary complication of the disease appears to be secondary infection because of localized loss of the skin-barrier function. Ultrastructural studies show that the physical stress-induced intraepidermal blistering is caused by cytolysis within the basal layer of epidermis. Except in the most severe cases of D-M EBS, the suprabasal layers typically appear normal. In addition, as revealed by both light and electron microscopy, the basal cells from the more severe cases of EBS show marked abnormalities in basal keratin filaments (Fig. 73-2). In the basal layer of D-M EBS skin, there are usually clumps of amorphous keratin or large aggregates of keratin filaments. In contrast, the perturbations in keratin-filament networks of W-C EBS can sometimes be very small, and indeed are often barely detectable. All other cell organelles seem to be normal and intact, although aberrations in the organization of mitochondria and/or irregularities in nuclear shape have been noted.

For a proper diagnosis of EBS, a skin biopsy is necessary. Ultrastructural analysis of the skin biopsy allows the correct determination of the cleavage site in the skin, thereby differentiating EBS from other types of EB. It also allows further distinction of other blistering skin disorders, such as epidermolytic hyperkeratosis (EH), which is similar to EBS in pathology, but which affects the suprabasal layers rather than the basal layer of the epidermis.

GENETIC BASIS OF EBS

For many years, the genetic basis of EBS remained elusive, although it had long been recognized as an autosomal-dominant Mendelian trait. Despite the ultrastructural data suggesting that keratin-filament disorganization preceded cytolysis, it was often postulated that EBS might be a disease of cytolytic enzymes or that it involved transcriptional or translational alterations in keratins. Our increased knowledge about the basal epidermal keratins, K5 and K14, led to the postulate that most cases of a human genetic disease involving K5 or K14 mutations would be autosomal dominant, since most of the keratin mutations behaved in a dominant-negative fashion when introduced into cultured basal epidermal cells or when assembled with its wild-type partner in vitro. Then, when Vassar et al. introduced a mutant K14 gene into the germline of transgenic mice and discovered that the mice developed phenotypic characteristics of D-M EBS, it became clear that EBS could be generated by a mutation in one of the two basal-keratin genes. This finding explained why cultured D-M EBS

Table 73-1
Characteristics of the Three Major Types of Epidermolysis Bullosa Simplex

	Dowling-Meara	*Koeber*	*Weber-Cockayne*
Inheritance	Autosomal-dominant	Autosomal-dominant	Autosomal-dominant
Blistering	Body	Body	Hands/feet
Basal cell cytolysis	+	+	+
Keratin filament disorganization	+	+	+/−
Keratin clumps in basal cells	+	−	−
Abnormalities in suprabasal cells	None	None	None

keratinocytes resembled those of normal keratinocytes transfected with a mutant K14 keratin gene.

Subsequent analyses of K5 and K14 genes of EBS patients led to the discovery of keratin mutations in all three major subtypes. Functional studies suggest that these mutations are responsible for the disorders. Additionally, whereas earlier linkage studies erroneously mapped the EBS disease to chromosome 1, more recent studies with higher lod scores map the disorder to either chromosome 12q11-q13 or 17q12-q21, the two locations where keratin K5 and K14 reside, respectively. Taken together, these lines of evidence demonstrate unequivocally that EBS can be caused by defects in the basal-specific keratin genes. Today, most EBS cases examined thus far have been found to carry point mutations in the coding region of either one of the two basal keratin genes. However, it is still possible that in some cases of EBS, the genetic defect may reside outside the K5 or K14 genes. This said, there is no convincing evidence at this time that demonstrates heterogeneity in the basic EBS disease. It has recently been shown that EBS with muscular dystrophy is a rare genetic disorder involving mutations in plectin, a keratin filament-associated protein.

Because of the relatively small size of the basal-keratin genes and their transcripts (1.8–2.1 kbp), screening for keratin mutations in EBS patients has still been conducted largely by DNA sequencing. This is particularly so when a skin biopsy is available, allowing keratinocyte culture and mRNA extraction. In one case, an antibody was used in diagnosis and analysis, and the generation of a battery of antibodies to critical regions of the keratin polypeptides may facilitate diagnoses in the future. In addition, with the introduction of methods such as conformation-sensitive gel electrophoresis (CSGE), which allow for rapid detection of single-base changes in DNA, screening for mutations in keratin genes may now become more straightforward. This method is extremely useful when a large number of patient samples are involved. It also eliminates the need to sequence the entire gene or transcript.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

The location of keratin mutations and their clinical relation is summarized in Fig. 73-3. A surprising finding emerging from the catalog of keratin mutations in different EBS subtypes is that mutations tend to be clustered, and sometimes the exact same residue is mutated in unrelated families with these diseases.

Figure 73-1 *(opposite)* Clinical pictures of EBS patients. **(A,B)** Patient with mild skin blistering on his hands and feet, typical of the mildest form of EBS, Weber-Cockayne. **(C)** Severe skin blistering of a patient who has the severe form of EBS, Dowling-Meara. (Courtesy of Amy S. Paller, Children's Hospital, Northwestern Medical School.) (*See* color insert following p. 684.)
Figure 73-2 Ultrastructure of epidermis from EBS patients showing abnormalities in keratin architecture. Punch biopsies from control and EBS skins of patient volunteers were fixed and processed for conventional or immunoelectron microscopy. Shown are representative examples of epidermal cells from the basal layer of: **(A)** control skin; **(B)** patient with Weber-Cockayne EBS; **(C,D)** patient with Dowling-Meara EBS. (D) Immunogold antikeratin 14 labeling of keratin clumps and filament aggregates, typical of D-M EBS. Abbreviations: Nu, nucleus; KF, keratin filaments; BL, basal lamina; KC, keratin clump. Arrowhead in B denotes intraepidermal split beneath the nucleus, a typical feature of W-C EBS. Asterisks in C and D denote cytolysis, typical of D-M EBS basal cells. (A) Bar = 1 μm. (B) Bar = 2 μm. (C) Bar = 0.7 μm. (D) Bar = 4 μm. (Courtesy of Qian-Chun Yu, The University of Chicago.)

Approximately 60% of all sequenced D-M EBS mutations are Arg to His/Cys substitutions at codon 125 of the K14 gene. In addition, there is a strong correlation between the location of mutation within the keratin polypeptide and disease severity of EBS. Thus, whereas many of the D-M EBS keratin mutations reside in the amino (1A) or carboxy (2B) ends of the central coiled-coil rod domain of the polypeptides, Koebner mutations tend to be more centrally located within the rod segment, and W-C mutations often reside either in a nonhelical linker (L12) segment within the rod, or in the head domain of K5. In order to appreciate the significance of these

findings, it is first necessary to review what is known about the overall structure of keratin filaments.

Keratins belong to the superfamily of 10-nm intermediate filaments (IFs), which, along with 6-nm actin microfilaments and 20-nm microtubules, constitute the basic features of the higher eukaryotic cytoskeleton. Keratins are encoded by multiple genes that are differentially expressed in nearly all epithelial tissues. They can be subdivided into two distinct groups, type I and type II, based on their protein sequence. Keratins assemble into obligatory heterodimers of the two subtypes. The mechanism for

K5 Mutation

No.	Subtype	Mutation	Domain
1.	M-P EBS	P23L	nonhelical head

Figure 73-3 Summary of mutations found in patients with EBS and correlation between the location of mutation within the keratin polypeptide and disease severity of EBS. Stick figure depicts secondary structure of human keratins. Large boxes encompass the central α-helical rod domain. Hatched boxes denote the highly conserved end domains of the rod. Lines denote the nonhelical linker segments. Solid bars denote the nonhelical head and tail domains, often conserved only for a single IF type. Note D-M EBS mutations are all clustered within the highly conserved ends, whereas K-EBS mutations are more internal. In contrast, W-C EBS mutations are mostly found in the nonhelical region of keratin. Patients with EBS and Mottled Pigmentation (EBS-MP) have a mutation near the N-terminus of K5. EBS-rec is a rare recessive case.

dimerization is based on the ability of keratins to form a coiled-coil. Based on secondary-structure predictions, each keratin has a conserved central-rod domain of about 310 amino acids, which is largely α-helical. The rod domain contains a repeating heptad motif $(a\text{-}b\text{-}c\text{-}d\text{-}e\text{-}f\text{-}g)_n$ in which the a and d residues are often hydrophobic. This heptad repeat presents a hydrophobic seal on the helical surface, enabling two IF molecules, aligned in parallel, to intertwine in a coiled-coil fashion.

The α-helical rod domain can be further subdivided into four smaller regions (helix 1A, 1B, 2A, 2B), which are separated by three short stretches (approximately 12–20 residues) of nonhelical linker regions (L1, L1–2, L2) that interrupt both the heptad repeat and the helix continuity. The rod is also flanked by nonhelical head (amino-end) and tail (carboxyl-end) domains that vary in size and

amino acid composition. The structure of these head and tail domains still remains unknown, although these domains are likely to protrude along the filament surface. Keratins can assemble into 10-nm filaments in vitro without auxiliary factors, indicating that this information is contained within the primary sequence of the IF polypeptide. Chemical crosslinking studies have suggested that, in the filament, linear arrays of parallel keratin heterodimers are linked in a head-to-tail fashion, with a slight overlap in their rod ends. These studies also indicate that the chains of keratin dimers are arranged antiparallely and half-staggered relative to each other. Scanning-transmission electron microscopy studies have indicated that the width of a keratin IF can accommodate 32 keratin polypeptides, or 16 linear arrays. Structural studies on other IFs have provided similar findings. So far, most of the known EBS mutations

have been found in regions that by deletion or point-mutation analyses, had already been shown to be important for IF structure and 10-nm filament assembly. Most of the known K14 and K5 point mutations of D-M EBS and K-EBS reside in the α-helical rod domains involved in coiled-coil heterodimerization (Fig. 73-3). Most of the D-M EBS mutations are clustered within the α-helical rod ends, which, in addition to being highly evolutionarily conserved, are also important for filament elongation in vivo and in vitro. Further verification that D-M EBS mutations tend to affect filament elongation stems from the engineering and testing of the precise D-M EBS mutations found in patients. This notion is particularly underscored by the recombinant DNA testing of a Y129D mutation found in a patient with an unusually severe case of D-M EBS. It is worth noting that chemically induced crosslinks have been detected between the beginning of helix 1A and the end of helix 2B, lending strong biochemical support to the notion that these segments play a critical role in the filament-elongation process. According to alignment models arising from cross-linking studies, a 1.6-nm (10–11 residue) overlap is predicted between the conserved rod ends of two head-to-tail oriented dimers. This is in good agreement with the fact that most of the D-M EBS mutations reside within the first or second heptads of helix 1A. Such associations may involve ionic associations, given that the beginning of helix 1A and the end of helix 2B are highly basic and acidic, respectively. This slight overlap between rod ends also explains why, in rotary shadowed IFs, the axial pitch is only 21–22 nm, rather than an exact half (23 nm) of the rod length. Thus, a knowledge of the severe EBS mutations has led to further experimentation and refinement of 10-nm filament structure. In contrast to the D-M EBS mutations, most of the K-EBS mutations are more internal, although still within the α-helical segments. It is interesting that Koebner mutations sometimes involve substitutions to proline residues, since it had already been shown by gene transfection and filament assembly studies that proline substitutions more centrally in the rod domain are less deleterious to those at the rod ends. On the other hand, most of the W-C EBS mutations are localized in the nonhelical domains, such as the nonhelical head of K5 and in particular, the L1-2 linker region of K5 and K14.

The majority of the L1-2 mutations reside within the carboxy end of the linker. Interestingly, in a model of linear arrays of dimers, where the helix 1A ends of one dimer have been postulated to overlap with the helix 2B ends of the next dimer in line, the carboxy ends of the L1-2 linker segments within one chain of dimers might be nearly opposite to the end-overlap segments within an adjacent row of dimers. If this model is correct, then this portion of the L1-2 linker is in a position to play a role in promoting appropriate staggered lateral associations between the linear arrays of alternating dimer chains. This segment could also participate in further stabilizing the end-overlap interaction (Fig. 73-4). The fact that mutations in the carboxyl end of the linker L1-2 region cause unraveling of filaments assembled in vitro is in agreement with this notion.

Taken together, it appears that keratin mutations giving rise to greater clinical severity cause perturbations in filament elongation, whereas mutations causing milder phenotypes often affect lateral associations within the filament (Fig. 73-5). Whereas the future may yet provide us with additional and important refinements to this trend, a knowledge of keratin structure has given us a better understanding of how the genetic defects give rise to the clinical manifestations of the disease.
Figure 73-4 Putative alignments of subunits in IF. Box denotes rod segments of the dimer; arrows indicate orientation of polypeptides, from base (N-terminus) to tip (C-terminus). Hatched boxes denote regions of putative rod overlap between the conserved rod ends of helix 1A and 2B. In the model, near, half-staggered antiparallel dimers occur at the level of protofilament, whereas unstaggered antiparallel alignments of dimers occur at the level of interprotofibril associations.

FUNCTION OF KERATIN NETWORK

It is now known that, in mice and humans, dominant-negative keratin mutations lead to cell fragility; it therefore seems likely that keratins function by imparting mechanical integrity to cells. This said, based on dominant-negative, i.e., autosomal-dominant, mutations, it is also possible that keratin aggregates alter the cellular physiology in a gain-of-function, rather than a loss-of-function manner. This notion was ruled out by: (1) two independent discoveries of EBS patients who have rare, homozygous premature stop codon mutations in their K14 alleles; and (2) a K14 null mutant mouse, generated by gene targeting. In all cases, the basal-epidermal-keratin network is largely missing, presumably since in the absence of its partner keratin, K5 is unstable and is rapidly turned over in the keratinocytes. These data lend strong support to the hypothesis that the major function of the basal keratins is to confer physical resilience to basal cells. Additionally, these knockouts revealed the presence of a residual network of keratin filaments that had a wispy appearance, which was quite distinct from the normal K14–K5 keratin network. Further exploration uncovered the presence of a second type I keratin, K15 in basal cells. Might some EBS cases have defects in K15? Although possible, it seems unlikely based on the fact that K15 has a different distribution than K14, being more highly expressed in internal stratified-squamous epithelia than in skin. K15 knockout studies may help to resolve this new issue.

Now that we know that the function of the keratin network is to provide mechanical stability to epidermal cells, it is understandable that keratin mutations that are more disruptive on IF structure have a greater effect on the mechanical stability of the cells. Thus, whereas D-M EBS mutations cause severe cytolysis in response to mild physical trauma, W-C EBS mutations result in mild cytolysis in response to more severe mechanical stress. Since blisters in EBS are trauma-induced, only areas of the body that are constantly
Figure 73-5 In vitro filament assembly studies of D-M EBS and W-C EBS mutants. Human K5 and K14 were expressed in bacteria, purified by FPLC, and assembled into filaments in vitro. **(A)** Filaments formed from normal K5 and K14. **(B)** Filaments formed from normal K5 and D-M EBS mutant (K14 R125C) giving rise to severely disrupted filaments. **(C)** Filament formed from normal K14 and W-C EBS mutant (K5 M327T) showing minor perturbation on IF structure, mostly unraveling of the filaments. Bar = 100 nm.

under mechanical stress, mostly the hands and feet, are subjected to blister formation in W-C EBS.

DIAGNOSIS, MANAGEMENT, AND TREATMENT

Diagnosis of EBS by ultrastructural analysis has long been a reliable method used by many physicians. In a few instances, this method has also been used for prenatal diagnosis. Understanding the genetic basis of EBS now allows for the possibility of prenatal genetic counseling for EBS, which can be done at an earlier stage in pregnancy and involves less risk to the fetus than skin biopsies.

Although the genetic basis of EBS has been elucidated, there is still no effective treatment available. The most useful treatment for EBS patients remains extensive counseling and prevention. Some patients find it useful to stay in a cool environment, as high temperature seems to worsen the condition. Since EBS has its onset at birth or early infancy and is largely trauma-induced, it is crucial for patients to learn to take good care of their health at an early age, such as avoiding activities that cause trauma. In addition, the tendency for blistering may diminish significantly over time to the point that blisters may be absent for months at a time, suggesting the disease may regress over time. Although the underlying reason for this age-dependent phenomenon remains unknown, it could be that the epidermis is naturally under less mechanical tension as it develops fully and as patients approach their adult size.

Another potential treatment is gene therapy, which is currently under extensive investigation in a number of recessive genetic disorders, such as cystic fibrosis and muscular dystrophy. Modern technology now makes it possible to introduce a missing healthy gene into the appropriate cells of the patient. The fact that EBS is inherited in an autosomal-dominant fashion makes gene therapy much more difficult, since expression of the mutant allele must be silenced. At present, the only obvious method to do this is to remove the patient's defective allele by homologous recombination technology. Whereas this should be feasible in basal keratinocytes cultured from a biopsy of the patient's skin, the frequency of homologous recombination is extremely low. Thus, even though mechanisms are already in place for grafting cultured keratinocytes back onto the patient's skin, engineering out the bad gene is likely to be very inefficient. This said, since the keratin

defect is expressed in the layer of epidermis where cells can move laterally, and because the healthy keratinocyte should have a tremendous selective advantage over a cytolysing one, it is possible that a small graft of healthy keratinocytes could expand to a larger region when grafted in an area of EBS skin. If technological advances continue to be made, as they certainly have in the past, there may be hope for this type of treatment in the future.

ADDITIONAL DISORDERS OF KERATIN AND OTHER INTERMEDIATE-FILAMENT DISEASES

EBS was the first disorder of keratin to be discovered. This knowledge set the paradigm for an intermediate-filament disease. A severe filament-disrupting defect in an IF gene would be predicted to cause mechanical stress-induced degeneration in the cells in which the gene is expressed, and, ultrastructurally, there should be aggregates or clumps of IFs in these cells. It is relevant that there are more than 60 different IF genes in the human genome. These genes are differentially expressed, and at least one IF gene is expressed in nearly all cells at nearly all stages of differentiation and development. Therefore, from the time when transgenic mouse studies predicted that EBS would be a keratin disorder, it seemed likely that there are additional disorders of IF genes.

Indeed, the field has moved rapidly since the discovery of EBS. Once the paradigm was set, other potential disorders of keratin were immediately and correctly predicted. Based on the known pattern of keratin expression, and the abnormalities in the keratin networks within cells that also undergo degeneration, it was quickly determined that the following diseases are disorders of particular keratins: (1) epidermolytic hyperkeratosis (EH), a disorder of keratins K1 and K10, that results in keratin clumping and generalized cytolysis in the suprabasal layers of the epidermis; (2) a milder form of EH caused by defects in K2, a keratin expressed in the upper living layers of the epidermis; (3) epidermolytic palmar plantar keratoderma (EPPK), arising from defects in K9, a keratin that is expressed only in the suprabasal layers of palmar and plantar skin; (4) pachyonychia congenita (PC), a hair and nail degenerative disorder involving mutations in K6, K16, and K17, known to be expressed in these cells; (5) white sponge nevus, an esophageal degenerative disorder of K4 and K13, known to be expressed in the esophagus; (6) Meesman's corneal dystrophy, a

corneal disorder of keratins K3 and K12; and (7) moni lethrix, a hair keratin disorder. Finally, it has recently been shown that some patients with amyotrophic lateral sclerosis (ALS), a degenerative disorder of the motor neurons, not only have abnormalities in neurofilament networks, but in addition, have point mutations in neurofilament genes. Although functional and chromosomal linkage analysis have yet to link ALS to neurofilament gene defects, it seems possible that some cases of this heterogeneous disease will have as their underlying basis neurofilament gene mutations. Another candidate disorder of IFs includes those forms of cardiomyopathies that are typified by not only cell degeneration, but also aberrations in their desmin IF networks. In the future, as more studies are conducted on degenerative cytoskeletal disorders and on the functions of intermediate filaments and their associated proteins, the list of human genetic diseases whose pathology is based on defects in IF networks will continue to grow.

74 Epidermolytic Hyperkeratosis

John J. DiGiovanna, Sherri J. Bale, and Peter M. Steinert

BACKGROUND

In 1902 Brocq described bullous ichthyotic erythroderma and distinguished the blistering type from the nonblistering type of congenital ichthyotic erythroderma. Whereas the original description included three unrelated patients whose clinical manifestations varied, this was probably the first description of epidermolytic hyperkeratosis (EHK). The best-recognized presentation of this rare disease is the severe, hystrix (porcupine-like) hyperkeratosis seen in adults with EHK. This appearance led to some patients' participation in traveling shows under the guise of "porcupine men." Today, the disease is named for histopathologic findings of keratinocyte lysis and associated hyperkeratosis. EHK is also known as bullous congenital ichthyosiform erythroderma, an earlier descriptive name signifying the blistering, neonatal presentation, scaling, and redness.

Information derived from a variety of approaches, including histology, ultrastructure, and molecular genetic studies in mice, and clinical, genetic, and molecular studies in humans have led to a greater understanding of EHK. The keratin intermediate-filament (KIF) network is responsible for the structural integrity of differentiated keratinocytes. Both clinical features (blistering and erosions) and morphologic studies (showing cell lysis and KIF clumps) suggested that EHK was caused by an aberration in the KIF network. This chapter will review the clinical, histologic, and ultrastructural features of EHK and the strategies used to identify the underlying defects.

CLINICAL FEATURES

The disease usually presents at birth with blistering, redness, and peeling. A generalized hyperkeratosis may develop over time either with or without erythroderma (Fig. 74-1). However, there is a striking clinical heterogeneity between EHK families. This includes differences in extent of body-surface involvement, quality of scale, presence of erythroderma, and palmar/plantar involvement. In some families, there is severe palmar-plantar involvement, whereas in others the palms and soles are normal (Fig. 74-1).

CLINICAL HETEROGENEITY IN EHK

DiGiovanna and Bale examined 52 patients with histologically confirmed EHK from 21 families and characterized specific clinical features and heterogeneity of this disorder. Patients were evaluated and graded for involvement of the palms and soles, scalp,

extensor vs flexor areas, erythema, infection, and blisters. Within this group of patients, six clinical subtypes were distinguished. Several features were useful for separating patients into clinical subtypes (Table 74-1). The most distinctive characteristic was presence vs absence of severe palmar/plantar hyperkeratosis. Twenty-nine patients in six families had this finding. These patients were grouped into the PS (palm/sole hyperkeratosis) types. The remaining 15 families (23 patients) were classified as NPS (no palm/sole hyperkeratosis) types. On the basis of additional clinical characteristics, three PS types and three NPS types were identified, distinguished by presence/absence of erythroderma, quality of scale, extent of involvement, presence of digital contractures, and gait abnormality (Table 74-1).

DIAGNOSIS

In contrast to most other ichthyoses, the histopathologic picture of EHK is distinctive. There is a tremendously thickened stratum corneum and vacuolar degeneration of the upper epidermis, leading to the histologic term "epidermolytic hyperkeratosis" (Fig. 74-2). Granular cells exhibit dense, enlarged, irregularly shaped masses that were thought to be keratohyalin granules. On electron microscopic examination, clumping of filaments is observed to begin in the first suprabasal layer. These aggregated filaments have been demonstrated to be clumps of KIF that contain the terminal differentiation specific keratins 1 and 10.

GENETIC BASIS OF DISEASE

EHK is an autosomal dominant ichthyosis that occurs in approximately 1:200,000–300,000 people. However, as many as one-half of the cases have no family history and represent new mutational events.

EHK IS A KERATIN DISEASE   Light and electron microscopic studies suggested that a defect in a terminal differentiation-specific epidermal-gene product might underlie EHK, causing KIF disorganization, increased numbers of keratohyalin granules, and vacuolated granular cells. Another clue came from the similarity observed in the filament clumping in EHK and epidermolysis bullosa simplex (EBS). The discovery that EBS is caused by a defect in either of the basal cell specific keratins keratin 5 or keratin 14, suggested that the keratins expressed suprabasally, keratins 1 or 10, were particularly good candidates for EHK. Compton et al. studied a large family with EHK primarily affecting the palms and soles, that segregated through three living generations. They tested for genetic linkage of the gene causing EHK to several candidate loci, including transglutaminase 1 (chromosome 14q),
Figure 74-1   Clinical heterogeneity in EHK. Left panels: Patients with PS type (PS2) showing fine, white scale (generalized erythroderma can not be appreciated in the black and white photograph) and extensive palmar hyperkeratosis, that limits full extension of digits. Right panels: patients with NPS type (NPS1) demonstrating hystrix-type scale on the dorsum of hands and complete sparing of palmar surface (*see* DiGiovanna et al.).

Table 74-1
Characteristics of Epidermolytic Hyperkeratosis[a]

	NPS-1	*NPS-2*	*NPS-3*	*PS-1*	*PS-2*	*PS-3*
Palm/sole hyperkeratosis	–	–	–	+	+	+
Palm/sole surface	Normal	Normal	Hyperlinear, minimal scale	Smooth	Smooth	Cerebriform
Digital contractures	–	–	–	–	+	–
Scale	Hystrix	Brown	Fine, white	Mild	White scale to peel	Tan
Distribution	Generalized	Generalized	Generalized	Localized	Generalized	Generalized
Erythroderma	–	–	+	–	+	–
Blistering	+	+	+	Localized	+	Neonatal

[a]NPS indicates types without severe palm/sole hyperkeratosis; PS, types with sever palm/sole hyperkeratosis; –, absent; +, present.

loricrin and profilaggrin (both chromosome 1q), and keratin 10 (chromosome 17q). Each of these candidates could be excluded as the disease-causing gene. The locus of type II neutral-basic keratins on chromosome 12q, which includes keratin 1, was also studied. Use of several anonymous DNA markers mapped near the type II keratin locus confirmed linkage to this region, and multilocus linkage analysis further supported this location. The data strongly implicated keratin 1 as the site of the molecular defect causing EHK in this family.

Fourteen affected individuals from three other EHK families were studied by Bonifas et al. and provided some evidence for linkage to markers on chromosome 12q, whereas linkage to markers on chromosome 17q, in the region including the keratin 10 gene, were strongly excluded.

Using a fundamentally different approach, Fuchs et al. arrived at a similar conclusion that mutations in the terminal differentiation specific keratin genes underlie the pathology of EHK. They inserted a severely truncated form of the keratin 10 gene in the germline of transgenic mice. This created a dominant negative effect in the epidermis of the animals that showed clumping of KIF and other phenotypic features reminiscent of EHK.

IDENTIFICATION OF KERATIN MUTATIONS   Chipev et al. sequenced the coding regions of both keratin 1 alleles of one patient in the family reported by Compton et al. A single basepair change in one allele was identified that causes a nonconservative amino acid substitution in codon 160 from leucine to proline in the H1 subdomain of the keratin 1 gene. One keratin allele of every affected member in this family had the proline substitution, whereas all unaffected members had two unsubstituted (normal) alleles. To confirm that the proline substitution was not merely a sequence polymorphism that, by chance, was segregating with EHK in this family, a further 100 alleles (from 50 normal control individuals of similar ethnic genetic background) were tested. None were found to have the mutant allele.
Figure 74-2 Histopathology in EHK. Tissue fixed in formalin, embedded in paraffin, and stained with hematoxylin and eosin shows epidermolysis and vacuolization of cells in the suprabasal layers of the epidermis. Extensive orthokeratotic hyperkeratosis is seen.
Figure 74-3 Known mutations in epidermolytic hyperkeratosis. In the center is a drawing of an idealized model of a keratin chain, displaying the four rod-domain segments, flanked by end-domain segments on either side. (Only the keratin 1 chain possesses well-defined H1 and H2 subdomains.) The locations of known amino acid substitutions, arising from point mutations, on the keratin 1 (upper) and keratin 10 (lower) chains are displayed with arrows. Notably, all substitutions occur within or immediately adjacent to the regions of the chains involved in molecular overlaps. We propose that these inappropriate substitutions destabilize the KIF so that they can no longer participate in their normal dynamic structural role in epidermal cells, ultimately leading to the pathogenesis of EHK.

Direct sequence analyses of both the keratin 1 and 10 genes has been used now to identify mutations in EHK.

From the existing catalog of EHK mutations, it is now clear that mutations in either the keratin 1 or 10 gene may cause EHK. In addition, most mutations are tightly clustered in exons 1 or 6 which encode the regions of the keratin chains forming the beginning and end of the rod domain. In particular, position 10 of the 1A rod domain segment of keratin 10 constitutes a "hot spot" for mutations (Fig. 74-3).

GENOTYPE/PHENOTYPE CORRELATION In an effort to correlate the clinical disease subtypes with specific mutations, DiGiovanna and Bale closely examined 11 families in which mutations had been found. All families with severe palmoplantar hyperkeratosis had abnormalities in keratin 1, whereas those without had abnormalities in keratin 10. Furthermore, the same mutation in keratin 10, R10H of the 1A rod domain segment, led to a wide range of NPS clinical presentations, including all three NPS subtypes.

MOLECULAR PATHOPHYSIOLOGY OF EHK

KIF STRUCTURE   What is the molecular basis of these findings? Studies have recently shown that KIF are built in an hierarchical manner from individual keratin chains. First, a type I chain and a type II chain, in this case keratin 10 and keratin 1 respectively, form a heterodimer molecule by entwining their α-helical rod-domain segments. Then, pairs of molecules align in three very precise ways to form antiparallel protofilaments. This alignment may be determined in part by the H1 and H2 subdomains, which immediately flank the rod-domain segments. In addition, molecules align in parallel in rows by overlapping approximately the last 10 amino acids of the 2B segment of one molecule with the first 10 amino adds of the 1A segment of the next molecule in the row. Finally, these protofilaments align to form a KIF in groups of 12–24 in ways that are not yet known. In addition, cell-biological experiments have shown that KIF are highly dynamic structures in living cells, continuously exchanging protofilamentous units along the entire length of the KIF from soluble pools. This process is believed to be under the control of phosphorylation (which favors disassembly) and dephosphorylation (which favors reassembly). The KIF form an elaborate network throughout the epidermal cell, and interconnect with those of neighboring cells through specialized desmosomal junctions. In this way, the KIF provide three-dimensional mechanical integrity to the entire epidermis. Most of the mutations that have been observed in EHK (Fig. 74-3), and more recently in other keratin diseases, reside in the regions of the molecular overlaps.

A FUNCTIONAL ASSAY FOR KERATIN MUTATIONS Based on these structural concepts, it was shown that synthetic peptides corresponding to the molecular overlap regions encompassing the H1, 1A, and 2B rod domain segments, can be used in vitro as specific probes of the structural integrity of KIF. When added to either preformed KIF or in KIF-assembly reactions, the peptides interfere with KIF structure, leading to disassembly or failure of assembly even in 1:1 molar ratios. Presumably the peptides compete with the same sequences on the intact chains, causing destabilization, leading to disassembly. On the other hand, synthetic peptides bearing amino acid substitutions seen in the disease cases had greatly reduced capacities to disassemble KIF in vitro. From this it is concluded that the structure of the mutant keratins is seriously compromised and no longer can participate efficiently in normal dynamic behavior in the epidermal cell.

A MODEL FOR EHK PATHOGENESIS   One of the hallmarks of EHK (and other keratin diseases) is the clumping of KIF. These clumps are likely caused by accumulations of the mutant keratin chain perhaps because the altered structure of the mutant keratin does not allow it to participate in the normal KIF. This accumulation of nonfunctional protein thus has secondary effects. First, there is thereby insufficient normal KIF to provide the necessary structural integrity of the cell. This may explain the cytolysis and vacuolization of cells and subsequent blistering of the suprabasal epidermal layers. In addition, the abnormal protein may interfere with the normal processes of terminal differentiation in the epidermis that involve the orderly expression and use of many other gene products, under the control of cytokines and various regulatory factors. This may explain the hyperkeratosis and erythema of some cases.

Further correlation of the clinical disease subtypes with the specific mutations should lead to a better understanding of the relationship between keratin structure and function in normal and diseased epidermis.

MANAGEMENT/TREATMENT

The management of EHK has acute and chronic aspects and varies with the clinical subtype. In the more severe, generalized types, there is usually erythema and blistering at birth. Because there is a high frequency of new mutations, the disease may not be expected and the diagnosis may not be immediately considered. Staphylococcal scalded-skin syndrome may be suspected and the infant treated with antibiotics. The newborn may require intensive care with fluid and electrolyte monitoring. Specialized skin care can minimize blistering and enhance healing of erosions. This could include lubrication to decrease friction and mechanical trauma, protective padding, specialized wound dressing, and so on. Both newborn and adult EHK skin is prone to infection, and rigorous monitoring and specific treatment of infection is essential. Over time, the skin usually thickens because of the development of hyperkeratosis. Areas of thick, hard, hyperkeratosis, which are not pliable are prone to mechanical trauma. Topical agents such as lubricants and keratolytics can reduce the thickened, rough areas and help to minimize blistering and erosion. Some patients have recurrent bouts of skin infections requiring topical or systemic antibiotics. In patients with extensive involvement, treatment with oral retinoid (isotretinoin, etretinate, acitretin) can be helpful in decreasing the hyperkeratosis and frequency of infections. However, since these drugs can enhance blistering, they must be administered carefully and used at the lowest effective doses.

SCREENING FOR MUTATIONS IN EPIDERMOLYTIC HYPERKERATOSIS   Genetic screening for keratin mutations in patients diagnosed with EHK is now feasible in the clinical setting. In families in which multiple family members are affected, linkage analysis can sometimes first be used to determine if the type I or type II keratin cluster is involved. Based on these results, the focus of screening would be directed to either the keratin 10 or 1 gene, respectively. Initially, it is most productive to use an allele-specific mutation detection assay to look for the most frequently reported mutations that occur in exons 1 or 6. If this screening is negative, complete genomic DNA sequencing of all exons should be accomplished.

Many cases of EHK are caused by new mutations, and therefore linkage analysis is not feasible in these families. In screening for mutations in these sporadic EHK patients, much work in the laboratory may be eliminated if a careful clinical assessment of the patient is first made. If the patient can be categorized as having PS type, it is likely that a mutation in the keratin 1 gene is responsible for the disorder. However, if the palms and soles are uninvolved (i.e., an NPS type), a mutation in the keratin 10 gene is more likely. Screening of the appropriate gene, as outlined above, can than proceed.

In the past, prenatal diagnosis of EHK has been accomplished by obtaining skin from a fetus by ultrasound-guided biopsy. This procedure was performed between 16 and 22 weeks of fetal gestation. Although fetal skin biopsy can be used with reasonably high levels of safety and confidence, the procedure cannot be performed before the middle of the second trimester of pregnancy because of the lack of differentiation of the epidermis before that time. Alternatively, amniotic fluid cells, obtained early in the second trimester, have been shown in one study to contain aggregates of keratin filaments, allowing prenatal diagnosis of EHK. However, both of these procedures are suboptimal, forcing the parents of a fetus diagnosed with EHK to make a decision about continuation vs termination at a late stage in the pregnancy.

Prenatal diagnosis of EHK using molecular methods avoids several of the problems of fetal-skin biopsy and structural analysis of amniotic cells. Chorionic villus sampling (CVS), performed as early as 8 weeks of fetal gestation, is a relatively noninvasive technique. CVS is a procedure whereby placental trophoblast tissue is obtained via transcervical aspiration. DNA from cells obtained by CVS can be analyzed directly for keratin mutations using PCR-based methods. Results of mutation analysis can be available for the parents of the fetus before the end of the first trimester. Should the parents choose to terminate a pregnancy based on the results, the termination procedure is much simpler from a clinical standpoint, and often easier for the parents to deal with psychologically. To date, prenatal diagnosis of EHK using direct gene sequencing has been reported in a pair of twins at risk to inherit the disease from an affected father.

One caveat for DNA-based prenatal diagnosis is that the affected carrier parent should have had his or her mutation defined at a molecular level prior to the fetus being tested. Failure to do so results in a delay in providing the parents the information about the disease status of the fetus, as the parent's mutation must first be identified before the fetus can be tested. Therefore, physicians who are caring for individuals with EHK should encourage the patient to have mutation analysis accomplished prior to any pregnancy.

In some cases, although linkage analysis will have established which of the two keratin clusters is involved (i.e., type I [chromosome 17] or type II [chromosome 12]) in EHK in a particular family, that family's mutation may have not yet been identified. In these cases, indirect prenatal diagnosis can be accomplished by analysis of the fetal DNA to determine which of the two parental chromosomes the fetus has inherited from the parent with EHK (the chromosome carrying the normal keratin gene or the chromosome carrying the mutated keratin gene). However, there can be some degree of statistical uncertainty using this technique.

Until there is curative treatment for EHK, the ability to screen for the disease in at-risk fetuses leaves families with only the choice to continue or terminate the pregnancy. Many parents would be pleased if they could be assured that pregnancy with an affected fetus would never occur, rather than having to make difficult choices once the pregnancy is established. To this end, a new technology in the field of assisted reproduction, preimplantation blastomere analysis, may prove to be one answer. This technique first requires in vitro fertilization. When the cultured embryo reaches the eight-cell stage of cleavage, one cell of the blastocyst is removed and analyzed by PCR. If the analysis shows that the blastocyst carries the keratin mutation causing EHK, it would be discarded. If the tested cell does not carry the mutation, the blastocyst would be implanted into the mother's uterus so that pregnancy may be established. To date, this approach has not been used for hereditary skin disease, although it is being offered clinically for cystic fibrosis and Huntington disease.

FUTURE DIRECTIONS

The immediate prospect for the cure of EHK is not optimistic. Effective treatment will probably involve the removal of the defective keratin chain. This implies shutting off the expression of the defective allele. Several ideas for gene therapy are in progress and include, for example, the use of gene replacement by homologous recombination, and methods to specifically correct the defective allele by use of antisense oligonucleotides, ribozymes, and so on. However, at this point in time, there are a number of technical

problems. A major problem is that current gene therapy procedures usually only offer a temporary correction of the gene defect: in this case corrected epidermal cells will differentiate and are then lost by desquamation. Thus, in order to avoid frequent repeated treatments, it will be necessary to identify and selectively target gene therapy to the epidermal stem cells that serve as the progenitors of the keratinocytes. Strategies should first be tested with experimental animal or cell culture model systems. Once the technical problems can be satisfactorily resolved in model systems, then in principle, a corrective regimen could proceed as follows: (1) Identification of the causative mutation in the affected individual or family; (2) isolation and in vitro culturing of epidermal keratinocytes from the patient; (3) gene therapy of the cells, isolation of corrected cell clones, and then growth into large epidermal rafts; and (4) surgical replacement of the patient's epidermis using techniques established for treatment of burn patients. Therefore, exploring novel approaches to the treatment of EHK remains an exciting challenge for the future.

75 Mosaicism and Epidermal Nevi

Amy S. Paller

BACKGROUND

Genetic mosaicism occurs when an organism contains two or more genetically different populations of cells that derive from a genetically homogeneous zygote. When mosaicism affects the skin, the resultant cutaneous patterning may follow several forms as classified by Happle: narrow or broad bands that follow Blaschko's lines; a checkerboard pattern; a phylloid pattern; or a patchy pattern without midline separation. Of these, the most common and best understood pattern follows the lines of Blaschko (Fig. 75-1), a nonrandom developmental pattern that differs from other skin-line patterns, such as dermatomes and Langer's lines of cleavage. Although never formally tested, these mosaic alterations in cutaneous morphology have been attributed to clonal proliferation of two genetically different cell populations during embryogenesis. Lesions along Blaschko's lines track linearly on extremities; the lines follow an arched S-shaped course on the sides of the trunk and abdomen, and form a striking V-shape over the dorsal midline caused by a marked caudal dip. The deviation of these designs from the expected transverse proliferation of embryonic cells has been explained by the concurrent longitudinal growth and flexion of the embryo.

The lines of Blaschko become visible in patients with various X-linked dominant genetic disorders, such as focal dermal hypoplasia, Conradi-Hünermann syndrome and incontinentia pigmenti, and in females who are carriers for certain X-linked recessive disorders, such as hypohidrotic ectodermal dysplasia. The lack of expression of the genetic mutation in all cells is thought to reflect the nonrandom inactivation of one of the X chromosomes (lyonization). These observations demonstrate a causal relationship between lyonization and lines of Blaschko, and further suggest that the lines serve as a marker of human development.

Several sporadic disorders also have cutaneous features that follow the lines of Blaschko. One of these sporadic disorders is the McCune-Albright syndrome, a disorder involving skin, bones and endocrine organs, in which hyperpigmented patches on the skin are symmetrically distributed, often along Blaschko's lines. A genetic mutation in the α-subunit of G protein that causes constitutive activation of adenylyl cyclase has been identified in patients with McCune-Albright syndrome, although a clear correlation between clinical and genetic mosaicism has not been demonstrated. This mutation is likely to be lethal, with survival possible only in the mosaic state with sufficient numbers of normal cells.

CLINICAL FEATURES

Epidermal nevi are organoid nevi that arise from the pleuripotential germinative cells in the basal layer of the embryonic epidermis. Lesions may not be present at birth, but tend to develop during the first few years of life. The clinical appearance of epidermal nevi varies, particularly in extent of body involvement, degree of epidermal thickening, and associated inflammation. These nevi have been classified by their major component into five major subsets: verrucous epidermal nevi and inflammatory linear verrucous epidermal nevi (keratinocyte origin); nevus comedonicus (hair follicle); nevus sebaceus (sebaceous gland); eccrine nevi (eccrine glands); and nevus syringocystadenosus papilliferus (apocrine gland). Although most patients with an epidermal nevus have no associated abnormalities, patients with the "epidermal nevus syndrome" have involvement of other organs, particularly involving the nervous system, eyes, or bones.

Epidermal nevi are almost always sporadic conditions, although rare examples of familial epidermal nevi have been described. In all forms of epidermal nevi, skin lesions tend to follow Blaschko's lines, suggesting the possibility of genetic mosaicism resulting from a postzygotic mutation.

GENETIC BASIS OF DISEASE

A subset of epidermal nevi that is clinically indistinguishable from verrucous epidermal nevi displays the typical histopathologic features of skin biopsies of patients with a rare autosomal dominant disorder, epidermolytic hyperkeratosis (EH) (Fig. 75-2A,B) (*see* Chapter 74). This type of nevus, even when extensively distributed, is not associated with other organ involvement. Epidermal nevi of the EH histologic phenotype also demonstrate ultrastructural changes similar to those of EH, with perinuclear clumping of keratin tonofilaments and epidermolysis in suprabasal layers. Epidermolytic hyperkeratosis, sometimes referred to as bullous congenital ichthyosiform erythroderma, is characterized by generalized epidermal thickening, superficial blistering, and variable-associated inflammation. A relationship between epidermal nevi of the EH type and generalized EH is further suggested by patients with generalized EH who have a parent with epidermal nevi, EH type.

The genetic basis for EH has been shown by several investigators to be mutations in the suprabasal, i.e., differentiation-specific keratins, K1 and K10 (*see* Chapter 74). These observations suggested that spontaneous somatic mutations in K1 and K10 may result in some forms of epidermal nevi. Paller et al. examined these keratin genes in three different cell types of patients with
Figure 75-1   Schematic representation of the surface lines of Blaschko. Several skin diseases display epidermal patterns of clinical mosaicism that follow these lines. The lines do not follow any known underlying vascular, neural, or dermal structures, but rather are thought to arise from genetic mosaicism as a consequence of postzygotic mutation.

epidermal nevi and of their offspring with EH, and demonstrated that genetic mosaicism is the underlying cause of the clinical mosaicism of epidermal nevi of the EH type. Sequence analysis and restriction-enzyme digests of CDNA from cultured skin keratinocytes revealed defects in up to 50% of the K10 alleles in lesional skin, but not in nonlesional areas of patients with epidermal nevi (Fig. 75-3A,B). In contrast, the mutation was either absent or underrepresented in their blood and fibroblast DNA. EH offspring displayed the same mutations detected in 50% of the K10 alleles from blood DNA. K10 mutation have subsequently been shown to cause epidermal nevi of the EH type in several other patients.

MOLECULAR PATHOPHYSIOLOGY

The embryologic alterations that lead to the somatic mosaicism are poorly understood. Presumably, an earlier postzygotic mutational event would lead to more extensive cutaneous involvement and a greater likelihood of gene alteration in multiple cell types. In the studies by Paller et al., K10 mutations could be detected by restriction enzyme digests in fibroblast DNA from all three different epidermal nevi patients, in blood DNA from two of these cases and, as judged by analyses of their offspring, in germline cells of all three cases. The epidermal nevi in these patients were multiple streaks. These findings are consistent with the notion that the mosaicism in these patients with epidermal nevi was established early.

The distinctly different program of epidermal and dermal development rules out the possibility that genetic diagnosis of epidermal nevus can be made reliably from any tissue other than lesional epidermis. The presence of a keratin mutation in many different cell types of an epidermal nevus patient increases the likelihood of germline transmission, and may warrant genetic screening at early stages of pregnancy to assess whether the keratin mutation has been transmitted to the unborn offspring. Prenatal

diagnosis has been performed for 15-week gestational age twins with EH by molecular analysis, born to a father affected by generalized EH. A similar approach is feasible for a parent with an extensive epidermal nevus of the EH type.

Given the parallels between EH and epidermolysis bullosa simplex (EBS), an autosomal-dominant blistering disorder caused by mutations in keratins 5 and 14, it is interesting that no mosaic disorder analogous to epidermal nevi is known for EBS (*see* Chapter 73). One explanation could be that a mutation expressed in the proliferative basal cell layer of skin, as in EBS, imparts a selective disadvantage in a mosaic state, so that the healthy basal cells would preferentially replace the cells with the expressed mutation. In contrast to basal cells, suprabasal cells terminally differentiate in upward columns of cells. Hence, as in EH, when cytolysis occurs in suprabasal cells, no compensation by lateral migration is possible, and clinical mosaicism is observed.

MANAGEMENT/TREATMENT

The current management of epidermal nevi is primarily surgical. Topical keratolytic agents are often not successful in ameliorating the cosmetic disfigurement that may result from epidermal nevi. Full-thickness excision is often difficult because of the orientation of the nevi, and is most commonly performed to completely remove nevus sebaceus, a premalignant lesion associated with a high risk of transformation to basal cell and adnexal carcinomas after puberty. Dermabrasion and the ultrapulse carbon-dioxide laser are the preferred treatments, although the pulsed-dye laser has been used successfully for patients with inflammatory linear verrucous epidermal nevi.

FUTURE DIRECTIONS

The underlying genetic basis for other types of epidermal nevi has not yet been elucidated. Interestingly, the lesions of nevus
Figure 75-2 **(A)** Verrucous epidermal nevus of the EH type along the lines of Blaschko. Immediately adjacent areas of skin are clinically normal. **(B)** Lesional skin from the epidermal nevus shows normal basal cells, but hyperkeratosis and cytolysis in suprabasal cells. (*See* color insert following p. 684.)

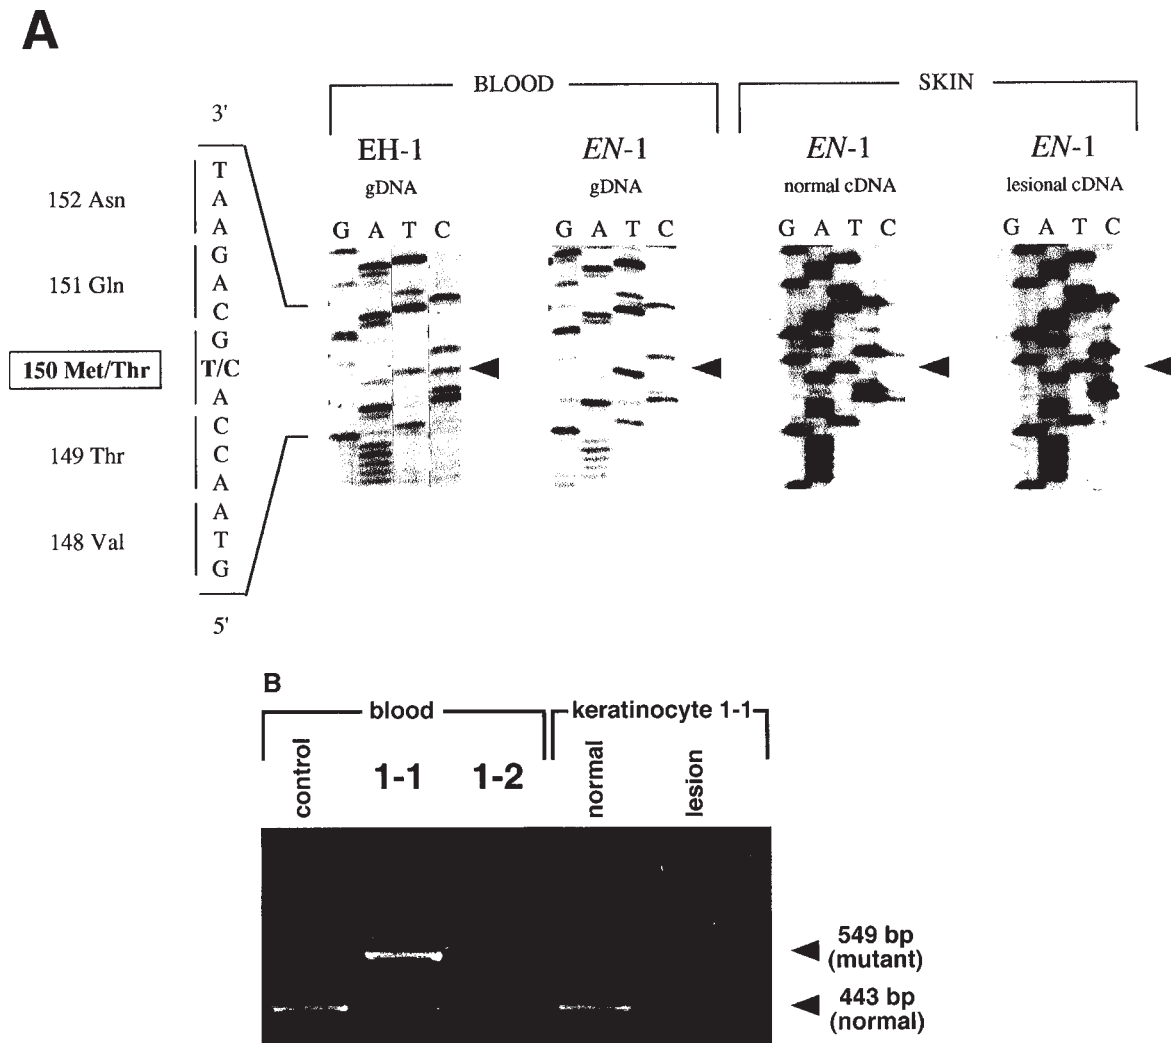
comedonicus may show histologic evidence of epidermolytic hyperkeratosis ("nevoid follicular EH"). Generalized EH has been described in a child of a parent with nevus comedonicus at more than one site, suggesting a common mutation. Epidermal nevi are also a feature of Proteus syndrome, a multisystemic sporadic mosaic condition that is presumed to be lethal in a generalized form. DNA fingerprinting has shown single-band differences in a pair of monozygotic twins discordant for Proteus syndrome and also differences between normal and affected areas of another patient with Proteus syndrome. A *de novo* mosaic chromosome


Figure 75-3 **(A)** Sequence analyses of K10 alleles from a family with epidermal nevus and EH show the mutation in lesional but not normal tissue. PCR-amplified fragments of K10-coding sequence were generated from keratinocyte cDNA or blood genomic DNA from the epidermolytic hyperkeratosis offspring and epidermal nevus parent. Note that the thymidine base is mutated to cytosine in up to 50% of the alleles in lesional skin, the same mutation that occurs in 50% of the K10 alleles of the offspring with EH, resulting in a methionine to threonine switch at amino acid 150. **(B)** Obliteration of a restriction endonuclease site in one of two K10 alleles in the epidermal nevus patient (1-1; EN-1) and offspring with EH (1-2; EH-1) shown in (A). DNA fragments with the K10 150Met→Thr mutation were amplified and digested with the restriction endonuclease Nla III. Samples were resolved by electrophoresis through agarose gels, and bands were visualized by staining with ethidium bromide. Bands characteristic of a normal and mutant K10 allele are indicated. Note that an Nla III cleavage site is lost as a consequence of the Met→Thr mutation, leading to the presence of uncleaved DNA (upper band). (Reproduced with permission from Paller AS, Syder AJ, Chan Y-M, et al. Genetic and clinical mosaicism in a type of epidermal nevus. N Engl J Med 1994;313:1408–1415.)

abnormality has been noted in still another patient with Proteus syndrome, suggesting the gene abnormality to reside within the lqll to lq25 region. Chromosomal breaks have also been demonstrated in cultured cells from epidermal nevi of the verrucous type without epidermolysis or Proteus syndrome in two patients at chromosome 1q21-25. This chromosomal localization, the site of a cluster of genes that code for several proteins specifically expressed during epidermal differentiation, including loricrin, trichohyalin, profilaggrin, involucrin, calpactin I, calcyclin, and cellular retinoic acid binding protein CRABP-II, suggests that verrucous nevi without epidermolysis may result from mosaicism of a gene mutation for one of these epidermal proteins.

At this time, localized gene therapy, either through ex vivo gene replacement and keratinocyte transplantation or by in vivo introduction, e.g., by gene-gun approach, injection of naked DNA, or lipo-

somes, is not theoretically feasible for correction of epidermal nevi of the EH type because of the dominant-negative nature of mutations of keratin genes. With the increasing knowledge of genes that cause the clinical mosaicism of epidermal nevi, it may be feasible to correct the defect by in vivo or ex vivo deletion of the mutated gene.

76 Darier's Disease and Hailey-Hailey Disease

Lowell A. Goldsmith and Ervin Epstein, Jr.

INTRODUCTION

These diseases are often discussed together because of some similarities in their histopathology. They map to different chromosomal locations and the clinical differences seem much more than the similarities. They will be discussed, in turn, in this chapter.

DARIER'S DISEASE

BACKGROUND Darier's disease (DD) is an autosomal-dominant disorder characterized by altered keratinization clinically limited to the epidermis, nails, and mucous membranes. The first American patient was described by White in 1889. That patient was well until he entered the Northern army in 1862, at the age of 22, and his skin disease appeared under his knapsack after a long march. In all families studied by positional cloning with microsatellite CA repeats, the gene defective in DD maps to a site on the long arm of chromosome 12-12q23-24.1. The mapping studies exclude keratins, desmosomal proteins, integrins, and retinoic acid receptors.

CLINICAL FEATURES DD usually begins in the first or second decade but is not present at birth. Multiple discrete, scaling, rough, crusted, pruritic, frequently malodorous, and disfiguring skin papules characterize DD (Fig. 76-1). Lesions rarely are bullous or hemorrhagic (Fig. 76-2). Characteristic sites of predilection are the face, forehead, scalp, chest, and back. Although these sites have many sebaceous glands, lesions also occur commonly in sites without sebaceous glands such as the palms and soles, as well as in nonkeratinizing epithelia. Males and females are affected equally. The nails are frequently abnormal and can be a clue for early diagnosis (Fig. 76-3). They characteristically are thin and fragile (with distal cracking and notching) and have distinctive red and white bands parallel to the long axis. The hair is normal, although the scalp frequently is covered with thick greasy scales and crusts.

DD frequently is worse in the summer and often is exacerbated by ultraviolet B (UVB) light (290–320 nm) and by mechanical trauma. Lesions have been precipitated by oral lithium, phenol, or ethyl chloride spray. Common complications of DD lesions are bacterial infection and infection with herpes simplex virus, but there are no consistent immunological abnormalities. The disease does not seem to predispose to cutaneous malignancies, although basal cell carcinomas and one rare sweat-gland tumor have been

reported. One family of two siblings with DD and retinitis pigmentosum is reported. Other associations reported in the literature include usually asymptomatic bone cysts. In a family with DD, one individual had concurrent renal and testicular agenesis and autoimmune thyroid disease. Epilepsy and affective disorders often have been associated with DD.

DIAGNOSIS The clinical features are associated with a distinctive histopathology that shows premature and abnormal keratinization and eosinophilic dyskeratotic cells in the spinous layer (corps ronds) and in the stratum corneum (grains). Suprabasal clefts (lacunae) are seen frequently and are interpreted as altered adhesion within the epidermis. Papillary overgrowth of the epidermis and hyperkeratosis are common.

GENETIC BASIS OF DISEASE DD is inherited as an autosomal dominant trait. The incidence of DD is at least 1:100,000 in Denmark and has been estimated to be 1:36,000 in northeast England. Cases caused by new mutations are frequent. The penetrance of the DD gene is high, at least 0.95; there is no skipping of generations in multiple pedigrees in the literature. No unique phenotype for the homozygote for the gene has been described, and there is no evidence for X-linked or autosomal-recessive forms of the disorder. There is no history of anticipation.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE Several groups using positional cloning with CA microsatellite repeats have reported the localization of DD to 12q23-24.1. This is the region of the DD trait in over two dozen reported kindreds. The most recently published studies limit the DD gene to a 1- to 2-cM region between the markers D 12S234 and D12S129. This location excluded the known keratin and cytoskeletal genes, retinoid receptors, desmosomal proteins, and other cell adhesion molecules.

The basic defect is not known and it is premature to discuss details of the molecular pathophysiology, but it is worthwhile to discuss some features of the general pathophysiology.

Electron microscopic studies show basal-cell vacuolization, decreased numbers of desmosomes on the lateral borders of basal cells, separation of tonofilaments from their insertions on the cell membrane, and tonofilaments in large aggregates around the nucleus. The corps ronds have many of the characteristics of apoptotic cells. Burge et al. found no abnormality of desmosomal structure by electron microscopy or of individual desmosomal proteins by immunofluorescent studies in uninvolved DD skin.

The identical tissue histopathology seen in the genetic forms of DD rarely has been described in epidermal nevi, warty dyskeratoma (a solitary scalp or oral lesion), actinic keratoses, Grover's disease (transient acantholytic disease), and some other
Figure 76-1   Hyperkeratotic irregular papules in Darier's disease are often on sun-exposed sites, trunk, and prominent in the hairline. (*See* color insert following p. 684.)

Figure 76-3   Red and white linear longitudinal bands occur in the nails of patients with Darier's disease. They are persistent and may represent clonal sites altered keratinization. (*See* color insert following p. 684.)

Figure 76-2   Hemorrhagic vesicle-papules occur in some kindreds with Darier's disease. This allele maps to the same 12q23-24.1 location as the common form of Darier's disease. (*See* color insert following p. 684.)

skin lesions. Hyperkeratotic papules on the dorsal surface of the hands of DD patients have a specific histopathology with a disordered acanthotic epidermis with angular, raised, church-spire-like epidermal changes. The pathology is consistent with acrokeratosis of Hopf. These lesions are almost always associated with DD, although there are rare families reported with only acrokeratosis of Hopf.

Hailey-Hailey disease is a disorder of the epidermis whose lesions have acantholysis but usually lack the extensive dyskeratotic changes seen in DD. Transient acantholytic disease (Grover's disease) occurs in middle-aged or elderly adults, usually men, has no familial incidence, and often begins after sun exposure. Individuals develop small pruritic skin lesions that are of variable duration and have the histopathology of DD. Similar lesions can be reproduced by the systemic injection of IL-4.

Chronic proliferative dermatitis is an autosomal-recessive mouse disorder that has frequent dyskeratosis and may be a model for some of the altered physiology in DD, but does not seem to be the mouse homolog of DD.

Cultured DD cells are able to induce the separation of cocultured normal keratinocytes. These data are intriguing and suggest the

need for studies of DD cells in skin equivalents to determine the effect of proteolytic enzymes in the production of lesions, and especially the potential therapeutic role of protease inhibitors (and the stimulators of protease inhibitors such as transforming growth factor-β) in preventing skin lesions.

MANAGEMENT/TREATMENT   As with several other genetic disorders affecting the epidermis, the disease is improved by therapy with systemic retinoids. UVB blockers are useful during the sunny portion of the year. Some patients are so sun-sensitive that systemic retinoids can be discontinued in the winter. All of the precautions relevant to systemic retinoids must be followed.

HAILEY-HAILEY DISEASE

BACKGROUND   Eponymic credit for the description of "their" disease clearly belongs to the (dermatologic) brothers Hailey who in 1939 described two sets of (patient) brothers, all four of whom were affected by a clinically similar chronic skin problem.

CLINICAL FEATURES   The primary lesions of Hailey-Hailey disease are small, grouped, clear vesicles that tend to spread peripherally with crusting and central clearing, leaving chronic plaques sometimes misdiagnosed as eczema or as dermatophyte or bacterial infection (Fig. 76-4). Lesions may be tender and malodorous. The usual location of lesions are the body folds—the groin and perineum, axillae, intra-, and inframammary areas—and the sides of the neck. The shoulders and upper back also frequently are affected. However, lesions unusually have been reported in a more generalized distribution on the skin and even on the mucosal surface including the vagina, buccal mucosa, and esophagus. Longitudinal white bands on the fingernails have been observed. Because of the presence of tender eroded patches, patients may find it difficult to engage in the physical activity necessary for gainful employment.

Onset is usually in the third or fourth decade but is after age 40 in approximately 12% of patients. Most patients find that their lesions are made worse by friction, heat, and sweating—with exacerbations in the summer and waning in the winter. Hailey-Hailey disease is diagnosed uncommonly, but the true incidence may well be considerably higher, for it is easy to misdiagnose lesions as a nonspecific intertrigo. Also, the common localization

Figure 76-4 Papules and erosions characterize Hailey-Hailey disease. (*See* color insert following p. 684.)

of disease to covered sites and some reticence to discuss afflictions in those areas means that even patients' families frequently do not know of the disease and therefore are not able to enhance their physician's diagnostic suspicion.

DIAGNOSIS The diagnosis generally can be made readily by skin biopsy. Pathognomonic changes are a floating apart of suprabasal epidermal keratinocytes. Typically, the split is just above an intact basal layer, and the cells of the roof appear to be falling down into the cleft, giving an appearance that has been described as that of "a dilapidated brick wall." Lateral connections between basal cells also may be tenuous, so that the basal cells resemble a "row of tombstones."

Although biopsies usually are taken from affected sites, similar changes may be found on biopsy of skin removed for incidental purposes, e.g., for pathologic examination of a worrisome nevus, and the acantholysis related to the physical trauma to the epidermis of the biopsy procedure. Occasionally, such Hailey-Hailey–like acanthoysis is found in patients without clinically manifest Hailey-Hailey disease, but no series has been published in which such patients were carefully examined and followed for the subsequent appearance of Hailey-Hailey lesions.

Acantholysis also is characteristic of several other diseases, but generally they can be distinguished from Hailey-Hailey disease without trouble. In addition to the autoimmune types of pemphigus discussed in Chapters 88 and 89, acantholytic blisters occasionally are found in idiosyncratic reactions to several drugs, e.g., penicillamine, captopril, and norfloxacin. No antiepithelial antibodies have been found in Hailey-Hailey disease.

GENETIC BASIS Analyses of multiple published kindreds all are consistent with an autosomal-dominant inheritance. Penetrance has been reported to be incomplete but the thoroughness of examination of apparent "skipped" individuals has not always been documented. By patient history, 16% of 58 patients in one series knew of no affected relative and therefore may represent new mutations.

Linkage analysis has localized the disease gene to an approximately 5-Mb region at chromosome 3q21. This is an area lacking in genes that encode proteins known to be involved in interkeratinocyte adhesion; e.g., none of the known desmosomal protein genes map to this site. Since inheritance of disease in at least a dozen kindreds has been reported to map to this region and since no family lacking linkage to this site has been reported, it appears likely that mutations at a single genetic locus cause all cases of Hailey-Hailey disease.

MOLECULAR PATHOPHYSIOLOGY Since the gene whose mutations cause Hailey-Hailey disease has been localized but not yet identified, it is not yet possible to describe pathophysiology. Once the gene has been cloned, it will be important to explain how mutations cause several somewhat puzzling phenotypic characteristics.

These include the relatively late, noncongenital onset, the exacerbation in the summer, the usual localization to characteristic body sites despite the ability to induce blisters experimentally (e.g., by suction) at other sites and in vitro abnormalities of keratinocytes cultured from unaffected sites, the clear (albeit inconsistent) response to therapy—both to antibiotics and corticosteroids and to resurfacing *(see below)*.

MANAGEMENT/TREATMENT Standard therapy for Hailey-Hailey disease includes antibiotics—both systemic and local—and topical steroids. Responses are inconsistent, but frequent enough to warrant their use. Stronger topical steroids often are needed, and their use in the body folds may produce striae.

Since the lesions often are localized, surgical ablation has been used. Success has been reported not only with full-thickness excision (including adnexae) but also with more superficial destruction by electrodesiccation, carbon dioxide laser vaporization, dermabrasion, or liquid nitrogen freezing. This suggests that removal merely of the interfollicular epidermis may be sufficient to render the new epithelium less abnormal. This is puzzling, since experimental data indicate that the cellular abnormality is generalized including, presumably, the resurfaced epithelium.

77 Junctional Forms of Epidermolysis Bullosa

Angela M. Christiano and Jouni Uitto

INTRODUCTION

The group of heritable genodermatoses known as epidermolysis bullosa (EB) are characterized by blistering and skin and mucous membrane fragility in response to mechanical trauma. EB is divided into three major categories based on the level of tissue separation, as determined by transmission electron microscopy. Mutations in different genes encoding proteins expressed within the layers of the dermal–epidermal adhesion zone provide the molecular basis for the wide variation in clinical phenotypes of the different subtypes of EB. In the simplex forms of EB, the tissue separation occurs within the basal keratinocytes, as a result of mutations in two genes expressed in the basal keratinocytes, *KRT5* and *KRT14*. The genetics of EB simplex are covered in detail in Chapter 73. In the dystrophic forms of EB (DEB), the tissue separation occurs below the lamina densa at the level of anchoring fibrils, attachment structures extending from the lamina densa to the upper papillary dermis. In all cases of both dominantly and recessively inherited dystrophic EB studied thus far, mutations in one gene, the type VII collagen gene *(COL7A1)*, have been shown to be pathogenetic. The molecular basis of the dystrophic forms of EB is described in depth in Chapter 78.

In contrast to the genetic homogeneity observed in EB simplex and dystrophic EB, the junctional forms of EB display a remarkable degree of genetic heterogeneity, with at least six different genes implicated in pathogenesis thus far. In junctional EB (JEB), tissue cleavage occurs within the dermal–epidermal basement membrane at the level of the lamina lucida or the overlying hemidesmosomes, and, ultrastructurally, abnormalities in the region of the hemidesmosome-anchoring filament complexes are observed. In a large number of patients with both the lethal and nonlethal forms of JEB, specific mutations have been identified in the three genes encoding the constitutive polypeptides, α3, β3, and γ2, of the anchoring filament protein, laminin 5, and, recently, mutations in the genes encoding other hemidesmosomal components have also been detected in certain subtypes of JEB. For example, mutations in the gene encoding the β4 subunit of the epithelial-cell–specific integrin, α6β4, have been detected in a patient with JEB and pyloric atresia, and mutations in the gene encoding the 180-kDa bullous pemphigoid antigen (BPAG2; also known as type XVII collagen) have been demonstrated in patients with generalized atrophic benign EB, a relatively mild variant of junctional EB. Our current understanding of the molecular basis of junctional EB, emphasizes the molecular complexity of the hemidesmosome-anchoring filament complex and its role in disease.

THE HEMIDESMOSOME-ANCHORING FILAMENT COMPLEX

The architecture of the entire cutaneous basement membrane zone is described in detail in Chapter 78; therefore, the focus of this discussion is restricted to the hemidesmosome-anchoring filament (HD-AF) complex. The hemidesmosomes extend from the intracellular compartment of the basal keratinocytes to the lamina lucida in the upper portion of the dermal–epidermal basement membrane. Within the lamina lucida, the hemidesmosomes complex with anchoring filaments, thread-like structures that tend to concentrate below the hemidesmosomes. Biochemical studies using isolated HDs have identified five major components of the HD, consisting of polypeptides with molecular masses of 500, 230, 200, 180, and 120 kDa, and named HD1–HD5, respectively. HD2 and HD4 are now known to be identical to the 230-kDa bullous pemphigoid antigen (BPAG1) and the 180-kDa bullous pemphigoid antigen (BPAG2/COL17A1), respectively. HD3 and HD5 correspond to the β4 and α6 integrins, respectively. HD1 has been extensively studied at the protein level and may be identical to the protein plectin, yet remains to be cloned and characterized. HD1 has been shown to localize to the cytoplasmic side of the HD, in a distribution slightly above, yet almost indistinguishable from BPAG1, at the level of the cytoplasmic periphery of the HD inner plaque. The intracellular hemidesmosomal plaque comprises the 230-kDa bullous pemphigoid antigen (BPAG1), a noncollagenous protein that serves as an autoantigen in an acquired autoimmune disease, bullous pemphigoid. The 180-kDa bullous pemphigoid antigen (BPAG2), a transmembrane collagen also known as type XVII collagen (COL17A1) extends from the intracellular compartment to the extracellular space. Associated with the hemidesmosomal proteins is the basal keratinocyte-specific integrin, α6β4, which contributes to the anchoring of basal keratinocytes to the underlying basement membrane. The anchoring filaments that traverse the lamina lucida, have been shown to consist of laminin 5, a distinct member of the laminin family of proteins. Laminin 5 consists of three constitutive subunit polypeptides, the α3, β3, and γ2 chains, which form the characteristic cross-shaped trimeric structure. Clearly, mutations resulting in abnormalities in any protein component of the HD-AF network could underlie the different forms of junctional epidermolysis bullosa.

MOLECULAR HETEROGENEITY OF JUNCTIONAL EB

The junctional forms of EB display considerable phenotypic heterogeneity, and on the basis of clinical severity, the disease can be divided into the classic, Herlitz (lethal) type, and non-Herlitz (nonlethal) forms. Within the nonlethal forms, several subtypes have

been described based on the associated extracutaneous manifestations and the extent and severity of the blistering tendency. This clinical heterogeneity apparently reflects the repertoire of underlying genetic lesions demonstrated thus far in at least five different genes. More precisely, mutations in different forms of JEB have now been identified in the genes encoding the macromolecular components of the hemidesmosome-anchoring filament complex.

MOLECULAR BASIS OF HERLITZ JEB: PREMATURE TERMINATION CODON MUTATIONS IN THE LAMININ 5 GENES

Early electron-microscopic data on JEB indicated ultrastructural abnormalities in the hemidesmosome-anchoring filament complexes, in which the hemidesmosomes were rudimentary and poorly formed. In the most severe, clinically devastating Herlitz type of junctional EB (Fig. 77-1), initial immunofluorescence staining for laminin 5 epitopes suggested the absence of this protein. Subsequent to the cloning of genes encoding the three constitutive polypeptides of laminin 5, mutation-detection strategies have revealed genetic lesions in each of the three genes, (*LAMA3*, *LAMB3*, and *LAMC2*), encoding the α3, β3, and γ2 chains, respectively. The majority of these mutations have been disclosed in the *LAMB3* gene, apparently reflecting the presence of two mutational hotspots leading to recurrent mutations, R42X and R635X. Also, it should be noted that, in the lethal, Herlitz form of JEB, all mutations disclosed thus far result in premature termination codons, leading to markedly reduced levels of the corresponding mRNA transcript through a nonsense-mediated mRNA decay mechanism.

MOLECULAR BASIS OF NON-HERLITZ JEB: COMPOUND HETEROZYGOUS MUTATIONS IN THE LAMININ 5 GENES

Within the nonlethal forms of JEB, laminin 5 gene mutations have been disclosed as well. In some cases, one of the mutations is a premature termination codon in one of the laminin 5 genes. However, the other genetic lesion consists of a missense mutation or an in-frame exon-skip mutation, in cases in which mutations in both alleles have been disclosed. These observations suggest that essentially full-length polypeptides with an intact carboxy-terminal end are able to assemble into trimer molecules, which serve a partial function in the anchoring filaments. This interpretation is consistent with the observation that immunofluorescence staining with an antilaminin 5 antibody, such as GB3, is positive, although frequently attenuated, in these nonlethal JEB patients.

MOLECULAR BASIS OF THE HEMIDESMOSOMAL SUBTYPES OF JEB

Whereas the molecular basis of many of the classic forms of Herlitz and non-Herlitz JEB are now well-understood on the basis of laminin 5 mutations, there is a group of patients in whom blisters form in and around the hemidesmosome (HD), and whose ultrastructural classification and clinical severity have been referred to as "pseudojunctional." The major components of the HD, consisting of polypeptides named HD1–HD5, respectively, are likely candidates for these forms of JEB. Although there may be additional structural components of the HD, these proteins are likely candidates for mutations in some of the unusual forms of EB in which cleavage occurs at the level of the HD. Ultrastructural classification of EB has identified at least three groups of patients with EB whose blisters form at the level of the HD, and whose clinical phenotype is unlike any of the classic forms of EB. These include
Figure 77-1 Clinical presentation of a newborn with Herlitz junctional epidermolysis bullosa. Note the widespread blistering and erosions over the neck and ears (**A**) and the back (**B**) of this affected infant.

generalized atrophic benign epidermolysis bullosa (GABEB), epidermolysis bullosa with pyloric atresia (PA-JEB), and epidermolysis bullosa with muscular dystrophy (EB/MD). Mutations have recently been identified in three HD-associated structural proteins in patients with these forms of EB, using ultrastructural and immunofluorescence data to identify candidate genes.

MUTATIONS IN BPAG2
IN GENERALIZED ATROPHIC BENIGN EB

Attesting to the molecular heterogeneity of the junctional forms of EB are our recent demonstrations of specific mutations in other genes encoding structural components of the hemidesmosome-anchoring filament complex. Specifically, we have recently identified mutations in the *BPAG2* gene in a specific subset of nonlethal JEB, known as generalized atrophic benign EB. Clinically these patients demonstrate a moderately severe blistering tendency, associated with characteristic extracutaneous involvement, including dystrophy of the fingernails, focal scarring alopecia of the scalp, loss of eyelashes, dental abnormalities, and patchy macular hyperpigmentation. The first patient demonstrating genetic abnormalities in *BPAG2* had two different mutations, R1226X and 4150insG, both resulting in premature termination codons of translation; subsequently, the mutation in the original GABEB family described by Hintner and Wolff has been reported to be a premature termination codon transmitted through many branches of a large geographically inbred family. More recently, a dominantly inherited glycine substitution in *BPAG2* was identified in a GABEB family, in which the proband had inherited a premature termination codon on the second allele, whereas all carriers of the glycine substitution alone had markedly abnormal dentition and enamel pitting. Clearly, the impact of a glycine-substitution mutation in *BPAG2* also impacts upon the basement membrane of the developing tooth, a previously undisclosed function for this transmembrane collagen.

IDENTIFICATION
OF β4 INTEGRIN MUTATIONS IN JEB

Yet another subtype of nonlethal JEB, a rare disorder characterized by pyloric stenosis and blistering of the skin as primary manifestations, has genetic alterations in another gene. We recently demonstrated distinct mutations in the β4 integrin gene *(ITGB4)* in a patient with this combination of clinical manifestations. The paternal mutation consisted of a 1-bp deletion causing a shift in the reading frame and premature termination codon, whereas the maternal mutation affected the donor splice site of an intron and resulted in in-frame exon skipping involving the cytoplasmic domain of the polypeptide. The phenotypic manifestation of pyloric atresia from mutations in the *ITGB4* gene suggest a tissue-specific role for this integrin both in the skin and the gastrointestinal tract.

EB AND MUSCULAR DYSTROPHY

To determine which of the candidate proteins of the HD (β4 integrin, *BPAG1*, or HD-1) is responsible for making the connection between the HD and the keratinocyte intermediate-filament network, Guo and colleagues recently reported a knockout mouse in which they targeted the ablation of *BPAG1*. Whereas the HDs in these mice were largely normal, they lacked the inner plate and demonstrated a complete severance of the connection between the HD with the intermediate-filament network. The zone of mechanical fragility of the basal keratinocytes was restricted to the region of the HD, quite distinct from the ultrastructural findings in classic EB simplex, yet strikingly similar to the cleavage plane reported in pseudojunctional EB. Unexpectedly, the *BPAG1* knockout mice also developed late-onset muscular dystonia and neurodegeneration, similar to a naturally occurring mouse, dystonia musculorum (dt). This constellation of phenotypic features together with the ultrastructural findings is remarkably consistent with the pathogenesis of EB with muscular dystrophy. On the basis of the striking similarities in the clinical phenotype of EB with muscular dystrophy and the *BPAG1* knockout mouse, it appeared likely that one of the two components of the hemidesmosomal inner plaque, *BPAG1* or HD-1, would be involved in the pathogenesis of this disorder.

HD-1 was first described as a ~500-kDa component of the hemidesmosome, and, at about the same time, an exceptionally large intermediate filament-binding protein, called plectin, was cloned from rat glioma cells. The plectin sequence has similarities to both desmoplakin and bullous pemphigoid antigen, is highly conserved between rat and human, and has a wide tissue distribution, including the central nervous system and muscle. Plectin has a remarkable number of versatile binding affinities for other proteins, including vimentin, glial fibrillary acidic protein, the neurofilament protein triplet, keratins 10 and 11, and lamin B. Although plectin is expressed in nearly all cell types, its precise cytoplasmic localization depends on the specific cell type, and it can appear diffused throughout the cell as a cytomatrix component, or in a restricted distribution as a focal adhesion protein.

Several independent lines of biochemical evidence suggest that plectin and HD-1 are the same protein, a notion confirmed by the recent cloning of human plectin. The biochemical and synthetic properties of cultured keratinocytes from patients with EB/MD using antibodies against HD-1 were studied, and plectin was found to be completely absent in the cells of several EB/MD patients. These findings strongly suggested a molecular defect in plectin/HD-1 in the pathogenesis of EB/MD, and implicated plectin/HD-1 as a novel candidate gene in the HD-AF complex. The recent definition of mutations in the plectin gene in patients with EB/MD will provide further insights into the relationship between the skin and the nervous system initially revealed by the knockout mouse, and the role of cytoskeletal and associated proteins in neurodegenerative disorders, both areas of research still in their infancy, yet of great potential scientific impact.

In summary, the junctional forms of EB reflect mutations in at least six different genes disclosed to date, and the specific clinical constellations apparently result from the combination of different types of mutations within the mutated genes (Table 77-1). Whereas the mechanism of action of these mutations has been explored at the mRNA and protein levels in many of the studies cited, the functional role of these components in HD assembly is also becoming increasingly clear through recent studies of protein–protein interactions. In the past year alone, an interaction between the 180-kDa bullous pemphigoid antigen and α6 integrin was described, the disruption of HD assembly by a tail-less β4 integrin subunit was reported, and a role for β4 integrin in signal transduction was defined. Whereas these components clearly represent functionally interdependent structural macromolecules in the dermal–epidermal adhesion zone, recent studies suggest a functionally dynamic and interactive role of some of these proteins in cell-matrix communication. Finally, it is worth noting that an extensive survey of the six genes demonstrated as candidate genes in the junctional forms of EB have thus far been negative in several families, suggesting additional, as yet undisclosed, candidate genes and uncharacterized protein components for this heterogeneous group of disorders.

APPLICATIONS OF MUTATION ANALYSIS
IN PRENATAL DIAGNOSIS OF JUNCTIONAL EB

The precise understanding of the underlying mutations in junctional EB has several translational implications in terms of genetic counseling, DNA-based prenatal diagnosis, and gene therapy.

Most immediately relevant to patient care is the development of DNA-based prenatal diagnosis, which can be performed as early as the 10th week of gestation through chorionic villus sampling, or at the 12–15th week of gestation through amniocentesis. Because of the extensive underlying genetic heterogeneity in the junctional forms of EB, prenatal diagnosis must be based on direct demonstration of the presence or absence of both mutations, since at least seven different genes can harbor the genetic lesion in different forms of JEB, and *de novo* hotspot mutations have been observed. These approaches have been applied to DNA-based prenatal diagnosis in a number of families at risk for recurrence of Herlitz JEB. The genetic information also provides the basis for development of preimplantation diagnosis through blastomere analysis, a technological advance that would obviate the necessity of termination of the pregnancy in case of an affected fetus, if elected.

GENE THERAPY APPROACHES FOR JUNCTIONAL EB

Precise understanding of the underlying mutations, and subsequent demonstration of the functional consequences of such mutations at the mRNA and protein levels, are prerequisites for the development of gene therapy approaches for this group of devastating skin diseases. Whereas the lethal Herlitz form of JEB may represent an ensemble of unrealistic clinical challenges, we believe that several forms of JEB are realistic targets for genetic therapies, including the nonlethal forms of junctional EB, such as GABEB. Introduction of the relatively small wild-type cDNAs for BPAG2 and ITGB4 into patient keratinocytes, by *ex vivo* and in vivo methods, is more likely to be successful than for larger mRNAs, when these techniques become the standard of care for JEB in the future. Whereas the genetic basis of junctional EB is still a work in progress, and we still have much to learn about the HD-AF complex, the immediate benefits of this work have provided prenatal diagnosis for families at risk for recurrence, and, importantly, the foundation for development of gene therapy approaches to counteract JEB at the level of the molecular defect.

78 The Dystrophic Forms of Epidermolysis Bullosa

Jouni Uitto and Angela M. Christiano

INTRODUCTION

Significant progress has recently been made in understanding the structural features of the epidermis and dermal–epidermal junction, largely through molecular cloning of genes that encode proteins critical for the structural integrity of the cutaneous layers. Disturbances in the expression of the genes within the stratified layers of the dermal–epidermal adhesion zone provide the basis for different forms of heritable blistering skin diseases with divergent clinical presentation (Fig. 78-1).

MOLECULAR COMPLEXITY OF THE CUTANEOUS BASEMENT MEMBRANE ZONE

Electron-microscopic examination of the cutaneous basement-membrane zone (BMZ) reveals the presence of several attachment structures, critical for integrity of the stable association of epidermis and dermis (Fig. 78-1). These include hemidesmosomes that extend from the intracellular compartment of the basal keratinocytes to the lamina lucida in the upper portion of the dermal–epidermal basement membrane. Within the lamina lucida, the hemidesmosomes complex with anchoring filaments, thread-like structures that tend to concentrate below the hemidesmosomes. At the lower portion of the dermal–epidermal attachment zone, fibrillar structures known as anchoring fibrils extend from the lamina densa of the basement membrane to the papillary dermis, where they associate with basement-membrane-like structures known as anchoring plaques.

Recent molecular cloning of the cutaneous BMZ components has allowed elucidation of the structural features of the macromolecules, which constitute these dermal–epidermal attachment structures. Specifically, hemidesmosomes have been shown to consist of at least four distinct proteins. The intracellular hemidesmosomal inner plaque comprises at least two proteins, the 230-kDa bullous pemphigoid antigen (BPAG1), a noncollagenous protein that serves as an autoantigen in an acquired autoimmune disease, bullous pemphigoid; and HD1, a ~500-kDa protein belonging to the plectin family of adhesion molecules. Extending from the intracellular compartment to the extracellular space is the 180-kDa bullous pemphigoid antigen (BPAG2), a transmembrane collag-

enous protein, also known as type XVII collagen (COL17A1). Associated with these hemidesmosomal proteins is the basal keratinocyte-specific integrin, α6β4, which contributes to the anchoring of basal keratinocytes to the underlying basement membrane.

The anchoring filaments, which traverse the lamina lucida, have been shown to consist of laminin 5, a distinct member of the laminin family of proteins. Laminin 5 consists of three constitutive subunit polypeptides, the α3, β3, and γ2 chains, which form the characteristic cross-shaped trimeric structure.

Early biochemical data at the protein level suggested that type VII collagen is the major, if not the exclusive, component of anchoring fibrils. Recently, type VII collagen primary structure has been elucidated through cDNA cloning, and the intron–exon organization of the entire gene has been determined.

Collectively, the data summarized above indicate that the cutaneous basement-membrane zone is a complex continuum of macromolecules that form a network providing the stable association of the epidermis to the underlying dermis. Thus, genetic lesions resulting in abnormalities in any component of this network could result in a blistering skin disease, such as the different forms of epidermolysis bullosa.

MOLECULAR BASIS OF DIFFERENT FORMS OF EPIDERMOLYSIS BULLOSA

The prototype of the diseases affecting the cutaneous BMZ is epidermolysis bullosa (EB), a group of heritable mechanobullous disorders, that manifest with considerable variability in clinical severity. Also, genetic heterogeneity is evident, and both autosomal dominant and autosomal recessive forms of EB can be recognized. Epidermolysis bullosa can be divided into three major categories based on the level of tissue separation as established by diagnostic transmission electron microscopy. In the simplex forms of EB, the tissue separation occurs within the basal keratinocytes, as a result of mutations in the basal keratin genes, *KRT5* and *KRT14*. In the junctional forms of EB, the tissue cleavage occurs within the dermal–epidermal basement membrane at the level of the lamina lucida, and ultrastructurally, the junctional forms demonstrate abnormalities in the hemidesmosome-anchoring filament complexes. In patients with the junctional forms of EB, specific mutations have been identified in the three genes encoding the constitutive polypeptides, α3, β3, and γ2, of the anchoring-filament protein, laminin 5. In addition, mutations in the genes encod-

Figure 78-1 Schematic representation of the epidermis and the underlying cutaneous basement membrane zone at the dermal–epidermal junction. The skin layers affected in genetic skin diseases are indicated on the left, and the specific gene products are listed on the right. Note that tissue separation in the dystrophic forms of epidermolysis bullosa (EB) occurs below the basement membrane within the upper papillary dermis, at the level of anchoring fibrils, which consist of type VII collagen. EHK, epidermolytic hyperkeratosis; PPK, palmoplantar keratoderma; BPAG, bullous pemphigoid antigen. (Modified from Christiano AM, Uitto J. Molecular diagnosis of inherited skin disorders: the paradigm of dystrophic epidermolysis bullosa. Advances Derm 1996;11:199–213.)

ing the hemidesmosomal components have also been detected in certain subtypes of junctional EB, including mutations in the gene encoding the β4 subunit of the α6β4 integrin, and the gene encoding the 180-kDa bullous pemphigoid antigen, BPAG2, also known as type XVII collagen. (For details on the junctional forms of EB, *see* Chapter 77.)

In the dystrophic forms of EB (DEB), the tissue separation occurs below the lamina densa at the level of anchoring fibrils, critical attachment structures extending from the lamina densa to the upper papillary dermis. This chapter will illustrate the power of molecular diagnosis of blistering skin diseases by reviewing recent revelations into the molecular basis of the dystrophic forms of EB.

THE DYSTROPHIC FORMS OF EB: SPECTRUM OF CLINICAL SEVERITY

The dystrophic forms of EB (DEB), which can be inherited in either an autosomal-dominant or autosomal-recessive pattern, demonstrate extensive variability in the clinical spectrum of severity. The less severe forms, such as dominantly inherited dystrophic EB (DDEB) or the mitis type of recessively inherited DEB (RDEB), are characterized by a significant blistering tendency, but they lack the extensive mutilating scarring that is the hallmark of the severe, generalized, Hallopeau-Siemens (HS-RDEB) type of recessive dystrophic EB. In addition to cutaneous manifestations, the dystrophic forms, particularly HS-RDEB, are associated with scarring of the esophagus and corneal erosions. The combination of cutaneous and extracutaneous manifestations is associated with considerable morbidity and mortality in the most severely affected patients.

MOLECULAR GENETICS OF DYSTROPHIC EB

Several lines of evidence initially suggested that the type VII collagen gene *(COL7A1)* is the candidate gene for mutations in the dystrophic forms of EB. First, the ultrastructural diagnostic hallmark of the dystrophic forms of EB is abnormalities in anchoring fibrils, attachment structures that are composed predominantly, if not exclusively, of type VII collagen. The anchoring fibrils can be shown by transmission electron microscopy to be morphologically abnormal, reduced in number, or even completely absent. Secondly, these ultrastructural observations are reflected by changes in the immunofluorescence pattern when anti–type VII antibodies are used for staining of the skin. In normal individuals, type VII collagen epitopes are readily evident in a linear pattern at the dermal–epidermal junction, whereas in generalized HS-RDEB patients, the immunostaining is entirely negative. In dominantly

Genotype	Wild type / Wild type	Wild type / PTC	Wild type / Missense	Wild Type / Glycine substitution	Missense / Missense	PTC / Glycine substitution	PTC / Missense	PTC / PTC
Consequences of Mutation	Normal	Markedly reduced mRNA from PTC; 50% number AFs; ± morphological abnormalities	Disturbed assembly of AFs; Reduced numbers of AFs	Reduced number of AFs; One in eight collagen molecules is normal; Chains bearing glycine substitutions are degraded intracellularly	Missense bearing chains have disturbed assembly; Little functional protein, few AFs	mRNA from PTC allele is greatly reduced; Chains bearing glycine substitutions are degraded intracellularly	mRNA from PTC allele is greatly reduced; Missense bearing chains have disturbed assembly	mRNA from PTC alleles is markedly reduced; No functional type VII collagen or AFs
Genetics	Normal	Normal carrier	Normal carrier	DDEB	RDEB	RDEB	RDEB	HS-RDEB
Phenotypic Severity	Normal	None	None	Mild to moderate	Moderate to severe	Moderate to severe	Moderate to severe	Severe

Figure 78-2 Schematic representation of genotype-phenotype correlations based on delineation of mutations in the type VII collagen gene in different subtypes of dystrophic epidermolysis bullosa. (Modified from Christiano AM, Uitto J. Molecular diagnosis of inherited skin disorders: the paradigm of dystrophic epidermolysis bullosa. Advances Derm 1996;11:199–213.)

inherited DEB, the immunostaining reveals a near-normal pattern, whereas in the mitis forms of RDEB, the intensity of the staining can be attenuated, although clearly positive. These ultrastructural and immunofluorescent findings suggested that type VII collagen was a candidate gene for mutations in the dystrophic forms of EB. This suggestion was subsequently strengthened by demonstration of genetic linkage between the *COL7A1* locus on chromosome 3p21, and both the dominantly and recessively inherited forms of DEB.

Recent cloning of the human type VII collagen cDNA sequences has allowed us to deduce the normal structure of type VII collagen polypeptides. Cloning and elucidation of the intron–exon organization of the entire human type VII collagen gene has revealed that the gene is highly complex, consisting of a total of 118 exons, the largest number of exons in any gene reported thus far. However, *COL7A1* is relatively compact, and the exons are contained within ~32 kbp of genomic DNA. The elucidation of the intron–exon organization of *COL7A1* has provided necessary information to undertake mutation analysis of this gene in families with DEB. In fact, specific mutations have now been disclosed in over 100 kindreds with different forms of DEB.

GENOTYPE/PHENOTYPE CORRELATIONS IN DEB

The wealth of information on specific mutations in different forms of DEB allows us to begin to establish genotype–phenotype relationships. In normal skin, type VII collagen molecules form antiparallel dimers that associate through their overlapping carboxy-terminal ends. This association is stabilized by interchain disulfide bonds, and such stable type VII collagen molecules laterally aggregate to form anchoring fibrils. Thus, following the synthesis of type VII collagen, several critical steps are required for proper assembly of anchoring fibrils. Consequently, mutations affecting the synthesis of type VII collagen at the transcriptional or translational level, or those interfering with its supramolecular assembly to anchoring fibrils can result in DEB phenotype (Fig. 78-2).

SEVERE, MUTILATING HS-RDEB: PREMATURE TERMINATION CODON MUTATIONS IN COL7A1

In a number of HS-RDEB patients in whom both mutations have been disclosed thus far, the consistent genetic lesion is a premature termination codon (PTC) in both alleles of the affected individual. The major effect of a PTC mutation is reduction in mRNA abundance as a result of nonsense-mediated mRNA decay. This phenomenon appears to be coupled to the splicing process itself, since the levels of unspliced, heteronuclear RNA (hnRNA) are equivalent for both the mutant and wild-type alleles, and the decay is evident only upon comparison of processed mRNA. The PTCs result in perturbations in synthesis of type VII collagen mRNAs at the transcriptional level, which are then unable to provide templates for translation of functional polypeptides. Even if the mutant allele containing a PTC is expressed at reduced levels,

the translated protein is truncated at its carboxy-terminus and is unable to assemble into anchoring fibrils. These interpretations are consistent with the ultrastructural demonstration of complete absence of the anchoring fibrils in HS-RDEB, which explains the extreme fragility of the skin, so characteristic of this phenotype (Fig. 78-2).

MILD RDEB: MISSENSE AND INFRAME DELETION MUTATIONS

In the mitis forms of RDEB, at least one, and possibly both, alleles encode for a full-length type VII collagen polypeptide. However, this allele usually contains a missense mutation that can change the conformation of the protein in a manner that anchoring-fibril assembly is perturbed. In some cases, one allele contains a missense mutation or in-frame deletion, whereas the second allele contains a PTC. The net result of the latter combination of mutations is a reduction in mutant RNA from the PTC allele at the transcriptional level, together with a mutation on the second allele, which is transcribed and presumably translated normally, yet is likely to impact on nucleation and assembly of anchoring fibrils. As a result of these more subtle mutations combined with a PTC on the other allele, mutant full-length type VII collagen molecules may be able to assemble into anchoring fibrils, which are, however, unlikely to be stabilized by disulfide bonding (Fig. 78-2). Thus, these attachment structures, although present, are weakened, resulting in moderately severe fragility of the skin, as observed in the mitis forms of RDEB.

DOMINANT DYSTROPHIC EB: GLYCINE SUBSTITUTION MUTATIONS

In the dominantly inherited forms of EB, the recurrent mutation detected thus far is the substitution of a glycine residue that occurs within the collagenous domain of the molecule characterized by the repeating Gly-X-Y amino acid sequence. Some of these nonfunctional molecules are able to associate with type VII collagen synthesized from the normal allele, through a mechanism known as dominant-negative interference. The glycine substitutions destabilize the collagen triple helix, interfere with the secretion of the molecules, and render them susceptible to intracellular degradation, thus exerting their effect at the posttranslational level. Since type VII collagen is a homotrimer consisting of three identical $\alpha 1$(VII) polypeptides, one out of eight triple-helical molecules (12.5%) is entirely normal, assuming equal expression of the mutant and wild-type alleles. As a result, some normal anchoring fibrils can be formed, consistent with ultrastructural demonstration of thin anchoring fibrils and the relatively mild clinical phenotype in DDEB. In addition to the classical forms of DDEB, we have recently demonstrated glycine substitution mutations in two clinical variants, known as pretibial DEB and Bart's syndrome, proving that these subtypes are indeed allelic to DDEB with mutations in COL7A1.

Collectively, the type and combination of mutations are able to predict, in general terms, the clinical severity and natural history of the disease. Since clinical severity represents a continuum in the spectrum of manifestations, the precise nature of the genetic lesions, their positions along the type VII collagen gene, and the dynamic interplay of the two mutant alleles on the individual's genetic background will determine the precise phenotype of the patient.

REVISIONS IN GENETIC COUNSELING IN DYSTROPHIC EB

As indicated above, the dystrophic forms of EB can be inherited either in an autosomal-dominant or autosomal-recessive fashion. The diagnosis of classic HS-RDEB in a patient with severe, mutilating scarring, with clinically unaffected parents, is usually made without difficulty. Similarly, inheritance of a blistering tendency and a relatively mild scarring phenotype in a vertical pattern, with multiple affected family members in several generations, allows unequivocal diagnosis of dominantly inherited DEB.

The difficulties arise during the diagnosis and ascertainment of the inheritance pattern in patients with a relatively mild phenotype and clinically normal parents. By ultrastructural analyses, these patients often demonstrate the presence, but a reduced number, of anchoring fibrils. Consequently, these cases are often diagnosed as dominant DEB, presumed to be caused by a new dominant mutation or parental germline mosaicism. This diagnosis obviously has serious implications in terms of genetic counseling of the affected individuals. If their disease is truly a new dominant mutation, the risk of their offspring being affected is one in two. In contrast, in case of a recessively inherited disease, the risk of their offspring being affected is approximately as low as in the general population, with the exception of consanguineous matings.

Careful determination of the genotype and mutation analysis of several patients with relatively mild disease and ultrastructurally detectable anchoring fibrils with positive immunofluorescence staining for type VII collagen, has demonstrated that many of them are compound heterozygotes or have homozygous missense mutations inherited in a recessive manner. For example, the first demonstration of type VII collagen mutations in the mitis type of DEB revealed the presence of a homozygous missense mutation, a methionine-to-lysine substitution (M2798K) at the carboxy-terminal end of the molecule. Similarly, in other cases, a missense mutation in one allele, including a glycine substitution in the collagenous domain, together with a premature termination codon mutation on the other allele, can result in mitis RDEB. Finally, our survey of a cohort of over 100 families, in which we have identified distinct COL7A1 mutations, only a few cases appear to be *de novo* dominant mutations at least one of them being derived from the maternal germline.

Based on these considerations, for genetic counseling purposes, it appears appropriate to consider each "new" case as a recessively inherited condition, unless proven to be a dominant mutation by molecular genetic analysis. Reclassification of DEB on the basis of the underlying mutations clearly impacts on the likelihood of the affected individual of having an affected offspring.

APPLICATIONS OF MUTATION ANALYSIS IN PRENATAL DIAGNOSIS OF EB

Precise understanding of the underlying mutations in different forms of DEB has several translational implications in terms of genetic counseling, DNA-based prenatal diagnosis, and gene therapy. Most immediately relevant to the patient care is the development of DNA-based prenatal diagnosis, which can be performed as early as the 10th week of gestation through chorionic villus sampling, or at the 12–15th week of gestation through amniocentesis. In the severe dystrophic forms of EB, such analyses can be performed either by direct mutation analyses or by genetic-linkage approaches, recognizing the fact that no evidence for genetic heterogeneity has been disclosed thus far. These approaches have

already been applied to DNA-based prenatal diagnosis in over 30 families at risk for recurrence of the severe, mutilating form of RDEB. The genetic information also provides the basis for development of preimplantation diagnosis through blastomere analysis, a technological advance that would obviate the necessity of termination of the pregnancy in case of an affected fetus, if elected.

GENE THERAPY APPROACHES FOR EB

Precise understanding of the underlying mutations, and subsequent demonstration of the functional consequences of such mutations at the mRNA and protein levels, are obligatory prerequisites for the development of gene therapy approaches for this group of devastating skin diseases. It is conceivable that several forms of EB are realistic targets for genetic therapies, including RDEB. However, because of the large size of the mRNA for type VII collagen (~9.2 kbp), conventional techniques of introduction of the wild-type cDNA by viral transduction of patient keratinocytes are unlikely to be successful. For this reason, we and others have begun to explore alternative technologies, including direct introduction of genetic material into the skin cells by biolistic particle bombardment, use of ribozyme-mediated repair of mutant mRNAs by targeted *trans*-splicing, and application of chimeric RNA/DNA oligonucleotides for targeted gene correction. Thus, establishing the genetic basis of different forms of EB has provided the necessary foundation for development of gene therapy approaches to counteract these devastating skin diseases in the future.

CONGENITAL DISEASES OF CUTANEOUS TISSUES

PART B:

GENETIC MUTATIONS THAT PREDISPOSE TO CANCER

79 Oculocutaneous Albinism

JEAN L. BOLOGNIA

BACKGROUND

In the premolecular biology era, there were two major clinical forms of oculocutaneous albinism (OCA): tyrosinase-negative (ty-neg) and tyrosinase-positive (ty-pos). Tyrosinase is the key enzyme in the melanin biosynthetic pathway (Fig. 79-1), catalyzing three steps in the formation of melanin: (1) tyrosine to dopa (dihydroxyphenylalanine); (2) dopa to dopaquinone; and (3) 5,6-dihydroxyindole to indole-5,6-quinone. This categorization of patients was based primarily upon their clinical appearance with ty-neg patients having the most severe phenotype, i.e., white hair, gray-blue eyes, and pink skin at birth as well as throughout life. An additional diagnostic test was the incubation of anagen hair follicles with tyrosine to determine the presence (ty-pos) or absence (ty-neg) of melanin deposition.

It is now possible to go beyond the clinical findings and determine if patients have type I OCA (mutations in the tyrosinase gene) or type II OCA (mutations in the *P* gene). However, many questions still remain unanswered including the molecular bases of Hermansky-Pudlak syndrome (OCA plus platelet-storage-granule deficiency) and Chédiak Higashi syndrome (OCA plus abnormal lysosomes)* as well as the role of both melanosomal matrix proteins and tyrosinase-related proteins in the regulation of human melanogenesis.

CLINICAL FEATURES

TYPE I OCA   In this autosomal-recessive disorder, the clinical features are a reflection of the amount of pigment produced in the eyes, hair, and skin. When there is a complete lack of tyrosinase activity caused by loss of function mutations in both copies of the tyrosinase gene (type IA OCA), the individuals have pink skin, white hair, and gray-blue eyes at birth and throughout life (Fig. 79-2). These are the patients who were previously referred to as having ty-neg OCA and, even with increasing age, they fail to produce any pheo- or eumelanin (Fig. 79-1). Of all the patients with OCA, this group is the one that is most susceptible to the development of cutaneous neoplasms, primarily squamous-cell carcinomas.

Because of the total lack of melanin in the retinal pigmented epithelium (RPE) and in particular the fovea (Fig. 79-3), patients with type IA OCA also have very poor visual activity (20/200 to 20/400+) and many are legally blind. In addition, they exhibit marked nystagmus, photophobia, and strabismus. The photophobia is because of the discomfort associated with excess light scatter in a hypopigmented fundus, whereas the nystagmus is more difficult to explain and is perhaps related to misdirected oculomotor reflexes.

As would be expected, some mutations in the tyrosinase gene do not lead to a complete lack of enzyme activity, but rather a decrease in function (type IB OCA). At birth, children with type IB OCA are similar in appearance to those with type IA OCA, i.e., they have white skin and their hair is usually white in color. However, as patients with type IB OCA age, they acquire more pigmentation so that, depending on their racial background, their hair can develop a yellow (pheomelanin)-to-brown (eumelanin) color, pigmented nevi can appear, and a tan can even develop in sun-exposed skin. As with type II OCA *(see below)*, some patients may not have a striking albino phenotype, but they will have the ocular abnormalities characteristic of OCA, e.g., nystagmus and decreased fundal pigment. However, the ocular findings are less severe than in type IA OCA.

Type IB OCA includes those patients who were previously referred to as "yellow mutant" albinos and, for this reason, type IB OCA is sometimes referred to as ym OCA. Yellow mutant OCA was first described in an Amish family in which affected members had hair that was white at birth but became yellow over time. Even before molecular analysis of the tyrosinase gene was done, it was known that ym OCA was allelic to ty-neg (IA) OCA.

The third subgroup of type I OCA has been referred to as temperature-sensitive OCA (type I, ts). This form was first described by King et al. who noted that a patient with OCA had lightly colored hair in warm areas of the body such as the axilla, but darkly pigmented hair in cooler parts of the body such as the leg. This phenotype was analogous to that of the Himalayan mouse or the Siamese cat in which darkly pigmented hairs on the ears, paws, and nose are the reflection of a tyrosinase enzyme that has minimal activity at 37°C, but some activity at 35°C. Because the majority of patients with type I OCA are compound heterozygotes (different maternal and paternal alleles), there are a number of potential combinations (Table 79-1) such that the boundaries between type IB OCA and type I ts OCA have become blurred.

TYPE II OCA   Two observations led to the hypothesis that there was at least one other gene involved in the regulation of

melanogenesis: (1) localization of the tyrosinase gene to human chromosome 11q and (2) the pigmentary dilution seen in some of the patients with Angelman and Prader-Willi syndromes (Fig. 79-4), both of which can be associated with deletions of chromosome 15q11-q13 (the two syndromes are discussed in detail in Chapter 117). Because type II OCA is an autosomal-recessive disorder, patients with type II OCA have mutations in both copies of the *P* gene located on chromosome 15q, but they have no mutations in their tyrosinase genes.

In general, type II OCA is a less severe form of pigmentary dilution as compared to type IA, although there can be an occasional patient with a fairly severe phenotype. As with type IB OCA, the skin, eyes, and hair become darker as the patient ages; however, in contrast to type IB OCA, the hair is usually not white

at birth. The eventual level of pigmentation depends on the racial background of the patient and individuals, especially adults, may go undiagnosed unless compared to first-degree family members. One clinical finding, which can be rather striking when it is present, is the development of multiple solar lentigines, ranging in size from 5 mm to 2 cm.

In Caucasians living in the United States, the incidence of type II OCA is similar to that of type I OCA, approximately 1 in 36,000. However, type II OCA is more common among African Americans with an incidence approaching 1 in 10,000 and, in certain tribes in Africa, the frequency can be as high as 1 in 1100.

TYPES IV, V, AND VI OCA   The designation OCA3 was given recently to an African-American child with "brown" albinism who had no detectable tyrosinase-related protein 1 (TRP-1),

Table 79-1
Relationship Between Genotype and Type I OCA Phenotype

Allele	T^+	t^-	ym	ts
T^+	Normal (T^+/T^+)	Normal (T^+/t^-)	Normal (T^+/ym)	Normal (T^+/ts)
t^-	Normal (t^-/T^+)	IA (t^-/t^-)	IB (t^-/ym)	I, ts (t^-/ts)
y	Normal (ym/T^+)	IB (ym/t^-)	IB (ym/ym)	IB (ym/ts)[a]
ts	Normal (ts/T^+)	I, ts (ts/t^-)	IB (ts/ym)[a]	I, ts (ts/ts)[a]

[a]No patient with the indicated genotype has yet been detected. ym, yellow mutant; ts, temperature-sensitive.

TRP-2 (DC tautomerase)	TRP2/DC	slaty	13	14

DC, dopachrome.

hypoplasia, abdominal wall defects, and mental retardation. However, an explanation for the associated hypopigmentation was not obvious given that only one copy of the TRP-1 gene was deleted in these individuals. Type V (rufous) OCA is characterized by mahogany-red to deep-red skin, reddish-brown hair, and red-brown to brown eyes. This form of albinism has been described primarily in New Guineans and Africans.

Type VIA OCA is better known as the Hermansky-Pudlak syndrome (HPS) and type VIB OCA represents the Chédiak-Higashi syndrome (CHS). In the former, ty-pos OCA is associated with a bleeding diathesis that is caused by a defect in platelet-storage granules. Additional clinical manifestations include restrictive lung disease and granulomatous colitis secondary to deposits of ceroid-like material in these organs. This autosomal-recessive disorder is seen primarily in individuals from the Arecibo region of Puerto Rico and Holland. In the Chédiak-Higashi syndrome, the patients often have silvery-blonde hair in addition to dysfunction of neutrophils and natural killer cells that results in recurrent infections. Abnormally large melanosomes and lysosomal granules are seen in melanocytes and granulocytes, respectively. Unless bone marrow transplantation is performed, patients usually enter an "accelerated phase" characterized by pancytopenia and rarely live beyond the age of 10.

DIAGNOSIS

The diagnosis of type IA OCA can be made on the basis of clinical findings in a child or adult and then confirmed by molecular analysis of the tyrosinase gene. However, the latter is not necessary unless it provides information required for future prenatal screening or genetic counseling of family members. In patients in whom there is some pigment production, albeit reduced, clinical clues (e.g., color of hair at birth) can help to distinguish type IB from type II OCA, but molecular analysis of the tyrosinase gene and the *P* gene is the most exact method for confirming the clinical diagnosis. Of note, in type I OCA, mutations will not be identified in approximately 15% of obligate mutant alleles (personal communication, Richard King).

If there is a clinical suspicion of OCA, but the patient has a rather subtle form of the disease, i.e., one that is associated with a significant level of pigment production, it is important to examine the first-degree relatives and to have an ophthalmologist perform a complete eye examination. In addition, a complete history should be taken in patients with ty-pos OCA with special attention paid to recurrent infections or a bleeding tendency suggestive of either the CHS or HPS. Simple screening laboratory tests for these syndromes include examination of a peripheral blood smear for abnormal lysosomes within leukocytes and performance of a bleeding time.

the product of a gene on chromosome 9p, which is the human homolog of the *brown* locus in the mouse (Table 79-2). This TRP family was discovered during the search for the human tyrosinase gene (Fig. 79-5). Compared to his fraternal twin, this child had diffuse pigmentary dilution characterized by light brown skin and hair. Of note, brown albinism was originally described in Africans and has also been referred to as type IV OCA.

There is a second report of two children with marked hypopigmentation of the skin and hair in association with the 9p– syndrome. The latter is characterized by craniosynostosis, midfacial

Figure 79-5 Comparison of the primary structures of the members of the tyrosinase family. The putative signal sequence (▨, SS), positions of cysteine residues (C), positions of histidine residues (H), possible N-linked glycosylation sites (CHO), putative transmembrane region (▩, TM), and potential cytoplasmic domain (CY) are indicated. Cys I and Cys II are the two cysteine-rich regions of the peptides. Cu I and Cu II are the putative copper-binding sites. The numbers indicate the positions of amino acids in the putative mature proteins. The negative numbers indicate the signal sequences. (With permission from Kwon BS. Pigmentation genes: the tyrosinase gene family and the pmel 17 gene family. J Invest Dermatol 1993;100:134S–140S.)

Other causes of diffuse pigmentary dilution of the skin, hair, and occasionally eyes should be considered and then excluded by lack of associated findings; they include Angelman, Prader-Willi (*see* Chapter 117) and Apert syndromes, phenylketonuria, histidinemia, and homocystinuria. Pigmentary dilution limited to the skin and hair is seen in Menkes' kinky hair syndrome, copper or selenium deficiency, kwashiorkor, and the EEC (ectrodactyly, ectodermal dysplasia, and clefting) syndrome.

Another entity that overlaps clinically with OCA is ocular albinism (OA), a disorder that is inherited in an X-linked fashion in the majority of patients. The gene responsible for the most common form of X-linked OA (OA1; Nettleship-Falls) has been cloned, but its function has yet to be determined. Classically, individuals with OA were said to have the eye, but not the cutaneous, findings of albinism. However, some of the patients were noted to have hypomelanotic macules or a mild generalized pigmentary dilution when compared to unaffected siblings. It is important to note that mutations in the tyrosinase gene and the *P* gene have been described in the smaller group of patients with autosomal-recessive ocular albinism.

Prenatal screening for type IA OCA has been performed successfully following molecular analysis of the tyrosinase genes in amniotic cells; obviously, such an analysis is aided by predetermination of the responsible mutations. In the past, scalp biopsies were performed between weeks 17 to 20 of gestation, and the diagnosis was based on the presence or absence of melanized melanosomes. There are no published reports to date of molecular prenatal screening for other forms of type I OCA or type II OCA.

GENETIC BASIS OF DISEASE

TYPE I Patients with type I OCA have mutations in both copies of the tyrosinase gene located on chromosome 11q. There are five exons in the tyrosinase gene and the entire gene spans more than 65 kbp of genomic DNA. Translation of tyrosinase mRNA results in a 529-amino acid polypeptide, but this includes an 18-amino acid leader peptide that is later cleaved. At least 70
Figure 79-6 Locations of mutations in the tyrosinase gene; the five boxes represent its five exons. Mutations associated with type IA OCA are represented by solid arrows and numbers; mutations associated with type IB OCA are represented by **bold** solid lines and numbers; the mutation associated with type I, ts OCA is represented by a broken line and bold number; and sites of polymorphism are represented by dotted lines and numbers outlined in black. Cu(A) and Cu(B) are the putative copper-binding sites. (With permission from Oetting WS, King RA. Molecular basis of type I [tyrosinase-related] oculocutaneous albinism: mutations and polymorphisms of the human tyrosinase gene. Hum Mutation 1993;2:1–6.)

different mutations have been described in patients with type I OCA and the associated phenotype depends on whether the mutations lead to a lack of enzyme activity vs a decreased level of enzyme activity. Patients with type IA OCA (the most severe phenotype) have no residual tyrosinase activity, whereas patients with types IB and I, ts have decreased or altered tyrosinase activity *(see above)*. The vast majority of patients with type I OCA are compound heterozygotes, that is, the maternal allele and the paternal allele are different; unfortunately, there is no predominant mutant allele in the general Caucasian population.

Several types of mutations in the tyrosinase gene have been described including missense, nonsense, and splice consensus mutations. In addition, some of the patients have had frameshift mutations, but deletions are rare. There are two dimorphic sites that are fairly common in Caucasians, at codon 192 and codon 402 (Fig. 79-6). When the sites of mutations are mapped, there is an
Figure 79-7 A model for the arrangement of the P polypeptide within the membrane of the melanosome; note the 12 transmembrane domains. (With permission from Rinchik EM, Bultman SJ, Horsthemke B, et al. A gene for the mouse pink-eyed dilution locus and for human type II oculocutaneous albinism. Nature 1993;361:72–76.)

obvious clustering near the amino-terminal end as well as the two putative copper-binding sites (Fig. 79-6). Although it seems logical that a mutation near one of the putative copper-binding sites would result in type IA OCA, there is limited supporting experimental evidence. For example, Spritz reported that the only amino acid substitution that involved one of the putative copper-binding histidines was associated with a mild phenotype. Also, an explanation for why amino acid substitutions at other sites result in a total lack of enzyme activity remains theoretical (*see* Type II section, *below*).

Murine tyrosinase cDNA also has been sequenced and mapped to the albino or *c* locus located on mouse chromosome 7. Pigment production has been observed in albino mice following the introduction of a minigene that contained mouse tyrosinase cDNA plus the genomic 5' noncoding flanking region.

TYPE II Type II OCA is caused by mutations in both copies of the *P* gene, which spans 250–600 kbp in chromosome segment 15q11-13 and contains 25 exons. The *P* gene is the human homolog of the pink-eyed dilution *(p)* gene on chromosome 7 in the mouse, and its protein product of 838 amino acids has 12 membrane-spanning domains (Fig. 79-7). The *P* protein was reported to have an approximately 20% homology with a tyrosine-specific transport protein from *E. coli* and given the observation that the *P* protein localizes to the melanosomal membrane, an initial hypothesis was that it was involved in the transport of tyrosine into the melanosome (Fig. 79-8). However, the exact function of the *P* protein remains unknown *(see below)*.

As with type I OCA, the majority of patients are compound heterozygotes. The types of mutations described to date include missense, splice junction, in-frame deletions, and frameshifts. An intragenic deletion of the *P* gene involving exon 7 is a commonly observed mutant allele in Africans with type II OCA. In contrast to the tyrosinase gene, the *P* gene has over 25 nonpathologic DNA sequence polymorphisms. When Caucasians with ty-pos OCA are evaluated, approximately one-third actually have type IB OCA and in 50% of the remaining patients, *P* gene mutations have been found. On the other hand, *P* gene mutations have been observed in at least 95% of Africans and African Americans with type II OCA.

In patients with either sporadic Angelman or Prader-Willi syndrome plus OCA II, one may find a deletion in either the maternal (Angelman) or paternal (Prader-Willi) copy of chromosome 15 in addition to a mutation in the second copy of the *P* gene. Uniparental disomy can also result in this constellation of findings but it is observed less commonly.

TYPE IV (BROWN) OCA (OCA3) The designation OCA3 was given to a patient who was homozygous for a single basepair deletion in the TRP-1 gene located on chromosome 9p. TRP-1 is the most abundant protein in melanocytes and is also known as gp75 (Table 79-2). Until recently, the function of TRP-1 was unknown. However, in 1994, Kobayashi et al. provided evidence that one of its functions is oxidation of dihydroxyindole-2-carboxylic acid (DHICA; Figs. 79-1 and 79-8), thus explaining the associated decrease in pigment production.

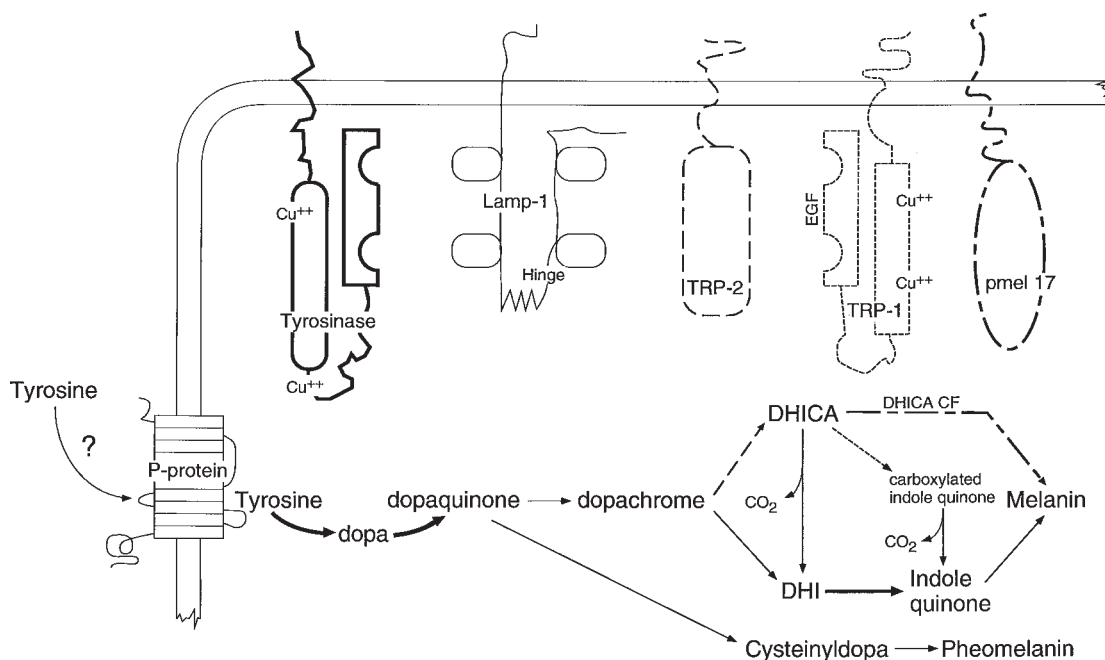
TYPE VIA The gene for HPS has been cloned recently. It encodes a transmembrane protein that may be a component of cytoplasmic organelles. Given the number of loci in the mouse


Figure 79-8 Hypothetical model of protein interactions on the melanosomal membrane. TRP-1, tyrosinase related protein 1; TRP-2, tyrosinase related protein 2; dopa, dihydroxyphenylalanine; DHICA, 5,6-dihydroxyindole-2-carboxylic acid; DHI, dihydroxyindole. (Adapted with permission from Jimbow K, Luo D, Chen H, et al. Coordinated mRNA and protein expression of human LAMP-1 in induction of melanogenesis after UV-B exposure and co-transfection of human tyrosinase and TRP-1 cDNAs. Pigment Cell Res 1994;7:311–319.)

that, when mutated, give rise to both decreased pigmentation and platelet-granule dysfunction, the possibility exists that more than one locus is responsible for HPS.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

Tyrosinase is a member of a family of copper-binding enzymes that includes hemocyanins, which explains why a pigmentary dilution is also seen in patients with Menkes' kinky-hair syndrome in which there are mutations in a copper-transporting ATPase. In patients with type IA OCA, there is a clustering of mutations in the tyrosinase gene near the two putative copper-binding sites (Fig. 79-6). Although this would seem to explain the associated phenotype, proof that amino-acid substitutions in these two regions affect copper binding is lacking *(see above)*. A total absence of enzyme activity can result from nonsense as well as frameshift mutations, but an explanation for why several of the known amino acid substitutions lead to loss of function remains theoretical. Based upon the three-dimensional structure of tyrosinase, one group of investigators proposed that the 5' end (amino-terminus) and the domain 3' of the copper B binding site (Fig. 79-6) are involved in substrate and/or cofactor binding as well as enzyme stabilization.

Several observations led to the proposal that the *P* protein might function as a tyrosine transporter including: (1) incubation of anagen hairbulbs from patients with type II OCA in the presence of excess tyrosine results in pigment production; and (2) the structural arrangement of the *P* protein (multiple transmembrane domains) is characteristic of several prokaryotic transporter proteins and significant sequence homology has been observed. Many of the *P* missense mutations that are within regions of homology occur at conserved residues, whereas mutations that result in a milder phenotype occur at less well-conserved residues. However, attempts to demonstrate abnormalities in melanosomal tyrosine

transport in pink-eyed dilution murine melanocytes have been unsuccessful.

MANAGEMENT/TREATMENT

The earlier in life the diagnosis of OCA is established, the sooner interventions that have an impact on development can be instituted. It is important to assess visual acuity in each child and to provide corrective eyewear as well as access to products that are specially designed for a visually impaired person. An example of the latter is large-print materials and an excellent source for a list of such products is the American Foundation for the Blind. In addition, it is important to identify any eye abnormality such as strabismus that can be corrected either medically or surgically.

Because of the increased risk for the development of cutaneous carcinomas, a sun-protection program needs to be instituted early in life. It has been estimated that, by the age of 18 years, a person has received a majority of his or her cumulative lifetime sun exposure, emphasizing the need for early intervention. Effective measures include avoidance of midday sun, application of sunscreens, and the use of hats and clothing made of tightly woven material. The closer a patient lives to the equator, the more important this aspect of clinical care becomes. For example, in a study of albinos from Tanzania, advanced (>4 cm) cutaneous squamous-cell carcinomas were common among patients in their late 20s and early 30s and less than 10% survived beyond 30 years.

Lastly, genetic counseling should be made available to all families. Prenatal diagnosis of type IA OCA can be performed as outlined above. Because there is currently no treatment that will reverse the major forms of this genetic disorder, both patients and their parents can receive valuable information and support by joining NOAH, the National Organization for Albinism and Hypopigmentation (1530 Locust Street #29, Philadelphia, PA

19102-4415). Allogeneic bone marrow transplantation has been used successfully in patients with CHS and 1-desamino-8D-arginine (DDAVP) has been reported as a potential treatment for the bleeding diathesis associated with HPS.

FUTURE DIRECTIONS

Just as genetic studies in albino mice and pink-eyed dilution mice shed a great deal of light on the molecular pathophysiology of type IA OCA and type II OCA, respectively, so will the studies of brown and beige mice provide insights into types IV and VIB OCA. Given the dysfunction of several organelles including melanosomes, platelet-storage granules, and lysosomes in patients with HPS and CHS, it is anticipated that the protein products of the genes responsible for these disorders will play an important role in the formation and/or function of intracytoplasmic organelles. The genetic mutation in the silver mouse leads to an abnormal melanosomal matrix protein as well as altered pigmentation, and it is possible that a similar situation will exist in humans. Lastly, the slaty mouse has been shown to have a mutation in the TRP-2 gene, whose protein product is dopachrome tautomerase (Table 79-2), an enzyme involved in the melanin biosynthetic pathway that converts dopachrome to DHICA (Figs. 79-1 and 79-8). The human TRP-2 gene has been cloned and is located on chromosome 13. Although the albino phenotype has been rescued in transgenic mice *(see above)*, gene therapy for humans with type IA OCA represents futuristic thinking, especially since the majority of pigment production in the eye occurs prior to birth.

80 Basal Cell Nevus Syndrome

Ervin Epstein, Jr.

BACKGROUND

The basal cell nevus syndrome (BCNS) (nevoid basal-cell carcinoma syndrome, Gorlin syndrome, McKusick MIM 109400) is a rare, multisystem, heritable disorder. Evidence exists for its presence in Egyptian mummies, and cases were described initially a century ago. The association of multiple basal-cell carcinomas with jaw cysts and skeletal abnormalities was well-described by midcentury, and subsequent descriptions have produced an extensive list of phenotypic abnormalities. Case reports by Howell and Caro in 1959 and by Gorlin and Goltz in 1960 focused much more widespread attention on the condition, and more recently the interest of several groups in molecular analysis of the syndrome has stimulated the collection of larger groups of patients and consequent better clinical characterization. Two recent estimates of disease frequency are 1:56,000 and 1:164,000 or greater.

CLINICAL FEATURES

Phenotypic abnormalities affect many organ systems. Individual patients have varying combinations of abnormalities, and intrafamilial variation is prominent. A listing of some of the abnormalities is given in Table 80-1.

SKIN   The most notable skin abnormalities are basal-cell carcinomas (BCCs). These are the commonest human tumor—perhaps a half million are treated each year in the United States, and in sunny areas their incidence plus that of cutaneous squamous-cell carcinomas may exceed the combined incidence of all other cancers. Although the dose–reponse relationship is not straightforward, it is clear that skin damage by sunlight predisposes to BCCs. Thus, they occur frequently on sun-exposed areas and much less frequently on covered sites; they occur more commonly in sunnier areas of the world; they occur commonly in individuals with white skin and seldom in patients with darker skin (although albinos of African or Asian descent are susceptible to their development); and they occur in high numbers in patients who have defective repair of ultraviolet radiation-induced DNA damage (i.e., patients with xeroderma pigmentosum). Typically, BCCs occur in individuals of middle-to-later ages and are one to several in number.

Some individual BCCs in patients with BCNS may have the pearly, translucent, telangectactic, papular appearance of BCCs in sporadic cases but others may appear as tiny tag-like papules that may be so widespread that they are dismissed unless the examina-

tion is quite careful. Histologically they are indistinguishable from BCCs in nonfamilial cases. The role of sunlight in producing BCCs in BCNS patients, like that in sporadic cases, is not straightforward. An active role of sunlight is suggested by the reported earlier age of appearance of the first BCCs in BCNS patients in Australia than in the North West of England (47 vs 4% by age 20), the small numbers of BCCs in black-skinned BCNS patients, and the predominant localization of BCCs on sun-exposed skin sites of patients with BCNS. However, the latter localization is less strict than in patients without BCNS, for the percentage of BCCs occurring in normally covered areas (i.e., not the face and arms) is higher in BCNS patients than in sporadic patients—42 vs 13%. BCCs in BCNS patients have metastasized to the lungs and heart, as in sporadic cases, such occurrences are quite rare. Uncontrollable local invasion is less rare but still very uncommon—4 of 70 patients in one series suffered facial mutilation such as loss of an eye or an ear.

The other very common skin abnormality in BCNS patients is the presence of pits of the palms and soles (Fig. 80-1). These typically appear during the second decade, are 1–2 mm in diameter, and may be made more prominent by soaking the skin in tapwater for 15 min, thus causing swelling of the surrounding normal stratum corneum. The pits are formed by local absence of the stratum corneum. Generally, the epidermis underlying the pits is unremarkable, but BCCs have arisen from them. BCNS patients also have a higher than normal incidence of epidermal inclusion cysts—perhaps 50%. Usually these are histologically unremarkable.

JAW   The most diagnostic extracutaneous abnormality is the presence of one or more cysts in the jaws. These cysts are lined by a stratified-squamous epithelium that produces parakeratotic keratinous debris and may have satellite epithelial cysts and/or islands resembling BCCs. They may be clinically silent and detected only by X-ray examination or may cause localized swelling or pain of the jaw. Their histology closely overlaps that of the odontogenic keratocysts of sporadic cases. Recurrences postoperatively are common—10/16 in one series—and loss or displacement of teeth because of local invasion of bone can occur. Malignant changes (development of squamous-cell carcinoma) in the lining are very rare. These keratocysts can develop at any age but they appear most commonly in the later part of the first decade through the second and third decade, and they are more common in the mandible than the maxilla.

SKELETAL   Calcification of the falx is present commonly in patients—in one report in 100% of patients 20 years of age and older as compared to a percentage that increases with age in nor-

Table 80-1
Diagnostic Findings in Adults with BCNS

50% or greater frequency
  Enlarged occipitofrontal circumference (macrocephaly, frontoparietal bossing, in index cases only?)
  Multiple basal-cell carcinomas
  Odontogenic keratocysts of jaws
  Epidermal cysts of skin
  High-arched palate
  Palmar or plantar pits
  Rib anomalies (e.g., splayed, fused, partially missing, bifid)
  Spina bifida occulta of cervical or thoracic vertebrae
  Calcified falx cerebri
  Calcified diaphragma sellae (bridged sella, fused clinoids)
  Hyperpneumatization of paranasal sinuses
49 to 15% frequency
  Calcification of tentorium cerebelli and petroclinoid ligament
  Calcified ovarian fibromas
  Short fourth metacarpals
  Kyphoscoliosis or other vertebral anomalies
  Lumbarization of sacrum
  Narrow sloping shoulders
  Prognathism
  Pectus excavatum or carinatum
  Pseudocystic lytic lesion of bones (hamartomas)
  Strabismus (exotropia)
14% or less, but not random
  Medulloblastoma
  Inguinal hernia (?)
  True ocular hypertelorism
  Meningioma
  Lymphomesenteric cyst
  Cardiac fibroma
  Fetal rhabdomyoma
  Ovarian fibrosarcoma
  Marfanoid build
  Anosmia
  Agenesis of corpus callosum
  Cyst of septum pellucidum
  Cleft lip and/or palate
  Low-pitched female voice
  Polydactyly, postaxial in hands or feet
  Sprengel deformity of scapula
  Syndactyly
  Congenital cataract, glaucoma, coloboma of iris, retina, optic nerve, medullated retinal nerve fibers
  Subcutaneous calcifications of skin (possibly underestimated frequency)
  Minor kidney malformations
  Hypogonadism in male subjects
  Mental Retardation

Figure 80-1 Right palm of patient with BCNS. The typical, distinctive, 2-mm in diameter pits in the stratum corneum are visible as darker spots.

mal individuals from 10 to 50% between ages 20 and 70. Calcification is more dense, even exuberant, in BCNS patients and is described as lamellar. Other intracranial membranes also may be calcified.

Dysmorphic changes also are reported frequently. One of the most common is an increased head size, but one recent study found increased head size only in index cases and not in their affected relatives. Large supraorbital ridges and wide-set eyes also are reported frequently as part of a characteristic facies. Ribs commonly are abnormal—bifid, flared, fused, hypoplastic, or miss-ing—and rib abnormalities and/or spina bifida occulta of the cervical or thoracic spine occur in approximately 50% of patients. The sternum may be concave or convex, and numerous other malformations have been cataloged. Some patients have a marfanoid habitus, and many adult patients are considerably bulkier than their parents. Phalangeal lucencies were common in one series in which hand X-rays were studied, and sclerotic bone changes resembling those of metastases have been reported.

VISCERAL TUMORS Medulloblastomas are the most serious extracutaneous tumors present in clearly higher frequency in BCNS patients. Like BCCs, they tend to arise at a younger age in BCNS patients than in sporadic cases (most before age 5 and half before age 2, at which age sporadic medulloblastomas are unusual). In larger series of BCNS patients, medulloblastomas have been found in 1–5% of patients, and the incidence of BCNS in patients with medulloblastomas is also 1–5%. BCNS patients with meningiomas have been reported but less commonly than those with medulloblastomas.

By contrast, ovarian fibromas are common, and these tumors frequently are calcified. They usually are asymptomatic and do not interfere with ovarian function. Cysts of the mesentery may be present, sometimes with calcification leading to notable radiological abnormalities. Several BCNS patients have had cardiac fibromas, some with onset in infancy, and in one instance a fibrous histiocytoma became so large as to necessitate cardiac transplantation.

DIAGNOSIS

Diagnosis of the classical case is straightforward, but the phenotypic variability of affected patients and the fact that all of the abnormalities may be seen, albeit less frequently, in otherwise normal individuals may make it difficult to be certain of the diagnosis, even in relatives of patients whose own diagnosis is indubitable. Both of two recent larger series proposed four major diagnostic criteria—BCCs, odontogenic keratocysts, palmoplantar pits, and lamellar calcification of the falx—and minor criteria including rib anomalies, medulloblastomas, cardiac or ovarian fibromas, and several of the other abnormalities listed in Table 80-1. For diagnosis, two major or one major plus two minor criteria are required. Without an inexpensive and sensitive screening for the underlying molecule defect, phenotype-based diagnosis is likely to continue to be difficult for many patients with less than classical findings.

GENETIC BASIS OF DISEASE

BCNS is inherited as an autosomal-dominant trait. New mutations are common (14–81% in one large series, this wide range reflecting the difficulty of being certain that unexamined parents lack all phenotypic abnormalities of the syndrome). The lack of obvious differences in phenotype according to whether disease has been inherited from the mother or the father suggests that imprinting does not underlie the phenotypic variability.

The autosomal-dominant inheritance and the cardinal manifestation of the development of BCCs in higher number and at an earlier age than in sporadic cases suggested to several observers more than a decade ago the possibility that the gene whose mutations underlie the BCNS might be a tumor-suppressor gene and that, like retinoblastomas, BCCs might require two "hits" for their development. Since one frequent mechanism of tumor-suppressor gene inactivation is allelic deletion, A. Bale and colleagues assessed BCCs arising in sporadic cases for such deletions. Indeed, they found a high incidence of loss of heterozygosity at chromosome 9q and then found significant linkage of the inheritance of BCNS to the inheritance of 9q22.3–9q31. This was confirmed rapidly by other groups. Further studies of loss of heterozygosity have confirmed an approximately 50% incidence of loss of this region with relatively little loss at other loci except at chromosome 1q. In patients with BCNS, the copy of chromosome 9q22.3–9q31 lost in BCCs is that predicted by linkage to contain the normal allele. Thus, these tumors are left with a single copy of this region, and that copy is predicted to harbor a nonfunctional allele.

No BCNS kindred has been reported in which the mutant gene fails to map to the same site on chromosome 9q, suggesting that there is a single locus whose mutations underlie all BCNS patients. Subsequent genetic mapping narrowed the region to an estimated 1.8–3.6 cM; YAC-BAC-cosmid contigs spanning the genetically delimited region were assembled; and several groups embarked on a search for isolating genes in this region. This search was capped in 1996 by the simultaneous reports by two groups of mapping of the human homolog of the *Drosophila patched* gene to the genetically defined BCNS region and of mutations of this gene in DNA both from leukocytes of BCNS patients and also from sporadic basal-cell carcinomas. Thus, it appears that this gene functions, at least in the skin, as a tumor-suppressor gene, that patients with the BCNS inherit one defective copy, and that somatic mutations that inactivate in keratinocytes the one functional allele in BCNS patients or both normal alleles in sporadic cases are a crucial step underlying the development of basal-cell carcinomas that arise sporadically. The nature of the mutations described in the skin tumors is consistent with some of them having been caused by ultraviolet radiation, as expected.

The fly *patched* gene has been studied extensively since its identification in 1989. It is a membrane-bound member of a signaling pathway that is critical in development. It acts to suppress expression of several genes, including cubitus interruptus, a member of the GLI gene family (so named because of the identification of GLI as an oncogene in human glioblastomas); *wingless*, a member of the WNT oncogene family; *decapentaplegic*, a member of the TGF-β gene family; as well as *patched* itself. It is opposed in these functions by the secreted product of the *hedgehog* gene. This pathway helps control segmentation and wing development in flies and appears to play analogous roles in vertebrates.

Mutations also have been described in BCCs in the genes encoding sonic hedgehog and smoothened, the other two members

of this pathway that interact with the patched protein at the cell surface. The mutant proteins appear to act dominantly as the products of activated oncogenes, and this identification provides evidence that it is activation of the signaling pathway that determines the abnormal behavior of keratinocytes.

Thus it seems reasonable now to consider the phenotypic abnormalities in BCNS patients in two categories—developmental (e.g., rib and spine abnormalities and generalized overgrowth) and tumors (e.g., BCCs, medulloblastomas, fibromas, cysts) and to consider that the *PATCHED* gene functions in humans embryologically to direct development and postnatally to control proliferation and/ or differentiation, i.e., as a tumor suppressor.

Many questions are raised by this gene identification, and the role of the hedgehog/patched signaling pathway in humans is likely to be a subject of intense investigation during the next several years.

TREATMENT

Individual BCCs in BCNS patients can be treated by the surgical approaches used for BCCs in sporadic cases. The often high number of tumors may make their excision impractical, and, e.g., cryotherapy with liquid nitrogen may be helpful for the many small lesions, especially those that are well-removed from the eye, ear, and other sites where BCCs may be particularly destructive. X-irradiation should be used with extreme caution because BCNS patients clearly are susceptible to X-ray carcinogenesis. Thus, patients successfully irradiated for medulloblastomas typically develop large numbers of BCCs in the overlying skin within a half decade. Also, instances of squamous-cell carcinomas and of fibrosarcomas with metastases have occurred soon after therapeutic irradiation of BCCs.

Several reports have documented significant reduction in the appearance of new BCCs during systemic treatment with 13-*cis*-retinoic acid but typically the side effects at the doses required to inhibit BCC growth eventually become intolerable. Topical retinoic acid and topical 5-fluorouracil may slow the growth of tumors.

81 Xeroderma Pigmentosum and Related Disorders

W. Clark Lambert, Hon-Reen Kuo, and Muriel W. Lambert

INTRODUCTION

Inherited diseases with cutaneous manifestations currently believed to be associated with defective DNA repair and/or chromosomal instability, of which xeroderma pigmentosum is the prototype, are all very rare. The more important of these, discussed here, are listed in Table 81-1. Diseases above the open space are all (mainly) autosomal recessive disorders; those below it, autosomal dominant. Of the recessive diseases, there are four major entities: (1) xeroderma pigmentosum, which may occur together with a distinctive autosomal recessive disorder, Cockayne disease, and the cells of which may show some very similar changes, with failure of complementation, with those of cells from some cases with yet a third disorder, trichothiodystrophy; (2) Fanconi anemia, an important variant of which, lacking only the congenital anomalies characteristic of Fanconi anemia, is the Diamond-Blackfan syndrome (also known as the Estren-Dameshek variant of Fanconi anemia); (3) Ataxia-Telangiectasia, which shares distinctive cell culture but not clinical characteristics with two other disorders, the Nijmegen breakage syndrome and the Berlin breakage syndrome, which complement each other in complementation assays but are otherwise identical; and (4) Bloom syndrome. There is also less-well-documented evidence for defective DNA repair and/or chromosomal instability in a number of other disorders, such as progeria of various subtypes and dyskeratosis congenita.

It is likely that the genetics of some of these rare recessive diseases is much more complex than the simple phrase "autosomal recessive" would imply. A number of cell lines from different ones of these disorders test positive in at least one assay, in which chromosome abnormalities are scored following irradiation in the G2 phase of the cell cycle. This implies that these diseases are indeed related to each other. There is convincing evidence for both intragenic and intergenic genetic heterogeneity within several of these entities. Thus, different involved loci or combinations of involved loci may produce different genetic subtypes of the same disease, or even subtypes of different diseases occurring together. It is possible that the extremely complex nature of chromatin structure, with different proteins often playing more than one role, interacting with each other and possibly partially compensating for any loss or deficiency of one another, may result in specific

diseases being traced only to very severe—or combined—deficiencies in these proteins. Many of the nuclear proteins identified to date as defective in one or more of these diseases are involved not only in DNA repair and maintenance of chromatin stability but also in such other cellular processes as initiation of transcription, DNA replication, and cell-cycle checkpoint controls. This may provide an explanation for some of the pleiotropic features of these disorders. A number of much more common diseases may also be related etiopathologically to less extreme defects in chromatin proteins and nuclear enzymes, but this is yet to be conclusively proved.

XERODERMA PIGMENTOSUM

BACKGROUND Xeroderma pigmentosum is a rare, [usually] autosomal recessively transmitted disease characterized by variable but usually extreme sun sensitivity associated with a marked tendency to develop precancerous lesions and, subsequently, skin cancers at a [usually] very early age in sun-exposed areas of the skin, lips, conjunctivae, and, sometimes, anterior tongue. These changes are absolutely dependent on sun exposure; sun-protected areas do not develop these changes. A subset of patients develop a progressive neurodegenerative disease, not related to sun exposure. The disease is genetically heterogeneous, with eight complementation groups known, labeled A, B, C, D, E, F, G, and V *(see below)*. Individuals in groups A, B, and G are the most sun-sensitive, whereas those in groups A and D are most prone to develop neurological disease. The first description of the disease, under the name "xeroderma" was in 1870 by Moritz Kaposi in a textbook edited by his father-in-law, Ferdinand von Hebra, professor of dermatology at the University of Vienna. Twelve years later he described additional patients and added the term "pigmentosum" to the name of the disease. The first case with neurological signs was described by Dr. Albert Neisser, better known for his work on the *Neisseria* species of bacteria named for him. In 1932, De Sanctis and Cacchione described a severely neurodegenerate case with microcephaly and mental retardation. The term "De-Sanctis-Cacchione syndrome" has subsequently been used to designate cases of xeroderma pigmentosum with a neurologic component. However, we believe that this term should only be applied in cases of severe neurologic deficiency, such as described by De Sanctis and Cacchione, with the remainder simply known as xeroderma pigmentosum with a neurological defect or component.

Table 81-1
Skin Disorders Associated with Defective DNA Repair and/or Chromosomal Instability

Xeroderma pigmentosum
Cockayne syndrome
Some trichothiodystrophies
Fanconi anemia
Diamond-Blackfan syndrome (Estren-Dameshek variant of Fanconi anemia)
Ataxia-telangiectasia (Louis-Barr syndrome)
Nijmegen breakage syndrome
Berlin breakage syndrome
Ataxia-telangiectasia Fresno
Bloom syndrome

Gardner syndrome (variant of Familial adenomatous polyposis [FAP] syndrome)
Turcot syndrome (variant of familial adenomatous polyposis [PAP] syndrome)
Muir-Torre syndrome (variant of the Human nonpolyposis colon carcinoma [HNPCC] syndrome)

Other diseases are also known with less well characterized DNA repair defects and/a chromosomal instabilities

Figure 81-1 Face of a 22-month-old white male with severely sun-sensitive xeroderma pigmentosum. Note early changes, as well as a neoplasm (keratoacomthoma) on the cheek and a dysplastic melanocytic lesion on his nose. (Reproduced with permission from Lambert et al., 1998.)

The study of xeroderma pigmentosum at the cellular/biochemical level has generated many justified "firsts" in the study of human genetic diseases. In 1968, James Cleaver reported that fibroblasts derived from a patient with xeroderma pigmentosum were unable to perform the nucleotide excision type of DNA repair following exposure to short wavelength ultraviolet C light emitted by a germicidal lamp. This finding was confirmed shortly afterwards by Richard Setlow and his coworkers in cultured fibroblasts, and by John Epstein and his collaborators in an in vivo assay carried out in the skin of a xeroderma pigmentosum patient. This was the first indication of a DNA repair defect associated with a human disease. In 1972, Dirk Bootsma and his laboratory modified the autoradiography assay, which had been used to detect defective DNA repair in fibroblasts, to develop a complementation assay, which demonstrated genetic heterogeneity within xeroderma pigmentosum. This was the first such cellular/biochemical assay developed for examination of genetic heterogeneity in a human genetic disease. Rufus Day and his coworkers modified a host-cell reactivation viral assay developed in bacteria and Michael Sideman and Kenneth Kraemer and their colleagues used a further modification of this assay, the shuttle vector assay, to examine DNA repair and mutagenesis in normal and xeroderma pigmentosum cells in culture. In 1982 our laboratory, and in 1988 Richard Wood and his colleagues developed cell-free assay systems for nucleotide excision repair and used them to demonstrate defective DNA repair in xeroderma pigmentosum cell extracts in cell-free systems. The former assay has been used to show defective interaction of xeroderma pigmentosum chromatin protein complexes involved in DNA repair with nucleosomal DNA (i.e., addition of histones to damaged DNA, so as to reconstitute the DNA into nucleosomal DNA, creates a substrate on which normal chromatin DNA repair protein complexes show enhanced activity, whereas the corresponding xeroderma pigmentosum protein complexes show decreased activity on this nucleosomal DNA). The latter system has been used extensively to examine the roles of different proteins and protein complexes involved in several cellular processes, particularly initiation of transcription, and DNA repair, and to determine which of them are defective in different complementation groups of xeroderma pigmentosum. In 1992, Tanaka and his colleagues cloned a gene defective in patients in group A of xeroderma pigmentosum; five other xeroderma pigmentosum "correcting" genes have subsequently been cloned. Many other "firsts" related to cellular/biochemical studies of xeroderma pigmentosum are beyond the scope of this review.
CLINICAL FINDINGS   Xeroderma pigmentosum has a worldwide distribution and has been reported in all major racial groups, including Blacks. In the United States and Europe, and probably most parts of the world, the incidence is approximately 2–4 per 10^6 live births, but it is significantly more common in certain areas, especially Japan, North Africa, and the Middle East. It has also been reported to be especially common among the Bantus of Africa. In Japan, the incidence has been estimated to be about one in 40,000 live births.

Xeroderma pigmentosum typically presents in infancy or early childhood with a sunburn following sun exposure. Less commonly, the child may cry when exposed to sunlight to the extent that this is called to the attention of a physician. Sometimes the initial sunburn may be so severe that the parents are suspected of some sort of child abuse. Depending on the sensitivity of the patient to sunlight and the extent of prior cumulative sun exposure, physical examination shows variable changes consisting of dryness (xerosis), induration, and dyspigmentation consisting of irregularly mottled freckling. The changes are absolutely limited to sun-exposed areas, and a sharp line of demarcation between involved and uninvolved skin is consistently present. As this process progresses, the freckles become larger, very irregular in shape, and some of them become darker. (Fig. 81-1). Areas of hypopigmentation and/or atrophy or scarring as well as telangiectasias also appear. These changes resemble those seen in the photoaging observed in older persons with light-complexioned skin who have undergone chronic sun exposure. They are often accompanied by eye lesions, such as extropion and entropion. A conspicuously absent feature, seen in these people but not in patients with xeroderma pigmentosum, however, is elastosis of dermal collagen.

Figure 81-2 Face of a 29-year-old man with xeroderma pigmentation. Note progression of changes (compared to Fig. 81-1).

Figure 81-3 Face of a 47-year-old woman with xeroderma pigmentosum. Hundreds of neoplasms have been removed, as have both eyes.

As these changes continue to progress, premalignant and, subsequently, malignant skin lesions begin to appear (Fig. 81-1). Solar keratoses and keratoacanthomas usually appear first, followed by basal and squamous cell carcinomas and, sooner or later, melanomas (Fig. 81-2). The melanomas may arise in progressively larger and more irregularly shaped freckles; since there may be hundreds to thousands of these freckles, early detection of melanomas is often difficult. Long survival of severely sun-sensitive cases is uncommon; patients who reach middle age often show numerous neoplasms as well as extensive scarring and loss of tissue due to numerous surgical procedures carried out over the years on limited areas of skin (Fig. 81-3).

A recent review of data obtained by the Xeroderma Pigmentosum Registry has provided the first reliable information regarding the distribution of melanoma and nonmelanoma skin cancers in patients with xeroderma pigmentosum. In both normal subjects and in patients with xeroderma pigmentosum, nonmelanoma skin cancers appear over areas of greatest cumulative sun exposure (Fig. 81-4). In contrast, melanomas appear at sites of intermittent sun exposure, closely correlating to areas exposed to the sun during sunbathing (upper body in men and upper body [sparing the breasts] and legs in women) (Fig. 81-5). These data, which for Xeroderma Pigmentosum Registry patients contrast sharply with those obtained from perusal of multiple case reports of xeroderma pigmentosum in the literature, are consistent with the hypothesis that xeroderma pigmentosum is a valid model for skin cancer in the general population. There are, however, some interesting differ-

ences. Some patients with xeroderma pigmentosum develop multiple carcinomas and only a few melanomas, but others develop numerous melanomas and few or no carcinomas. At least two patients have developed numerous melanomas, which, unaccountably, have failed to metastasize, and another has shown a dramatic response of melanomas to injection with interferon-α. Computerized morphometry has found that the nuclei of melanomas arising in xeroderma pigmentosum patients are smaller and less pleomorphic than those arising in otherwise normal subjects, and in many cases these melanomas arise from solar lentigos, whereas this is rarely the case in melanomas that arise in the general population. Despite these discrepancies, however, these data indicate at least one major difference in the pathogenesis of nonmelanoma vs melanoma skin cancers in both normal subjects and in patients with xeroderma pigmentosum, even though they appear to share the same etiology, ultraviolet light damage due to sunlight.

Skin cancers of all types are about 1000 or more times more frequent in patients with xeroderma pigmentosum and arise about 40 years earlier than in the general population. If patients survive to adulthood they may have had hundreds to thousands removed, with extensive morbidity due to both the lesions, themselves, and the surgery necessary to remove them. Often, enucleation of the eyes is necessary (Fig. 81-3). In addition to skin cancers, premalignant and malignant conjunctival lesions often develop, as well as premalignant and malignant lesions of the lips and anterior tongue (Fig. 81-6). Sooner or later, patients with xeroderma pigmentosum usually die from complications due to these cancers, either from metastatic disease in developed countries or, in more primitive countries where it is impossible to treat so many tumors, from sepsis due to the tumors.

Xeroderma pigmentosum is an extremely heterogeneous disease, both clinically and genetically *(see below)*. Despite the fact that the typical patient shows extensive changes early in life, there are others with much milder disease that develops much more slowly. These patients often present much later in life, and are more difficult to diagnose, than their more typical counterparts.

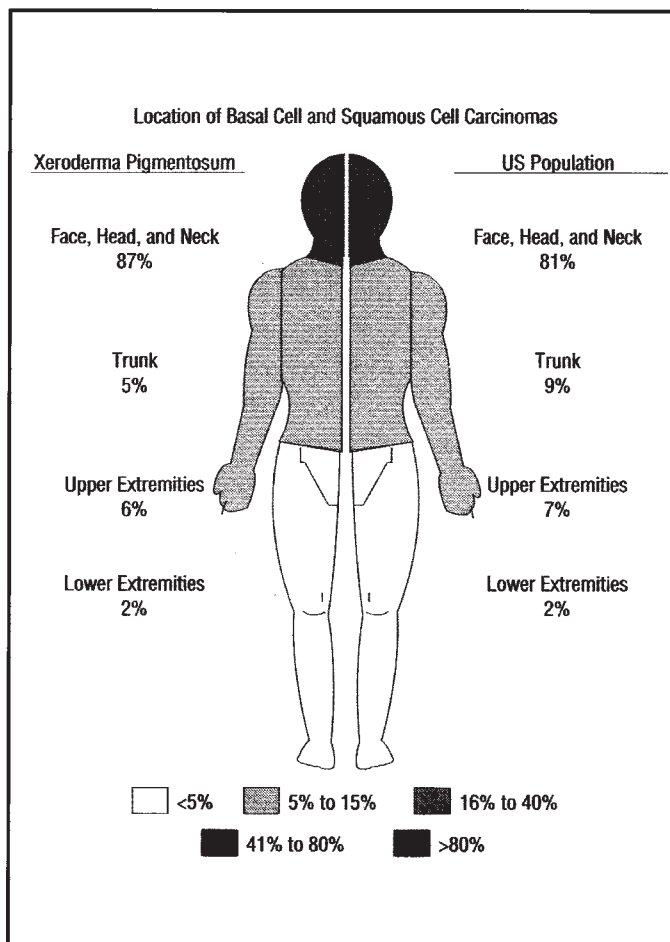
In sharp contrast to the above skin, ocular, and oral stigmata, which are absolutely related to cumulative exposure to ultraviolet


Figure 81-4 Location of basal cell and squamous cell cancers in normal subjects and patients with xeroderma pigmentosum. Data from 401 cancers in xeroderma pigmentosum patients and 26, 817 cancers in the US white population. (Reproduced with permission from Kraemer et al. Arch Dermatol 1994.)

Figure 81-5 Location of melanomas in normal subjects and in patients with xeroderma pigmentosum. Data from 58 cutaneous melanomas in xeroderma pigmentosum patients and 5844 cutaneous melanomas in the general US population. (Reproduced with permission from Kraemer et al. Arch Dermatol 1994.)

radiation, neurologic abnormalities in patients with xeroderma pigmentosum occur independent of any known environmental influence. These changes affect only a minority of patients; most show either no abnormalities or subclinical abnormalities detectable only using special methods. When they do occur, these changes are progressive. The most common abnormality is loss of high-frequency hearing. Also, an abnormality in REM sleep has been reported. In most cases, however, these changes, although progressive, are mild, and the worst that most patients can expect is a need to use a hearing aid. A very small subset of patients with xeroderma pigmentosum shows severe neurologic abnormalities, as well as microcephaly, present at birth. As noted *above*, we believe that the term "De Sanctis-Cacchione syndrome" should be reserved for these unfortunate patients. Severe mental retardation is usually present. A few patients with xeroderma pigmentosum also have evidence of a second inherited disease with neurologic signs, Cockayne syndrome, as discussed *below*.

The most important diagnostic assay, for xeroderma pigmentosum, the unscheduled DNA synthesis (UDS) test, is often not done, simply because it is expensive and not really necessary for the diagnosis in many cases. Even when the test is done, further tests, using fused cells, are needed to establish the complementation group;

and since these tests are also expensive, they are often not performed. Sometimes an assignment of "complementation group" is made based on clinical characteristics and the degree of depression of UDS following ultraviolet light exposure, rather than on tests using fused cells, so that the complementation group assignment is not as definitive as it should be. Nevertheless, despite these limitations, it is possible to state some significant general clinical facts about xeroderma pigmentosum complementation groups, as follows:

Complementation Group A   Patients in this group are severely sun-sensitive, and some but not all of them develop, prior to age 21 years, neurodegenerative disease, which is often severe. Group A is a relatively common complementation group of xeroderma pigmentosum, and is the most common group in Japan.

Complementation Group B   Only three patients in this group, one American and two in the same family in Europe, have been reported. The American patient was severely sun-sensitive, the European patients much less so. All three patients also had Cockayne syndrome.

Complementation Group C   Patients in this group are moderately to severely sun-sensitive but do not usually have neurological disease, although special testing reveals a subclinical hearing loss of high frequency sounds. Group C is probably the

Figure 81-6 Lip and anterior tongue lesions in late xeroderma pigmentosum (same patient as in Fig. 81-3). (Reproduced with permission from Lambert et al., 1998.)

most common group worldwide, and is the most common group found in the United States, Europe, and the middle East. Two patients in this group have shown typical skin changes of xeroderma pigmentosum but have developed only melanomas that have not metastasized, and no other skin cancers.

Complementation Group D Patients in this complementation group have mild-to-moderate sun-sensitivity and typically develop neurodegeneration that is mild and of late onset. It consists mainly of deafness. It is moderately common, comprising about 20% of cases of xeroderma pigmentosum worldwide. A few patients in group D have also had unequivocal stigmata of Cockayne disease. Some patients with an entirely different disease, trichothiodystrophy, have also tested positive for the XP-D trait in the complementation assay *(see below)*.

Complementation Group E Patients in this complementation group have only mild sun sensitivity and are not usually neurologically abnormal or are minimally so. Only a few cases have been reported.

Complementation Group F Most group F patients have been moderately sun-sensitive, with development of only a few skin tumors and no neurologic abnormalities. However, one patient has been markedly sun-sensitive with severe neurological disease. Only a handful of patients have been reported, most of them Japanese.

Complementation Group G Group G patients are severely sun-sensitive. Only five patients have been reported, two of which also had unequivocal stigmata of Cockayne disease. The remaining three did not show clinically evident neurologic defects.

Complementation Group V (Variant group) Group V patients' cells test normal in the UDS assay following exposure to ultraviolet light but can be induced to show low UDS by treatment with caffeine. These patients are moderately sun-sensitive and usually are not neurologically defective. This is a relatively common group, comprising about one-third of xeroderma pigmentosum patients worldwide. It is especially common in Japan.

Dominantly Inherited Cases Two documented families— one Scottish, the other Australian—have shown an autosomal dominant pedigree for a mild type of xeroderma pigmentosum. Complementation studies have not been carried out on these patients' cells.

DIAGNOSIS In children in whom skin tumors have begun to develop, the diagnosis of xeroderma piqmentosum can usually be made with confidence purely on clinical grounds (dry, oddly pigmented, often slightly scaly skin sharply limited to sun-exposed areas, along with the tumors). In younger children, in whom tumors have not yet developed, or in older patients with milder forms of the disease, however, diagnosis may be more difficult. Children with xeroderma pigmentosum can be differentiated from those with other light-sensitive disorders by the usual tests for those disorders. For example, porphyrias can be eliminated by testing for porphyrins in the blood, urine, and feces. Although Gorlin (nevoid basal-cell carcinoma) syndrome may show multiple basal-cell cancers at an early age, the other stigmata of Gorlin syndrome (palmer pits, jaw cysts seen on X-ray) are usually easily recognizable. The dysplastic nevus syndrome may be associated with development of melanoma at a relatively young age, but the numerous dysplastic nevi usually make diagnosis relatively straightforward.

Although, ideally, one would like to perform the UDS assay *(see below)* as well as complementation group analysis on all patients with xeroderma pigmentosum, these tests are expensive, and probably need only be done when the diagnosis is in doubt. A positive UDS test is a highly specific, although not absolutely specific, indication that the patient has xeroderma pigmentosum.

The UDS test is currently performed at the following laboratories:

GENETIC BASIS OF DISEASE With the exception of a few families—one Scottish and one Australian family on which published data are available, a third family in North Carolina, and a possible fourth family in Ohio—in which xeroderma pigmentosum has been transmitted as an autosomal dominant trait, and one pedi-
Figure 81-7   Formation of cyclobutane pyrimidine dimers and (6-4) photoproducts in cellular DNA by ultraviolet light. (From Lambert WC, Andrews AD, German J, et al. Xeroderma pigmentosum. In Thiers BH, Dobson RL, eds. Pathogenesis of Skin Disease. New York: Churchill Livingstone, 1986; pp. 576–599; with permission.)

gree in Italy in which the disease may have been sex-linked, xeroderma pigmentosum has been found to arise in pedigrees consistent with an autosomal recessive condition. The autosomal-dominant cases have all been of mild degree; none have been confirmed by UDS studies or analyzed for complementation group to date. The sex-linked cases were found to complement in xeroderma pigmentosum group A.

It has been known for many years that "classical" cases of xeroderma pigmentosum, those in complementation groups A–F, but not V, are defective in the initial, damage recognition and incision step in the nucleotide incision repair (NER) pathway of adducts introduced into cellular DNA by ultraviolet light. These adducts consist mainly of cyclobutane pyrimidine dimers and

6-4 pyrimidine-pyrimidone linkages, both of which occur between successive pyrimidines on the same strand of the duplex DNA molecule (Fig. 81-7). The dimers have outnumbered the 6-4 photoproducts by a ratio of at least two to one in most studies, but the 6-4 photoproduct causes a much greater degree of distortion in cellular DNA. Cells derived from patients with xeroderma pigmentosum have been found to be defective in repair of both adducts, but not in repair of other adducts due to reactive oxygen species generated by ultraviolet light, such as thymidine glycols, repaired by the base excision repair (BER) pathway.

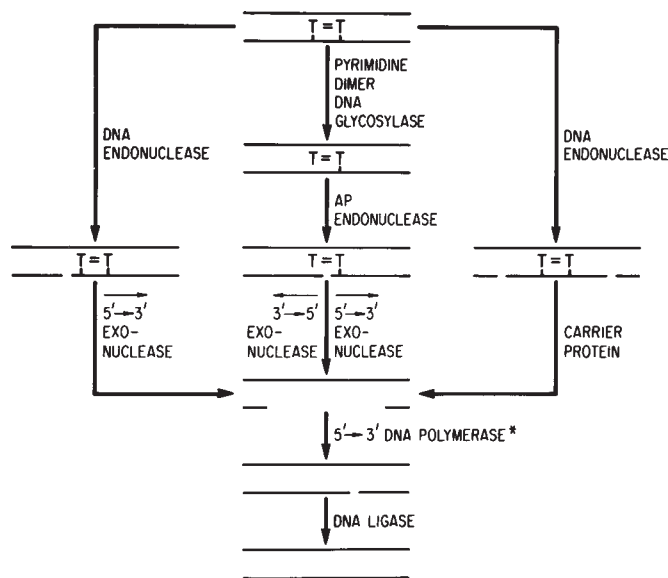
Figure 81-8 outlines the base and nucleotide excision repair pathways in both mammalian cells and in cells of many other species, including yeast and *Escherichia coli*. On the left a mecha-


Figure 81-8 Alternate excision repair pathways proposed for both prokaryotes and eukaryotes. (From Lambert WC, Andrews AD, German J, et al. Xeroderma pigmentosum. In: Thiers BH, Dobson RL, eds. Pathogenesis of Skin Disease. New York: Churchill Livingstone, 1986; pp. 576–599; with permission.)

Figure 81-9 Autoradiograms of normal **(A)** and xeroderma pigmentosum, complementation group A **(B)** fibroblasts following irradiation with UV-C (254 nm) light and treatment with ^{3}H-thymidine. S-phase cells show large numbers of grains (A, lower left, and B, lower right, one cell in each), whereas cells undergoing unscheduled DNA synthesis show moderate numbers of grains (seven cells in A). Xeroderma pigmentosum, complementation group A cells show few or no grains (four cells in B). (From Lambert WC, Lambert MW. Diseases associated with DNA and chromosomal instability. In: Alper JC, ed. Genetic Disease of the Skin. St. Louis, Mosby-Year Book, 1991; pp. 320–358; with permission.)

nism is depicted in which a nick is created by an endonuclease on one side of the adduct, followed by digestion of the part of the same strand containing the adduct by an exonuclease, creating a single strand gap in the DNA. This was once thought to be the way in which mammalian NER proceeded, but is now known to be incorrect. The correct mechanism for NER in both mammalian cells and bacteria is shown on the right of the figure. A nick is made endonucleolytically on both sides of the adduct and the portion of the strand containing the adduct is removed, not necessarily by an exodonuclease. In bacteria this is mediated by the products of the *UvrABC* and *D* genes (called the UvrABC system) and the term "exinnuclease" has been used to describe the resulting combinations of enzyme activities. In mammalian cells and in yeast, these steps are mediated by protein complexes, more about which we shall explore below. The end result is again a single-stranded gap in the double-stranded DNA molecule (Fig. 81-8). In the center of Fig. 81-8 is depicted the base excision repair (BER) pathway in which an adduct, usually a simpler single-base alteration, is removed first by the action of a glycosylase, which removes the adduct so as to create an apurinic/apyrimidinic (AP) site, followed by the action of an AP endonuclease, which cuts the phosphodiester bond at the AP site. The two activities are often present in the same enzyme molecule. This eventuates, again, in the creation of a single-stranded gap in the double-stranded DNA molecule, although it is believed to be a shorter gap than that created by the NER pathway.

Whatever the mechanism, the single-stranded gap that results is then filled in by a DNA polymerase and then sealed by a DNA ligase. This affords a way to assay the process in intact cells in culture, since a small amount of DNA synthesis must occur. Replicative DNA synthesis occurs in a discrete phase of the cell cycle known as S phase, with phases both before and after it, called respectively G_1 and G_2 phases, in which no DNA synthesis occurs. However, when NER or BER are active, a small amount of DNA synthesis, called unscheduled DNA synthesis (UDS) occurs in G_1 and G_2 as well. This can be measured in UV-irradiated cells using a ^{3}H thymidine pulse followed by autoradiography, thus providing a measure of repair related DNA synthesis.

The UDS assay has become the gold standard for establishing a diagnosis of xeroderma pigmentosum in cases where the clinical diagnosis is uncertain. In this assay, a patient's cells are irradiated in culture with ultraviolet (UVB or C) light, pulsed with tritiated thymidine (an exclusive DNA precursor), and subjected to autoradiography. High-grain-count cells are discounted (as S phase cells) and low-grain-count nuclei scored as cells undergoing a limited amount of non–S-phase unscheduled DNA synthesis (UDS). Figure 81-9 shows an example of a normal and abnormal UDS test in fibroblasts; and Fig. 81-10 shows this test in lymphblastoid cells. Recently our laboratory has applied a new computerized image analysis system to these autoradiograms, which has allowed a vast improvement in the results obtained. Figure 81-11 shows a
Figure 81-10 (**A** and **B**) Autoradiogram of human lymphoblastoid cells in culture following 1-h exposure to 1 m*M* methyl methane-sulfonate, a DNA-damaging agent, and labeling with ³H-thymidine. Cells show both scheduled (heavily labeled) and unscheduled (lightly labeled) DNA synthesis. This test, with ultraviolet radiation (UVR) or UVR-mimetic chemicals, is frequently employed in lymphoblasts or fibroblasts to confirm a clinical suspicion of xeroderma pigmentosum. This autoradiogram was examined by direct (transmission) microscopy in which the silver grains appear dark (A) and also by incident polarized light fluorescence microscopy in which the sliver grains appear bright (B), and the two images integrated by electronic image analysis (*see* Figs. 81-11 and 81-12). This eliminates most nonspecific background.

computer-generated image of a UDS assay; Fig. 81-12 shows the results generated from the assay. This system greatly facilitates and improves the accuracy of these assays. The UDS assay is, however, not completely specific; at least one normal person and one individual with hydroa vacciniforme have been found to have very low UDS levels, and, as noted above, a number of patients with trichothiodystrophy have also had low UDS results. Thus the UDS assay must be evaluated in the proper clinical context to be meaningful.

The UDS assay has also been used as the basis for the complementation assay in xeroderma pigmentosum, the first such assay to be developed in human genetics. In this assay, cells from different patients are fused and the UDS assay performed. In cells from different complementation groups, both nuclei show normal or near-normal UDS, which is not seen in cells from either patient fused with themselves (Fig. 81-13). This is interpreted as evidence for genetic heterogeneity. Nuclei of fused cells from patients in the same complementation group fail to show this phenomenon: UDS remains low.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE The correlation between decreased nucleotide excision repair capability and development of skin lesions, especially skin cancer, following ultraviolet light exposure has been demonstrated in several ways. Sun protection leads to avoidance of these cutaneous lesions, which also occur in sun-exposed areas *(see above)*. Within the cutaneous lesions, mutation analysis shows that critical cancer-related genes, such as p53, are mutated with a markedly increased incidence in xeroderma pigmentosum patients. Moreover, these mutations can be traced to the types of adducts produced (and not repaired properly in xeroderma pigmentosum patients) by ultraviolet light. The roles of various products of xeroderma pigmentosum genes in the nucleotide excision repair pathway have recently become elucidated. This has been made possible by several recent developments.

The first development is the successful cloning of several xeroderma pigmentosum "correcting" genes. Successful cloning of the *XPA* gene by Tanaka et al. has been alluded to above. Some other human genes have been identified based on their ability to restore mutant, ultraviolet-sensitive rodent cells to normal following their introduction by artificial means. These genes were first termed ERCC (Excision Repair Cross-Complementing), followed by the number of the rodent cell complementation group (the rodent groups are labeled 1–11) that the human gene can complement. A number of these genes have now been cloned and found to also function to correct ultraviolet light response of cells in a xeroderma pigmentosum complementation group, at which point, by convention, they are renamed *XP* (complementation group) C genes, as *XPAC*, *XPBC*, and so on. Recently the final "C" has been deleted, so that *XPAC* is now *XPA*, and so on (Table 81-2).

The second development has been the improvement of in vitro cell-free systems for examination of nucleotide excision repair. The first of these systems, developed in our laboratory in 1983, has been most useful in elucidating the role of chromatin proteins in enhancing the repair process. The second major system, developed by Richard Wood and Tomas Lindahl in 1988, has been used to examine the role of individual proteins in nucleotide excision repair (NER). Using this system, it has been found that NER in bacteria requires 6 proteins, in mammalian cells at least 30 proteins.

The third major development has been the realization that a major protein complex serving as a regulator of initiation of human RNA polymerase II, called TFIIH, is required for NER, and that NER progresses much more rapidly in the transcribed strand of actively transcribed genes than in other DNA. TFIIH contains the products of the xeroderma pigmentosum-correcting genes *XPB*, *XPD*, and *XPG*. This fact may help to explain why some or all patients in these complementation groups have also had Cockayne syndrome, and why those Cockayne syndrome patients have been of short stature. Furthermore, those patients with trichothiodystrophy who have tested positive in the UDS assay have fallen into complementation group D (most patients) or B of xeroderma pigmentosum.

A scheme for the current concept of how these genes interact in NER has been proposed by Alan Lehmann, as follows (Table 81-2): First, the XPA gene product recognizes and binds to the damaged site in DNA via a zinc-finger domain on the XPA molecule. A
Figure 81-11 Computer-generated image generated from analysis of Figs. 81-9 and 81-10. Virtually all background has been eliminated and accurate counts of 0 to several hundred grains per nucleus may be obtained.

different domain on this same XPA protein molecule also binds to the single-stranded DNA binding protein, RPA (also known as SSB). Second, the XPA and RPA proteins act together to recruit the large TFIIH protein complex, which contains both the XPB and the XPD proteins. These latter proteins are helicases with opposite polarity, which unwind the double-helial DNA molecule, respectively, 5' and 3' to the adduct, creating a loop or "bubble" in the DNA molecule. Third, two different DNA endonucleases, one consisting of a complex of two proteins, XPF and ERCC 1, and the other consisting of the XPG protein, cut the strand of the DNA molecule containing the adduct on its 5' and 3' sides, respectively. Fourth, DNA polymerase epsilon and accessory proteins, replication factor C (RPC) and proliferating cell nuclear antigen (PNCA), fill in the resulting gap in the damaged DNA molecule. This is the step that produces the UDS phenomenon. Finally, the newly synthesized DNA is joined at its 3' end to the DNA beyond the repair gap by a DNA ligase.

This pattern of activities for the xeroderma pigmentosum gene products is, however, almost certainly quite simplistic, and should be regarded as only a first approximation of the events that occur in NER. Our laboratory, for example, has produced evidence that complementation group A cells are lacking a different product, which functions not in adduct recognition but rather in interaction of the repair proteins with chromatin. Indeed, it appears likely that, for xeroderma pigmentosum and/or some of these other disorders of DNA and chromatin instability *(see below)*, more than one biochemical defect may be necessary to produce the clinical disease. We have proposed a model, corecessive inheritance, which accounts for many of the discrepancies found in these diseases, such as, for example, the finding of a single genetic defect, in the *ATM* gene, in several different complementation groups of ataxia-telangiectasia *(see below)*. This model proposes an overlap in the function of some of these DNA repair/surveillance genes, so that

the product of one can take effect where another may fail. Thus, to clinically have the disease, one must be homozygous for defective alleles (or hemizygous, should a sex-linked gene be involved) at two or more loci simultaneously. This model, should it or something like it prove correct, has profound implications for human biology. For example, it predicts extremely high carrier frequencies for these defective alleles in the general population (Fig. 81-14), so that the genes responsible for these very rare diseases may also play important roles in the etiopathogenesis of common disorders, such as cancer, ageing, and even age-related neurodegenerations. This model is by no means accepted as proven or even probable, however. It may, for example, be argued that the existence of XP "knockout" (KO) mice mitigates against it. On the other hand, KO mice are generated in inbred strains that have lost nearly half the genetic material present in the wild type, and the phenotypes of these KO mice are incomplete.

MANAGEMENT/TREATMENT Avoidance of sun exposure and vigilant surgical removal of tumors in xeroderma patients are the mainstays of treatment. It is important that surgery be performed with as little loss or destruction of normal tissue as possible, noting a high likelihood that surgery may have to be performed in the same site again and again, as malignancies continue to arise.

Particularly in severely affected small children, there is usually an interval in which skin damage due to sun exposure is evident in xeroderma pigmentosum patients, yet skin cancers have either not yet appeared or have just begun to appear. Parents at this time are hopeful that this situation may persist, but it rarely does. At this time they are loath to believe the dire prognosis their physicians present to them, and are extremely vulnerable to proponents of "alternate medicine," further compounding their problems and often draining their pocketbooks. Moreover, even if sufficient sun protection is afforded to prevent acute discomfort, this may be
Figure 81-12 Unscheduled and scheduled (S phase) DNA synthesis in a lymphoblastoid cell line, derived from a normal individual, treated with progressively increasing doses of the DNA-damaging agent and mutagen, methyl methansulfonate (MMS). This plot was computer-generated based on grain counts and cell morphology analysis of autoradiograms of cells incubated for two hours in ^{3}H-thymidine following a 1-h exposure to MMS, performed in our laboratory using data generated by the Leitz Quantimet 500 Plus Image Analysis System (Leica, Cambridge, UK). The back plane corresponds to untreated cells; the front plane to cells treated with 3 m*M* MMS. On the far left, the proportion of cells with 0–25 grains, indicating little or no DNA synthesis, is seen. On the right, a ridge, indicative of the population of cells in S phase, each showing multiple grains, is seen. Between them is a trough in which there is overlap between low-labeled S-phase cells (mostly cells entering and leaving S phase during the radiolabeled thymidine pulse) and cells undergoing UDS. (For this reason, in this experiment, UDS was measured as loss of cells from the unlabeled population on the far left.) In untreated cells, approximately 35% of the cells showed little or no DNA synthesis (a). With progressively higher doses of MMS, this proportion fell to near zero as non–S-phase, intephase cells underwent UDS, making a modest amount of new DNA (b). At still higher doses of MMS, cells lost viability and were unable to synthesize DNA by either mechanism (c, d, and e). At the same time, cells in S phase, making large amounts of DNA progressively diminished their rate of replicative DNA synthesis (f in untreated cells to g in cells treated with 3 m*M* MMS). Determinations were made at 0.0, 0.1, 0.5, 1.0, 1.5, 2.0, 2.5, and 3.0 mM MMS with over 2500 cells counted. (Reprinted with permission from Lambert et al., 1995.)

insufficient to prevent the appearance of tumors later. Conversely, parents with limited resources and/or other healthy children may elect to limit the special care that they afford the child with xeroderma pigmentosum. These are difficult choices that only the family can make, and there is usually no correct or incorrect solution.

Several other modes of treatment are emerging, but they remain experimental at present. High-dose retinoids have been shown to retard rates of tumor growth. They also produce a "phasing" effect, allowing multiple tumors to be removed at one time. These high doses, however, are not without side effects, especially bone abnormalities. Application of bacterial DNA repair enzymes via topically applied microcoeles, which allow penetration of the superficial cornified layer of the skin, are also a promising
Figure 81-13 Complementation assay (UDS, fibroblasts) showing a heterokaryon (fusion product of one cell from each patient) with normal UDS and a homokaryon (fusion product of two cells from one patient) with depressed UDS. (Courtesy Dr. H. Takebe.)

approach. Dermabrasion of the skin has also been recently applied, with some success. Finally, surgical replacement of severely damaged skin by undamaged skin has been done in selected cases with some success (Fig. 81-15). Even though the replaced skin is still sun-sensitive, the accumulated mutagenic damage has not occurred, and new tumor growth is very much diminished.

In families with an affected child, prenatal diagnosis should be done whenever possible, and acceptable to the parents.

FUTURE DEVELOPMENTS   Improved prenatal diagnosis of xeroderma pigmentosum using cloned genes or even in vitro selection of nonaffected embryos may become possible in the near future. Effective gene therapy, possibly using cutaneous application of corrective genes in vehicles such as microcoeles, may make it possible for patients with this disease to live nearly normal lives. If these genes play important roles in the etiopathogenesis of more common diseases, screening of the normal population for these defective alleles may allow earlier diagnosis of some of these diseases to be made. In any case, further studies on xeroderma pigmentosum are certain to provide additional information regarding human DNA repair processes and chromatin biology.

ATAXIA-TELANGIECTASIA (LOUIS-BARR SYNDROME)

BACKAROUND   Ataxia-telangiectasia is an uncommon disorder characterized by development of large telangiectatic lesions on the conjunctivae and face, progressive cerebellar ataxia and other neurological deficiencies, immunological defects, and marked hypersensitivity to ionizing radiation. Although the first report of this disease is attributed to Madame Louise Barr in 1931, it may have been described earlier.

Peripheral blood lymphocytes of these patients show somatic translocations, primarily involving chromosomes 7 and 14. Cultivated cells derived from these individuals show a tendency for chromosomes to fuse at their telomeres and defective cell cycle checkpoint controls, especially following exposure to ionizing radiation.

[b]ERCC1 and ERCC11 are candidates based on recent studies in cell-free systems.
From Lambert WC, Lambert MW. DNA repair deficiency and skin cancer in xeroderma pigmentosum. In: Mukhtar H, ed. Skin Cancer, Mechanisms and Human Releance. Boca Raton: CRC, 1994, with permission.

The disease is transmitted as an autosomal recessive disorder with four complementation groups, A, C, D, and E, currently recognized, although a number of others have also been proposed. In 1995, an international consortium identified a single gene, known as the *ATM* (Ataxia-Telangiectasia Mutated) gene, which, surprisingly, is mutated in patients in all of these complementation groups as well as some other patients with ataxia-telangiectasia not assigned to a specific group.

Heterozygotes for the *ATM* gene are believed to be at increased (two - to threefold) risk to develop certain types of cancer, particularly breast cancer in women. The breast cancer risk in these women has been proposed to be four to five times that of women in the general population, and it has been estimated that the *ATM* gene is responsible for approximately 8% of human breast cancer. However, some studies have shown lower associations between ATM gene carrier state and breast cancer, and the subject is controversial.

Three related diseases—The Nijmegen breakage syndrome, the Berlin breakage syndrome, and ataxia-telangiectasia Fresno—have clinical or cellular features closely related to those of ataxia-telangiectasia.

CLINICAL FEATURES Ataxia-telangiectasia is by far the most common entity among those discussed in this chapter, affecting approximately one individual per 30,000 live births. The pedigrees of these cases have been consistent with an autosomal recessive mode of inheritance. The Nijmegen breakage syndrome and the Berlin breakage syndrome are both characterized by microcephaly and mental retardation, but by none of the other clinical features of ataxia-telangiectasia. Ataxia-telangiectasia Fresno has clinical features of all of these diseases. If microcephaly, mental retardation, or both are present, this essentially rules out a diagnosis of ataxia-telangiectasia. However, a patient with ataxia-telangiectasia may appear to be retarded when in reality he or she is only socially repressed.

The first sign of the disease is invariably ataxia, which typically begins at about the time the child learns to walk and is progressive, so that by the age of 10 years the patient usually requires a wheelchair. The ataxia is truncal and of cerebellar type. It initially affects gait but later is of intention type as well.

A second, also very characteristic clinical finding in ataxia telangiectasia is ocular apraxia. When a patient is asked to follow an object moved across the visual fields with his or her eyes, the head is turned to follow the object, the eyes following afterward.

The characteristic telangiectatic oculocutaneous stigmata of ataxia-telangiectasia often appear years later than the neurologic signs, but by the age of 10 years almost all patients have markedly dilated, thin-walled blood vessels visible over the bulbar conjunctivae. These large vessels contrast sharply with the finely telangiectatic rash seen over the face of patients with Bloom syndrome, and do not show blistering, ulceration, or any association with sunlight. These dilated vessels are often also present on the eyelids, the bridge of the nose, on the pinnae of the external ears, and, less commonly, over the antecubital and popliteal fossae.

In addition to these stigmata, very young patients may also, occasionally, show a few gray hairs and hypertrichosis, the latter especially over the forearms.

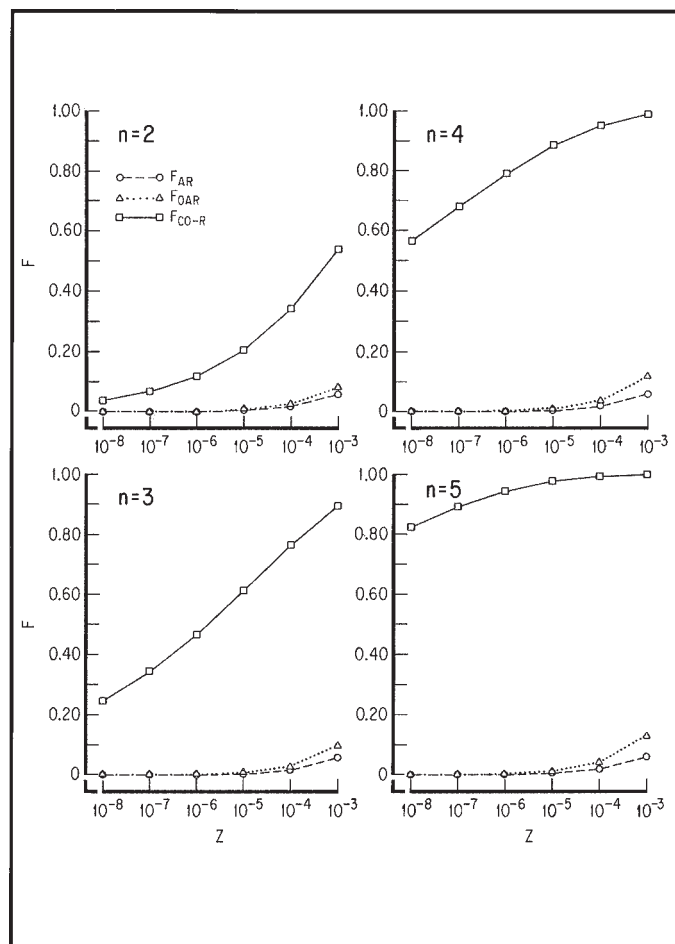
Ataxia-telangiectasia patients are markedly prone to develop malignancies involving the lymphoid system. About 75% of these are lymphomas, most commonly B-cell lymphomas. These often occur in young patients; of the approximately one-fourth of these malignancies that arise later, most are leukemias, usually of the T-cell chronic lymphatic type. Often the malignant cells show


Figure 81-14 Carrier frequencies in the general population for defective alleles for DNA repair and chromosomal stability genes associated with xeroderma pigmentosum and related disorders predicted by the classical autosomal recessive (AR) and corecessive inheritance (C-RI) models. n, number of genes. (For C-RI: number of equally prevalent autosomal recessive genes which must be homozygously defective for the disease to be observed.) Z, proportion of live births in which the disease is present; F, frequency (1.00 is 100% for the population) who are carriers; F_{AR}, for AR; F_{OAR}, for oligogenic AR (i.e., AR with complementation groups); F_{C-RI}, for C-RI. inversions or translocations involving chromosome 14. Nonlymphoid malignancies, when they occur, almost always are found in older patients with ataxia-telangiectasia.

These patients are extremely radiosensitive, and may even develop an erythematous rash or other symptoms after diagnostic X-ray examination. Occasionally a patient develops a leukemia or lymphoma prior to being diagnosed with ataxia-telangiectasia. This may lead to administration of a dose of X-irradiation or of one or more chemotherapeutic agents that are contraindicated in ataxia-telangiectasia. The results are usually dramatic and tragic. It is imperative that the diagnosis of ataxia-telangiectasia be considered, and appropriate diagnostic steps taken, if necessary, prior to treating a very young patient for cancer.

Although some type of immunodeficiency is present in most patients with ataxia-telangiectasia, there is great heterogeneity in both type and degree of this between patients and often even

between siblings. Four-fifths of patients have decreased serum levels of IgG2, IgE, or IgA. Although blood T-cell counts are often normal, T-cell responsiveness to mitogens or allogenic cells is often low. At autopsy, the thymus is typically rudimentary.

About 95% of patients with ataxia-telangiectasia have elevated levels of α-fetoprotein in their sera. The 5% of patients who do not have this abnormality do not appear to differ from those that do in any other respect. In 5–10% of peripheral blood lymphocytes of most patients with ataxia-telangiectasia, there is a translocation involving chromosomes 7 and 14. Skin fibroblasts do not show these characteristic translocations.

DIAGNOSIS   If early onset cerebellar ataxia, ocular apraxia and the characteristic telangiectasia of the bulbar conjunctive are all recognized, the diagnosis of ataxia-telangiectasia may be considered to be virtually established. In these cases laboratory tests are simply confirmatory. In cases in which not all of these signs are present, however, the laboratory plays a more important role. This is rather frequently the case in young children, since the telangiectatic eruption often arises years later than the ataxia and ocular apraxia. The indicated tests are serum α-fetoprotein and immunoglobulin determinations, and karyotyping and radiosensitivity assays on mitogen-stimulated peripheral blood lymphocytes and/or cultured cells. Tests for radiation-resistant DNA synthesis may also be done, but are usually a research procedure. The recent cloning of the *ATM* gene *(see below)* may soon provide molecular assay for this disease, but this is not yet available.

α-Fetoprotein levels are elevated in about 95% and serum IgE, IgG2, or IgA levels are depressed in about 80% of patients with ataxia-telangiectasia. As for most clinical laboratory tests, these studies should be done at least twice.

Cytogenetics assays of mitogen-stimulated peripheral blood lymphocytes may be complicated by the fact that ataxia-telangiectasia lymphocytes do not show an optimal mitogenic response to phytohemagglutinin. Thus a cytogenetics laboratory may return a report of "no metaphases observed." To avoid this, the laboratory should be advised to use at least one additional (higher) dose of phytohemagglutinin in separate cultures and also to harvest some of the lymphocyte cultures at 72 h rather than 48 h. This will allow metaphases to be visualized in most cases of ataxia-telangiectasia.
Figure 81-16 Chromosome preparation of a metaphase cell from a patient with ataxia-telangiectasia. Note fusion of telomeres (arrows).

Karyotypes of ataxia-telangiectasia cells show abnormalities, especially telomere–telomere linkages (Fig. 81-16). Most ataxia-telangiectasia patients' peripheral blood lymphocyte karyotypes show translocations between chromosomes 7 and 14 in 5–10% of metaphases examined.

Survival studies of cells derived from patients suspected of having ataxia-telangiectasia following radiation or other treatments are not routine procedures in most centers, but can provide valuable information when available. Colony-forming ability (CFA), colony survival assay (CSA), and cloning efficiency (CE) assays of peripheral blood lymphocytes irradiated with 1 Gy of X-irradiation typically show CFA values in ataxia-telangiectasia cells that are less than 20% of control levels and also less than 20% of levels of ataxia-telangiectasia heterozygotes. In some assays, heterozygote cells may show levels of activity intermediate between those of normal and those of homozygote cells.

Prenatal diagnosis is an extremely important aspect of diagnosis in a family in which a child with ataxia-telangiectasia has been identified. Until very recently the standard technique has been based on haplotype analysis of chromosome band 1 lq.22.3 in both parents and the affected child, to determine which is associated with the defective ataxia-telangiectasia gene, and then testing the DNA of the fetus, obtained either from amniocytes or from chorionic villus cells, to identify which of the parents' haplotypes have been inherited. This is then compared to the haplotypes of the affected sibling. An estimate of the likelihood of the fetus being affected is then computed. This procedure has provided extremely accurate prenatal diagnosis, due to the fact that the gene has been very well localized. Now that the *ATM* gene has been identified and cloned *(see below)*, prenatal diagnosis should become simpler and even more accurate.

GENETIC BASIS OF DISEASE Pedigrees of individual families of patients with ataxia-telangiectasia have consistently shown an autosomal recessive pattern of inheritance. However, an exten-

sive epidemiologic study of incidence of ataxia-telangiectasia in a defined region of central-north England produced data that could not be well-fitted by any inheritance model. Subsequent examination of those reported data by two of us (WCL and MWL) indicate that they may be fitted by the corecessive inheritance model *(see above)*. However, there may be other explanations for these findings.

Cells in culture derived from patients with ataxia-telangiectasia—as well as those from patients with the Nijmegen breakage syndrome, Berlin breakage syndrome, and ataxia-telangiectasia Fresno—show a number of distinctive features: Peripheral blood lymphocytes, but not skin fibroblasts, show inversions and recombinations in chromosomes 7 and 14 in 5–10% of metaphases. All cell types tend to show chromosome breaks and a tendency of chromosomes to fuse at their telomeres (Fig. 81-16). All cells are radiosensitive and, in some but not all assays, cells derived from ataxia-telangiectasia heterozygotes show an intermediate level of radiosensitivity between that of normal cells and ataxia-telangiectasia cells. The increase in stability of p53 seen in normal cells after irradiation is significantly delayed in ataxia-telangiectasia cells and fails to reach normal levels. Ataxia-telangiectasia cells show additional breaks and other abnormalities in their metaphase chromosomes following irradiation, in excess of those seen in normal cells. Unlike normal cells, ataxia-telangiectasia cells fail to slow their rate of DNA synthesis following X-irradiation, a distinctive phenomenon termed by Painter and his colleagues "radiation-resistant DNA synthesis" (RRDR); several cell-cycle checkpoint controls, including G_1 and G_2 checkpoint controls, are defective. This phenomenon (RRDS) has been used, in fused cells, to identify complementation groups in ataxia-telangiectasia. Nuclei of cells fused from different individuals with ataxia-telangiectasia, which separately show RRDR, show normal responses to X-irradiation when the patients are in different complementation groups, but show RRDS when they are in the same group. On this basis, four complementation groups of ataxia-telangiectasia have been proposed; A, C, D, and E. What was formerly group B has been incorporated into group A. Not all of the cellular studies have produced unequivocal results, however, and additional groups have been proposed. In addition to these groups, cells from patients with the Nijmegen breakage syndrome and the Berlin breakage syndrome have been found to show similar changes in culture to those of ataxia-telangiectasia cells, but complement both each other and all ataxia-telangiectasia cell lines tested in the RRDS complementation assay. Therefore cells derived from patients with the Nijmegen breakage syndrome and the Berlin breakage syndrome are said to be in ataxia telangiectasia complementation groups V1 and V2, respectively. The complementation group analysis is essentially the only criterion that separates these latter two disorders, which are otherwise very similar in both clinical and cell culture characteristics, although different in the former from ataxia-telangiectasia.

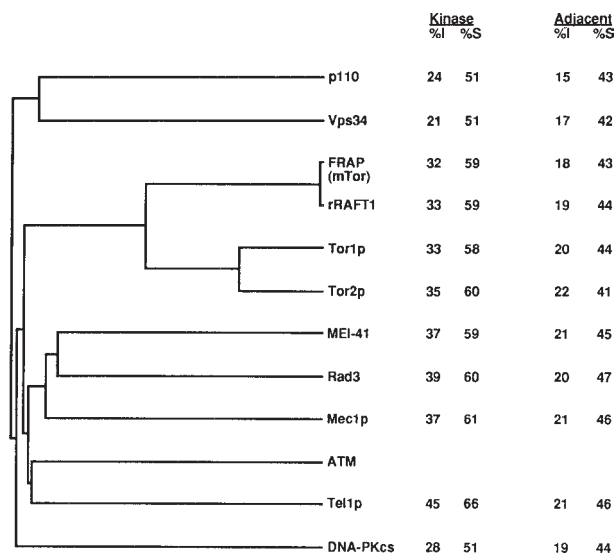
In 1995, a large, international consortium of coinvestigators isolated and cloned a gene, which they termed the *ATM* (Ataxia-Telangiectasia Mutated) gene, which was found to be defective in each of a large group of ataxia-telangiectasia cell lines examined. Surprisingly, the *ATM* gene was defective in cells derived from patients in each of the four well-characterized complementation groups. They attributed this result to intragenic complementation, but the issue has not been resolved. They did not, in fact, explore this issue in any sort of detail, and consequently did not consider that defective alleles at one or more other genetic loci, in


Figure 81-17 Sequence homology of the COOH-terminal region of the human *ATM* gene with other members of the PI3K family. At the right the % identity (I) and similarity (S) of both the kinase domains and the adjacent 10³ amino acids is given. (Reproduced with permission from Zakian VA. Cell 1995;82:685–687.)

addition to the *ATM* gene, might be necessary to produce clinical ataxia-telangiectasia.

Based on linkage studies performed to date, the *ATM* gene is unlikely to be associated with either the Nijmegen breakage syndrome on the Berlin breakage syndrome. The *ATM* gene is on chromosome band 1 lq22-23 and has a transcript of 12 kb. Following discovery, it was quickly found to be homologous to a number of other known eukaryotic and prokaryotic genes *(see below)* and was immediately recognized as having a gene product similar to phosphatidylinositol-3-kinase.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE The *ATM* gene product, predicted from its cDNA, was found to have, in the approximately 400 amino acids composing its carboxyl (-COOH) end (believed to have seronine/threonine protein kinase activity), strong homology to a group of proteins in humans and other species known as phosphatidylinistol-3-kinases (PI3Ks). PI3Ks phosphorylate both lipids and—in proteins, serines, and threonines—play a central role in a number of signal transduction pathways, including those that regulate certain cell-cycle checkpoints and such other cellular processes as transport of certain substances across membranes.

Figure 81-17 shows the degree of sequence homology between the predicted *ATM* gene product and a number of products of other genes in the PI3K gene superfamily in various species. As is immediately apparent, the protein products of certain genes, particularly the *Drosophila melanogaster* (fruit fly) gene *MEI41*, the *Saccromyces cerevisiae* (yeast) genes *TEl 1* and *Esr 1/Mec 1*, the *S. pombe* (yeast) gene Rad 3, and the human gene *ATM* share significantly more sequence homology with each other than they do with the other gene products listed. There is also close homology with the products of the *S. cerevisiae* genes *Tor 1* and *Tor 2* and with those of their mammalian homologs, *FRAP(mTor)* and *rRAFT 1*. Slightly less homologous to all of these is the catalytic subunit (cs) of human DNA-protein kinase (DNA-PK), an important DNA repair enzyme *(see below)*. Least homologous to the

other gene products within this group are those of the most homologous PI3Ks known, p110 (bovine) and Vps 34 *(S. cerevisiae)*.

Table 81-3 lists some of the properties of ataxia-telangiectasia cells along with those of cells mutant in the most homologous of these genes, *Tel 1*, *Esr 1/Mec 1*, *Rad 3* and *D. melanogaster MEI41*. Phenotypes of *S. pombe Rad 3-* and *D. melanogaster MEI41-* mutant cells clearly resemble those of ataxia-telangiectasia cells, as do those of *S. cerevisiae* cells mutant in both *Tel 1* and *Esr 1/Mec 1*. All of them are hypersensitive to several DNA damaging agents, including X-irradiation, and all show defective cell-cycle checkpoint controls, particularly following X-irradiation. Interestingly, yeast cells with a truncated mutant form of *Esr 1/Mec 1* but normal *Tel 1* show partial resistance to the lethal effects of X-irradiation when they have one or two extra normal copies of *Tel 1*. Cell lines for which this information is available also show chromosomal abnormalities, particularly defective telomere stability, and these defects are exacerbated by X-irradiation. Human ataxia-telangiectasia cells are hypersensitive to treatment with bleomycin or streptonigrin, hypersensitivities to which are present in *S. cerevisiae* cells only if mutant in both *Tel 1* and *Esr 1/Mec 1*, further reinforcing the idea that both genes together function rather like the *ATM* gene in man. The degree of overlap in these phenotypic characteristics is not perfect, however. For example, all of these nonhuman mutated cell lines are hypersensitive to ultraviolet radiation, whereas most ataxia-telangiectasia cell lines show normal sensitivity to this agent. *Esr 1/Mec 1* apparently has some function in yeast which it lacks in humans, since *Esr 1/Mec 1* mutants are lethal.

The yeast *TOR 1* and *TOR 2* gene products, working together, and their mammalian homologs, FRAP and rRAFT, working together, are required for the G₁ and S phase cell cycle progression in their respective species. DNA-PKcs, when bound to the remaining subunits of DNA-PK, kDa 70 and kDa 80, which together comprise the Ku nuclear antigen important in certain autoimmune diseases, forms an active DNA-protein kinase (DNA-PK). However this binding is in turn dependent on recognition and binding of the Ku subunits to DNA double strand (ds) breaks. Such DNA ds breaks are an important consequence of X-irradiation. DNA-PK is a serine/threonine protein kinase which activates a number of different proteins, including those that modulate certain cell-cycle checkpoints, so as to arrest the cell cycle, and the nuclear protein, p 43, which leads to stabilization of p 53, a tumor suppressor gene product the stabilization of which, following X-irradiation, is delayed in ataxia-telangiectasia cells. Activity of DNA-PK is also important in B and T lymphocytes undergoing V(D)J gene recombination. Thus a defective *ATM* gene, related to the DNA-PK gene, may be responsible for the immunodeficiency seen in ataxia-telangiectasia. Human and mouse *SCID* (Severe Combined Immuno-Deficiency) mutant cells with deficient DNA-PK activity are hypersensitive to X-irradiation, show DNA repair defects, and are unable to support V(D)J recombination. Interestingly, *S. cerevisiae* telomeres also interact with DNA double strand breaks, resulting in cell cycle arrest at the G₂ to M checkpoint.

Notably, DNA-PK does not phosphorylate lipids (such as phosphatidylinositol). It is likely that many or all of the above gene products, except the PI3Ks (p 110 and VPS-34), exert part of their effects by phosphorylation of proteins but not lipids. This further distinguishes them from PI3Ks.

Thus the *ATM* gene is a reasonable candidate to play a role in the pathophysiology of numerous cellular and clinical features of ataxia-telangiectasia. However, much needs to be done to delin-

Table 81-3
Properties of Ataxia-Telangiectasis Cells and of Cells with Mutant Genes with Product Homology to the ATM Gene

eate this. It is notable that the amino (-NH$_3$) end of all of the gene products discussed above are very different, often with little or no homology present. The presence of the same mutated gene in at least four different complementation groups of ataxia-telangiectasia is also yet to be explained.

TREATMENT/MANAGEMENT   Because the ataxia and ocular apraxia usually occur in the first few years of life, whereas the characteristic oculocutaneous telangiectasias often appear much later, at about 6 or 8 years of age, the diagnosis of ataxia-telangiectasia may be suspected as one of several possible causes of the neurologic signs, but not confirmed as the cause, for an interval of as long as several years during childhood. This may complicate management as well as genetic counseling to the family. As soon as possible appropriate cytogenetic studies should be carried out. Once the diagnosis has been made, the patient should be carefully followed during childhood for evidence of development of a lymphoma, especially a B-cell lymphoma in early childhood and a T-cell leukemia later. Older patients should be screened for development of other types of cancer as well. Infections should be treated promptly and aggressively because of the immune dysfunction often present in these patients.

X-ray exposure must be carefully limited, especially therapeutic X-irradiation, as well as chemotherapeutic drugs used to treat lymphomas, which these patients are prone to develop. These modalities are often valuable and useful in ataxia-telangiectasia patients, but at carefully controlled, lower doses.

An underlying ataxia-telangiectasia should be considered in all young patients with lymphoma or leukemia prior to administration of therapeutic X-irradiation or chemotherapy. Obligate heterozygotes and other family members should be advised that the risk of developing cancer in an ataxia-telangiectasia heterozygote may be two to three times that of age-matched normal persons. This risk in female heterozygotes may be as high as five times normal for breast cancer. However, how large this increased risk is, and even whether it is present, are subjects of controversy in the current literature, and patients should be advised of the uncertainty due to this as well.

Since the prime mode of early detection of mammary cancer at present is the mammogram, which uses X-rays (which are also carcinogenic), and since ataxia-telangiectasia heterozygote cells are hypersensitive to X-rays in some (although not all) assays, this may pose a dilemma for female ataxia-telangiectasia heterozygotes. However, since the energy level of the X-rays used in mammograms is extremely low, it would seem prudent for these women to obtain regular mammograms, as well as to practice frequent periodic self-examination of their breasts.

FUTURE DIRECTIONS   Many more studies of the *ATM* gene need to be, and soon will be, done. Why is it defective in all complementation groups of ataxia-telangiectasia? Are other genes involved in the etiopathogenesis of this disease as well? What is the phenotype of *ATM* knockout mice? The answers to these and other questions should be forthcoming.

Perhaps even more important than its use in elucidating the pathophysiology of ataxia-telangiectasia is the role the cloned *ATM* gene is expected to play in delineating the significance of the carrier state for this gene. What proportion of patients who are carriers develop cancer, and what kinds of cancer do they develop? Do the cancers that arise in these patients have a different course, prognosis, or biologic behavior? Is the carrier state associated with an increased sensitivity to X-irradiation or chemotherapy, and, if so, can the effectiveness of radiotherapy and chemotherapy in all patients be improved by culling these patients out and designing different dose regimens for them, with other patients able to receive higher (and thus more effective) doses?

NIJMEGEN BREAKAGE SYNDROME/ BERLIN BREAKAGE SYNDROME/ ATAXIA-TELANGIECTASIA FRESNO

These three disorders all show the same cellular abnormalities seen in ataxia-telangiectasia. However, the first two (the breakage syndromes) have different clinical manifestations (microcephaly and mental retardation, without the neurologic changes or the telangiectatic eye and skin changes seen in ataxia-telangiectasia), whereas ataxia-telangiectasia Fresno shows the clinical manifestations of all three diseases. Presumably all of these entities are associated with a predisposition to develop lymphomas and cancer, but the case numbers reported have been so small that the data base is inadequate.

The term "breakage" in the first two disorders refers to chromosome breakage in their karotypes. They are clinically very similar,

and are separated on the basis of ability of their cells to complement each other in the complementation assay discussed above for ataxia-telangiectasia. Since cells from both breakage syndromes can complement those from all complementation groups of ataxia-telangiectasia they have been assigned their own complementation groups V1, for the Nijmegen breakage syndrome, and V2, for the Berlin breakage syndrome, respectively. Linkage studies indicate that neither breakage syndrome is defective at the *ATM* locus; this should (and presumably will) become elucidated by molecular studies using the cloned *ATM* gene.

BLOOM SYNDROME

BACKGROUND Bloom syndrome is a rare, autosomal recessive disorder characterized by small body size, one or both of two distinctive types of cutaneous lesions, characteristic cytogenetic abnormalities in cultured cells, and a marked predisposition to develop cancer at a young age. The cutaneous eruptions consist of a telangiectatic rash over sun exposed areas appearing in early childhood and more variable hyper- and hypopigmented areas appearing primarily on the trunk. The cancers appear in multiple organs and tissues. Bloom syndrome was first described by Dr. David Bloom, a New York City dermatologist, in 1954.

Of the multiple abnormalities present in cultured cells derived from Bloom syndrome patients (discussed below), the most characteristic are a high rate (about 10 or more times normal) of sister chromatid exchanges and multiple quadriradial figures representing abnormal linkages between two homologous chromosomes seen in cultured cells treated with bromo-deoxy-uridine. In 1995, Dr. James German and his colleagues identified and cloned the gene responsible for these and other anomalies in Bloom syndrome, which they named the *BLM* gene. This was achieved using a new cloning method, somatic crossover point mapping (SCPM) based on the *BLM* gene itself. SCPM should allow extremely rapid and precise localization of a recessive gene responsible for virtually any phenotype identifiable in cultured cells. It thus should be applicable to the study of many other recessively inherited diseases. Therefore, in addition to being of interest in the etiopathogenesis of Bloom syndrome, the *BLM* gene is likely to become an important tool in the study of inherited diseases generally, and to provide a rapid means for gene localization and cloning.

CLINICAL FEATURES Bloom syndrome is extremely rare. As of August 1993, fewer than 170 patients had been entered into the Bloom Syndrome Registry maintained by Dr. James German at the New York Blood Center in New York City.

Small, but proportionate, body size is the most characteristic and consistent sign of Bloom syndrome. Only four of 82 males and three of 53 females in the Bloom Syndrome Registry for whom this information was available as of 1995 had birth weights within two standard deviations of the normal mean. This small size persists throughout life.

Almost as characteristic as small body size is the marked tendency of Bloom syndrome patients to develop cancer at a moderately early age. These cancers are of virtually all types, with 41 carcinomas, 21 leukemias, and 4 sarcomas reported in the 165 individuals in the Bloom Syndrome Registry as of August 1993.

A telangiectatic cutaneous eruption, varying from severe to mild to undetectable, occurs over sun exposed areas, especially of the face where it tends to involve the cheeks and nose in a strikingly "butterfly" distribution (Figs. 81-18 and 81-19). Less commonly, a similar, but milder, eruption is present on the dorsa of the hands and forearms. When the facial rash is severe, it may also
Figure 81-18 Young mother with Bloom's syndrome, demonstrating the typical telangiectatic eruption in a butterfly distribution over the malar eminences and nasal bridge. (From Friedberg EC. DNA Repair. New York: WH Freeman, 1985, with permission; and courtesy of Dr. James German.)

involve the ears, neck, and suprasternal area. In these cases, the shoulders and chest may show a mild telangiectatic eruption as well. This telangiectatic eruption does not involve other areas, however, and a telangiectatic rash on the legs, upper arms, trunk or buttocks essentially rules out Bloom syndrome as a diagnosis. This eruption is not congenital, as once thought, but rather usually appears in the first two years of life. When it is severe, loss of inferior eyelids and blistering of the inferior lip are common. Younger affected siblings often show less severe skin changes, due to being better protected by the parents. The eruption tends to be more severe in boys, possibly accounting for the fact that slightly more boys than girls have been reported to the Bloom Syndrome Registry (94 vs 71 cases). In marked contrast to the sun-damaged skin seen in xeroderma pigmentosum and to the other eruption characteristic of Bloom syndrome *(see below)*, there is no dyspigmentation associated with this eruption. Regardless of whether the eruption is present, Bloom syndrome patients tend to be hypersensitive to sunlight, in areas exposed to sun in infancy, throughout their lives (Fig. 81-20). In other areas, however, they are not particularly sun-sensitive.

The second characteristic cutaneous stigma seen in many cases of Bloom syndrome consists of well-circumscribed areas of (usually) coffee-colored, *cafe au fait* type hyperpigmentation, with or without areas of hypopigmentation, located mainly over the trunk but which can occur anywhere. These areas vary widely in size and shape. The hypopigmented areas are most easily visualized using a Wood's lamp. These changes are more easily detected in dark complexioned and Black patients, and are most often noted in early childhood, rather than in infancy.

Figure 81-19 Young man with Bloom's syndrome. With much less severe "butterfly rash" but present some related lip lesion. (Courtesy of Dr. James German.)

Figure 81-20 Lip of patient in Fig. 81-19. (Courtesy of Dr. James German.)

Immunodeficiency, which is generalized and very variable, is characteristic of Bloom syndrome. Most patients experience at least one severe bacterial pulmonary infection during infancy or childhood, which, if inadequately treated, may lead to severe chronic lung disease. After cancer, this has been the most common cause of death in Bloom syndrome patients. A variable degree of vomiting and diarrhea also occurs during infancy; whether it is related to an immunodeficiency is unknown. This can rapidly produce life-threatening dehydration.

Other, less constant characteristics of Bloom syndrome include a high-pitched voice, a tendency to develop diabetes mellitus, a tendency to have minor anatomic anomalies, mildly restricted intellectual ability, and, in men, small testes and a total failure of spermatogenesis; in women, reduced fertility and a short menstrual life.

DIAGNOSIS The diagnosis of Bloom syndrome usually depends on recognition of the small but proportionate stature in combination with the characteristic telangiectatic facial rash. It is unusual for the diagnosis to be made if these two features are not recognized. The small stature can be detected as in utero growth deficiency. Conversely, if the birth weight is within the normal range and the postnatal height is in the third percentile or greater, it is very unlikely that the patient has Bloom syndrome.

The diagnosis of Bloom syndrome can be confirmed cytogenetically using the Sister Chromatid Exchange (SCE) assay *(see below)*. Because the characteristic telangiectatic cutaneous eruption is not always recognizable, Dr. James German has recommended that cells obtained from the following groups of patients with abnormally small, but proportionate, stature also be examined with this assay:

1. Those with excessive numbers (i.e., more than five) *cafe au lait* macules, especially if hypopigmented macules are also present.

2. Those with unexplained immunodeficiency.
3. Those with an unexplained restriction in intelligence.
4. Those in whom diabetes mellitus develops later than the usual age of onset for Type I and earlier than this age for Type II diabetes mellitus.
5. Infertile men with abnormally small testes for which no explanation can be found.
6. Women with early onset of menopause.
7. Those patients who develop any type of cancer, especially if this occurs at a relatively young age for the type of cancer in question.

Not surprisingly, Bloom syndrome is often misdiagnosed as another type of dwarfism. Of these, it is perhaps most commonly confused with Russel-Silver dwarfism.

GENETIC BASIS OF DISEASE Bloom syndrome is transmitted by autosomal recessive inheritance with no evidence of genetic heterogeneity. This distinguishes it from most of the other major entities (xeroderma pigmentosum, ataxia telangiectasia, and Fanconi Anemia) discussed in this chapter, all of which are genetically heterogeneous.

Cultured cells derived from patients with Bloom syndrome show a number of distinctive features. Some of these are also detected in circulating lymphocytes in Bloom syndrome patients. These abnormalities include chromosome breaks, gaps, translocations, and an increased frequency of intra- and inter-chromosomal strand exchanges. The latter are detected in the Sister Chromatid Exchange assay. The results of an SCE assay on cells derived from a patient with Bloom syndrome are shown in Fig. 81-21. Note the presence of numerous sister chromatic exchanges (SCEs) as well as a balanced (i.e., symmetrical) quadriradial figure, indicative of a recombination event between two homologous chromosomes. These recombinations between homologous chromosomes are responsible for "crossovers" which occur in Bloom syndrome cells, similar to the crossovers between portions of homologous chromosomes that otherwise occur mainly in meiosis. These crossovers are exploited in a novel gene localization technique, Somatic Crossover Point Mapping (SCPM), which has recently allowed identification and cloning of the gene responsible for Bloom syndrome, the *BLM* gene *(see below)*.

Figure 81-21 Chromosome preparation of a metaphase cell from a patient with Bloom syndrome, processed through two cell cycles so as to reveal sister chromatic exchanges. Note the presence of numerous exchanges per chromosome (identified as exchanges between dark and light strands) as well as a homologous chromosome exchange (quadriradial figure) between the long arms of chromosome 1. (Reproduced with permission from Cell cover image, V.83, #4, Nov. 17, 1995.)

Bloom syndrome cells in culture have accumulated markedly elevated numbers of mutations, compared to normal cells, in all loci in which this has been examined. These loci have included both coding sequences for actively transcribed genes and noncoding repetitive DNA.

Bloom syndrome cells in culture show a prolonged generation time and in particular a long DNA synthetic (S) phase. The rate of nascent DNA chain elongation is retarded and the distribution of DNA replication intermediates is abnormal. Bloom syndrome cells also show increased sensitivity to DNA damaging agents, including ultraviolet light, mitomycin C, ethyl methanesulfonate and *N*-nitroso-*N*-ethylurea. However, not all Bloom syndrome cells show these hypersensitivities and they do not show up in some standard assays. Moreover, no defect in a DNA repair pathway has been found in Bloom syndrome cells.

A number of enzymes associated with DNA replication and/or repair have been reported to have abnormal activities in Bloom syndrome cells. These include DNA ligase I, topoisomerase II, thymidylate synthetase, uracil-DNA glycosylase, *N*-methylpurine DNA glycosylase, 0^6-methylguanine methyltransferase, and superoxide dismutase. Interestingly, some but not all Bloom syndrome cell lines have shown these defects, and the nature of abnormalities observed has been very variable. For example, both increased and decreased activities of DNA ligase I have been reported in different cell lines by different authors, and studies on a purified uracil glycosylase from Bloom syndrome cells showed that a number of properties of the enzyme, itself, are markedly abnormal.

In 1994 James German and his colleagues noted that, in Bloom syndrome patients who are the product of nonconsanguineous matings, a proportion of peripheral blood lymphocytes are phe-

notypically normal. Based on this observation they developed a new technique, which they termed "Somatic Crossover Point Mapping" (SCPM). In this system, peripheral blood lymphocytes of Bloom syndrome patients are analyzed very much like progeny meiotic cells, using crossovers to obtain extremely precise mapping information. It allowed rapid localization and then cloning of the *BLM* gene, which is mutated in Bloom syndrome cells. The normal phenotype is produced by a crossover event within this gene between the parental mutations. Previously, conventional methods had already localized the *BLM* gene to chromosome band 15q26.1. The BLM gene encodes a 4437 bp cDNA encoding a 1417 amino acid peptide with homology to the RecQ helicases of *E. coli*.

The SCM technique is extremely interesting because it offers a way to exploit the BLM gene to study other inherited diseases in which the cells show associated phenotypic abnormalities.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE Whether the defective *BLM* gene can account for all of the clinical, cellular, and biochemical abnormalities present in Bloom syndrome is at present unknown; however it would appear to be an excellent candidate for many of them. The *BLM* gene is homologous to the RecQ helicases in *E. coli*; these helicases are a subfamily of DExH box-containing DNA and RNA helicases. Although no universal function for the RecQ helicases has been postulated to date, a number of genes in the DExH family have been implicated in DNA repair processes. The *BLM* gene product may also have homologous functions to those of the yeast *SGS 1* gene. *SGS 1* mutants show slow growth, poor sporulation, chromosomal nondisjunction in mitosis, missegregation in meiosis, and elevated recombination frequencies. Also, an interaction between the *BLM* protein and topoisomerase II has been suggested.

MANAGEMENT/TREATMENT Upon establishing a diagnosis of Bloom syndrome, the physician should immediately notify the Bloom Syndrome Registry (even though the Registry was officially closed several years ago). The Registry (c/o Dr. James German, The New York Blood Center, 213 East 31st St., New York, NY 10023) is a very valuable source of information and support.

Patients with Bloom syndrome should avoid sunlight, although the importance of this is not nearly as great as in xeroderma pigmentosum. The clinician should be constantly on the alert for development of cancer in these patients, paying special attention to such signs as hoarseness or throat pain, mild dysphagia, hematochezia or melena, a breast lump, a positive Papanicolaou smear, abdominal discomfort or pain, intussusception, or convulsions, which might otherwise be given less notice, especially in a young patient. Unless or until the prognosis of leukemia is shown to be better if the disease is diagnosed and treated before symptoms develop, however, periodic hematologic surveillance of children with Bloom syndrome is unnecessary and may be inappropriate.

Since children with Bloom syndrome are of small stature, and also tend to be poor eaters; they should be encouraged but never coerced to eat well, and a vitamin supplement provided each day. Gastric intubation is currently being tried in a few patients, but no long-term benefit has yet been demonstrated.

Growth hormone levels in Bloom syndrome patients have been found to be normal to low normal. Exogenous administration of growth hormone has resulted, in a few cases, in development of cancer, both in Bloom syndrome patients and in other patients. This has tempered enthusiasm for administration of growth hormones to these patients.

Table 81-4
Clinical and Molecular Characteristics of Fanconi Anemia

Complementation group	Relative frequency	Chromosome location of gene	Characteristics of gene product
A	66.0	16q24.3	163 h Dalton protein Primary nuclear localization
B	4.3	Unknown	Unknown
C	12.7	9q22.3	63-kDa protein Primary cytoplasmic localization
D	4.3	3q22-26	Unknown
E	12.7	Unknown	Unknown

Several additional coplementation groups likely.

Counseling of patients and their families, carefully advising them of the nature of the disease, is probably the most important service the physician can provide. It is important that parents of a Bloom syndrome child be advised of the risk of having another affected child should they conceive again.

FUTURE DIRECTIONS   More precise methods for diagnosing Bloom syndrome using the *BLM* gene in molecular assays will now be developed. Also the precise etiopathogenesis of this disease can now be examined in greater detail in molecular studies using this gene.

By inactivating the *BLM* gene in other types of mutant cells in culture, perhaps by using incisional mutagenesis or antisense DNA or RNA, the SCPM method should be applicable to rapid precise mapping of many other genes unrelated to the *BLM* gene.

FANCONI ANEMIA

BACKGROUND   Fanconi anemia is a rare, autosomal recessive disorder characterized by diverse congenital anomalies, a predisposition to develop aplastic anemia, and an increased risk to develop cancer, particularly acute myelogenous leukemia. The clinical features of the disease are quite variable, making a diagnosis on basis of clinical findings quite difficult. This clinical heterogeneity is both interfamilial and intrafamilial. Cases in which no congenital anomaly is recognized, but who nonetheless have cell culture abnormalities and develop bone marrow changes characteristic of Fanconi anemia, are said to have the Diamond-Blackfan syndrome, also known as the Estren-Dameshek variant of Fanconi anemia.

Cells in culture derived from patients with Fanconi anemia show several distinctive characteristics, among which are an increased number, compared to cells derived from normal individuals or first-degree relatives of Fanconi anemia patients, of chromosome breaks in untreated cultures, as well as hypersensitivity to both the cytotoxic and clastogenic effects of DNA crosslinking agents such as mitomycin C, psoralen plus UVA light, and diepoxybutane. The latter property has formed the basis for development of a diagnostic test for the disease in cultured cells, known as the DEB, or diepoxybutane, test. Because the clinical manifestations of the disease are so variable, the definitive diagnosis of Fanconi anemia is currently made based on this test. Five genetic complementation groups, A, B, C, D, and E, have been defined (Table 81-4). It is very likely that several others will be found.

Fanconi anemia was first described in three brothers with congenital anomalies, anemia, and a fatty aplastic bone marrow by Guido Fanconi in 1927. The diepoxybutane test for diagnosis of Fanconi anemia was developed by Arleen Auerbach and her colleagues in 1977. Androgen therapy, one of the clinical mainstays for treatment of hypoplastic anemia short of bone marrow transplantation or gene therapy, was introduced by Nasrollah Shahidi, previously a junior associate of Fanconi. In 1992 one of the genes responsible for Fanconi anemia, the Fanconi anemia [group] C gene, was cloned by Manuel Buchwald and his associates. In 1996 two groups simultaneously reported cloning of the FAA gene. Quite recently, Lin and Walsh and their associates at the National Institutes of Health (US) Clinical Center in Bethesda, MD, performed the first successful gene therapy for Fanconi anemia using the FAC gene.

It has been proposed that Fanconi anemia heterozygotes comprise at least 0.5% of the general population. It has also been proposed that many cases of aplastic anemia without Fanconi anemia may be etiopathogenically related to this carrier state.

CLINICAL FEATURES   The incidence of Fanconi anemia is thought to be similar to that of xeroderma pigmentosum, approximately 2–4 per million live births. The true incidence may be significantly higher, however, with many cases not being diagnosed. The disease appears to occur worldwide in all ethnic groups. It is much more common among Ashkenazi Jews. A recent study showed that over 1% of normal Jewish individuals of Ashkenazi ancestry are carriers of a gene for Fanconi anemia, complementation group C. This would indicate (Hardy-Weinberg law) that matings within this group would produce affected individuals in over 1/40,000 births.

Clinical features seen in some but not all patients with Fanconi anemia include the following: (1) short stature, with over 50% of patients below the fifth percentile in height, sometimes associated with low birth weight or "failure to thrive"; (2) congenital anomalies of the thumb and radius (Fig. 81-22); (3) other congenital musculoskeletal anomalies, including hip, spinal and rib malformations, and scoliosis; (4) congenital structural renal malformations, including agenesis of a kidney, fused kidneys, and misshapen kidneys; (5) hyperpigmented areas on the skin, sometimes resembling coffee colored *cafe au fait* macules. These are often large and irregular in shape (Fig. 81-23); (6) microcephaly; (7) microphthalmia; (8) congenital gastrointestinal malformations, with many patients with no observable internal defects also experiencing digestive problems; (9) hypogonadism; (10) congenital cardiac defects, especially involving the atrial or ventricular septum; and (11) mental retardation, sometimes manifested only as a learning disability without other evidence of mental deficiency. Expression of these features is extremely variable, even between affected siblings; some patients who develop aplastic anemia or acute
Figure 81-22 Hands and arms of patient with Fanconi anemia showing radial deformities. Such deformities are heterogeneous and not present in every patient (courtesy of Dr. N. Shahidi, University of Wisconsin, Madison, WI).

myelogenous leukemia and who have a positive DEB test show none of these features.

Viruses, including those commonly encountered in childhood, particularly the herpes varicella/zoster virus, may elicit abnormal responses in patients with Fanconi anemia, particularly thrombocytopenia and hypoplastic anemia. These viruses include, besides herpes varicella/zoster, parvovirus B 19 (the cause of fifth disease), hepatitis viruses, the Epstein-Barr virus, and cytomegalovirus. Not uncommonly the disease is first suspected and diagnosed based on a child's response to infection with one of these, particularly the former. Since most children are immunized against a number of other viruses, including rubella (German measles), rubeola (measles), mumps, and influenza A, it is unknown whether these viruses might also induce thrombocytopenia or hypoplastic anemia in Fanconi anemia patients. Bacterial infections may also induce thrombocytopenia or aplastic anemia in patients with Fanconi anemia.

In some cases, the diagnosis of Fanconi anemia is only suspected after development of aplastic anemia or, less commonly, myelodysplastic syndrome or even acute myelogenous leukemia. Anemia in Fanconi anemia patients is characteristically macrocytic, often with elevated fetal hemoglobin levels.

Patients with Fanconi anemia should be expected, sometime during childhood or early adulthood, to develop bone marrow failure and/or leukemia. Moreover, especially in patients who survive childhood, there is an increased risk of development of cancer not involving the bone marrow. These, as far as is known, may occur anywhere and may be of any type; especially common are squamous-cell carcinomas of the oral cavity, esophagus, vagina, and cervix uteri.

A more controversial issue is whether patients with Fanconi anemia have an increased susceptibility to oxygen free radicals in their cells and tissues. Hypersensitivity to agents which produce oxygen free radicals has been demonstrated convincingly in Fanconi anemia patients' cells in tissue culture (discussed below), but this hypersensitivity is lost in some of these cell lines after undergoing transformation (immortalization) in tissue culture. These transformed cells continue to test positive in other assays for Fanconi anemia. It has been proposed that patients with Fanconi anemia also show clinical evidence of this hypersensitivity, such as defective responses to bacterial infections, which induce oxygen free radical formation by neutrophils and other inflammatory
Figure 81-23 Large pigmented macule in chest of boy with Fanconi anemia (courtesy of Dr. N Shahidi).

cells, but this evidence can also be explained by other defects in Fanconi anemia cells, as noted above.

Patients with Fanconi anemia eventually require therapy for their disease, and thus develop side effects of this therapy. Most patients receive blood transfusions, leading to a risk of iron overload. Those who receive androgen therapy develop the usual side effects of this therapy, including virilization in females and a risk of hepatotoxicity in both sexes. Increased susceptibility to infection and graft vs host disease are important potential complications of bone marrow transplantation.

DIAGNOSIS   Every author of a report of a large series of cases of Fanconi anemia has emphasized the enormous clinical heterogeneity of the disease, even among siblings and, in one report, even between monozygotic twins. It is thus very difficult to make specific recommendations as to when a diepoxybutane (DEP) test should be obtained. Certainly a patient with congenital anomalies affecting the thumb or radius should be suspected of having the disease, as should a small patient with thrombocytopenia or hypoplastic, macrocytic anemia not due to folate or vitamin B 12 deficiency. Beyond this it is difficult to make a specific recommendation. The DEB test is the gold standard for the diagnosis of Fanconi anemia, and should be carried out whenever the diagnosis is seriously entertained. This test is performed by the following laboratory:
Figure 81-24 Chromosome preparation of a metaphase cell from a patient with Fanconi anemia. Note acentric (a), dicentric (d), and quadriradial (q) chromosomes (courtesy of Dr. N. Shahidi, University of Wisconsin).

New York, NY 10021
212-327-7533

It is strongly recommended that the physician telephone in advance regarding optimal ways to submit samples, which must be live (never fixed) cells.

A more challenging problem is what to do with patients who test negative in the DEB assay but who have other manifestations of Fanconi anemia. Despite the great helpfulness of this test, we do not know for certain that it is 100% sensitive in detecting cases of Fanconi anemia, or 100% specific in excluding patients with other disorders.

The DEB test has been used very successfully to identify affected fetuses in prenatal diagnostic examinations of amniocytes or chorionic villi cells, and should be carried out in all cases where the parents are known heterozygotes. A more specific test, based on a known mutation in the Fanconi anemia C gene, has been used successfully in Ashkenazi Jews to identify heterozygotes *(see below)*.

GENETIC BASIS OF DISEASE Pedigrees of families of patients with Fanconi anemia have been consistent with autosomal recessive inheritance. We are unaware of any reported case in this is untrue or in doubt.

Cultured cells derived from patients with Fanconi anemia are both hypersensitive to killing by agents that produce interstrand crosslinks in cellular DNA and show markedly increased numbers of breaks and other abnormalities in metaphase chromosomes following exposure to such agents. This latter characteristic has formed the basis for the most definitive test for this disease yet available, the diepoxybutane (DEB) assay, in which cells derived from a patient suspected of having Fanconi anemia are exposed to the DNA crosslinking agent, diepoxybutane, and subsequent metaphases arrested and analyzed cytogenetically. Fanconi anemia cells show increased numbers of acentric and dicentric, as well as quadriradial, chromosomes, which result from chromosome breaks, compared to normal cells, both with and without drug treatment, although the increased frequency of abnormalities is much easier to detect in treated cultures (Fig. 81-24). In up to

30% of cases, cells derived from circulating lymphocytes fail to show these abnormalities, which are then detected in cells derived from skin fibroblasts. This is thought to be due to recombination events in the precoursers of the former cell type. If the patient is a compound heterozygote, such recomination could produce phenotypically normal cells doubly mutated or one allele and wild type on the others. With a selective growth advantage, these cells would then become predominant among circulating lymphocytes. Interestingly, the Fanconi anemia cells show a wide range in their numbers of chromosomal abnormalities, although these are consistently outside of the range of numbers seen in normal cells. Despite this variability, the diepoxybutane (DEB) test remains the gold standard on which the diagnosis of Fanconi anemia is made, due to the very variable clinical presentation of the disease, which virtually precludes use of clinical criteria to make the diagnosis in most cases.

In addition to diepoxybutane, Fanconi anemia cells are hypersensitive to other DNA crosslinking agents, including mitomycin C, nitrogen mustard (mechlorethamine), cyclophosphamide, cisplatin, and psoralen plus ultraviolet A (long wavelength) radiation. Elegant cell cycle studies have shown that this hypersensitivity is associated with prolongation of, or arrest in, the G2 phase of the cell cycle. Not only the first G2 phase but also subsequent G2 phases are prolonged after exposure to these agents.

In addition to its use in establishing the diagnosis of Fanconi anemia, the diepoxybutane test is also the basis for a complementation assay in patients known to have Fanconi anemia. Fused cells (heterokaryons) from patients in different complementation groups show numbers of metaphase chromosome abnormalities, following treatment with diepoxybutane or other DNA crosslinking agents, similar to those of similarly treated normal cells, whereas fused cells from patients in the same complementation group continue to show increased levels of chromosome abnormalities following this treatment. In this way five complementation groups, A, B, C, D, and E, of Fanconi anemia patients have now been identified. Initially, Fanconi anemia cell lines were assigned to complementation groups strictly on the basis of whether or not they complemented, in this assay, within group A. Unfortunately, all other cell lines were initially classified as "group B," regardless of whether or not they complemented each other in this assay. In consequence, some of these cell lines, once classified as in "complementation group B," are now in different complementation groups. One example is cell line HSC 62 (GM 13023), once classified as in group B, now in group D. This has led to some confusion in the literature. In reviewing the research literature on Fanconi anemia cell lines, it is important to determine precisely which cell line was examined in each study, and to corelate this information with the current complementation group classification of each cell line. Such a classification is to be found in Liu, et al., Table 1. Since only a rather small number of cell lines have been analyzed by complementation group analysis to date, it is likely that additional ones exist, beyond the five already identified, in Fanconi anemia.

A gene that corrects hypersensitivity to crosslinking agents in Fanconi anemia group C, and therefore named *FACC* now *FAC*, was isolated and portions of it cloned by Manuel Buchwald and his colleagues in 1992, who used this property as a selection method, which hastened the progress of their work. Unfortunately, this has not proved a successful strategy, to date, for isolation and cloning of other Fanconi anemia genes. The *FAC* gene does not comple-

ment Fanconi anemia cells in other complementation groups. The cDNA codes for a protein of 63 kDa, with alternative 5' and 3' untranslated sequences. Examination of available data banks has failed to identify any different human or nonhuman protein with significant amino acid sequence homology. The gene itself appears to be larger than 100 kb and has 14 exons. By *in situ* hybridization it has been mapped to chromosome band 9q22.3. The gene product localizes primarily in the cytoplasm.

A number of specific mutations have now been identified in Fanconi anemia, complementation group C, patients. These include a splice mutation in intron 4 (IVS4+4A to T), which is the predominant mutation in Ashkenazi Jews, and mutations 322delG, Q13X, R185X, and D19SV. Among the Ashkenazi, the IVS4 mutation is associated with much more severe disease than is the 322delG mutation. Alterations introduced into the gene product by site-directed mutagenesis, along with the locations of the Fanconi anemia mutations discovered to date, indicate that the carboxy (-COOH)-terminal portion of the protein is essential for activity. There is no known homolog to the human FAC gene product. The mouse *FAC* gene, found using probes based on the human sequence, is 68% homologous to it. The mouse FAC protein is identical at 65% and similar at 78% of its amino acid residues to the human FAC protein; where examined, it has a similar number of exons.

The FAA gene cDNA codes for a protein of 163 kDa with two overlapping bipartite nuclear localization signals and a partial lencine zipper consensus region. It localizes primarily in the nucleus. Again, examination of available data banks has failed to identify any different human or nonhuman protein with significant amino acid homology. The gene localizes to chromosome 16q24.3.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE The molecular basis for the increased numbers of chromosome breaks and for the hypersensitivity of Fanconi anemia cells in culture to DNA crosslinking agents remains incompletely understood. It has been suggested that both defects may be due to inappropriate activation of the gene rearrangement mechanism, which normally is functional only in T and B cells undergoing final differentiation. Our laboratory has identified two endonuclease complexes in the chromatin of normal cells, pI 4.6 and pI 7.6, which cleave psoralen plus ultraviolet A light induced monoadducts as well as interstrand crosslinks. The complex, pI 7.6, acts primarily on the former type of adduct; the complex, pI 4.6, acts primarily on the latter. Using a molecularly defined substrate DNA in which the adducts were precisely localized, the exact sites of cleavage of these adducted DNAs were determined. The endonuclease complex pI 4.6, from Fanconi anemia group A cells was deficient in ability to incise DNA containing intrastrand crosslinks activity, whereas the complex, pI 7.6, was able to incise DNA containing the monoadducts. This correlates with a higher degree of sensitivity of these cells to DNA interstrand crosslinking agents. Moreover, when normal endonuclease complexes were introduced into these cells by electroporation, repair function, as measured by a computerized UDS assay based on autoradiography, was restored to normal. Fanconi anemia group A cells are also deficient in a DNA binding protein; how this relates to the endonuclease defect is under investigation.

Other laboratories have also identified DNA repair deficiencies in Fanconi anemia cell lines, but results have been inconsistent, perhaps because well-defined systems were not used. At present, the function of the FAC gene product remains unknown.

While it would seem likely that it, too, is active in a DNA damage recognition and/or repair process, this has been thrown into question by the discovery that the FAC protein is mainly localized to the cytoplasm. Even if the FAC protein is primarily cytoplasmic, however, it could still function as a DNA repair enzyme. A number of other proteins that act on DNA, such as some hormone receptors and some enzymes active on DNA, are known to be localized mainly in the cytoplasm, entering the nucleus only when specifically activated to do so. Alternatively, the FAC protein has been reported to bind to the cyclin-dependent kinase, cdc2, suggesting a possible role of this protein in cell-cycle regulation. The function of the FAA gene product, which localizes to the nucleus, is similarly unknown.

In addition to increased sensitivity to both the cytotoxic and clastogenic effects of DNA crosslinking agents, Fanconi anemia cells in culture show at least three additional general features: (1) prolongation, compared to normal cells, of the G_2 phase of the cell cycle (this is in addition to the additional prolongation of G_2 following treatment with DNA crosslinking agents; (2) hypersensitivity to oxygen; and (3) overproduction of tumor necrosis factor (TNF-α). In addition to these features, X-irradiation of Fanconi anemia cells in G_2 also produces increased numbers of chromatic aberrations seen in the following metaphase, a feature Fanconi anemia cells share with a number of other genetic diseases reviewed in this chapter, as discussed above.

Fanconi anemia cells in culture grow very poorly at ambient oxygen levels (atmospheric 20%) but well at reduced oxygen tensions (atmospheric 5%). Cell-cycle/flow cytometric studies indicate that this oxygen sensitivity is associated with the elongation of the G_2 phase also seen in these cells; the G_2 phase becomes shortened at lower oxygen tensions. Even in normal cells, treatment with oxygen or reactive oxygen radicals produces elongation of the G_2 phase. It has been suggested that this effect may be due to interference of oxygen with the function of one or more DNA topoisomerases.

The hypersensitivity of Fanconi anemia cells to oxygen and to reactive oxygen species might be due to one or more of three mechanisms: (1) overproduction of reactive oxygen species in Fanconi anemia cells due to malfunction of the very complex cellular system that controls this rate of production; (2) deficient antioxidant defense mechanisms; or (3) an intrinsic inability of Fanconi anemia cells to tolerate oxygen-induced damage. Data have been reported (from a number of different laboratories) that are consistent with all three mechanisms at work in Fanconi anemia cells. However, not all cell types in Fanconi anemia patients show these deficiencies, or show them to the same extent or in the same way. In erythrocytes and leukocytes of these patients, activities of superoxide dismutase (SOD) are decreased; but in their fibroblasts, activity of at least one SOD, magnesium-SOD, is paradoxically increased. Also, transformation of Fanconi anemia fibroblasts in culture with the SV40 large T-antigenic protein has been reported to cause them to lose their hypersensitivity to oxygen. For these reasons, Liu et al. have argued that oxygen hypersensitivity is a secondary, rather than a primary, effect of mutations in Fanconi anemia genes.

Whether primary or secondary, the hypersensitivity of Fanconi anemia cells in culture to oxygen, and the associated abnormalities in these cells in antioxidant defense mechanisms, has prompted clinical use of antioxidants in Fanconi anemia patients. Following a report that treatment of Fanconi anemia fibroblasts so as to

increase their activity of copper-zinc superoxide dismutase (CuZn-SOD)—an important antioxidant that reduces the oxygen species, superoxide anion (O_2)—decreased the cytotoxic effect of mitomycin C, pilot clinical trials using CuZn-SOD were initiated. These produced results suggesting that, indeed, chromosome breakage, at least, is reduced in Fanconi anemia patients receiving this treatment. These findings have also prompted Shahidi to recommend high daily doses of dietary antioxidants for Fanconi anemia patients.

It appears likely that the prolongation of the G_2 phase of the cell cycle, increased numbers of G_2 irradiation induced chromatic anomalies, and even TNF-α overproduction by Fanconi anemia cells in culture are also secondary events. The G_2-to-M cell-cycle transition is genetically controlled to proceed only if DNA damage has been repaired. Thus excess DNA damage, or inadequate DNA repair, might be responsible for G_2 prolongation, rather than a primary cell-cycle disturbance. Also, TNF-α acts preferentially during G_2 and is known to be able to prolong it. Thus TNF hypersecretion by these cells may be due to an autocrine stimulatory loop. We thus agree with Liu et al. that "A defective response (recognition or processing) to DNA lesions is likely to be a key feature of Fanconi anemia."

TREATMENT/MANAGEMENT   Once a diagnosis of Fanconi anemia has been established by the diepoxybutane (DEB) test, the patient should be entered into the International Fanconi Anemia Registry (IFAR). If the DEB test is done at the Rockefeller University, this is virtually automatic, since the IFAR is in the same location. An excellent manual for patients and physicians (Frohnmayer and Frohumayer: *Fanconi Anemia. A Handbook for Families and their Physicians*) is published by the Fanconi Anemia Research Fund, Inc., 1902 Jefferson Street, Eugene, OR 97405 (tel: 503-687-4658; fax: 503-687-0548). This is also an excellent support group with which families of patients should interact.

Management of patients with Fanconi anemia has, until very recently, consisted largely of monitoring the blood and bone marrow for appearance of a premalignant or malignant clone or for development of aplastic anemia, treatment with androgens where appropriate to delay the latter, and bone marrow transplantation when one or the other of the above events seems to have progressed to the point to warrant this high-risk procedure. This entails some challenging decisions. For example, bone marrow transplants are less likely to succeed after long androgen therapy; however, androgen therapy also becomes less effective after long-term application. When, then, does one decide to discontinue androgens and opt for bone marrow transplantation? The introduction of gene therapy, for patients in complementation group C and in the future for other Fanconi anemia patients, promises to brighten this picture. Using an adenovirus vector, Liu, Walsh, and their associates have recently successfully repopulated group C patients' bone marrows with their own bone marrow cells with a corrected FACC gene introduced via an adenovirus vector into CD34$^+$ bone marrow stem cells.

At present, bone marrows of Fanconi anemia patients are examined yearly, unless a clone has been identified, in which case they are examined every 3 months. At each examination, chromosome analysis is carried out. The diepoxybutane test, already done to establish the diagnosis, should be extended to determine the complementation group. This is especially important now that it appears that it may soon become possible to offer group C patients the possibility of gene therapy. HLA typing, in anticipation of finding a bone marrow donor, is, of course, necessary.

In addition to these considerations, it is important to examine the status of other organ systems that may be affected by Fanconi anemia or its treatment. Ultrasound examination of the kidneys and urinary tract should be done. Periodic developmental assessments of children should be carried out, as well as formal hearing testing, and in all patients, blood chemistry studies, that include those for liver and kidney functions as well as iron status.

Patients should probably avoid noxious fumes, such as in automobile exhaust, gasoline, formaldehyde, herbicides, pesticides, organic solvents, and tobacco smoke. Supplementation of the diet with antioxidants, such as vitamins C and E, is also probably a wise step, even though it is uncertain whether oxygen hypersensitivity is really significant in this disease *(see above)*. Even if it is only a secondary problem, it may be well worth treating.

In addition to treating patients with Fanconi anemia, it is important that patients at risk be screened as well. The DEB test should be done on parents and siblings of patients. Also, the cloning of the FAC gene and identification of specific mutations among Ashkenazi Jews have made it possible to do molecular screening of large numbers of individuals to determine carrier status. This is now being done. This has proved to be more difficult in the FAA gene because of great heterogeneity in the mutations found.

FUTURE DIRECTIONS   Since the most important problems that arise in Fanconi anemia patients are in their bone marrow cells, and since adenovirus vectored gene therapy of hematogenous stem cells has already been shown to be effective in some Fanconi anemia group C patients, it is possible that identification and cloning of other Fanconi anemia genes will lead to effective gene therapy for patients in other Fanconi anemia complementation groups. However, in some patients with Fanconi anemia, intragenic recombination, or some other event, has produced phenotypically normal clones of cells in their blood, yet they still have the disease. This indicates that gene therapy for this disease may be less effective than currently hoped. Alternatively, it is now possible to imagine that this disease may be "cured" within a decade. The term "cured" is in quotes because these patients will still have other problems, including increased tendency to develop carcinomas and whatever consequences they may have from their congenital structural abnormalities. As they come to live much longer, other problems, presently unanticipated, may also arise.

82 The Skin as a Vehicle for Gene Therapy

Soosan Ghazizadeh, Tadeusz M. Kolodka, and Lorne B. Taichman

INTRODUCTION: DNA AS A NEW FORM OF DRUG THERAPY

Gene therapy involves the introduction and expression of new genetic material in a subset of somatic cells for therapeutic purposes and links the capacity for identifying and cloning new genes together with the ability to introduce and express these recombinant constructs in specific cell types. Gene therapy is a fast-moving, but young, enterprise. For the moment, much of the effort is concentrated on developing effective methods for gene transfer and gene expression. Clinical trials are underway covering a broad range of target cells and disorders, but in almost all instances the goal is to establish safety not efficacy. None of the current trials involves gene transfer to epidermal cells. The purpose of this chapter is to review the current state of knowledge for gene therapy, particularly as it applies to epidermal keratinocytes and dermal fibroblasts. Gene transfer to melanocytes and Langerhans cells is outside the scope of this review.

Gene therapy has features that offer a new approach to the treatment of disease (Table 82-1). Unlike previous pharmacological agents, DNA has the potential to become a permanent part of the cell and the cell's descendants by integrating into the chromosome and replicating along with the host chromosome. In this way, the newly introduced DNA is inherited by all descendant cells and therefore is a potential permanent therapy. If the gene or its expression is restricted to a specific subset of cells and if the gene product remains intracellular, unwanted toxic effects on nontargeted cells, commonly encountered with classical drug therapy, will not be seen. Gene therapy also enjoys another more subtle feature that simplifies development of new applications. For more classical drug-based therapies, each new drug has its own unique half-life, mode of action, distribution, and so on. In gene-based therapies, the same "drug" is used throughout, namely a polynucleotide. What differs is the sequence of nucleotides and the information encoded therein. This simplifies commercial manufacturing and implies that once the hurdles of safety and efficacy are overcome, new applications will be forthcoming at a very rapid rate.

FEATURES OF CUTANEOUS BIOLOGY RELEVANT TO GENE THERAPY

RENEWAL   In epidermis, loss of surface cells is balanced by mitotic replication of a progenitor population located primarily in the basal compartment (Figure 82-1). This progenitor population consists of two types of replicating cells: a stem cell, the true progenitor; and amplifying cells, which undergo a limited number of rounds of replication followed by terminal differentiation and migration out of the basal compartment. As seen in Figure 82-1, the only cell that remains in the epidermis is the stem cell. Amplifying cells and terminally differentiated cells are eventually lost. If the goal of gene therapy is to provide a new gene product for prolonged periods, the target of gene insertion must be the stem cell. Putative stem cells have been localized both to the bulge region of the hair follicle by virtue of their prolonged cell cycle and to regions of interfollicular epidermis by virtue of intense staining with antibodies to β1 integrins.

CULTURE MODELS   Cutaneous biology is fortunate to have several culture models that permit in-depth analysis of gene transfer and gene expression under controlled conditions and allow for accurate preclinical testing prior to human clinical trials. These models range from the relatively simple submerged cultures in which keratinocyte growth is favored but differentiation is poor, to the more complex organotypic culture in which the in vivo architecture is approximated. In addition, these cultures have been used for autologous grafting in severe thermal injuries, suggesting that stem cells are present in culture.

BARRIER   A primary function of skin is to act as a barrier. Attempts, therefore, to introduce new genetic information into cells within the skin will encounter a permeability barrier and an interconnected, multilayered epidermis, making access to the progenitor population of keratinocytes problematic.

IN VIVO AND EX VIVO GENE THERAPY

There are two basic approaches to gene therapy (Table 82-2). In vivo transfer involves insertion of the new gene directly into the tissue, whereas ex vivo transfer involves gene transfer to cells while in culture, followed by transplantation to the donor. Accessibility of epidermis makes the in vivo approach attractive, but the barrier property and the multilayered nature of the tissue prevent easy access to the basal or progenitor population. Ex vivo gene therapy is more complex, requiring additional cultivation and grafting steps. But the ex vivo approach does offer two advantages: first, gene transfer methods generally work more effectively in culture than in vivo; second, with ex vivo therapy, the performance of genetically altered keratinocytes can be assessed prior to transplantation. One drawback with ex vivo therapy is the requirement for grafting, especially for keratinocytes. Autologous grafting of cultured epithelial sheets has been established for burn

Table 82-1
How Gene Therapy Differs
from Classical Pharmacological Therapy

DNA can become a permanent part of the cell and be inherited by its descendants.

If gene transfer or gene expression is restricted to a particular cell type, unwanted side effects on other cell types are reduced or eliminated.

In gene therapy, the "drug" is a polynucleotide, for all applications.

Table 82-2
Comparison of Ex Vivo and In Vivo Gene Therapy

In vivo	*Ex vivo*
Direct transfer to tissue	Involves gene transfer to cells in culture followed by transplantation
Preclinical testing not possible	Allows preclinical testing of gene altered cells in advance of therapy
Gene transfer usually less efficient	Gene transfer techniques work optimally in culture
Figure 82-1 Keratinocyte renewal in a stratified squamous epithelium. The progenitor population of cells in epidermis consist of stem cells, the true progenitor cell, and amplifying cells that undergo a limited number of cycles of replication followed by terminal differentiation. Amplifying and terminal differentiating cells are eventually lost from the tissue by desquamation. Only the stem cell remains as a permanent resident of the epidermis. For long-term gene therapy, the stem cell must be the target of gene transfer.

therapy, but these techniques require full-thickness excision at the recipient graft site, a procedure that usually leads to scarring and contracture. Ex vivo gene therapy with fibroblasts may be more acceptable as autologous gene-altered fibroblasts can be implanted without having to excise normal tissue at the graft site.

GENE TRANSFER

GENE TRANSFER BY TRANSFECTION Transfection involves gene transfer with purified DNA in a plasmid vector. There are several methods for transfection in vitro, each designed to facilitate DNA delivery to the interior of the target cell. For example, in calcium phosphate-mediated transfection, formation of a calcium phosphate precipitate entrains DNA and facilitates accessibility to the cell surface and endocytic uptake. In liposome- or lipid-mediated transfection, transport of the DNA through cell membranes is facilitated by membrane fusion. Electroporation works by creating temporary holes in the cell membrane through which DNA may enter. Transfer of DNA in vivo has been achieved by use of the "gene gun," which accelerates microscopic gold

particles coated with DNA and forces the projectiles into the cell interior. Recently, intradermal injection of purified DNA into mouse or pig skin has been shown to result in expression of the encoded gene product in dermal fibroblasts as well as overlying epidermal keratinocytes. The mechanism of DNA uptake by any transfection method is unclear.

Transfection methods are simple to use and can achieve transfer of relatively large molecules (>8 kbp). However, transfection in most cell types is inefficient, achieving gene transfer in a small percentage (usually 1–10%) of the target population. Transfected DNA does not ordinarily integrate into the chromosome of the target cell and, as a result, is diluted out by repeated cycles of cell replication. Expression, therefore, is transient, reaching peak levels in 2–3 days and abating after 5–10 days. However, expression can persist for much longer periods if the cell does not ordinarily cycle, such as mature muscle cells.

GENE TRANSFER BY VIRAL TRANSDUCTION The use of viral vectors to transduce cells for gene therapy capitalizes on the capacity of viruses to insert and express their own genetic material in a cell with high efficiency. To harness the transducing powers of a viral vector, an infectious, but crippled virus is constructed in which viral genes required *in trans* for viral replication are replaced by a gene(s) of interest. The infectious property of the virus is maintained, but deletion of essential viral genes renders the vector replication incompetent, unable to complete its life cycle in the target cell. The end result is a system for efficiently introducing and expressing new genetic information in a cell without the risk of reinfection and viral spread. Assembly of viral vectors is carried out in packaging cell lines that are designed to constitutively express *in trans* the deleted viral genes.

Three types of viruses have been approved for use in human gene therapy trials: adenovirus, retrovirus, and adeno-associated virus (*see* Table 82-3). Adenovirus vectors are noted for high titers and their ability to transduce nonreplicating cells, a feature that allows transduction of tissues with a low mitotic index. Adenoviral vectors have been used to transduce keratinocytes in vivo. As the vector does not have a mechanism for integration or self renewal, it does not persist and expression is lost within several days. Adenovirus vectors can be toxic at high multiplicities of infection and development of an immunological response limits duration of expression and prevents reinoculation. Attempts to reduce the immunological rejection by reducing the antigenicity of the vector or suppressing the immunoresponsiveness of the host have met with some success.

Retrovirus vectors are currently the most widely used agents for gene transfer in clinical trials. These RNA vectors are derived from the Moloney murine leukemia virus and require cell replication for successful infection, as there is no mechanism to transport the viral replication complex into the nucleus. A reverse-tran-

Table 82-3
Viral Vectors for Gene Therapy

	Retrovirus	*Adenovirus*	*AAV*
Virus structure	RNA	Linear, duplex DNA	Linear, single-stranded DNA
Titer (CFU/mL)	10^6–10^7	10^{11}–10^{12}	10^3–10^6
Insert size	7–8 kbp	~10 kbp	5.2 kbp
Target cell	Replicating cells	Replicating and nonreplicating cells	Replicating and nonreplicating cells
Integration	At random sites	No integration	Wild-type integrates at chromosome 19q13
In vivo transfer	Not reported in skin	Very effective in variety of tissues	Bronchial airway epithelial cells
Safety concerns	Insertional mutagenesis	Toxicity at high input	Without known pathology

scribed, double-stranded DNA copy of the viral genome integrates at high efficiency in the host-cell genome at random sites. Integration provides a mechanism for ensuring persistence of vector sequences in descendant cells. Retrovirus vectors are therefore quite suitable for transducing stem cells, if these cells can be induced to replicate. Recent advances in retrovirus vector design include: (1) high-titer stocks by encapsidating the viral genome in the capsid protein of vesicular stomatis virus, thereby enabling concentration to titers $\geq 10^9$ colony forming units per mL (CFU/mL) and expanding its host range; (2) lentivirus vectors capable of transducing nondividing cells; (3) receptor-binding sequences allowing targeting to a specific cell type; and (4) vectors with inactivated 5' promoter sequences that may allow unfettered expression of an internal promoter. A concern with retrovectors is the potential for mutagenesis at the site of integration. However, the likelihood of disrupting a vital gene is remote and no untoward effects of retroviral transduction have been reported to date in human trials.

Cultured keratinocytes are highly transducible with recombinant retroviruses. At titers above 5×10^6 CFU/mL, all clonogenic keratinocytes in the culture are transduced. In culture, putative stem cells are successfully transduced with no apparent loss of growth potential. No one has yet succeeded in using retrovirus vectors for direct gene transfer to epidermis or dermis, either for short-term or prolonged expression.

Wild-type adenoassociated virus has several features that make it an attractive vector system including the lack of any known pathology associated with infection, its ability to infect nonreplicating cells, and its potential for integrating at a specific site in the chromosome. However, the size of the transgene it can transfer is limited and site-specific integration is likely to require the presence of the viral *rep* gene, further limiting the size of the transgene.

Papillomaviruses induce benign warts and condyloma in stratified squamous epithelia. Papillomaviruses have not received much attention as a vector but two factors make these viruses particularly attractive for keratinocyte gene therapy. First, they have a natural tropism for keratinocytes of stratified squamous epithelium; second, their circular DNA genome replicates as a stable, multicopy episome. Three viral genes are required for episomal replication: an origin of replication, the E1 and E2 genes. The E5, E6, and E7 genes, which encode products with oncogenic potential, can be removed without loss of episomal replication. No packaging cell line for papillomavirus is available. However, infectious, but empty viral capsids have been produced by expressing viral-capsid genes at high levels. It may be possible to develop this system further to produce infectious, replication-incompetent papillomavirus.

Table 82-4
Potential Applications for Cutaneous Gene Transfer

Treatment of a cutaneous disorder (inherited or acquired)
Vaccination
Systemic delivery of gene product
Creation of an enzyme reservoir for processing of circulating metabolites

EXPRESSION OF THE THERAPEUTIC GENE

For gene therapy to succeed, the therapeutic gene must not only be inserted in the target cell it must also be expressed at a level sufficient to achieve a therapeutic effect. Some gene products may need to be regulated to achieve a suitable response. Promoters from Moloney murine leukemia virus, SV40, and cytomegalovirus have been widely used and provide high level activity in a variety of cell types including keratinocytes. For reasons that remain unclear, activity from these viral promoters remains stable while the host cell is maintained in culture, but drops precipitously when the same cells are transplanted to an animal host. The mechanism behind this tissue-induced inactivation is unknown but may be related to methylation of cytosine residues in the viral promoter. Experiments with fibroblasts, myoblasts, and hepatocytes suggest that tissue-specific promoters normally active in the particular cell type are not subject to this inactivation. The use of keratinocyte-specific promoters to overcome this inactivation has not been reported.

GENE THERAPY FOR INHERITED AND ACQUIRED CUTANEOUS DISORDERS

INHERITED DISORDERS   An inherited cutaneous disorder in which the mutant gene has been identified and the normal allele cloned is a candidate for gene therapy (Table 82-4). However, there is a key difference between dominant and recessive disorders in terms of their suitability for gene therapy (Fig. 82-2). In a dominant disorder, the mutant phenotype is induced by a single copy of the mutant allele. The presence of the normal allele in the same cell has no sparing effect. Expressing an additional copy of the normal allele is therefore not likely to alter this situation. For example, epidermolysis bullosa simplex (*see* Chapter 73) and epidermolytic hyperkeratosis (*see* Chapter 74) are two dominantly inherited skin diseases in which mutation in keratin structural genes cause collapse of the intermediate filament network and cytolysis. Insertion of an additional normal allele is not likely to offset the disruptive effects of the mutant protein on the filament network. A more effective therapy is likely to require selective inactivation of the mutant gene by homologous recombination or by an antisense or ribozyme strategy.

Dominant disorders

Recessive disorders

chromosome with dominant mutation

chromosome with recessive mutation
Figure 82-2 Gene therapy for dominant and recessive disorders. In a dominant disorder, a single mutation in one of the two alleles causes the mutant phenotype, whereas, in a recessive disorder, both alleles must be mutated for the mutant phenotype to be present. In carriers of a recessive disorder, the presence of one normal allele spares the cell from the mutant phenotype. Insertion and expression of a normal allele in a recessive disorder is therefore likely to result in reversion to the normal phenotype, whereas such a strategy is not likely to succeed for a dominant disorder.

Recently, a new methodology has been described that may allow targeted correction of a known dominant point mutation. A chimeric DNA/RNA oligonucleotide homologous to a specific host sequence in all but one nucleotide is introduced into a cell, and by a mechanism possibly involving DNA mismatch repair, the host sequence is altered to correspond with that of the oligonucleotide. In this way, the point mutation in the hemoglobin β allele was corrected. The use of chimeric DNA/RNA oligonucleotides has not been described in cutaneous cells.

In a recessive disorder, the mutant phenotype appears when both alleles in a cell are mutant (Fig. 82-2). Inserting a normal allele into cells from such an individual is likely to recreate conditions resembling the carrier state in which there is a single copy of the mutant and the normal allele. Lamellar ichthyosis *(LI)* is a case in point. LI is a recessive disorder associated with mutations in keratinocyte transglutaminase I (TGaseI) and results in abnormal epidermal differentiation and defective barrier function. By inserting a copy of the normal TGaseI allele into LI-keratinocytes, a more normal phenotype is evident when these gene-altered cells are grafted to athymic mice. Among the changes seen in the genetically modified epithelium were reduced hyperkeratosis, a more normal distribution of filaggrin and a reduction in transepidermal water loss. Although gene therapy is not possible over the entire epidermis, it may be possible to treat selective areas of skin. If the gene-corrected cells possess a selective growth or attachment advantage, they may be capable of replacing the defective epithelium.

ACQUIRED DISORDERS It is not clear at this time what acquired cutaneous disorders might be approached with gene therapy. Several factors are responsible for this lack of clarity. First, because of the untried nature of keratinocyte gene therapy, clinical trials are likely to be approved only for cutaneous disorders in which all current therapies have proven to be unsatisfactory. Second, because of limitations on the size of the transferred gene, only a single gene can be effectively transferred. Therefore, the disease in question must be one that can be treated with a single gene product. Third, with current methods of in vivo gene transfer, expression is transient, thereby limiting applications to conditions such as wound healing.

CUTANEOUS GENE TRANSFER FOR SYSTEMIC DISORDERS

Expressing new genetic information in skin may be used to induce effects that have systemic implications. Three types of systemic applications are described:

VACCINATION Uptake and expression of naked plasmid DNA by epidermal and dermal cells can be followed by development of long-lasting humoral and cellular immune responses to the encoded protein, suggesting that intradermal gene vaccination may constitute an alternative to traditional immunization. For example, when mice receive an intradermal injection of a plasmid encoding the influenza nucleoprotein, antinucleoprotein antibodies and cytotoxic T lymphocytes developed and the mice gain resistance to challenge with a heterologous strain of influenza virus. The mechanism of immunization is not well-understood. Immunogenicity of plasmid DNA is not based on the level of protein expression, but rather the presence of short immunostimulatory DNA sequences in the plasmid backbone that elicits production of proinflammatory cytokines by keratinocytes and antigen-presenting cells. The induction of immune responses may also involve transfection of skin-derived dendritic cells that localize to the draining lymph node.

SYSTEMIC DELIVERY Systemic delivery from epidermis was first demonstrated in the case of apolipoprotein E (apo E), a 34-kDa protein naturally secreted by keratinocytes. Insertion of a recombinant tagged apo E gene under the control of a viral promoter into keratinocytes with subsequent grafting to athymic mice resulted in the presence of both the endogenous and the tagged apo E in the animal's bloodstream. Systemic delivery of apo E may be useful for the treatment of familial hypercholesterolemia III. Other gene products that have been induced in keratinocytes and delivered systemically include human growth hormone, factor IX, and α1 antitrypsin (Table 82-5).

METABOLIC PROCESSING OF A CIRCULATING SUBSTRATE In inherited metabolic disorders with a nonfunctional enzyme and toxic accumulation of its substrate, one therapy has

been to replace the missing enzyme by injection. Gene-transfer techniques may allow creation of a permanent intracellular enzyme reservoir to metabolize circulating substrate. A case in point is severe-combined immunodeficiency caused by mutation in adenosine deaminase (ADA). ADA normally deaminates deoxy-adenosine (dAdo) to produce deoxyinosine. In ADA deficiency, dAdo accumulates in the bloodstream and is toxic to T- and B-cell development. Classical therapy for this disease has been to furnish ADA enzyme either by injection or by transfusion of red-blood cells. Recently, human gene therapy trials have successfully introduced the ADA gene into peripheral lymphocytes and hematopoietic stem cells. Dermal fibroblasts transduced with an ADA-retrovirus vector have been shown to express high levels of the enzyme and deaminate significant quantities of the dAdo sub-strate and the suggestion has been made to employ these cells to create a cutaneous enzyme reservoir.

CONCLUSION

If gene therapy is an infant science, cutaneous gene therapy is at an earlier, embryonic stage. To date no clinical trials have been initiated or approved using skin as the target organ. The first clinical trials are likely to entail genetic vaccination as this application does not require sustained expression of the gene product and methods are in place for gene transfer and expres-sion. For applications that require long-term expression of a gene product, two hurdles must be overcome: If ex vivo gene transfer is to be attempted, then methods for autologous transplantation of the genetically modified cells must be developed that are not destructive to tissues at the recipient site; if in vivo gene transfer is to be used, then vectors must be available that efficiently integrate into the host genome or undergo autonomous episomal replication. Cutaneous gene therapy will undoubtedly bring a new dimension to the treatment of cutaneous as well as sys-temic disorders.

ACQUIRED DISEASES
OF CUTANEOUS TISSUES

83 Acquired Diseases of Cutaneous Tissues

Introduction

THOMAS S. KUPPER

INTRODUCTION

Over 2000 skin diseases have been described to date, and the majority of these are not genodermatoses, but rather are acquired over the course of the individual's lifetime. Many of these are likely to have a genetic component that is presently undefined. In addition, the skin can be an important indicator of systemic disease, including metabolic, oncologic, and infectious disorders. A careful and encyclopedic description of all acquired skin diseases, and skin signs of systemic disease, is well beyond the scope of this section and is further precluded by considerations of space. The reader is referred to several excellent comprehensive textbooks of Dermatology (listed below). In compiling this section, we elected not to simply list a large number of skin diseases (for which the etiopathogenesis is often completely obscure); rather, we decided to focus on several selected important skin diseases for which the molecular genetic basis is currently being rigorously explored.

Cutaneous oncology is a particularly important area in modern dermatology; much of what we know about the mechanism of carcinogenesis in animal models and humans stems from the study of murine models of cutaneous carcinogenesis. The molecular genetics of the most common skin cancers are discussed, including squamous-cell carcinoma, basal-cell carcinoma, and melanoma. These cancers all share, at least to some extent, an etiopathogenesis based on ultraviolet B (UVB)-radiation-mediated DNA damage. Genodermatoses associated with excessive sensitivity to UVB irradiation with respect to cutaneous carcinogenesis are discussed in Chapter 81. Less-common skin cancers, including cutaneous T-cell lymphoma (CTCL), are not discussed in detail here. This interesting non-Hodgkins lymphoma, which, in its most common form (mycosis fungoides), represents a malignancy of mature (CD7−), memory (CD45RO), skin homing (CLA+), or helper (CD4+) T cells, often presents initially as an inflammatory skin disease. A comprehensive review of these lymphomas was recently published *(see below)*. Merkel-cell carcinomas and fibrosarcomas are beyond the scope of this section.

Psoriasis and atopic dermatitis (Chapters 86 and 87) are, collectively, the most common inflammatory skin diseases that appear also to have a genetic basis, and significant evidence has emerged implicating T cells and the immune system in their etiopathogenesis. Moreover, the type of T cell involved (CLA+, CD45RO, or CD3+ T cells) in the initiation of lesions of psoriasis and atopic dermatitis shares many cell-surface markers with the transformed skin-homing T cell of CTCL *(see above)*. Whereas T cells, antigen-presenting cells, and cytokines are important in the pathogenesis of psoriasis and atopic dermatitis, there is evidence that a more complex polygenic pattern of inheritance underlies these diseases. Although certain major histocompatibility complex (MHC) associations appear to be solid, other of these candidate genes are likely to not be directly related to the immune system. However, it is important to recall that immunosuppression mediated by drugs such as cyclosporin and FK506 can clinically suppress these diseases. Bullous diseases, discussed in Chapters 88 and 89, often involve an immune-mediated assault on structural elements of the skin. The relevant antigen in pemphigus vulgaris was recently found to be a cadherin-like adhesion molecule. The gene defect in a form of junctional epidermolysis bullosa involves the deficiency of a molecule first described in the context of the blistering disease bullous pemphigoid (the BPAG1) as an antigen. Finally, Chapters 90 and 91 describe two classes of disease long considered to have an autoimmune etiology: lupus erythematosis and scleroderma. It has been extremely difficult to dissect the pathogenesis of these complex diseases, and physicians have had to attempt to classify and treat these disorders in the absence of a clearly defined etiologic mechanism. These chapters review the current state of knowledge about these diseases, and suggest future directions for clinical investigation.

It is important for internists and other physicians to appreciate that there are many important skin signs of systemic diseases, and it is unreasonable to expect nondermatologists to be conversant in these. In addition, as our pharmacologic armamentarium grows and new powerful systemic therapies emerge, the already large number of drug reactions involving skin will grow. Excellent texts exist that include photographs and descriptions of these disorders, and the reader more than casually interested is encouraged to seek these out. Unfortunately, the molecular bases for most of these skin manifestations of systemic disease or drug reactions remain completely unknown. As our understanding of the molecular basis of skin disease grows, it is anticipated that this state of affairs will change. Space precludes an exhaustive discussion of other acquired skin diseases in this section.

84 Basal- and Squamous-Cell Carcinomas

Paul Nghiem and Thomas S. Kupper

EPIDEMIOLOGY

In 1996, nearly one million skin cancers were diagnosed in the United States alone. This number approaches the sum of all other types of cancer combined. Malignant transformation can occur in each of the three major call types of the epidermis: the basal cells, the squamous cells, or the pigment-producing melanocytes. Cancer of the melanocytes, or malignant melanoma, is the most lethal and, fortunately, least common type of skin cancer. Of approximately 38,000 cases in 1996, there were approximately 7000 deaths. (Melanoma will be covered in Chapter 85.) The nonmelanoma skin cancers, basal-cell carcinoma (BCC) and squamous-cell carcinoma (SCC), together comprise more than 95% of skin cancers, but cause few deaths as they rarely metastasize. Early diagnosis and excision is highly effective in treating all three forms of skin cancer, including melanoma.

It is now well-established that ultraviolet (UV) radiation, especially in the UVB range from approximately 280–320 nanometers, is responsible for most skin cancers. However, the complex pathway from sun exposure encountered in youth to skin cancers developing years later is only beginning to be unraveled.

RISK FACTORS
FOR NONMELANOMA SKIN CANCER

ULTRAVIOLET LIGHT   Australia has served as an inadvertent experiment on the effects of sunlight on minimally pigmented skin following the colonization of this sunny land with Caucasians from the British Isles. Whites in Australia have the highest rates of skin cancer of any people in the world, much higher than their British relatives who remained in the north or the Australian Aborigines who are protected by darker skin. Similar trends exist in the United States where southerners have higher rates of all three types of skin cancer than their less-exposed northern relatives.

At the molecular level, sunlight has also left telltale signs of its association with skin cancer. One of several types of mutations that can be induced by UV radiation involves adjacent cytosines on the same strand of DNA and is essentially unique to this mutagen. Specifically, light induces the formation of aberrant chemical bonds between adjacent cytosines. These so-called cyclobutane-pyrimidine dimers are then misread by DNA polymerase, causing them to be paired with adenine instead of guanine. When the next strand is copied, the adenines are paired with thymines instead of

the original cytosines resulting in a so-called C-to-T mutation in the original strand of DNA. C-to-T mutations occurring in adjacent pyrimidines are highly suggestive of UV radiation as no other mutagen routinely causes this change. A high percentage of DNA mutations detected in skin cancer involve such signature mutations. Interestingly, the vast majority of these mutations occur in the nontranscribed strand of DNA, as the transcriptional machinery has significant DNA repair capacity and typically corrects mutations in the transcribed strand prior to replication.

INHERITED CANCER SYNDROMES   Basal-cell nevus syndrome (BCNS) and xeroderma pigmentosum are examples of familial skin cancer syndromes. Both of these diseases have contributed to our understanding of the etiology of sporadic skin cancers and are covered in detail in separate chapters in this text. In basal-cell nevus syndrome, hundreds or thousands of basal-cell carcinomas (BCCs) develop in sun-exposed areas. In this autosomal dominant disorder, one copy of the human homolog of drosophila *patched*, a tumor-suppressor gene, is mutated, leading to multiple developmental abnormalities in addition to these tumors. The molecular pathway involving this tumor suppressor will be discussed below as it is relevant in sporadic BCCs as well.

In xeroderma pigmentosum, defective DNA repair enzymes allow rapid accumulation of UV-induced mutations. Xeroderma pigmentosum patients suffer from profound sun damage after trivial UV-light exposures and develop all three types of skin cancer within the first decades of life.

IMMUNE SUPPRESSION   Through an important but poorly understood mechanism, the immune system plays a significant role in controlling skin cancers. This hypothesis is derived from the observation that organ transplant patients on prolonged immunosuppression with agents such as cyclosporine, prednisone, and azathioprine have markedly increased risks of developing basal- and especially squamous-cell carcinomas. By 20 years after kidney transplantation and beginning immunosuppression, approximately 40% of patients have developed SCCs and/or BCCs as compared with 6% for the age-matched normal population. The rates are even higher following heart transplantation, as these patients require more intensive immunosuppression and undergo transplantation later in life when precancers are presumably more advanced.

In addition to elevated rates of occurrence, SCCs especially tend to be highly aggressive when they develop in the setting of immune compromise, with a much higher rate of metastasis and lack of response to therapy, especially if immunosuppression is continued. Whereas these epidemiologic studies support the concept of tumor surveillance, we do not know the critical mecha-
Figure 84-1 Proposed model of *Sonic Hedgehog* (Shh) signaling pathway in vertebrates, relevant in development and BCC. Shh is a diffusible signaling molecule that binds the 12 transmembrane-spanning receptor *patched* (Ptc), which is mutated in both BCNS and in many sporadic BCCs. The binding of Shh to wild-type Ptc causes disinhibition of the pathway, allowing the seven transmembrane-spanning receptor *Smoothened* (Smo) to transmit an intracellular signal affecting cellular differentiation. The critical nature of this pathway in vertebrate development is demonstrated by transgenic mice deficient in either Shh or Smo which have a phenotype of multiple skeletal and neurological defects and die before birth. Mutation or loss of Ptc (and its normal inhibitory action on Smo) causes constitutive signaling by this pathway, and leads to the development of BCCs. (Adapted from Stone DM, et al. Nature 1996;384:133.)

nisms by which the immune system recognizes most nascent skin cancers yet fails to detect others (the ones that progress). Are the products of mutant cancer-associated genes expressed as novel antigens? Does immunosuppression induced by UV light (which is potent enough to block immune-related diseases such as psoriasis for example) play a clinically relevant role in allowing tumor progression? Do tumors actively suppress the immune system by engaging the lymphocyte Fas apoptotic pathway or elaborating diffusible factors? Answers to these questions have biological and potential therapeutic implications.

HUMAN PAPILLOMA VIRUS The E6 protein product of human papilloma virus (HPV) types 16 and 18 has been shown to induce ubiquitin-mediated degradation of the p53 tumor-suppressor protein. This mechanism is believed to be central in the strong association of these particular subtypes of HPV with SCC. Genital warts caused by HPV, the most common sexually transmitted disease, is also relevant in cervical carcinoma (HPV types 6, 11, 16, and 18). SCCs are also associated with some cases of immunocompromised patients with disseminated HPV lesions.

MOLECULAR ETIOLOGY OF NONMELANOMA SKIN CANCER

BASAL-CELL CARCINOMA Two lines of investigation, genetic-disease linkage analysis and drosophila developmental biology, converged in 1996 to shed some light on the molecular basis of BCCs by identifying the affected gene in the BCNS. The developmental role of this gene product is suggested by the constellation of findings in this syndrome: jaw cysts, rib, vertebral, and shoulder abnormalities; characteristic pitting of the palms; and numerous BCCs. The affected gene, *Patched*, is 67% identical between human and fly at the nucleotide level and functions in the hedgehog (drosophila) or sonic hedgehog (vertebrate) signaling pathway. In vertebrates, sonic hedgehog (Shh) is involved in the development of motor, serotonergic, dopaminergic, and forebrain neurons, vertebrae, hindgut mesoderm, and distal limb structures. As depicted in Fig. 84-1, this pathway involves the diffusible signal protein, Shh, as well as *Patched* (Ptc) and *Smoothened* (Smo), both of which are transmembrane receptors. The normal function of Ptc appears to be the inhibition of intracellular signaling by Smo except in the presence of Shh. Loss of signaling in this pathway

through the targeted disruption of either the diffusible activator protein, Shh, or the intracellular signaling molecule, Smo, leads to numerous developmental defects and embryonic lethality in transgenic mice. Conversely, loss of Ptc is associated with constitutive signaling through this pathway and the development of BCCs.

In BCNS, patients have lost a single copy of the *Patched* gene, which is encoded on chromosome 9. In a classic pattern analogous to that described for retinoblastoma and other tumor suppressor genes, this leads to a disease that is autosomal dominant at the level of the individual but autosomal recessive at the cellular level. The loss in all cells of the body of one functional copy of the tumor suppressor gene leaves only a single copy as a target of mutagens or possible errors in DNA replication. In a normal individual, a sporadic mutation of a given tumor suppressor in a somatic cell would have a minimal effect as the second copy would remain functional, but in an affected individual, a single sporadic mutation would leave the cell without function of that tumor suppressor, leading to cancer in that cell's progeny.

Although it appears that, in BCNS, loss of *Patched* function underlies development of BCCs, what is the mechanism in the much more common sporadic BCCs? Several early studies suggest that *Patched* is also mutated in a significant number of sporadic BCCs. In these cases, typically one copy is deleted by allelic loss of the 9q22 chromosomal region which encodes *Patched*, whereas the other is the target of an inactivating mutation in its sequence often as a result of a characteristic CC-to-TT mutation from UV light. Studies of *Patched* mutations in sporadic BCCs are difficult because of its large size (4330 bp) and the fact that virtually all tumors characterized thus far have distinct mutations. Recent data suggest that, although many mutations in sporadic BCCs occur in the *Patched* gene, mutation of other target proteins can also induce these tumors. Specifically, mutations have been found in the *Smoothened* gene in several sporadic BCCs as well. Indeed, when an activating mutant version of the *Smoothened* gene was overexpressed in the skin of transgenic mice, they developed BCC-like lesions. This mutation thus activated the *Smoothened* protein to generate its signal even in the absence of *Sonic hedgehog*. The nature of the signal from *Smoothened* has also recently been elucidated. A critical target of *Smoothened* signaling is a zinc finger transcription factor called Gli1. As one would predict for a

target of this pathway, overexpression of Shh and loss of *Patched* both cause an upregulation of Gli1. Moreover, Gli1 is upregulated in sporadic BCCs (46 of 47 cases) but not in SCCs (0 of 10 cases). Thus, this pathway can be disrupted at several sites, all of which appear to cause an upregulation of the Gli1 transcription factor, which mediates the effects of *Sonic hedgehog*.

SQUAMOUS-CELL CARCINOMA The 1980s brought exciting progress in understanding the molecular basis of carcinomas arising in a classic model of multistage carcinogenesis in mouse skin. The experimental design involves shaving an area of mouse skin, applying a single dose of an "initiator" chemical such as DMBA (dimethylbenzanthracene), followed by twice-weekly applications of a "promoter" such as TPA (tetradecanoyl-phorbol-acetate). This treatment leads to benign skin tumors called papillomas, a small percentage of which eventually become invasive carcinomas. Elegant experiments led to the discovery that the initiator causes mutations in the *ras* gene most often in the 12th, 13th, or 61st codons. When the normal cellular form of the Harvey *ras* (H-*ras*) gene is mutated in such a manner it loses its ability to act as a GTPase-activating protein (hence becoming unable to turn off G protein-mediated signaling) and is referred to as an activating H-*ras* mutant. Whereas activated H-*ras* is adequate to transform the immortalized mouse NIH-3T3 cell line, it is incapable of transforming primary cell lines. Presumably, H-*ras* is complementing pre-existing mutations in the immortalized 3T3-cell line not present in normal cells. For example, the combination of H-*ras* with an oncogenic version of *fos* is capable of transforming normal epidermal cells. In the mouse multistage paradigm, H-*ras* mutation by an initiator must be followed by weeks of promotion, involving (among other things) repeated activation of protein kinase C, known to alter the differentiation state of cells. Unfortunately, the critical targets of this second stage of mutagenesis, promotion, remain unknown in this model of chemically induced SCCs.

A further limitation in this model system is that the vast majority of human SCCs are induced by UV light rather than chemicals. What is the relevance of *ras* mutations in typical human SCCs arising in sun-exposed areas? *Ras* mutations are present in a minority (13% in one study) of human SCCs, and evidence exists that this mutation favors an increased growth rate and diminished ability of keratinocytes to differentiate, both features that may be relevant at least to the early stages of tumorigenesis. On the other hand, a larger proportion (30%) of benign and self-regressing skin tumors called keratoacanthomas displayed *ras* mutations, arguing that activating *ras* mutations are neither capable of causing a malignant transformation nor adequate in maintaining growth of benign tumors.

More recently, mutations have been discovered in the p53 gene which are likely to be relevant as they are present in a large fraction (between 60 and 90%) of human SCCs and bear the hallmark of UV-induced damage, the C-to T substitution. p53 is a tumor suppressor that functions in at least two important ways: (1) It halts the cell cycle following DNA damage allowing repair to occur prior to DNA synthesis; and (2) it induces programmed cell death in cells in which DNA damage is too extensive for reliable repair. The loss of p53 function would thus favor tumorigenesis as DNA mutations could accumulate in cells much more rapidly. Indeed, at least one copy of p53 may be lost at a surprisingly early stage in the UV induction of cancer as p53 mutations are detectable in more than 70% of "normal" skin samples from sun-exposed sites on patients who had developed skin cancers elsewhere. No p53 muta-

tions were detected in skin from sun-protected sites on control individuals without skin cancer. High rates of p53 mutations were also noted in the common premalignant lesions known as actinic keratoses.

p53 mutant cells typically display nuclear accumulation of p53-immunoreactivity that represents nonfunctional p53 protein. Clones of cells displaying such immunoreactivity were present in sun-exposed skin at 10 times the rate of sun-protected skin. Interestingly, sun-exposed skin was five times more likely to have large clones than was sun-protected skin, arguing that sunlight was acting both to induce the mutations and to promote their subsequent growth.

Whereas p53 mutations are likely to be relevant, there is ample evidence to suggest that they are not sufficient in keratinocyte carcinogenesis. In p53-knockout mice challenged with chemical carcinogens, both initiation and promotion steps were required, although carcinomas did develop more rapidly than in wild-type mice. Importantly, mutant *ras*, even in the setting of homozygous p53 loss, was not adequate to induce carcinoma in this model, which required promotion with TPA, an activator of protein kinase C. The relevant targets of TPA in this system remain unknown. Similar arguments about the insufficiency of p53 mutations in the induction of SCCs are derived from humans with Li-Fraumeni syndrome, in which one copy of p53 is lost in the germline. Patients with Li-Fraumeni syndrome suffer from extremely high rates of leukemia, breast carcinoma, and soft-tissue sarcoma, yet not of sun-induced skin cancers.

SUMMARY

A series of molecular events is required to generate a true cutaneous carcinoma and, within the past few years, some of the critical steps have been identified. In the case of basal-cell carcinomas, the discovery of *Patched* is a development that will further our understanding of these most common cancers. Major questions include: Is *Patched* necessary for the development of BCCs or do other molecular pathways exist for generating these cancers? Is its homozygous loss in a cell sufficient for malignant transformation? What is the nature of the signal generated in the Sonic hedgehog pathway by Smoothened? Can it be pharmacologically inhibited in order to revert tumor cells to their normal phenotype?

The puzzling observation that sunlight exposure in youth participates in carcinogenesis decades later may be partially explained by the following: (1) p53 mutations are detectable very early on in life following UV exposure and even when present on only one chromosome seem to lead to a modest growth advantage likely as a result of decreased apoptosis of these cells following UV. (2) Homozygous p53 mutations and, to a lesser degree, certain heterozygous mutations favor the accumulation of genetic mutations because of loss of function of this critical guardian-of-the-genome protein. (3) Estimates as to the number *(n)* of genetic mutations required for malignant transformation to carcinoma vary from 2 to 7, whereas the probability that a given cell has acquired mutations in all *n* genes needed to generate a cancer increases as the *n*th power of age. Taken together, these observations argue that youthful UV exposure may damage cells, allowing subsequent UV exposure to more effectively accumulate the mutations required to generate a cancer.

For squamous-cell carcinoma, although p53 and activated H-*ras* appear relevant, ample evidence suggests that more steps are required for complete malignant transformation, as mutant H-*ras*, even in the setting of doubly p53-negative keratinocytes is inadequate for carcinogenesis. In squamous-cell carcinoma, a series of

genetic hits, the accumulation of which is favored by the loss of p53 function, is likely to be the route to malignancy. It would appear that some of these critical hits by sunlight are directed against target proteins that have not yet been identified.

85 Melanoma Genetics

DANIEL B. DUBIN AND SAUMYEN SARKAR

INTRODUCTION

Cancer is currently being viewed as the cellular accumulation of activated oncogenes and inactivated tumor suppressor genes (*see* Chapter 7). Detailed studies on the genetics of adenocarcinoma of the colon have provided the empirical framework for the stepwise genetic progression of benign proliferations to frank malignancy. Similar to adenocarcinoma of the colon, melanoma has a putative precursor lesion, the dysplastic nevus, and may arise sporadically or in clusters within predisposed families.

Recently, germline mutations have been identified in several hereditary cancer syndromes, including Gardner's syndrome (APC), familial breast and ovarian cancer (BRCA1/2), and basal-cell nevus syndrome (BCNS) (PATCHED). Mutations in these cancer-predisposing genes are intriguing as they have been found in both sporadic and inherited malignancies. Identification of these genes has already resulted in the commercialization of a genetic-screening test (BRCA1/2) for familial breast and ovarian cancer. The discovery of veritable "melanoma-susceptibility genes" would facilitate the development of not only screening and diagnostic tests, but also gene-reconstitution treatment strategies.

The increasing incidence of melanoma and the dismal prognosis for advanced-stage disease have spurred investigation for genetic alterations responsible for sporadic and inherited forms of melanoma. Linkage analysis in melanoma-prone kindreds and karyotyping of melanomas and their derived cell lines have implicated nonrandom abnormalities of chromosomes 1, 6, 7, 9, and 10 in the pathogenesis of melanoma. Several candidate melanoma-predisposing genes and loci have been reported; however, controversy regarding the identity of veritable "melanoma-susceptibility genes" abounds.

CHROMOSOME 1

Investigators have identified alterations of chromosome 1 in primary melanomas and melanoma cell lines. The majority of these mutations have represented deletions or translocations involving 1p22–36. However, one group has reported t (1:19) translocations involving 1q in 3 cases of advanced stage melanoma. Another study identified 4/30 melanoma cell lines with transforming *N-ras* mutations that map to 1p22; however, given their relative infrequency, there is concern that such *N-ras* mutations may represent an epiphenomenon of transformation. The beta chain of NGF maps

to the 1p22 region, but no alterations in this gene have been found in melanoma.

Using restriction-fragment-length polymorphism analysis, one group demonstrated loss of heterozygosity (LOH) for 1p in 15/35 melanomas and 11/21 melanoma cell lines, thus suggesting the residence of a melanoma suppressor gene in this region. Certain genetic studies have linked alterations in the 1p32-36 region, which contains the Rh gene, to melanoma and the dysplastic nevus syndrome in distinct families; however, this association has been questioned by other studies.

CHROMOSOME 6

Deletions in the 6q1 2–27 region are the most common chromosome 6 alterations that have been found in melanoma. Although the proto-oncogenes c-*ros* and c-*myb* have been mapped to the long arm of chromosome 6, mutations of these genes in melanoma are not common. Reported LOH of the 6q22–23 and 6q24–27 regions in melanoma implies that melanoma suppressor gene(s) may reside in these loci. Microcell melanoma cell hybrids into which a normal chromosome 6 has been introduced lose their capacity to form tumors in nude mice. The loss of the normal chromosome 6 from these melanoma-cell hybrids results in a restoration of their tumorigenicity in nude mice.

CHROMOSOME 7

Duplication of all or part of chromosome 7 has been reported in 36/58 advanced stage melanomas in a recent study. Similar duplications of chromosome 7 have been found in glioblastoma cell lines in which overexpression of c-*erbB*, a component of the epidermal growth factor receptor (EGF) occurs. The notion that overexpression of c-*erbB* could contribute to tumorigenesis in melanoma is intriguing but not proven.

CHROMOSOME 9

By genetic-linkage analysis, a locus responsible for melanoma predisposition has been mapped to a 2-cM interval in the chromosomal region 9p21. This locus could function to act as a somatically recessive tumor suppressor gene in the manner proposed by Knudson. Consistent with this notion, the 9p21 locus is the site of frequent somatic chromosomal deletions and/or translocations in melanoma tumor cells and cell lines. Linkage data and mutational analysis have suggested that the cyclin-dependent kinase inhibitors (CDKI), p16 and p15, both of which map to the 9p21–22 region, represent the mts-1 and mts-2 genes, respectively. In fact, p16 and/or p15 deletions and/or mutations

have been detected in tumors such as pancreatic adenocarcinoma, esophageal adenocarcinoma, non–small-cell lung carcinoma, leukemia, lymphomas, osteosarcomas, bladder carcinomas, glioblastoma, and mesothelioma.

Mechanistically, the CDKIs p15, p16, and possibly p18, the protein product generated from the alternative reading frames of the INK4a gene, represent attractive tumor-suppressor gene candidates (*see* Chapter 6). The CDKIs act to reinforce the START checkpoint that regulates G1 to S phase transition. By inhibiting cyclin-dependent kinases (CDKs), CDKIs prevent phosphorylation of Rb. Therefore, Rb continues to bind tightly and inactivate the transcription factor E2F, which is essential for driving the G1 to S phase transition. Both p15 and p16, when transfected into transformed mammalian-cell lines can diminish their proliferative capacity. Furthermore, p15 is upregulated by TGF-β, a cytokine which inhibits cellular proliferation in vivo. Therefore, it is an attractive hypothesis to consider that loss of p15 results in a loss of TGF-β–maintained restraint of proliferation.

Since p15, p16 deletions/mutations are more common in either tumor-derived cell lines or tumor explants than in the primary tumors, there is concern that loss of p15/p16 function may represent an epiphenomenon of transformation. In fact, a recent report that cites in vitro upregulation of p16 as a key event in the terminal stage of growth arrest in senescence could explain why p16 but not p15 is commonly inactivated in established melanoma cell lines. However, the detection of p15/p16 mutations in some primary tumors has preserved hope that these genes do represent mts-1 and mts-2.

Although p16 gene mutations in melanoma cell lines are well documented, linkage studies in kindreds with familial melanoma syndrome linked to 9p21–22 have been inconclusive. One study identified six relevant mutations of p16 in 9/18 kindreds. A second study found a single common p16 mutation in 13/15 families. Recently, germline mutations of p16, one of which has been independently tightly linked to two Australian melanoma pedigrees, have been reposted in 5/33 (18%) of patients with a family history of melanoma. On the other hand, in an analysis of 38 melanoma-prone families, 13 of which segregate 9p linkage, only two relevant mutations of p16 were detected. Furthermore, p16/19 knockout mice demonstrated a greater than expected spontaneous development of lymphomas and sarcomas. The knockout data and the mixed-linkage studies raise doubt as to whether or not p16 represents the authentic MLM gene.

Could p15 be MLM? Kamb et al. did not find relevant p15 (mts-2) mutations or deletions in their analysis of melanoma-cell lines and germline DNA derived from melanoma prone kindreds. However, we (SS) have found homozygous p15 deletions of exon 2 in 6/10 human melanoma cell lines; by contrast, no homozygous p16 deletions of exon 2 were detected in these same cell lines. Two of the cell lines in which p15 deletions were detected were primary tumor-cell cultures. In cell lines without homozygous deletion of p15, several mutations of both p15 and p16 were noted. The final word on p15's role in melanoma is pending further study.

CHROMOSOME 10

Translocations and deletions of chromosome 10 have been described in a dysplastic nevus, early-stage melanoma, and late-stage melanomas. No specific genes on chromosome 10 have been implicated. One group found both chromosome 10 deletion and chromosome 7 duplication in 10/58 of advanced-stage melano-

mas. This association may actually be greater since LOH of regions of chromosome 10 may occur without gross cytogenetic loss. Nowell has hypothesized that chromosome 10 may contain a trans-acting suppressor of c-*erbB*. In theory, the combination of loss of expression of the erbB suppressor and gain of an extra copy of c-*erbB* would provide a proliferative advantage.

OTHER RELEVANT GENES

Two studies have found *ras* mutations in 5–25% of melanoma tumors. However, Gerhard et al. analyzed 58 patients with sporadic melanoma and concluded that the distribution of *ras* mutations did not differ from that in a normal population.

Recently, a specific germline cyclin-dependent kinase 4 (CDK4) mutation that renders it resistant to CDKI inhibition has been detected in two melanoma pedigrees with an inheritance not linked to a locus on 9p21. This CDK4 mutation may subvert the delicate START checkpoint that is maintained in part by CDKIs such as p16 and p15 and, thus, confer a proliferative advantage to cells with such a mutation.

Several lines of evidence have implicated p53 and Rb mutations, two guardians of the START checkpoint, as pathogenic in the development of melanoma. In one study, mutations of p53 were found in 85% of primary and metastatic melanoma. Additionally, patients with Li-Fraumeni syndrome (-/p53) as well as up to 7% of survivors of hereditary retinoblastoma (-/Rb) have been reported to develop melanoma. Further evidence that p53 and Rb alterations may be important in the pathogenesis of melanoma can be gleaned from a transgenic mouse line whose melanocytes express large T antigen, a putative inactivator of p53 and Rb function. These transgenic mice develop ocular and cutaneous melanomas.

CONCLUSIONS

The literature is flush with circumstantial evidence implicating alterations of various genes and chromosomal regions in the pathogenesis of melanoma. Given the lessons of colon adenocarcinoma progression, manifestation of the melanoma phenotype likely requires the accumulation of several genetic hits, but not necessarily in any particular order. Furthermore, the array of genetic alterations necessary and sufficient for melanoma development in any one tumor may represent only a small subset of the genetic mutations that could potentially combine to cause melanoma. Cytogenetics and molecular analysis have defined several chromosomal regions in which putative melanoma suppressor genes may lie. However, the identification of true "melanoma susceptibility genes" will likely require further linkage analysis in melanoma-prone kindreds, functional studies, and more detailed sequencing of candidate chromosomal regions.

86 Psoriasis

JAMES T. ELDER AND JOHN J. VOORHEES

BACKGROUND

HISTORICAL PERSPECTIVES Psoriasis was first clearly described by Celsus (25 BC–45 AD), and conditions resembling psoriasis are present in the works of Hippocrates. In 1809 Robert Willan was the first to accurately describe the various forms of psoriasis, which were finally recognized as one entity and distinguished from leprosy by von Hebra in 1841. The association of psoriasis with a distinctive form of arthritis was first recognized by Alibert in 1818. Careful histopathologic studies of psoriasis were first carried out by Auspitz, Unna, and Munro in the late 1800s.

DISEASE DEFINITION Psoriasis is a chronic, inflammatory, hyperproliferative disease of the skin, scalp, nails, and joints, affecting 1–2% of the United States population at an estimated annual cost of $1.6 billion in 1985. Psoriasis is found worldwide, although its frequency varies widely among different ethnic groups. It has a variety of clinical presentations, most of which eventuate into erythematous, scaly plaques with or without nail disease, and arthritis. Susceptibility to psoriasis is unmistakably heritable, but environmental factors, notably trauma, stress, and infections, are also important determinants of disease onset and severity. At the cellular level, psoriasis is characterized by: (1) markedly increased epidermal proliferation and incomplete differentiation; (2) elongation, dilatation, and "leakiness" of the superficial plexus of dermal capillaries; and (3) a mixed inflammatory and immune-cell infiltrate of the epidermis and papillary dermis. A multitude of plausible pathomechanisms can be envisaged for psoriasis. However, true molecular insight into the cause of psoriasis is lacking. As stated by Lomholt over 30 years ago:

Question upon question may be asked—the disease is capricious and refuses to part with its innermost secret.

SCOPE In this chapter, we will review what has been accomplished to solve the long-standing riddle of psoriasis, particularly in the areas of immunology and genetics. In addition, we will attempt to summarize its protean clinical manifestations, and review its diagnosis, differential diagnosis, and management.

CLINICAL FEATURES

SKIN Several types of psoriatic skin lesions are recognized, including chronic plaque, guttate, pustular, inverse, palmoplantar, and generalized (Fig. 86-1). Of these, chronic plaque lesions are

by far the most common, and over time, most other forms eventuate into chronic plaque disease. The typical chronic plaque is a well-demarcated, erythematous lesion with loose, silvery scales that can vary from a few millimeters to many centimeters in diameter. The scale can be lifted off the surface of lesions, revealing a shiny base and microscopic points of bleeding (Auspitz sign). Lesions are typically located over the extensor surfaces of the extremities, and often display striking symmetry. Other areas of predilection include the scalp, umbilicus, intergluteal cleft, and genitalia. Plaques may assume a variety of shapes, described as annular, circinate, gyrate, and serpiginous. Scalp lesions can be particularly thick and refractory to therapy, and often show a sharp cutoff at the hairline. With the exception of childhood cases, the face is usually spared. Eruptive, or guttate psoriasis (Latin *gutta*, "drop") appears rapidly as tens to hundreds of 5- to 10-mm papules on the trunk and proximal extremities, usually in young patients following a streptococcal or other upper respiratory-tract infection. Generalized pustular psoriasis presents as waves of sterile pustules 2–3 mm in diameter that appear on erythematous skin, usually accompanied by fever. This is the form of psoriasis most likely to evolve into erythroderma, defined as total-body skin involvement. Inverse psoriasis presents as red plaques with moist scaling, typically located in the inframammary or inguinal folds, umbilicus, intergluteal cleft, axillae, or under the prepuce. Sebopsoriasis lesions feature a more yellowish, greasy scale in the scalp, facial, presternal, and upper back—a distribution reminiscent of seborrheic dermatitis. Localized pustular psoriasis of the palms and soles and geographic tounge are unusual forms, probably distinct from psoriasis.

NAILS Psoriasis produces three distinctive nail changes, at least one of which can be found in approximately 50% of psoriasis patients (Fig. 86-2). These include pitting, onychodystrophy, (destruction of the nail plate), and "oil drop" spotting. Pits are typically well-demarcated, randomly distributed, 1- to 2-mm depressions in the surface of the nail plate, produced by defective terminal differentiation of keratinocytes in the nail matrix. Onychodystrophic changes arise from disease of the nail bed and range from separation of the nail plate (onycholysis) to thick, yellowish, crumbly nails, to complete loss of the nail, especially in pustular cases. Oil-drop spots are orangish-to-brown discolorations underneath the nail, resulting from the leakage of serum proteins through the nail-bed capillaries.

JOINTS Essentially the only systemic manifestation of psoriasis, psoriatic arthritis typically presents between the ages of 35 and 45, usually but not always after onset of skin disease (Fig. 86-3).
Figure 86-1 Morphology of psoriasis skin lesions. **(A)** Chronic plaque lesions of the knees. Note silvery scale that reveals a shiny base when removed. **(B)** Guttate and chronic plaque lesions of the lower back. **(C)** Inverse (intertriginous) psoriasis of the axilla. **(D)** Scalp psoriasis. Note thick, adherent scale and relatively sharp cutoff at the hairline. (Photos courtesy of Harrold Carter and James Rasmussen.)

The incidence of arthritis in psoriatics is unclear, but is at least three times that of the general population. Disease is oligoarticular and asymmetrical in over 80% of patients, and is most severe in the small joints of the hands and feet and the large joints of the legs. Involvement of the distal interphalangeal joints distinguishes psoriatic from rheumatoid arthritis, which tends to be more proximal and symmetrical. Fortunately, only approximately 5–8% of psoriatic arthritis patients develop highly severe, deforming joint disease (arthritis mutilans). Enthesopathy is the result of mononuclear cell accumulation at tendon or ligament insertions, and can progress to involve the entire digit (dactylitis, "sausage digit").

COURSE The natural history of psoriasis is highly unpredictable. Onset is usually in childhood to the early 20s, with a median age of 15–20 years and over 75% of cases presenting by the age of 40 *(see below)*. Typically, lesions wax and wane, and may reappear in the same or in different locations. Approximately 25% of patients experience a complete remission at some point in their lives, which may last from 1 to 50 years. The Köebner phenomenon, also known as the isomorphic response, refers to the tendency of psoriasis to arise at sites of cutaneous injury. The phenomenon is reported by 25% of patients, requires epidermal and possibly high dermal injury, and is usually seen in the setting of flaring rather than stable or regressing disease.

DIAGNOSIS

CLINICAL EVALUATION Based on the foregoing clinical features, the diagnosis of psoriasis is generally straightforward. The Auspitz sign is well-known but is neither sensitive nor specific for psoriasis. Fungal infection, seborrheic dermatitis, chronic eczema, candidiasis, cutaneous T-cell lymphoma, drug eruptions, syphilis, pityriasis rosea, lichen planus, and lupus erythematosus can present an occasional diagnostic challenge. Skin biopsy can be very useful in these cases.

HISTOPATHOLOGY The histopathologic features of psoriasis are variable yet distinctive (Fig. 86-4). These include: (1) epidermal edema and hyperplasia; (2) loss of the granular layer with retention of keratinocyte nuclei (parakeratosis) with or without collections of neutrophils in the stratum corneum; (3) dilatation and tortuosity of the superficial dermal capillaries; and (4) a moderate mononuclear cell infiltrate of the epidermis and dermis *(see below)*.

LABORATORY Several serologic, hematologic, and metabolic abnormalities may be present. However, they have no value as diagnostic tests because of lack of sensitivity and specificity. Whereas antistreptolysin O titers suggestive of recent infection are found in 30–40% of psoriasis patients, specific *Streptococci* can often be recovered from intertriginous sites, and *Staphylococcus aureus* colonization is increased in frequency, the diagnostic value of cultures and examination of skin scrapings is limited to ruling in other entities, rather than ruling out psoriasis. Mild anemia with folate and iron deficiency is common, and negative nitrogen balance is occasionally seen, because of loss of these nutrients in scale. Acute-phase reactants including C-reactive protein and α-2 macroglobulin correlate with elevated erythrocyte-sedimentation rate and disease severity. Serum uric acid levels are also increased in about one third of patients, although frank gout is rare. Psoriasis displays very strong HLA associations that correlate with age of onset and disease severity *(see below)*; however, HLA typing is only a research tool at this time.

Note progressively more severe distal involvement. (Photos courtesy of Harrold Carter and James Rasmussen.)

GENETIC BASIS OF DISEASE

GENETIC EPIDEMIOLOGY Although the inheritance patterns found in certain psoriasis kindreds seem to suggest autosomal-dominant inheritance with reduced penetrance (Fig. 86-5), the weight of evidence from population-based studies indicates that susceptibility to psoriasis is determined by multiple genes as well as environmental stimuli (multifactorial inheritance). Two parameters are often used for estimating the genetic component of multifactorial diseases: heritability (h^2), that portion of the variability in the manifestation of psoriasis ascribable to genetic factors; and risk ratio (λ_R), the risk of psoriasis in relatives of degree R relative to the general population. Psoriasis displays one of the highest h^2 values known in the multifactorial diseases (0.8–0.9). Although identical-twin concordance rates were much lower in Australia than in Scandinavia, h^2 (which depends on the ratio of concordance rates in identical vs fraternal twins) was very similar in both locations. Given the therapeutic effects of ultraviolet (UV) light *(see below)*, it is possible that sun exposure may be an important environmental factor in psoriasis. At present, it is not clear how many genes are involved in psoriasis; however, the parameter λ_R can be used to infer that the number must be greater than 1.

λ_R is also a useful measure of the practicability of identifying genes in multifactorial diseases. For specific genes to be identifiable by genetic-linkage methods, λ_R for siblings (termed λ_S) should exceed a value of 3. In psoriasis, estimates of λ_S vary from 4 to 10.

JUVENILE-ONSET PSORIASIS Two types of psoriasis have been distinguished, largely on the basis of age of onset. The onset of psoriasis peaks between 15 and 25 years, with onset before the age of 40 in 75–90% of patients. A second, much smaller, peak is detectable at 65–70 years of age. Psoriatics who are under 40 years old at onset are much more likely to have affected first degree relatives (Fig. 86-6A), to express known HLA susceptibility alleles, and to experience severe and recurrent disease. As adult-onset psoriatics display a different HLA profile, this population may actually have a different disease, more closely related to the spondyloarthropathies.

HLA ASSOCIATIONS AND THE EFFECT OF LINKAGE DISEQUILIBRIUM There can be no doubt that one or more genes in the HLA locus strongly influence psoriasis susceptibility.
Figure 86-4 Histopathology of psoriasis. **(A)** Normal skin (scale bar = 60 μ). **(B)** Chronic plaque psoriasis (scale bar = 150 μ). Compared to normal skin, note striking regularity of epidermal downgrowth (acanthosis), loss of the granular layer, and retention of nuclei in the stratum corneum (parakeratosis). **(C)** Psoriasis lesion, high-power view (scale bar = 30 μ). Note prominent capillary dilatation (C), dermal dendritic cells, identifiable by their plump nuclei (D), mononuclear cell infiltrate in the dermo-epidermal junctional zone (M), widening of the extracellular spaces (E), and mitotic keratinocytes (arrowheads). (Photomicrographs courtesy of Harrold Carter, James Varani, and John Headington.)

HLA-B13, -B17, -B39, -B57, -Cw6, and -Cw7 (Class I), as well as HLA-DR4 and -DR7 (Class II), all show highly significant positive associations, especially in juvenile-onset disease (Fig. 86-6B). Whereas HLA-Cw6 has consistently produced the strongest associations with psoriasis worldwide, the frequencies of Cw6 and DR7 are approximately the same in psoriatic patients. The tendency of Cw6 and DR7 to be found together is not confined to psoriatics, but is also observed in the general population (allelic association). Population and family studies have revealed the basis of this allelic association: Cw6 and DR7 are linked together on the same chromosome much more often than would be predicted by chance in both affected and unaffected individuals (linkage disequilibrium).

Linkage disequilibrium in HLA is not confined to Cw6 and DR7, but involves multiple alleles at *HLA-A*, *-B*, and *-C* in the Class I region, several loci in the Class III region, and *HLA-DRA*, *-DRB*, *-DQA*, and *-DQB* in the Class II region (Fig. 86-7). (Curiously, disequilibrium does not appear to extend to *HLA-DP*.)

Through the use of family studies, these allele combinations can be shown to be caused by cosegregation on the same haploid chromosome, and are therefore referred to as haplotypes. Certain haplotypes are particularly prevalent in one or more world populations, and appear to be of ancient origin. It is estimated that all HLA haplotypes found worldwide today represent one of approximately 50 of these so-called ancestral haplotypes or their recombinants.

The ancestral HLA haplotype 57.1, which carries HLA-B57 in addition to HLA-Cw6 and -DR7, is 15 times more common in German psoriatics than in the German population. However, this haplotype is neither necessary nor sufficient for disease, as only about 35% of German psoriatics carry 57.1, and only 20–25% of the German 57.1$^+$ population develops psoriasis. Studies of those rare individuals carrying only the Class I or Class II "ends" of this haplotype strongly suggest that the major susceptibility determinant resides on its Class I end, in the vicinity of *HLA-C*. However, several lines of evidence indicate the susceptibility determinant is not HLA-Cw6 itself, but rather an allele at one of at least 10 other genes in the centromeric HLA Class I region. At this writing, the HLA-linked susceptibility gene remains to be identified.

NON-HLA GENES Several laboratories are conducting genome-wide searches for psoriasis susceptibility genes, using both recombination-based and affected sibling pair (ASP) methods of linkage analysis (*see* Chapter 4 for a discussion of genetic analysis methods). In insulin-dependent diabetes mellitus, at least six such non-HLA loci have been confirmed using these methods (*see* Chapter 57). Two large-scale genome-wide scans for psoriasis susceptibility loci have recently been published (Trembath et al., 1997; Nair et al., 1997). Both of these studies confirmed HLA involvement and identified a candidate region on the short arm of chromosome 20. One study (Nair et al.) confirmed an earlier report of a non-HLA locus on the distal long arm of chromosome 17 (Tomfohrde et al., 1994), and identified a region of linkage on the long arm of chromosome 16. Interestingly, this region coincides with a confirmed region of linkage to Crohn's disease. Psoriasis is seven times more common in Crohn's disease patients than in the general population. It is attractive to speculate that a proinflammatory genetic mutation or polymorphism common to both diseases may reside in this chromosomal region.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

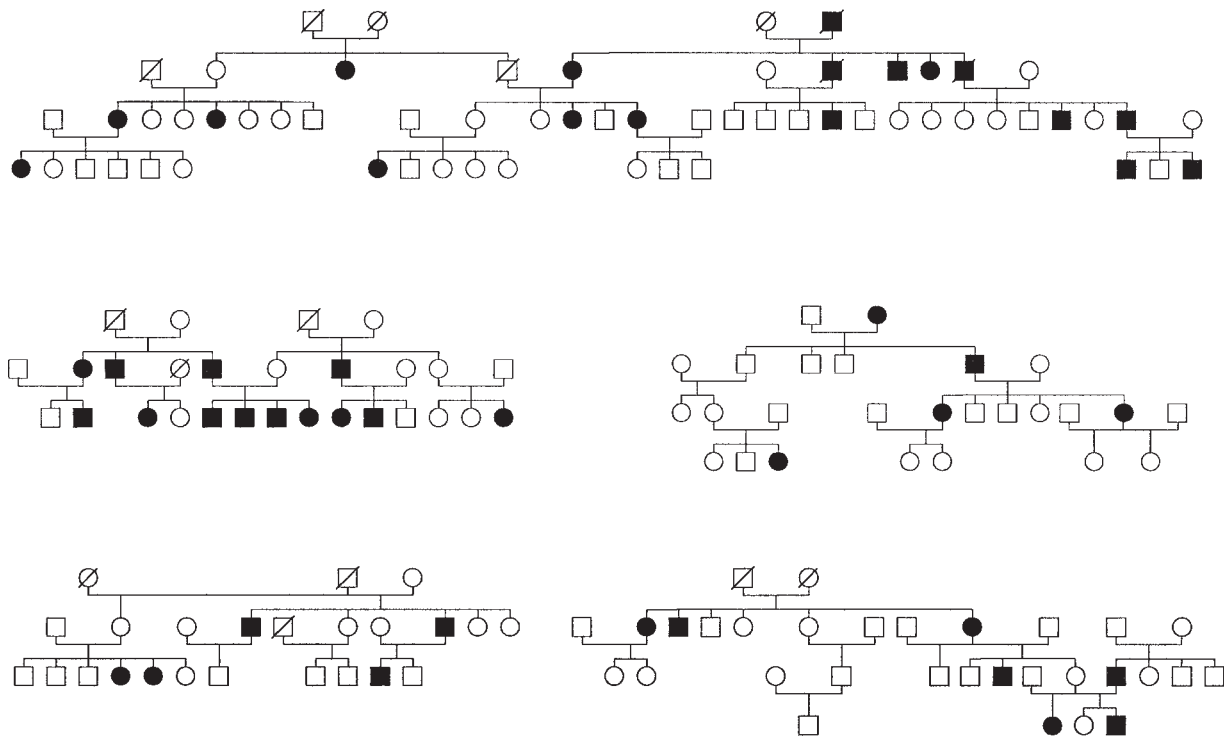
EVOLUTION OF LESIONS Early lesions of psoriasis display mast-cell degranulation, capillary dilatation, papillary dermal edema, and the appearance of a mononuclear infiltrate. However, the exact sequence of events in emerging lesions has been a subject of debate since the late 19th century. Most studies agree that as mononuclear cells begin to invade the epidermis, intercellular edema (spongiosis) of basal keratinocytes appears, followed by focal vacuolization, and patchy loss of granular layer keratinocytes and the appearance of parakeratotic cells with or without neutrophilic infiltration of the stratum corneum. During this transition, the time required for keratinocyte transit from the basal layer to the granular layer decreases from 2 weeks to 2 days, the keratinocyte mitotic rate increases approximately 10-fold, and a characteristic pattern of altered keratin synthesis ensues, with a transition in suprabasal keratins from keratins 1 and 10 to keratins 6 and 16. More chronic lesions continue to be markedly hyperplastic, resulting in a regular pattern of epidermal thickening (acanthosis) with greatly elongated and edematous rete ridges, dilation, and tortuosity of superficial capillaries, and a complete loss of granular cells with diffuse parakeratosis.


Figure 86-5 Examples of multiplex psoriasis pedigrees. Note generation-to-generation and male-to-male transmission, suggestive of autosomal dominant inheritance with reduced penetrance. (Modified from Nair et al., Human Heredity 1995;45:219–230.)
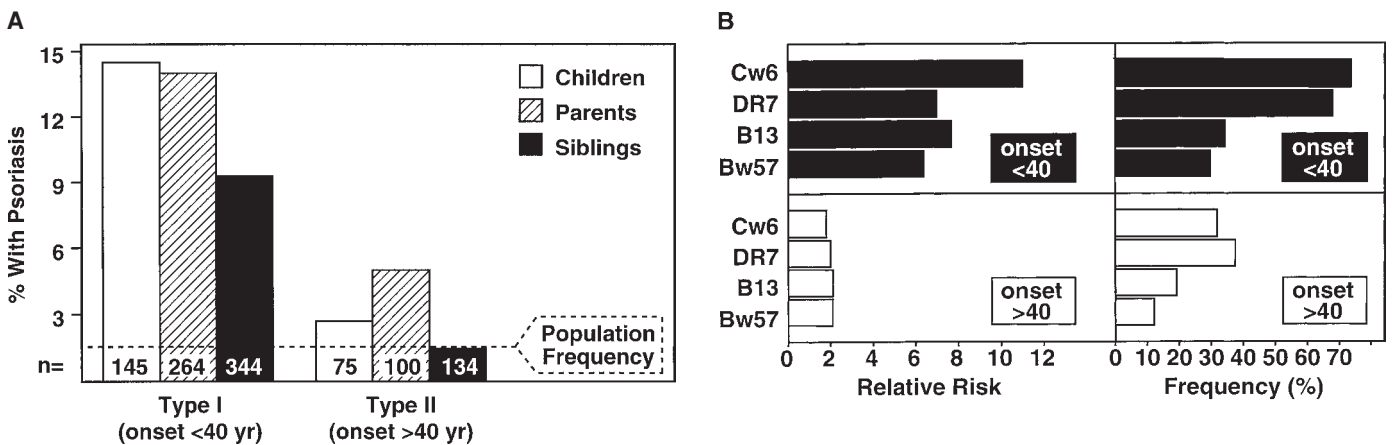

Figure 86-6 (A) Increased heritability of juvenile-onset (type I) psoriasis. (B) HLA associations in Type I vs Type II psoriasis. (From Elder et al., Arch Dermatol 1994;130:216–224.)

THE CASE FOR T-CELL INVOLVEMENT Given its known specificity for T cells, the marked efficacy of the immunosuppressant cyclosporine A (CsA) in psoriasis has provided important functional evidence of T-cell involvement. Besides cyclosporine, other T-cell–specific immunosuppressants including FK506, peptide T, anti-CD3 and -CD4 monoclonal antibodies (MAb), and diptheria toxin-coupled interleukin-2 (IL-2) have all proven efficacious in limited studies, albeit not without side effects. Additional evidence for T-cell involvement comes from reports of disease exacerbation after IL-2 and interferon-γ (IFN-γ) therapy, and after bone marrow transplantation from a psoriatic donor. Conversely, complete clearing of severe psoriasis has been reported after transplantation from a nonpsoriatic donor.

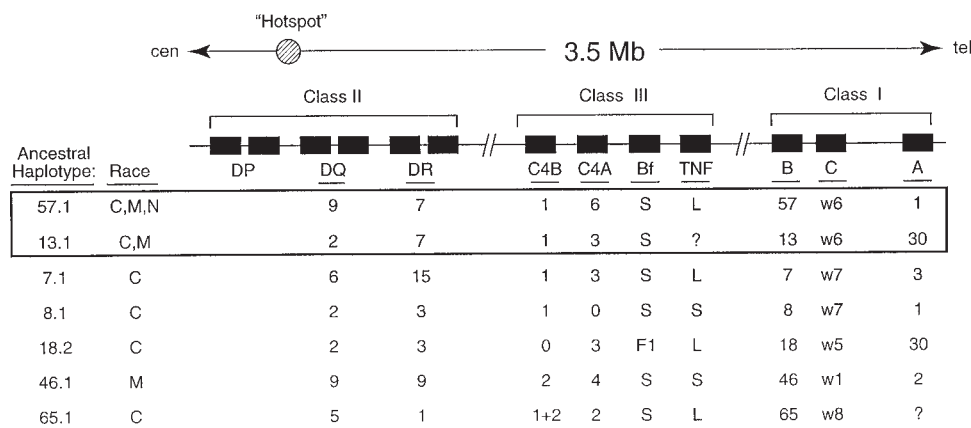
In recent years, it has become increasingly clear that psoriatic lesions contain substantial numbers of dendritic antigen-presenting cells (APCs) in addition to T cells. Most of the T cells present are not naive, but rather memory T cells capable of binding to skin-specific homing receptors on superficial dermal capillary endothelial cells. In addition, accessory factors required for efficient T-cell activation are present in the lesion, including costimulatory APC surface ligands such as B7-1 and B7-2, and a rich cytokine milleu produced by surrounding keratinocytes, mast cells, and mononuclear cells. Several lines of evidence argue for ongoing T-cell activation by antigen in the lesion itself. These include: (1) the presence of actively dividing memory T cells in contact with APCs in the dermis and epidermis of psoriatic lesions; (2)


Figure 86-7 HLA region map, showing ancestral haplotypes. Psoriasis-associated ancestral haplotypes are boxed. Depiction of HLA loci are incomplete and not to scale. cen, centromere; tel, telomere; Mb, megabases; C, Caucasoid; M, Mongoloid; N, Negroid. "Hotspot" indicates approximate region of loss of linkage disequilibrium described in the text. (Data from Degli-Epsoti et al., Immunogenetics 1992;36:345–356, Hum Immunol 1992;34:242–252, and Wu et al., Hum Immunol 1992;33,89–97.)

oligoclonal usage of TCR Vβ chains in the CD8+ subset of lesional T cells; and (3) maintenance of the psoriatic phenotype after transplantation of lymph node-free, split-thickness skin to globally immunodeficient (SCID) mice. Thus, psoriatic lesions appear to feature all components of the classical "ternary complex" required for T-cell activation: MHC, antigen, and the responding T-cell receptor. It is attractive to speculate that preferential Vβ subset usage reflects an important role for superantigen as the initial stimulus for T-cell activation, followed by further activation by nominal antigen; however, this concept remains to be confirmed.

Both helper (CD4+) and suppressor (CD8+) T cells are present in lesions, with most CD8+ cells being found in the epidermis and most CD4+ cells in the dermis. A case has been made for greater importance of CD8+ T cells, based on: (1) the strength of MHC class I associations in psoriasis; (2) the principle that Class I molecules usually present antigens to CD8+ T cells; (3) the evidence for oligoclonal expansion of CD8+ T-cells; and (4) the selective depletion of CD8+ by UVB light treatment. Whereas this is an attractive hypothesis, it does not explain why IL-2, IFN-γ, and IL-12 strongly predominate over IL-4, -5, and -10 in psoriatic lesions, fitting the so-called Th1 lymphokine profile usually considered characteristic of CD4+ helper T cells. However, it must be remembered that both CD4+ and CD8+ cells can contribute to the Th1 lymphokine profile. Adding to the complexity, we have already discussed the confounding effects of linkage disequilibrium on the interpretation of Class I vs Class II associations in psoriasis, and there is evidence that anti-CD4 MAbs can clear psoriasis. Therefore, until more is known, it seems prudent to acknowledge the potential roles of both CD4+ and CD8+ T cells in lesion development.

Recently, T cells cloned from psoriatic lesions have been used to prepare lymphokine-rich conditioned media. Interestingly, these media stimulated the proliferation of short-term keratinocyte cultures from uninvolved skin of psoriasis patients, but not cells cultured from normal epidermis. Neutralization studies showed that IFN-γ was a major mitogen in the context of other as-yet-unidentified lymphokines in the conditioned medium, whereas it is growth inhibitory when used alone. In the long-term, however, keratinocyte proliferation in psoriasis appears to be maintained by autocrine stimulation of the EGF receptor via one of at least three EGF-like growth factors: TGF-α, amphiregulin, and HB-EGF.

Based on the foregoing observations, the following working model for maintenance of psoriatic lesions can be envisaged (Fig. 86-8): Memory T cells enter the skin, having been directed to the skin by upregulated adhesion molecules on activated endothelial cells. Once present in epidermis and dermis, these T cells may encounter bacterial and/or viral superantigens, leading to an expansion of a subset of cells with restricted utilization of TCR Vβ chains. These superantigen-activated cells will also encounter foreign or host-derived standard antigens on the surfaces of dendritic antigen-presenting cells, to which a limited number of the superantigen-activated T cells will respond by further expansion in the presence of appropriate costimulatory signals. T-cell activation causes release of IFN-γ, which may in turn stimulate keratinocyte proliferation, whereas IL-2 and other lymphokines may promote further activation of T cells, APCs, endothelial cells, and/or keratinocytes via a cytokine cascade. Alternatively, T cells may exert sublethal damage to keratinocytes, which respond by entering a wound-healing pathway of epidermal differentiation. Whether the psoriatic keratinocyte is genetically more susceptible to growth stimulation by lymphokines from these T cells requires further study.

MANAGEMENT/TREATMENT

In view of its genetic basis, lifelong duration, and low mortality, avoidance of toxicity is a cornerstone of psoriasis therapy. Nevertheless, effective treatment of moderate to severe psoriasis can entail substantial toxicity and demands careful management.

Because of incomplete terminal differentiation, the stratum corneum of the psoriatic plaque is fragile and presents a defective barrier to epidermal water loss. Recent research has shown that loss of epidermal barrier function is a trigger for keratinocyte production of various pro-inflammatory cytokines and adhesion molecules including IL-8, TNF-α, and ICAM-1. Emollients have long played an important role in psoriasis therapy, presumably by improving barrier function. Although the density of the bacterial flora in psoriasis lesions is double that of normal skin, antibiotic treatment is only occasionally helpful.

CORTICOSTEROIDS/RETINOIDS/VITAMIN D Whereas the antipsoriatic efficacy of topical and systemic steroids has been known since the 1950s, their cellular target remains unclear. Irrespective of their site of action, it is now clear that steroids
Figure 86-8   Model for T-cell pathogenesis of psoriasis. APC, dendritic antigan presenting cell; MHC, HLA Class I or Class II molecules; SAg, superantigen; T, T cell; Tm, memory T cell; Tm*, superantigen-activated memory T cell; M, monocyte/macrophage; KC, keratinocyte; PMN, polymorphonuclear leukocyte; EC, endothelial cell; EC*, activated endothelial cell expressing E-selectin (receptor for CLA), ICAM-1 (receptor for LFA-1), and VCAM (receptor for VLA-4). (*See text* for details.)

exert their beneficial effects via binding to specific nuclear receptors, which serve as ligand-dependent transcription factors. These nuclear receptors are encoded by a superfamily of related genes that encompasses the receptors for not only corticosteroids, but also other effective antipsoriatic agents including vitamin D derivatives and retinoids. At present, the full spectrum of steroid-responsive genes is unknown; however, steroids are known to inhibit the transcription of major immunomodulatory genes such as IL-2 by interfering with the binding of other activating transcription factors such as AP-1. Systemic steroids were initially highly popular but are now little used because of their well-known complications as well as "rebound" flaring of disease upon their withdrawal. In their stead, many different topical corticosteroid preparations of varying potency and vehicle formulations have appeared. Systemic side effects and local effects such as atrophy and hypopigmentation are a concern for only the most potent of these compounds, generally fluorinated derivatives.

Retinoids and vitamin D3 derivatives constitute the other two "legs" of the "therapeutic triad" of nuclear receptor ligands with antipsoriatic effects. The synthetic retinoid etretinate has been used for nearly 20 years, especially in pustular and guttate flares alone or in combination with ultraviolet light. Recently, a topical retinoid has been found to be effective; this compound may interfere with AP-1 activity in addition to activating retinoic acid receptors. Topical vitamin D3 derivatives have also emerged as useful compounds in the 1990s. At present, the major vitamin D3-related compound is calcipotriol, a short-lived structural analog of 1,25 dihydroxy vitamin D3, which lacks most of the hypercalcemic side effects of vitamin D3 itself. As with the corticosteroids, the cellular and molecular targets of retinoid and vitamin D3 action remain unclear. Both classes of compounds have profound effects upon keratinocyte differentiation, and must be used with care in psoriasis, as they produce their own characteristic patterns of skin irritation.

ULTRAVIOLET LIGHT   Psoriasis therapy with combinations of high-energy ultraviolet B (UVB) light (290–320 nm) with crude coal tar was introduced in 1925, and the combination of psoralens with lower-energy UVA light (320–400 nm) followed in 1974. Initially, both regimens were thought to act directly on keratinocyte proliferation. However, it is now recognized that both therapies induce immunosuppression in addition to a complex pattern of keratinocyte effects, including immunosuppressive cytokine production and induction of apoptosis.

CYCLOSPORINE A   As discussed earlier, CsA exerts potent antipsoriatic effects, with nearly immediate clearing of psoriasis when used at transplantation dose of 14 mg/kg/d. The drug remains highly effective at less nephrotoxic doses as low as 3 mg/kg/d. Its mechanism of action is thought to involve binding to the protein cyclophilin, with subsequent inhibition of the calmodulin-dependent protein phosphatase regulatory subunit calcineurin B and subsequent inability to translocate a component of the transcription factor NF-AT from the cytoplasm to the nucleus of the T cell.

METHOTREXATE   As in the case of UV therapy, methotrexate was initially thought to exert its effects via inhibition of keratinocyte proliferation. However, it is effective under doses and schedules of administration that fail to inhibit keratinocyte proliferation in vitro. It now appears that this drug exerts profound antiinflammatory effects by promoting the extracellular accumulation of adenosine.

OTHER AGENTS   Anthralin is a strong reducing agent long used topically in psoriasis, either alone or in combination with UVB light. Although quite effective, its use is limited by skin staining and irritation. Its mechanism of action is likely to be multifactorial. Sulfasalazine is a systemic drug that is effective in a subset of psoriasis patients, with only limited toxicity and the advantage of low cost. Its mechanism of action is also unknown, but is thought to be anti-inflammatory and/or immunosuppressive.

FUTURE DIRECTIONS

As can be appreciated from the previous sections, it appears that the actions of nearly all antipsoriatic drugs can be understood in terms of immunosuppressive and/or antiinflammatory effects, with T-cell activation as a likely primary target via the ternary complex of APC, antigen, and T-cell receptor in the context of appropriate accessory signals. Thus it is not surprising that a variety of novel molecular approaches to blocking this activation event are currently under development. These include vaccination against specific peptides of the TCR Vβ families characteristic of oligoclonal and presumably pathogenic T cells; administration of soluble CTLA-4 to block the accessory signal; administration of IL-10 to shift the lymphokine phenotype away from the disease-associated Th1 and toward the countervailing Th2 state; and additional agents that can block T-cell signal transduction with fewer side effects than CsA and FK506.

As a genodermatosis, the question remains whether psoriasis will prove to be amenable to gene therapy. The issue of direct correction of mutant gene function must await further identification of the genes involved. Assuming that defective gene function can be documented in bone-marrow-derived cells, it will not be unreasonable to expect to reintroduce the normal version of the gene via autologous transplantation of genetically engineered stem cells or long-lasting hematopoietic precursors of appropriate linage. Moreover, inasmuch as simple approaches to introduction of DNA into the skin by direct injection or even topical application are proving to be feasible, it is also reasonable to consider the introduction of various immunomodulators at the level of the gene, rather than the cognate protein. Under either scenario, the future prospects of gene therapy for psoriasis deserve serious consideration.

87 Atopic Dermatitis and Atopy

Donald Y. M. Leung and Larry Borish

BACKGROUND

Atopic dermatitis (AD) is a chronic inflammatory skin disease frequently seen in patients with a personal or family history of asthma and allergic rhinitis. The term atopic dermatitis was first introduced in 1933 by Hill and Sulzberger in recognition of this close association between AD and respiratory allergy. During the past 10 years, there have been extraordinary strides made in our understanding of the immunopathogenesis of allergic diseases. In particular, this constellation of inherited illnesses have now been demonstrated to be associated with activation of a specific group of cytokine genes encompassing interleukin (IL)-3, IL-4, IL-5, IL-13, and granulocyte-macrophage colony-stimulating factor (GM-CSF). The molecular basis for selective activation of this cytokine gene cluster and their immunologic consequences are now actively being pursued by many laboratories. However, it is clear that allergic diseases result from a polygenic inheritance pattern that not only involves cytokine-gene activation but other less-well-defined gene products as well. In addition, the clinical expression of allergic diseases is highly dependent on a complex interaction between the host and its environment, e.g., allergen exposure. This chapter will review some of these recent developments and their clinical implications.

DIAGNOSTIC AND CLINICAL FEATURES OF AD
