Due diligence has been taken by the publishers, editors, and authors of this book to assure the accuracy of the information published and to describe generally accepted practices. The contributors herein have carefully checked to ensure that the drug selections and dosages set forth in this text are accurate and in accord with the standards accepted at the time of publication. Notwithstanding, as new research, changes in government regulations, and knowledge from clinical experience relating to drug therapy and drug reactions constantly occurs, the reader is advised to check the product information provided by the manufacturer of each drug for any change in dosages or for additional warnings and contraindications. This is of utmost importance when the recommended drug herein is a new or infrequently used drug. It is the responsibility of the treating physician to determine dosages and treatment strategies for individual patients. Further it is the responsibility of the health care provider to ascertain the Food and Drug Administration status of each drug or device used in their clinical practice. The publisher, editors, and authors are not responsible for errors or omissions or for any consequences from the application of the information presented in this book and make no warranty, express or implied, with respect to the contents in this publication.

Cover design by Thomas B. Lanigan and Patricia F. Cleary.

This publication is printed on acid-free paper. ∞

Foreword

Until recently, medical genetics and molecular medicine were considered the exclusive province of academic specialists in tertiary-care medical centers. Queried about their familiarity with molecular genetic aspects of clinical medicine, most primary-care providers only a few years ago would have responded that such matters were irrelevant to their daily practice.

Yet few could say that today. Few internists or general practitioners have not prescribed recombinant insulin, tPA, or erythropoetin; few pediatricians have not gone through the molecular evaluation of a child with dysmorphology or learning disability; few obstetricians have not performed amniocentesis or CVS for couples at increased genetic risk; and few general surgeons have not faced penetrating questions about the role of genetic testing or prophylactic surgery from women with a strong family history of breast or ovarian cancer.

This level of emergence of molecular genetics into clinical medicine is still quite modest, however, compared to what is coming. As the human genome project hurtles toward completion of the sequence of a reference human genome, and the identification of all human genes, by 2005, the pace of revelations about human illness will continue to accelerate. Until recently, most disease-gene discoveries have related to single-gene disorders (cystic fibrosis, fragile X syndrome, and so on) or to Mendelian subsets of more common illnesses (BRCA1 and BRCA2, the hereditary nonpolyposis colon cancer syndromes, and so on). But with the initiation in 1998 of an aggressive new genome project goal, cataloging all common human sequence variations, it is expected that the weaker polygenic contributors to virtually all diseases will begin to be discerned. Many consequences will result. Individualized preventive medicine strategies, rooted in the gene-based determination of future risk of illness, will become part of the regular practice of medicine. New designer drugs, based not on empiricism but on a detailed understanding of the molecular pathogenesis of disease, will appear. Pharmacogenomics, wherein the efficacy and toxicity of a particular drug regimen can be predicted based on patient genotype, will become a standard component of designing optimum therapy for the individual. And gene therapy, fed by a wealth of disease-gene discoveries, will mature into a significant part of the physician's armamentarium against disease.

As we watch this train coming down the track, this is an ideal time to collect information about molecular medicine into one authoritative text. *Principles of Molecular Medicine* aims to do just that, bridging the current gap between basic science and the bedside. It will thus be useful to researchers and clinicians alike. With more than 100 chapters covering a wide variety of topics, its distinguished cohort of section editors, and its abundant tables and illustrations, it provides an accessible and much needed manual to the present and the future of molecular genetics and medicine.

Francis S. Collins

Preface

For most physicians, molecular medicine and genetics have not traditionally played a major role in day-to-day clinical practice. However, new insights into the molecular basis of disease are being generated at an ever-increasing rate, resulting in a transformation in our understanding and management of diseases. This explosion of information has been ignited by a variety of technological advances, and has been fueled by the rapid progress of the human genome project. It is widely recognized that molecular biology is now causing a paradigm shift in the teaching and practice of medicine. The promise of molecular medicine is exciting, but there are also great challenges in the integration of this rapidly advancing field into our understanding and treatment of disease. *Principles of Molecular Medicine* attempts to close the gap between traditional textbooks of medicine and the burgeoning database of new knowledge that has been generated by molecular biology.

The book's title, *Principles of Molecular Medicine*, reflects our effort to translate the advances provided by genetics and molecular biology into each of the major specialties of medicine. By analogy with traditional textbooks of medicine, the book is organized according to major organ systems. This format is familiar to most medical readers and thus conforms to the specialty areas of many authors and readers. We believe that this book will be of value to a broad audience that includes sophisticated students, specialists who are seeking updates in their own areas or on topics that they have not followed closely, and practicing physicians who remain vitally interested in learning about the remarkable changes in molecular medicine.

Each of the various specialty sections of *Principles of Molecular Medicine* have been edited by experts in their respective fields. The book opens with a series of introductory chapters, and each specialty section contains additional background overview chapters that address issues of molecular pathophysiology specific to their respective organ systems. Even though the field of molecular medicine is evolving quickly, the book contains up-to-date reviews of the genetic basis of diseases, with an emphasis on principles that should allow the reader to integrate basic knowledge with all the latest breakthroughs. Our authors have aspired to clarify complex topics with many lucid figures that depict cellular and genetic pathways. And we have placed particular emphasis on the molecular mechanisms of disease and on those new concepts resulting from application of the tools of molecular biology. An especially exciting dimension of the book is the translation of the many recent advances in research into clinically useful information; each of our authors has attempted to project the future implications of recent developments in their specialty areas.

Beyond the insights afforded into the pathophysiology of disease, it can be argued that genetics plays a role in virtually every medical condition. It has been estimated that the human genome contains between 50,000 and 80,000 genes. Though many diseases are caused by mutations in critical genes, it is becoming increasingly evident that one's "genetic background" can result in predisposition to many diseases or can modify the host response to environmental events. In some cases, such as hypertension and cardiovascular disease, the genetic contributions are polygenic, and we are still in the early stages of identifying the many genes that contribute to these conditions. In other instances, such as hemophilia, cystic fibrosis, and hundreds of other disorders, the responsible genes have already been well-characterized.

From one perspective, the onslaught of new information can seem daunting and difficult to assimilate, particularly because much of the technology and terminology is new. Ironically, the new insights provided can in fact greatly simplify areas that were previously mysterious. For example, several different genetic defects can cause peripheral neuropathies, but disruption of the normal folding of myelin sheaths appears to represent a common final pathway. Likewise, several genetically distinct forms of Alzheimer disease appear to share a common final pathway that involves the formation of neurofibrillary tangles. Identification of the nature of the defective genes (e.g., dystrophin, CFTR, FGF-receptor) can pinpoint the pathway that is involved in key physiologic processes. Similarly, transgenic and gene "knockout" models can reveal the physiologic function of genes.

One of the surprises in this new field of molecular medicine is its already pervasive impact in every specialty of medicine. For example, cardiologists are unraveling the molecular basis of inherited cardiomyopathies and ion chan-

nel defects that predispose to arrhythmias. Neurologists have identified a startling number of genes in which mutations lead to neurodegenerative disorders. Not surprisingly, hematology has progressed rapidly from the classic genetic descriptions of hemoglobinopathies to define the molecular basis of other disorders, including red cell membrane defects, clotting disorders, and thrombotic disorders. The genetic causes of leukemias and lymphomas have created important paradigms for understanding mechanisms of neoplasia. The identification of the cystic fibrosis transporter allows molecular diagnosis of this disease, and gene therapy protocols are underway at several centers. Inherited variations in the immune system impact upon susceptibility to infectious agents, as well as an array of inflammatory and autoimmune disorders. Our understanding of such viral infections as hepatitis and HIV has been aided greatly by the use of recombinant DNA technology. In endocrinology, new insights into hormone action, sexual differentiation, and mechanisms of endocrine neoplasia have been gained by elucidating the nature of genetic defects. Moreover, the field of hormone and signal transduction has revealed a remarkably intricate network of interacting pathways that mediate cellular responses to external signals. In nephrology, a cause of polycystic kidney disease has been identified and the molecular pathogenesis of ischemic and inflammatory disorders are becoming clearer. In dermatology, there has been remarkable progress in mechanisms of neoplasia, the molecular pathogenesis of pemphigoid diseases, and a variety of other autoimmune disorders. Psychiatry too is an area in which the role of genetics is rapidly emerging as highly important; the foundations for this development are outlined in our chapters on behavior, schizophrenia, affective disorders, and alcoholism. Molecular mechanisms have also now been elucidated for many "classic" genetic disorders. Studies of Prader-Willi, Angelman, and Beckwith-Wiedemann syndromes have revealed a critical role for imprinting. The impact of nucleotide repeat disorders has been documented in the fragile X syndrome, as well as for such neurologic disorders as Huntington disease. In most cases, our new knowledge of these disorders has improved the feasibility and accuracy of diagnostic testing, enhanced our understanding of pathophysiology, and is beginning to unmask new avenues for therapy, including gene therapy.

We have been fortunate to enlist the expertise of a renowned international group of section editors and authors for *Principles of Molecular Medicine*. They have generously taken time from their full palette of research, teaching, and clinical activities to prepare chapters in a manner that is useful to individuals both within and outside of their specialty areas. Although the book contains more than 120 chapters, it is not all-inclusive. Rather, we have focused on disorders in which there has been substantial recent progress and for which there appear to be gaps in coverage elsewhere. The reader is encouraged to seek out further sources for additional information. A particularly valuable resource is the on-line version of Mendelian Inheritance of Man (OMIM), which can be accessed at www3.ncbi.nlm.hih.gov./OMIM. The molecular basis of metabolic disorders has been well-covered in textbooks of internal medicine and in Scriver's, *The Metabolic and Molecular Basis of Inherited Disease*. We anticipate that *Principles of Molecular Medicine* will evolve with the field, retaining an emphasis on clinical molecular medicine.

In addition to the dedication and scholarship of our section editors and authors, a great many individuals have contributed to the success of this book. The idea for the text was conceived in discussions with Victoria Reeders. Mary Kay McMahon provided enormous effort toward the timely completion of this project, superimposed upon her many other responsibilities. Kristina Stanfield, Patty Kalan, Joanne McAndrews, and William Lowe helped to ensure that last-minute updates were included. I am also grateful to the many colleagues who took the time to proofread and critique chapters. Many thanks are owed to Thomas Lanigan at Humana Press for his enthusiastic support and for ushering this concept to completion. I am grateful to many mentors and students for stimulating my interest in molecular medicine. Among these individuals, I especially acknowledge Joel Habener and William Crowley, with whom I have shared the excitement that comes with new insight and discovery. On a personal note, my wife, Michele, and my children, Ryan, Christina, and Jimmy, provided the encouragement that has allowed me to work in the mode of a perpetual student.

1 Organization of the Human Genome, Chromosomes, and Genes

SARAH H. ELSEA AND PRAGNA I. PATEL

INTRODUCTION

DNA is the chemical basis of heredity. Within its sequence is the information necessary for cells to live, grow, differentiate, and replicate. It is the DNA that provides both consistency (all humans generally look the same) and variability (height, eye, and hair color) among organisms. While the human genome is extremely polymorphic and the majority of deviations in DNA sequence are thought to be benign, variations in its sequence can and do lead to genetic disorders. Although we currently understand the roles of only a small percentage of the total number of genes, great strides are being made toward elucidating the physical and molecular structure and function of the human genome. Through this knowledge we can more fully appreciate the complex physiology of the human organism.

With the evergrowing number of diseases thought to have a genetic basis, it is important to understand the structure and function of DNA and chromosomes, as well as the genes they encode. This knowledge will enhance determination of the gene(s) underlying a particular disease as well as design of potential treatments and cures for the disease. This chapter will provide a basis for general understanding of the principles behind the field of molecular genetics.

GENOME ORGANIZATION

Human DNA is packaged in 23 pairs of chromosomes, specifically 22 homologous pairs of chromosomes (autosomes numbered 1–22) and two sex chromosomes, XX in females and XY in males; this represents the diploid genome. The human genome consists of approximately 6 billion bp of DNA and is estimated to contain 50,000–100,000 genes. For a chromosome to function properly, it must be able to replicate, segregate, and maintain itself from one generation to the next. These fundamental processes require that a chromosome contain at least one origin of replication, a centromere for proper segregation of daughter chromosomes, and a telomere for complete replication and maintenance of the DNA (Fig. 1-1).

Each chromosome is comprised of a single linear duplex DNA molecule that is complexed with numerous proteins. This DNA–protein complex is termed chromatin during interphase of the cell cycle (Fig. 1-2). If the DNA contained in a single cell were stretched from end to end, it would measure about two meters in

length. One can imagine that such an enormous amount of DNA would be difficult to contain in the nucleus of a single human cell. Indeed, an elaborate system of packaging/folding (or supercoiling) is necessary for replication, transcription, recombination, and maintenance of the DNA from one generation to the next. As illustrated in Fig. 1-1, during this very orderly process, basic proteins (called histones) provide a core around which the DNA is wrapped, forming nucleosomes. Nucleosomes are not formed randomly but rather are phased along the DNA such that the position of a nucleosome along any given stretch of DNA is the same from cell to cell. These nucleosomes are further organized into higher order solenoid structures, which are packed into loops attached to a nonhistone protein scaffold. As the cell cycle progresses into prophase, the loops thicken into chromomeres, which can be seen as densely staining regions of the chromosomes. This thickening process continues and eventually the DNA condenses into the highly organized ultrastructure of mitotic chromosomes, thus compacting the DNA ~8000-fold at metaphase (Figs. 1-1 and 1-2). This higher order packaging process not only compacts the DNA within the nucleus but is also important for gene regulation and protection of the DNA from nucleases. The higher order structure of the chromatin is fluid and dynamic, with condensation/decondensation of the DNA occurring throughout the cell cycle (Fig. 1-2).

There are several classes of DNA within the human genome. In general, less than 10% of the genome actually encodes genes. The more densely packed regions of the chromosomes, particularly near the centromeres, are termed heterochromatin and are not transcribed, whereas transcriptionally active sequences are located within less densely packed regions termed euchromatin. Approximately 75% of the genome is made of unique or single-copy DNA, whose sequences are represented only once per haploid genome (haploid refers to half the complement of chromosomes; in other words, the DNA donated by either a sperm or an egg). In contrast, the remaining portion of the genome consists of several classes of repetitive DNA, whose sequences are present anywhere from two to as high as 10^7 copies per haploid genome. While it is not known what role repetitive DNA plays in the cell, it is thought to either function in maintenance of chromosome structure or gene regulation, or, in fact, it may have no function at all.

Even though unique DNA makes up the majority of the sequences in the genome, only a small proportion of this DNA actually codes for proteins (coding regions of genes). Some of the
Figure 1-1 Chromatin structure. Chromatin is a complex of DNA and proteins. DNA is wrapped around histones and other nonhistone proteins in an orderly fashion to form nucleosomes, which are then further organized into solenoid structures and finally form the highly condensed metaphase chromosome.

Figure 1-2 Condensation/decondensation of DNA in the cell cycle. The interphase nucleus contains chromatin that is dispersed throughout the nucleus. In prophase, the replicated chromosomes begin to condense, and, by metaphase, the chromatin has condensed ~8000-fold.

DNA functions in the regulation of these genes (noncoding sequences within the gene). Long stretches (>25 kb) of unique DNA are rare, and these single-copy sequences are often found interspersed between stretches of repetitive sequences.

Repetitive DNA can either be clustered within or dispersed throughout the genome. Clustered repeat sequences comprise 10–15% of the genome and comprise arrays of short repeats organized in a head-to-tail fashion. These tandem repeats are collectively called satellite DNAs. These repeats can vary in length from a few nucleotides to several million. Their location varies as well, with some repeats found only in the heterochromatin of the centromeres or telomeres and some found only on particular chromosomes. Minisatellite DNA repeats are generally 15–465 bp in length but can run up to ~20 kb. These repeats are typically found along the length of each chromosome and are used as DNA markers for mapping of the genome as well as for chromosome analysis.

Another class of repeat sequences includes related sequences that are dispersed throughout the genome (sometimes within genes), constituting approximately 15% of the total DNA. While several subclasses of these repeats exist, two are of particular importance. SINES are short interspersed sequences. The best characterized of these elements are those belonging to the Alu family, so named because these repeats contain an *Alu*I restriction site near the middle of the sequence. SINES, while not precisely conserved, are of similar sequence, ~300 bp in length, and are present in about 300,000–500,000 copies per haploid genome, accounting for ~3–6% of the genome. Although the function of these repeats is not known, the sequence is related to that of 7SL RNA. In addition, Alu sequences are of medical importance because these repeats may act as transposable elements, causing aberrant recombination between different Alu family members resulting in mutations that may lead to genetic disease.

A second major class of repetitive DNA is termed LINES, or long interspersed sequences of DNA. A well-represented member of this family is L1, which is found in ~20,000–50,000 copies per human genome, runs about 6 kb in length, and makes up ~3–4% of the total DNA in a cell. A portion of the L1 sequence is similar to the viral enzyme reverse transcriptase. These sequences have also been implicated in the cause of several mutations in hereditary disease due to their potential function as transposable elements.

GENE STRUCTURE AND ORGANIZATION

As discussed, DNA is the hereditary material of the cell. Its sequence encodes genes which, in turn, code for RNAs and ultimately, proteins. Basically, DNA is transcribed into RNA, which is then processed and translated into protein (Fig. 1-3A).

A

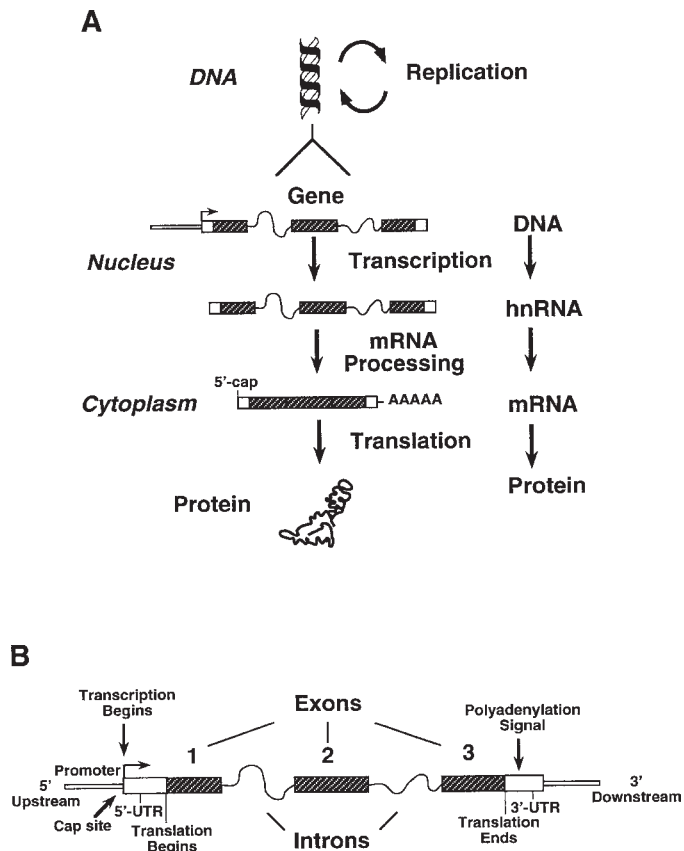
B


Figure 1-3 How does a gene work? **(A)** DNA is replicated and transcribed into RNA, which is then processed to remove introns. Translation then produces a functional protein. **(B)** Diagram of the basic aspects of a gene necessary for proper transcription and translation of the DNA.

Proteins were originally thought to be encoded by continuous segments of DNA, but actually very few genes contain uninterrupted coding regions. The vast majority of genes are interrupted by one or, typically, several noncoding regions called intervening sequences or introns (Fig. 1-3B). Introns are transcribed into RNA but are removed when it is processed into its mature form (mRNA); therefore, the sequences contained in the intron are not represented in the translated product. The coding sequences, called exons, actually dictate the protein sequence.

A schematic representing the features of a typical gene are shown in Fig. 1-3. Genes have been found that range in size from ~100 bp to ~2.3 Mb, but most genes are thought to range between 1 and 200 kb. As illustrated in Fig. 1-3, genes not only include the coding region but also include surrounding sequences that may help in regulation of that gene's expression. These sequences include: "start" and "stop" signals for both transcription and translation; the promoter region, which lies 5' to the coding region and helps regulate transcription; the 5'-untranslated region (5'-UTR), which may function in regulation; and the 3'-untranslated region (3'-UTR), which contains the polyadenylation signal important for maturation of mRNA and also may be involved in other aspects of RNA processing, transport, degradation, and translation.

New genes arise during evolution as a consequence of duplication, divergence, recombination, and mutations in old or existing genes. As a result, many genes are related to others and belong to a larger family of genes with related sequence, structure, and/or function. There are several examples of gene families found either dispersed throughout or sometimes in gene clusters in the human genome. These include genes for globin, myosin, visual pigment, seven-transmembrane-spanning receptors, small nuclear RNAs, and immunoglobulins.

Just as functional genes are found in the genome, so are related genes that either have lost their function or were not fully functional from the start. These sequences, referred to as pseudogenes, are thought to be byproducts of evolution and can arise as a result of incomplete duplication events, mutations, or from processed or unprocessed transcripts becoming incorporated into the DNA. They are abundant throughout the genome.

CYTOGENETICS

While the distribution of genes and repetitive sequences across the genome is not uniform, chromosomes do form consistent and interesting patterns in their organization. Chromosomes can be stained and examined microscopically to reveal distinct light and dark banding patterns. For example, it is thought that metaphase bands that stain lightly with Giemsa (termed G-banding) harbor more housekeeping and tissue-specific genes, SINES, and GC-rich regions of DNA, whereas the darker-staining Giemsa bands tend to contain fewer genes, more LINES, and have a lower GC content.

Chromosomal abnormalities contribute significantly toward congenital malformations and are responsible for >50% of all spontaneous abortions/miscarriages. In addition, ~0.7% of newborns (and ~2% of live births in women over 35 years of age) have significant chromosomal abnormalities. Furthermore, many cancers result from these types of aberrations as well. Chromosome analysis is indicated under several circumstances, including multiple miscarriages, fertility problems, hematological malignancies, multiple congenital anomalies, sexual differentiation disorders, and/or if there is a known or suspected abnormality, such as a family history of mental retardation in males.

Cytogenetic analysis of chromosomes in peripheral blood lymphocytes has facilitated the identification of many chromosomal abnormalities. In these analyses, the lymphocytes are blocked at metaphase and stained with Giemsa. This process results in the light and dark staining mentioned above. G-banding gives ~350–550 bands per haploid set, where 1 band is equal to ~5–10 million bp, representing a few to many genes. Alternatively, a prophase block can give a higher resolution of ~850 bands.

Basic chromosome morphology is illustrated in Figs. 1-4 and 1-5. The short arm is termed "p" for petite and the long arm is designated "q." Chromosomes are acrocentric if the centromere lies near the end of the chromosome, metacentric if the centromere lies near the middle, and submetacentric if the centromere is located between the center and the end of the chromosome. The numbering of the bands on each chromosome is from the centromere to the telomere on each the short and the long arms. The chromosomes in a single cell are arranged by number into karyotypes, which provide a visual representation of an individual's chromosomes (Fig. 1-4). Karyotypes may reveal deletions, duplications, and/or rearrangements and can help to localize the region of DNA responsible for the genetic disorder in question. The nomenclature used for describing chromosome morphology is detailed in Table 1-1.
Figure 1-4 A human karyotype of G-banded chromosomes. A normal female (46, XX) karyotype is shown. Chromosomes are placed in groups based on their size and structure. (Karyotype kindly provided by Lisa Shaffer, PhD.)
Figure 1-5 Fluorescence *in situ* hybridization to metaphase chromosomes. Pictured is a metaphase spread of a patient with Smith-Magenis syndrome. This syndrome results from an interstitial deletion on chromosome 17p11.2. Controls probes for 17q are present on each chromosome 17, while the diagnostic probe for Smith-Magenis syndrome is present on only one chromosome at 17p11.2.

Table 1-1
Karyotype Terminology

1–22	Autosome numbers
X,Y	Sex chromosomes
cen	Centromere
del	Deletion
der	Derivative of a chromosome
dic	Dicentric chromosome
du	Duplication
fra	Fragile site
i	Isochromosome
ins	Insertion
inv	Inversion
mar	Marker chromosome
mat	Maternal origin
p	Short arm of chromosome
pat	Paternal origin
q	Long arm of chromosome
r	Ring chromosome
rcp	Reciprocal translocation
t	Translocation
ter	Terminus (i.e., pter or qter)
+ or −	Placed before a chromosome number, indicates addition or loss of entire chromosome, as in +21 for Down syndrome. Placed after the chromosome number, indicates gain or loss of a part of that chromosome, as in 5q- for Cri-du-Chat.
:	Breakage
::	Breakage and reunion
/	Mosaicism (i.e., 46/47 indicates a mixed cell population in which some cells have 46 and others have 47 chromosomes)

There are several relatively common types of chromosomal abnormalities. The most common aberration is aneuploidy, which can mean either an extra chromosome or a deleted chromosome. Normal human genotypes have 46 chromosomes, including two sex chromosomes (46, XX for females; 46, XY for males). Down syndrome (47, XX, +21) would be an example of aneuploidy or trisomy 21, while Turner syndrome (45, X) is an example of monosomy. Other gross abnormalities include uniparental disomy (both chromosomes in a pair come from a single parent), marker chromosomes (extra chromosomal pieces or supernumerary chromosomes), ring chromosomes (partial chromosomes containing centromeres resulting from the deletion of the telomeric ends of the p and q arms), and mosaicism (where a fraction of the cells in the body have normal chromosomes, while the remaining cells carry an aberration; this may or may not produce a phenotype). Structural problems can also result from deletions, duplications, translocations, inversions, and unequal crossing-over.

MOLECULAR CYTOGENETICS

Preparations of intact chromosomes can also be used for molecular genetic diagnosis, analysis of gene deletions and duplications, and mapping of genes within the genome. Fluorescence *in situ* hybridization (FISH) uses fluorescently tagged DNA probes and fluorescence microscopy to determine the relative location of that particular DNA sequence (Fig. 1-5). This allows for localization of the DNA probe to subchromosomal regions of the genome that G-banding cannot determine. Standard FISH analysis with metaphase chromosomes provides resolution to within 5–10 Mb and serves to bridge the gap between standard cytogenetic analysis and detailed molecular analysis using purified DNA. This technique is rapidly improving. With the use of multicolor probes and interphase chromosomes (where the DNA is less compact), resolution of probes can be obtained to within 100 kb. Additionally, sets of markers can be applied that effectively "paint" the chromosomes so that it can be determined if small segments of DNA have been rearranged and to diagnose aneuploidies. FISH is fast becoming important for long-range genome mapping and ordering of markers within a segment of DNA.

2 Recombinant DNA and Genetic Techniques

Marcus Grompe, Wade Johnson, and J. Larry Jameson

INTRODUCTION

Although DNA was recognized as the chemical substrate of heredity in the early 1940s, studies to examine its structure and function were historically quite difficult because of the lack of tools for its isolation and experimental manipulation. In the early 1970s, a series of technological breakthroughs began that dramatically changed our ability to study the role of DNA in biology and genetics. The impact of methodologic advances in the fields of molecular biology and genetics cannot be overemphasized. Since the mid-1970s, eight Nobel prizes have been awarded for research that led directly or indirectly to major methodological advances in addition to their profound new insights into biology and chemistry. Examples include the discovery of reverse transcriptase, restriction enzymes, plasmid cloning vectors, DNA sequencing, PCR, and others (Table 2-1).

The methods available for research in molecular biology and genetics continue to increase rapidly. Although many of these techniques are relatively complex, a basic knowledge of a limited number of basic procedures will be sufficient for the general reader of this book. In practical terms, many common laboratory protocols are now available as "kits" that are provided by biotechnology companies. These kits typically provide detailed instructions as well as relevant controls. Despite the ready availability of such reagents, it is still important to understand the biochemistry of the reactions and the limitations of protocols if success is to be achieved. A number of excellent molecular biology manuals have been published, many devoting several hundred pages to individual protocols (*see* Selected References). The methods have been divided into six general groups:

1. Important chemical and enzymatic manipulations of DNA and RNA.
2. Methods for the production of DNA and RNA for various applications.
3. Techniques for analysis of DNA and RNA.
4. Expression of recombinant proteins.
5. Determination of protein–DNA interactions.
6. Identification of protein–protein interactions.

ENZYMATIC MANIPULATIONS OF DNA AND RNA

RESTRICTION ENDONUCLEASES   Restriction endonucleases are bacterial enzymes that cut double-stranded DNA in a sequence-specific manner. Biologically, the function of these enzymes is to "restrict" the entry of foreign DNA by cleaving it at recognition sites that do not exist in the host bacterium. Each enzyme has a specific sequence that it recognizes, binds, and cuts. These recognition sites usually consist of a code of 4–8 bp, and the restriction endonucleases will only cut sequences that perfectly match this code. For example, the recognition sequence for the enzyme *Eco*RI is GAATTC. All sites with this sequence will be cleaved by the enzyme (Fig. 2-1), but even a single base mismatch, such as CAATTC, will prevent DNA digestion. The chance of finding a specific restriction site in a given piece of DNA is largely dependent on the number of bases in the recognition site. Based on the probability that the four nucleotides (GATC) will create a characteristic restriction site, a 4-base cutter should cut human genomic DNA every 2.5×10^2 bp, whereas an 8-base cutter would cut on average of every 1.0×10^6 bp.

Restriction enzymes can cut DNA in three basic ways: they can cut the recognition site asymmetrically to leave ends with 5' or 3' overhangs, or they can cut symmetrically to leave blunt ends (Fig. 2-1). Restriction enzymes are named according to the bacteria from which they were isolated (e.g., *Eco*RI from *Escherichia coli*). Hundreds of different restriction endonucleases are commercially available today.

In practical terms, the restriction enzyme is incubated with DNA in a compatible buffer solution and cuts the DNA into pieces of a defined size. Because the cleavage is sequence-specific, different DNAs will produce a characteristic digestion pattern (Fig. 2-2). These unique DNA fingerprints can be recognized after separation of the different size fragments by gel electrophoresis. The production of such restriction maps represents one of the major uses of these enzymes. A second major use of restriction endonucleases is to "cut and paste" DNA in order to generate novel DNA sequences that are used in a variety of methods.

DNA LIGASES   DNA ligases are enzymes that attach two pieces of DNA covalently to one another. T4 DNA ligase is the most commonly used enzyme. The reaction occurs between the 3' hydroxy group of one DNA strand and the phosphate group of the partner strand (Fig. 2-3). ATP provides the energy for the reaction. DNA ligation can occur efficiently only between compatible ends of DNA fragments, and this specificity gives the investigator some control over how different DNA fragments ligate together in a reaction mix. The most common use of ligation is to incorporate a piece of DNA into a cloning vector.

Table 1-1
Recent Nobel Prizes and Molecular Genetic Technology

Figure 2-1 Restriction enzyme cleavage. Three enzymes are shown which digest DNA in three separate ways. *Eco*RI, 5' overhang; *Sma*I, blunt end; *Kpn*I, 3' overhang. Arrowheads indicate the site of cleavage within the restriction site for each enzyme.

DNA POLYMERASES DNA polymerases are enzymes that use a single strand of DNA as a template for the synthesis of a second strand. All DNA polymerases require a primer, and all DNA polymerases synthesize new DNA in a 5' to 3' direction. A primer is a small piece of DNA that is complementary to the strand to be copied. Polymerases attach to the primer sites and then extend the primer in a 5' → 3' direction using individual deoxynucleotides as building blocks (Fig. 2-4). DNA polymerases have multiple uses. Among these are the production of radioactively labeled DNA, the polymerase chain reaction, and DNA sequencing.
Figure 2-2 DNA digestion pattern. Restriction digestion pattern of DNA with *Eco*RI and *Hin*dIII as well as the two enzymes combined. After electrophoresis, the DNA smaller fragments migrate through the gel faster than larger fragments. Basepair sizes are indicated on the left side of the gel.
Figure 2-3 Ligase reaction. T4 DNA ligase will catalyze the joining of complementary ends of DNA by joining the 5' phosphate group to the 3' OH group of two strands of DNA. This reaction requires ATP as well as compatible ends of DNA.

REVERSE TRANSCRIPTASE Reverse transcriptase (RT) enzymes are a subtype of DNA polymerase that utilize RNA as a template to produce DNA. They also require a primer and synthesize in the 5' → 3' direction. Reverse transcriptases are isolated from retroviruses, which have the ability to reverse copy their RNA genome for their life cycle in mammalian cells. The major use of RT is to copy mRNA into DNA, which is then called "complementary DNA" or cDNA. The reaction of RT on an RNA template produces a hybrid RNA-DNA molecule. The DNA in this hybrid is called "first-strand cDNA" and can be used to generate another complementary copy of DNA to create double-stranded DNA (dsDNA). In this manner, cDNA is used to generate libraries representing the expressed genes of a tissue *(see below)* and as a substrate for polymerase chain reaction (PCR) in the sequence analysis of RNA species.

RADIOLABELING Radioactive DNA is an important reagent in molecular biology, as it serves as a valuable hybridization probe. There are two basic ways to incorporate radioactivity into DNA: internal labeling and end-labeling. For internal labeling, DNA is denatured into single strands by boiling, and DNA polymerase is used to copy the strand in the presence of a radioactively labeled nucleotide (most commonly ^{32}P-dCTP). The newly synthesized strand is therefore highly radioactive. Polynucleotide kinase is used for end-labeling. This enzyme transfers the radioactivity from an ATP molecule to the 5' end of single-stranded DNA. Only the most 5' base is labeled, and no radioactivity is incorporated internally in the DNA molecule. Several nonradioactive methods are also available for "labeling" DNA. For example, biotinylation allows detection with avidin-based systems, and digoxygenin can be detected with enzyme-linked assays.

ISOLATION OF GENOMIC DNA, TOTAL RNA, AND POLY(A) RNA

In order to be accessible for manipulation, diagnostic studies, and therapeutic uses, DNA and RNA must be isolated in suitable form and quantity. The best method of DNA or RNA isolation, and propagation depends on the intended use. Although most techniques are labor-intensive and require large amounts of starting material, the use of isolation kits from a variety of biotechnology companies have made the isolation of DNA and RNA a relatively simple matter. Both classical isolation and kit isolation methods utilize the basic principles outlined below.

ISOLATION OF TOTAL GENOMIC DNA Genomic DNA is double-stranded and can be isolated from any kind of cell, including bacteria, yeast, plants, and animal cells. For most uses, it is desirable that the DNA remain as undamaged and the highest molecular weight as possible. The process of purifying DNA tends to introduce strand breaks and to reduce its molecular weight, but proper precautions can minimize shearing. There are many variations in the details of DNA isolation protocols, but all involve lysis of the cell and nucleus (if the cell has a nucleus) as a first step. A suspension of the DNA-containing cells is incubated with detergents and/or lytic enzymes for this purpose. The next step involves dissociation of the DNA from any attached proteins (such as histones). Most protocols utilize a strong protein degrading enzyme (proteinase K) for this purpose. This step also inactivates any DNA degrading cellular enzymes (nucleases). The partially degraded proteins are removed from the solution by phenol/chloroform extraction, salt precipitation, or the solution being passed over a column, which retains the DNA. DNA is precipitated from the remaining solution by ethanol precipitation. High-molecular-weight DNA (such as human genomic DNA) will form threads when precipitated in this way and can then be "spooled" from the solution with a glass rod. The DNA is then dried and redissolved in an aqueous buffer for further use and is stable in this form for several years.

ISOLATION OF TOTAL CELLULAR RNA Several different forms of RNA exist in cells, including messenger RNAs (mRNA), ribosomal RNAs (rRNA), transfer RNAs (tRNA), and others. For many types of studies (Northern blots, RT-PCR), the isolation of total cellular RNA species is acceptable. In contrast to DNA, RNA is single-stranded and relatively unstable. During RNA isolation and storage, constant caution should be taken to avoid degradation by RNase enzymes, which are ubiquitous. For RNA isolation, cells, or tissues are homogenized in a solution that contains RNase-inhibiting compounds, such as the chaotropic chemical guanidinium isothiocyanate. Many different methods are available for the next step, which involves separating the RNA from genomic DNA. As in DNA isolation, the purified RNA is precipitated with ethanol during the final step of all procedures. Aqueous RNA solutions should be stored frozen.

ISOLATION OF mRNA For certain applications, total cellular RNA is inadequate. Ribosomal RNA represents the bulk of total cellular RNA and only 1–3% of all RNA is mRNA. In order to make libraries of expressed sequences or to detect rare mRNA species on Northern blots, it is important to isolate mRNA as the starting material. Most mRNAs are poly-adenylated (poly[A]RNA), and this feature can be exploited for their capture. Total cellular RNA is passed over a column or resin of polydeoxythymine (oligo d/T column, poly-dT) bound to a solid phase. Poly(A) RNA binds to the poly-dT and is immobilized on the solid phase. The remaining unbound RNA is then washed off, and the poly(A) RNA is eluted in a subsequent step.
Figure 2-4 DNA polymerase-mediated synthesis of DNA. DNA polymerase will attach free nucleotides to an existing primer in the 5' to 3' direction in a complementary fashion. The dashed line indicates the complementary bases.

CLONING DNA

In the DNA isolation method described above, the genome of cells is the source of DNA; therefore, all sequences will be represented in the same abundance as they exist in the cell. Depending on the genome size of the organism, individual genes of interest represent only a minute fraction of the total DNA in a cell. For example, the average single gene in humans (~100,000-bp size) represents only 0.003% of the total genome. Thus, individual genes are much too dilute in such samples to be useful for detailed studies (such as DNA sequencing).

This problem is solved by the cloning of DNA, which allows the preparation of large and pure quantities of a single DNA species. All methods of DNA cloning involve the ligation of a sequence of interest (such as a human gene) into a cloning vector. Cloning vectors are DNA sequences that exist inside a cell (in most cases the bacterium *E. coli*) but are not part of the genome of that cell. The cloning vehicle (and the cloned DNA within it) replicates inside the host cell, producing large quantities of a specific DNA sequence that can be isolated for further study.

***E. Coli* PLASMIDS**   Cloning into *E. coli* plasmids remains the most important method for preparing large quantities of pure DNA. Plasmids are small circles of double-stranded DNA (2000–5000 bp) that replicate inside bacterial cells (Fig. 2-5). Plasmids have their own origin of replication and can propagate themselves with the help of the endogenous cellular machinery. Cloning plasmids contain a selectable marker, usually a gene that confers resistance to an antibiotic. *E. coli* cells containing this antibiotic-selectable plasmid are then able to grow in media containing the respective antimicrobial agent. Many plasmids contain the β-lactamase gene, allowing growth in ampicillin. Low- and high-copy-number plasmids are distinguished. Pure plasmid DNA can be isolated from *E. coli* genomic DNA, because plasmid DNA is much smaller in size than *E. coli* genomic DNA (the *E. coli* genome is ~1×10^6 bp). The plasmid-containing *E. coli* cells are grown in a large volume of liquid culture media containing the antibiotic of choice. The cells are then pelleted by centrifugation and lysed, either with alkali, or using detergents. All plasmid preparation methods use size selection to remove the high-molecular-weight genomic DNA and RNA leaving only the small circular plasmid DNA. Milligram quantities of pure plasmid DNA can be prepared from a 1-L culture of *E. coli* cells containing a high-copy-number plasmid.

Modern *E. coli* plasmids have been engineered to contain a region with multiple useful restriction endonuclease sites (polylinker sites). In order to clone a gene of interest, the following procedure is followed (Fig. 2-5): DNA from the parental plasmid is cut with a restriction endonuclease, thus opening the ring and converting it to a linear molecule. A linear double-stranded DNA sequence of interest is generated with matching ends and is then ligated into the gap to regenerate a circular plasmid. The ligated plasmid is introduced by a process called transformation into a strain of *E. coli* that is sensitive to the antibiotic resistance marker carried by the plasmid. Transformation of bacteria can be accomplished by either heating the DNA-bacteria mix at 42°C for 1 min or by a quick pulse of electricity (electroporation). Both methods move the plasmid DNA through the bacterial wall and into the bacterial cell. After transformation, the bacteria are grown on antibiotic-containing plates. Only cells that have taken up a circular plasmid are able to survive and form colonies in the presence of the antibiotic. Individual bacterial colonies are also called "clones," because every cell in the colony is genetically identical. Individual clones can be expanded in liquid media for the preparation of large amounts of plasmid DNA. Since bacterial cells are immortal and can continue to divide without limit, plasmid-containing clones represent a permanent source of DNA. The cells can be stored frozen indefinitely, and clones can be mailed and shared with other laboratories.

Modern high-copy-number plasmids are about 3 kb in size and can accommodate inserts of up to 15 kb. Most DNA cloned in plasmids, however, is less than 10 kb in size and larger sequences are frequently unstable. Thus, only relatively small pieces of DNA can be cloned in plasmid vectors. For this reason, multiple cloning vectors capable of harboring larger DNA sequences have been developed. The most important of these will be briefly described below.

PHAGE CLONING VECTORS   Bacteriophage λ is a virus that infects *E. coli* cells and has been used extensively for cloning. Its structure is very different from plasmids. Virus particles consist of a protein envelope and core and a linear double-stranded DNA genome. For cloning purposes, much of the wild-type genome has been removed to allow replacement by exogenous DNA. In contrast to plasmids, inserts of up to 23 kb in size are stable in phage.

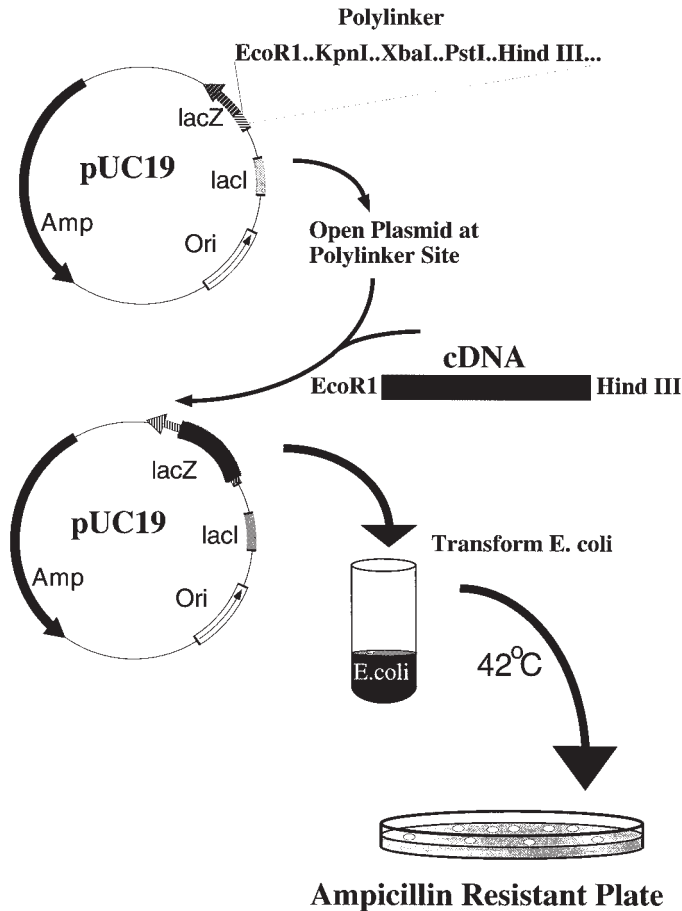
Cloning in phage (Fig. 2-6) is performed in the following way: A large internal portion of the wild-type phage genome is removed by restriction digestion leaving a long (or left) and short (or right)


Figure 2-5 Subcloning in bacteria. pUC 19 cloning vector is used to propagate cDNA. The plasmid carries a bacterial origin of replication (ORI). Also, a resistance gene for selection in ampicillin media (Amp), as well as a gene that can be used to detect for insertion of cDNA (*lac*Z). After opening the plasmid and introduction of the cDNA through restriction enzyme digestion and ligation, the construct is transformed into bacteria *(E. coli)* through either heat shock or electroporation. After transformation, bacteria are plated on resistant media, allowing the bacteria to grow only if they have taken up the plasmid containing the resistance gene. Growing the colonies with X-gal, a substrate for B galactosidase, clones that have been inserted into the *lac*Z gene and disrupted its reading frame, will no longer be able to metabolize X-gal and will appear white on the media plate. However, those colonies that may have religated and still contain a functional *lac*Z gene will metabolize X-gal and have a blue appearance.

arm. Neither of these two arms alone contains enough sequence to produce an infectious phage nor are the arms large enough to be packaged. The DNA sequence of interest is then ligated between the two arms, restoring a single large DNA genome. A "packaging extract" containing viral structural proteins isolated from wild-type phage is then used to package the recombinant phage and to infect *E. coli* cells.

After infection of a bacterial cell, λ phage replicates to high copy numbers within the cell and then lyses it. Phage particles are released and can infect other *E. coli* cells. When propagated on agar plates, phage will then lyse bacterial cells and leave a hole or "plaque" in the lawn of bacteria. Each plaque represents a clone of DNA, because all the phage in a plaque are genetically identical.

When a liquid culture of *E. coli* is infected with phage, most of the cells will lyse and a high density of phage particles is attained. Phage particles can then be purified and their DNA isolated in large quantities.

Recently, one other *E. coli* bacteriophage has become an important cloning vehicle. Phage P1 can stably harbor DNA inserts of up to 100 kb and is therefore used to clone long stretches of genomic DNA.

COSMIDS Cosmids harbor inserts of ~40 kb and are very useful cloning vectors. Their properties are similar to plasmids in many aspects. Cosmids can propagate in *E. coli* and do not lyse their host cell. Antibiotic resistance genes (usually ampicillin) are used to select for cosmid-containing cells, which form colonies on plates. Inserts are ligated into convenient restriction sites.

BACTERIAL ARTIFICIAL CHROMOSOMES Bacterial artificial chromosomes (BACs) are a special *E. coli* plasmid that can stably replicate very large inserts of genomic DNA. BAC inserts can be as large as 180 kb, and complete libraries of the human genome are now available in BACs. In contrast to YACs *(see below)*, BAC inserts are usually pure (nonchimeric), and the BAC DNA is very easy to isolate.

YEAST ARTIFICIAL CHROMOSOMES Yeast artificial chromosomes (YACs) have become very important in the human genome project, because they can harbor by far the largest inserts (up to 2000 kb). Because of this, a single YAC can cover a relatively large genomic region. In contrast to all other cloning vehicles described here, YACs are not grown in bacteria, but in the yeast *Saccharomyces cerevisiae*. YACs consist of a artificial centromere, the insert, and an artificial telomere, thus literally representing an artificial chromosome. Both the artificial centromere and the telomere contain different selectable marker genes. In order to generate a YAC, large pieces of DNA are ligated to the centromere on one end and the telomere on the other. This construct is then introduced into yeast, which is incubated on selective media plates. Only those yeast cells that contain both the telomere and centromere (and therefore both selectable marker genes) will survive and form colonies. Individual colonies (clones) can then be picked, grown in liquid culture, and YAC DNA can be isolated from the yeast cells.

YACs have the advantage of containing very large inserts, but they have the disadvantage of frequently being chimeric. Chimeric YACs contain inserts from more than one region of the genome, which can limit their experimental utility. For example, a chimeric YAC may contain an insert from chromosome 3p fused to a portion of chromosome 15.

LIBRARIES Cloning vectors such as those described above can be used to replicate a DNA sequence of interest and purify large quantities. But how are genes of interest found in the first place? The process by which gene(s) are isolated from the complex mix of DNA sequences found in cells of higher organisms will be described briefly.

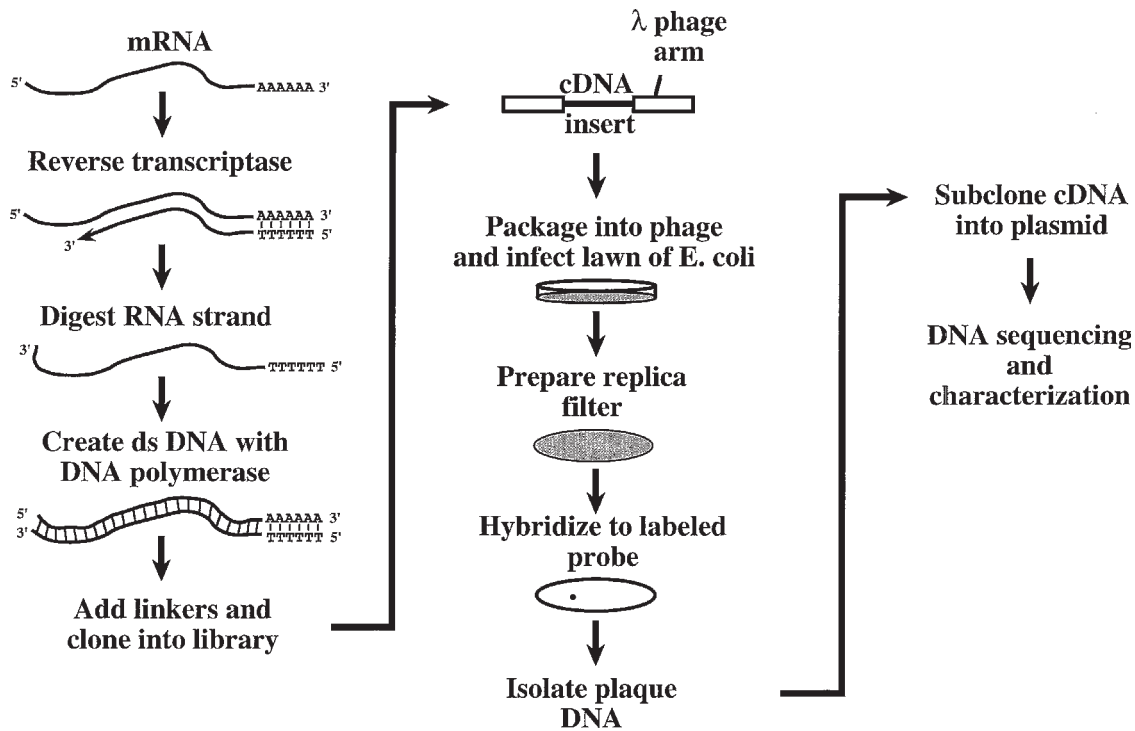
Most gene-isolation strategies have traditionally involved the generation of a library of DNA or RNA sequences. The beginning material for the library is a complex mix of DNA known to contain the sequence of interest. For example, the starting material for the isolation of a human gene would be total genomic DNA isolated from human cells. This DNA is then broken down into fragments of the appropriate size by mechanical shearing or by restriction endonuclease digestion. The appropriate size depends on the cloning vector to be used. For λ phage libraries, the average fragment


Figure 2-6 Construction of a cDNA library. mRNA is isolated and reverse-transcribed by reverse transcriptase. The RNA strand is digested away leaving single-stranded DNA to which oligo d/T primers and DNA polymerase are added. These primers will anneal to the poly (A) tail of the cDNA and are extended by DNA polymerase. The double-stranded cDNA is ligated into λ phage arms, and bacteria are infected. Filter lifts are performed on the lysed bacteria and hybridized with the appropriate probe. Following hybridization and autoradiography, the appropriate plaques may be isolated and the corresponding phage purified and characterized. Adapted with permission. (Jameson JL. Applications of molecular biology in endocrinology. In: DeGroot LJ, ed. Endocrinology, 3rd ed., Philadelphia, PA: WB Saunders, 1995; pp. 119-147.)

size should be 8–25 kb. This mixture of fragments is ligated into a cloning vector and the ligation reaction is used to infect or transform *E. coli* bacteria. The biology of cloning vectors assures that each individual bacterium will contain only one cloning vector with an insert. Thus, this procedure divides the initial complex mix of DNA into millions of individual clones, each of which contains only a single DNA sequence, a library. Libraries can be produced from any source of double-stranded DNA.

In order to identify the protein-coding regions of genes, however, it is necessary to generate libraries from expressed sequences. This type of library is called cDNA library and the starting material is messenger RNA (Fig. 2-6). To isolate the gene for a liver metabolic enzyme, for example, mRNA would be purified from homogenized liver. This material contains all mRNAs that are present in the liver. Some mRNAs will be very abundant, because they encode proteins present in high amounts in liver. Others transcripts will be rare. Reverse transcription is then used to copy the mix of mRNAs into first-strand cDNA. The cDNAs are then converted to double-stranded DNA and ligated into a cloning vector to produce the cDNA library. It is important to note that cDNA libraries are tissue-specific, because each tissue expresses a different set of genes. Similarly, cDNA libraries are specific for a developmental stage of the organism.

Once a library of clones has been generated from the nucleic acid source of interest, the challenge is to find the specific individual clone with the gene among the millions of clones in the library. This is achieved by library screening. The bacteria containing the library are spread on agar plates at a defined density, which is low enough to permit the isolation of individual clones.

A phage library produced from human genomic DNA, for example, would be plated a density of 50,000 plaques per plate. At this density, 20 plates represent about 1,000,000 individual clones. Part of each colony/plaque on a plate is then transferred, as an exact copy, onto a nitrocellulose or nylon filter in a procedure termed "filter lift." These filters are then processed to covalently bind either the DNA or the expressed proteins of the transferred plaques/colonies. The filters are incubated with a radioactively labeled DNA probe or specific antibodies, which will bind to the position on the filter occupied by a individual clone containing the desired DNA or expressing the sought-after protein. The corresponding clone is then picked from the original plate based on the position marked on the filter. DNA in the clone can then by amplified and isolated as described above, usually by subcloning it into plasmid vectors.

CHEMICAL PROPAGATION OF DNA

Large amounts of pure double-stranded DNA can be produced chemically by a method called the polymerase chain reaction (PCR) rather than by propagating cloning vectors inside living cells. Relatively small quantities of single-stranded DNA can be synthesized from individual nucleotides by oligonucleotide synthesis.

OLIGONUCLEOTIDES   A prerequisite for the advent of the now ubiquitously used polymerase chain reaction was the ability to chemically synthesize short pieces of DNA of defined sequence (oligonucleotides). This process begins with the attachment of the most 5' base in the oligonucleotide sequence to a solid polymer support. Each new base in the sequence is then added to the 3' OH-group of the attached bases in a stepwise fashion until the entire desired sequence has been synthesized. During each cycle of syn-

Polymerase Chain Reaction
Figure 2-7 PCR reaction. DNA template, primers A and B, and DNA polymerase *(Taq)* are combined in a reaction that will cycle through denaturation, annealing, and extension temperatures, allowing the amplification of DNA between the primer pairs.

thesis, only one new base is added, providing strict control over the sequence of the completed oligonucleotide. Conventional oligonucleotides contain one of the four bases contained in DNA at each position. However, it is also possible to customize the procedure and to utilize unusual nucleotides (e.g., inosine), modified nucleotides (tagged with fluorescent dyes or digoxygenin), or more than one base in a single position (degenerate oligonucleotides).

POLYMERASE CHAIN REACTION   PCR permits the investigator to generate large quantities of a specific DNA sequence from a complex mix of DNA within a very short period of time and without cloning. The procedure uses a thermostable DNA polymerase and two synthetic oligonucleotides (Fig. 2-7). The DNA sequence of the gene to be amplified needs to be partially known, so that two oligonucleotide primers corresponding to the ends of this target can be synthesized. The procedure then consists of repeated cycles of three steps: (1) denaturation of dsDNA, (2) primer annealing to DNA, and (3) primer extension. During denaturation, heat (94–98°C) is used to separate the two strands of the target DNA into single strands. These single strands are then available to hybridize to the matching oligonucleotide during the annealing step if the temperature of the reaction is lowered below the melting point for the oligonucleotide-DNA hybrid (usually 50–68°C). Once a primer has annealed, the DNA polymerase (*Taq* polymerase from the bacterium *Thermophilus aquaticus*) can copy the remainder of the single strand at 72°C, if the required

deoxynucleotide triphosphates (dNTPs) are provided. Each of the originally present strands of the target DNA is copied and the amount of DNA is doubled with each cycle. Thus, after 25–30 cycles, the desired sequence can be enriched over a millionfold. This allows direct visualization as a distinct band in an agarose gel, and this amount of DNA is more than adequate for cloning or DNA sequencing. The sequential temperature changes required for PCR are performed by machines called thermocyclers. A complete PCR typically takes about 1–3 h and is therefore the most rapid method to produce a specific DNA sequence for further study. Limitations of PCR include misincorporation of nucleotides by the *Taq* polymerase (*Taq* errors) and the inability to amplify relatively large lengths of DNA (several kilobases). Modified versions of *Taq* polymerase with higher fidelity can reduce the rate of PCR errors and increase the length of fragments that can be amplified.

PCR has numerous uses that are reviewed in detail in the attached references. As examples, PCR is used to: (1) amplify specific regions of DNA for genetic engineering strategies that do not depend on the presence of restriction enzymes; (2) amplify genomic DNA for diagnostic studies; (3) amplify DNA for sequencing protocols; (4) to insert site-directed mutations; and (5) in combination with reverse transcriptase, to quantify to the amount of starting mRNA (RT-PCR).

SITE-DIRECTED MUTAGENESIS

PCR has greatly enhanced the ease with which site-directed mutagenesis can be performed (although other procedures are also available for mutagenesis). Site-directed mutations have many valuable applications, including structure-function studies of receptors, transcription factors, enzymes, and other transcription factors. Site-directed mutations are also introduced into the regulatory elements of genes to alter transcription factor binding sites and assess the effects on promoter function. Site-directed mutations also facilitate genetic engineering by allowing the introduction of new restriction sites.

Mutagenesis typically involves a single nucleotide substitution, although it is also possible to change several basepairs at once (including small deletions or insertions). One commonly used protocol is referred to as overlap extension mutagenesis (Fig. 2-8). In this procedure, mutagenesis is performed by creating an oligonucleotide primer that is complementary to the normal DNA sequence except for the mutant base, which is generally positioned near the 5' end of the oligonucleotide to assure adequate priming. Using PCR, the mutant primer is incorporated into the newly synthesized DNA. Subsequently, the DNA products of this first PCR (now containing the mutation) are used to prime a second PCR in conjunction with a new oligonucleotide primer. After a few PCR cycles, a long mutant template is created that can be amplified further by using traditional PCR. Several variations of this strategy are reviewed in the listed references.

ANALYSIS OF DNA AND RNA

GEL SEPARATION   The size-based separation of DNA and RNA fragments by electrophoresis in various gels systems is a very important basic technique in molecular biology and is outlined briefly. At neutral pH, DNA and RNA are negatively charged and will migrate toward the anode in an electrical field. If this migration takes place within a polymer matrix (gel), small fragments move more rapidly than larger fragments (Fig. 2-2). Thus, electrophoretic migration through a gel gradually separates a mixture of DNA fragments of different sizes into distinct bands. Many
Figure 2-8 Site-directed mutagenesis. A mutant primer (asterisk) and normal 3' primer are used to amplify a cDNA template. The product of this reaction is used to amplify the template in conjunction with a normal 5' primer. This reaction results in a mutagenized cDNA that can be amplified further using normal primers.

Figure 2-9 Southern blot. Genomic DNA is isolated and digested with the appropriate restriction enzymes. DNA is then run on an agarose gel and transferred to a membrane support to which the DNA is covalently attached. Following transfer, the DNA is hybridized to the appropriate ^{32}P-labeled probe. Specific interactions between the DNA and labeled probe are detected by exposing the membrane-DNA to autoradiographic film. Adapted with permission. (Jameson JL. Applications of molecular biology in endocrinology. In: DeGroot LJ, ed. Endocrinology, 3rd ed., Philadelphia, PA: WB Saunders, 1995; pp. 119–147.)

different gel matrices can be used for nucleic acid separations, but agarose and polyacrylamide gels are used most commonly. Agarose gels are suitable for the separation of DNA fragments in the 0.1- to 20-kb range, whereas polyacrylamide are used to separate small DNA fragments in the 0.025- to 2-kb range. The inclusion of denaturants such as urea allows single-base resolution in polyacrylamide gels (e.g., for DNA sequencing). A specialized kind of agarose gel electrophoresis termed pulsed field gel electrophoresis (PFGE) is used for the separation of very large fragments (up to 1000 kb). Different techniques are used to visualize the DNA fragments after separation by gel electrophoresis. If the fragment is relatively abundant, gels can be stained during or after electrophoresis, and the DNA can be directly visualized. Ethidium bromide will bind to DNA and lead to red fluorescence under UV light. If there is too little DNA for direct visualization, radioactivity is used for detection (*see* hybridization, *below*).

NUCLEIC ACID HYBRIDIZATION   One of the most commonly used analytical methods is nucleic acid hybridization. This technique is used for Southern blotting, Northern blotting, and for screening libraries. The goal of this method is to visualize a specific nucleic acid (DNA or RNA) sequence in the background of a complex mixture of other sequences. The technique takes advantage of the fact that the two complementary strands of nucleic acids will bind to each other (hybridize) with very high specificity. In contrast, noncomplementary nucleic acid sequences do not bind very efficiently, because nucleotide mismatches lower the melting temperature. To detect a particular species of DNA or RNA in a complex mixture, the constituents are first immobilized on a membrane and converted into a single-stranded form (*see* Southern and Northern blotting, *below*). A hybridization solution containing

radioactively labeled single-stranded probe is added and the radiolabeled probe allowed to hybridize under defined conditions. The temperature and salt concentration of the hybridization fluid determine the specificity of binding. At high temperature and low salt concentration, the probe will bind only to a perfectly complementary target sequence. After hybridization, the excess nonbound radioactivity is washed off, leaving a radioactive signal to be detected only at the location of the specific target sequence. The radioactive signal is visualized by exposure to an X-ray film yielding a black spot or band at the site of the radioactivity.

SOUTHERN BLOTTING   When genomic DNA is digested with restriction endonucleases and separated by gel electrophoresis, individual fragments cannot be visualized, even if large quantities of DNA are used. Because of the complexity of genomic DNA, restriction digests will invariably result in a "smear" of thousands of DNA fragments when visualized with ethidium bromide staining. In order to detect specific fragments within this smear, hybridization with radioactive probes is used in a procedure termed Southern blotting (after Ed Southern) (Fig. 2-9). Southern blotting begins with the separation of restriction-digested

Table 2-2
Summary of Blotting Procedures

Procedure	Substance detected	Probe	Major application
Southern blot	DNA	Nucleic acid	Gene structure
Northern blot	RNA	Nucleic acid	Gene expression
Western blot	Protein	Antibody	Protein levels
Southwestern blot	Protein	DNA	DNA–protein interactions
Farwestern blot	Protein	Protein	Protein–Protein interactions

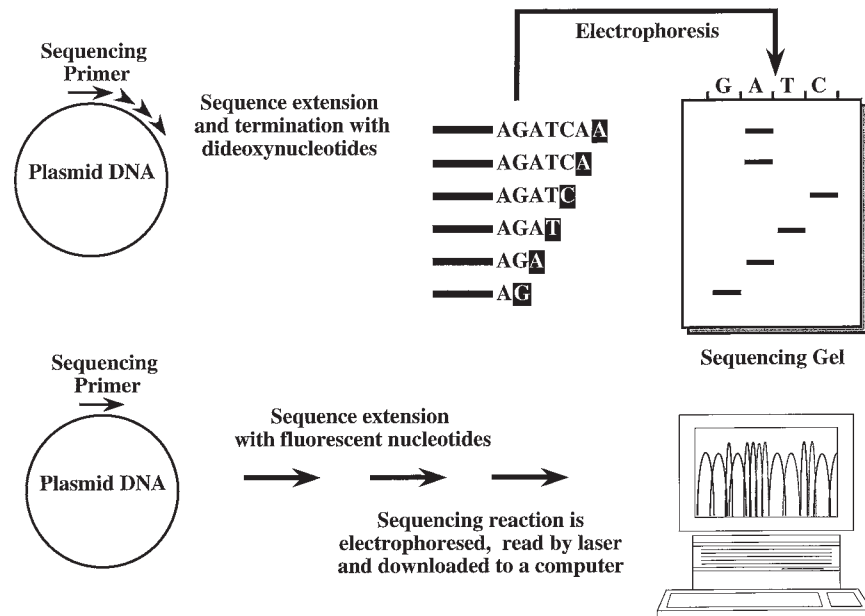

Figure 2-10 Sequencing of DNA. Template, primer, and polymerase are added to a reaction in which both dideoxy and deoxynucleotides are present. Four separate reactions are used in which ddATP, ddTTP, ddCTP, and ddGTP are used individually. Each of these reactions is run on a polyacrylamide gel. Alternatively, the sequencing reactions can be carried out using fluorescently labeled nucleotides (or primers) to allow detection by a laser. The DNA sequence is then downloaded into a computer. Adapted with permission. (Jameson JL. Applications of molecular biology in endocrinology. In: DeGroot LJ, ed. Endocrinology, 3rd ed., Philadelphia, PA: WB Saunders, 1995; pp. 119–147.)

DNA by gel electrophoresis. After the separation, the DNA is denatured (separated into two single strands) by treatment with alkali, and the single strands are transferred onto a membrane by capillary transfer. The DNA binds covalently to the membrane and is immobilized on this solid phase, creating a replica of the fragments in the gel. Specific DNA fragments can then be identified on the membrane using hybridization probes that are specific for the gene fragment of interest.

NORTHERN BLOTTING   Gel separation and nucleic acid hybridization can also be used to analyze RNA in a procedure termed Northern blotting (Table 2-2). There are several important differences in comparison with Southern blotting. First, RNA is more susceptible to degradation than DNA. Electrophoresis is therefore carried out in a buffer that contains protective chemicals (usually formaldehyde). Second, RNA is already single-stranded and requires milder denaturation. Third, specific RNA species already have a defined size, and therefore enzymatic digestion is not needed in order to obtain a band pattern. The two procedures are similar, however, in that the RNA is transferred onto a membrane via capillary diffusion after electrophoresis. Usually ultraviolet light is used to crosslink the RNA onto the membrane to immobilize it.

DNA SEQUENCING

The determination of the actual nucleotide sequence represents the most detailed level of DNA analysis. Several different techniques are available for DNA sequencing, but the dideoxy chain termination method originally developed by Sanger is now used the most widely (Fig. 2-10). DNA must first be denatured and separated into single strands by heating. A single radioactively labeled oligonucleotide primer is then added to the reaction and anneals to its matching sequence on the target DNA. DNA polymerase is then used to copy the single-stranded DNA. In the presence of saturating quantities of all four deoxynucleotide triphosphates (dATP + dTTP + dGTP + dCTP = dNTPs), a large extension product radioactively labeled at its end would be generated, whereas no sequence information would be generated. The addition of small quantities of dideoxy nucleotide triphosphates (ddNTPs) to the dNTP mix, however, leads to sequence information. Dideoxynucleotides are incorporated into the 3' end of the newly synthesized strand, but the DNA polymerase cannot add new bases onto the ddNTP. Thus, the incorporation of a ddNTP leads to chain termination. By adding appropriate ratios of dNTP

and ddNTPs, it is possible to achieve conditions in which chain termination occurs randomly at each nucleotide position. For example, if a primer extension was performed in the presence of dATP, dTTP, dGTP, and ddCTP, the polymerase will synthesize a new strand of DNA until it has to use ddCTP (e.g., when the complementary base is G). The ddCTP will be incorporated, but the polymerase cannot extend beyond this point. The length of the radioactive extension product therefore defines the position of the first G in the strand that is being copied. In order to determine the position of not only the first G, but additional Gs in the DNA, real sequencing reactions would be performed in the presence of a mix of dCTP and ddCTP at a molar ratio of ~200:1. In this setting there is a ~1:200 chance for a chain termination to occur when a G is present in the strand being sequenced. Extension products of multiple lengths will be generated and can be visualized after electrophoresis in a polyacrylamide gel. Based on its length, each fragment precisely defines the position of a G. In order to determine the positions of all four bases, four separate sequencing reactions are performed for each sample. In each case, a mixture of a given dNTP and its corresponding ddNTP is used in combination with saturating amounts of the three other dNTPs. The four reactions are then electrophoresed in adjacent lanes in a sequencing (denaturing polyacrylamide) gel, thereby permitting direct reading of the DNA sequence. Despite the relative complexity of chain termination theory, DNA sequencing in practice is relatively straightforward.

Modern technology has allowed partial automation of DNA sequencing. For large-scale projects, robotics can be used to prepare sequencing reactions. Perhaps more importantly, instrumentation allows real-time "reading" of DNA sequencing gels and automated entry into computer databases. In addition to the reduction in human effort, such automation reduces errors inherent in reading and entering DNA sequence manually. Currently, most automated sequencers use fluorescent dyes rather than radioactivity. The dyes can be incorporated into either the sequencing primers or into the incorporated nucleotides. As with manual sequencing, gel electrophoresis (or capillary electrophoresis) is used to separate DNA fragments by size. However, with automated sequencers, detection of the fluorescent DNA fragments occurs via a laser beam, and the signal is processed by a computer. Other methods of automated sequencing are in development, including the use of DNA chips. In this strategy, a large ordered array of oligonucleotides are attached to DNA chips. Hybridization of DNA fragments to the chips allows the detection of overlapping sequences that can be converted into a contiguous sequence of DNA. This technology is particularly promising for the detection of polymorphisms and mutations, because a known sequence can be applied to the chips with specific variations at each nucleotide.

DETECTION OF DNA SEQUENCE POLYMORPHISMS

DNA sequence polymorphisms play an important role in molecular genetics. A DNA polymorphism is a DNA sequence alteration that is found at a frequency of >1% in a given population. In contrast to mutations, these sequence alterations do not adversely affect the function of genes. They can be thought of as neutral variations in DNA sequence. Polymorphisms are important, because they permit the tracking of gene loci and attached regions in pedigrees. Many different classes of DNA polymorphisms and methods for their detection exist. The most important of these will be reviewed here.
Figure 2-11 Restriction fragment length polymorphism (RFLP). Genomic DNA is isolated and primers are added with DNA polymerase to amplify the targeted region of DNA. The two alleles differ in a *Eco*RI restriction site, the first allele having a *Eco*RI site (GAATTC), the second allele having a C for a G base change (CAATTC). Following amplification and digestion with *Eco*RI, the products are run on an agarose gel along with uncut samples. Individual 1 is homozygous for allele 1, individual 2 is heterozygous for the alleles, and individual 3 is homozygous for allele 2.

RESTRICTION FRAGMENT-LENGTH POLYMORPHISMS

The simplest kind of DNA polymorphism is a single-base change. If the altered base lies within a recognition site for a restriction endonuclease, it may destroy the recognition sequence of this enzyme and abolish the site (Fig. 2-11). Alternatively, the polymorphism may create a new site. Single-base polymorphisms of this nature will alter the size of DNA fragments resulting from a digestion with this enzyme. The altered size bands can be detected after agarose gel electrophoresis and Southern blotting. If a restriction site was destroyed, the polymorphic band will be larger, and if a new site was generated, it will be smaller than the prevalent band in the general population. Single-base polymorphisms have been estimated to be present approximately every 1 kb in the human genome. About 1/6 of these changes will be detectable as a restriction fragment-length polymorphism (RFLP). Although RFLPs are relatively abundant in the genome, their use is limited by the fact that there are only two possible alleles for each polymorphism. The restriction site is either present or absent. In addition, Southern blotting requires relatively large amounts of DNA for analyses (5–10 µg).

Table 2-3
Techniques Used for the Detection of Mutations

Method	Gene deletions	Gene rearrangements	Loss of heterozygosity	Linkage	Point mutations

VARIABLE NUMBER TANDEM REPEATS Another important class of polymorphisms are the variable number tandem repeats (VNTRs) (minisatellites), used for forensic applications and paternity testing. VNTRs consist of reiterated repeats of small DNA sequences (0.1–10 kb) in multiple copies. The number of repeats in a VNTR is highly polymorphic (e.g., very variable between individuals in a population). To detect the polymorphism, a restriction endonuclease is used, which cuts outside of the repeat. The fragments obtained from such a digest will vary depending on the number of repeats and are readily distinguished by agarose gel electrophoresis and Southern blotting. In contrast to RFLPs, VNTR polymorphisms can have many different alleles (in some cases over 100), resulting in many different fragment sizes. However, VNTRs are relatively rare polymorphisms, and their density in the human genome is insufficient to permit linkage analysis for all human chromosomes.

MICROSATELLITES Microsatellite repeats are similar to VNTRs in that a simple sequence is reiterated in multiple copies, and the alleles are distinguished by their sizes. However, the repeats in microsatellites are much more simple. The most commonly used repeat sequences are dinucleotide, trinucleotide, and tetranucleotide repeats. Dinucleotide repeats are common in mammalian genomes, particularly the dinucleotide CA. Microsatellite repeats are detected by PCR. Two primers flanking the repeat are used to amplify the region, and the products of the PCR reaction are then analyzed in a denaturing polyacrylamide gel (*see* Chapter 5). If a dinucleotide repeat differs from the population by a single repeat unit, this will give rise to a PCR product that is differs in size by 2 bp. Differences of this magnitude, however, are detectable in polyacrylamide gels. Similar to VNTRs, microsatellite repeats usually have many different alleles (repeat sizes). Because their detection is PCR-based, and because they are common in the genome, this class of polymorphisms has become the most important for gene mapping and diagnostic linkage analysis (*see* Chapters 4 and 5).

DETECTION OF MUTATIONS

Mutations are DNA sequence alterations that change the function of a gene or the protein encoded by the DNA sequence. Many different kinds of changes can disrupt gene function. These include: gene rearrangements, deletions of DNA (large and small),

insertions, and single-base changes. The optimal technique for the detecting mutations is dependent on the nature of the mutation (Table 2-3). Large chromosomal rearrangements, insertions, and deletions (megabases in size) are best analyzed by cytogenetic techniques, including fluorescent *in situ* hybridization (FISH). FISH uses fluorescently labeled probes to hybridize to chromosomes. A catalog of fluorescent probes is available for mapping each chromosome as well as typical inversions and deletions. Southern blotting is used to detect sequence changes that involve hundreds to thousands of bases.

More subtle mutations, including insertions and deletions of a few base pairs, and single-base changes, require specialized techniques for screening and characterizing mutations. There are two basic starting materials for mutation analyses: mRNA and genomic DNA. In comparison to genomic DNA, the analysis of mRNA has the advantage that the entire transcript can be analyzed in one piece (the introns have been spliced out). The disadvantage of mRNA analysis is that the gene of interest has to be expressed in accessible tissue. For example, a gene responsible for a brain disorder may not be expressed in skin or blood cells. On the other hand, it is sometimes possible to extract mRNA from leukocytes to characterize a gene that is expressed predominantly in another tissue (e.g., thyroid-stimulating hormone receptor mRNA). In order to analyze mRNA for mutations, reverse transcriptase is used to produce first-strand cDNA. This cDNA is then specifically amplified by PCR. This procedure is termed reverse transcriptase-PCR (RT-PCR). Genomic DNA is present in all cells regardless of whether or not the gene is expressed. However, the "interesting" protein coding sequences of the gene are dispersed on multiple exons, which can be thousands of base pairs apart (*see* Chapter 1). Therefore, in order to analyze genomic DNA for mutations, individual exons are amplified by PCR for analysis. Several methods exist to detect mutations on PCR products derived from mRNA or genomic DNA. These include a variety of screening methods that detect altered DNA secondary structure including denaturing gradient gel electrophoresis (DGGE), single-stranded conformational polymorphism (SSCP), and several mismatch cleavage techniques. These techniques are most useful for screening large genes in which mutations occur in a widely distributed manner. The protein truncation test (PTT) is also useful for detecting frameshift or premature stop mutations in large genes. In this case, the mRNA

Table 2-4
Selected Uses of Recombinant Proteins

Purpose of recombinant protein expression	Examples
Unlimited amount of biologically active drug	Insulin, growth hormone, erythropoietin
Abundant source of pure enzyme	Restriction endonucleases, *Taq* polymerase
Protein structural studies	X-ray crystallography, NMR
Structure–function studies	Transcription factors, enzymes
Drug screening	Receptors, enzymes
Raise antibodies	Protein antigen
Detect protein–protein interactions	Yeast two-hybrid assays, farwestern screening

is converted to cDNA, transcribed, and translated in vitro, allowing the detection of mutations that truncate the protein. For genes that have "hot spots" for recurring mutations, oligonucleotide-specific hybridization (OSH) can be used to detect specific mutations that allow mutant oligonucleotides to hybridize to mutated genomic DNA. As noted above, DNA chip technology is likely to play an analogous role in mutation detection in the future. DNA sequencing is the most definitive technique for detecting mutations and will determine the exact nature of the genetic change. Using a combination of PCR and direct DNA sequencing, it is practical to screen many small genes for mutations. Improvements in the protocols for automated DNA sequencing now allow reliable detection of heterozygous mutations (dominant or compound heterozygotes). These protocols allow about 500 bp to be sequenced reliably in a single run.

EXPRESSION OF RECOMBINANT PROTEINS

The ability to express large quantities of functional recombinant proteins is one of the many advantages conferred by the cloning of cDNAs. There are many practical uses for recombinant proteins (Table 2-4). They provide unlimited sources for reagents such as restriction enzymes and represent an invaluable source for hormones and growth factors, such as human insulin and erythropoietin, that are difficult to isolate in abundance from natural sources. The availability of abundant amounts of recombinant proteins has greatly facilitated biophysical studies and structure-function analyses of proteins.

IN VITRO TRANSLATION OF RECOMBINANT PROTEINS
There are now numerous methods and hosts for expressing recombinant proteins, only some of which will be reviewed here. The simplest form of expression involves in vitro translation using reticulocyte lysates. In this method, mRNA (usually transcribed in vitro from a cDNA cloned into a plasmid) is translated using crude preparations of ribosomes present in reticulocyte lysates. Although the amount of protein is not large, it is possible to label it by including radioactive amino acids (e.g., ^{35}S-methionine). In vitro translated proteins can be used as substrates for enzymes, in catalytic reactions, immunoprecipitations, DNA–protein interaction assays, and so on.

E. Coli EXPRESSION OF RECOMBINANT PROTEINS   *E. coli* were an early host for expression and continue to represent an important source for producing recombinant proteins. Expression in *E. coli* works best for relatively small, intracellular proteins that do not require extensive posttranslational modification for func-

tion. Proteins are expressed using plasmid expression vectors, many of which can be induced by treatment with reagents such as IPTG (relieves promoter repression), to cause high-level expression before purification. Attaching proteins of interest to other molecules such as β galactosidase can sometimes stabilize a protein that is otherwise subject to degradation in *E. coli*. It is also common to add a purification tag to the expressed protein to facilitate its recovery after expression. Common tags include glutathione-*S*-transferase (GST) for isolation on glutathione columns or a polyhistidine tag for isolation on nickel columns. Advantages of *E. coli* expression include the relative ease of the recombinant DNA manipulations (similar to plasmid cloning) and the rapid selection and expression process. Disadvantages include its inability to perform complex processing like glycosylation, and the fact that some proteins are labile (or toxic) in this host. Also, large proteins are not usually produced or folded efficiently.

BACULOVIRUS-MEDIATED EXPRESSION OF RECOMBINANT PROTEINS   Baculovirus-driven expression in insect cells is another very common strategy for recombinant protein expression. Using transfer plasmids containing the cDNA of interest, recombination occurs with the baculoviral DNA in Sf9 cells such that the DNA sequence encoding a major viral coat protein, polyhedrin, is replaced with the protein of interest. This results in very high expression of the recombinant protein. Sf9 cells can carry out glycosylation (although structurally distinct from mammalian cells), and it is also possible to coexpress more than one protein subunit (e.g., immunoglobulins). The recombinant protein often assumes a relatively normal cellular localization (e.g., receptors on the membrane; transcription factors in the nucleus), although the high level of overexpression ultimately distorts this pattern. The high level of expression facilitates purification unless aggregation occurs. However, the requirements of recombination and selection make this system somewhat cumbersome if a large array of mutant proteins need to be investigated.

EXPRESSION IN MAMMALIAN CELL LINES   For many proteins, it is desirable to perform expression in mammalian cell lines. These systems, while they rarely produce proteins as efficiently as *E. coli* or Baculovirus, have the advantage of processing complex polypeptides using intracellular machinery adapted for this purpose. In addition to requirements for precise peptide processing, folding, or glycosylation, the purpose of producing many recombinant proteins requires their expression in an homologous or tissue-specific system. For example, studies of certain receptors or transcription factors require their expression in cells that contain appropriate cofactors or targets. In the case of mammalian cell lines, expression of a cDNA is usually driven by a strong viral promoter. Alternatively, inducible expression vectors have been developed that allow selection of a clonal cell line followed by induction of the promoter by the addition (or removal) of reagents (e.g., tetracycline) that modulate promoter activity. Proteins with appropriate leader sequences may be secreted into the media. Although this results in dilution, there are many fewer contaminants in the extracellular media compared to the intracellular contents.

EXPRESSION BY ADENOVIRAL VECTORS   A variety of viruses have been used for expression in mammalian cells, taking advantage of the natural tropism of viruses and their ability to induce alterations in the intracellular protein synthesis machinery that results in high-level expression. Adenoviral vectors have been of interest because they infect a wide spectrum of mammalian cells and because the adenoviral genome has been successfully altered

to create replication-deficient viruses that can harbor mammalian gene sequences. Adenoviruses have been used to express recombinant proteins in cell lines and tissues that are otherwise difficult to transfect with high efficiency. However, their use as vectors for gene therapy has made them a particularly attractive system for gene expression.

By deleting key adenoviral genes, the modified virus can function as a carrier of mammalian genes. Introduction of the viral vector containing the gene of interest into E1a-expressing 293 cells allows the virus to be packaged and harvested, but it does not replicate in other cells. Adenovirus vectors have been used to express normal genes in defective organs (e.g., expression of CFTR in the lungs of patients with cystic fibrosis), to express toxic genes in tumors (e.g., *thymidine kinase* in brain tumors), and to target cell-cycle arrest genes in proliferating vascular cells. Limitations of adenovirus include an inability to accept foreign DNA greater than about 10 kb, relatively short-term expression in vivo (weeks to months), cytotoxicity, and induction of immune responses. Several other viral delivery systems are under investigation including Adeno-associated virus, Herpes virus, and retroviruses (which integrate in the host genome). Vaccinia viruses have also been used to express recombinant proteins in cell lines, such as HeLa cells, and provide an efficient mechanism for high-level expression of genes in mammalian cell lines.

OTHER SYSTEMS FOR RECOMBINANT PROTEIN EXPRESSION   Although some of the guidelines noted above can help to direct the choice of an expression system, often this requires empiric trials of different systems to determine which one yields the highest levels of expression, the best bioactivity, or is most cost-effective in terms of reagents or labor. Thus, it is valuable to have an array of other alternative expression systems. Discussion of each of these is beyond the scope of this chapter, but they are described in the references. Other expression systems are as diverse as production in animal milk, *Drosophila*, yeast, and plants.

PROTEIN INTERACTIONS WITH DNA

Studies of protein–DNA interactions usually involve transcription factors that bind to regulatory elements in the promoters of genes (*see* Chapter 3). Characterization of these interactions can be accomplished by a variety of footprinting assays and more direct studies of protein binding to DNA, such as electrophoretic mobility shift assays. The goal of these studies is to identify the protein binding region of a gene, to characterize the transcription factor, and to correlate these results with functional studies of the promoter regulation.

DNA FOOTPRINTING   Footprinting techniques refer to the fact that proteins can protect DNA from digestion by a nuclease, thereby leaving a footprint in the position where the protein was bound (Fig. 2-12). Footprinting assays can be performed in vivo and in vitro, and these approaches often give different results, suggesting that the interactions (or proteins involved) may be different in the intact cell in comparison to naked DNA that has been mixed with nuclear protein extracts.

For in vitro footprinting, DNA is labeled on one of the two strands and mixed with nuclear proteins. After allowing the sequence-specific proteins to bind to DNA, the nuclease DNase I is added at a concentration that will digest the DNA in a nearly random manner. The DNase I concentration used should cause somewhat less than one digestion per template to produce a ladder

of labeled fragments. Where protein is bound to DNA, there will be an area that is protected from DNase I digestion. As a control, digestion of the same DNA fragment is carried out in the absence of nuclear proteins, or better still, using extracts that lack specific transcription factors. Digestion reactions are run on a DNA sequencing gel, such that a ladder of fragments is obtained. The areas that were protected by proteins are undigested compared to control DNA and appear as gaps. In vivo footprinting is similar except that permeabilized cells, or intact nuclei, are exposed to DNase I before isolation of DNA. The pattern of protection and digestion can be determined by using ligation-mediated PCR. Some footprinting procedures detect the ability of chemical modifications of specific residues (e.g., methylation) to modify access to DNA. For example, cells can be treated with dimethyl sulfate (DMS), which methylates guanine residues on the N7 position. DMS moves freely into the cell and methylates about 1 in 50 guanine residues. If a protein contacts a specific guanine residue, it will protect it from methylation and subsequent cleavage by piperidine. In addition, DMS treatment and piperidine cleavage can be combined when ligation-mediated PCR with gene-specific primers is used to amplify the gene of interest.

Although they are valuable for defining protein-binding regions, footprinting assays have several shortcomings. It is only possible to analyze about 150–200 bp at a time. Although one may identify a protected region of a gene, little information is gained concerning the number or nature of the bound proteins. The sensitivity of the assay is relatively low and detects primarily abundant, high-affinity proteins, since any free DNA in the reaction will partially obscure a footprint. The resolution of the binding site is relatively low, as DNase I cleavage may occur several basepairs away from a binding site and is somewhat sequence-specific. Last, it is relatively difficult to carry out detailed mutagenesis studies of the protein interaction site. For these reasons, other procedures such as the electrophoretic mobility shift assay (EMSA) have gained favor.

ELECTROPHORETIC MOBILITY SHIFT ASSAYS (EMSA) The EMSA is based on the fact that proteins bound to DNA shift its mobility during gel electrophoresis, forming new low-mobility complexes (Fig. 2-12). Whereas footprint analyses provide information about a broad region of interaction (150–200 bp), the labeled DNA used for EMSA is generally 10–50 bp in length. EMSA is highly sensitive and, because mutant oligonucleotides can be readily synthesized, the assay is particularly useful for determining the exact nucleotides necessary for protein binding. The changes in mobility of the DNA-protein complexes are somewhat proportional to the molecular mass of the protein complexes. For this reason, EMSA is useful for studies of protein dimerization and for resolving oligomeric protein complexes. EMSA also allows further characterization of the protein of interest by performing competition studies with unlabeled oligonucleotide and by using antibodies to supershift specific proteins.

The assay is performed by labeling an oligonucleotide with ^{32}P and performing incubations with proteins in nuclear or whole-cell extracts. It is usually necessary to include nonspecific oligonucleotides or carrier DNA to reduce the nonspecific binding to the labeled probe. The reactions are then subjected to non-denaturing polyacrylamide gel electrophoresis and exposed to autoradiographic film. The unbound DNA and DNA–protein complexes appear as distinct bands, reflecting their original mobility in the gel. Excess unlabeled oligonucleotide can be used as a
Figure 2-12 DNase I footprinting and electrophoretic mobility shift assays (EMSA). A variety of techniques can be used to detect DNA–protein interactions. **(A)** Schematic illustration of a transcription factor bound to DNA. **(B)** DNase I digestion of labeled DNA generates a ladder of labeled fragments. Protein bound to DNA protects it from digestion with DNase I, creating the appearance of a footprint. **(C)** EMSA refers to a delayed migration of labeled DNA caused by the binding of protein to DNA. The mobility shift of labeled DNA in the presence of protein is depicted in lane 2. Addition of unlabeled competitor DNA displaces bound protein (lane 3). Addition of an antibody (Ab) against the protein causes a supershift of the complex (lane 4).

competitor to establish the specificity of binding to the labeled probe. By using distinct oligonucleotide sequences that are known to bind particular proteins, it is possible to provide evidence for the nature of the bound proteins. As noted above, it is possible to further define the identity of binding proteins by using antibodies against candidate proteins. Antibodies can cause two different outcomes. If the antibody recognizes the protein in such a way that it alters DNA binding (e.g., recognizes the DNA binding domain), it may inhibit binding. Alternatively, an antibody may interact with the protein while it is bound to DNA, causing a supershift because of the addition of the high-molecular-mass antibody.

DNA AFFINITY COLUMN   Isolation of unknown proteins can sometimes be accomplished by the use of an oligonucleotide affinity column. Using the methodologies described above, specific protein-binding DNA sequences can be identified along with mutations that disrupt protein binding. These oligonucleotides (usually multimerized) are biotinylated and attached to an avidin-containing column matrix. After partial purification, relatively crude protein extracts can be passed over the DNA affinity column that will retain specific binding proteins. It is sometimes useful to apply the eluted proteins to a mutant oligonucleotide column to eliminate nonspecific binding proteins. Several cycles of affinity chromatography can greatly enrich the specific activity of binding proteins. A common goal in this procedure is to obtain enough protein with sufficient purity for peptide sequencing to allow identification and cloning (using degenerate oligonucleotides) of the cognate transcription factor. Other uses include partial purification of transcription factors for in vitro transcription assays.

PROTEIN–PROTEIN INTERACTIONS

Protein–protein interactions can be identified by a variety of methods. Three methods will be discussed below: farwestern, immunoprecipitation, and yeast two-hybrid analyses.

FARWESTERN   In a farwestern analysis, a protein is labeled and used to detect interacting proteins in a manner somewhat analogous to the use of antibodies in a Western blot (Table 2-2). The protein of interest must be expressed and labeled. If the protein is a phosphoprotein, in vitro phosphorylation with labeled ^{32}P-ATP and an appropriate kinase can be used. Alternatively, a protein kinase A tag may be added to the cDNA, allowing in vitro phosphorylation of the protein with protein kinase A. In vitro translation with radioactive amino acids such as ^{35}S-Met can also be used to label proteins that are to be used as probes. The assay is performed by subjecting whole cell extracts or nuclear extracts (or known proteins) to denaturing gel electrophoresis and allowing the proteins to renature during the transfer to a membrane. The labeled protein is then used to detect specific proteins on the membrane, providing an indication of the number of protein interactions and the approximate molecular weights of interacting proteins.

An analogous procedure can be used to screen expression cDNA libraries. Usually, farwestern blots of protein extracts are used to demonstrate that the protein probe works well and to establish specificity before a library is screened. This strategy was used, for example, to clone CREB binding protein (CBP) using ^{32}P-labeled CREB (cAMP response element-binding protein).

IMMUNOPRECIPITATION   Immunoprecipitation involves the use of a specific antibody directed against a protein to precipi-

tate it (along with other interacting proteins) from crude extracts. Currently, many antibodies (either polyclonal or monoclonal) are raised against recombinant proteins. Alternatively, if an antibody is unavailable, an epitope tag can be added to a cDNA to allow immunoprecipitation of the expressed protein.

In many cases, immunoprecipitation is carried out using cells that have been metabolically labeled with ^{35}S-methionine to allow detection of relatively small amounts of protein. After metabolic labeling, cells are lysed and incubated with the antibody to a specific protein. Precipitation is often performed using Staph A to recognize antibody complexes. After denaturing gel electrophoresis, precipitated proteins can be visualized by autoradiography. As noted above, in addition to the protein that the antibody is directed against, immunoprecipitation may also bring down proteins that are associated with the protein of interest. It is important to distinguish candidate-associated proteins from proteins that are precipitated nonspecifically.

YEAST TWO-HYBRID   The yeast two-hybrid method takes advantage of the modularity of proteins. Construction of a hybrid molecule between the DNA-binding domain of a yeast transcription factor, Gal 4, and the protein of interest, creates a "bait" with which one can search for protein–protein interactions. The other construct is created by fusing a candidate-interacting protein to the transcription-activating domain, VP16. In this manner, a successful protein–protein interaction will bring the VP16 transactivation domain to the Gal 4 DNA binding domain, inducing transcription of genes that contain Gal 4 target sequences (Fig. 2-13). A variation of this procedure inserts a library of cDNA sequences into the VP16-containing construct to test for clones that interact with the bait protein, thereby inducing the transcription of selectable genes in yeast.

In a common version of this procedure, yeast cells are transformed with the cDNA-VP 16 fusion genes and transferred to restricted media. The gene necessary for growth on the restricted media is under the control of the Gal 4 transcription factor. The Gal 4 is fused with the protein-interaction domain of interest and should be designed to lack a transactivation domain. In this manner, for the yeast to grow on restricted media, protein–protein interactions must occur that bring the VP16 activation domain to the Gal 4 DNA-binding domain. From yeasts that are selected, clones of the VP16 fusion proteins can be isolated and analyzed further.

ASSAYS OF GENE TRANSCRIPTION

Transcription assays are used to identify pathways that induce gene expression at the level of transcriptional initiation. In this manner, they extend the information gained by studies of steady-state mRNA levels, which are usually determined by techniques such as Northern blots, RNase protection assays, or RT-PCR. Using reporter genes as a reflection of the activity of transfected promoter–reporter fusion genes, it is possible to dissect the DNA regulatory elements within the promoter. An overview of nuclear run-on transcription assays and reporter gene assays will be presented in this section.

NUCLEAR RUN-ON ASSAYS   Having demonstrated regulation of a mRNA by Northern blot or alternative methods, it is often important to know whether alterations in steady-state mRNA levels are because of changes in transcription of the gene or changes in mRNA stability. The nuclear "run-on assay" is classic approach for studies of transcriptional regulation. In this procedure, nuclei are isolated after a specific stimulus and allowed to
Figure 2-13 Yeast two-hybrid assay. A cDNA library is inserted into the VP16 fusion construct and introduced into yeast cells carrying the Gal 4 fusion construct, bait. A Gal 4 construct is created by fusing the Gal 4 DNA binding domain and the gene of interest. If protein–protein interactions take place between the gene of interest and the random cDNA-VP16 fusion, expression of the *leucine* gene will allow for the growth of yeast on leucine minus media.

carry out mRNA synthesis in vitro, because the amount of mRNA synthesis under these conditions reflects the number of transcripts initiated prior to isolation of nuclei. The initiated transcripts are elongated in the presence of radiolabeled ribonucleotides, and the labeled mRNA is hybridized to specific clones of immobilized DNA to allow quantitation.

TRANSIENT GENE EXPRESSION AND REPORTER GENE ASSAYS IN TRANSFECTED CELLS   Transient gene expression studies provide an alternative technique for examining transcriptional control (Fig. 2-14). This method also allows detailed mutagenesis of cloned promoter sequences prior to their introduction into cells. In this procedure, the promoter sequences of genes are fused to a reporter gene that can be assayed readily. Common reporter genes include *chloramphenicol acetyltransferase* (CAT) and *luciferase* (LUC). In each case, these reporter genes represent enzyme activities that are not normally found in eukaryotic cells. Thus, in the absence of gene transfer, the background activity of these reporter enzymes is negligible. A host of commercial vectors are now available to allow the insertion of promoter or enhancer elements into various reporter gene constructs.

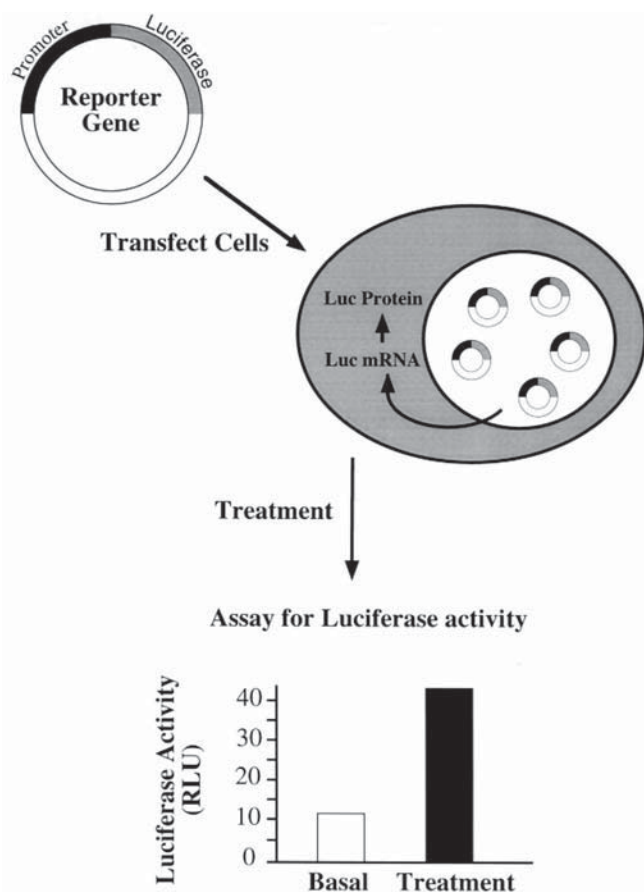
CAT assays catalyze the transfer of the acetyl group from acetyl-CoA to the substrate, chloramphenicol, and can be monitored by thin-layer chromatography, enzyme-linked immunosorbent assay (ELISA), or by liquid scintillation counting.


Figure 2-14 Luciferase reporter assay. Reporter plasmid is transfected into cells. Reporter plasmids mediate the transcription of the *luciferase* gene, which is then translated into luciferase protein. Six to forty-eight hours later the cells are lysed and assayed for luciferase activity. Adapted with permission. (Jameson JL. Applications of molecular biology in endocrinology. In: DeGroot LJ, ed. Endocrinology, 3rd ed., Philadelphia, PA: WB Saunders, 1995; pp. 119–147.)

Luciferase assays use the *luc* gene from the firefly, *Photinus pyralis*, which catalyzes the reaction of D-luciferin and ATP in the presence of O_2 and Mg^{+2}, to result in light emissions than can be measured using a luminometer. For both assays, the amount of enzyme activity is proportional to the amount of mRNA expressed, which, in turn, reflects the activity of the promoter being used. Luciferase assays are 30–100 times more sensitive than CAT assays. A variety of other reporter genes are also used, including β *galactosidase*, *growth hormone*, *alkaline phosphatase*, and *green fluorescent* protein genes.

The promoter–reporter fusion gene constructs are introduced into cells using a process referred to as transfection. Common transfection protocols include $Ca^{2+}PO_4$, DEAE-dextran, lipid-based, and electroporation. Transfected genes are transcriptionally active over 24–72 h, allowing relatively rapid analyses of promoter function. Alternatively, transfected genes can be stably introduced into cells by selecting for a resistance marker such as neomycin or dihydrofolate reductase. The principal goal of transfection experiments is to define DNA sequences that are required for promoter function or that respond to a specific extracellular signal or second messenger pathway. A variety of methods are now available to allow deletion or site-directed mutagenesis of promoter elements (Fig. 2-8). This approach has been critical for defining DNA sequences that regulate tissue-specific expression, basal promoter activity, and responses to intracellular signaling pathways.

3 | Transcriptional Control of Gene Expression

WADE JOHNSON AND J. LARRY JAMESON

INTRODUCTION

The concepts of gene function and transcriptional control are intimately intertwined. Early ideas about genes were based on specific traits that could be transmitted in a predictable manner through generations. From Gregor Mendel's studies of peas, the principle of using statistical approaches to understand genetics was established. His studies revealed the ability to predict the proportions of peas that would be yellow or green or exhibit smooth or wrinkled traits. The notion that these or other transmissible features were conveyed by genes was made more concrete by the studies of T. H. Morgan, who studied genetic transmission in Drosophila. Morgan demonstrated that certain traits were inherited together (or linked), reflecting their locations on the same chromosome. He also found that genes underwent recombination in a manner that reflected their distance from one another on a chromosome. Thus, genes that are widely separated have a greater statistical chance to undergo recombination than do genes that are immediately adjacent. These concepts of genes predated, of course, any understanding of the physical structure of a gene.

Pivotal concepts in the field of gene expression were articulated by Francois Jacob and Jacques Monod. They formulated the idea of a "messenger," now known to be mRNA, that linked genes to their biochemical effectors, such as enzymes and structural proteins. Inherent in the proposal of a messenger is the need to control gene expression. Thus, Jacob and Monod postulated an "operator," which would serve as a control switch for gene expression. This model proposed that repressors acted on the operator element and that expression could be activated by blocking the repressor.

The idea that gene expression (mRNA synthesis) is a regulated event is linked to the genetic concepts of alleles that act in *cis* and *trans*. Initially, these terms described the results of genetic complementation tests that were designed to determine whether recessive mutations reside in the same (*cis*) gene or in different (*trans*) genes. More recently, these terms have been adapted to describe other features of gene expression. Specifically, it has been convenient to conceptualize the promoter regions of genes in terms of *cis* and *trans*. For example, *cis*-acting mutations in an operator, normally controlled by a repressor protein, result in constitutive activation. Such a mutation affects only the genes that are directly linked to, and regulated by, the operon. Thus, the *cis*-acting sequences often

refer to the regulatory DNA elements that control a gene. In contrast, *trans*-acting mutations refer to a diffusible factor, often a transcription factor. The conceptualization of *trans*-acting factors interacting with *cis*-elements in target genes helps to transfer genetic concepts into biochemical terms.

The field of gene regulation has a long history of creating models that predate detailed biochemical explanations. The idea of regulatory cascades required accepting the notion of diffusible factors before there was direct evidence for their existence. The *cis*-acting regulatory elements in promoters have often been characterized by mutagenesis before obtaining direct evidence that they bind a transcription factor. In practice, this is almost always true. Now that transcription factor interactions with DNA can be demonstrated more readily using sensitive techniques such as DNA-protein mobility shift assays, a new set of questions has arisen concerning how these DNA-bound proteins interact with the basal transcription apparatus. There is now a large body of evidence for the presence of adaptor or coactivator proteins, and the ability to use transcription factors to clone interacting coactivator proteins has greatly expanded our understanding of this family.

This chapter will focus largely on the principles of transcriptional control in higher eukaryotes. We acknowledge that many lines of thinking have arisen from studies of prokaryotes, yeast, and viruses. Indeed, the conservation of protein structure and regulatory pathways is very useful. Reflecting this conservation, many mammalian transcription factors are functional in yeast and vice versa. Nevertheless, space limitations necessitate a more limited review. Although the major focus is on transcriptional regulation, gene expression ultimately integrates many distinct regulatory steps, including transcription termination, mRNA stability, and the control of mRNA translation. Discussion of these other topics can be found in the listed references. We also hope to link information on transcriptional regulation to other topics covered in this book, including disease states that involve mutations in transcription factors.

The function of normal and mutant genes is influenced by their levels and patterns of expression as well as by the properties of the expressed proteins. Some disorders are caused by mutations in the regulatory regions of genes (e.g., some thalassemias) or more commonly because of mutations in transcription factors *(see below)*. In disorders that involve imprinting, the clinical manifestations largely reflect diminished gene expression from one of the parental alleles (e.g., Prader-Willi Syndrome). At least 20% of expressed genes are involved in gene and protein expression. By

comparison, it has been estimated, based on the composition of expressed sequence tagged (EST) genes from many different tissues, that cell structure and motility involve 8%, cell signaling involves 12%, and cell division involves 4% of the expressed genes. Although these results are preliminary (based on 7000 of an estimated 50,000–80,000 expressed genes), and the categorization is somewhat arbitrary, it is clear that a major fraction of genes are devoted to the control of gene expression. In addition to severe mutations in transcription factors, it is likely that many polygenic disorders will involve alterations in the levels of expression of certain genes or the sensitivity of a promoter to environmental effects.

STRUCTURE OF GENES

STRUCTURE AND FUNCTION OF THE NUCLEOSOME The formation of chromatin is a characteristic feature of eukaryotic DNA (*see* Chapter 1). Chromatin is composed of histones, non-histone proteins, and DNA. The histones are highly conserved proteins involved in the packaging of DNA into nucleosomes (Fig. 3-1). Most DNA (~ 95%) is associated with nucleosomes. The nucleosomes function at several levels to provide hiercheal organization of DNA. The first order of organization consists of 10-nm "beads on a string" in which nucleosomes and DNA are arranged in a linear fashion. The second order (30-nm fiber) arises when the nucleosomes are compacted into an helical array in a process that requires nonhistone proteins. The third order occurs when the fibers are packed on themselves to form euchromatin (low packaging) or heterochromatin (high packaging).

Histones 2A, 2B, 3, and 4 (H2A, H2B, H3, and H4) form the core nucleosome. Two molecules of H2A, H2B, H3, and H4 form the octameric core of the nucleosome. Histone 1 (H1) protein is probably not involved in the formation of the core nucleosome, as 10-nm fibers can be constructed without H1. However, second-order packing into the 30-nm fiber requires H1, which resides on the outside of the DNA-nucleosome complex and stabilizes the higher order structure. Based on digestion patterns generated by monococcal nuclease, it has been established that approximately 200 bp of DNA are associated with each nucleosome. DNA (80 bp) wraps around each core nucleosome twice like thread around a spool. A spacer (40 bp of DNA) links nucleosomes together to create the "beads on a string" appearance seen using electron microscopy.

In addition to playing a structural role in DNA packaging, it is likely that nucleosomes also participate in gene regulation. During the cell cycle, the structure of nucleosomes changes. In S phase, when DNA replication occurs, nucleosomes are acetylated. Acetylation occurs on lysine residues at the carboxyterminus of histone proteins and may alter their interactions with DNA. During G2 and mitosis, the nucleosomes are deacetylated and highly condensed.

Transcription factors have been shown to modulate the acetylation of histones, potentially modifying nucleosome structure as a mechanism of controlling gene transcription. For example, histone acetylation may create a more open chromatin configuration that allows other transcription factors to gain access to the regulatory regions of a gene. The transcriptional coactivator, CREB-binding protein (CBP), possesses intrinsic histone acetyltransferase (HAT) activity. CBP also recruits other HAT proteins such as P/CAF. It has been speculated that histone acetylation may be an important mechanism by which CBP increases gene transcription. Other transcription factors (often repressors) recruit histone deacetylases. MAD/MAX and Mxi1/MAX heterodimers bind Sin3, which acts as a scaffold protein to bind histone

deacetylases 1 or 2 (HDAC 1, 2). Myc transformation of tissue culture cells can be blocked by MAX/Sin3 fusion proteins, but this inhibition is not seen using Sin3 proteins that do not bind to HDAC 1 or 2. Nuclear receptor co-repressors such as NCoR and SMRT also bind Sin3 and HDAC1 and 2 *(see below)*.

STRUCTURE OF THE TRANSCRIPTION UNIT A gene refers to an individual transcription unit that encodes either a single protein or a protein subunit. Genes are divided structurally into 5' and 3' regulatory regions that flank either side of the exons and introns (*see* Chapter 1). Exons refer to the portion of genes that are eventually spliced together to form messenger RNA. Introns refer to the spacing regions between the exons that are spliced out of precursor RNAs during RNA processing. The upstream 5' flanking regions of genes typically contain hormone response elements and other regulatory regions, including sequences involved in the initiation of transcription *(see below)*. This regulatory region of the gene is also referred to as the promoter, although this term is generally reserved for the proximal 100–300 bp upstream from the transcriptional start site. The minimal core promoter consists of a TATA box (which binds TBP, TATA-binding protein) and initiator sequences that enhance the formation of an active transcription complex. Transcriptional termination signals reside at the 3' end of the gene. In some instances, regulatory elements also reside downstream of the gene or in introns. Specific signals such as the AAUAAA sequence at the 3' end of the mRNA are involved in designating the site for polyadenylation (poly[A] tail).

With the exceptions noted above, the regulatory regions of genes generally reside in the 5' flanking DNA sequence of the gene. There is, however, great variation in the amount of DNA sequence that is required for normal expression of a gene. Almost all genes contain numerous (10–20) regulatory elements within the first 300 bp of the promoter (although comprehensive studies may be required to identify all elements). Most genes also contain several enhancer elements that are located further upstream. In some cases, such as the globins and the immunoglobulin genes, enhancers are located at great distances (>5 kb) from the remainder of the gene. An enhancer element was traditionally defined as a regulatory element that could operate over great distances and in an orientation-independent manner. However, further characterization of these elements, and the transcription factors that they bind, reveals considerable functional overlap with other promoter regulatory elements. Therefore, the distinction between enhancers and promoter regulatory elements has become blurred. The properties of these regulatory elements are strongly influenced by their locations in the gene and by the nature of surrounding DNA sequences.

The organization of a prototypical promoter is depicted in Fig. 3-2. The promoter contains a TATA box located about 30 bp upstream from the site of transcriptional initiation. Initiator sequences typically surround the transcriptional start site. The initiation of translation starts at the first ATG triplet codon within eukaryotic mRNA. The sequences prior to this ATG comprise the 5' untranslated region (5' UTR) and the most 5' base within the 5' UTR constitutes the transcriptional start site (designated as +1). The 5' UTR varies greatly in length in different genes, and it may contain several exons. For this reason, it can be challenging to identify the location of the promoter, even when the coding region of the gene has been found.

Several techniques are used to characterize the transcriptional start site(s) and, thereby, the location of the promoter. The S1 nuclease protection assay uses a single-stranded radio-
Figure 3-1 Role of nucleosomes in gene transcription. DNA is wrapped around nucleosomes, resembling thread on a spool. Actively transcribed genes exhibit an open chromatin structure in which nucleosomes have been disrupted or shifted to a different location along DNA. Altered nucleosome positioning allows the binding of transcription factors which, in turn, recruit coactivators and other components of the basal transcription apparatus (TBP, GTFs, Pol II). GTFs, General Transcription Factors; TBP, TATA-binding protein; Pol II, RNA Polymerase II.
Figure 3-2 Structure of the regulatory region of a gene. A prototypical gene is depicted with an array of DNA regulatory elements. The core promoter includes the TATA-box that binds TATA-binding protein (TBP) and an initiator (INR) at the site of transcriptional initiation. The proximal promoter contains a CAAT-box that can bind several different transcription factors including CAAT-box/enhancer-binding protein (C/EBP), a cAMP response element (CRE) that binds members of the CREB/AP-1 family, an Sp-1 site (binds Sp-1), and an AP-2 site (binds AP-2). A composite enhancer is shown in the more distal 5'-flanking region of the promoter. It contains several closely spaced regulatory elements including a tissue-specific element (TSE), an E box (binds members of the bHLH family), and an AP-1 (c-Jun/c-Fos heterodimer) site. The composite nature of the enhancer allows combinatorial interactions of several different transcription factors to result in highly specific regulation. An adjacent hormone response element (HRE) is a binding site for members of the nuclear receptor family. Note that some regulatory elements, such as the AP-1 site, might reside in either enhancer or proximal promoter (e.g., CRE) locations.

labeled DNA probe that spans the 5' UTR and the transcription start site. S1 nuclease digests single-stranded RNA and DNA, leaving the protected DNA-RNA hybrid undigested. The length of the protected fragment allows the position of the start site to be deduced. An alternative approach uses primer extension in which a radiolabeled primer and reverse transcriptase are used to extend the mRNA to its 5' end. The promoter sequence adjacent to the identified transcriptional start site often contains characteristic sequences such as a TATA box and other DNA regulatory elements.

The TATA box is the site of binding for TATA-binding protein (TBP), which is a key component of transcription factor II D (TF$_{II}$D). The proximal region of the promoter is generally densely packed with transcription factor binding sites, only some of which are shown. This region often contains sites for ubiquitous proteins such as Sp-1, CAAT box/enhancer-binding protein (C/EBP), cAMP response element-binding protein (cAMP), or Activator Protein-1 (AP-1). However, factors involved in cell-specific expression may also bind to these sequences. Examples include interactions of bHLH proteins with E boxes in the myogenic genes (*see* Chapter 92), steroidogenic factor-1A (SF-1) for the steroidogenic enzyme promoters (*see* Chapter 57), or Pit-1 for the growth hormone promoter (*see* Chapter 49). At greater distances from the promoter, additional regulatory elements are often clustered in such a way that they form composite enhancers. These elements may be small, or they may contain several repeats of

different transcription factor-binding sites dispersed over several hundred basepairs. In some cases, these distant enhancers are important for developmental expression (e.g., globins), cell-specific expression (e.g., immunoglobulins), or hormonal regulation (e.g., glucocorticoid response elements [GREs]). Although enhancer and promoter elements are usually depicted in a linear manner along DNA, it is likely that DNA looping occurs to allow interactions of enhancer-bound transcription factors with components of the basal promoter (Fig. 3-3). When active, these enhancer sites may confer DNase I sensitivity, reflecting the absence of nucleosomes, and an open configuration that allows increased access of DNase I (and other transcription factors).

The anatomy of a promoter is usually defined by a combination of gene transfer experiments to assess the effects of promoter mutants and studies of protein–DNA interactions *(see above)*. In the gene transfer experiments, various promoter regions are linked to a reporter gene, such as the gene encoding luciferase. Sequential deletions of the promoter provide a gross delineation of the locations of regulatory elements, but this strategy may miss functional elements that act in combination with sequences that have been deleted. Ideally, point mutations are introduced into candidate regulatory elements to assess their role in the context of the native promoter. It is advantageous to simultaneously search for transcription factor binding sites, either using DNase I footprinting or gel shift assays. DNase I footprinting is most useful for screening 100- to 300-bp regions of DNA for the locations of protein-bind-
Figure 3-3 Enhancer interactions with proximal promoter elements. Many enhancers reside a great distance from the site of transcriptional initiation. DNA bending, or looping, has been proposed to allow protein–protein interactions. In the model shown, an enhancer binds a dimeric transcription factor that interacts with the coactivator protein, CREB-binding protein (CBP). CBP integrates the actions of many different transcription factors, including phosphorylated cAMP response element-binding protein (CREB). CBP, or its homolog, p300, interacts with other proteins including histone acetyltransferase (HAT) and general transcription factors (GTFs) such as $TF_{II}B$, and so on to induce transcription by RNA Polymerase II (Pol II).

ing sites. After the identification of protein binding sites by footprinting, the electrophoretic gel mobility shift assay (EMSA) is useful for more detailed analyses of protein–DNA interactions. EMSA is a very sensitive measure of protein–DNA interactions and is relatively simple to perform from a technical perspective. Competition studies using unlabeled DNA or supershift studies using antibodies directed against candidate transcription factors can help to verify the nature of the bound transcription factor.

CLASSIFICATION AND FUNCTION OF TRANSCRIPTION FACTORS

Because of the large number and diverse functions of transcription factors, it is helpful to group them into several classes based on their roles in gene transcription. In this chapter, transcription factors are divided into general transcription factors (GTFs), DNA sequence-specific transcription factors, and transcriptional coactivators and corepressors. The general transcription factors include a large number of proteins that are involved in the assembly of the basal transcription apparatus. As their name implies, the sequence-specific transcription factors include proteins that bind to DNA regulatory elements in the enhancers or promoters of genes. Coactivators and corepressors bind to other transcription factors through protein–protein interactions and regulate transcription by altering chromatin structure or by making contacts with the basal transcriptional machinery.

GENERAL TRANSCRIPTION FACTORS   Eukaryotic cells contain three RNA polymerases that catalyze the transcription of DNA into RNA. Polymerase I transcribes ribosomal RNAs (rRNA), polymerase II transcribes protein coding genes (mRNAs), and polymerase III transcribes tRNAs. Although RNA polymerase II and its core proteins are able to catalyze RNA synthesis, they are

insufficient for regulating gene-specific transcription. A large number of proteins are required for polymerase II (Pol II)-mediated transcription. Sequences associated with the core promoter (TATA box, Initiator) and gene-specific enhancers each serve to bind additional general transcription factors (GTFs) including TF_{II} A, B, D, E, F, and H, as well as RNA polymerase II and associated proteins such as suppressor of RNA polymerase B (II) (SRB). Purification of the RNA polymerase holoenzyme, which is transcriptionally inactive, with TF_{II} B, E, F, and H already bound, suggests that two major complexes of GTFs may be present in the cell: RNA polymerase holoenzyme and TF_{II}D.

TF_{II}D refers to a protein complex composed of TBP and several TBP-associated factors (TAF_{II}'s). TBP is highly conserved through evolution. Drosophila TBP and mammalian TBP can be substituted for one another in vitro transcription assays. TBP binds specifically to the TATA box, binding in the minor groove of DNA, creating a 90° bend in the DNA. Some promoters do not contain a consensus TATA box, but TBP is still necessary for transcription. In the case of these TATA-less promoters, other GTFs apparently tether TBP and TF_{II}D to the promoter. Many of the TATA-less promoters are characterized by multiple transcriptional start sites, suggesting that one role of the TATA box is to specify a precise position for transcriptional initiation. In addition to TBP, TF_{II}D contains at least eight TAF_{II}s that recognize various promoters and establish contacts with other transcription factors. TF_{II}A contacts TBP and stabilizes the TATA box interaction. TF_{II}B contacts DNA on both the 5' and 3' side of the TATA box, specifies the transcriptional start site, and it is important for enhancer-mediated stimulation of transcription in vitro. TF_{II}H contains helicase and kinase activities that are necessary for the initiation of transcription. As noted later, mutations in TF_{II}H are one cause
Figure 3-4 Classes of transcription factors. The structures of selected classes of transcription factors are depicted schematically. In general, the factors are classified according to their DNA-binding domains. Examples of transcription factors are shown at the left and the class of transcription factor is shown at the right. Some of the identified functional domains are shown. Q1 and Q2, represent activation domains; KID, kinase inhibitory domain; HLH, helix loop helix; SRF, serum response factor; SP/TP, serine, threonine phosphorylation; HMG, high mobility group; POU, Pit-1/Oct-1/Unc.

of xeroderma pigmentosa, which is characterized by DNA repair defects in response to UV irradiation. TF$_{II}$E recruits TF$_{II}$H to the preinitiation complex, and modulates the activity of TF$_{II}$H. TF$_{II}$F recruits RNA polymerase II to the preinitiation complex.

In higher eukaryotes, the role that TAFs play in transcription is only partially understood. The composition of TAF$_{II}$s associated with the TF$_{II}$D-TBP complex provides a degree of specificity for RNA polymerase II. TAF function has been examined for a few transcription factors such as Sp1, which interacts with dTAF$_{110}$ in vitro. Transcription factor-TAF interactions likely serve as a bridge between enhancer regions and the basal transcription apparatus. Transcriptional activation via TAFs is influenced by the DNA sequence surrounding the TATA box and the Initiator. Hence, the core promoter architecture plays an important role in gene-specific regulation by recruiting the appropriate basal transcription factors.

DNA SEQUENCE-SPECIFIC TRANSCRIPTION FACTORS
The ability of the basal transcriptional apparatus to respond to cell-specific and environmental signals is accomplished through DNA sequences that are specific to a given gene. These DNA regulatory sequences often reside in enhancer elements that are capable of conferring functions to a broad array of minimal promoters. Transcription factors that bind to enhancer regions are usually modular in structure and contain a DNA-binding domain and one or more activation domains. A partial compilation of various classes of sequence-specific transcription factors is shown in Fig. 3-4. This

classification is based on the domain that binds to DNA and includes bZip, bHLH, homeodomain, and zinc-finger-containing classes of transcription factors. This classification is somewhat arbitrary, because some factors contain more than one type of domain or DNA-binding regions that are poorly defined. Examples of the functional roles of some of these sequence-specific factors are discussed later in this chapter.

It is striking that a relatively small number of DNA-binding structures have been used to generate tremendous diversity among the thousands of sequence-specific transcription factors. A transcription factor database on the Internet (http://transfac.gbf.de/) contains hundreds of different transcription factors and allows a promoter region to be searched for recognition sites for sequence-specific transcription factors. However, empirical determination of factor binding and function is ultimately necessary, because many consensus sequences are not particularly selective and transcription factor interactions can be dramatically influenced by surrounding DNA sequences or DNA-bound proteins.

TRANSCRIPTIONAL COACTIVATORS AND COREPRESSORS This class of transcription factors has been identified relatively recently. Because these proteins do not interact directly with DNA, it has been challenging to isolate these factors. However, largely based on techniques that detect protein–protein interactions (e.g., yeast two-hybrid, farwestern techniques), the list of identified members of this family is growing rapidly (Table 3-1).

Table 3-1
Transcriptional Coactivators and Corepressors

Cointegrators	Interacting proteins
CBP/p300	Nuclear Receptors[a]: (RAR, RXR, ER, TR, PR, GR) CREB, c-Fos, c-Jun, JunB, YY1, E1a, SV40 Tag, c-Myb, SRC-1, Sap 1a, STAT2, MyoD, E2F-1, TBP, $TF_{II}B$, p/CAF, $pp90^{RSK}$, Tax, SREBP-2, p53
Coactivators	**Nuclear receptors**
ARA_{70}	AR
GRIP 95, GRIP 120, GRIP 170	GR
p140 (ERAP 140, RIP 140)	ER, RAR
p160 (ERAP 160, RIP 160)	ER, RAR
SRC-1/ Nco-A1	PR, ER, RAR, RXR, TR, GR
Sug 1/Trip 1	TR, RAR, RXR
TIF 1	ER, RAR, RXR
TIF 2/GRIP 1	PR, ER, RAR, RXR
Corepressors	**Nuclear receptors**
NCoR 1	TR, RAR
SMRT	TR, RAR

[a]*See* Fig. 3-9 for abbreviations.

Coactivators have been identified primarily by using yeast two-hybrid screening assays. This assay takes advantage of the modularity of proteins. A yeast transcription factor, Gal 4, is fused to the protein of interest to create a "bait" with which to test for protein–protein interactions. By introducing a library of expressed cDNAs linked to a known transactivation domain (e.g., VP16), it is possible to select (by transcription of selectable genes) for interactions between the bait and proteins expressed from the cDNA library. An alternative to the yeast two-hybrid approach is to use farwestern analysis to screen for direct protein–protein interactions. The protein of interest is expressed, radiolabeled, and used to detect interacting proteins either from cell extracts (analogous to a Western blot) or from expression libraries. This method allowed phosphoCREB to be used to isolate clones for CBP.

It is likely that most sequence-specific transcription factors will be shown to interact with transcriptional coregulators. These proteins provide a mechanism for integrating the effects of several different transcription factors, and they also provide a linkage between enhancer-binding proteins and general transcription factors. Examples of regulation by coactivators are discussed later in this chapter using CBP/p300 as an example of an activator and the interaction of the thyroid hormone receptor with NCoR (nuclear receptor corepressor) as an example of a repressor.

OVERVIEW OF MODELS FOR TRANSCRIPTIONAL CONTROL

There is enormous variability in mechanisms of transcriptional control. In fact, every gene is controlled uniquely, whether in its spatial or temporal pattern of expression, or in its response to extracellular signals. Examples of signaling pathways that activate transcription factors are depicted in Fig. 3-5 (*see* Chapter 46). Thus, in addition to the diversity of transcription factors that are available, there is substantial diversity in the pathways that can activate transcription factors. Despite the myriad pathways and mechanisms for transcriptional activation (and repression), it is useful to consider fundamental models that recur for different genes.

TRANSCRIPTIONAL ACTIVATION   Transcriptional activation can be divided into three main mechanisms (Fig. 3-6): (1) altered chromatin structure, (2) posttranslational modifications such as phosphorylation, (3) displacement of a repressor protein. These models are not mutually exclusive and some transcription factors participate in several different types of regulation.

The topic of chromatin reorganization was discussed above. Regulation of the *MMTV* promoter by the glucocorticoid receptor appears to involve alterations in chromatin structure. In this case, the glucocorticoid receptor is proposed to displace nucleosomes in a manner that allows the binding of additional transcription factors such as NF-1. CBP, which transduces the actions of many transcription factors *(see below)*, may also function in part through alterations in chromatin as several of the proteins that it recruits possess histone acetyltransferase activity.

Phosphorylation and dephosphorylation are key steps in the covalent modification of many transcription factors. Phosphorylation of the aminoterminal δ domain of c-Jun by Jun N-terminal kinase (JNK) stimulates the transcriptional activity of c-Jun. However, phosphorylation by mitogen-activated protein kinase (MAPK) near DNA binding domain of c-Jun inhibits transactivation. Hence, for maximal activation of c-Jun, both phosphorylation and dephosphorylation must occur in different regions of the protein. The role of phosphorylation in the control of CREB transcription has also been studied extensively. In this case, phosphorylation of a key serine residue (Ser 133) by one of several different kinases is required for transcriptional activation. Phosphorylation induces conformational changes in CREB that are necessary for interactions with CBP.

Ets-1 is phosphorylated by MAPK. When binding to its consensus DNA sequence, Ets-1 undergoes a conformational change, which induces its full activation. However, Ets-1 must interact with another factor to stabilize its interactions with the DNA. This type of synergism is exemplified by the c-*fos* promoter, where the binding of serum response factor (SRF) to the serum response element (SRE) recruits ternary complex factors (Ets-1). The synergistic interaction between SRF and Ets-1 accounts in part for rapid induction of the c-*fos* promoter in response to serum.
Figure 3-5 Signal transduction and transcriptional control. A diverse array of signaling pathways activate transcription (*see* Chapter 46). A highly simplified schema is shown to illustrate some of these pathways. Steroids (or other nuclear receptor ligands) diffuse through the cell membrane to act on nuclear receptors. For some of these receptors (e.g., RAR, TR), the ligand displaces a nuclear corepressor (NCoR) and allows interactions with a steroid receptor coactivator, SRC-1. Growth factors activate a variety of tyrosine kinase receptors that stimulate kinase cascades including mitogen-activated kinase (MAPK) and c-Jun kinase (JNK). These kinases activate transcription factors such as AP-1 (c-Jun/c-Fos) and Ets-1. Hormones (e.g., catecholamines, peptide hormones) can interact with seven transmembrane G-protein-coupled receptors to activate adenylyl cyclase (AC), resulting in cAMP production and stimulation of protein kinase A (PKA). This pathway activates transcription factor CREB, which can also be stimulated by other kinase pathways, including Ca^{2+}-mediated activation of CaMK (Ca^{2+}-mediated kinases). Cytokines stimulate the Janus kinases-signal transducers and activators of transcription (JAK-STAT) pathway, resulting in translocation of phosphorylated STAT transcription factors to the nucleus. Several cellular stress pathways (UV, ultraviolet light; LPS, lipopolysaccharide; TNF, tumor necrosis factor) activate NFκB (p50/p65) by dissociating the inhibitor, IκB. CREB-binding protein (CBP) binds to many different transcription factors, providing a mechanism for integration (or competition) among transcription factors.

In other cases, posttranscriptional modifications influence the cellular localization of a transcription factor (Fig. 3-5). NFκB is found in a cytoplasmic complex that consists of two subunits, p50 and p65, along with IκB. IκB binds to the two subunits and prevents their nuclear localization by masking the nuclear localization signal (NLS) within NFκB. Activation of NFκB requires the ubiquination and subsequent degradation of IκB, which allows translocation of NFκB to the nucleus. Signal transducers and activators of transcription (STAT) proteins are also found in an dormant state in the cytoplasm. Activation of cytokine receptors stimulates Janus Kinase (JAK), which phosphorylates the receptors, allowing recruitment of the STAT proteins (*see* Chapter 46). Once localized to the cytokine receptors, the STATs are phosphorylated, inducing dimerization and translocation to target genes in the nucleus.

Mechanisms of Transcriptional Activation
Figure 3-6 *(right)* Mechanisms of transcriptional activation. Several models of transcriptional activation are shown (*see text* for details). **(A)** An activator protein induces an alteration in nucleosomes, thereby changing chromatin structure and allowing the recruitment of additional activators to DNA. **(B)** An activator is stimulated by a posttranslational modification such as phosphorylation, leading to the recruitment of additional activator proteins. **(C)** An activator displaces a repressor protein that binds to the same, or to an overlapping, site.

Figure 3-6

Mechanisms of Transcriptional Repression
Figure 3-7 Mechanisms of transcriptional repression. Several models of transcriptional activation are shown (*see text* for details). **(A)** A repressor protein induces an alteration in nucleosomes, allowing the recruitment of additional proteins that silence transcription. **(B)** A repressor protein competes for coactivator proteins. This mechanism is sometimes referred to as transcriptional "squelching." **(C)** A repressor protein displaces an activator that binds to the same, or an overlapping, site.

Another model for transcriptional activation involves displacement of a repressor by an activator. This model applies in particular to developmental cascades, in which the induction of a new transcription factor may be sufficient to stimulate transcription, or it may displace a pre-existing repressor. The orphan nuclear receptor, COUP-TF, acts as a repressor of many genes that contain nuclear receptor binding sites. Under circumstances in which other nuclear receptors are induced or activated, they can displace COUP-TF and activate transcription.

TRANSCRIPTIONAL REPRESSION In general, mechanisms of transcriptional repression have not been studied to the same extent as mechanisms of transcriptional activation. In part, this reflects the technical challenges involved in measuring inhibition from a basal state of transcription. In certain respects, models for transcriptional repression are the reciprocal of activation, but there are also differences.

As shown in Fig. 3-7, some repressors act by causing histone deacetylation (as opposed to acetylation in activation). As described, this pathway has been investigated recently for the MAD/MAX proteins and nuclear receptors (RAR, TR). In these cases, the transcription factors bind Sin3 and recruit histone deacetylases. For nuclear receptors, transcriptional silencing is seen in the absence of ligand, and this is reversed at ligand binding (*see below*).

Also analogous to mechanisms of activation is the possibility that repressors can act by displacing activators. A good example

of this pathway involves expression of inducible cAMP early repressor (ICER), which can compete for the binding of CREB or CREM to cAMP response elements. ICER contains the bZip DNA binding domain of CREM, but does not contain the transactivation domains. Thus, when it occupies the DNA binding site, it is inactive and blocks access of other transactivators. The functional role of ICER is discussed later as a model for autoregulation of gene expression.

A distinct mechanism for transcriptional repression involves the inhibition of transcriptional activators, either by direct interactions between the repressor and an activator or by competition for a coactivator. An example of direct inhibition involves Id inhibition of bHLH factors. In this case, Id lacks a DNA binding domain, but it retains a dimerization domain, allowing interactions with bHLH proteins such as Myo D, E12, and E47. Dimerization of these proteins with Id forms an inactive complex and blocks the action of these transcription factors. Another example of direct interactions is illustrated by inhibition of NFκB or c-Jun by the glucocorticoid receptor. The glucocorticoid receptor has been shown to interact directly with these transcription factors to inhibit their action. However, it has also been suggested that the activated form of the glucocorticoid receptor may compete for the coactivator, CBP, which is also shared by c-Jun. Thus, negative regulation by the glucocorticoid receptor may occur by direct interactions and by competition for coactivators. Competition for rate-limiting coactivators may prove to be a relatively common model for transcriptional repression. For example, most cases of transcriptional squelching likely involve competition for limiting amounts of transcriptional coactivators.

PRINCIPLES OF TRANSCRIPTIONAL CONTROL

TRANSCRIPTION FACTORS ARE COMPOSED OF MODULAR FUNCTIONAL DOMAINS Soon after transcription factors were cloned, structure–function studies revealed a remarkable property: The functional domains of transcription factors are often separable and transferable. For example, domains involved in DNA binding can be localized to a relatively limited region of the protein and even swapped or exchanged into other transcription factors. Similarly, domains involved in dimerization, nuclear localization, phosphorylation, ligand binding, and transcriptional activation can also be localized and transferred to other proteins. These features suggest that for many transcription factors, functional domains are localized and are not created by complex three-dimensional interactions between distant parts of the protein. Another implication of this finding is that functional domains are often conserved during evolution. These "evolutionary modules" diverge, but retain enough similarity that homology is readily detected. Homeodomains provide an example of a conserved functional region that has become greatly diversified during evolution. The homeodomain proteins are typically involved in developmental events such as segmentation or cell lineage. The homeodomain itself is involved in DNA sequence recognition.

Two examples of transcription factors with well-characterized modular domains are shown in Fig. 3-4. The transcription factor, CREB, is representative of the basic leucine zipper (b-Zip) family of transcription factors. The carboxyterminal end of CREB contains a highly basic region adjacent to a series of repeated hydrophobic residues (primarily leucines) that are part of an amphipathic α-helix. The rotation of the α-helix positions the hydrophobic residues on the same surface of the protein. This feature has led to

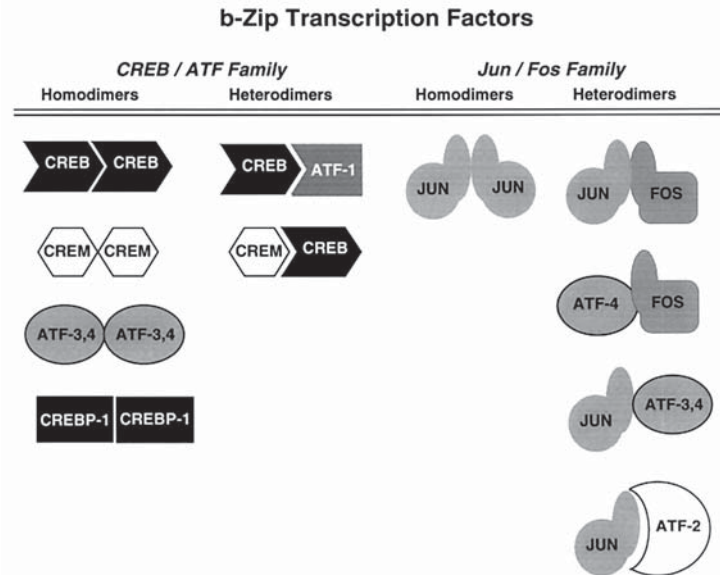
b-Zip Transcription Factors


Figure 3-8 b-Zip family of transcription factors. b-Zip transcription factors are characterized by a domain comprised of a basic region adjacent to a leucine zipper. This domain mediates dimerization and DNA binding. The family can be subdivided into the CREB/ATF and Jun/Fos family. Different members of the family preferentially form homodimers or heterodimers. CREB, cAMP response element binding; CREM, cAMP response element modulator; ATF, activating transcription factor; CREBP, cAMP response element-binding protein.

the description of a "leucine zipper," in which a series of leucines (or other hydrophobic amino acids) are aligned with their hydrophobic side chains protruding from the protein. The hydrophobic amino acids create a dimerization interface that results in a coiled-coil of the two α helices. The adjacent basic residues are available to make contacts with negatively charged DNA. The DNA-sequence recognition sites for this family of transcription factors are palindromic in nature. Thus, there is twofold symmetry (e.g., TGAC • GTCA) in the DNA sequence, and the structure of the DNA element reflects in the symmetry of the transcription factor dimer. The binding affinity of the dimer is much greater than the protein monomers. This probably reflects conformational changes that occur after protein dimerization, as well as the additional interactions with DNA that are conferred by having two proteins make contacts with DNA. Members of the b-Zip family can form homodimers (e.g., CREB-CREB) or heterodimers (e.g., Jun-Fos), providing a mechanism for diverse interactions (Fig. 3-8). Subtle variations in the DNA recognition site provide specificity for the binding of different dimers.

In addition to its DNA-binding and dimerization domains, CREB also contains well-characterized transcriptional activation domains in its central and aminoterminal regions. These regions contain numerous sites for phosphorylation by enzymes such as protein kinase A and Ca^{2+}-dependent kinases. These phosphorylation events alter protein conformation and result in transcriptional activation. The modularity of this domain has been revealed by its ability to transfer transcriptional activation to the DNA binding domain of GAL4. The GAL4-CREB fusion protein recognizes a GAL4 target gene, but it is transcriptionally activated by protein kinase A. In this experimental paradigm, it has been possible to mutate specific serine residues in CREB to demonstrate that they are involved in phosphorylation-dependent transcription. As described below, phosphorylation of CREB allows the recruitment of a transcriptional coactivator, CBP.

The modular structure of the TR is also shown in Fig. 3-4. This receptor is representative of other nuclear receptors such as the glucocorticoid receptor, estrogen receptor, and retinoic acid receptor (Fig. 3-9). This nuclear receptor superfamily also includes a number of so-called orphan nuclear receptors for which a specific ligand has not been identified. Each member of this family contains a centrally located DNA-binding domain that is formed by two zinc fingers. The modular properties of this domain have been demonstrated in swapping experiments. For example, exchanging the DNA-binding domains of the thyroid hormone and glucocorticoid receptors switches their DNA recognition properties. Thus, a gene that is normally a target for the thyroid hormone receptor can be activated by glucocorticoids when the DNA binding domain from the thyroid hormone receptor is inserted into the glucocorticoid receptor. DNA-binding specificity is provided primarily by a stretch of amino acids (P-box) at the carboxy-terminal base of the first zinc finger. This region was identified because, in evolutionary comparisons of the zinc fingers in different receptors, it represented an area of hypervariability. Thus, substitution of this motif in the glucocorticoid receptor with that from the estrogen receptor switches its DNA-binding specificity to that of the estrogen receptor.

The carboxy-terminal region of the nuclear receptors contains several functional domains, including nuclear localization, dimerization, ligand binding, repression, and activation domains. The locations of these domains have been demonstrated by swapping protein region experiments to create chimeric nuclear receptors as well as by performing site-directed mutagenesis. The ligand-binding properties of these receptors require most of the carboxy-terminus. Consistent with this, the X-ray crystal structures demonstrate that the ligands bind deep in a pocket formed by several α-helical loops. During ligand binding, the receptor undergoes conformational changes, including repositioning of the transcriptional activation domains that contact coactivators.
Figure 3-9 Comparison of nuclear receptors. Nuclear receptors share a highly conserved central DNA-binding domain (DBD) that consists of two (C2H2) zinc fingers. The carboxy-terminal region contains several functional domains including ligand binding, dimerization, transcriptional repression, and transcriptional activation. The amino-terminal domain is highly variable in length and contains additional transactivation domains. The lengths (in amino acids) are shown at the right side of the figure. MR, mineralocorticoid receptor; PR, progesterone receptor; AR, androgen receptor; GR, glucocorticoid receptor; ER, estrogen receptor; RAR, retinoic acid receptor; TR, thyroid hormone heceptor; VDR, vitamin D receptor.

Somewhat analogous to the b-Zip family of transcription factors, the nuclear receptors also form dimers. In this case, the dimerization domain is less clearly defined than the leucine zipper, but probably also involves hydrophobic interactions. In many cases, the nuclear receptors form heterodimers as well as homodimers. For example, the thyroid hormone receptor can homodimerize, but it also forms a heterodimer in combination with the retinoid X receptor (RXR). A second dimerization interface exists in the zinc-finger DNA-binding domain. The zinc fingers thereby orient the two monomers by interacting with specific DNA sequences. Thus, the target DNA site participates in a ternary complex of DNA and two protein subunits. In the case of the thyroid hormone receptor, the DNA recognition sites are surprisingly complex. Although most sites conform to a conserved half-site (AGGTCA) that interacts with one of the receptor monomers, the orientation of the two half-sites relative to one another is quite variable. For example, the half-sites can be arranged head-to-head (as a palindrome), head-to-tail (direct repeat), or tail-to-tail. These distinct orientations would predict that the carboxy-terminal dimerization domains would be positioned very differently or even on opposite sides of the DNA. However, these receptors appear to have a remarkably flexible hinge domain between the DNA binding domain and the carboxy-terminal dimerization domain. This hinge allows dimerization to occur irrespective of the alignment of the zinc-finger domains. In this way, the hinge has preserved the modularity of

functional domains, while allowing great diversity in the DNA target sequences.

Transcriptional activation domains in the nuclear receptors have been localized in the carboxy-terminus, but also in the amino-terminus. The amino-terminal activation domains are constitutive or ligand-independent. This region of the nuclear receptors varies greatly in length and in sequence (Fig. 3-9). The activation domain in the carboxy-terminus is usually located near the extreme end of the protein. For many nuclear receptors, this function localizes to an amphipathic α helix that undergoes a marked conformational change during ligand binding. This region of the receptor contains a signature motif, LXXLL, that appears to be involved in interactions with coactivators (Table 3-1). The coactivators interact with the carboxy-terminal domain in a ligand-dependent manner, and it is thought that the recruitment of coactivators leads to interactions with the basal transcription apparatus, resulting in increased transcription.

The nuclear receptor carboxyterminal domain also interacts with corepressors such as NCoR and SMRT (Table 3-1). The corepressors bind close to the nuclear receptor hinge domain. In the case of the thyroid hormone receptor, the corepressors interact only in the absence of ligand. Thus, the ligand acts as a transcriptional switch (Fig. 3-10). In its absence, corepressors bind to the receptor and suppress transcription. Addition of the ligand dissociates the corepressor and allows the recruitment of coactivators. In physiologic terms, these properties allow thyroid hormone to induce a dynamic range of responses in its target genes.

DIMERIZATION PROVIDES A MECHANISM FOR DIVERSITY USING A LIMITED REPERTOIRE OF TRANSCRIPTION FACTORS   Dimerization is common for many classes of transcription factors. The ability to dimerize accomplishes several goals:

1. Dimers allow the generation of diverse combinations of related factors.
2. Dimers provide the opportunity for variations in DNA sequence to specify interactions with different combinations of related factors.
3. Dimers can increase the affinity of transcription factor binding to DNA by contributing the energy (and conformational changes) induced by protein–protein interactions as well as by making additional contacts with DNA.
4. Dimers create an opportunity for pivotal transcriptional switches if some partners activate, whereas others inhibit it.

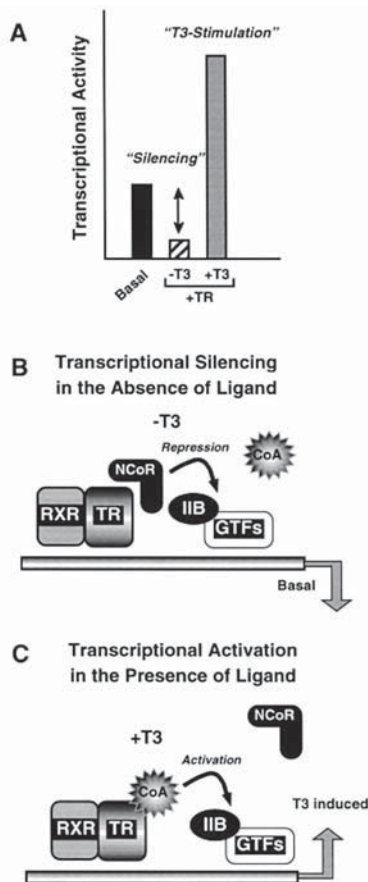
Many of these principles of dimerization have already been illustrated in the discussions of the modular domain of the b-Zip and nuclear receptor families of transcription factors. The basic helix-loop-helix (bHLH) family of transcription factors also emphasize the important role of dimerization. The helix-loop-helix motif was first identified as a DNA binding domain in λ-phage repressors. Variations of this structure are also found in homeodomain proteins and in the bHLH proteins. In the latter group, amphipathic helices that are connected by the loop create a dimerization surface and the basic regions of the protein partners make contacts with DNA. The DNA consensus sequence is typically an imperfect palindrome (CANNTG), reflecting the symmetry of the dimer. This family of transcription factors is often involved in cell lineage and growth regulation. Some of the factors such as E12 and E47 are expressed ubiquitously, whereas other factors (e.g., MyoD) are expressed in a tissue-specific manner (*see* Chapter 92). The ability to form homodimers and heterodimers is variable. For


Figure 3-10 Transcriptional silencing and activation by the thyroid hormone receptor. **(A)** The thyroid hormone receptor (TR) silences transcription in the absence of its ligand, T3. Addition of the ligand reverses transcriptional silencing and induces transcription above the initial basal level of transcription. **(B)** Schematic depiction of transcriptional silencing based on the ability of TR to recruit a nuclear corepressor, NCoR. NCoR, in turn, recruits additional proteins (not shown) such as Sin3 and histone deacetylases, which may function to alter chromatin structure. **(C)** Depiction of transcriptional activation. T3 dissociates NCoRs and allows the recruitment of coactivators such as SRC (steroid receptor coactivator) to induce transcriptional activation.

example, E47 forms homodimers efficiently, but MyoD does not, and it preferentially forms heterodimers with one of the ubiquitous factors (e.g., E12/MyoD). The array of ubiquitous and cell-specific factors creates a combinatorial code that leads to selective gene expression. The bHLH family of dimers is also notable for the presence of a class of inhibitory domain partners, (Id). The Id proteins retain dimerization but lack DNA binding, thereby blocking the action of their protein partners. The availability of proteins such as Id provides an alternate mechanism for controlling target genes. For example, overexpression of Id can prevent MyoD-directed myogenesis. An analogous inhibitory pathway may also exist in the b-Zip proteins. In this case, inhibitory proteins such as CHOP or CREM (isoforms α, β, γ), can form inhibitory complexes with selected other members of the b-Zip family. In the nuclear receptor family, proteins such as COUP-TF dimers usually function to block target DNA sites, and a splicing variant (lacking the

transactivation domain) of the thyroid hormone receptor, TRα2, binds RXR to form an inactive heterodimer.

UNIQUE COMBINATIONS OF TRANSCRIPTION FACTORS PROVIDE MECHANISMS FOR TISSUE-SPECIFIC EXPRESSION   The issue of cell-specific expression has fascinated molecular biologists since the first Northern blots revealed that some genes are only expressed in one or a limited number of cell types. Among some of the early human cDNAs that were cloned, several exhibited highly restricted patterns of expression (e.g., globin, growth hormone, insulin, chorionic gonadotropin). Initially, investigators analyzed the promoter regions of these genes in search of cell-specific transcription factors in order to account for this property. Although such factors exist, it has been discovered repeatedly that the expression and function of many promoters are controlled by multiple regulatory elements and their cognate transcription factors. In the case of growth hormone, for example, the tissue-specific transcription factor, Pit-1, has been identified. Pit-1 is a member of the POU-homeodomain family, expressed specifically in the pituitary gland. The growth hormone promoter contains multiple binding sites for Pit-1. When coexpressed with the growth hormone promoter in nonpituitary cells, Pit-1 enhances growth hormone expression in the "ectopic" locus. However, in the absence of other enhancer binding factors, Pit-1 activates the growth hormone promoter rather weakly. When combined with other ubiquitous factors such as the thyroid hormone receptor, there is synergistic stimulation of the promoter. Synergistic interactions of transcription factors are commonly observed, particularly when an element contains adjacent cell-specific and ubiquitous factor-binding sites.

Mechanisms of cell-specific expression have expanded to embrace the concept of a "combinatorial code." This model holds that combinations of several different transcription factors allow unique patterns of transcription, including cell-specific expression. This idea is illustrated for several genes that are uniquely expressed in the thyroid gland, such as *thyroglobulin* and *thyroid peroxidase*. An array of transcription factors that bind to these promoters have been identified. TTF-1 (thyroid transcription factor-1) is highly expressed in the thyroid, but it is also expressed in the lung and brain. Another factor, PAX-8 (a paired box member), is expressed in thyroid, but also in the kidney. Although each of these factors are expressed selectively in the thyroid, they are also expressed in other tissues. However, their combined expression is unique to the thyroid gland. The absence of expression of thyroglobulin in other locations such as lung or kidney emphasizes the need for the combinations of transcription factors to achieve high-level tissue-specific expression.

Transgenic studies provide additional evidence that highly stringent mechanisms control gene transcription. Although transient expression studies often suggest that a limited region of a promoter is sufficient for high-level expression in a cell-type specific manner, transgenic studies frequently show different results. It is not uncommon to find that the proximal promoter sequence alone results in relatively low expression in the expected target tissue, or that leaky expression occurs in other cell types. In many cases, additional 5'-flanking sequences, or the inclusion of other regions of the gene (exons, introns, 3'-flanking sequences), allow recapitulation of the native pattern of expression (e.g., *proopiomelanocortin*, *vasopressin*). Presumably, control elements that either enhance cell-specific expression or suppress ectopic expression reside in these other regions of the gene.

Studies of c-*fos* promoter elements dramatically demonstrate the importance of combinatorial regulatory elements for normal function of the promoter in vivo. Transfection studies delineated a number of c-*fos* promoter elements including a sis-inducible element (SIE), SRE, an AP-1 site, and a Ca^{2+}-cAMP response element (CARE). Each of these elements functioned independently in transfection assays and only partially decreased c-*fos* promoter activity when mutated. In contrast, a mutation in any one of these elements was sufficient to preclude c-*fos* expression in transgenic mice, indicating strong interdependence in vivo.

TRANSCRIPTION FACTORS THAT INTERACT DIRECTLY WITH DNA SERVE TO RECRUIT ADDITIONAL REGULA-TORS THROUGH PROTEIN–PROTEIN INTERACTIONS The methods used to identify transcription factors have generally relied on interactions with DNA. For example, proteins that interact with enhancer elements can be identified by DNase I footprinting or gel shift assays. Using these and other strategies for transcription factor isolation, a large array of sequence-specific DNA-binding transcription factors have now been identified (Fig. 3-4). Although identification of these transcription factors represents a major advance, important questions remain concerning how the DNA-bound transcription factors act to initiate transcription.

Several lines of evidence have suggested that additional proteins serve as intermediates between enhancer binding factors and components of the basal transcription machinery. Genetic studies in yeast have identified a set of genes *(SWI1, SWI2/SNF2, SWI3, SNF5, SNF6)* that are involved in transcriptional activation and analogous proteins have been identified in *Drosophila*. Some of these proteins, such as SWI2/SNF2, appear to function by converting chromatin into a transcriptionally active, open form. A variety of viral proteins also appear to function as coactivators. For example, the adenovirus E1a protein can activate or repress transcription that is mediated by a variety of cellular genes, even though E1a does not bind directly to DNA.

Attempts to reconstitute transcription systems in vitro also supports the existence of non–DNA-binding coactivators. Early studies were able to reconstitute basal transcription in vitro using proximal promoter regions and initiator elements. However, the addition of upstream regulatory elements that have major effects on transcription in transfected cells, or in transgenic models, rarely induces marked activation, even when cognate transcription factors are added. Although there have been some success in the reconstitution of enhancer-mediated transcription (e.g., progesterone receptor), most such experiments still employ relatively unpurified nuclear extracts. The presence of coactivators in these systems is suggested by the loss of transcriptional activation with additional purification steps and by the ability to inhibit transcription by including excess amounts of transcription factors. Alternatively, it has been possible to demonstrate potentiation of in vitro transcription by supplementing the reaction with rate-limiting factors. Complementation of HeLa cell extracts with fractionated proteins from B cells was shown to enhance the activity of Oct-dependent transcription from the *immunoglobulin* promoter. An additional line of evidence suggesting the presence of coactivators involves overexpression experiments in transfected cells. In this paradigm, overexpression of many DNA-binding transcription factors is inhibitory. This "squelching" phenomenon has been proposed to involve the titration of rate-limiting coactivators (Fig. 3-7B). Moreover, when different transcription factors are used, there is often crosstalk of the squelching effect, suggesting that

some coactivators are shared by several different transcription factors. For example, overexpression of an estrogen receptor can inhibit transcription by the glucocorticoid receptor, suggesting that they share a common coactivator (this is now known to be SRC-1, among others). In other cases, the squelching phenomenon appears to be less specific. For example, overexpression of a strong transactivator, such as the viral protein, VP16, can inhibit transcription by most genes. A key issue has been to elucidate whether these effects are nonspecific or actually serve as a bioassay for coactivators.

Several experimental approaches now provide direct evidence for coactivators. Using a yeast one-hybrid approach, a B-cell coactivator, Bob-1, that interacts with the octamer-binding protein, was isolated. This factor contains an interaction domain that contacts the POU domain of Oct-1 or Oct-2 and can modify its DNA binding specificity as well as enhancing transcriptional activation. As noted, a number of coactivators for the nuclear receptors have been isolated (Table 3-1), primarily by using a yeast two-hybrid strategy, in which the activation domain of the receptor is used as bait. The coactivators interact directly with the nuclear receptors without making contacts with DNA. They interact with the receptor in a ligand-dependent manner, implying a conformational change in the receptor. One class of the steroid receptor coactivators, SRC, interacts with the carboxy-terminal activation domain through a hydrophobic motif, LXXLL. The coactivator contains additional sequences that are involved in transactivation. Exactly how the coactivators facilitate transactivation remains unclear, but it is likely that additional intermediates connect these factors with the basal transcription machinery.

The CREB-binding protein (CBP), was identified based on direct protein–protein interactions. CREB was shown to detect a high molecular weight protein in farwestern blot assays, but only after phosphorylation of CREB at a residue (Ser 133) known to be required for transactivation. Based on this observation, radiolabeled phosphorylated CREB was used to screen cDNA expression libraries, allowing identification and cloning of CBP. CBP is postulated to function as an integrator of transcription, because in addition to CREB, it appears to mediate the actions of a large array of transcription factors and other coactivators (Fig. 3-11). A homolog of CBP, referred to as p300, was identified initially as target of adenovirus E1a protein. CBP contains distinct interaction domains for various classes of transcription factors. For example, the nuclear receptors interact with the aminoterminal region of CBP, whereas CREB interacts with a more central motif. CBP has been shown to enhance nuclear receptor transcription, particularly when combined with other coactivators such as SRC. Some experiments suggest that limiting amounts of CBP may provide a mechanism for transcriptional crosstalk between pathways. For example, AP-1-mediated transcription is inhibited by the activated glucocorticoid receptor, but this inhibition is reversed by the addition of excess CBP. CBP contains endogenous histone acetyltransferase (HAT) activity, and it also recruits a histone acetyltransferase to the promoter. One mechanism by which CBP may function is by altering histone acetylation and nucleosome structure.

As noted at the beginning of this chapter, initial concepts of gene regulation were based on models of repressors. In addition to repressors that bind directly to DNA, there is now good evidence for corepressors that act to silence gene transcription through interactions with DNA-bound proteins. This group of factors is exemplified by the nuclear receptor corepressors, silencing
Figure 3-11 Domains of CBP. CREB-binding protein (CBP) is a large (270 kDa) protein that interacts with a many different transcription factors. Its domains are shown above the figure and interacting transcription factors are shown below the figure. RAR, retinoic acid receptor; ER, estrogen receptor; TR, thyroid Hormone receptor; RXR, retinoid X receptor; GR, glucocorticoid receptor; PR, progesterone receptor; STAT2, signal transducers and activators of transcription; CREB, cAMP response element binding; SV40 TAg, Simian virus 40 large T antigen; TBP, TATA-binding protein; TFIIB, transcription factor IIB; SRC-1, steroid receptor coactivator.

mediator of retinoid and thyroid receptors (SMRT) and nuclear receptor corepressor (N-CoR). These proteins were also cloned by a yeast two-hybrid approach. However, rather than binding to the receptors in the presence of ligand, they only interact in the absence of ligand. In addition to transfection studies, the ability of these factors to silence transcription has also been demonstrated using in vitro transcription assays, in which relief of silencing can be demonstrated by the addition of excess unliganded receptor (opposite of squelching). The mechanism of transcriptional silencing appears to involve Sin3A, which is a homolog of the yeast transcriptional repressor, Sin3p. In addition, a histone deacetylase interacts with Sin3A to form a multisubunit repressor complex. Thus, modifications of the state of histone acetylation, and the nature of nucleosome phasing near the regulatory region of genes, may represent a common pathway for control by transcriptional repressors and activators.

FEEDBACK MECHANISMS CONTROL THE TRANSCRIPTION OF MANY GENES

Although much work has focused on mechanisms of transcriptional activation, it is also important to switch genes off in a controlled manner. In some cases, this is a matter of reversing the step that leads to activation. For example, transcription factors that are activated by phosphorylation can be dephosphorylated by specific phosphatases. For a few genes, a pathway of autoregulation has been identified in which the product of a gene acts to regulate its own promoter. Autoregulation can be positive to result in rapid induction, or it can be negative to inhibit transcription once a certain level of the gene product has been achieved.

An example of both positive and negative feedback control occurs for the *Pit-1* gene. The *Pit-1* promoter contains regulatory elements that bind Pit-1, resulting in a positive feedback loop. However, high levels of Pit-1 are inhibitory, apparently because they bind to low-affinity sites downstream of the transcriptional start site. Thus, low levels of Pit-1 act positively, but high levels are inhibitory.
Figure 3-12 Autoregulation of transcription. Control of *cAMP response element modulator (CREM)* gene expression is shown as an example of autoregulation. The *CREM* gene contains two promoters, P1 and P2. The P1 promoter drives expression of a full-length protein that contains both activation domains (Q1, P-Box, Q2) and DNA-binding domains (DBD). The P2 promoter is located within an intron and drives expression of a small protein that only contains the CREM dimerization and DNA-binding domains. The P2 promoter contains a series of cAMP response elements (CREs) that are activated by the adenylyl cyclase (AC)-cAMP-protein kinase A (PKA) cascade. This pathway stimulates CREB and CREM, which induce the activity of the P2 promoter as well as other cAMP-responsive genes. Activation of the P2 promoter results in expression of *inducible* cAMP early repressor (ICER), which functions as repressor of CREs. Thus, ICER terminates its own production from the CREM gene and also inhibits a subset of other cAMP-responsive genes.

Another type of feedback inhibition is illustrated by control of *CREM* gene expression (Fig. 3-12). Like CREB, CREM is a phosphoprotein that regulates cAMP-responsive genes. However, CREM has multiple isoforms that act as either activators or repressors of transcription. CREM isoforms α, β, and γ are repressors, whereas isoforms τ, $\tau1$, $\tau2$, and $\tau\alpha$ are activators. Each of these isoforms are splicing variants derived from the P_1 promoter. The *CREM* gene also contains an intronic promoter, P_2, which transcribes ICER. The P_2 promoter contains several cAMP response elements. Thus, activation of the cAMP pathway and CREM expression results in rapid induction of ICER. ICER is a 120-amino acid (13.4-kDa protein) that contains only the DNA binding and dimerization domains of CREM. Because it binds to DNA, but lacks transactivation domains, ICER functions as a powerful repressor of cAMP-induced transcription. ICER may also inhibit CREB and CREM by forming inactive heterodimers.

Physiologically, the induction of ICER appears to terminate or dampen activation by the cAMP pathway. During spermatogenesis, CREMτ is initially induced in mature germ cells in response to stimulation by follicle-stimulating hormone (FSH). CREMτ

expression leads to an increase in CRE-driven promoters, including the P_2 promoter that expresses ICER. Increasing levels of ICER feed back to attenuate the duration and amplitude of cAMP-responsive gene transcription. Hence, the increase in ICER protein downregulates its own transcription to terminate the cycle. This pathway also plays a role in the control of circadian rhythms. In the pineal gland, ICER levels vary dramatically during the 24-h cycle, with peak levels occurring at night. The enzyme serotonin *N*-acetyltransferase (NAT), which is involved in melatonin synthesis, is increased in CREM-deficient mice. Characterization of the NAT promoter revealed an ICER binding site, suggesting that increased expression results from the absence of ICER inhibition in the CREM-deficient mice.

ROLE OF TRANSCRIPTION FACTORS IN GENETIC AND ACQUIRED DISORDERS

As noted, a substantial fraction of expressed genes encode transcription factors. It is therefore not surprising that transcription factors have been associated with a number of different genetic disorders (Table 3-2). Transcription factors are obvious candidates to cause genetic and neoplastic disorders because of their roles as regulators of developmental pathways and as switches that respond to environmental signals. Therefore, it is possible to eliminate the expression of a gene, not only by a direct mutation in that gene, but also as a result of a mutation in a transcription factor that controls expression of the gene *(in trans)* or by preventing the development of the cell lineage in which the gene is expressed. Pit-1 mutations illustrate these points. Pit-1 is a POU-homeodomain protein that is selectively expressed in certain pituitary gland cell types. Pit-1 directly regulates the expression of pituitary genes including the *growth hormone* and *prolactin* genes (*see* Chapter 49). Mutations in Pit-1 cause deficiencies in growth hormone and prolactin and also impair the development of the somatomammotrope cell lineage that produces these hormones. In this manner, the transcription factor mutation results in clinical manifestations that resemble mutations in the target genes *(growth hormone, prolactin)*. However, in this case, the phenotype is broadened (includes thyroid-stimulating hormone) because the transcription factor participates in a cascade that controls the development of cell lineage in the pituitary.

Several other examples of transcription factors that control developmental cascades are summarized in Table 3-2. Genes in the paired box homeotic (PAX) family cause a wide variety of development disorders, which reflect their restricted patterns of distribution (*see* Chapter 112). The bHLH (basic helix-loop-helix) group of transcription factors have also been identified in many genetic disorders (e.g., Twist, MITF, MXI-1). This family of factors, which typically bind to DNA as heterodimers, are frequently involved in cell lineage development and tissue-specific expression (*see* Chapter 92). In addition to disorders that have already been identified, gene knockout experiments in mice predict an important role for these factors in other developmental disorders. The high-mobility group (HMG) proteins, SRY and SOX-9, comprise part of a pathway that leads to normal male sexual differentiation (*see* Chapters 57 and 58). Mutations in SRY cause XY sex reversal, and mutations in SOX-9 cause sex reversal in addition to skeletal abnormalities. The exact function of the HMG proteins remains unclear, but they are thought to induce DNA bending, which may facilitate the transcription of target genes. The homeodomain proteins, HNF-4α, HNF-1α, and IPF-1, participate

in a pathway that leads to normal pancreatic islet cell development and function (*see* Chapter 47). Mutations in HNF-4α and HNF-1α cause a form of late-onset diabetes mellitus referred to as maturity onset diabetes of the young (MODY). Homozygous mutations in IPF-1 cause pancreatic agenesis, whereas heterozygous mutations appear to cause another form of MODY. These genes illustrate how mutations in several different steps in the same developmental pathway can result in phenotypically similar disorders (nonallelic genetic heterogeneity).

Mutations in the steroid hormone superfamily of nuclear receptors cause hormone resistance syndromes. For example, androgen receptor mutations (X-linked) cause androgen insensitivity. Severe mutations result in a syndrome referred to as testicular feminization, in which there is absolute resistance to androgen action, and the sexual phenotype appears female, even though inguinal testes are present and high levels of testosterone are produced (*see* Chapter 60). Similarly, estrogen, glucocorticoid, and vitamin D resistance syndromes result from mutations in their respective nuclear hormone receptors. Although these phenotypes can be predicted in part, the naturally occurring mutations have helped to elucidate the functional roles of the hormones and their receptors. For example, the estrogen receptor mutation prevented epiphyseal closure in the long bones, revealing that estrogen action is required (and cannot be substituted by androgens) for this event. In contrast to the other nuclear receptors, mutations in the thyroid hormone receptor illustrate a distinct property of some transcription factor mutations: the ability to function in a dominant negative manner. Thyroid hormone receptor mutations are transmitted in an autosomal dominant manner and cause partial end organ resistance to thyroid hormones (*see* Chapter 50). The basis for dominant transmission has been shown to involve the binding of mutant thyroid hormone receptors to target genes to block the function of the receptor from the normal allele. Consistent with this model, these receptor mutants retain the ability to form dimers and to bind to DNA, but they lack the ability to bind hormone or to initiate transcription. Analogous dominant negative mutations have been described for Pit-1, and are likely to be relatively common among transcription factor disorders, because they are manifest in the heterozygous state, and the modular nature of transcription factors lends itself to mutations that selectively inactivate one functional domain while preserving other features such as dimerization or DNA binding.

The relevance of modular functional domains in transcription factors in disease is also illustrated by the formation of chimeric factors in neoplasia (*see* Chapter 7). Particularly in leukemias and lymphomas (*see* Chapters 26 and 27), but also in soft tissue tumors (*see* Chapter 95), translocations combine different transcription factor domains or bring a transcriptional activation region under the control of a heterologous gene. Several examples of such translocations are listed in Table 3-2. In one case, the t(1;19)(q23; p13) translocation in pre–B-cell acute lymphoblastic leukemia fuses the PBX homeodomain gene to the transactivation domain of the E2A transcription factor gene. Similarly, in promyelocytic leukemia, a translocation t(15;17)(q22;q21) combines a zinc finger ring domain (PML) with the ligand binding and transactivation domain of the retinoic acid receptor. In this case, the chimeric receptor retains responsiveness to retinoic acid, which has been shown to induce differentiation of leukemic cells. The FUS-CHOP translocation (12;16)(q13;p11) may combine features of chimeric proteins and dominant negative activity and is associated with myxoid

Table 3-2

Examples of Transcription Factor Mutations and Rearrangements That Cause Disease

Transcription factor	Class of factor	Disorder
Developmental/multi-organ		
Brn-4[a]	POU domain	X-linked deafness; stapes fusion
PAX-2	Paired box homeotic	Colobomas optic nerve/ renal hypoplasia
PAX-3	Paired box homeotic	Waardenburg syndrome type 1
PAX-6	Paired box homeotic	Aniridia; Peter's anomaly
Ptx-1	Bicoid homeodomain	Rieg syndrome
Twist	bHLH	Saethre-Chotzen syndrome
MITF	bHLH	Microphthalmia; Waardenburg 2A
CBFα1	Runt domain	Cleidocranial dysplasia
GLI-3	Kruppel	Greig cephalopolysyndactyly
CBP	Bromodomain coactivator	Rubenstein-Taybi syndrome
Endocrine		
Pit-1	POU-homeodomain	Pituitary insufficiency
SRY	HMG	Sex reversal
SOX-9	HMG	Campomelic dysplasia; sex reversal
HNF-4	Nuclear receptor	MODY1
HNF-1α	Homeodomain	MODY3
IPF-1	Homeodomain	Pancreatic agenesis; MODY 4
TRβ	Zinc finger nuclear receptor	Resistance to thyroid hormone
AR	Zinc finger nuclear receptor	Androgen insensitivity
ERα	Zinc finger nuclear receptor	Estrogen resistance
GR	Zinc finger nuclear receptor	Glucocorticoid resistance
VDR	Zinc finger nuclear receptor	Vitamin D-resistant rickets type IIA
DAX-1	Nuclear receptor-like	Adrenal hypoplasia congenita
Cancer/hematology		
Rb	Cell cycle	Retinoblastoma; other cancers
p53	HLH-like; cell cycle	Li-Fraumeni syndrome; other cancers
WT1	Zinc finger	Wilm's tumor; Denys-Drash syndrome
MXI-1	bHLH	Prostate cancer
TFIIH	General transcription factor	Xeroderma pigmentosa; Cockayne syndrome
VHL	Transcription elongation	Von-Hippel-Lindau syndrome; Renal Ca
XH2	Chromatin remodeling	Mental retardation; α thalassemia
HMGI-C	HMG	Benign mesenchymal tumors
PTH-Cyclin D1	Translocation; cell cycle	Parathyroid adenoma
FUS-CHOP	Trans. factor-b-Zip	Mixed liposarcomas
Pax-3,7-FKHR	Paired box homeotic-forkhead	Alveolar rhabdomyosarcoma
EWS-ATF-1	Translocation; b-Zip	Ewing's sarcoma
E2A-PBX	Transc. factor-Homeodomain	Acute lymphoblastic leukemia
MLL-ELL	Translocation; elongation	Acute myeloid leukemia
CBFβ-MYHII	Translocation; MYHII	Acute myeloid leukemia
MLL-AF9	Translocation; AF9	Acute myeloid leukemia
PML-RAR	Translocation; Retinoid action	Acute promyelocytic leukemia
PDGFR-ETS	Translocation; ETS	Chronic myelogenous leukemia
TCR-Hox-11	Translocation; Homeodomain	T-cell leukemia
TCR-TTG-1,2	Translocation; LIM	T-cell leukemia
TCR-TAL-1,2	Translocation; Twist	T-cell leukemia
MLL-AF4	Translocation; AF4	Leukemia
TEL-AML1	Translocation; AML1	Leukemia
E2A-HLF	Translocation; b-Zip	Leukemia
Ig-MYC	Translocation; bHLH	Lymphoma; leukemia
RFX-A	RFX	Bare lymphocytes; MHC class II deficiency

[a]Many transcription factor abbreviations are now standard nomenclature. Selected abbreviations include: Brn-4, Brain-4; PAX, paired box homeotic gene; Ptx, pituitary homeo box; MITF, microphthalmia associated transcription factor; CBF, core-binding factor; GLI, amplified in Glioblastoma; CBP, CREB (cAMP responsive element binding)-binding protein; Pit, pituitary specific transcription factor; SRY, sex determining region Y; SOX, SRY box; HNF, hepatocyte nuclear factor; IPF, insulin promoter factor; TR, thyroid hormone receptor; AR, androgen receptor; ER, estrogen receptor; GR, glucocorticoid receptor; VDR, vitamin D receptor; DAX, dosage-sensitive sex-reversal-adrenal hypoplasia congenita critical region on the X-chromosome; Rb, retinoblastoma; WT, Wilm's tumor; MXI, MAX-interacting protein; VHL, Von Hippel-Lindau; HMG, high-mobility group; PTH, parathyroid hormone; FUS, fusion; EWS, Ewing's sarcoma; ATF, activating transcription factor; CHOP, C/EBP homologous protein; FKHR, Forkhead related; PBX, pre–B-cell leukemia; MLL, mixed lineage leukemia; ELL, elongation factor homologous to MLL; MYH, myosin heavy-chain polypeptide; PML, promyelocytic leukemia; RAR, retinoic acid receptor; PDGFR, platelet-derived growth factor receptor; HOX, homeobox; TCR, T-cell receptor; TAL, T-cell acute leukemia; TEL, translocation ETS leukemia; RFX-A, regulatory factor associated.

liposarcomas. The CHOP protein is normally a dominant inhibitor of members of the b-Zip family of transcription factors. However, in combination with FUS, which contains a transactivation domain, its inhibitory properties may be converted to activation. In other cases, the translocation results in ectopic expression of a transcription factor. This property is illustrated by translocations such as TCR-TAL, in which the T-cell receptor gene results in targeted overexpression of the twist-like protein, TAL. Similarly, the fusion of the *Ig* promoters to *Myc* causes overexpression of Myc in certain lymphomas and leukemias, and the *PTH* promoter has been shown to drive expression of cyclin D1 in a subset of parathyroid adenomas (*see* Chapter 51).

Transcription factors that are linked to cell-cycle control, such as Rb and p53, play major roles in neoplasia (*see* Chapter 7). Rb was discovered as a result of mapping the locus for the childhood disorder, retinoblastoma (*see* Chapter 105). This disorder established the principle of the so-called two-hit model for certain dominantly transmitted cancer syndromes. In this case, an inherited mutation in one copy of Rb creates a circumstance in which a second somatic mutation results in the inactivation of both alleles, leading to clonal expansion of neoplastic cell. Subsequent studies have shown that somatic Rb mutations occur in many different kinds of cancers (e.g., osteosarcoma, brain tumors, breast, genitourinary), some of which overlap with the tumors that develop in patients with germline mutations in Rb. The principle of the two-hit model for germline mutations is also illustrated by p53, which causes Li-Fraumeni syndrome (early breast cancer, soft tissue sarcomas, brain tumors, adrenal tumors, and so on). p53 activates a number of genes involved in cell cycle control including p21. p53 acts at the G1/S checkpoint and also governs the ability to arrest cell growth and to permit cells to undergo apoptosis (*see* Chapter 6). In addition to germline mutations in p53 in Li-Fraumeni syndrome, somatic mutations in p53 are among the most common tumor suppressor gene mutations in cancer (*see* Chapter 40).

It is surprising that mutations in factors such as the RARs do not have even more severe effects on cellular function. The phenotypes of the mice with knockouts of individual RAR isoforms (e.g., α, β, γ) are relatively subtle (occasional skeletal defects). The absence of a more severe phenotype has been attributed to the possibility of redundant function by the other isoforms. Other examples are emerging in which mutations in factors presumed to play a fundamental role in the function of the cell (and therefore assumed to be embryonic lethal) actually cause relatively specific postnatal syndromes. For example, a mutation in a component of the general transcription factor, TF$_{II}$H, is one cause of xeroderma pigmentosa. Similarly, the Von Hippel-Lindau gene product, which is involved in the control of transcriptional elongation, causes a syndrome consisting of predisposition to renal cancers, pheochromocytomas, retinal angiomas, and hemangiomas of the central nervous system (*see* Chapter 71). Another example is provided by the protein, CBP, which serves as a transcriptional integrator that links other transcription factors to the basal transcription factors. CBP is a coactivator for an enormous number of transcription factors including CREB and AP-1, nuclear receptors, c-myb, and STAT proteins (Fig. 3-11). Haploinsufficiency of CBP causes a severe, and characteristic, syndrome referred to as Rubenstein-Taybi. These patients have mental retardation, characteristic facies, broad thumbs, and great toes. In addition to its remaining normal allele, CBP function may be complemented to some degree by a homologous protein, p300. In view of the fraction of the genome that is dedicated to expression of transcription factors, we can expect the list of disorders caused by transcription factor mutations to grow further.

4 Transmission of Human Genetic Disease

PETER KOPP AND J. LARRY JAMESON

INTRODUCTION

Molecular DNA analysis has become an integral part of all medical specialties. Although the immense size and complexity of the human genome is daunting, recent progress in the Human Genome Project has greatly increased our knowledge of the genetic basis of many human diseases (*see* Chapter 5). The impact of molecular DNA analysis and genetics in clinical medicine includes new approaches for the diagnosis of diseases, the detection of pathogens, screening for disease predisposition, genetic counseling, drug development, pharmacotherapy, and, in selected cases, gene therapy.

More than 3000 human diseases are known to be caused by defects in single genes and to follow a Mendelian mode of inheritance. Moreover, many disease processes are influenced by the genetic background of the affected individual. There is often a complex interaction between environmental factors and genetic predisposition. Many of these disorders (e.g., hypertension, coronary artery disease, asthma, diabetes) represent major public health problems and the elucidation of their pathogenesis remains an extraordinary challenge. Other genetically determined forms of disease include the syndromes caused by chromosomal aberrations and inherited cancer syndromes, as well as nonhereditary somatic cell DNA defects that occur in cancer.

DNA AND THE TRANSMISSION OF GENETIC INFORMATION   The double-stranded macromolecule DNA contains the genetic information. It consists of two complementary strands that wrap around one another to form a double helix. Each strand is a linear arrangement of four different bases: adenine (A), thymine (T), cytosine (C), and guanine (G). The order of the bases forms the DNA sequence. The two DNA strands are held together by hydrogen bonds formed between the complementary bases G and C, or A and T. Because the nucleotide chains within the double-stranded DNA are strictly complementary, each can serve as template for the formation of a new strand. This semiconservative form of replication ensures that each dividing cell receives an identical copy of DNA (*see* Chapter 6).

In the coding sequence of a gene, each set of three DNA bases forms a codon, the genetic code for the incorporation of one of the 20 amino acids found in proteins (Fig. 4-1). A series of codons thus defines which amino acids will be synthesized into a given polypeptide. The protein-coding instructions found in the DNA

sequence of a gene are first transcribed into mRNA. The mRNA is translocated from the nucleus into the cytoplasm, where it is translated by ribosomes into a string of amino acids (protein synthesis).

CHROMOSOMES, GENES, AND DNA

A detailed description of molecular genetic techniques is beyond the scope of this chapter, but it is useful to present some of the key concepts and techniques that are essential for the analysis of the genome and genetic diseases (*see* Chapters 1 and 2). Aspects of gene manipulation are also covered in chapters on transgenic models (*see* Chapter 10) and gene therapy (*see* Chapter 18).

SIZE AND ORGANIZATION OF THE HUMAN GENOME   The genome is encoded by a coiled polymer of deoxyribonucleic acid (DNA) that is separated into several segments, the chromosomes (*see* Chapter 1). In humans, every somatic cell is diploid and contains two sets of 23 chromosomes. A child receives one copy of every chromosome from its mother, and one copy from its father. The 22 autosomal chromosomes are present in two copies, and are similar in females and males. The sex chromosomes, X and Y, are dissimilar. Only a small segment of the short arm of both the X and Y chromosomes, the pseudoautosomal region (PAR), shares homology. Females have two X chromosomes (XX), while males are heterogametic (XY). The DNA of a single or haploid set of chromosomes consists of approximately 3×10^9 bp (3000 Mb), with the smallest chromosome containing ~50 Mb (chromosome 21) and the largest ~263 Mb (chromosome 1).

A gene consists of regulatory DNA sequences, coding sequences (exons), and intervening noncoding sequences (introns). The sequences of a gene that encode a protein are located in exons, which are spliced together to form the messenger ribonucleic acid (mRNA). Based on the number of expressed mRNAs, it has been estimated that the human genome contains about 70,000 to 100,000 genes. The size and structure of genes is highly variable. Some small genes consist of a few hundred basepairs, while the largest gene known to date, the X-chromosomal gene encoding the protein dystrophin, contains about 2×10^6 bp with more than 100 introns. Mutations in this gene lead to two distinct clinical conditions, Duchenne Muscular Dystrophy (DMD) and Becker Muscular Dystrophy (BMD). Some chromosomal regions, particularly near the centromeres, do not contain genes, while others display a high gene density. Occasionally, genes are grouped into clusters in which several copies of genes with similar function are located near one another. Examples of gene clusters are the growth hormone genes, or the genes encoding α and β globin. In other

Figure 4-1 Genetic code. A codon for an amino acid consists of three nucleotides (triplet). One amino acid may be encoded by several different codons (degeneracy of the genetic code). The code includes sequences for the start codon and the stop codon.

Figure 4-2 Crossing-over and recombination. During chiasma formation, either of the two chromatids on one chromosome pairs with one of the chromatids of the homologous chromosome. Genetic recombination through crossing-over results in recombinant and nonrecombinant chromosome segments in the gametes. Such recombination events occur frequently and, together with the random segregation of maternal and paternal chromosomes, generates genetic diversity in gametes.

instances, functionally related genes are located on different chromosomes.

Expressed genes encompass only about 20% of the total genome. A large amount of genomic DNA is not formed of single-copy sequences, but consists of repetitive sequences of various types. Short interspersed repetitive elements (SINE; 100–500 bp) and long interspersed repetitive elements (LINE; 6000–7000 bp) are spread throughout the genome. Another form of repetitive sequences, microsatellites, consist of 10–50 copies of simple sequence repetitions. Their functional role is not well defined, but they provide an important tool for establishing genetic maps and performing linkage studies *(see below)*.

MITOSIS AND MEIOSIS For tissue development and growth, eukaryotic cells progress through cycles of cell division and differentiation (*see* Chapter 6). Each cell division (mitosis) results in two genetically identical diploid (2n chromosome sets) daughter cells that are derived from the precursor cell. The first step in mitosis is the duplication of each parental chromosome, yielding two pairs of sister chromatids ($2n \rightarrow 4n$). The chromosomes then condense and the nuclear membrane disappears. Subsequently, the chromosomes are arranged along the equatorial plate at metaphase. The two identical sister chromatids, held together at the centromere, are attached to the mitotic spindles. They then divide and migrate to opposite poles of the cell. After formation of a nuclear membrane around the two separated sets of chromatids, the cell divides and two diploid daughter cells are formed.

The gametes, oocytes or sperm, contain a single copy of each chromosome, a haploid (1n) chromosome set. When a sperm fertilizes an egg, the two haploid sets are combined, resulting in a new zygote containing two copies of each chromosome (diploid or 2n). The generation of the haploid gametes from diploid germ cells (oogonia, spermatogonia) occurs through meiosis, which consists of two cell divisions. During the first mitotic cell division, there is an exchange between homologous chromosomes generating

genetically unique gametes. After formation of the two sister chromatids ($2n \rightarrow 4n$), homologous chromosomes pair and form chiasmata (Fig. 4-2). Either of the two chromatids can pair with the homologous chromosome and undergo a process called crossing-over, in which segments of the maternal homolog recombine with the paternal homolog to form hybrid chromosomes in the place of the original ones. Such recombination events occur frequently, and it appears that at least one chiasma occurs on each chromosome arm. After these exchanges have been completed, the chromosomes segregate randomly. Because there are 23 chromosomes, there are 2^{23} (>8 million) possible combinations of chromosomes. Together with the exchanges that occur during recombination, chromosomal segregation generates great genetic diversity in gametes. After the first meiotic division, which gives rise to two daughter cells (2n), the two chromatids of each chromosome are separated during the second meiotic division and this results in four gametes with one chromatid (1n).

GENOTYPE AND PHENOTYPE A segment of DNA that is inherited in a Mendelian fashion (e.g., a gene) is called a locus. The genetic information at a given gene locus is defined as a genotype. Differences in the DNA sequence, and thus the genotype, are defined as alleles. If two alleles are present at a given locus, there are three possible genotypes. The genotype can be identical (homozygous) for one or the other allele, or it can consist of the combination of the two alleles (heterozygous). If there are more than two alleles, the number of possible genotypes increases accordingly.

The phenotype defines the visible or measurable characteristics of an individual. The term wild type describes the normal gene, including different allelic variants. A mutant genotype may or may not change the phenotype. If the phenotype of a mutant allele can be recognized in the heterozygous state, it is dominant. If alleles can only be recognized in the homozygous state, they are recessive. If both alleles can be recognized in the heterozygous state, they are codominant (e.g., the alleles A and B in the ABO blood system).

The widespread nature of genetic diversity is illustrated by subtle phenotypic variations between, and within, different ethnic groups. Biochemical polymorphisms, not readily perceptible by phenotype, can also be detected in many normal proteins that exist in various forms in a population. These variants are explained by the existence of multiple alleles at the level of the gene. The first such polymorphism to be clearly defined was the ABO blood group system. Molecular genetic analyses have revealed a surprisingly great degree of genetic variation. About 1 in 200 bp in the human genome is polymorphic. They are particularly frequent in noncoding regions of the genome and include single-basepair changes and variations in repetitive sequences. A polymorphism may change the protein sequence when it is located in coding regions and the substitution changes the amino acid specified by a codon. Polymorphisms are inherited according to Mendelian laws, a feature that is used in linkage studies or forensic applications.

Polymorphisms may have no impact on phenotype, or they may contribute to population diversity without being associated with disease. Alternatively, they may contribute to the susceptibility to, or expression of, certain diseases. A high degree of genetic diversity increases the ability of a population to adapt to changing environmental conditions, and it decreases the risk of recessive diseases.

GENETIC HETEROGENEITY   Genetic heterogeneity refers to a similar phenotypic alteration that results from defects in different genes. For example, genetic heterogeneity occurs in Maturity-Onset Diabetes of the Young (MODY), which can result from defects in the glucokinase gene, as well as the genes encoding HNF-1α (Hepatocyte nuclear factor-1α) or HNF-4α (*see* Chapter 47).

Allelic or intragenic heterogeneity refers to alternate genotypes at the same locus that result in the same or similar phenotype. In cystic fibrosis, more than 600 mutations have been identified in the gene encoding the cystic fibrosis transmembrane conductance regulator protein (*see* Chapter 37). In allelic heterogeneity, linkage studies will identify the same locus. In contrast, genetic heterogeneity results in a similar phenotype, but linkage analyses identify distinct loci in different families.

TECHNIQUES USED IN GENETICS

RESTRICTION ENDONUCLEASES   Restriction endonucleases are bacterial enzymes that recognize and cleave DNA at specific nucleotide sequences, called restriction sites (*see* Chapter 2). The most common restriction sites are sequences of 4–6 bp. Many of these sequences are palindromic (twofold axis of symmetry). A restriction enzyme recognizing a four-base sequence will find a target sequence every 4^4 (256) bases, a six-base cutter every 4^6 (4036) bases in a randomly composed DNA fragment. Cleavage can result in blunt ends of DNA or short single-stranded ends known as cohesive or sticky ends. The ability to manipulate DNA with restriction enzymes is of fundamental importance and includes applications like Southern analysis *(see below)* and the cloning of DNA fragments. If a sequence variation leads to loss or introduction of restriction sites, it is called a restriction fragment length polymorphism (RFLP). These polymorphic markers can be used for linkage studies.

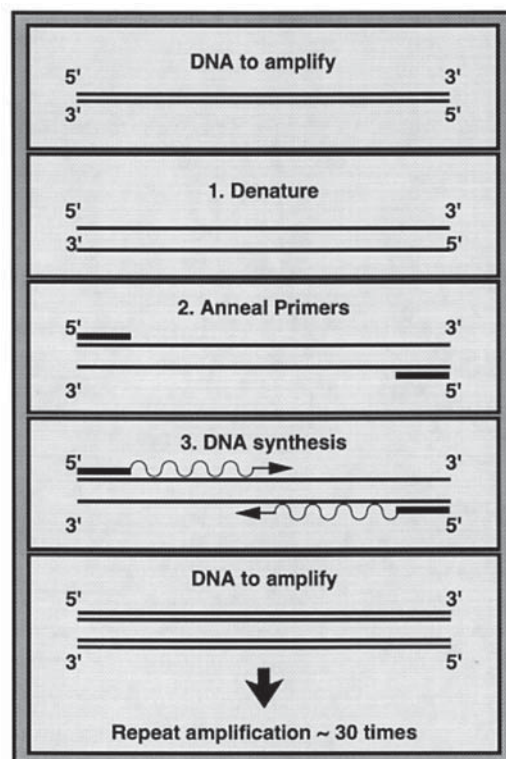
PCR   The polymerase chain reaction (PCR), introduced in 1985, has profoundly changed the way DNA analyses are performed, and it has become a cornerstone of molecular biology and


Figure 4-3 Polymerase chain reaction. The polymerase chain reaction (PCR) generates multiple copies of a DNA segment. The double stranded (ds) template DNA is denatured, specific synthetic oligonucleotides primers of about 20 bp are annealed on each side of the segment of interest, and the complementary strand is then synthesized by a heat-stable DNA polymerase. After each cycle, the dsDNA from the preceding cycle serves as template. The amount of DNA is therefore doubled after every cycle, resulting in an exponential increase.

genetic analysis. PCR allows the amplification of a defined DNA segment several millionfold. In the first step, the double stranded (ds) template DNA is denatured by heating (Fig. 4-3). Second, specific synthetic oligonucleotides primers of about 20 bp are annealed on either side of the segment of interest. The complementary strand located between the primers is then synthesized by a DNA polymerase. This procedure is usually repeated for about 30 cycles using automated heating blocks. After each cycle, all the dsDNA present from the preceding cycle serves as template. The DNA is therefore doubled after every cycle, resulting in an exponential increase in the amount of replicated DNA.

Reverse transcriptase-PCR (RT-PCR) is another important strategy for molecular analysis. The starting material in this case is mRNA. The mRNA is reverse-transcribed into cDNA by the enzyme reverse transcriptase (first-strand synthesis). Subsequently, cDNA segment(s) can be amplified by PCR as described above.

DNA SEQUENCING   Several protocols have been developed for the determination of DNA nucleotide sequence. In both traditional methods (Maxam-Gilbert or Sanger), the template DNA is used to generate fragments of DNA, which differ in size. Using high-resolution gel electrophoresis, these DNA molecules are separated at single-base resolution, allowing the sequence of the template DNA to be deduced. Maxam-Gilbert sequencing takes advantage of chemicals that cleave DNA at specific bases, thus resulting in fragments of different lengths. In the Sanger sequenc-
Figure 4-4 Automated DNA sequencing using fluorescently labeled dideoxynucleotides. Among the many methods in use for DNA sequencing, the chain termination methodology is widespread, and automated procedures are now used with increasing frequency. Automated procedures use fluorescently labeled dideoxynucleotides (or primers) and direct computer analysis of the sequence. A sequencing primer is bound to the template DNA. Dideoxynucleotides carrying different fluorescent labels are included in these reactions to terminate DNA polymerization when they are incorporated instead of the normal nucleotide. Electrophoresis of these reactions allows separation of the elongation products, which are directly analyzed by a computer.

ing method, DNA chains of varying length are generated by using dideoxynucleotides to terminate extension of the sequence by a DNA polymerase (chain termination method). By running four reactions in parallel (one for each dideoxynucleotide) and separating the products by electrophoresis on polyacrylamide gels, it is possible to determine the sequence of the template. Automated procedures are now used with increasing frequency to analyze DNA sequences. These procedures are usually based on the chain termination method and employ fluorescently labeled dideoxynucleotides or primers followed by direct computer analysis of the sequence. A typical example is shown in Fig. 4-4. These methods are, however, still relatively labor- and cost-intensive. For example, it has been estimated that sequencing the whole human genome by such an approach would result in costs of at least $3 billion at $1–$2 per base, and that it would require 30,000 work-years.

Currently, efforts are underway to develop new DNA sequencing technologies that are faster, more sensitive, and more cost-effective. Methodologies that are being explored include detection of fluorescently labeled bases in flow cytometry, direct reading of the base sequence on a DNA strand with the use of scanning, tunneling, or atomic force microscopies, mass spectrometric analy-

sis of DNA sequence, and sequence analysis with DNA chips consisting of large arrays of oligonucleotides to which the DNA can be hybridized.

CYTOGENETICS AND FLUORESCENT *in situ* **HYBRIDIZATION (FISH)**   Chromosomes can be stained and visualized under a light microscope. They display a characteristic pattern of light and dark bands reflecting regional variations in DNA composition. Differences in size and banding patterns allows one to distinguish the 22 autosomes and sex chromosomes to determine the karyotype of an individual. This type of cytogenetic analysis reveals the presence of major chromosomal abnormalities, including missing or extra copies of a chromosome, gross deletions, insertions, or translocations.

Fluorescent *in situ* hybridization (FISH) combines conventional cytogenetics with DNA hybridization. Chromosomes are prepared from nucleated cells and hybridized with fluorochrome-labeled DNA probes specific for various loci. Numerical and structural aberrations can then be detected by analysis of the fluorescence pattern. FISH is gradually replacing conventional cytogenetic analyses. The high resolution of FISH is useful for diagnostic purposes, and it is also helpful in the construction of chromosomal maps. Using interphase chromosomes, such probes can improve map resolution to about 100,000 bp.

GENE MAPPING   Given the size and complexity of the human genome, the identification and location of genes is not trivial. Maps of the entire genome have now been developed to facilitate the localization of a gene of interest. Different types of maps (genetic or physical) describe the order of markers and the distances between them on each chromosome. One of the primary goals of the Human Genome Project is to increase the resolution of these maps until the exact location of every gene is known (*see* Chapter 5).

A genetic map determines the relative position of a gene or locus based on the recombination frequencies relative to other loci on the same chromosome. It is expressed in recombination units or centiMorgans (cM). The genetic map is up to 40% longer in chromosomes derived from females because of a higher frequency of recombination during the formation of oocytes. Any polymorphic sequence whose inheritance pattern can be followed is useful for mapping purposes. Examples of useful markers include RFLPs and microsatellite repeats. The genetic map is then constructed by assessing how frequently two markers are inherited together by linkage studies. The chromosomal location of a gene responsible for an inherited disease can be determined by tracking the inheritance of DNA markers *(see below)*.

Physical maps indicate the position of loci in absolute values. The various types of physical maps differ in their degree of resolution. A cytogenetic or chromosomal map determines the position of genetic loci relative to characteristic chromosomal bands observed under light microscopy. cDNA maps are of particular interest because they allow analyses of expressed genomic regions. After synthesis of cDNA from mRNA using reverse transcriptase, the origin of the cDNA can be mapped to particular chromosomal regions by hybridization. Sequence-tagged sites (STS) are short DNA segments with known locations on the genetic map (*see* Chapter 5). They can be used to array DNA fragments that have been cloned into yeast artificial chromosomes (YACs). The presence or absence of a given STS in a cloned fragment of DNA can then be compared in different YACs to identify overlapping clones. This leads to the characterization of contiguous DNA
Figure 4-5 STS content map. The presence or absence of sequence tagged sites, short DNA segments of known sequence, can be determined in various clones of yeast artificial chromosomes (YAC). The comparison of STS sequences in different YAC clones allows their order to be determined.

Figure 4-6 Linkage analysis in multiple endocrine neoplasia type 1 (MEN-1). **(A)** Schematic representation of human chromosome 11 depicting the position of the MEN 1 gene at band q13. In any individual, there is a paternal and a maternal allele for MEN 1. Hypothetical microsatellite markers A and B are shown near the MEN 1 locus. The A marker is closer to the MEN-1 gene. Based on the number of repeats in the microsatellites, genotypes are defined such that the paternal allele is "3-4" and the maternal allele is "2-2." Based on the pedigree (or DNA sequencing if available), the "3-4" genotype is shown to be linked to the MEN 1 gene. **(B)** Pedigree of a family with MEN 1. Alleles of family members are denoted by the genotypes based on microsatellites at A and B. Within the affected family, the disease is carried on the "3-4" allele (bold). Those affected or carrying the disease are shaded. Note that the male in generation II, who is not part of the original family, also possesses the "3-4" allele, but is not affected, indicating that a specific genotype is linked only within a family, not in the general population.

sequences, commonly referred to as contigs (Fig. 4-5). The highest resolution physical map will provide the complete DNA sequence of each chromosome in the human genome.

LINKAGE Genetic linkage provides the basis for the development of genetic maps, and it is used for the detection of new genes by positional cloning *(see below)*. Linkage is also used diagnostically to predict transmission of a disease gene. A prerequisite for linkage analyses are various types of sequence polymorphisms, like RFLPs, variable number of tandem repeats (VNTR), or microsatellites, which are used to distinguish the parental origin of alleles. Gene loci in the parental chromosomes may undergo recombination or remain nonrecombinant. The observed frequency of recombination between two loci is a function of their distance and is expressed in centiMorgans (cM). If the recombination frequency between two loci is 1%, the two loci are said to be 1 cM apart (1 cM corresponds to about 1 Mb of DNA). Because recombination frequency increases as a function of genetic distance, the closer together two loci are, the higher the likelihood that they will be inherited together (genetic linkage). A set of closely linked markers that are inherited together define a haplotype. DNA loci are identified by a specific nomenclature. For example, the locus D7S525 refers to human chromosome 7, segment 525, and is found on the short arm of chromosome 7.

In order to identify a chromosomal locus that segregates with a disease, it is necessary to determine the genotype of DNA samples from one or several pedigrees. Subsequently, one can determine whether certain marker alleles cosegregate with the disease. When a series of genetic markers are used to establish linkage to a disease phenotype in large informative kindreds, markers that are closest to the disease gene are less likely to undergo recombination events and will attain a higher linkage score. The data resulting from the

characterization of multiple loci are then analyzed by computer programs. Linkage is usually expressed as a Lod (logarithm of odds) score, which is a ratio of the probability that the disease and marker loci are linked rather than unlinked. Lod scores are expressed as the logarithm to the base 10 such that positive numbers favor linkage and negative scores support nonlinkage. Lod scores of +3 (1000:1) are generally accepted as supporting linkage, whereas a score of –2 is consistent with the absence of linkage.

An example of the use of linkage analysis is shown in Fig. 4-6. In this case, the gene for the autosomal dominant disorder, multiple endocrine neoplasia type 1 (MEN-1), is known to be located on chromosome 11q13. Hypothetical polymorphic microsatellite markers are close to the MEN-1 gene, which encodes a protein, menin (currently of unknown function). In the pedigree shown, the affected grandfather in generation I carries alleles 3 and 4 on the

chromosome with the mutated MEN-1 gene and alleles 2 and 2 on his other chromosome 11. Consistent with the linkage of the 3/4 genotype to the MEN-1 locus, his son in generation 2 is affected, whereas his daughter (who inherits the 2/2 genotype from her father) is unaffected. In the third generation, transmission of the 3/4 genotype indicates risk of developing MEN-1, assuming no genetic recombination between the 3/4 alleles and the MEN-1 gene. If a specific mutation in the MEN-1 gene is identified within a family, it is possible to track transmission of the mutation itself, thereby eliminating uncertainty caused by recombination.

CLONING OF GENES   DNA may be amplified by cloning DNA fragments into suitable vectors that can be propagated in host cells. Vectors include DNA molecules derived from viruses, bacteria, or yeast that replicate independent of the genome of the host cell. After digestion of both the vector and the DNA to be inserted with restriction enzymes, they can be joined using DNA ligase. The vector carrying the fragment is then transferred into host cells (bacteria, yeast, or eukaryotic cells) where it is replicated. These manipulations allow the generation of large amounts of DNA for further experimental studies (*see* Chapter 2).

This type of manipulation can be performed with a single DNA fragment to be amplified, or one can create libraries in which all fragments derived from genomic DNA are represented in the final collection of colonies. In principle, a genomic library represents multiple cloned fragments of the entire genome. Genomic libraries can also be generated from single chromosomes after selection with fluorescence-activated cell sorters (FACS). cDNA libraries can also be created, using the mRNA of a selected tissue, and several modifications allow enrichment for certain mRNAs (e.g., poly[A] or size-selected), thus increasing the chance to find clones of interest.

After the preparation of libraries, the next step consists of isolating the recombinant clone containing the genomic or coding sequence of a gene. If there is some information on the protein encoded by this gene, microsequencing of a partial amino acid sequence allows synthesis of oligonucleotides based on the genetic code. Because of the degeneracy in the genetic code, this strategy employs a group of oligonucleotides. The oligonucleotides are radiolabeled and hybridized to clones within the library. Clones with a positive signal are isolated and propagated. Sequencing the DNA fragment inserted in the vector will provide information on at least a part of the gene of interest.

It is also possible to clone genes without having prior information on the protein. This strategy is referred to as positional cloning or reverse genetics (Fig. 4-7). This approach was introduced in the late 1980s has been successful for the identification of many genes, including those causing cystic fibrosis, Duchenne muscular dystrophy, polycystic kidney disease, and the MEN syndromes. The first step consists of establishing genetic linkage between a disease phenotype and DNA markers. This allows determination of the chromosomal region where the candidate gene is located. The identification of markers residing close to a gene provides the starting point for chromosome walking or jumping, which can be used to move progressively closer to the gene of interest. These methods allow one to screen sequences between the markers for the presence of functional genes. If one or several candidate genes are identified, they can be cloned and sequenced. The final step involves the demonstration that the isolated gene harbors a mutation that segregates with the disease.

1. Define disease phenotype and mode of inheritance

2. Collect DNA samples from family members

3. Genotype DNA (Microsatellites, RFLP, VNTR) Search for markers cosegregating with disease locus

4. Localize chromosomal region of candidate gene

5. Search for more closely linked markers

6. Chromosome walking/jumping Move towards disease gene locus

7. Identify genes in candidate region

8. Detect mutation in candidate gene, confirm cosegregation of mutation and disease

Figure 4-7 Positional cloning. A schematic outline is presented for the typical steps involved in the identification of a disease gene by positional cloning.

MUTATIONS   In a broad sense, a mutation can be defined as any change in the primary nucleotide sequence of DNA, regardless of its functional consequences. A mutation in germ cells will lead to its presence in every cell of an organism, and it will be transmitted to the offspring. Some mutations may be lethal, while others are less deleterious, and some confer an evolutionary advantage. Somatic mutations, limited to a clone of cells in a given tissue, play an important role in the development of neoplasms. With the exception of triplet repeats which can expand *(see below)*, mutations usually remain stable.

Structurally, mutations are very diverse. They can involve the entire genome as in triploidy, as well as gross numerical or structural alterations in chromosomes (Table 4-1). Large deletions may affect a portion of a gene, an entire gene, or if several genes are involved, they may lead to a contiguous gene syndrome. Unequal crossing-over between homologous genes can result in fusion gene mutations, well-illustrated by color blindness. Mutations can also involve changes in only a few or a single basepair. Mutations involving single nucleotides are referred to as point mutations. Analogous to gross chromosomal changes, point mutations may consist of substitutions, deletions, or insertions. Substitutions may be silent or change the respective codon. If the change occurs in a coding region, it is called a missense mutation. Substitutions are called transitions if a purine is replaced by another purine base (A↔G) or a pyrimidine is replaced by another pyrimidine (C↔T). Changes from a purine to a pyrimidine or vice versa are referred to as transversions. Deletions or insertions cause a shift of the translational reading frame, typically resulting in a premature stop (nonsense mutation). Mutations in intronic sequences may eliminate or create splice donor or splice acceptor sites, resulting in an abnormally spliced mRNA from the mutated gene. Mutations may

Table 4-1
Examples of Different Types of Mutations

Type of mutations	*Example*
Genome	
Abnormal chromosome set	Triploidy, tetraploidy
Chromosome	
Abnormal number of autosomal chromosomes	Trisomy 21, 18, 13
Abnormal number of sex chromosomes	Klinefelter syndrome, Turner syndrome
Translocation	Acute myeloid leukemia t(9;22)(q34:q11) "Philadelphia chromosome"
Deletion	Cri du chat syndrome 5p-
Duplication	Dosage-sensitive sex reversal (Xp dup)
Inversion	Ret oncogene inv (10)(q11.2q21) in papillary thyroid carcinoma (PTC)
Gene	
Deletion	Duchenne muscular dystrophy, Thalassemia
Duplication, insertion	Charcot-Marie-Tooth Type I
Fusion	Glucocorticoid-remediable aldosteronism
Inversion	Hemophilia A
Triplet expansion	Fragile X syndrome, Huntington disease
Missense point mutation	Cystic fibrosis
Nonsense point mutation	Cystic fibrosis
Frameshift	Cystic fibrosis
Splicing mutation	β Globin

also be found in the regulatory sequences of genes and can cause reduced or absent transcription of genes.

In some cancer syndromes, there is an inherited predisposition to tumor formation (*see* Chapter 7). In retinoblastoma, the tumor develops when both copies of the retinoblastoma gene become defective through two somatic events (sporadic retinoblastoma) or through a somatic loss of the normal allele in an individual with an hereditary defect in the other allele (hereditary retinoblastoma) (*see* Chapter 105). This "two-hit model," initially proposed by Knudson, applies to several other inherited cancer syndromes. The defective allele is inherited in a Mendelian fashion and follows a dominant pattern, but tumorigenesis results from a recessive loss of the tumor suppressor gene in an affected tissue. In other instances, the development of cancer typically requires defects in multiple genes, a process termed multistep carcinogenesis (*see* Chapter 7).

Testing for DNA mutations has several advantages in comparison to analyses at the protein level. DNA is easy to isolate and, in contrast to proteins, it is not differentially regulated in various tissues. DNA can be isolated from many sources, including white blood cells, tissue samples, exfoliated cells, and hair roots. A variety of methods have been developed for mutational analyses (Table 4-2). Large mutations, deletions, insertions, rearrangements, or expansions of triplet repeats can be detected by Southern blotting or PCR. In Southern analysis, high molecular DNA is digested with restriction enzymes. This results in multiple DNA fragments that can be separated by gel electrophoresis. After transfer of DNA to a membrane, the DNA can be denatured and hybridized with radioactive probes that detect a particular sequence among the countless other fragments. Differences in the hybridization patterns obtained by Southern blotting can indicate deletions or insertions in the genomic DNA (Fig. 4-8). For example, Southern blotting can be used in the diagnosis of the α-thalassemia variant found in Southeast Asia (*see* Chapter 20). In some cases of this autosomal recessive disorder, there is a large deletion of both α-globin genes from the 30 kb gene cluster on chromosome 1. Because the deletion

encompasses the ζ-globin gene, it leads to hydrops fetalis and intrauterine death.

RT-PCR can be useful for detecting absent or reduced levels of expression of an mRNA resulting from a mutated allele. Screening for point mutations can be performed by numerous methods (Table 4-2). They are based on the recognition of mismatches between nucleic acid duplexes, electrophoretic separation of single or double-stranded DNA, or sequencing of DNA fragments amplified by PCR. DNA sequencing can be performed directly on PCR products or by using fragments cloned into plasmid vectors. The sensitivity of these methods varies between 80 and 100%. Protein truncation tests (PTT) can be used to detect mutations resulting in premature termination of a polypeptide during its synthesis. The isolated cDNA is transcribed and translated *in vitro* and the proteins are analyzed by gel electrophoresis. Comparison with the wild-type protein allows detection of truncated mutants. This approach is particularly helpful for the detection of loss of function mutations in large genes.

GENETIC DISEASES

CATEGORIES OF GENETIC DISEASE Taken together, genetic diseases form a substantial group of human disease. More than one-third of all pediatric hospital admissions are because of disorders that are caused, at least in part, by genetic factors. About 6–8% consist of single-gene defects, 0.4–2.5% are from chromosomal disorders, and the remaining group are genetically influenced. Overall, 3–5% of diseases in the general population are estimated to be genetically determined. Accurate estimates are difficult because different genetic defects can lead to the same phenotype (genetic heterogeneity), and a large number of genetic diseases are relatively rare. These difficulties should be kept in mind when assessing genetic risk. If one includes disorders with a strong polygenic predisposition, such as Type 2 diabetes mellitus, hypertension, or hyperlipidemias, then the role of genetics in common disorders is even greater.

Every classification of genetic diseases harbors some degree of oversimplification because of overlaps between the different cat-

Table 4-2
Methods Used for the Detection of Mutations

Method	Principle	Type of mutation detected
Cytogenetic analysis	Numerical and structural analysis of chromosomes	Numerical or structural abnormalities in chromosomes
FISH (fluorescent *in situ* hybridization)	Hybridization to chromosomes with fluorescently labeled probes	
Southern blot	Hybridization with DNA probe after digestion of high molecular DNA	Large deletions, insertions, rearrangements, expansions of triplet repeats, amplifications
PCR (polymerase chain reaction)	Amplification of DNA segment	Expansion of triplet repeats, variable number of tandem repeats (VNTR), gene rearrangements, translocations
Sequencing	Direct sequencing of PCR products Sequencing of DNA segments cloned into plasmids	Point mutations, small deletions, and insertions
SSCP (single-strand conformational polymorphism)	PCR of DNA segment: mutations result in conformational change and altered mobility	Point mutations, small deletions, and insertions
DGGE (denaturing gradient gel electrophoresis)	PCR, altered mobility of amplified segment harboring a mutation	Point mutations, small deletions, and insertions
OSH (oligonucleotide specific hybridization)	Hybridization of oligonucleotides ± altered sequence to amplified genomic DNA	Point mutations, small deletions, and insertions
RNase cleavage	Cleavage of mismatch between mutated and wild-type sequence	Point mutations, small deletions, and insertions
RFLP (restriction fragment length polymorphism)	Detection of altered restriction pattern of genomic DNA (Southern blot) or PCR products	Point mutations, small deletions, and insertions
RT-PCR (reverse transcriptase-PCR)	Reverse transcription, amplification of DNA segment → absence or reduction of mRNA	Indirect evidence for presence of mutation, cDNA cloning for sequencing
PTT (protein truncation tests)	Transcription/translation of cDNA isolated from tissue sample	Mutations leading to premature truncations

egories. Genetic diseases can be classified generally into the following major categories:

1. Chromosomal disorders with numerical or structural abnormalities in one or several chromosomes.
2. Mendelian or monogenic disorders, characterized by a single mutant gene inherited according to Mendelian rules.
3. Multifactorial diseases or complex disease traits, defined by the interaction of multiple genes and one or multiple environmental factors.
4. Nonclassical forms of genetic disease, a heterogeneous group that includes disorders influenced by genomic imprinting, or caused by uniparental disomy, trinucleotide repeats, and various forms of mosaicism.
5. Mitochondrial disorders resulting from mutations in the mitochondrial genome. Because mitochondrial DNA is transmitted through the maternal line, the pattern of inheritance differs from Mendelian disorders.
6. Mutations arising in differentiated somatic cells, which are of particular importance in the development of neoplasms. Although they are not inherited, they may occur in individuals with an inherited predisposition.

CHROMOSOMAL DISORDERS Chromosomal or cytogenetic disorders are defined by numerical or structural aberrations in chromosomes. They are frequent causes of abortions, developmental disorders, malformations, and malignancies. In humans, numerical chromosome aberrations occur in approximately 1 of 400 neonates. Triploidy and tetraploidy refer to circumstances in which each chromosome is present threefold or fourfold, respectively, instead of the usual diploid set. Triploidy is one of the most frequent chromosomal aberrations in humans and is found in about 15% of spontaneous abortions and severe malformations. The additional set of chromosomes may be of paternal or maternal origin. Aneuploidy describes a deviation from the normal chromosome number in a single pair of chromosomes. In a trisomy, three copies of a chromosome are present, and in a monosomy, one of the chromosomes is missing. Trisomies and monosomies are caused by nondisjunction in the first or second meiotic division and may be of paternal or maternal origin. Some of the most frequent abnormalities of chromosome number are listed in Table 4-3.

Structural defects in chromosomes arise from translocations, deletions, inversions, insertions, isochromosomes, dicentric chromosomes, and ring chromosomes. If no chromosomal material has been lost or gained, the rearrangement is referred to as balanced. If it is unbalanced, there is either a loss or gain of chromosomal DNA. A large number of congenital syndromes caused by structural changes in chromosomes can be recognized based on their characteristic clinical phenotype. Furthermore, chromosomal translocations play an important role in certain malignancies, such as leukemias and lymphomas (*see* Chapters 26 and 27).

MENDELIAN OR MONOGENIC DISORDERS Because most traits examined by Mendel were caused by single genes, monogenic human diseases are frequently referred to as Mendelian disorders. Information about many of these genetic disorders
Figure 4-8 Southern blot. A Southern blot can be used to detect alterations in gene structure (e.g., deletions, insertions, variable number tandem repeat [VNTR], or restriction fragment length polymorphism [RFLP]). Genomic DNA is digested with one or several restriction enzymes. The digestion products are separated on an agarose gel and transferred to a membrane. Hybridization of the immobilized DNA with a radiolabeled probe allows detection of specific fragments by autoradiography. As illustrated, an RFLP can lead to differences in the length of the detected fragments. Such polymorphisms are used in linkage studies to assess whether a disease cosegregates with a genetic marker.

can be found in a large, continuously evolving compendium, Mendelian Inheritance in Man (MIM), initiated by V. A. McKusick. It is also accessible on-line (OMIM: On-line Mendelian Inheritance in Man, http://www3.ncbi.nlm.nih.gov/Omim).

The Mendelian laws predict the transmission of alleles within a family, and these are depicted graphically in family trees or pedigrees. Standard symbols used for describing pedigrees are shown in Fig. 4-9. As an example, the segregation of genotypes in the offspring of parents with two distinct alleles, one dominant and one recessive, is illustrated in Fig. 4-10. Some relatively common Mendelian disorders are listed in Table 4-4, and the characteristic modes of inheritance are shown in Fig. 4-11. A dominant allele, *A*, and a recessive allele, *a*, can display three Mendelian modes of inheritance: autosomal dominant, autosomal recessive, and X-linked. The mode of inheritance for a phenotypic trait or disease

is determined by pedigree analysis. In autosomal dominant disorders, individuals can be affected in each generation. The disease does not occur in the offspring of unaffected individuals. Males and females are affected with equal frequency (Fig. 4-11A). The child of an affected individual has a 50% risk of inheriting the mutated gene. In an autosomal recessive disease, both parents of an affected individual are obligate heterozygotes (Fig. 4-11B). The affected individual, who can be of either sex, can be a homozygote or compound heterozygote (distinct mutations in each copy of the gene) for a gene defect. Normally, heterozygous carriers of a defective gene are clinically normal. There is a 25% chance that an offspring will be affected. Many autosomal recessive diseases are rare and often occur in cases of parental consanguinity. X-chromosomal inheritance refers to the transmission of genes located on the X chromosome (Fig. 4-11C). A daughter always inherits her father's X chromosome together with one of the two maternal X chromosomes. A son inherits the Y chromosome from his father and one of the maternal X chromosomes. Thus, there is no father-to-son transmission in X-linked inheritance, and all daughters of an affected male are obligate carriers of the mutant allele. Since males have only one X chromosome, they are hemizygous for a mutant allele and are therefore more likely to develop the mutant phenotype, regardless of whether the mutation is dominant or recessive. A female may be either heterozygous or homozygous for a mutant allele, which may be dominant or recessive. In addition, the expression of X-chromosomal genes is influenced by X chromosome inactivation *(see below)*.

The frequency of Mendelian disorders varies substantially in different populations. For example, the autosomal recessive disorder sickle-cell anemia occurs with the highest frequency in populations originating from West Africa, β thalassemia is frequently found in Asians, and cystic fibrosis occurs most often in individuals of European descent. In many of the more prevalent disorders, a selective advantage has been proposed for heterozygous gene carriers and may provide an explanation for the high frequency of the mutated allele. In disorders with a low prevalence, but a relatively high frequency within a defined population, a founder effect is more likely.

PHENOTYPIC VARIABILITY IN MENDELIAN DISORDERS

The phenotype associated with certain mutations can vary in the degree of penetrance. For example, in hypertrophic obstructive cardiomyopathy (HOCM), an autosomal dominant disorder characterized by obstruction of left ventricular outflow resulting from ventricular hypertrophy, some mutations in the myosin heavy-chain β gene exhibit 100% penetrance in adults. In other words, all carriers of the mutation will develop the disease (*see* Chapter 13). Other mutations in the same gene display a penetrance of about 50%, such that an individual carrying the mutant genotype may not manifest the disease phenotype. In this situation, the mutant gene is called nonpenetrant. Although a carrier of the mutant gene may not develop the disease, it will still be transmitted to the next generation where it may be penetrant or nonpenetrant. In addition, the HOCM phenotype may be caused by molecular alterations in other genes, a phenomenon referred to as genetic heterogeneity *(see above)*. Determination of penetrance may be dependent on the sensitivity of the methodology used for the assessment of the phenotype. Penetrance can also be dependent on the presence or absence of environmental factors: If there is no exposure to disease-causing agents, some genetic defects may not become apparent. This is illustrated by hyperlipidemias, hemochromatosis, or porphyrias, all disorders that are significantly modulated by diet.

Table 4-3
Frequent Chromosome Abnormalities

Disorder	Chromosomal genotype	Frequency
Abnormal no. of chromosome sets		
Triploidy	69XX, 69XY	Frequent in miscarriage
Tetraploidy	92XX, 92XY	Frequent in miscarriage
Abnormal no. of autosomes		
Trisomy 21		1/600
Trisomy 18		1/5000
Trisomy 13		1/15,000
Abnormal no. of sex chromosomes		
Klinefelter syndrome	47XXY	1/1000 males
XYY-syndrome	47XYY	1/1000
Turner syndrome	45X0, 45X/46X0, 45X/46XY (mosaicism)	1/10,000 females
Triple-X syndrome	XXX	1/1000
Figure 4-9 Symbols used in pedigree analyses.

Figure 4-10 Segregation of alleles. Segregation of genotypes in the offspring of parents with a dominant (A) and a recessive (a) allele. The distribution or segregation of the parental genotypes to their children depends on the combination of the alleles in the parents. The Mendelian laws predict the combinations and frequencies in the offspring *(see text)*.

Variability in clinical expressivity characterizes the spectrum of phenotypic changes among different individuals with a given genotype. It includes differences in the type and severity of symptoms, as well as the age of onset of a disease. A classical example is the multiple endocrine neoplasia syndrome type 1 (MEN-1), an autosomal dominant syndrome characterized by tumors of the parathyroid glands, the anterior pituitary, and the endocrine pancreas. By age 50, almost 100% of the gene carriers develop parathyroid tumors (*see* Chapter 51). In contrast, there is a great variability in the development of other manifestations of MEN-1 among siblings carrying the mutated gene.

AUTOSOMAL DOMINANT DISORDERS   Diseases inherited in an autosomal dominant manner result from one mutant allele and a normal allele on the other chromosome. Unless it is a new germline mutation, each affected child has an affected parent. The probability that an offspring will be affected is 50% because the alleles segregate at meiosis. Children with a normal genotype will have only unaffected offspring (Fig. 4-11A). Both males and females can be affected, since the defective gene is on one of the 22 autosomes. Autosomal dominant disorders can, however, manifest themselves in a sex-limited pattern as exemplified by familial male-limited precocious puberty, which is caused by activating mutations in the gene encoding the LH-receptor (Chapter 57). The clinical manifestations of autosomal dominant disorders may be variable because of differences in penetrance or expressivity *(see above)*. In certain cases, a mutant gene may be nonpenetrant. These variations can lead to difficulties in the recognition that a disorder is inherited.

Approximately 1 in 100,000 newborns will harbor a new mutation at a given locus, and in the case of a dominant allele, this may result in phenotypic changes. *De novo* germline mutations are thought to occur more frequently during later cell divisions in gametogenesis, which explains why siblings are rarely affected. In some cases, however, the mutation may occur early in gametogenesis, resulting in gonadal mosaicism, which can lead to multiple affected sibs, despite the fact that somatic cells of the parents do not harbor the mutation. Gonadal mosaicism is, for example, found in Duchenne muscular dystrophy and osteogenesis imperfecta.

Table 4-4
Selected Monogenic Disorders

Autosomal dominant disorders
    Familial hyperlipidemia
    Familial hypercholesterolemia
    Huntington disease
    Polycystic kidney disease
    Spherocytosis
    Marfan syndrome
    Neurofibromatosis
    Hereditary nonpolyposis colon cancer
    Polyposis of the colon
    Familial breast cancer
    Willebrand disease
    Hypertrophic obstructive cardiomyopathy (HOCM)
    Myotonic dystrophy
    Otosclerosis
Autosomal recessive disorders
    Cystic fibrosis
    Sickle-cell anemia
    β-Thalassemia
    α1-antitrypsin deficiency
    Congenital adrenal hyperplasia
    Phenylketonuria
    Hemochromatosis
    Tay-Sachs disease
X-linked disorders
    Color blindness
    Hemophilia A
    Hemophilia B
    Glucose-6-phosphate dehydrogenase deficiency
    Duchenne muscular dystrophy
    Becker muscular dystrophy
    Fragile X syndrome
    X-linked ichthyosis

Figure 4-11 Mendelian inheritance. Pairs of alleles can display three Mendelian modes of inheritance: autosomal dominant, autosomal recessive, and X-chromosomal. The mode of inheritance for a given phenotypic trait or disease is determined by pedigree analysis. **(A)** In autosomal dominant disorders, affected individuals are found in successive generations. The disease does not occur in the offspring of unaffected individuals. Both males and females can be affected. The offspring of an affected individual have a 50% risk of inheriting the mutated gene. New mutations in one allele may lead to disease. **(B)** In an autosomal recessive disease, both parents of an affected individual are usually heterozygotes for a defective allele. The affected individual, who can be of either sex, is a homozygote or compound heterozygote. Generally, heterozygous carriers of a defective allele are clinically normal. There is a 25% chance that an offspring will be affected (homozygous recessive). Many autosomal recessive diseases occur in cases of parental consanguinity. **(C)** Characteristic features of X-linked inheritance are that there is no father-to-son transmission, and all daughters of an affected male are obligate carriers of the mutant allele. Males are hemizygous for the mutant allele, and they are more likely to develop the mutant phenotype, regardless of whether the mutation is dominant or recessive. A female may be either heterozygous or homozygous for the mutant allele, which may be dominant or recessive. *De novo* mutations in males may result in disease.

New germline mutations occur more frequently in fathers of advanced age. The average age of fathers with new germline mutations causing Marfan syndrome is 37 years, whereas fathers who transmit the disease by inheritance have an average age of 30 years. The ability to reproduce may be affected by autosomal dominant disorders, and the frequency of the disease will then reflect the occurrence of new mutations during gametogenesis.

A mutant dominant allele may result in an abnormal phenotype because of several pathogenic mechanisms. Haploinsufficiency refers to the fact that half of the normal gene product may not be sufficient to result in a normal phenotype. This applies, for example, to rate-limiting enzymes in heme synthesis causing porphyrias (*see* Chapter 42). An increase in dosage of a gene product may also result in disease. In Charcot-Marie-Tooth type 1a, a duplication of the *PMP22* gene results in high levels of expression of peripheral myelin protein 22, and this dosage effect underlies the demyelinating neuropathy (*see* Chapter 101). A mutant protein may also interfere with the function of the normal protein and act as a dominant negative. This is illustrated by mutations in the thyroid hormone receptor β in the syndrome of resistance to thyroid hormones (*see* Chapter 50).

    AUTOSOMAL RECESSIVE DISORDERS   Autosomal recessive disorders are clinically manifest only if the patient is a homozygote or compound heterozygote (distinct mutations in the gene from the two different chromosomes) for a defect in a single

gene. Heterozygous carriers of a defective allele are clinically normal. Although many recessive disorders appear to be truly recessive, it should be emphasized that heterozygotes may display subtle differences in phenotype that only become apparent with more precise testing or in the context of certain environmental influences. For example, in sickle-cell anemia, heterozygotes

are normally asymptomatic. In situations of dehydration or diminished oxygen pressure, they can occasionally experience sickle-cell crises.

In most cases of a recessive disorder, an affected individual is the offspring of two heterozygotes. In this situation, there is a 25% chance of a normal genotype, a 50% probability of a heterozygous state, and a 25% risk of disease. If a heterozygote mates with a homozygote, the probability of disease increases to 50% for each child and the pedigree analysis may mimic an autosomal dominant mode of inheritance. If a mutant recessive allele is rare in a population, affected individuals are often the offspring of consanguineous parents. In contrast to autosomal dominant disorders, new mutations for recessive alleles rarely manifest themselves, because they result in an asymptomatic carrier. Males and females are affected with the same frequency unless the mutation has a sex-specific effect (e.g., steroid 5α-reductase type II deficiency, which affects only males; *see* Chapter 59).

The clinical expression of autosomal recessive disorders is usually more uniform than in autosomal dominant disorders. Most mutated alleles lead to a complete or partial loss of function. They frequently involve enzymes in metabolic pathways, receptors, or components of signaling cascades. Recessive disorders are generally rare because of the fact that homozygotes may have reduced biological fitness. The high frequency of certain autosomal recessive disorders such as sickle-cell anemia, cystic fibrosis, and thalassemia has been proposed to reflect a biological advantage for heterozygotes.

X-LINKED DISORDERS   The characteristic pattern of inheritance of X-linked disorders is shown in Fig. 4-11C. In X-linked inheritance, there is no father-to-son transmission, and all daughters of an affected male are obligate carriers of the mutant allele. The risk of developing a disease resulting from a mutant X-chromosomal gene is thus different in males and females. While males hemizygous for the mutant allele are always affected, the heterozygous females may be asymptomatic (X-linked recessive) or affected (X-linked dominant). New mutations can result in affected males or heterozygous females. As described below, X chromosome inactivation may influence the expression of an X-linked disease in a heterozygous female. Some X-linked disorders are listed in Table 4-4. In some cases (e.g., incontinentia pigmenti), the mutated allele is lethal in the hemizygous males, and affected women have an increased frequency of spontaneous abortions of male fetuses.

Y-LINKED DISORDERS   Only a few genes are known on the Y chromosome. One of these, the sex-region determining Y factor (SRY) or testis determining factor (TDF), is crucial for the development of the normal male phenotype. Since the SRY region is close to the pseudoautosomal region of the sex chromosomes, crossing-over occasionally occurs between the X and Y chromosomes. Translocations between the X and Y chromosome can subsequently result in XY females with the Y chromosome lacking the SRY gene or XX males harboring the SRY factor on one of the X chromosomes (*see* Chapter 58). Point mutations in the SRY gene may also result in individuals with an XY genotype and an incomplete female phenotype. Most of these mutations occur *de novo*. Men with oligospermia/azoospermia frequently have microdeletions on the long arm of the Y chromosome that involve the azoospermia factor (AZF).

MULTIFACTORIAL DISEASES OR COMPLEX DISEASE TRAITS   In many diseases that appear to have some genetic com-

ponent, there is no clear evidence for classical Mendelian inheritance. However, many common diseases such as asthma (*see* Chapters 35 and 36), rheumatoid arthritis (*see* Chapter 34), diabetes mellitus (*see* Chapter 47), schizophrenia (*see* Chapter 109), hypertension (*see* Chapter 16), and many others exhibit familial predisposition. In many of these cases, interactions between genetic factors and the environment may be involved in the pathogenesis of the disease.

Several lines of evidence point towards polygenic (multiple genes) inheritance. A role for genetics is supported if a disorder occurs at a higher frequency in certain ethnic groups. Since environmental factors may have an important influence, it is important to assess whether the disease frequency is modulated if members of such a population move to a different environment. A genetic component in a multifactorial disease is also suggested if the disorder occurs at a higher frequency in the immediate relatives of an index case in comparison to the general population. Finally, the concordance in monozygotic and dizygotic twins may give important clues for the presence or absence of complex traits. If the concordance rate is high in monozygotic twins in comparison to dizygotic twins, genetic factors are likely to be important.

X-CHROMOSOME INACTIVATION, GENOMIC IMPRINTING, AND UNIPARENTAL DISOMY   Although females contain two X chromosomes, the expression of many X-chromosomal genes is not greater in females than in males. This is because of random inactivation of either the paternal or the maternal X chromosome in each somatic cell of a female during early embryogenesis, a phenomenon also referred to as lyonization. X-inactivation is caused by differential methylation of cytosine nucleotides. Methylation of the inactive copy of the X chromosome results in formation of the X chromatin, which is visible as a Barr body. X-inactivation is not reversible, and the same chromosome is inactivated in daughter cells.

Methylation is not only involved in X-chromosome inactivation, but also plays an important role in the regulation of gene expression. Active genes often display diminished or absent methylation, whereas inactive genes are hypermethylated. Methylation occurs at the 5' position in the cytosine of cytosine-guanine (CpG) dinucleotides. Unmethylated or hypomethylated CpG (cytosine-phosphate-guanine) clusters often indicate the beginning of a structural gene that is being expressed, and they are sometimes used in positional cloning for the identification of genes. The mechanism by which methylation leads to inactivation of gene expression is not well-understood. It could alter chromatin structure or interfere with the binding of transcription factors to regulatory DNA sequences. Alternatively, methylation might be an epiphenomenon that occurs following the inactivation of a gene by other mechanisms. The complex control of gene expression at the transcriptional level is discussed in Chapter 3.

According to Mendelian principles, the parental origin of a mutant gene is irrelevant for the expression of a phenotype. As described above in the context of X-chromosome inactivation, there are some important exceptions to this rule. Inactivation of genes or chromosomal regions on one of the two chromosomes also occurs on autosomes. This phenomenon, referred to as genomic imprinting, leads to preferential expression of an allele, depending on its parental origin, resulting in transmission of disease in a manner that is dependent on the sex of the transmitting parent. The fact that identical regions can differ in their functional activity depending on whether they are of maternal or paternal

origin is also illustrated by zygotes with two maternal or two paternal sets of chromosomes. Cells with two copies of maternal chromosomes develop into the inner cell mass of the embryo, whereas cells with two sets of paternal chromosomes almost exclusively form the extraembryonal cells of the trophoectoderm. These observations indicate that some genes are differentially expressed from paternal and maternal chromosomes.

The principle of genomic imprinting has important implications for a subset of human disorders. Classical examples are the Prader-Willi-Syndrome and the Angelman Syndrome (Chapter 117). The Prader-Willi-Syndrome, characterized by diminished fetal activity, obesity, hypotonia, mental retardation, short stature, and hypogonadotropic hypogonadism, is caused in most cases by deletions on the short arm of chromosome 15. The deletions in the Prader-Willi-Syndrome occur exclusively on the paternally derived chromosome. In contrast, patients with Angelman syndrome (which is characterized by mental retardation, seizures, ataxia, and hypotonia) have deletions at the same site of chromosome 15, but they occur only on the maternally derived chromosome (Fig. 4-12A). The two syndromes may also result from uniparental disomy (Fig. 4-12B). In this case, the syndromes are not caused by deletions on chromosome 15, but by inheritance of either two maternal chromosomes (resulting in Prader-Willi syndrome) or of two paternal chromosomes (causing Angelman syndrome).

Genomic imprinting, or uniparental disomy, is involved in the pathogenesis of several other disorders and malignancies. Hydatiform mole contains a normal number of diploid chromosomes, but they are all of paternal origin. The opposite occurs in ovarian teratomata with 46 chromosomes of maternal origin. Overexpression of the imprinted gene for insulin-like growth factor II (IGF-II) is involved in the pathogenesis of the cancer-predisposing Beckwith-Wiedemann syndrome (BWS) (*see* Chapter 116). These children show somatic overgrowth with organomegaly and hemihypertrophy, and they have an increased risk of developing embryonal malignancies such as Wilm's tumor (*see* Chapter 71). Normally, only the paternally derived copy of the IGF-II gene is active. Imprinting of the IGF-II gene is regulated by H19, an RNA transcript that is not translated into protein. Disruption or lack of methylation of H19 leads to a relaxation of IGF-II imprinting which subsequently results in overgrowth.

TRINUCLEOTIDE REPEATS   Trinucleotide repeats are found in several genes and their number can vary among healthy individuals (*see* Chapter 100). For example, the number of CAG repeats in the first exon of the androgen receptor (AR) gene is lowest in African Americans, intermediate in Caucasians, and highest in Asians (Chapter 60). Of note, the frequency of prostatic cancer is inversely proportional to the length of the repeats.

An increase in the number of repeats above a certain critical threshold is associated with several diseases (Table 4-5). The repeats can be located within the coding region as in Huntington disease (*see* Chapter 97) or the X-linked form of spinal and bulbar muscular atrophy (SBMA, Kennedy syndrome), which is caused by an expansion in the polyglutamine tract encoded by CAG repeats in the first exon of the androgen receptor. In other instances (e.g., in myotonic dystrophy and in the fragile X syndrome), the repeats are not located in coding regions of genes. If an expansion is present, the DNA fragment is unstable and generally tends to expand further with additional cell divisions.

The length of the expansion and the age of onset, or the severity of a disease, often correlate. Since the repeat length tends to
Figure 4-12 Genomic imprinting and uniparental disomy. Model for Prader-Willi syndrome and Angelman syndrome. The two distinct disorders are caused by loss of function of two closely adjacent loci on chromosome 15, which undergoes genomic imprinting. (**A**) Normal situation. The maternal PWS locus and the paternal AS locus are inactivated. (**B**) PWS and AS caused by deletions of the paternal and the maternal alleles, respectively, of chromosome 15q11-13. Southern blots with the marker D15S11 illustrate the absence of a positive hybridization for the paternal (PWS) or maternal (AS) alleles. (**C**) Uniparental disomy, the inheritance of two maternal copies (PWS) or two paternal copies (AS) can lead to the same phenotypes. In this case, a Southern blot with the probe D15S11 shows an increased intensity for one of the maternal (PWS) or paternal alleles (AS).

increase from generation to generation, the manifestations of the disease are observed at an earlier age, a phenomenon called anticipation. In addition, the repeat number may vary in some disorders within an individual in a tissue-specific manner. In myotonic dystrophy, the CTG repeat can be tenfold higher in muscular tissue compared to lymphocytes (Chapter 94). The mechanism by which the expansion of such repeats occurs is still debated. Moreover, the molecular mechanisms leading to the respective diseases are poorly defined.

Table 4-5
Selected Disorders Caused by Nucleotide Repeats

Disease	Locus	Repeat	Triplet length	Gene product	MIM no.
Spinobulbar muscular atrophy (SBMA)	X	CAG	Normal: 11–34 Disease: 40–62	Androgen receptor	313200
Fragile X-syndrome FRAXA	Xq27.3	CGG	Normal: 6–50 Disease: 200–300	FMR-1 protein	309550
Fragile X-syndrome FRAXE	Xq28	GCC	Normal: 6–25 Disease: >200	FMR-2 protein	309548
Myotonic dystrophy	19q13.3	CTG	Normal: 5–30 Disease: 200–1000	Myotonin protein kinase	160900
Huntington disease	4p16.3	CAG	Normal: 11–34 Disease: 37–121	Huntingtin	143100
Spinocerebellar atrophy type 1	6p21.3-21.2	CAG	Normal: 19–36 Disease: 43–81	Ataxin 1	164400
Dentatorubral pallidoluysian atrophy	12p	CAG	Normal: 7–23 Disease: 49–75	Atrophin	125370
Machado Joseph	14q24.3-32	CAG	Normal: 13–36 Disease: 68–79	MJDI	109150
Friedreich ataxia	9q13	GAA	Normal: 7–22 Disease: 200–900	Frataxin	229300

MOSAICISM   Mosaicism refers to the presence of two or more cell lines in an individual that differ in their genotype. Cell mosaicism can result from a mutation that occurs during embryonic, fetal, or extrauterine development. The developmental stage at which the defect arises will determine whether germ cells or only somatic cells are involved. Chromosomal mosaicism results from nondisjunction at an early embryonic mitotic division, leading to the persistence of more than one cell line.

Somatic mosaicism is characterized by a patchy distribution of somatic cells containing a mutation. For example, the McCune-Albright syndrome is caused by activating mutations in the stimulatory G protein, Gsα, that occur early in development. The clinical phenotype varies depending on the tissue distribution of the mutation. The manifestations can include ovarian cysts that secrete sex steroids and cause precocious puberty, polyostotic fibrous dysplasia, *café au lait* skin pigmentation, pituitary adenomas, and hypersecreting autonomous thyroid nodules. Germ cell mosaicism or gonadal mosaicism should be suspected when parents seem to be normal on genetic testing, but have several affected offspring with a dominant or X-linked disorder. In these instances, the mutation may have occurred early in gametogenesis.

MITOCHONDRIAL INHERITANCE   Several diseases arising from mutations in the mitochondrial genome are known in humans (*see* Chapter 103). Each mitochondrion has several copies of a circular chromosome. This DNA predominantly encodes proteins that are components of the respiratory chain. They are transmitted through the maternal line because sperm do not contribute cytoplasmic components to the zygote. The disease will therefore not be transmitted from an affected man to his children, but all the children from an affected mother will be affected.

In contrast to the nuclear chromosomes, the mitochondrial chromosome is present in numerous copies in the cell, and variable numbers of mitochondria are present in cells of different tissues. Different offspring may inherit various ratios of mutant and wild-type mitochondrial genomes (heteroplasmy) that lead to phenotypic variability. During cell replication, the genotype may also shift in the direction of the wild type or mutant chromosomes. Examples of mitochondrial diseases are listed in Table 4-6.

SOMATIC MUTATIONS   Mutations that occur during embryogenesis, or later in development, are referred to as somatic mutations. Because these mutations do not involve the germline, they are not transmitted to the offspring. Somatic mutations have their most important role in various forms of neoplasia (*see* Chapter 7). Undoubtedly, many mutations occur that are silent, because they fail to alter the expression or function of genes. Another large group of somatic mutations may be deleterious to cellular function, but they result in apoptosis or programmed cell death, and are therefore not discovered (*see* Chapter 6). Rarely, mutations will enhance cell proliferation or prolong cell survival, and this group is associated with the development of tumors. These mutations can be identified because they confer a selective survival advantage, resulting in clonal expansion of cell population harboring the mutation.

Activating mutations have been described in many oncogenes. Some of these mutations activate growth factor receptors (e.g., *ret*), whereas others stimulate growth factor signaling pathways (e.g., *ras*). Another group of somatic mutations inactivate tumor suppressor genes such as *retinoblastoma* (*Rb*). Somatic "second hits" in tumor suppressor genes occur in several inherited cancer syndromes in which the "first hit" has already been transmitted in the germline. Examples of these syndromes include retinoblastoma (*Rb*), Li-Fraumeni (*p53*), and multiple endocrine neoplasia type I (*MEN-I*). Many models of tumorigenesis invoke the concept of multistep carcinogenesis. In this scenario, an individual may inherit certain mutations or a predisposition to errors in DNA repair. However, these features alone are not usually sufficient for neoplasia in the absence of additional, somatic mutations. Multistep carcinogenesis proposes an accumulation of mutations, some of which may involve the activation of oncogenes, others inactivate tumor suppressor genes, and another group may impair apoptosis (e.g., *p53*). The characterization of these types of somatic mutations is used increasingly to classify tumors for the purpose of prognosis and may eventually provide new strategies for treatment.

SCREENING FOR GENETIC DISORDERS

The detection of genetic disorders by means of DNA testing is playing an increasing role in prenatal diagnosis, newborn, and

Table 4-6
Selected Mitochondrial Diseases

Disease/syndrome	MIM no.
MELAS syndrome: mitochondrial myopathy with encephalopathy, lactic acidosis, and stroke	540000
Leber optic atrophy: hereditary optical neuropathy	535000
Kearns-Sayre syndrome (KSS): ophthalmoplegia, retinal pigment degeneration, cardiomyopathy	530000
MERRF syndrome: myoclonic epilepsy and ragged red fibers	545030
Maternally inherited myopathy and cardiomyopathy (MMC)	590050
Neurogenic muscular weakness with ataxia and retinitis pigmentosa (NARP)	551500
Progressive external ophthalmoplegia (CEOP)	258470
Pearson syndrome (PEAR): bone marrow and pancreatic failure	557000
Autosomal dominant inherited mitochondrial myopathy with mitochondrial deletion	157640

population screening, as well as predictive testing (*see* Chapter 9). Although these tests are extremely helpful in some instances, they are associated with difficult ethical questions, some of which are briefly addressed at the end of this chapter.

Chorionic villus sampling (CVS) and ultrasound-guided umbilical vein puncture allow analyses of fetal DNA during the first trimester, and amniocentesis is used to test for genetic diseases during the second trimester. Generally accepted indications to perform such analyses include the presence of a known familial genetic disease and advanced maternal age. Disorders for which prenatal diagnosis is routinely available include the thalassemias, hemophilias A and B, cystic fibrosis, and chromosomal abnormalities that can be identified by fluorescent *in situ* hybridization (FISH). Determination of the sex has major implications in X-linked disorders (e.g., Duchenne muscular dystrophy or hemophilia). Other applications of prenatal DNA testing include the diagnosis of congenital infections and Rhesus blood group incompatibility.

Newborn screening for frequent diseases is well-established for disorders that can be altered by early treatment, such as congenital hypothyroidism, phenylketonuria, and galactosemia. In some countries, these newborn screening programs have been expanded, and the application of PCR to newborn blood spots opens the door for further testing, as exemplified by screening for cystic fibrosis, sickle-cell disease, or congenital adrenal hyperplasia. Issues that have to be addressed before accepting new screening programs include cost-effectiveness, adequate counseling, and therapeutic consequences.

Population screening strategies are also becoming more practical because PCR allows testing of a large number of samples relatively rapidly and economically. Population screening can be performed using different strategies. In selective screening programs, DNA testing is performed by mutational analysis or linkage studies in individuals at risk for a genetic disorder known to be present in a family (e.g., Tay-Sachs disease). Mass screening programs require tests of high sensitivity and specificity in order to be cost-effective. In epidemiological surveys, this type of screening program allows determination of the prevalence of certain disorders. Prerequisites for their success are that the disorders be potentially serious, that they can be influenced at a presymptomatic stage by changes in behavior, diet and/or pharmaceutical manipulations, and that the screening does not result in any harm or discrimination ("primum nil nocere"). Screening for the autosomal recessive neurodegenerative storage disease, Tay-Sachs, in Jewish populations resulted in a reduction of the number of affected individuals. In contrast, the screening for sickle-cell trait and disease in African Americans led to unanticipated problems of discrimination by health insurers and employers. Mass screening

programs harbor further potential problems. Although screening for the most common genetic alteration in cystic fibrosis (ΔF508 mutation), with a frequency of ~70% in Northern Europe, is feasible and seems to be effective, it is important to keep in mind that the disease can be caused by more than 600 other mutations. The search for these less common mutations would substantially increase the costs and workload, but result in little impact on the effectiveness of the screening program as a whole.

Population screening is also performed as a part of occupational screening programs that aim to detect increased risk for certain activities (e.g., α1-antitrypsin deficiency and smoke or dust exposure). Detection and exclusion of individuals with increased risk should not replace or diminish efforts to increase the safety of the working environment.

ETHICAL CONSIDERATIONS

Ethical issues surrounding genetics and genetic testing continue to be a topic of considerable debate. The sequencing of the human genome, the identification of its genes, and the association of genetic defects with disease raise many issues concerning the implications for the individual and mankind. The recent cloning of mammals underlines the relevance of these issues.

Ethical discussions are influenced by education, cultural traditions, religion, attitudes toward human values, and also political structures and historical context. Progress and the advantages of genetic medicine have to be balanced against their potential risks. Although the magnitude of benefits is difficult to predict, it is essential that genetic testing does not result in harm for individuals or groups within a society. Modern genetics has demonstrated that the concept of eugenics as a strategy for the elimination of human disease cannot be effective. The fact that this approach has been misused in the past must not be forgotten.

Testing for disease predisposition may lead to a profound change in the way we screen and treat disease, and it opens the possibility for early recognition. However, it also entails a risk of discrimination and loss of privacy, health benefits, and employment. In many countries, lawmakers are therefore establishing legislation that will prevent health plans from discriminating against people on the basis of their genetic inheritance, or using genetic screening to deny coverage or to establish premiums.

Prenatal diagnosis of a disorder may lead to ethical dilemmas for parents (*see* Chapter 9). The ethical implications of terminating a pregnancy continue to be controversial in many societies. In all these situations, adequate counseling is therefore paramount.

Other difficult situations may arise if DNA testing results in detection of nonpaternity, which occurs in 3–5% of randomly stud-

ied children in many cultures. Particular problems may arise when healthy children are tested. Testing may be acceptable in the context of a disorder for which early intervention will improve prognosis, but it is more problematic when this is not the case. This leads to the question of when or whether tests for these types of inherited disorders should be performed. For example, in Huntington disease, which cannot currently be influenced by any form of treatment, individuals are not tested before they are able to give informed consent (*see* Chapter 97). The complexity of these issues will probably increase further as multifactorial disorders are characterized more thoroughly at the genetic level.

The hope that molecular medicine will contribute significantly to diminish the burden of disease in the long term seems, however, realistic. For molecular medicine to be successful, it is essential that the ethical principles of social justice, equality of treatment, confidentiality of test results, and the absence of discrimination based on genetic screening are fully respected.

5 The Human Genome Project

J. Larry Jameson

INTRODUCTION

The Human Genome Project (HGP) was conceived in the mid-1980s as an ambitious effort to characterize the human genome, ultimately culminating with a complete DNA sequence by the year 2005. The accomplishment of this goal would locate the ~80,000 genes and provide the DNA sequence (~3×10^9 bp) for the entire genome at an estimated cost of $3 billion over 15 years. The project has evolved as an international effort, driven forward by numerous scientific groups and funding agencies. Exchange of information and biological materials has been facilitated by the Human Genome Organization (HUGO). In the United States, the genome project was officially launched in 1990 by the National Institutes of Health (NIH) and the Department of Energy (DOE). The goals, as initially conceived were (1) creation of genetic maps, (2) development of physical maps, and (3) determination of complete sequence of human DNA.

INITIATION OF THE GENOME PROJECT AS "BIG SCIENCE"

From its inception, the goals of the HGP seemed daunting, and some considered it unrealistic, if not foolhardy. In addition to issues of cost, there was much debate concerning the goals of the genome project, its organization and timetable, and whether it would raise insurmountable ethical issues. There was particular concern that resources committed to the genome project would detract from traditional investigator-initiated research. On the other hand, proponents emphasized that analyses of the genome were inevitable and that, in the absence of a systematic approach, genetic studies would be inefficient and even more costly. In terms of its potential impact, analogies were drawn to the space program and to attempts to unravel the periodic table of elements. Most anticipated that the genome project would spin off new technologies in parallel with completion of its scientific goals. Moreover, it was expected that progress in the genome project would provide even more opportunities for hypothesis-driven research and for applications to clinical medicine. As described below, the genome project appears to be living up to the expectations of its proponents.

SCOPE OF THE PROJECT

A few facts help to appreciate the scope of the human genome project. The 23 pairs of human chromosomes are thought to encode

approximately 50,000–80,000 genes. It is estimated that only about 5–10% of the human genome encodes protein-coding regions of genes. The remainder of the genome comprises regulatory regions, introns, and repetitive sequences. Thus, only a minority of the genome is expressed in the form of mRNA, which is subsequently translated into protein. It is for this reason that analyses of expressed sequence tags (ESTs), short fragments of cDNA sequence from a particular tissue, provide a powerful approach for identifying gene sequences that encode proteins. The total length of DNA is about 3 billion bp, nearly 1000-fold greater than the *Escherichia coli* genome. At the outset of the HGP, most molecular biologists might be able to sequence and analyze a 30,000-kb locus over the course of a year. Thus, in the absence of technological advances, 100 years would be required for 1000 such individuals to complete DNA sequencing. For this reason, initial emphasis was placed on mapping and on the development of new sequencing and computer database technologies.

An analogy that has been used to illustrate the complexity of the human genome is to compare it with the amount of information in an encyclopedia that is written in the four-letter code of DNA (A, G, T, and C). Thus, the chromosomes might be analogous to volumes of the encyclopedia, with genes corresponding to paragraphs. This analogy emphasizes the challenge of identifying single nucleotide changes that might cause a disorder such as cystic fibrosis or sickle-cell anemia. In this case, the mutation would consist of a single letter change on one of the pages of the encyclopedia. In addition to identifying disease-causing genes, a critical first step is to create a table of contents and an index for the book, which allows one to find the relevant genes. This is the goal of genetic and physical mapping stages of the genome project.

GENETIC MAPS

The complexity of the human genome emphasizes the importance of first establishing a genetic and a physical map. In this manner, the locations of genes can be described. In addition, it allows genetic linkage to be determined. That is, genes that are physically close to one another on a chromosome will be transmitted together, except when a recombination event has occurred during meiosis to exchange homologous regions of DNA. The genetic and physical maps differ in the following manner. A genetic map is measured in centiMorgans (cM) and is based on distances between genes that are estimated by recombination frequency. The physical map is the actual distance (in bp of DNA sequence) between genes.
Figure 5-1 Detection of allelic variants using microsatellite markers. An example of a microsatellite consisting of a triplet nucleotide repeat (CAG) is shown. PCR primers on either side of the repeat results in PCR products of varying length, depending on the number of triplet repeats. In this example, the father has alleles of 110 and 113 and the mother has alleles of 107 and 116. The children each inherited the 116 allele from their mother and distinct alleles from their father. In this manner, microsatellites allow determination of chromosomal transmission within a family.

The unit of genetic distance, centiMorgans, is named after Thomas H. Morgan, a geneticist who provided early evidence for genetic linkage and established the concept that recombination frequency varies as a function of the distance between two genetic loci. By definition, 1 cM corresponds to a recombination frequency of 1%. For example, consider two polymorphic markers (A, B) on chromosome 11 that are linked to the gene causing multiple endocrine neoplasia type 1 (MEN-1). If sufficient pedigrees are examined, it is possible to determine which marker is closer to the disease locus by determining the frequency with which each marker undergoes recombination relative to the disease phenotype. If marker A undergoes recombination at a rate of 0.2, whereas marker B exhibits a lower recombination frequency (0.1), it can be concluded that marker B lies between marker A and the MEN-1 gene as long as there is data that neither marker is on the other side of MEN-1.

There are several reasons why there might be discrepancies between a genetic and a physical map. For example, some genomic regions may exhibit relatively high recombination frequencies. This would result in a greater genetic distance relative to a physical map. Recombination appears to be about twice as common during meiosis in females. Thus, most of genetic distances are "sex-averaged" distances.

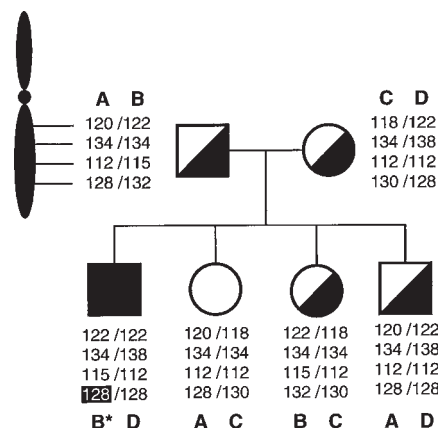
Rapid progress in the creation of a genetic map reflects synergistic interactions among investigators from many countries. In addition, there have been important technical advances, particularly involving the use of highly polymorphic microsatellite markers. Microsatellites consist of di-, tri-, or tetranucleotide repeats. Within any given microsatellite marker, the number of repeats is highly variable in the population (Fig. 5-1). This makes it probable (~70% chance) that an individual will be heterozygous for the marker. In addition, their spouse is also likely to be heterozygous, or may even have a distinct set of repeats, greatly enhancing the power of linkage studies (Fig. 5-2). In the example shown, the array of microsatellite markers makes it possible to determine genetic transmission within a family with great certainty. A large array of these markers have now been identified and have been ordered throughout the genome.


Figure 5-2 Genotype analysis using microsatellite markers. The pedigree illustrates autosomal recessive transmission. An array of microsatellite markers are shown along the long arm of one of the chromosomes. Note that some markers are dinucleotide repeats whereas others are trinucleotide repeats. The parents are heterozygous for most of the markers, which have been selected based on their high degree of heterozygosity within the population. Thus, when several markers are combined, it is relatively easy to document chromosomal transmission within the pedigree. One can assign letters (A–D) that correspond to the various chromosomes, reflecting the transmission of linked alleles. In this case, a putative disease gene is carried by each parent. The mutation resides on chromosome B in the father and chromosome D in the mother. Thus, a son with the BD genotype is affected, a daughter with genotype AC is unaffected, and the children with genotypes BC and AD are each carriers even though they inherited the disease gene from different parents. An example of recombination is illustrated in the affected son. In this case, the chromosome labeled B* received the 128 (black shading) microsatellite marker, which must be derived from the father's chromosome A. Because this son is affected, this crossover event indicates that the disease-causing gene resides centromeric to this microsatellite.

The Genethon human linkage map was updated in 1996. At that point, the map consisted of more than 5000 microsatellite repeat polymorphisms with a mean heterozygosity of 70%. Genotyping with the microsatellite markers was performed using the CEPH (Centre d'Etudes du Polymorphisme Humaine) families. The estimated length of the map is 3699 cM, with an average interval size of about 1.6 cM. In combination with other genetic maps and markers, most regions of the genome can now be analyzed at the cM level. In the future, it may be possible to develop an array of single nucleotide polymorphisms that could be used in conjunction with DNA chip technology. In addition to increasing the density of markers, chip technology would be amenable to begin high throughput screening of genetic loci.

CONSTRUCTION OF PHYSICAL MAPS AND CLONING OF THE ENTIRE GENOME

In physical terms, 1 cM is roughly 1 million bp (1 Mb). The physical map reflects the arrangement and distances between genes and exists at several levels of resolution. A low-resolution map would reveal which chromosome carries a particular gene. The use of such techniques as fluorescence *in situ* hybridization (FISH) allows determination of the location of a particular gene on a chromosome. By using different fluorescent tags, it is possible to "paint" chromosomes and demonstrate the relative locations of genes, but still at a relatively low resolution. A higher level of

Table 5-1
Size of DNA Inserts in Various Vectors

Vector	DNA insert, kb
Yeast artificial chromosome (YAC)	1000
Bacterial artificial chromosome (BAC)	250
Cosmid	35
λ Phage	15
Plasmid	10

Figure 5-3 A physical genomic map with an ordered array of "contigs." A genetic map is shown with polymorphic markers A and B, shown on either side of a disease gene. Below the genetic map, a physical map consisting of overlapping clones is shown. The group of clones are referred to as a contig and can be ordered based on shared sequences, usually a sequence-tagged site (STS).

resolution can be achieved after cloning large DNA fragments and estimating distances using empiric methods such as gels to determine the sizes of an array of overlapping fragments, or DNA sequencing to determine the actual length between genes. As noted below, a parallel goal of the genome project is to insert large segments of the human genome into cloning vectors such as yeast artificial chromosomes (YACs) (Table 5-1). Additional mapping often involves the use of BACs (bacterial artificial chromosomes) and traditional cloning vectors such as lambda phage. Although YACs allow insertion of large fragments of DNA, BACs are gaining favor because of less frequent recombination. The isolation and physical separation of chromosomes has also allowed the preparation of chromosome-specific libraries.

The cloning of large segments of genomic DNA into YACS and cosmids greatly facilitates high-resolution gene mapping, particularly using "contigs," in which an ordered array of overlapping clones can be established (Fig. 5-3). An example of this approach on chromosome 21 is described further in Chapter 117. The goal of achieving a high-resolution physical map of the human genome has now been achieved and greater than 95% of the genome has been cloned into overlapping fragments. A major advance has been the use of sequence tagged sites (STSs) as a standard unit for physical mapping. The STSs serve as landmarks that allow overlapping cloned fragments to be arranged in the same order in which they occur in the genome. The STSs consist of 200–500 bp, which can be retrieved from computer databases as opposed to having to use stored clones. Thus, using PCR, investigators can amplify an STS to gain ready access to map locations.

The Whitehead group has now described the locations of more than 15,000 STS markers, which were screened against about 30,000 YAC clones from the CEPH-Genethon libraries. As of 1995, this map had an average distance of about 200 kb between markers. Ideally STSs would be available at intervals between 50 and 100 kb, which would allow the rapid localization of most disease genes. This will require at least 30,000 STSs. The feasibility of this approach has been enhanced by automation using a "genomatron" that performs 150,000 PCR reactions per run.

DNA SEQUENCING

A long-term goal of the genome project is to obtain DNA sequences for the entire human genome as well as model organisms, such as *Saccharomyces cerevisiae* (now completed, 12.4 million bp), *Caenorhabditis elegans*, and the mouse. At present, only a few percent of the human genome have been sequenced. The amount of DNA sequencing required is daunting for several reasons. Currently available technology is relatively expensive (0.20–0.30 dollars/base) and slow. Sequence accuracy and information management must be assured in parallel with technical advances. A current goal is to achieve 99.99% (1 error in 10,000 bp) accuracy. The issue of polymorphic variants in

human sequence will only be addressed in the long term. There are probably polymorphic sequence variants approximately 1 out of every 1000 bp. Although this variation is low (99.9% identical), it suggests as many as 3 million sequence differences between any two unrelated individuals.

Despite these challenges, there have been remarkable advances in sequencing capabilities. A decade ago, most DNA sequencing was performed manually. Radioactive sequences had to be developed onto film and the nucleotide sequence was entered into databases manually. Automated DNA sequencing has made a major impact on throughput, particularly because the fluorescently labeled sequence can be read directly into computer systems. A goal is to develop sequencing capability of approximately 50–80 Mb per year. This will require the combined use of robotics and automation in conjunction with informatics. It is presently unclear whether the DNA sequence of the entire genome will be completed by the year 2005. However, several aspects of the genome project have progressed at an accelerated rate because of unanticipated technological advances. At present, most sequencing efforts remain based on gels that resolve DNA sequence at a single nucleotide level. There are efforts to develop new sequencing technologies, including the use of DNA chips. This technology, based on the use of arrays of oligonucleotides that are applied to DNA chips, is particularly promising for detecting variations and mutations in known DNA sequences.

MAJOR ADVANCES AND FUTURE CHALLENGES

Considering its controversial inception, the human genome project has progressed remarkably well. The genome project has already catalyzed many advances in human genetics. The development of a high-resolution genetic and physical map makes it possible to more rapidly identify disease-causing genes by positional cloning. These efforts in turn provide additional sequence and physical map information about specific regions of the genome. As depicted in Fig. 5-4, the number of disorders identified by positional cloning has increased markedly in recent years; this trend can be expected to continue. The identification of the cystic fibrosis gene in 1989 represented a landmark example of positional cloning. In 1996, examples of positional cloning included Friedrich's ataxia, long QT syndrome, basal cell nevus syndrome, hemochromatosis, a form of Maturity Onset Diabetes of the Young (MODY), and Treacher Collins syndrome, among many others.

The genome project has stimulated interest in the private sector in the applications of genetics. Characterization of expressed sequence tags (ESTs) has greatly enhanced the database of known
Figure 5-4 Number of genes that cause inherited disorders identified by positional cloning.

expressed genes. In the future, we can expect these databases to be merged with physical maps such that expressed genes can be superimposed onto physical maps. We can also expect increasing interest in changes in pattern of gene expression in disease states, including cancer.

Implicit in the human genome project is the idea that identifying disease-causing genes can lead to improvements in diagnosis, prognosis, and treatment. It is estimated that most individuals harbor several serious recessive genes. Because the frequency of mutations in most of these genes is low, it is unlikely that both members of a couple would carry mutations in the same gene, unless there is consanguinity or a restricted gene pool. However, the polymorphic variation in DNA also confers risk to a large number of less serious susceptibility genes. Most polygenic disorder reflect the cumulative risk of several different susceptibility genes. The ability to test for disease genes, whether serious mutations with relative high gene frequencies or various susceptibility genes, is already a reality and can be expected to expand rapidly with improvements in technology. The diagnosis of most disorders is currently made on clinical grounds in conjunction with radiographic or laboratory tests. Nevertheless, there is often some degree of uncertainty, resulting in a "differential diagnosis." The ability to add genetic tests will not always remove uncertainty, but it adds a powerful new dimension. For example, a patient with medullary thyroid cancer and a germline mutation in the ret oncogene can be diagnosed with multiple endocrine neoplasia type II. Molecular genetics also improves the categorization of disease. For example, Duchenne's and Becker's muscular dystrophies are now known to involve the same genetic locus (dystrophin), but the mutations differ in their impact on the encoded protein. Similarly, the "classic" and "adult-onset" forms of congenital adrenal hyperplasia are now known to represent mutations in the 21-hydroxylase gene that vary in severity. In general, the diagnostic capability of molecular diagnostics is much greater than the prognostic information that results. In part, this reflects still-limited genotype–phenotype correlations. In addition, genetic background and environmental influences can greatly modify the course of many genetic diseases. For example, individuals with lipoprotein abnormalities can have a highly variable clinical course, depending on other genes that act on lipid metabolism as well as environmental influences such as diet composition and weight gain.

An ultimate goal is to use the results of the genome project to improve the therapy of diseases. Success in this area might result from several venues. Perhaps the first advance will come from

screening and prevention. Thus, patients known to carry a risk factor gene could be screened selectively for certain diseases or treated prospectively. For example, individuals known to carry genes that predispose to colon cancer would undergo earlier and more intensive screening. Individuals with genes that predispose to non–insulin-dependent diabetes mellitus could receive counseling about diet and weight gain, and may be treated early to prevent metabolic decompensation. Gene discovery will provide targets for screening for new drugs. The availability of recombinant hormones such as growth hormone, insulin, and erythropoietin has already had a major impact on clinical medicine. The potential role of gene therapy has received much attention. For certain enzyme deficiency disorders, such as adenosine deaminase deficiency, the technique has great promise. Its role for many other diseases, such as cystic fibrosis or sickle-cell anemia, remains to be established. In addition to classic genetic disorders, gene therapy may have an adjunctive role in the management of atherosclerotic lesions or the treatment of cancers. Currently, major issues that face gene therapy include the need to target therapy to specific tissues (e.g., cancers), the need to regulate gene expression (e.g., insulin in diabetes), and the need to sustain long-term expression (e.g., cystic fibrosis).

The genome project raises many ethical issues, which have been addressed in parallel with the other major goals of the project. Advances in such areas as the predisposition to cancer, atherosclerosis, or degenerative neurologic diseases such as Huntington's or Alzheimer's disease raise important questions concerning genetic counseling, privacy, and genetic discrimination in the workplace or by insurance companies. In addition, the scientific advances of the genome project require ongoing public and professional education, and there is the potential for unrealistic fears or expectations. The US federal government has established the "Ethical, Legal, and Social Implications" (ELSI) working group to help address ethical issues that arise from the genome project. Analogous groups exist in several other countries.

Many issues raised by the genome project are familiar in principle to medical practitioners. For example, a patient with increased LDL cholesterol, high blood pressure, or a strong family history of early myocardial infarction, is known to be at increased risk of coronary heart disease. Likewise, patients with phenylketonuria, cystic fibrosis, or sickle-cell anemia are often identified as having a genetic disease early in life. These precedents can be helpful for adapting policies that relate to genetic information. The genome project is, nevertheless, accelerating the rate of new information. In addition, the new information is greatly expanding the repertoire of diseases that can be characterized at the genetic level. One confounding aspect of the rapid expansion of information is that the ability to make clinical predictions often lags behind the genetic advances. For example, when genes that predispose the breast cancer, such as BRCA1, are described, there is tremendous public interest in the potential to predict disease; but many years of clinical research are required to rigorously establish genotype and phenotype correlations.

In the future, increased education will be required to adequately address many of the issues related to advances in molecular medicine. Whether related to informed consent, participation in research, or the management of a genetic disorder that affects an individual or their families, there is great need for more information on the fundamental principles of genetics. The lay press has glorified many aspects of genetics and, in such

cases as gene therapy, expectations have been raised to unrealistic levels. The pervasive nature of molecular medicine also makes it imperative for physicians and other health care professionals to become more informed about genetics and to provide advice and counseling in conjunction with trained genetic counselors (*see* Chapter 9).

6 The Cell Cycle

Lynda Q. Nguyen and J. Larry Jameson

INTRODUCTION

The cell cycle consists of a set of highly ordered events that result in the duplication and division of a cell. This process requires the synthesis of a new copy of DNA, segregation of chromosomes, mitosis, and apportionment of the cellular contents. Multiple extracellular signals control entry and exit from the cell cycle to coordinate normal cell growth and to avoid uncontrolled cell proliferation. Various steps in the progression of the cell cycle are regulated rigorously to allow surveillance of the cycle and to avoid errors in DNA replication. This chapter reviews the molecular basis for control of the cell cycle. Much progress has come from studies of yeast, clams, and other model systems. These mechanisms are largely conserved in mammalian systems, which are the main focus of this chapter.

GENERAL MECHANISMS

Early studies using light microscopy allowed some of the events the cell cycle, such as mitosis, to be observed. When DNA was radiolabeled with ^{3}H-thymidine, it was possible to visualize the segregation of chromosomes. From these experiments, it was learned that newly replicated DNA becomes condensed and aligned at the mitotic spindle, and that sister chromatids segregate to opposite poles of the cell before the actual division of the cell. There are few visible changes during the interval between cell divisions (interphase) except for the increase in cell volume and mass. For this reason, molecular and genetic approaches have been essential for understanding the processes that control the cell cycle.

Cellular replication can be divided into several distinct phases. Mitosis (M phase) refers to the process of chromosomal segregation and actual cell division. Mitosis results in the division of one cell into two identical daughter cells, each bearing a complete diploid (2n) complement of chromosomes. Mitosis is divided into prophase, metaphase, anaphase, and telophase. These stages, along with several additional subdivisions, are based on characteristic features associated with chromosomal segregation, mitotic spindle formation, and cell division (Fig. 6-1). The cell cycle may also lead to meiosis, producing gametes with a haploid (1n) number of chromosomes. Although the mechanisms controlling mitosis and meiosis have some similarities, this chapter will focus on the mitotic cycle of the somatic cell. The interval between cell divisions is referred to as interphase, which is classically divided into three stages: G1, S, and G2 (Fig. 6-2). In addition, G0 refers to a resting state when cells have exited from the active cell cycle and have not committed to reenter the process of cell division. During G1, the effects of extracellular nutrients, mitogens, and growth factors induce the transcription of genes that are necessary for DNA synthesis, and the cell transitions into a committed state that will ultimately lead to the replication of DNA during the S (synthetic) phase. During G2, there is additional cellular growth and repair of DNA replication errors before the cell enters mitosis (M phase). After mitosis, cytokinesis, the actual process of cell division, occurs. If conditions are not appropriate for another round of cell division, G0 can be entered for an indefinite period of time before the cell makes the transition back into G1.

In a rapidly proliferating somatic cell, the entire cycle requires about 18–24 h. G1 occupies the longest time and may require up to 12 h. DNA replication during S phase may last from 6 to 8 h, depending on the size of the genome and the number of replication origins that are initiated simultaneously. G2 requires approximately 3–4 h, and mitosis can occur within an hour.

THE CYCLINS AND THEIR CYCLIN-DEPENDENT KINASES

The cyclin-dependent kinases (CDKs) coordinate specific transitions that occur at defined times during the cycle. Originally described by Hartwell in his studies of the budding yeast *Saccharomyces cerevisiae*, the genes encoding these proteins were named cell-division cycle or *cdc* genes. Mutations in the *cdc* genes caused an arrest at specific points in the cell division cycle. One of the first *cdc* genes to be isolated was *cdc2*, which was found by Nurse during studies of the fission yeast, *Schizosaccharomyces pombe*. Mutations in *cdc2* caused arrest at two points in the cell cycle; either before "start," where the yeast cell becomes committed to DNA replication, or just before mitosis. The *cdc2* gene encodes a 287 amino acid protein with high homology to protein kinases. As opposed to the yeast *S. cerevisiae*, which contains a single cell cycle CDK (cdc28), and *S. pombe* (cdc2), mammalian cells have several: Cdc2, CDK2, CDK3, CDK4, CDK6, and CDK7, which act at different transitions in the cell cycle.

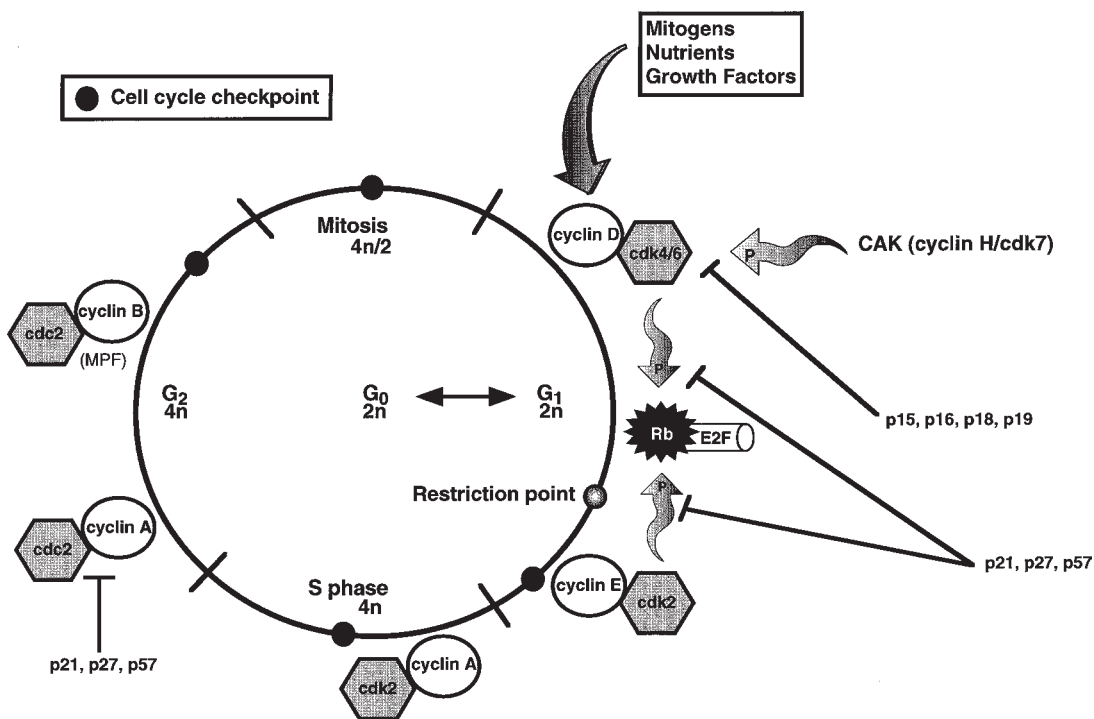
Activation of CDK activity requires their association with another group of proteins known as the cyclins (cyclin D, H, E, A, and B). Cyclins were initially identified by Hunt in developing sea urchin and clam eggs. The levels of the various cyclins fluctuate during the cell cycle in a characteristic manner (Fig. 6-3). Cyclin D is induced during G1 and remains elevated throughout the cell
Figure 6-1   Stages of mitosis. For simplicity, only the nucleus is shown, and only two chromosomes are illustrated. Although mitosis is a continuous process, it is useful to divide it into several distinct stages. Prophase refers to the initial stage of mitosis during which chromosomes begin to condense, centrioles appear and initiate the formation of the mitotic spindle, and the nucleus begins to disintegrate. Metaphase is characterized by the alignment of chromosomes along the equitorial plate of the cell. The chromosomes are highly contracted at this stage and are attached to the microtubules via kinetochores. Anaphase begins with the separation of the two chromatids of each chromosome. Telophase is characterized by reformation of the nuclear envelope around the dividing nuclei and by the decondensation of chromatids as the cells are restored to the interphase state. Several of these stages of mitosis that can be subdivided into intermediate events are not shown.


Figure 6-2   Overview of the cell cycle. A schematic representation of various changes in cyclin/CDK activity during the cell cycle is depicted. Growth factors induce the synthesis of D-type cyclins, thereby causing an association with CDK4 and CDK6 in early G1. Additional phosphorylation of CDK4/CDK6 by CAK is required for CDK activation. Phosphorylation of Rb by cyclin D/CDK4/CDK6 is required to drive the cell past the restriction point, where mitogenic stimulation is no longer needed, and signals the entry into S phase. Cyclin E/CDK2 kinase activity is subsequently needed to maintain Rb in its hyperphosphorylated state. Although cyclin A is synthesized in late G1, it associates with CDK2 throughout S phase and later with cdc2 in late S phase and early G2. Cyclin B complexes with cdc2 during G2; this complex was originally known as MPF. CDK inhibitors either block cyclin/CDK assembly and/or inhibit CDK activities, serving to arrest cells at specific points until conditions are optimal to reenter the cell cycle. Cells emerging from quiescence in G0 or from mitosis may reenter G1 and continue with the division process.

cycle. Cyclin E is produced transiently in late G1 and declines before S phase. Cyclins A and B are also known as the mitotic cyclins. Cyclin A is synthesized in late G1 and throughout S phase. It activates CDK2 during S phase and cdc2 during G2. Cyclin B is produced during G2 and also activates cdc2. Both cyclins A and B are degraded during M phase. All cyclins contain a characteristic

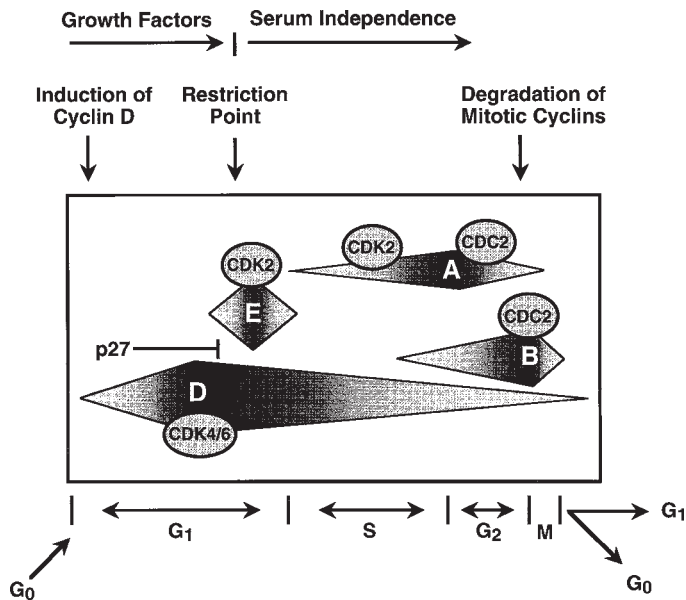
100-amino acid "cyclin box" which is located in the amino-terminal region. Proteolysis of the mitotic cyclins is conferred by a 9-amino acid motif referred to as the destruction box (D box), which is also located at the amino-terminal region of the proteins. The D box is necessary for ubiquitination and subsequent proteolytic degradation. Proteolysis of cyclins A and B triggers exit


Figure 6-3 Changes in cyclins during the cell cycle. The levels of different cyclins are depicted schematically. Early in G1, growth factors and mitogens induce the transcription of the D-type cyclins (D1, D2, D3) that accumulate and persist through most of the cell cycle. After G1, cyclin D is translocated from the nucleus to the cytoplasm. Cyclin associates with several CDKs (CDK 2, CDK 4, CDK 6). Cyclin E accumulates in late G1, associates with CDK2, and is destroyed rapidly as cells enter S phase. The mitotic cyclins, cyclin A and cyclin B, increase in S phase and G2, and are degraded by the anaphase promoting complex (APC) before the end of mitosis. Cyclin A associates with CDK 2 during S phase and with cdc 2 during G2. cdc2-cyclin B complexes are restricted to M phase.

from mitosis. As described below, proteolysis also occurs at other phases of the cell cycle to enable specific transitions (e.g., proteolysis of CDK inhibitors during G1; proteolysis of inhibitors to allow transition from metaphase to anaphase).

The cyclin-CDK complexes are subject to input from multiple pathways. The kinase activity of the CDKs is regulated by phosphorylation (both positively and negatively) and by dephosphorylation. The cyclin/CDK complexes are also negatively controlled by several groups of inhibitors (Fig. 6-2). Proteins such as p21$^{WAF1/CIP1}$ act by directly inhibiting CDK kinase activity, whereas proteins such as Suc1 modify the specificity or accessibility of CDKs for regulatory proteins. Cyclins also contribute to CDK substrate specificity. The phosphorylation of substrates (e.g., Rb) by specific cyclin/CDK complexes induces the transcription of genes, whose products are needed to drive the cell through each transition of the cell cycle. It can be speculated that each of these regulatory proteins, in addition to the cyclins and their associated kinases, are potential targets for dysregulation of cell cycle control.

RESTRICTION POINT CONTROL AND G1 TO S PROGRESSION

Mitogenic signals, such as growth factors, induce cells to enter and progress through G1. The D-type cyclins (D1, D2, and D3) serve as growth factor sensors and are transcribed in response to growth factor stimulation (Fig. 6-3). Cyclin synthesis, and interaction with their CDK partners (CDK4 and CDK6), also depends on mitogenic stimulation. As long as nutrient and growth factor availability is sustained, cyclin synthesis and the assembly of cyclin D/CDK4 and cyclin D/CDK6 complexes continue to occur. After a cell reaches the restriction point (R) in late G1, it is committed to DNA replication and subsequently enters S phase, where mitogenic stimulation is no longer required for cell cycle progression.

Cyclin D/CDK4/CDK6 complexes are activated through phosphorylation by a CDK-activating enzyme known as CAK, which is now recognized to be a complex between cyclin H and CDK7. The kinase activities of these cyclin/CDK complexes are crucial in the activation of substrates that play a vital role in the G1 to S phase transition. A primary target of the cyclin/CDK complex is the protein product of the *retinoblastoma* (*Rb*) tumor suppressor gene. Phosphorylation of Rb results in the dissociation of E2F transcription factors and is necessary for passage through the restriction point *(see below)*.

A family of inhibitors known as the Inhibitors of CDK4 (INK4) proteins block the activities of the cyclin D/CDK4/CDK6 complexes. These inhibitors, which include p16^{Ink4}, p15^{Ink4B}, p18^{Ink4C}, and p19^{Ink4D}, can induce G1 arrest (Fig. 6-2). Inactivation of these inhibitors allow uncontrolled cell proliferation and increased genomic instability, and p15 and p16 are targets for mutations in certain malignancies (*see* Chapters 7 and 85). Inactivation of the *Rb* gene shortens the G1 phase, reduces cell size, and decreases the dependence on mitogenic stimulation. Disruption of the Rb pathway occurs in several forms of cancer (*see* Chapters 7 and 105). In cultured cells that lack Rb, the ectopic expression of INK4 proteins no longer arrests cells, confirming that Rb is an important target for these inhibitors.

In late G1, the synthesis of cyclin E is upregulated, presumably through E2F, since the *cyclin E* gene has been shown to contain an E2F-response element. Cyclin E/CDK2 activity may therefore be regulated by a positive feedback mechanism. Entry into S phase is highly dependent on the proteolytic degradation of cyclin E by ubiquitin-dependent pathways. Phosphorylation by its catalytic partner, CDK2, targets cyclin E for destruction. As cyclin E/CDK2 activity decreases, cyclin A synthesis is induced. Accumulation of the cyclin A/CDK2 complexes signals entry into S phase. Cyclin D/CDK2 and cyclin A/CDK2 complexes may interact with the DNA replication origins. Cyclin A/CDK2 also binds E2F/DP-1 dimers, phosphorylating a regulatory residue on DP-1, thereby preventing DNA binding of the E2F/DP-1 complex. Inactivation of E2F helps to ensure cell cycle progression into S phase and prevents reversion back to G1.

The cyclin D/CDK4/CDK6, cyclin E/CDK2, and cyclin A/CDK2 kinase activities are inhibited by another group of proteins that includes p21$^{WAF1/CIP1}$, p27^{KIP1}, and p57^{KIP2} (Fig. 6-2). These CDK inhibitors (CDKIs) also impair CAK activity. The *p27* gene product may be one the most important proteins involved in restriction point control; p27 represses the activity of cyclin E/CDK2 and cyclin A/CDK2 until entry into S phase. Depriving proliferating fibroblasts of serum mitogens increases p27, thereby causing an immediate arrest at G1. The tumor suppressor gene, *p53*, also induces p27. In addition, p15 and p27 may provide a pathway for TGF-β-mediated growth suppression. The *p15* gene is activated in response to TGF-β, a growth factor that suppresses the proliferation of several cell types, including colon and prostate epithelial cells; p15 binds cyclin D/CDK4 and cyclin D/CDK6 complexes to displace p27, allowing it to bind cyclin E/CDK2 and block cell cycle progression.

S PHASE

Once a cell is committed to the initiation of DNA replication, the process continues until duplication of the entire genome is complete. In the human genome, this entails the accurate duplication of approximately 3 billion bp of DNA. An enormous level of replication fidelity is required to accurately synthesize this amount of DNA. In addition to a highly regulated and well-conserved replication system, the existence of a proofreading mechanism (3' to 5' exonuclease) that detects misincorporated nucleotides, and a mismatch-repair system, helps to assure replication fidelity. In eukaryotes, an intricate network of DNA repair systems can delay the cell cycle to allow polymerase errors to be recognized and repaired. These systems also repair DNA damage that is induced by mutagens, such as oxidation products, spontaneous depurination or depyrimidination, chemical adducts, and the effects of ultraviolet (UV) radiation and ionizing radiation.

Defects in the DNA repair process predispose to several forms of cancer. The cancer-prone disorder, xeroderma pigmentosum (XP), results in deficient repair of UV-induced and oxidation-induced lesions (*see* Chapter 81). DNA repair defects and hypersensitivity to DNA damage are also associated with several other autosomal recessive syndromes, including Bloom's syndrome (BS), Fanconi's anemia (FA) and ataxia telangiectasia (AT).

The search for the human homologs of yeast mismatch-repair genes allowed the identification of *MSH2*. Soon thereafter, defects in this gene were shown to cause hereditary nonpolyposis colon cancer (HNPCC). In addition, *MSH2*-deficient mice have been shown to be highly susceptible to lymphoid tumors. Several other genes, including *MLH1* and *PMS2*, whose products are also involved in mismatch repair, are additional causes of HNPCC. Another form of DNA repair, called transcription-coupled repair, occurs during the transcription of DNA into RNA. Long strands of DNA that are unwound during transcription must be mended to reform the double strands. Patients with Cockayne syndrome (CS) exhibit defective mechanisms in transcription-coupled repair.

One of the important roles of the p53 tumor suppressor occurs during times of damage to DNA. DNA strand breaks induced by UV or ionizing radiation induce production of the p53 protein; this in turn stimulates the expression of genes (e.g., *p21*) that cause cell cycle arrest. p21 prevents DNA synthesis by binding proliferating cell nuclear antigen (PCNA), a subunit of the DNA polymerase δ enzyme complex involved in both DNA replication and repair. p53 also induces GADD45 and cyclin G, both of which contribute to G1 cell cycle arrest, allowing time for DNA repair. Germline mutations in *p53* cause Li-Fraumeni syndrome (LFS), which is associated with a high incidence of multiple cancers, including breast, ovary, and brain tumors (*see* Chapter 7). Inactivating p53 mutations are also among the most common somatic mutations in malignancies, emphasizing its importance in the maintenance of normal cell growth.

MECHANISMS CONTROLLING DNA REPLICATION

Important insight into mechanisms controlling DNA replication initially came from a series of cell fusion experiments. When a cell in G1 was fused to a cell in S phase, the nucleus of the G1 cell began to replicate its DNA prematurely, indicating that the G1 nucleus is competent for replication and that the S phase cell contains an activator. However, when G2 cells were fused with G1 cells, the G2 nuclei failed to reinitiate DNA replication, whereas the G1 nuclei replicate normally, indicating that G2 nuclei cannot rereplicate DNA until passage through mitosis. The same held true when G2 nuclei were fused with cells in S phase. Several conclusions were drawn from the above experiments. First, only chromosomes from the G1 phase of the cell cycle are competent for DNA replication. Second, cells in S phase contain an activator that initiates DNA replication from G1 chromosomes. Third, G2 cells do not contain repressors and their nuclei must progress through mitosis before DNA replication can occur.

The control of DNA replication relies on the ordered assembly of specific proteins at the origins of replication. These proteins are necessary to form a competent, prereplicative chromosomal state. In eukaryotes, the origins of replication are determined by *cis*-acting sequences called replicator elements, and *trans*-acting proteins (initiator proteins) bind to the replicators. Because of the large amount of DNA that must be duplicated in eukaryotic genomes, multiple origins of replication are formed to accommodate the constraints of size and time. In the eukaryotic genome, approximately 10^3 to 10^5 replication initiation events occur during each cell cycle.

Recent discoveries in yeast have further elucidated this process. In *S. cerevisiae*, a multisubunit complex known as the origin recognition complex (ORC) has been shown to bind the initiator elements A and B. Consisting of six proteins, the ORC serves as a docking site for protein–protein interactions that regulate the initiation of replication. Other proteins, including cdc6p from budding yeast, and cdc18$^+$ from fission yeast, are also needed to form the prereplication complex. The proper assembly of this multisubunit complex defines the prereplicative state of the chromosomes in G1.

Studies using *Xenopus* egg extracts have provided evidence for activators of DNA replication. G1 nuclei from human HeLa cells are able to initiate DNA replication in the presence of egg extracts, but G2 nuclei are not. When the G2 nuclei are permeabilized and then repaired, DNA replication occurs. This finding led to the idea that G1 nuclei are competent, because factors sequestered in the cytoplasm are able to interact with chromatin when the nuclear envelope is disassembled during mitosis. However, once initiation of DNA replication occurs, the factor is destroyed, thereby preventing rereplication of the DNA.

Using yeast genetics, the mini-chromosome maintenance (MCM) family of proteins have been identified as factors that confer the replication-competent state of chromatin in G1. The MCM proteins include MCM2, MCM3, MCM4/cdc54, MCM5/cdc46, and MCM7/cdc47, and mutations in their genes cause a high rate of mini-chromosome loss. MCM proteins that are bound to chromatin are degraded as S phase progresses.

The formation of a prereplication complex therefore consists of the ORC, proteins such as Cdc6p, and the MCM complex. The activity of cyclins and their associated CDKs is important for activating DNA replication as well as blocking the reassembly of the prereplication complex once DNA synthesis is complete. During S phase, this requires the association between cyclin A and CDK 2, and in M phase, cyclin A/cdc2 and cyclin B/cdc2.

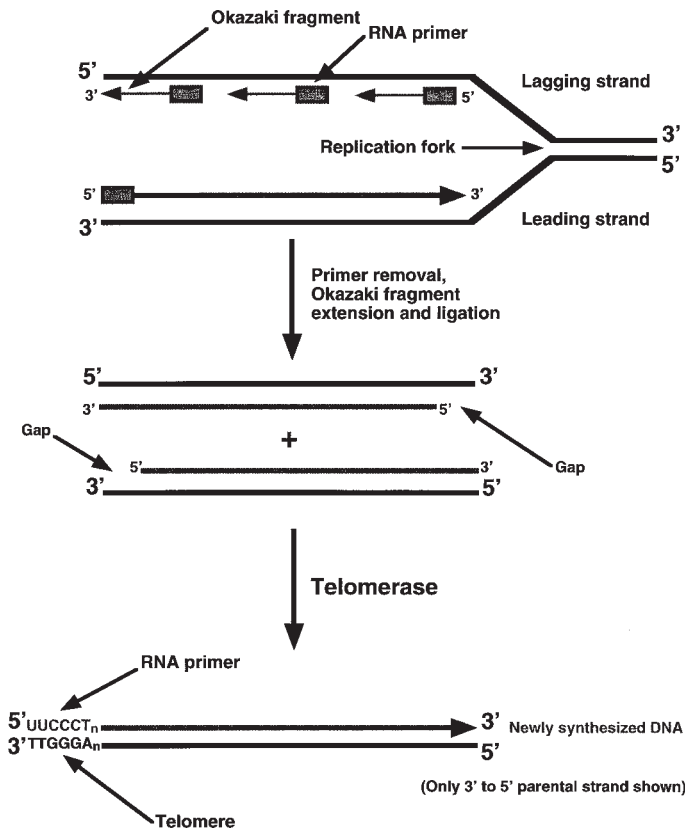
The mechanisms involved in the actual process of DNA replication are reasonably well-understood. As described above, DNA synthesis is initiated from multiple independent replicons. Because DNA is double-stranded, it is necessary to copy both strands simultaneously (Fig. 6-4). This can occur in either a unidirectional


Figure 6-4 Replication of DNA. A replication fork is illustrated. After separation and unwinding of the DNA double helix, DNA replication proceeds in the 5' to 3' direction on opposite strands. The leading strand is synthesized continuously towards the replication fork. Synthesis of the lagging strand is initiated discontinuously as the fork unwinds, resulting in Okazaki fragments that are subsequently ligated together. At the end of chromosomes, telomeres exist to allow repair of the ends of DNA. The enzyme, telomerase, extends the 3' end of the parental strand, providing an elongated template.

(one replication fork) or bidirectional (two replication forks) manner. An RNA fragment that is complementary to the single-stranded region exposed by the replication fork serves as a primer for DNA synthesis, which occurs in a 5' to 3' direction. On the "leading" strand, DNA synthesis occurs continuously, whereas it is discontinuous on the opposite "lagging" strand, which is made available as the fork unwinds. The discontinuous Okazaki fragments on the lagging strand are subsequently ligated together.

A unique circumstance arises for DNA replication at the ends of the chromosomes. Since DNA polymerase requires a labile RNA primer to initiate synthesis, some bases at the 3' end of each template are not copied. Thus, the DNA strands would become progressively shorter with each cycle of replication in the absence of a mechanism to repair the ends. The identification of repeated GC-rich fragments at the ends of chromosomes, referred to as telomeres, provides a compensating mechanism for this process. Telomeres act as a template for the enzyme, telomerase, which extends the repeats (in the 3' direction) with each cycle of division. The presence of telomerase is required for ongoing cell division, and the loss of telomerase activity may represent a mechanism of cellular senescence.

G2 TO M PHASE TRANSITION

During G2, there are checkpoints to assure that DNA has been faithfully copied before entry into mitosis. DNA repair systems can be activated to correct errors that may have occurred during the replication process. In addition, cellular proteins involved in the assembly of the mitotic spindle and cell division are produced.

The cyclin/CDK complex involved in M phase was first identified through use of the *Xenopus* oocyte assay. When meiotic oocytes arrested in G2 are injected with M-phase cytoplasm from a mature unfertilized egg, the recipient oocyte is driven into M phase. These experiments led to the conclusion that a maturation promoting factor (MPF) in the cytoplasm of the egg caused the oocyte to complete cell division. MPF is now known to be a complex between the mitotic cyclin B and cdc2. Cyclin B, which is synthesized in late S phase, complexes with unphosphorylated cdc2. In *S. cerevisiae*, an additional level of regulation is provided by the competing actions of the tyrosine kinase Wee1 and the phosphatase cdc25. Phosphorylation by Wee1 on tyrosine 15 inactivates cdc2 kinase activity, whereas dephosphorylation of the same residue by cdc25 reactivates the complex. It is likely that mammalian homologs of these proteins also exist. Targets for MPF are not well-characterized, but both mitogen activated kinase (MAPK) and MPM2 kinase are potential substrates.

PROTEOLYSIS AND THE M TO G1 TRANSITION

Protein degradation is required for the preparatory events that occur before DNA replication and for entry into and exit from mitosis. Two major ubiquitin-dependent pathways mediate proteolysis at distinct points in the cell cycle (Fig. 6-5). The first pathway, involving a protein called cdc34, initiates DNA replication by degrading the CDK inhibitor SIC1. Using temperature-sensitive *cdc34* mutants in budding yeast, it was discovered that *cdc34* encodes a ubiquitin-conjugating enzyme, E2. Following activation by the E1 ubiquitin-activating enzyme, ubiquitin is transferred to the target protein, SIC1, by cdc34 (E2) through a transesterification reaction. Subsequent multiubiquitination by the ubiquitin-ligating enzyme E3 targets SIC1 to the 26S proteasome for degradation; cdc34 also participates in the destruction of the G1 cyclins, CLN2 and CLN3, in yeast. Ubiquitin-dependent degradation of a CDK-inhibitor represents a crucial event needed for entry into S phase.

The second pathway involves a multiprotein complex called the anaphase-promoting complex (APC). This complex mediates the entry and exit from mitosis by targeting anaphase inhibitors (PDS1 and CUT2) and mitotic cyclins A and B for destruction, also via the ubiquitin-proteasome pathway (Fig. 6-5). Although APC appears to be a large E3, it acts primarily by bringing together ubiquitin-charged E2s and D-box-containing substrates. As discussed previously, the D-box is a 9-amino acid motif in the aminoterminal domain of mitotic cyclins, which is necessary for degradation via the ubiquitin pathway. This degradation represents an irreversible step that assures exit from mitosis.

CELL-CYCLE CHECKPOINTS

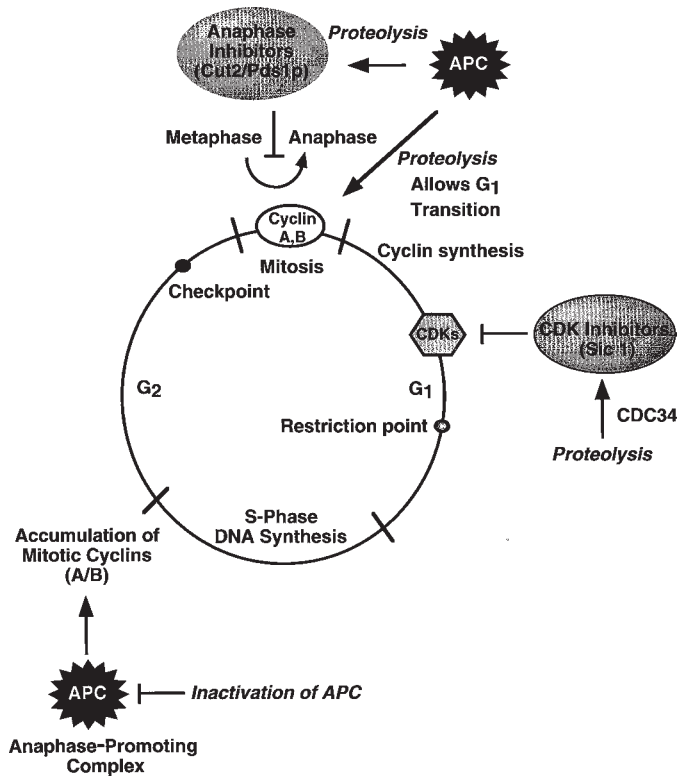
The empirical definition of a cell-cycle checkpoint was provided by Hartwell and Weinert as an event B that is dependent on the completion of a prior event A. A checkpoint occurs if a loss-of-function mutation relieves the dependence. In biochemical terms, a checkpoint represents a surveillance system that allows the detection of an incomplete previous step in the cell cycle or


Figure 6-5   Role of proteolysis in cell cycle control. Proteolysis plays a critical role in several transitions during the cell cycle (*see* review by Kirschner and colleagues for details). Degradation of the mitotic cyclins (cyclin A and B) is mediated by the APC and is required for exit from mitosis. During G1, the cdc34 pathway degrades inhibitors of G1 CDKs (e.g., CDK2, CDK4), allowing passage into S phase. Inactivation of the APC allows the accumulation of mitotic cyclins that are involved in S-phase as well as the transition into mitosis. The APC also mediates proteolysis of anaphase inhibitors, permitting a transition from metaphase to anaphase.

damage to the genome or mitotic spindle. When cell-cycle checkpoint pathways are functioning correctly, cells arrest at specific phases, depending on when damage is sensed, to allow time for repair and to activate genes involved in the repair process.

Checkpoint regulatory pathways have been elucidated primarily based on analyses of *cdc* mutants in budding and fission yeast. Checkpoints exist for DNA damage, DNA replication blocks, and improper spindle assembly. The DNA damage checkpoint can be implemented at three times during the cell cycle: G1/S transition, progression through S phase, and at the G2/M transition. Four genes in *S. cerevisiae*, *RAD9*, *RAD17*, *RAD24*, and *MEC3*, serve as sensors of single-strand DNA, and they are required for G1 and G2 arrest in response to DNA damage.

Three genes act at the replication checkpoint in budding yeast: *POL2*, *DPB11*, and *RFC5*. They are all candidate sensors of DNA replication. DPB11 is required for replication arrest in response to hydroxyurea, an inhibitor of ribonucleotide reductase. DNA damage occurring during S phase is sensed by POL2, whereas DNA damage incurred during G1 and G2 is sensed by RAD9. RCF5 is a component of the replication factor C that binds to gapped DNA (e.g., during lagging-strand DNA synthesis). RCF5 recruits PCNA and DNA polymerase δ for repair. Two proteins, MEC1, a member

of the phosphoinositide kinase family, and RAD53, a protein kinase, transduce the DNA damage signals to the repair systems. The sensors of spindle assembly are less well characterized. However, several yeast genes—*MAD1*, *MAD2*, and *MAD3* (mitotic arrest defective), and *BUB1*, *BUB2*, and *BUB3* (budding uninhibited by benzimidazole)—have been implicated in the spindle assembly checkpoint.

Similar checkpoint control pathways exist in mammalian cells, although fewer of the proteins have been identified. Three proteins controlling the DNA damage checkpoint include ATM (mutated in ataxia telangiectasia), the tumor suppressor p53, and the CDK inhibitor p21. p53 is a transcription factor that is induced in response to DNA damage, although how it is activated remains unknown. As noted above, p53-mediated G1 arrest results from activation of the *p21* gene. p21 directly inhibits the activity of CDKs needed for entry into S phase, and p21 knockout mice exhibit a partial failure to arrest at G1. Inactivation of p53 (e.g., by SV40 large t-antigen) may extend the life of cells that are of late passage, thereby inplicating p53 in cellular senescence. Cells from p53 nullizygous mice are able to escape cellular senescence and produce aneuploid immortalized cell lines.

p53 appears to be at least partially regulated by ATM, as cells lacking ATM show reduced and delayed activation of the *p53* gene in response to DNA damage. However, independent regulatory mechanisms must exist, as ATM mutant cells can still undergo p53-dependent apoptosis. Apoptosis can be considered a type of cell-cycle checkpoint. In the intact organism, destruction of damaged cells by apoptosis provides an important control against the accumulation of genetic damage. The *p53* gene is one of the most frequent mutations in human cancers. The *ATM* gene is a target of mutations as well; cells from patients with the cancer-prone syndrome ataxia telangiectasia exhibit defects in all three DNA damage-induced checkpoints.

Cellular senescence may also be considered as a cell-cycle checkpoint. This phenomenon is especially evident in culture, where normal cells undergo a limited number of divisions before reaching senescence. As noted above, shortened chromosomal telomeres and suppression of telomerase activity may be a mechanism for cell senescence. The re-expression of telomerase activity often occurs in tumorigenesis, resulting in the development of immortal cells.

CONTROL OF CELLULAR PROLIFERATION AND DIFFERENTIATION

A multitude of factors influence the ability of a cell to proceed through the cell cycle, to advance into a more differentiated state, or to undergo apoptosis. Factors such as cell-to-cell contact, viral infection, and mitogenic or inhibitory signals (or their withdrawal) initiate intracellular cascades that communicate signals to the molecular machinery in the nucleus. Many of these pathways, including their respective receptors and corresponding intracellular signaling molecules (second messengers and protein kinases), have been identified, and some have been implicated in tumorigenesis (*see* Chapters 7 and 46).

Although remarkable progress has been made in our understanding of the complex signaling pathways for growth factors, the mechanisms by which they induce cell division remain unclear. Terminally differentiated cells do not reenter the cell cycle. However, many growth factors induce both cell proliferation and differentiation, presumably by acting on progenitor cells that have

not progressed beyond an irreversible stage of differentiation. For example, insulin stimulates the division of many cells, but it also induces differentiation (e.g., 3T3-L1 fibroblasts into differentiated adipocytes). In the case of hematopoietic cells, various cytokines stimulate the division of progenitor cells, but also move cells along a differentiation pathway. One explanation for these dual effects of growth factors involves their ability to activate parallel signaling cascades that ultimately have distinct cellular effects. It is also important to view the effects of a growth factor in the context of other extracellular stimuli that may act synergistically or antagonistically. Thus, the convergence of signaling pathways from different growth factors can elicit selective cellular responses. The pattern and timing of growth factor exposure is also important in determining cellular responses. For example, brief exposure to nerve growth factor (NGF) may induce cell division, whereas prolonged exposure favors neuronal differentiation.

Extracellular signals exert their strongest influence on the cell cycle during a narrow window of time in G1. Signals from growth factors such as epidermal growth factor (EGF) and insulin-like growth factor-1 (IGF-1) are integrated along with those from inhibitory factors such as transforming growth factor-β (TGF-β). An example of growth factor signaling is illustrated by EGF, which is a potent stimulator of cell proliferation. EGF binds to its membrane-bound tyrosine kinase receptor, resulting in receptor dimerization and autophosphorylation of specific tyrosine residues. These phosphorylated tyrosines induce the recruitment of Grb2 through its SH2 domain and the Sos protein through its SH3 domain. This complex activates the Ras signaling pathway (*see* Chapter 46). GTP-bound Ras stimulates the serine-threonine kinase Raf, which phosphorylates the mitogen-activated protein kinase (MAPKK or MEK). MAPKK phosphorylates the mitogen-activated protein kinase MAPK (or extracellular signal-related kinase; ERK). MAPK acts in the nucleus to phosphorylate and regulate the activity of oncogene products involved in cell cycle progression and growth, including c-*fos*, c-*jun*, and c-*myc*. In addition, cyclin D is upregulated in response to mitogens, leading to the activation of cyclin-dependent kinase activity.

Interactions mediated by cadherins provide an additional means of cell–cell as well as intracellular signaling. Cadherins are transmembrane Ca^{2+}-dependent adhesion receptors that play important roles in cell recognition and sorting during development and in the maintenance of solid tissue. Cadherins form complexes with cytoplasmic proteins known as catenins (α and β catenin). The association of cadherins with catenins is important for cytoskeletal alterations associated with cell recognition and morphogenesis. The intracellular domain of several cadherins (e.g., E cadherin) interacts with cytoskeletal-related proteins, such as globular actin, α actinin, vinculin, and ankyrin. The cadherins can also associate with signaling molecules such as the protein tyrosine kinases, Src, and Yes. β catenin is a substrate for Src, and its phosphorylation perturbs cadherin-mediated cell–cell adhesion. Intracellular signaling by cadherins can influence the availability of free β catenin, which serves as a substrate in the Wnt signaling pathway that regulates early development and cell fate in *Drosophila*. Defects or downregulation in cadherin or β-catenin function has been implicated in tumorigenesis (e.g., APC [adenomatous polyposis coli], DCC [deleted in colorectal cancer]), as loss of cell adhesion is associated with increased invasiveness of tumor cells.

Other proteins activated by less direct mechanisms also contribute to the control of cell-cycle progression. Several growth
Figure 6-6 Control of Rb activity during G1 to S progression. **(A)** In its hypophosphorylated form, Rb is capable of binding E2F, preventing E2F-mediated transcriptional activation. **(B)** Phosphorylation of Rb by the active cyclin/CDK complexes during mid-to-late G1 causes the release of E2F from Rb, allowing E2F to heterodimerize with members of the DP family of transcription factors. As long as Rb is maintained in its hyperphosphorylated state, E2F/DP-mediated transcription of genes required for G1 to S phase progression continues. Factors favoring mitogenesis can regulate transcriptional activity by modulating Rb phosphorylation. In turn, growth inhibitory factors acting through CDKIs can reverse the hyperphosphorylated state of Rb.

factors activate phospholipase C, which hydrolyzes phosphatidylinositol-4, 5-*bis*-phosphate (PIP$_2$) into two second messengers: diacylglycerol (DAG) and inositol 1, 4, 5-*tris*-phosphate (IP$_3$). DAG is able to activate protein kinase C, thereby stimulating gene transcription and cell proliferation. IP$_3$ releases calcium ions from intracellular stores and calmodulin, a calcium-binding protein, can also regulate the activities of other kinases in the cell.

Accumulating evidence suggests that Rb is a central target for the convergence of many of these signaling pathways (Fig. 6-6). Cells emerging from mitosis require prolonged and continuous growth factor stimulation until the restriction point is reached during mid to late G1. After the restriction point, serum is no longer required, and the cell can progress through S phase and the remainder of the cell cycle.

Regulation of the activity of Rb occurs largely as a result of phosphorylation. In its hypophosphorylated form, Rb associates with the E2F family of transcription factors (E2F1–E2F5). E2F-1 through E2F-3 associate with Rb (p105), whereas E2F-4 and E2F-5 associate preferentially with the Rb-related proteins, p107 and p130. The association with Rb can occur while the E2Fs are bound to the promoters of various genes and may account for the ability of hypophosphorylated Rb to actively repress gene tran-

scription. Cyclin D/CDK4/CDK6 mediate the phosphorylation of Rb, and cyclin E/CDK2 is required to maintain Rb in a hyperphosphorylated state. When Rb is hyperphosphorylated, E2Fs dissociate and heterodimerize with the DP family of transcription factors (DP-1, DP-2, DP-3). These heterodimeric transcription factors bind to sequences in the regulatory regions of genes important in the control of cell growth, including c-*myc*, B-*myb*, *cdc2*, *DHFR*, *thymidine kinase*, and *E2F-1* itself.

Growth inhibitory factors prevent Rb phosphorylation through modulation of the CDKs that phosphorylate Rb. These signals block Rb phosphorylation by activating various CDK inhibitor proteins. Three signals have been identified that block Rb phosphorylation in this manner: TGF-β, cyclic AMP (cAMP), and contact inhibition. As described previously, TGF-β prevents Rb phosphorylation by inducing the expression of p15, which competes with D cyclins for binding to CDK4/CDK6. In addition, TGF-β has been shown to decrease levels of CDK4 in certain cell types. cAMP activates the protein kinase A (PKA) signaling cascade, which can inhibit Rb phosphorylation. cAMP also results in the phosphorylation of transcription factors, such as the cAMP response element-binding protein (CREB). Phosphorylated CREB recruits the coactivator CBP (CREB-binding protein), which links CREB to the basal transcription machinery, promoting the induction of gene transcription (*see* Chapter 3). In some cell types, activation of cAMP-responsive genes in combination with the inhibition of Rb phosphorylation leads to cellular differentiation.

It is important to note that a variety of other Rb-binding proteins have been identified. Among these are Elf-1, MyoD, PU.1, ATF-2, and c-Abl, although the effector functions of these proteins are largely unknown. Hypophosphorylated Rb has been shown to bind the catalytic domain of the nuclear tyrosine kinase c-Abl. This interaction blocks the kinase function of the proto-oncogene; phosphorylation of Rb releases c-Abl and allows it to phosphorylate nuclear substrates, some of which may be involved in cell growth.

APOPTOSIS

Apoptosis, or programmed cell death, is a normal cellular process that occurs in response to many different stimuli, including UV and ionizing radiation, chemotherapy, hypoxia, viral agents (E1A and E7), proto-oncogene expression (*E2F-1* and c-*myc*), and growth factor or hormone withdrawal. As opposed to cellular senescence, apoptosis is an energy-dependent process that results in distinct morphological changes in the cell. Nuclei become condensed and fragmented, DNA is degraded, and cells shrink and are eventually degraded by a lysosome-mediated pathway. Apoptosis plays a critical role in development and homeostatic processes, including development of the nervous system and in the lymphoid selection process of the immune system.

The apoptotic response can vary depending on the cell type and the nature of the stimulus. A number of gene products involved in cell cycle control mediate this response, including *Rb* and c-*myc*, although most work has centered around the actions of p53. p53-mediated apoptosis occurs primarily in response to DNA damage induced by UV radiation, hypoxia, or viral infection. A growing body of evidence points toward a cooperative interaction between the p53 and Rb/E2F pathways. The adenovirus E1A and the human papilloma virus (HPV) E7 proteins stabilize and activate p53, thereby inducing p53-dependent apoptosis. In response to p53 actions, viral proteins such as the HPV E6 protein and E1A can bind the tumor suppressor Rb and inactivate it. This relieves Rb-mediated repression of E2F-DP-1 complexes. If p53 is absent, free E2F can promote uncontrolled progression through the cell cycle. In fact, overexpression of E2F results in failure of cells to arrest in G1 or to exhibit apoptosis. Similar effects have been seen with the loss of Rb.

The apoptotic response appears to be induced by separate p53 transcription-dependent and transcription-independent pathways. The *bax* and *insulin-like growth factor-binding protein 3* (IGF-BP3) genes are both regulated by p53. The *bax* gene encodes a protein with homology to the survival factor Bcl-2. Heterodimerization with Bax inactivates Bcl-2, thereby promoting cell death. p53 regulation of IGF-BP3 can block the mitogenic response of cells to IGF-1 by inhibiting IGF-1 interaction with its receptor.

Although programmed cell death can occur by pathways independent of p53 (e.g., glucocorticoids), the p53-mediated pathways prevail in most circumstances. In situations in which DNA damage has occurred, or when the supply of survival factors is low, the p53-dependent apoptotic response becomes engaged. This response is important to preclude the development of tumors, and it also appears to play a role in effective responses to cancer therapy, including chemotherapy and radiation treatments.

7 Oncogenes and Tumor Suppressor Genes

J. LARRY JAMESON

DEFINITION AND DISCOVERY OF ONCOGENES AND TUMOR SUPPRESSOR GENES

Cancer is caused by an accumulation of genetic alterations that confer a survival advantage to the neoplastic cell. These genetic changes can affect multiple facets of cellular function, including an increased rate of cell proliferation, resistance to apoptosis, altered tissue invasiveness, production of growth and angiogenic factors, and the ability to escape immune surveillance. Different cancers reflect these features to varying degrees, depending on the nature of their cellular functions and genetic changes.

The genetic basis for cancer is reflected in the clonal nature of neoplastic cells. As depicted in Fig. 7-1, cell proliferation can involve either polyclonal or monoclonal expansion of the cell population. Polyclonal growth or hyperplasia reflects the response to an extrinsic growth factor or to an intrinsic genetic alteration that is shared by all (e.g, MEN-2, germline ret mutation) or some (e.g., McCune-Albright, postzygotic somatic Gsα mutation) of the cells. Hyperplastic cells may subsequently acquire one or more somatic mutations and develop clonal derivatives. Monoclonal growth reflects the acquisition of somatic mutations that confer a survival advantage. Multistep models of tumorigenesis *(see below)* postulate that multiple different mutations are acquired over time. Thus, an initial clone would give rise to additional clonal variants as they acquire distinct mutations, some of which may foster tumor growth and expansion by favoring tissue invasion or metastasis.

The recognition that cancer is a genetic disease has led to an intensive effort to characterize genetic alterations in tumors and to understand how these genes function in the context of the normal and neoplastic cell. The idea that cancer might be caused by genetic changes has long been suspected by clinicians who noted that certain cancers tend to "run in families." Several landmark advances in virology, cytogenetics, and molecular biology have converted this intuitive assessment into a firm scientific foundation. In the early 1900s, Rous demonstrated transmission of sarcoma in chickens by using cell-free filtrates that contained a virus now known to be a retrovirus, Rous sarcoma virus (RSV). Identification of the transforming principle in the virus revealed that it harbored an altered form a normal cellular gene, *src*. The viral gene product was referred to as an oncogene, derived from the Greek, *onkos*, which refers to a mass or tumor. Subsequent studies have shown that many viral oncogenes correspond to altered versions of normal cellular genes, which are referred to as proto-oncogenes. The ability of retroviruses to "reverse transcribe" mRNA accounts for their ability to capture cellular gene products. Analyses of such viral oncogenes has helped to identify many critical cellular genes including *src*, *ras*, *raf*, *kit*, *jun*, *fos*, *ets*, and others.

DNA tumor viruses have also played an important role in our current understanding of neoplasia. In this case, the viruses produce proteins that target key cellular regulatory proteins, such as retinoblastoma (Rb) and p53. For example, the SV40 large T antigen associates with, and inactivates, Rb. Remarkably, other viral products including adenovirus E1A and papilloma virus protein E7 also target Rb. Although these viral proteins are structurally unrelated, they each appear to associate with the so-called pocket of Rb to prevent interactions with cellular transcription factors like E2Fs, which are involved in control of S-phase genes (Fig. 7-2). These cellular targets of DNA tumor viruses are now known to be tumor suppressor genes.

Historically, the presence of tumor suppressor genes was suspected, based on several lines of evidence. The malignant phenotype of certain tumors could be suppressed by fusion with normal cells, implying the presence of a suppressor gene in the normal cell. Chromosomal losses in the hybrids eventually resulted in reversion back to the malignant phenotype. Ultimately, it was possible to observe partial alterations in tumorigenicity by the introduction of single chromosomes into the malignant cells. For example, insertion of chromosome 11 (now known to harbor the *WT-1* gene) was sufficient to suppress tumorigenicity in a Wilm's tumor cell line.

These laboratory experiments were paralleled by observations in humans that certain hereditary forms of cancer are transmitted in an autosomal dominant manner *(see below)*. Based on the age-dependent appearance of retinoblastoma, Knudson postulated a "two-hit" model for the disorder (Fig. 7-3). In this model, the first "hit" or mutation is inherited in the germline and the second mutation is acquired as a somatic event involving either the remaining normal allele or another gene. As described below, the second hit typically involves the remaining normal allele. This model, which has proven to explain a number of hereditary cancer syndromes, implied a loss of function, and was in a sense, recessive.

The identification and characterization of the *Rb* gene has converted this statistical model into concrete mechanisms (*see* Chapter 105). Cytogenetic studies in patients with inherited forms of retinoblastoma revealed deletions of chromosome 13q14. Additional studies showed that tumors from patients with retinoblas-
Figure 7-1 Clonal expansion of cancer cells. Growth responses can be divided into hyperplasic (polyclonal) or monoclonal expansion of cells. Hyperplasia reflects the actions of growth factors that increase the proliferation of a population of cells. In contrast, monoclonal expansion reflects increased proliferation from a single ancestral cell, reflecting a growth advantage conferred by a somatic mutation. Monoclonal and polyclonal tumors can be distinguished based on patterns of X-chromosomal inactivation (in females) or based on the presence of a characteristic somatic mutation in a monoclonal tumor. Hyperplasia may predispose cells to develop somatic mutations, allowing a monoclonal population to emerge. Additional mutations in monoclonal tumors allows new clonal populations with increased rates of growth or invasiveness to emerge. Adapted with permission. (Jameson JL. Principles of hormone action. In: Weatherall DJ, Ledingham JGG, Warrell DA, eds. Oxford Textbook of Medicine, 3rd ed. Oxford, U.K.: Oxford Medical, 1996; pp.1553–1573.)

Figure 7-2 The pivotal role of the Rb tumor suppressor gene in control of the cell cycle. The cell cycle is depicted schematically with its characteristic stages (G_0, M, G_1, G_2, S). G_0 represents a quiescent state in which cells exit or enter the cell cycle. A key restriction point is noted in G_1. After passage through this point, cell are committed to progress into the S phase. An additional checkpoint is noted in G_2 before cells initiate mitosis. The Rb gene product plays a key role in progression through the restriction point. In its hypophosphorylated state, Rb binds E2F transcription factors, making them inaccessible for transcription of S-phase genes. Increasing amounts of cyclin D1 in association with cdk4 or cdk6 result in hyperphosphorylation of Rb. Cyclin E, in association with cdk2, also contributes to Rb phosphorylation. Phosphorylated Rb no longer associates with E2Fs, freeing them to interact with target genes (e.g., DNA polymerase, thymidine kinase, dihydrofolate reductase) that are involved in S phase. p16 is capable of blocking the actions of Cyclin D1/cdk 4,6, and this may account for its role as a tumor suppressor in some malignancies, as the absence of p16 would favor unrestricted progression through the cell cycle. A possible role for p53 is also shown. Cell injury can stimulate p53 levels leading to increased p21, a probable inhibitor of the actions of Cyclins D and E. Thus, the absence of p53 might prevent restriction of cell division in damaged cells. Viral gene products (E1a, large TAg, E7) bind Rb and dissociate E2Fs, therefore having similar effects as Rb hyperphosphorylation.

toma frequently showed loss of heterozygosity (LOH) in this region of chromosome 13, and that the remaining abnormal allele was transmitted from the affected parent. These experiments confirmed the loss of function hypothesis and established the importance of using loss of heterozygosity as a means for detecting tumor suppressor genes. The cloning of the *Rb* gene allowed demonstration of germline mutations in patients who did not have deletions. In addition, it was shown that patients with sporadic forms of retinoblastoma had acquired two somatic hits in which each allele received an independent mutation.

The Rb protein plays a pivotal role in control of the cell cycle. As depicted in Fig. 7-2, Rb helps to govern the restriction point between G1 and S phase (*see* Chapter 6). Hypophosphorylated Rb binds transcription factors, including E2Fs. Upon Rb phosphorylation by Cyclin-CDK complexes, E2Fs (particularly E2Fs 1–3) dissociate from Rb to stimulate the transcription of genes that are involved in DNA synthesis. The loss of both *Rb* genes is therefore predicted to enhance cell proliferation. Because *Rb* is expressed ubiquitously, it is unclear why only certain tumors (retinoblastomas, osteosarcomas, soft tissue sarcomas, melanomas) develop with increased frequency in patients with germline *Rb* mutations.

Cytogenetics have played an important role in the characterization of genetic alterations, particularly in hematologic malignancies (*see* Chapters 26 and 27). Characteristic chromosomal rearrangements suggested the presence of an oncogene. For example, in chronic myelogenous leukemia (CML), the description of the Philadelphia chromosome t(9;22)(q34;q11) was recognized early as a characteristic cytogenetic abnormality. This

translocation is now known to fuse the *bcr* gene on chromosome 22 with the c-*abl* gene on chromosome 9. The fusion protein combines the tyrosine kinase activity of c-*abl* with abnormal regulation and cellular localization conferred by *bcr*. Another striking example involves a translocation t(8;14)(q24;q32) of the IgH chain gene with c-*myc* in Burkitt's lymphoma. In this case, the regulatory regions of the immunoglobulin gene result in the overexpression of c-*myc* in lymphoid cells, causing increased cell proliferation. A number of such translocations and chromosomal inversions have now been described (Table 7-1). In general, they involve either abnormal expression of a cellular kinase or transcription factor or, the production of a fusion protein with altered functional properties.

CLASSES AND FUNCTIONS OF ONCOGENES

GROWTH FACTORS Oncogenes can be categorized according to their cellular functions (Fig. 7-4). A few oncogenes function as growth factors (Table 7-2). For example, v-sis is structurally related to β chain of platelet-derived growth factor (PDGF), and int-2 corresponds to members of the fibroblast growth factor (FGF) family. Although these oncogenes do not play major roles
Figure 7-3 Two-hit model for retinoblastoma inactivation. The principles involved in the "two-hit" model are illustrated schematically. The *Rb* gene is located on chromosome 13q14. The Maternal (M) and Paternal (P) chromosomes are denoted as A or B. The first hit involves a germline mutation (depicted by an **X**) on chromosome M_B. Subsequently, several different types of somatic second hits can occur. A second point mutation can inactivate the normal allele inherited from the father (P_A). Deletions of part of chromosome 13, internal deletions, or translocations can also lead to inactivation of the normal *Rb* gene. Nondisjunction with loss of the normal chromosome 13 can cause loss of the normal *Rb* gene. The germline mutation causes a predisposition to retinoblastoma, as any inactivating second hit will be selected because of clonal proliferation. An analogous series of events can occur in sporadic tumors. In this case, both the first and second hits occur somatically.

in human cancer, they illustrate the importance of growth factors and their signaling pathways for the growth of tumors.

A more prominent functional role for growth factors stems from their overproduction as a consequence of the actions of other oncogenes. Many tumors produce growth factors, such as insulin-like growth factor-1 (IGF-1), IGF-2, epidermal growth factor (EGF), and tumor growth factor-α (TGF-α), which stimulate cell growth in an autocrine manner. The mechanisms that lead to growth factor overexpression are relatively obscure, but account in part for the ability of transformed cells to grow in the presence of reduced serum and for the ability of conditioned media from transformed cells to foster the growth of other cell lines. As depicted in Fig. 7-2, growth factors act in the cell cycle to enhance the entry from the quiescent state (G_0) and they stimulate progression to the restriction point in G_1. Other growth factors, such as TGF-β, can oppose entry into the cell cycle, in part by increasing levels of cyclin dependent (cdk) inhibitors. Thus, the balance of growth factors and the activity of their receptors can have profound effects on cell proliferation. Growth factors also influence

Table 7-1
Examples of Oncogene Rearrangements and Fusions

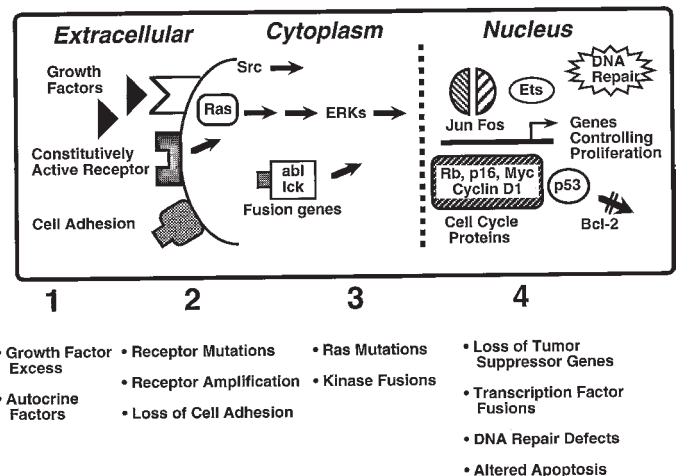
Type of rearrangement	Rearranged oncogene(s)	Disorder
Gene activation	IgH-c-MYC	Burkitt's lymphoma
	IgH-Cyclin D1	Mantle cell lymphoma
	TCR-β-TAL-2	T-cell acute lymphoblastic leukemia
	TCR-α-HOX11	T-cell acute lymphoblastic leukemia
	PTH-Cyclin D1	Parathyroid adenomas
Gene fusions	ELE1-RET	Papillary thyroid cancer
	BCR-ABL	Chronic myelogenous leukemia
	AML-1-CBFα	Acute myelogenous leukemia
	FUS-CHOP	Myxoid liposarcomas
	EWS-FLI-1	Ewing's sarcoma
	PML-RARα	Promyelocytic leukemia


Figure 7-4 Sites of cellular actions of oncogenes and tumor suppressor genes. Oncogenes act at multiple sites of cellular function. (1) The extracellular environment can influence cell function by the overproduction of various growth factors. Not shown are important extracellular effects of angiogenic factors and proteolytic enzymes. (2) At the level of the cell membrane, adhesion molecules such as DCC and APC influence tumor invasiveness. Membrane receptors can be constitutively activated (e.g., Ret, TSH-R) or the receptors can be amplified (e.g., ErbB-2). (3) Ras is a prototypical example of signal transduction molecule that stimulates proliferation when activated. (4) Nuclear proteins include a number of targets for oncogenesis. Proteins such as AP-1 (Jun/Fos) and Ets are targets for several of the transducing signal transduction cascades, including Src, Ras, and ERKs. Some nuclear proteins, such as Myc, are amplified or overexpressed (Cyclin D1) in certain tumors. p53 plays a role in controlling the cellular response to injury (inhibits G_1/S) and helps to direct apoptosis. Several DNA repair enzymes cause familial adenomatous polyposis when mutated. Adapted with permission. (Jameson JL. Principles of hormone action. In: Weatherall DJ, Ledingham JGG, Warrell DA, eds. Oxford Textbook of Medicine, 3rd ed. Oxford, U.K.: Oxford Medical, Oxford, 1996; pp.1553–1573.)

the initiation of apoptosis (programmed cell death). Withdrawal of growth factors (or other nutrients) favors apoptosis, and their presence helps to prevent it.

Table 7-2
Functional Classes of Oncogenes
and Tumor Suppressor Genes

Class	Oncogene	Function
Growth factors	sis	Homologous to the β chain of platelet-derived growth factor (PDGF)
	int-2	Integration site for MMTV; fibroblast growth factor-3,4 (FGF-3,4) genes
Receptor tyrosine kinases	erbB-2	Orphan receptor related to the epidermal growth factor receptor (EGF-R)
	ret	Activated form of tyrosine kinase; binds glial derived nerve growth factor
Non-receptor tyrosine kinases	abl	Translocates to bcr; interacts with cell cycle proteins
	src	Membrane associated tyrosine kinase; activates mitogenic signaling cascades
Cell surface proteins	DCC	Deleted in colorectal cancer gene involved in cell adhesion
	APC	Adenomatous polyposis gene that interacts with β-catenin and E-cadherin
GTPases	ras	Activates signaling cascades including MAPKs/ERKs
	Gsα	Activates adenylyl cyclase
Protein kinases	mos	A MEK-like enzyme
	raf	Serine kinase in the ras pathway
Transcription factors	jun	B-Zip protein that complexes with fos to form AP-1
	myc	bHLH protein that regulates cell cycle factors
Cell-cycle factors	Rb	Retinoblastoma undergoes phosphorylation to regulate cell cycle progression
	p53	Transcription factor that regulates cell-cycle genes and apoptosis
DNA repair	ATM	Ataxia-telangiectasia gene involved in cell-cycle checkpoints and p53 directed apoptosis
	hMSH2	Human mutS homolog involved in DNA mis-match repair
Programmed cell death	Bcl-2	Blocks apoptosis; interacts with other cell proteins such as Bax to control apoptosis

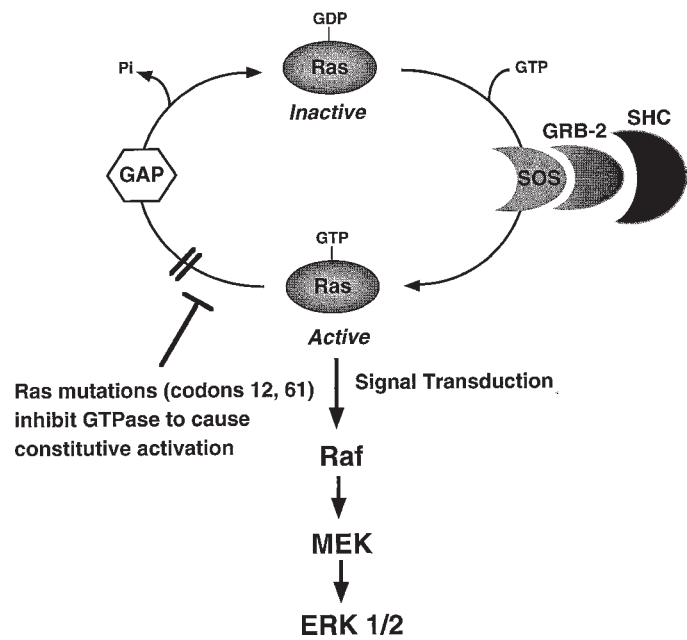
The functional effects of growth factors on tumor development are emphasized by several transgenic models. Disruption of the inhibin α-subunit gene results in ovarian granulosa cell tumors with nearly complete penetrance (*see* Chapter 10). Inhibin normally combines with a β-subunit of activin and antagonizes the action of the activin homodimer. Activin is a member of the TGF-β family of growth factors that exerts pleomorphic growth effects in


Figure 7-5 The cycle of ras activation and effect of mutations. Ras is a guanine-nucleotide protein. When GTP is bound, Ras is active, and it is normally inactivated by hydrolysis of GTP to GDP, resulting in an inactive state. SOS (son of sevenless), also called guanine-nucleotide releasing protein (GNRP), regulates Ras activity and responds to input from the SH2 domain proteins, GRB-2 and SHC. The catalytic activity of Ras is also modulated by GAP (GTPase activating protein). The *NF-1* gene (causes Von Recklinghausen's neurofibromatosis) is homologous to *gap*. Mutations in *ras* prevent GTP hydrolysis, resulting in constitutive activation. Ras participates in several signaling pathways, including activation of Raf, MEK, and ERKs, which stimulate mitogenesis.

various tissues, including the ovary. In this model, the loss of inhibin is thought to result in unopposed actions of activin, which induce ovarian and adrenal tumors. Crossbreeding the inhibin-deficient mice with p53-deficient mice greatly accelerates the development of tumors. This model illustrates the profound effect of unbalanced growth factor action and its ability to act in a tissue-selective manner. Another informative model involves disruption of the gene encoding the IGF-1 receptor. Fibroblast cells derived from these mice are resistant to transformation by SV40 large T antigen and/or activated *ras*. Reintroduction of the receptor confers the ability to undergo transformation, emphasizing the role of the IGF-1 pathway in cell proliferation and transformation.

Growth factors act by initiating a variety of signaling cascades that involve other oncogenes. These signal transduction pathways are discussed further in Chapter 46. EGF, for example, activates a tyrosine kinase receptor. Ligand-induced homodimerization of the EGF-receptor results in autophosphorylation that allows the recruitment of SH2 domain-containing adaptor proteins such as Grb-2. Grb-2, in turn, associates with the guanine-nucleotide exchange protein, son of sevenless (SOS), through an SH3 domain to enhance the activation of Ras (Fig. 7-5). Ras plays a pivotal role in growth factor signaling. It can also be activated by mitogenic Giα-coupled seven transmembrane receptors, probably through the release of βγ-subunits and by activation of *src* kinase. Activation of focal adhesion kinase (FAK) by integrins can also lead to

Ras activation. Ras initiates a mitogen-activated kinase (MAPK) cascade that includes Raf, MEK, and ERKs (extracellular regulated kinases). These kinases act on numerous cellular targets including the cytoskeleton and activation of transcription factors such as AP-1 (c-Jun/c-Fos) and Ets-1. c-*jun* and c-*fos*, which are themselves early response genes, form the AP-1 complex that activates a variety of genes involved in cell growth control.

RECEPTOR TYROSINE KINASES   Growth factor receptors not only serve to transduce the signals of extracellular growth factors, but they are also important targets of mutations or altered expression that contribute to tumorigenesis. The tyrosine kinase class of receptors includes oncogenes such as *ret* (a receptor tyrosine kinase that binds glial derived nerve growth factor), *trk* (nerve growth factor class), kit (steel receptor), *fms* (colony stimulating 1 receptor), *erbB* (epidermal growth factor, EGF, receptor), and *erbB-2/neu* (EGF-related receptor). As noted above, this group of receptors are thought to act primarily by signaling through the *ras*-MAPK cascade.

In some cases, such as *erbB* and *erbB-2/neu*, receptor amplification leads to marked overexpression. When amplification involves deletion of the ligand binding domain, constitutive activation can result. Amplification of these receptors is particularly common in head and neck cancers, esophageal and gastric cancers, and in breast cancer.

Point mutations can also activate tyrosine kinase receptors. The *ret* receptor is a prototype for activation by point mutations that cause constitutive activation of the receptor. Mutations in *ret* cause multiple endocrine neoplasia type 2 (MEN-2) (*see* Chapter 54). The MEN-2 mutations are clustered in a group of cysteines that are thought to form disulfide bonds in the extracellular ligand-binding domain of the receptor. MEN-2 is transmitted in an autosomal dominant manner. Individuals who inherit a mutant *ret* receptor exhibit hyperplasia of the calcitonin-producing medullary thyroid cells at a very early age. Subsequently, they have a high incidence of developing medullary thyroid cancer. Presumably, the development of medullary thyroid cancer involves a second hit, although the target(s) of subsequent mutations are not known. In practical terms, it is now recommended that patients who inherit *ret* mutations undergo prophylactic thyroidectomy and receive screening for additional features of MEN-2 (pheochromocytoma and hyperparathyroidism).

It is notable that the action of the *ret* oncogene is conceptually distinct from that described above for *Rb*, even though both are transmitted in an autosomal dominant manner. As a tumor suppressor gene, *Rb* requires inactivation of both alleles, whereas the mutant form of *ret* initiates the process of tumorigenesis directly. Interestingly, mutations in the tyrosine kinase domain of *ret* cause a phenotypically distinct disorder, MEN-2b, which differs by including mucosal neuromas. *Ret* also plays a role in papillary cancer of the thyroid. In this case, chromosomal inversions (inv[10]) bring the tyrosine kinase domain of *ret* under the control of one of several fusion genes (e.g., *ELE-1*). This recombination leads to overexpression of the activated form of *ret* in the thyroid cell (where it is not normally expressed). Further expanding the role of *ret* in human disease is the observation that inactivating mutations cause Hirschprung's disease.

SIGNAL TRANSDUCTION   The role of signal transduction molecules as oncogenes is exemplified by *ras*. There are three *ras* genes (*N-ras*, *H-ras*, *K-ras*) that were initially identified as transforming rodent sarcoma viruses. Mutant forms of *ras* were later identified as the transforming principle in DNA derived from sev-eral types of human tumors. *Ras* is now recognized as one of the most common genetic alterations in human cancers. Ras mutations occur in 90% of certain cancers (e.g., pancreatic) and in 10–30% many other types of cancer including leukemias, melanomas, thyroid cancer, colon cancer, and lung cancer. Although the *ras* gene is amplified in some tumors, more commonly it is activated by point mutations.

The biochemical basis of *ras* mutations is now well understood in terms of protein structure and activity. Ras activity is controlled by the binding and hydrolysis of GTP. The cycle of Ras activation and inactivation is depicted in Fig. 7-5. When GTP is bound, Ras is active, and it is inactivated by hydrolysis of GTP to GDP. Extensive structural, mutagenesis, and biochemical analyses have revealed that *ras* mutations act by preventing GTP hydrolysis, retaining the protein in an active state. The locations of *ras* mutations are clustered in amino acids 12, 13, and 61, each of which has been shown to play a critical role in nucleotide binding and/or hydrolysis. The inability to inactivate Ras leads to stimulation of the MAP kinase signal transduction cascade and uncontrolled cell proliferation.

Ras catalysis of GTP is regulated by SOS, also called guanine-nucleotide releasing protein (GNRP), which responds to input from the SH2 domain-containing proteins, GRB-2 and SHC. In this manner, Ras activity can be activated by numerous growth factor pathways (Fig. 7-6). The catalytic activity of Ras is also modulated by GAP (GTPase activating protein). The *NF-1* gene (which causes Von Recklinghausen's neurofibromatosis type 1) is homologous to GAP. Inactivating mutations of both *NF-1* alleles are predicted to result in diminished GTPase activity and increased activity of Ras or other related proteins. Thus, *NF-1* functions like a tumor suppressor gene.

Ras is tethered to the cytoplasmic side of the cell membrane by farnesylation. Mutations that eliminate the farnesylation site in the carboxyterminus of Ras eliminate its signaling function, presumably because of a requirement for subcellular localization to contact other components of the signal transduction cascade. Efforts to inhibit Ras farnesylation represent a promising therapeutic strategy for blocking the actions of activated forms of *ras*.

The guanine nucleotide-binding G proteins are structurally related to Ras. Moreover, homologous mutations have been described in Gsα, Giα2, and Giα3. In the case of Gsα, the mutations occur in codons 201 and 227, and also prevent GTP hydrolysis, resulting in constitutive activation of the adenylyl cyclase pathway. Gsα mutations that develop postzygotically cause McCune-Albright syndrome, which is characterized by polyostotic fibrous dysplasia, *café au lait* spots, hyperfunctioning ovarian cysts, and autonomous function in other glands, including the thyroid and pituitary glands (*see* Chapters 46 and 59). The development of these lesions reveals tissues in which the cAMP pathway is mitogenic. Somatic mutations in Gsα occur in about 30% of GH-secreting pituitary tumors (*see* Chapter 48) and can cause autonomously functioning thyroid nodules. It is notable that mutations have also been identified at other steps in the cAMP signaling pathway. Activating mutations have been described in the thyroid-stimulating hormone (TSH) receptor. These mutations, which appear to cause hormone-independent coupling to Gsα, cause congenital hyperthyroidism and nodular goiter when transmitted in the germline or autonomous nodules when acquired as somatic mutations (*see* Chapter 50).
Figure 7-6 Growth factor signaling pathways. Representative growth factor receptors are shown including a cytokine receptor, the insulin-like growth factor-1 (IGF-1) receptor, a tyrosine kinase receptor (e.g., EGF), and a G-protein-coupled receptor (different members can signal via Giα or Gsα). Each of these receptors can activate an array of signaling pathways, not all of which are shown, and the central role of ras is emphasized. Cytokine receptor signaling may also interface with the Ras cascade, but most prominently activates the STAT (signal transducers and activators of transcription) proteins, which, during phosphorylation by Janus kinase (JAK), translocate to the nucleus to activate transcription of target genes. Tyrosine kinases induce the binding of an SH2 domain protein Grb2, which binds to guanine nucleotide exchange factor, SOS. This pathway can also be activated by the IGF-I receptor via insulin related substrate (IRS). Gsα-coupled receptors act primarily through the cAMP-PKA (protein kinase A) pathway, which is mitogenic in some cell types. Giα-coupled receptors can activate the Ras pathway through βγ-subunits, likely through src kinase. Ras activates several downstream kinases in a cell type specific manner. The preferential activation of a particular mitogen activated protein kinase (MAPK) module, such as activation of the extracellular-regulated kinase (ERK) rather than the stress-activated protein kinase (SAPK) pathway provides a mechanism for specific responses. There are many targets of these kinases, including a variety of transcription factors that are involved in cellular growth responses.

TRANSCRIPTION FACTORS Several of the oncogenic transcription factors were initially identified based on their association with transforming viruses (e.g., Jun, Fos, Ets, Myb, Rel, Erb-A). Others were recognized because of their presence as fusion products that result from translocations, inversions, or retroviral insertions (Table 7-1). These rearrangements can activate transcription factors in inappropriate tissues, at the wrong stage of cellular development, or at increased levels (*see* Chapter 3). In some cases (e.g., PML-RARα), the transcription factor prevents normal cellular differentiation and allows cells to retain responsiveness to proliferative signals. In other cases (e.g., IgH-Myc), overexpression of Myc favors cell proliferation by enhancing entry into the cell cycle.

A number of the signal transduction pathways discussed above converge on the transcription factor proto-oncogenes. c-Jun and c-Fos form the transcription factor, AP-1, which is a member of the B-Zip family of transcription factors that dimerize via a leucine zipper motif. Reflecting its dimeric structure, AP-1 recognizes variations of a palindromic DNA element, TGAGTCA, that resides in the regulatory regions of target genes. Numerous genes contain AP-1 sites, although the genes involved in v-Jun-mediated transformation remain unknown. Jun is one of the transcription factor targets for the Ras signaling pathway. Amino-terminal phosphorylation of Jun by Jun N-terminal kinases (JNKs) and stress-activated protein kinases (SAPKs) enhances its ability to transactivate genes.

CLASSES AND FUNCTIONS OF TUMOR SUPPRESSOR GENES

Tumor suppressor genes are defined as genes that sustain loss of function in the development or progression of neoplasms. Thus, tumor suppressor genes are characterized by inactivating mutations, whether inherited in the germline or acquired by somatic mutation. Although the initial tumor suppressor genes like *Rb* are involved in cell-cycle control, the class of tumor suppressors has broadened to include genes with a variety of cellular functions. As described below, the products of tumor suppressor genes include proteins involved in transcriptional regulation (e.g., WT-1), cell-cycle progression (e.g., p53, p16), RNA elongation, (e.g., VHL), signaling pathways (e.g., NF-1, DPC-4, Patched), and DNA repair (e.g., MSH-2). As a group, tumor suppressor genes function at key junctures in the control of cell proliferation, differentiation, apoptosis, and response to genetic damage.

CELL-SURFACE PROTEINS Cell-surface proteins other than receptors are now recognized as important sites for oncogenesis. These factors function like tumor-suppressor genes in the sense that loss of function (by mutation or deletion) contributes to tumorigenesis. Examples in this class include *DCC* (deleted in colorectal cancer) and adenomatous polyposis coli (*APC*). *DCC* was recognized because of localization to a region of chromosome 18q that was frequently deleted in colorectal cancer (~70% of cases). The *DCC* gene encodes a large protein that is involved in cell adhesion. Loss of *DCC* also occurs in other types of tumors including brain, breast, and pancreatic cancers.

The *APC* gene causes familial adenomatous polyposis (FAP) with a prevalence of about 1 in 7000 individuals. It was localized to chromosome 5q21 based on cytogenetic and linkage studies. The *APC* gene encodes a large protein that contains β-catenin binding sites that allow linkage to the cytoskeleton and E-cadherin. In this manner, APC probably plays a role in linking the extracellular matrix to intracellular signaling pathways, and it may play a role in apoptosis. Germline mutations in *APC* cause the development of multiple benign colonic polyps. Most mutations result in truncation of the protein and, because of the size of the gene,

mutations can be screened using a protein truncation test. Tumorigenesis caused by *APC* mutations follows the two-hit model that charaterizes classic tumor suppressor genes. In FAP, neoplasia is initiated on inactivation of the remaining normal allele. *APC* mutations are also very common in sporadic colon cancers, which occasionally demonstrate inactivation of both *APC* alleles.

CELL-CYCLE CONTROL PROTEINS Not unexpectedly, a number of tumor suppressor genes play a role in control of the cell cycle. *Rb* was the first of these to be recognized. As shown in Fig. 7-2, Rb acts primarily at the restriction point in G_1 of the cell cycle. Early in G_1, Rb is hypophosphorylated and binds transcription factors E2F 1–3. E2Fs dimerize with a family of DP proteins (DP 1–3). The E2F/DP complexes bind to a consensus sequence, TTTCGCGC, which is present in the promoters of many genes, including *thymidine kinase*, *dihydrofolate reductase*, c-*myc*, and *E2F* itself. When Rb is bound to E2F/DP complexes, it can function as a repressor. On the other hand, dissociated E2Fs are transcriptional activators. Overexpression of E2F appears to be sufficient to push cells through the restriction point in G1. Phosphorylation of Rb by cyclin D/cdk4,6 complexes results in dissociation of E2Fs from Rb. Several pathways can act to prevent Rb phosphorylation and inhibit E2F dissociation from Rb. In the setting of cell damage, p53 levels are increased, and induce the cdk inhibitor, p21, which inhibits the actions of cyclin E/cdk2, another activator of Rb. p16 can also inhibit cyclin D1/cdk4.

In addition to *Rb* mutations in retinoblastoma, somatic mutations in *Rb* are relatively common in small cell lung cancer, sarcomas, and bladder cancer (*see* Chapters 40 and 105). Deletion of *p16* has been observed in small cell lung cancers in which the *Rb* gene is expressed. The absence of p16 would be expected to diminish inhibition of Rb-mediated progression through G_1. Expression of the papilloma virus E7 protein in cervical cancers functionally inactivates Rb. Overexpression of cyclin D1 occurs by amplification in some breast, esophageal, and squamous cell carcinomas. In addition, cyclin D1 is ectopically expressed as a result of translocations in some parathyroid tumors (PTH-cyclin D1) (*see* Chapter 51) and B-cell lymphomas (IgH-cyclin D1).

Mutations of *p53* and LOH at 17p occurs commonly in colorectal, lung, breast, and bladder cancers. Germline mutations of *p53* are found in Li-Fraumeni syndrome, which is characterized by a greatly increased risk for multiple tumors including breast cancer, soft-tissue sarcomas, osteosarcomas, brain tumors, and leukemias. Although *p53* is one of the most prevalent mutations in advanced stages of tumorigenesis, its cellular functions are only partly understood. p53 is capable of acting as a transcription factor and induces the expression of inhibitors (e.g., p21) of the G_1/S transition. p53 also appears to govern entry into the apoptosis pathway (by stimulating *bax*) in response to genotoxic damage. Thus, the absence of p53 not only favors progression through the cell cycle, but it also allows cells with damaged DNA to avoid undergoing apoptosis.

TRANSCRIPTION FACTORS The Wilms' tumor (*WT-1*) suppressor gene causes renal tumors in children (*see* Chapter 71). The *WT-1* locus on chromosome 11p13 was identified based on a contiguous gene syndrome, WAGR (Wilm's, aniridia, genitourinary disorders, retardation). The *WT-1* gene encodes a transcription factor that contains zinc finger domains and is expressed in the urogenital ridge and in the developing kidney. WT-1 appears to suppress gene expression, including the *IGF-II* gene, which is also overexpressed in Beckwith-Wiedeman syndrome (*see* Chapter

116). Mutations in *WT-1* are found in only a minority of cases of Wilm's tumor, suggesting that other loci are also involved in the pathogenesis of this tumor.

Von Hippel-Lindau (VHL) syndrome includes retinal angiomas, predisposition to renal cancer, pheochromocytomas, hemangioblastomas of the central nervous system, and cysts in several tissues. The *VHL* gene was identified on chromosome 3p based on linkage. Tumors in patients with germline mutations of *VHL* show mutations or loss of the remaining normal *VHL* gene. Somatic mutations in both alleles of *VHL* are also found in the majority of clear cell renal cancers (*see* Chapter 71). *VHL* encodes a protein that binds to elongin and is involved in transcriptional elongation. The normal function of VHL appears to be inhibition of elongin activity.

The *BRCA 1* (breast cancer predisposition) and *BRCA 2* genes are located on chromosomes 17q21 and 13q, respectively (*see* Chapter 63). The proteins are weakly homologous and likely function as transcription factors. Germline mutations predispose to early breast and ovarian cancers (especially *BRCA 1*). Although the *BRCA 1* and *2* genes were identified in large pedigrees with early breast cancer, these genes appear to account for a relatively small fraction of increased breast cancer risk, even when there is an affected first-degree relative. Their functional roles and their importance for genetic testing and counseling remain to be determined.

DNA REPAIR PROTEINS The role of DNA repair processes is most clearly illustrated in hereditary nonpolyposis colorectal cancer (HNPCC). Based primarily on studies by Lynch and colleagues, this form of hereditary colon cancer was strongly suspected to be caused by predisposing "cancer genes." HNPCC is now known to be caused mutations in one of several different DNA repair enzymes (*hMSH2*, *hMLH1*, *hPMS2*). Initially, linkage analyses indicated association with chromosomes 2p16 or 3p21. However, unlike the situation with *Rb*, *MEN-1*, and other heritable tumor suppressor genes, tumor samples did not always exhibit loss of heterozygosity in the putative normal allele at these loci. Rather, new microsatellites (highly polymorphic repeat sequences, *see* Chapters 4 and 5) were detected, and these aberrations were present throughout the patient's genome, suggesting microsatellite instability. This type of genomic instability is similar to that found in microorganisms with mutations in mismatch repair (proofreading) enzymes (e.g., mutS, mutL), spurring a search for human homologs of these genes. Germline mutations have now been identified in the human mismatch repair enzyme genes (*hMSH2*, *hMLH1*, *hPMS2*) in kindreds with HNPCC. Of these, mutations in *hMSH2* and *hMLH1* appear to account for the majority of HNPCC cases. Although HNPCC is relatively uncommon (2–4% of colorectal cancer), sporadic mutations in DNA repair enzymes may result in genomic instability in as many as 15% of colorectal cancers. The TGF-β receptor, which mediates apoptosis of colon cells, has been hypothesized as a target of inactivation by microsatellite instability.

The *mutated in ataxia telangiectasia (ATM)* gene represents another example of a DNA repair enzyme defect. Heterozygotes who carry this gene appear to be at increased risk for breast cancer. The defective *ATM* gene product appears to cause impaired p53 responses to DNA damage. Thus, ATM may play an important role in cell cycle checkpoints for DNA damage. Xeroderma pigmentosa represents another example of defects in DNA repair. In this case, a mutation in one of several different genes involved

in nucleotide excision and repair leads to a high incidence of skin tumors, particularly in response to UV radiation (*see* Chapter 81).

APOPTOSIS-RELATED PROTEINS   Although cancer is frequently conceptualized in terms of cell proliferation, the role of abnormalities in cell death, or apoptosis, is now becoming more fully appreciated. Most malignancies demonstrate abnormalites in programmed cell death. In addition to contributing to the immortality of the replicating cell, alterations in the apoptotic pathway also favor the accumulation of additional genetic alterations that would normally induce cell death. Responses of tumors to certain types of chemotherapy or irradiation also appear to correlate with the ability of tumors to undergo apoptosis.

Bcl-2 was initially discovered based on its translocation in follicular lymphomas. In this case, the recombination of the immunoglobulin locus on chromosome 14 with the *Bcl-2* gene on chromosome 18 causes persistent overexpression of *Bcl-2* in lymphoid cells. It was shown that the clonal expansion of lymphoid cells reflected increased survival rather than enhanced proliferation. *Bcl-2* is a member of a family of proteins that regulate the apoptotic pathway. While Bcl-2 protects against cell death, others such as Bax, favor cell death. Bcl-2 and Bax can form homodimers or heterodimers, and the balance of *Bcl-2* and *Bax* expression regulates the predisposition to cell death.

As noted above, p53 also plays an important role in apoptosis. Since *p53* mutations are found in up to 50% of human cancers, its role in cell-cycle checkpoints and in apoptosis may represent one of the most common lesions in neoplastic cells. The exact function of p53 in the apoptotic pathway has not been fully defined. Thymocytes from mice deficient in p53 fail to undergo apoptosis in response to DNA damage. However, glucocorticoids can still induce apoptosis in the absence of p53. Thus, p53 is not absolutely required for all pathways of cell death. It has been suggested that p53 may induce apoptosis primarily in the presence of DNA damage or when survival factors are limiting. It is notable that p53 can increase *Bax* expression, providing one mechanism for shifting the cell into an apoptotic pathway.

INHERITED CANCER SYNDROMES

Several inherited cancer syndromes have already been described as examples of the functional roles of oncogenes *(MEN-2)*, tumor suppressor genes *(Rb)*, or DNA repair enzymes (HNPCC). Although many of these syndromes cause relatively rare disorders, they have been enormously important for the identification of cancer-related genes and for establishing principles of cellular abnormalities in neoplasia. In addition, many of the genes that cause inherited forms of cancer are frequent targets for somatic mutations in sporadic tumors. Thus, these syndromes often identify candidate oncogenes or tumor-suppressor genes.

Some of the inherited cancer syndromes are listed in Table 7-3. Most of these disorders are discussed in greater detail in specific specialty sections of the book. In general, inherited forms of cancer are caused by a limited number of mechanisms. The classical two-hit model for neoplasia, in which one copy of the mutant gene is inherited and the second normal copy is subsequently lost (*see* Fig. 7-3), is illustrated by disorders such as retinoblastoma *(Rb)*, Li-Fraumeni *(p53)*, MEN-1 *(MENEN)*, and Wilm's tumor *(WT-1)*. MEN-2 *(Ret)*, and some of the signaling pathway disorders such as neurofibromatosis type 1 likely involve inherited stimulation of cell growth followed by the accumulation of additional mutations that lead to malignancy. Another group of disorders involve

Table 7-3
Inherited Cancer Syndromes

Syndrome/cancer	Oncogene	Function
Retinoblastoma	Rb	Cell cycle control
Li-Fraumeni	p53	Cell cycle; apoptosis
Familial adenomatous polyposis	APC	Cell-cell interactions
Lynch's syndrome (HNPCC)	MSH2, MLH1, PMS1,2	DNA repair
Von Hippel-Lindau	VHL	Transcriptional elongation
Von Recklinghausen's	NF-1	GAP-like
Neurofibromatosis type 2	NF-2	Ezrin-like
Wilms' tumor	WT-1	Transcriptional repression
Ataxia-telangiectasia	ATM	DNA repair
Nevoid basal cell cancer syndrome	Patched	Transmembrane protein
Multiple endocrine neoplasa type I	MENIN	Tumor suppressor
Multiple endocrine neoplasa type II	Ret	Tyrosine kinase
Xeroderma pigmentosa	XP A-G	DNA repair
Bloom's syndrome	BLM	DNA helicase
Breast cancer	BRCA1, BRCA2	Tumor suppressors

abnormalities in DNA repair, predisposing to a high frequency of genetic alterations at numerous loci. This group includes genes that cause HNPCC, xeroderma pigmentosa, Bloom's syndrome, and ataxia-telangiectasia.

MULTISTEP THEORY OF NEOPLASIA

Pathologists have long recognized a spectrum of histologic abnormalities that correlate with different degrees of tumorigenicity. These observations have led to various grades of malignancy based on the degree of abnormal cellular morphology or to stages of invasiveness such as dysplasia, carcinoma *in situ*, locally invasive tumors, or metastatic lesions that have spread beyond their original site of growth. There is now strong evidence that these morphological and clinical characteristics of tumors can be explained in molecular terms.

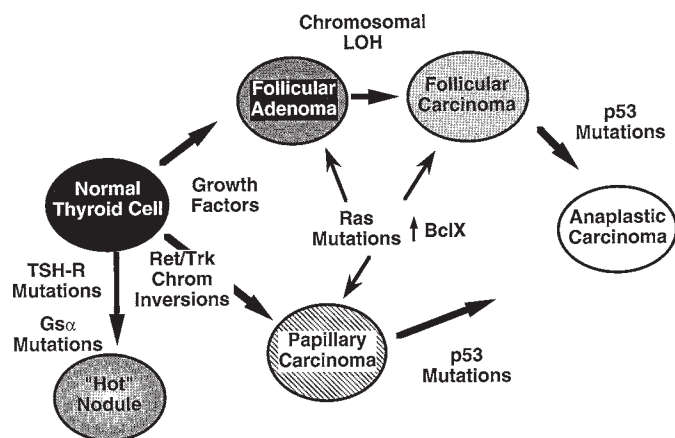
The process of "multistep carcinogenesis" has been studied in many different models. It is sometimes divided into stages of initiation, promotion, and progression. These categories are undoubtedly oversimplistic, and it is likely that different tumor types involve distinct pathways for progression. In addition to developing altered pathways for proliferation and escape from apoptosis, tumors require angiogenesis and escape from immune surveillance in order to continue clonal expansion. Early models for cellular transformation demonstrated cooperation among different classes of oncogenes such as *ras* and *myc*. However, analogous events do not hold true for all malignancies. Many hematologic malignancies harbor distinct translocations that are not found in other tumor types. In some of these cases, however, it remains true that progression to more aggressive tumors involves the acquisition of additional genetic abnormalities. In fact, surveys of most


Figure 7-7 Example of multistep carcinogenesis involving thyroid carcinoma. There is evidence for multistep carcinogenesis for most cancers. In the case of thyroid cancer, various mutations affect the differentiated phenotype of the cancer as well as the degree of invasiveness. The normal thyroid follicular cell can be converted to an autonomously functioning "hot" nodule by two different types of mutations. Mutations in the TSH-receptor can activate Gsα and the cAMP signaling pathway, which is mitogenic in the thyroid. Gsα is a guanine nucleotide-binding protein that is structurally related to Ras. Gsα mutations that inhibit GTP hydrolysis also cause constitutive activation of the cAMP pathway. Follicular adenomas exhibit *ras* mutations (~30%) and, in the progression to follicular cancers, there is an increasing prevalence of loss of heterozygosity (LOH) at several distinct loci. Papillary cancers have a high frequency (20–40%) of a unique mutation caused by an inversion on chromosome 10 that brings the ret tyrosine kinase receptor under the control of several different genes. *Ras* mutations are found in papillary cancer with similar prevalence to follicular neoplasms. Mutations in *p53* are relatively common in anaplastic cancer, most of which are thought to arise from follicular cancers. Adapted with permission. (Jameson JL. Applications of molecular biology in endocrinology. In: Degroot LJ, ed. Endocrinology, 3rd ed. Philadelphia, PA: WB Saunders, pp. 119-147.)

hematologic malignancies for genetic alterations reveal numerous examples of gene amplification or loss of heterozygosity.

The concept of multistep carcinogenesis has been particularly well-studied for colon cancer by Vogelstein and colleagues. In colon cancer, it appears that seven or more genetic events (*APC*, *ras*, *DCC*, mismatch repair, *TGF-b-R*, *p53*, and others) may be required before an invasive carcinoma or metastases develop. Based on this list of genetic alterations, it is apparent that colon cancers can contain nearly every type of oncogene, tumor-suppressor gene, and DNA repair defect. Patients with germline *APC* mutations may first develop a second hit in this gene and subsequently develop additional growth promoting mutations such as mutations in *ras* or *p53*. However, the order in which these mutations occurs is variable in different patients.

Another example of multistep carcinogenesis is depicted for thyroid cancer in Fig. 7-7. Thyroid cancer is appealing as a model because several mutations give rise to distinct tumor phenotypes and because some of the growth promoting factors have been well-characterized. Proliferation of the thyroid follicular cell is largely dependent on thyroid-stimulating hormone (TSH) and IGF-1 (*see* Chapter 50). TSH stimulates growth through a Gsα-coupled receptor that acts via the cAMP pathway, whereas IGF stimulates a tyrosine kinase receptor that activates IRS-1, PI-3 kinase, and the

Ras pathway. These pathways function synergistically to induce cellular proliferation. Activating mutations in the TSH-R, or in Gsα, cause constitutive activation of the cAMP pathway. These mutations cause clonal proliferation of a highly differentiated (benign) nodule that functions autonomously and secretes excess thyroid hormone. Although these mutations cause cellular proliferation, this mutation pathway is rarely observed in malignant thyroid cancers, which are not well-differentiated and rarely produce excess hormone. A group of inversions on chromosome 10 bring the *ret* oncogene under the control of various promoters. These fusion genes were initially termed papillary thyroid cancer (PTC) because they are essentially unique to this histologic variant. Approximately 20–30% of papillary thyroid cancers contain PTC rearrangements. *Ras* mutations (*K-ras*, *N-ras*, *H-ras*) have been found in all types of thyroid neoplasms, including benign macrofollicular adenomas, papillary cancers, and follicular cancers. As in most other cancers, the more malignant thyroid tumors show numerous examples of loss of heterozygosity, presumably involving tumor-suppressor gene loci. LOH is particularly common in follicular thyroid cancer, which has a greater tendency to metastasize. Anaplastic thyroid cancers have a very poor prognosis and show a marked increase in *p53* mutations. Although it is unclear whether tumors show a gradual progression from *ras* mutations to loss of tumor suppressor loci, to *p53* mutations, this seems likely, as anaplastic lesions are often noted to develop within a pre-existing follicular cancer. The loss of *p53* may represent a pivotal step in which there is a defect in normal apoptosis pathways and a more rapid accumulation of additional genetic abnormalities. Superimposed on these genetic abnormalities, it is well-established that thyroid cancers respond to normal growth factors such as TSH, leading clinicians to suppress TSH with thyroid hormone as one means of therapy. This feature of the thyroid tumors emphasizes the overlap between normal and abnormal influences on cell growth. Thus, in the model of thyroid cancer, there are examples of mutations that are associated with specific tumor phenotypes (e.g., *TSH-R*, *PTC*), but other mutations are less specific (e.g., *ras*) for distinct tumor types.

IMPLICATIONS FOR DIAGNOSIS AND TREATMENT

Ideally, one would hope to "genotype" a tumor to establish a specific diagnosis and to aid in prognosis. In some cases, such as hematologic malignancies, specific translocations can be used for diagnostic purposes. Characteristic genetic changes can also be used to detect minimal residual disease using PCR or other sensitive techniques. However, for most malignancies, the array of genetic alterations is too large and the pattern of mutations is too variable to provide a diagnostic or prognostic code. It is possible in the future that the growing body of correlations between clinical course and genetic alterations will allow such analyses, at least for some tumors.

In the short term, the greatest advances are likely to involve assessment of genetic risk based on inheritance of predisposing cancer genes. Thus, in kindreds with autosomal dominant MEN-2, it is now possible to determine early in life whether or not an individual carries the mutant *ret* gene. In conjunction with genetic counseling and clinical assessment, this has allowed careful monitoring for characteristic tumors (medullary thyroid cancer, pheochromocytoma, parathyroid adenomas) and, in some cases, prophylactic thyroidectomy to prevent thyroid cancer. In addition, unaffected family members can be spared the anxiety associated with repeated testing for possible malignancy. By analogy, earlier

and more careful screening procedures can be anticipated in affected individuals with inherited cancer syndromes such as FAP and HNPCC. In addition to issues of medical intervention, the assessment and detection of genetic risk carries an obligation for genetic counseling and raises numerous ethical issues involving health insurance, effects on the individual's sense of self, and interpersonal relationships.

For many disorders, there is an opportunity for prevention as well as enhanced surveillance. In patients with increased risk of colon cancer, changes in diet to reduce red meat and to increase fiber content are reasonable, and nonsteroidal anti-inflammatory agents may be protective. Patients with xeroderma pigmentosa have increased sensitivity to UV light and need to avoid or block UV exposure.

In the long term, it is hoped that an improved understanding of the molecular basis of neoplasia will provide new avenues for therapy. The field is still very new and, given the usual timeline for drug discovery, it is not surprising that there are relatively few successes at this stage. The recognition that *ras* and *p53* are commonly involved in many types of tumors has led to aggressive efforts to find agents that can alter their functions. In the case of Ras, it has been possible to inhibit farnesylation, which is required for the protein to function. Efforts are underway to search for drugs that might mimic some of the actions of p53. The recognition that the retinoic acid receptor was involved in a translocation in promyelocytic leukemia led to trials of its ligand, all *trans*-retinoic acid, which has proven to differentiate the tumor cells. Glucocorticoids induce apoptosis in many lymphoid malignancies, and antagonists of estrogens have been useful in hormonally responsive breast cancers. Further studies of the mechanisms of oncogene action and apoptosis may provide additional therapeutic strategies.

Finally, gene therapy holds some promise for cancers. Because of the large number of abnormalities in most cancer cells and because of rapid clonal selection, it is unlikely to be practical to replace or to correct mutant genes. However, strategies to target toxic genes to malignant cells hold some promise. The primary challenge (as with many chemotherapeutic approaches) is to achieve specificity for the tumor and to target a very high fraction of the tumor cells. Several strategies are underway to augment immunologic responses (using cytokines) or to alter the drug sensitivity of tumors. Attempts are also being made to genetically modify (e.g., with multidrug resistance genes) normal bone marrow constituents to make them more resistant to chemotherapy.

8 Molecular Diagnostic Testing

C. Sue Richards and Patricia A. Ward

BACKGROUND

Molecular diagnostic testing is a rapidly evolving field that currently includes analysis for single-gene disorders, multifactorial disorders, some forms of cancer, infectious disease, microbial epidemiology, and personal identification. The era of molecular medicine began in the late 1970s with the cloning of the β-globin gene and identification of the point mutation responsible for sickle-cell anemia. At the same time, population-based carrier testing, using other technologies, for common genetic diseases such as Tay-Sachs and sickle-cell disease and prenatal diagnosis for chromosomal abnormalities were becoming widely available. The diagnostic capability of molecular technology has expanded tremendously, and there are now tests available for more than 300 genetic diseases being performed in greater than 200 diagnostic laboratories, academic and commercial, throughout the country (information provided by *Helix*; Seattle, Washington). The completion of the Human Genome Project will facilitate the identification of all disease genes, making a greater number of molecular diagnostic tests possible. While improved technological tools are essential for molecular diagnostics to move forward, the basic strategies for designing and implementing testing, which we describe in this chapter, will be long-lasting. To illustrate these principles, we will focus on the application of molecular diagnostic testing for single-gene disorders using DNA technology.

METHODS AND MUTATIONS

DNA testing becomes feasible when the disease gene responsible is mapped or identified. If the gene has been mapped but not identified or if the mutations in a particular gene have not been characterized, then linkage analysis may be possible. If the gene has been cloned and mutations characterized, then it may be possible to perform direct mutation analysis. Direct mutation analysis is the method of choice, since it is more accurate and offers confirmation of diagnosis, in addition to precise carrier and fetal risk prediction. In contrast, linkage analysis cannot be used to confirm a diagnosis and provides a less accurate statistical prediction of carrier or fetal risk based on analysis of DNA markers surrounding a gene.

DIRECT MUTATION DETECTION

Both the technology and the strategy used for mutation detection is determined by the nature of the specific mutation. The

availability of gene sequence information and probes specific for the gene are essential for technology transfer from research to diagnostic laboratory. For the purpose of this limited discussion we will present examples of well-characterized mutation types represented in several common genetic diseases.

DELETION AND DUPLICATION MUTATIONS IN DUCHENNE MUSCULAR DYSTROPHY

Duchenne muscular dystrophy (DMD) is an X-linked recessive neuromuscular disorder affecting approximately 1 in 3500 males with one-third of isolated cases resulting from a new mutation in the *dystrophin* gene. The *dystrophin* gene, located on Xp2l, is the largest gene identified to date, having greater than two megabases encompassing 79 exons. Two-thirds of patients have structural mutations with approximately 60% having intragenic deletion mutations and 6% duplication mutations. In addition, these mutations occur more frequently in certain regions of the gene reported as "hot spots for recombination." This knowledge, gene sequence information, and the full-length cDNA *dystrophin* probe provide the tools needed to design a comprehensive and efficient strategy for molecular analysis of DMD.

MULTIPLEX PCR DNA from affected males can be analyzed for the presence or absence of specified exons in the *dystrophin* gene, utilizing multiplex PCR reactions. Our laboratory examines 32 of the 79 *dystrophin* exons in three multiplex amplification reactions. These exons have been shown to account for over 98% of detectable deletions in the *dystrophin* gene. In addition, careful design of multiplexing strategy allows for establishment of deletion endpoints, which may be useful for phenotype–genotype correlations. Results from the multiplex reactions are analyzed for the presence or absence of specified exons, using agarose gel electrophoresis and ethidium bromide detection of DNA fragments (Fig. 8-1A). A positive result—i.e., the absence of a single PCR product or several gene contiguous PCR products from this multiplex—is virtually diagnostic of Duchenne or Becker muscular dystrophy. In contrast, a negative result—i.e., the presence of all exonic PCR products—neither confirms nor refutes the diagnosis. *Dystrophin* gene duplications can be problematic to detect by PCR analysis as band intensity can be modified by PCR conditions. Various approaches to overcome this technical challenge have included fluorescence-labeled primers and automated gene analyzer equipment to visualize fragment intensities compared to normal male and female control DNAs.

A Multiplex

B Southern
Figure 8-1 *Dystrophin* DNA analysis for deletion and duplication mutations. (**A**) Multiplex PCR analysis. For the two multiplex PCR panels shown, lanes represent: (a) a patient deleted in exons 46 through 48, and (b) a normal male control. Arrows point to deleted exons. (**B**) Southern analysis of *Hin*dIII fragments using cDNA probe 47-4B. Patient samples are in lanes b–k; male control (a), male patients (b–f); female patients (g–k); female control (l). Patient b is deleted for exons 44–47; patients c and d, deleted for exons 45–47; patient e, deleted for exon 45 only; patient f, no deletion detected. Carrier analysis of female relatives (lanes j and k) of affected male in lane c identifies the familial deletion (*see* Fig. 8-2).

SOUTHERN DELETION ANALYSIS   For male probands with a negative result by multiplex PCR or in the absence of endpoint resolution, Southern analysis should be done to examine the entire *dystrophin* gene for deletions and duplications. In our laboratory we use eight cDNA probes that cover the entire *dystrophin* gene to probe *Hin*dIII-digested patient DNAs to examine for the presence or absence of *Hin*dIII-fragments and their intensity as compared to a known male control DNA (Fig. 8-1B). Carrier detection in females can also be performed using Southern and dosage analysis for deletions and duplications (Fig. 8-2). Dosage analysis is also used for identification of duplication mutations in male probands. Ideally, a male proband is analyzed first to determine whether an identifiable mutation is present. If a mutation is identified in the affected male, then females at risk are examined for the presence or absence of the specific mutation using scanning densitometry to determine gene dosage as compared to a known female control DNA. Whereas two copies of each *dystrophin* exon are normal for females, one copy indicates a gene deletion in a female, and three copies indicate a duplication. In the event that an

Fraction	%	EXON

2	32.9	44
3	30.2	46
4	29.4	45

Fraction	%	EXON
1	4.3	47
2	57.1	44
3	19.7	46
4	19.0	45
Figure 8-2 *Dystrophin* gene dosage analysis by scanning densitometry. Scans of Southern *dystrophin* analysis in Fig. 8-1B, control female (lane 1), and deletion carrier female (lane k). Arrows indicate deleted exons at approximately half gene dosage as compared to the normal female control.

affected male is unavailable for DNA analysis, females can undergo DNA testing for carrier determination. However, in the absence of a male proband, female mutation analysis using DNA dosage analysis is less reliable. Recently, deletion and duplication analysis by fluorescence *in situ* hybridization (FISH) has proven useful for diagnosis of female carriers of DMD when the familial deletion or duplication has been previously identified by DNA analysis.

In the family shown in Fig. 8-3, the proband II-1 with a suspected diagnosis of DMD is analyzed by multiplex PCR and found to have a deletion of exons 45 through 50, confirming the diagnosis. Thus, molecular analysis of a blood specimen has avoided the invasive and costly procedure of muscle biopsy to confirm the diagnosis. The mother, I-2, who prior to DNA analysis has a 66% carrier risk, is analyzed by Southern deletion analysis and densitometry and found to carry the same deletion in one of her *dystrophin* genes. Similar analysis of the daughter, II-2, who has a prior carrier risk of 33%, does not identify this deletion mutation in either *dystrophin* gene. Thus her carrier risk is the same as a female from the general population, less than 1 in 2000. The male fetus, II-3, has a prior risk of 33% to be affected with DMD and is analyzed using multiplex PCR and does not have the familial

DMD RISK MODIFICATION FOLLOWING DIRECT MUTATION DETECTION

	I - 2	II- 2	II- 3
PRIOR RISK	0.66	0.33	0.33
POST TEST RISK	1.00	<0.01	<0.01

deletion mutation. Additional comparative studies using highly polymorphic DNA markers are performed on the maternal and fetal samples in order to rule out maternal cell contamination and demonstrate inheritance of one maternal allele. These results indicate that this fetus is unaffected with DMD. Accurate prenatal diagnosis is available for future pregnancies of I-2 and for her other female relatives at risk.

POINT MUTATION ANALYSIS IN CYSTIC FIBROSIS

Cystic fibrosis (CF) is a common autosomal recessive disorder that, in US Caucasians of Northern European background, has an incidence of approximately 1 in 2000 and a carrier frequency of 1 in 25. With the cloning of the *cystic fibrosis transmembrane regulator gene (CFTR)* in 1989 and the subsequent identification of a number of common mutations, a DNA-based laboratory test was quickly put in place to provide more precise carrier detection and prenatal diagnosis for CF families. In addition, molecular analysis is helpful to confirm a CF diagnosis for some patients and is indicated for abnormal fetal ultrasound suggesting echogenic bowel. Recent guidelines recommend that potential gamete donors also have CF carrier screening performed, as appropriate to the donor's ethnic background. Although debate in the genetics community has inhibited general population screening protocols, the general trend has been for progressive genetics centers to offer such testing. While hundreds of mutations have been identified, a detection rate of approximately 90% in US Caucasians can be achieved with the analysis of only 20–30 mutations. Carrier frequency and detection rate will vary, depending on ethnicity and geographical location of a specific population.

Although various mutation detection methods exist, we will present the method used in our laboratory, allele-specific oligonucleotide (ASO) hybridization. This test uses multiplex PCR to analyze 10 exons and one intron in the *CFTR* gene for the presence or absence of 30 CF mutations. A partial test result illustrating the most common CF mutation, ΔF508, is shown in Fig. 8-4. This
Figure 8-4 CF mutation analysis for ΔF508. Autoradiogram from exon 10 PCR products from appropriate controls and patient DNAs spotted on membranes and hybridized to the normal (F508) and mutant (ΔF508) radiolabeled ASOs. For example, patient specimens in positions GI, E1, and E2 represent an affected child and both parents, respectively. Homozygote G1 shows hybridization only to ΔF508, while heterozygotes E1 and E2 hybridize to both F508 and ΔF508.

CF RISK MODIFICATION FOLLOWING MUTATION ANALYSIS

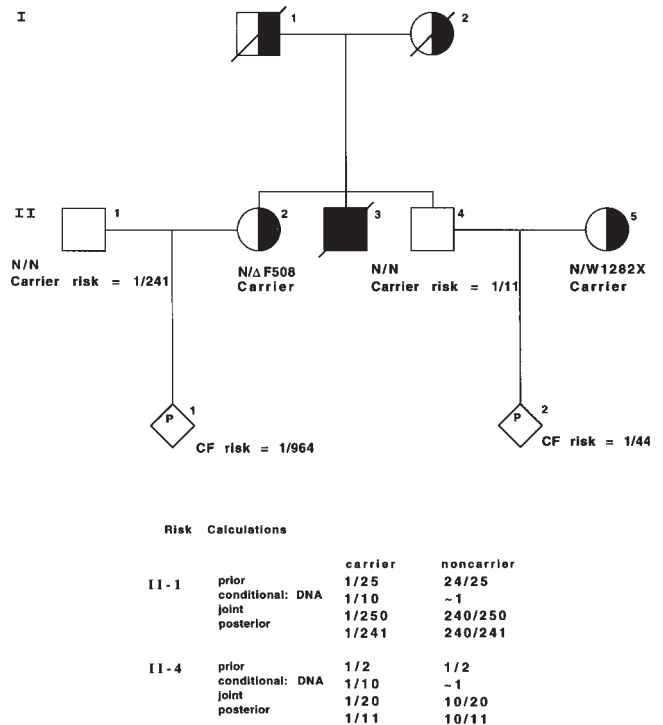
Risk	Calculations		carrier	noncarrier
II-1	prior		1/25	24/25
	conditional: DNA		1/10	~1
	joint		1/250	240/250
	posterior		1/241	240/241
II-4	prior		1/2	1/2
	conditional: DNA		1/10	~1
	joint		1/20	10/20
	posterior		1/11	10/11


Figure 8-5 CF modification following mutation analysis.

analysis can be partially automated using robotics, multiplexing, and pooling strategies. In addition, this strategy is applied in our laboratory to other genetic diseases, including Tay-Sachs, Gaucher, Canavan, Fanconi anemia, achondroplasia, sickle-cell and hemoglobin SC disease, and α-1-antitrypsin deficiency.

The case shown in Fig. 8-5 illustrates the impact of molecular analysis on CF risk modification. All individuals are of Northern European Caucasian descent. Individuals II-2 and II-4 had a brother affected with CF who died prior to CF testing and the two carrier parents, I-1 and I-2, are also deceased. Thus, the prior carrier risk for II-2 and II-4 is two-thirds and their fetuses are both at 1 in 150 risk to be affected. CF testing reveals that II-2 is a CF carrier with one copy of a ΔF508 mutation. Individual II-1, the spouse of individual II-2, has a negative family history for CF; thus

his prior carrier risk is 1 in 25. His CF mutation analysis is negative. His modified carrier risk is 1 in 241. Thus, the modified CF risk for fetus III-1 is now 1 in 964 and prenatal diagnosis is not recommended. In contrast, individual II-4 does not have a ΔF508 or any of the other 29 CF mutations tested. The carrier risk for II-4 can be modified using Bayesian analysis. Based on detection of a ΔF508 mutation in II-2, the prior risk for II-4 is 1 in 2, since only one parental mutation has been identified. Based on a ~90% detection rate using this panel of 30 CF mutations, the prior risk of 50% can be conditionally modified using a 10% chance that a mutation will not be detected. Thus, II-4s modified carrier risk is 1 in 11. The reproductive partner, individual II-5, who has a negative family history of CF and a prior carrier risk of 1 in 25, is found by molecular analysis to carry a W1282X mutation, and thus, is a definite CF carrier. As a result, fetus III-2 is at a 1-in-44 risk to be affected with CF. This presents a complex prenatal diagnosis situation. If prenatal diagnosis is performed and the results are negative for W1282X, the fetus is unaffected with CF, but carrier risk is ambiguous at a 1-in-22. However, if the fetus inherits the W1282X mutation, then the fetus is a definite carrier and at 1 in 22 risk to be affected with CF.

TRINUCLEOTIDE REPEAT MUTATION AND METHYLATION ANALYSIS IN FRAGILE X MENTAL RETARDATION SYNDROME

Fragile X syndrome was the first disorder in which the molecular basis was explained by the expansion of a trinucleotide repeat. Fragile X is the most common cause of inherited mental retardation, occurring in approximately 1 in 1500 males and 1 in 2500 females in all ethnic groups studied. Prior to the cloning of the *FMR-1* gene, cytogenetic analysis was used for diagnostic confirmation. However, cytogenetic analysis proved unreliable, particularly for carrier detection and prenatal diagnosis. With the cloning of the *FMR-1* gene and identification of a trinucleotide repeat expansion, the phenomenon of anticipation and reduced penetrance in fragile X families, the Sherman Paradox, was explained, and molecular analysis became the method of choice for fragile X testing. A CGG repeat occurs within the 5' untranslated region of the *FMR-1* gene, which in normal individuals varies in size up to approximately 40 repeats and is inherited stably over generations. However, in affected individuals this CGG repeat region expands to greater than 200 repeats and becomes hypermethylated. In unaffected carriers, an intermediate size repeat region, termed as premutation, is seen ranging from approximately 60 to 200 repeats, but hypermethylation is not present. Premutation alleles are unstable during female meiosis and, depending on size (>70 repeats), have a significant likelihood of expanding to a full mutation in the next generation. However, unstable premutation alleles found in normal transmitting males generally do not expand to a full mutation in transmission to their carrier daughters. An indeterminate range between 40 and 60 repeats presents a challenge in counseling families regarding the potential risk of fragile X occurring in their future generations. Alleles in this range can be either normal stable alleles or unstable premutations, but have never been shown to be transmitted as full mutations. Fragile X testing is indicated for individuals with mental retardation or developmental delay of unknown cause, or individuals with a positive family history of fragile X. While general population carrier screening for fragile X carrier detection has been done primarily on an investigational basis, this application may become more widely accepted in the future.
Figure 8-6 Fragile X PCR analysis. Radiolabeled PCR products from patient DNA generated from primers flanking CGG repeat are separated by electrophoresis and analyzed by comparison to a standardized sizing ladder to determine allele size. An amplification control is included to rule out test failure in males with large expansions that fail to amplify by PCR. Normal alleles range up to 42 repeats; inconclusive, 43–59 repeats; premutation, 60 to approximately 200 repeats.
Figure 8-7 Fragile X Southern analysis. *Eco*RI- and *BSS*HII-restricted DNAs from patients (b–k) and normal control (female, l and male, m) hybridized to radiolabeled pE5.1 probe isolated from the CGG repeat region of FMR-1. The normal *Eco*RI fragment size detected by this probe is 5.2 kb. In normal males additional digestion using the methylation-sensitive enzyme, *BSS*HII, results in a 2.8-kb fragment only, representing an active X chromosome. Normal females have one 5.2-kb fragment, due to normal X inactivation, and one 2.8-kb fragment. Lanes b and e show affected males with full hypermethylated mutations; lane c and h, mosaic males having a full mutation and a premutation, respectively; lane d, a female with two premutations, the mother of affected male in lane e; lane f, a female with a full mutation; lane g, a female with a small premutation (68 repeats); lanes i, j, k, females having no detectable expansion.

Fragile X analysis is performed in our diagnostic laboratory using simultaneous PCR analysis to determine the size of normal and small premutation alleles (Fig. 8-6), and Southern analysis to examine methylation status and to estimate the size of large premutation and full mutation alleles (Fig. 8-7).

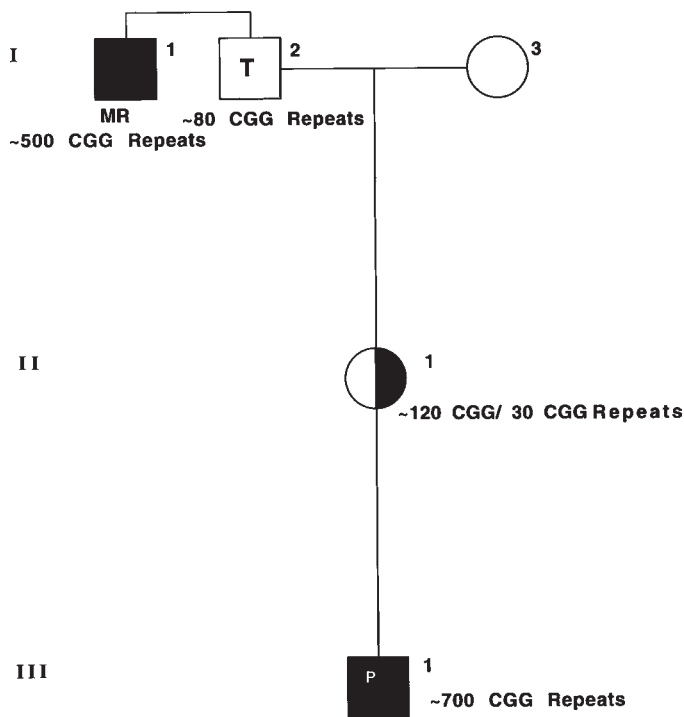
FRAGILE X MUTATION ANALYSIS


Figure 8-8 Fragile X mutation analysis.

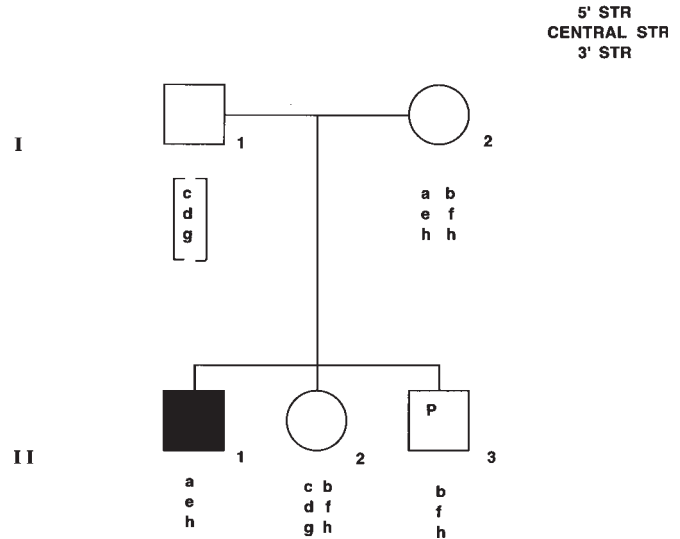
DMD LINKAGE

Figure 8-9 DMD Linkage.

The family shown in Fig. 8-8 illustrates the impact of direct mutation detection for fragile X for diagnostic clarification as well as carrier and fetal risk prediction. Individual II-1 reports to her obstetrician that she has a paternal uncle with mental retardation of unknown cause. DNA analysis of the uncle, I-1, reveals an expansion of approximately 500 CGG repeats, thus confirming his diagnosis as fragile X. Subsequent PCR analysis of her father, I-2, who is of normal intelligence, identifies a premutation allele of 80 repeats, thus indicating that he is a normal transmitting male. His daughter, II-1, is found to have one normal allele of 30 repeats and one premutation allele of 150 repeats, confirming her carrier status. Thus, her male fetus, III-1, is at a 1-in-2 risk to be affected with fragile X. PCR analysis of fetal DNA indicates a null allele, i.e., failure of amplification across the CGG region, suggesting the presence of a full mutation. Southern analysis of this fetus reveals a CGG expansion of >700 repeats with hypermethylation, thus predicting that this fetus is affected with fragile X mental retardation syndrome.

LINKAGE ANALYSIS

When direct mutation detection is not possible, either because the gene has not been cloned or a particular family does not have an identifiable mutation, then linkage analysis may be possible, provided that key family members are available and willing to be studied and that the necessary molecular tools are available for the analysis. For example, in the Duchenne muscular dystrophy case depicted in Fig. 8-3, if molecular analysis did not detect a mutation in the affected male, then linkage analysis in this family would be possible and could provide risk modification for the sister and the fetus. PCR analysis of highly polymorphic intronic DNA markers


within the *dystrophin* gene can be used to rapidly accomplish this analysis. However, due to the large size and high mutation frequency within the *dystrophin* gene, intragenic recombinations do occur and must be accounted for in the risk analysis. We analyze DNA markers at the 5', central, and 3' regions of the *dystrophin* gene. Those females whose two-*dystrophin* marker patterns (haplotypes) can be distinguished are termed "informative." If all markers are informative, a 1% chance of unrecognized recombination remains. If 5' and central, 3' and central, or only central markers are informative, a 5% chance for unrecognized recombination exists. If only 5' or 3' markers are informative, a 10% chance of recombination is used in the risk calculation.

In this example shown in Fig. 8-9, the affected male, II-1, does not have an identified deletion or duplication mutation. Linkage analysis of the mother is informative at the 5' and central sites, but not at the 3' site. The sister of the affected and the male fetus has inherited the opposite maternal haplotype. The paternal haplotype of II-2 can be deduced from the data without the analysis of her father's DNA. Based on the new mutation rate in DMD, I-2's carrier risk is 67% and linkage analysis does not modify her risk. The carrier risk for individual II-2 based on family history is 33%; but, using linkage data and taking into account two possible recombination events with a 5% recombination frequency for each event, this risk can be modified to 6.4%. Similarly, the risk that the male fetus, II-3, is affected can also be modified from 33 to 6.4%, based on linkage analysis.

FUTURE DIRECTIONS

With the expansion of molecular diagnostics will come improved health care. To date, the major impact of molecular analysis has been reproductive decision making regarding single gene disorders, which occur in a small percentage of the population. Future trends in genetic testing will include more predictive tests for susceptibility to common diseases, including cancer, cardiovascular disease, diabetes, and psychiatric disorders. When offering genetic testing, particularly for those disorders with adult onset, the molecular laboratory must be aware of the legal and ethical implications. Comprehensive protocols attentive to

national guidelines must be implemented that should include genetic counseling, medical and (in some instances), psychological evaluations, and informed consent. Predictive testing is currently being performed for several adult onset diseases having trinucleotide repeat expansion mutations, including Kennedy disease, myotonic dystrophy, Huntington's disease, spinocerebellar ataxia type 1, dentatorubral-pallidoluysian atrophy, and Machado Joseph/spinocerebellar ataxia type 3. In addition, cancer susceptibility genes, including those responsible for some inherited breast and ovarian cancer and colorectal cancer, have been identified, and tests have been developed for individuals at risk. While susceptibility testing is currently performed under research protocols, it is likely that testing will become more widely available. Predictive testing, while having positive implications for the individual and family, has the potential risk of insurance or employment discrimination and other negative implications. Such legal, social, and ethical issues specific to genetic testing are currently being debated and addressed at a national level. A key component to the future success of this discipline is the evolution of technology development to address volume and cost issues. Laboratory testing, which is now routinely done in highly specialized genetic testing laboratories in both academic and industrial settings, may eventually be done in hospital chemistry laboratories and physician offices. Gene and technology patenting issues further complicate and potentially limit the widespread application of genetic testing. However, the major challenge to ensure widespread access to genetic testing is education of health care professionals, consumers, and insurance carriers.

9 Genetic Counseling

BETH A. FINE

INTRODUCTION

The practice of genetic counseling has evolved in the last quarter century into a communication process between an appropriately trained health professional and a patient/client, couple, and/or family, regarding the occurrence or risk of occurrence of a genetic condition and relevant implications. In response to advances in molecular genetics and diagnostic technologies, a new health care professional, the master's-level genetic counselor, emerged in the early 1970s to participate in a multidisciplinary team approach to meeting the informational, psychosocial, and medical needs of individuals and families affected with or at risk for genetic conditions.

In this chapter, a historical perspective on the profession and practice of genetic counseling in the United States will be followed by a discussion of the principles and types of service delivery in the settings in which genetic counseling is conducted. Next, the philosophical underpinnings of genetic counseling along with a review of the psychosocial, ethical, religious, and ethnocultural contexts in which patients experience genetic counseling and testing will be reviewed. The chapter will end with a description of genetic-counselor education, training, and credentialing. Since more nongenetics health professionals are participating and will continue to participate in aspects of genetic-counseling activities, the aim of this chapter is to introduce the components of genetic counseling together with the relevant issues faced by professionals and patients and their families as the Human Genome Project progresses. Resources for referrals to genetic counselors are included in Table 9-1.

THE PROFESSIONAL GENETIC COUNSELOR

Genetic counselors are health professionals with specialized graduate degrees and experience in medical genetics and counseling, often with undergraduate education in biology, genetics, psychology, public health, social work, or nursing. Approximately 1500 genetic counselors are members of the National Society of Genetic Counselors (NSGC); most practice in university or community hospitals.

Genetic counselors work as members of a health-care team, providing information and support to individuals and families who have members with birth defects or genetic disorders, and to families who may be at risk for a variety of inherited conditions. They identify individuals and families at risk for genetic conditions,

birth defects, or disease-susceptibility, and investigate the problem in the family. Genetic counselors analyze inheritance patterns and risk of occurrence/recurrence, interpret and communicate information about the disorder, and explore and discuss available options with the family.

Genetic counselors aim to communicate complex genetic and medical information to individuals and families in a manner that makes sense within the context of the patients' lives. A patient's educational level, culture, religion and psychosocial issues inform the way that genetic counselors frame risks and discuss the implications of genetic risk with families. Therefore, the information must be presented in a culturally sensitive manner in order to facilitate informed decision-making. Genetic counselors often work with patients and families in crisis, at the time of a diagnosis, or during loss of a pregnancy or family member. They provide supportive counseling to families, serve as patient advocates, and refer individuals and families to community resources/services.

Some genetic counselors also serve as educators and consultants for other health-care professionals and for the general public. Genetic counselors work in the public-health setting, in academic and commercial laboratories as liaisons to clinicians, and are involved in clinical research and public policy.

THE GENETIC-COUNSELING PROCESS

In 1974, an *ad hoc* committee of the American Society of Human Genetics defined genetic counseling as a communication process that deals with the human problems associated with the occurrence or risk of occurrence of a genetic disorder in a family. This process involves an attempt by one or more appropriately trained persons to help the individual or family to:

1. Comprehend the medical facts, including the diagnosis, probable course of the disorder, and the available management.
2. Appreciate the way heredity contributes to the disorder and the risk of recurrence in specified relatives.
3. Understand the options for dealing with the risk of recurrence.
4. Choose the course of action that seems appropriate to them in view of their risk and the family goals and act in accordance with that decision.
5. Make the best possible adjustment to the disorder in an affected family member and/or to the risk of recurrence of that disorder (Fraser, 1974).

Historically, the practice of genetic counseling, defined as providing information about recurrence risks for particular conditions within a family, began in the early part of this century. Genetic

counseling was conducted by biologists with research interests in particular conditions. The goal of providing risk information in the absence of diagnostic or preventive measures reflected the eugenic philosophy of the time. In fact, the first genetic-counseling clinic, the Eugenics Records Office, was established in the early 1900s in Cold Spring Harbor, NY. The only options available to these families were to "take their chances" and initiate a pregnancy or to refrain from having biological children.

In the 1940s, heredity clinics staffed by physicians who were interested in genetic diseases were established. Genetic counseling at that time was conducted by physicians and PhD geneticists. They primarily used a medical/preventive model that involved providing "facts"—risk figures, natural history, and treatment information— so that couples and families could make informed reproductive decisions. Geneticists assumed that these decisions were based on the patients' perception of the risk, while studies revealed the importance of the perception of the burden of the disease. In essence, the genetic counseling was primarily an education process.

With the advent of carrier testing and prenatal diagnosis in the late 1960s and early 1970s, families' range of choices broadened. Geneticists recognized that information alone regarding genetic conditions and testing procedures was not enough to facilitate decision making and to truly serve the patients and families.

Dr. Melissa Richter, a visionary, initiated the development of a master's degree program in genetic counseling at Sarah Lawrence College to prepare a new professional to address the needs of families at genetic risk. These new professionals would also serve as "physician-extenders," providing the genetic information in a psychosocial context using skills the physicians did not possess. Thus, the team approach to genetics services began.

As genetic counseling and related services moved from a more preventive focus to a more client-centered approach, some practitioners adhered to the decision-making model in which information is presented within the psychological and cultural context, so that patients can come to an appropriate decision regarding genetic testing and reproductive options. Genetic counselors came to espouse a nondirective approach to genetic counseling about reproductive issues to demonstrate respect for the patients' autonomy and to move away from the eugenic underpinnings of earlier genetic counseling.

Today, it is recognized that many psychosocial and medical factors influence the genetic-counseling process. The information communicated in most genetic-counseling sessions is emotion-laden, often leading to a crisis. Therefore, many contemporary genetic counselors adhere to the psychotherapeutic genetic counseling model that involves psychosocial assessment, provision of information, psychological support and counseling, and referrals to other mental-health professionals as needed. It is often true that the genetic counselor functions as a liaison to the other specialists dealing with a patient and the family, providing a forum for sharing feelings, having them validated, and for processing information and resources. Genetic counselors work in pediatric or obstetric settings as well as in a wide array of specialty clinics, focusing on a particular disorder or group of disorders. While the contexts may differ, the process remains the same.

Genetic counseling involves developing a relationship and rapport with a patient or family, usually in a short time period. In many instances, there is only one encounter between a patient and a genetic counselor, although many individuals affected with genetic conditions are followed on a long-term basis. The goal of genetic counseling is to make genetic and medical information relevant to the patient or family accessible and useful so that they can optimize their health care and lifestyle decisions. The genetic counselor begins each session by asking the patient what his or her goals are for the session and the relationship, e.g., their questions about diagnosis, testing, options for dealing with risks, therapeutic modalities, support, access to resources. The genetic counselor then places the patient's expectations in context for what is possible within the limitations of scientific knowledge and available technology. Whether the genetic-counseling process occurs in one clinic visit or on a periodic basis over many years, the following components are necessary for the goals that the patient and professional wish to meet.

INFORMATION GATHERING   Geneticists and genetic counselors have been compared to detectives with regard to their work in making a diagnosis or discovering an underlying etiology for a condition that runs in a family. The sleuth work begins with gathering a great deal of information from the patient, his or her physician, and other family members. Whereas an accurate diagnosis is the most important component of quality genetic counseling, several types of histories must be obtained to arrive at that diagnosis.

First, the genetic counselor will elicit a detailed ***family history***, constructing a pedigree or a family tree. The purpose of the pedi-

gree is to create a graphic record of the family history for use in the medical record. The pedigree may lead to an accurate diagnosis and precise risk assessment for a particular condition in family members. Approaches to testing or treatment may be determined at least partially by information gathered for a pedigree.

There are standard symbols used for pedigree notation that have been approved by the National Society of Genetic Counselors and the American Society of Human Genetics (Bennett et al., 1996). The pedigree should include at least three generations, including the proband (the affected person about whom the consultation is sought) or consultand (an unaffected individual seeking risk information), their children, siblings, parents, grandparents and aunts, uncles and cousins. Since most patients do not have complete medical information on all family members, it is important to encourage them to inquire about health histories from their relatives. They should inquire about symptoms or traits that run in families, as they can provide clues to a diagnosis. For example, if several relatives in more than one generation experienced sudden death from aortic dissection, one might consider the diagnosis of Marfan syndrome.

The genetic counselor will pose questions about any medical, developmental, or physical abnormalities that may run in the family. In addition, questions will be asked about pregnancy losses, stillbirths, environmental exposures during pregnancy, birthdates or ages of individuals, ages and causes of death, and about ethnicity and possible consanguinity. When necessary, medical records may be requested to confirm diagnoses. This type of questioning also helps build a rapport with the patient, so that difficult or emotional issues can be addressed more easily. Genetic conditions are considered taboo or shameful in some families, so that the patient must feel safe and comfortable in discussing such matters.

The questioning may be focused on features of specific conditions when the patient seeks genetic counseling for a particular disorder. For preconceptual counseling or prenatal diagnosis because a woman is over 35 years of age, the family history should be more general. However, if a family history of a particular condition is discovered, genetic counseling can address the risks for that condition if the patient is interested.

The pedigree is useful as a communication tool in genetic counseling. When the patient or family is involved in constructing the diagram, it often jars their memory about other family members. It can be used to illustrate modes of inheritance and how risk figures are calculated.

Finally, when genetic testing in a family is conducted, the pedigree is useful in determining which family members need to be tested and in interpreting their test results. In general, the pedigree is the genetic counselor's primary tool for conducting risk assessment and counseling.

Second, if there is an affected individual in the family, the genetic counselor must gather information about the ***medical history***. This should include symptoms prior to diagnosis, age at diagnosis, confirmatory tests, course of the disorder, and current treatment. Confirmation of a diagnosis is necessary for accurate genetic counseling.

Third, a ***developmental history*** is important, particularly in pediatric genetic counseling, since a large proportion of children with inherited conditions have developmental disabilities. Knowledge of specific disabilities is essential for accurate diagnosis in some cases. In other situations, a geneticist may make recommendations for special education or other therapies based on the specific condition or constellation of problems.

Finally, the genetic counselor gathers information about ***patient*** and/or ***family concerns***, fears and questions regarding the genetic counseling process, the condition, or possible testing or treatment. It is also important to understand the ***family dynamics*** and ***support systems*** that often influence the care for the affected individual. In addition, the genetic counselor must assess the ***level of baseline knowledge*** and understanding of genetics, the genetic disorder, and the medical components of the condition. This information will guide the genetic counselor in presenting the information being offered to the patient and family.

DIAGNOSIS   An accurate diagnosis is central to providing appropriate and effective genetic services. A genetic diagnosis can be made in a variety of ways, depending on the age of the patient and the nature of the symptoms or characteristics leading to the referral to a genetics center.

The physical examination provides a great deal of information, particularly in the case of dysmorphic features. The identification of physical findings, which include a constellation of characteristics and symptoms that represent a known syndrome, is important in providing answers about prognosis, natural history, and possible therapies or management strategies. In addition, a genetic diagnosis may lead to prevention of adverse symptoms or amelioration of a particular condition. For example, a healthy baby born with macrosomia, macroglossia, characteristic facies, and creases in the earlobes may carry the diagnosis of Beckwith-Wiedemann syndrome. While the features described here are not medical problems, infants with this syndrome are at increased risk for hypoglycemia, which, if left untreated, can lead to mental retardation. In addition, these children are at increased risk for Wilms' tumor. Thus, by making the diagnosis, mental retardation can be prevented by monitoring blood sugar levels, and screening for early diagnosis of the kidney malignancy is possible.

Many genetic diagnoses are made in the laboratory. Cytogenetic analysis performed on a blood sample from a child or adult, or on amniocytes or chorionic villi obtained by prenatal diagnosis leads to the preparation of a karyotype that reveals aneuploidy or chromosomal rearrangements. Chromosome analysis is the most frequently ordered genetic test, since the majority of women who have prenatal diagnosis are age 35 or older and are therefore at increased risk for chromosomal abnormalities such as Down syndrome.

Biochemical assays are available to diagnose many inborn errors of metabolism in individuals and in fetuses. These conditions are primarily autosomal recessive conditions in which the gene product has been identified. For example, an assay to measure the level of α-iduronidase in a child with coarse facial features, hepatosplenomegaly, and developmental delay may lead to the diagnosis of Hurler syndrome. Biochemical assays are also used for carrier detection for rare recessive disorders. In most cases, carrier testing is offered for individuals with a specific ethnic origin who are at increased risk for carrying a gene for a specific condition. For example, carrier testing for Tay Sachs disease among Ashkenazi Jews involves measurement of the level of hexosaminidase A in a blood sample. The accuracy, specificity, and sensitivity of such tests vary; genetic counselors remain current on the standard procedures of this type of testing.

Increasing numbers of genes for inherited conditions have been mapped and sequenced over the last several years. With the completion of the Human Genome Project, the genes for all genetic conditions will be mapped and sequenced. While the goal of the

Human Genome Project is to understand how genes work under normal circumstances, many of these discoveries have resulted in the availability of DNA-based genetic tests. The large number and varied frequencies of mutations in each disease gene result in a range of accuracy for each test. The complexity of the interpretation of DNA test results necessitates genetic counseling that involves an informed consent process and psychosocial counseling before, during, and after testing. Again, as technology changes rapidly, genetic counselors are obligated to remain current on standard clinical tests and to identify appropriate research studies for their patients and families.

Imaging techniques, such as ultrasonography, particularly in prenatal diagnosis, and X-rays for diagnosis of skeletal dysplasias and other syndromes, are often useful in diagnosing specific conditions. The use of ultrasonography in pregnancy to identify fetuses at increased risk for chromosomal abnormality or syndromes that involve structural abnormalities is increasing. Again, genetic counseling to explain the benefits and limitations of ultrasound diagnosis and issues surrounding uncertainty and loss is important to maximize patients' ability to cope successfully.

RISK ASSESSMENT   Many patients seek genetic counseling with the explicit question, "What is the chance that this condition will occur in one of our family members?" or "What is the chance that this will happen again?" Geneticists use a variety of sources to attempt to answer one or both of these questions. While many patients and clinicians believe that arriving at a specific, accurate number to quantify the risk is the information desired, studies have shown that reproductive decisions are more likely to be based on a patient's perception of the burden of the disease, rather than the magnitude of the risk of occurrence or recurrence. Also, the risk must be considered within the context of the patients' lives, including an understanding of how the individual processes numerical values such as percents or ratios. Risk assessment followed by communication is a prerequisite to any type of decision making regarding reproduction or taking genetic tests.

Recurrence or occurrence risks may be calculated by pedigree analysis in which a known mode of inheritance is identified. If two parents are found to be carriers of a recessive gene, then the risk for each future offspring is 25%. This information will affect different couples' reproductive decisions in different ways. Empiric risks are often used when disorders are not caused by single genes, but are polygenic or multifactorial in nature. Empiric risks are derived from studying disease frequencies in a given population. If the data is gathered in an unbiased manner, using appropriate study design, the risk figures provide a sound basis for counseling. However, one must critically evaluate whether such studies are applicable to an individual patient because of differences in ethnic groups, factors that modify gene expression, and whether new developments led to reclassification of disorders that were once thought of as multifactorial.

Calculations based on genetic testing results can also lead to risk assessment that is specific to a particular family. For example, a woman, with a brother affected with cystic fibrosis (CF), and her husband, who has no family history of CF, asked about their risk of having a child with CF. This risk, prior to any testing, is 1/120. The affected brother is found to have two copies of the common dF508 mutation; DNA analysis for the woman revealed that she carries this mutation. Her husband, of Northern European descent, tested negative for 30 common mutations. Since this test detects about 90% of all mutations, his risk of being a carrier is about 1/240. Thus, after testing, their risk to have an affected child is 1/1920, much lower than the *a priori* risk. Again, changes in the detection rates for many DNA tests occur often; genetic counselors must remain aware of new standards in testing and counseling.

PROVISION OF INFORMATION   Genetic counseilng is truly a communication process, designed to answer the concerns of patients and their health care providers about diagnosis, prognosis, and treatment/management options. Genetic counseling can be thought of as a conversation between genetic counselor and the patient and his or her family members. In meeting the needs of patients, genetic counselors often discuss the risk of recurrence or occurrence of a disorder in the patient and/or other relatives. The genetic counselor assesses the patient's emotional and cognitive status so as to present the information in an appropriate manner.

A significant component of genetic counseling involves a discussion of genetic testing as an option for patients. While not all genetic-counseling sessions involve a discussion of genetic testing, genetic counseling should be part of any genetic testing process. Obtaining informed consent for testing includes reviewing the risks, benefits, limitations, costs, ramifications, and accuracy of any genetic test. The genetic counselor must then facilitate the decision-making process regarding testing, based on the patient's response to the informed consent process. If a patient elects to undergo genetic testing, either in the form of prenatal diagnosis of chromosomal disorders by amniocentesis, or in the form of a blood test on an individual, plans are made for the disclosure of results either by telephone or in person.

Once a patient consents to testing, the genetic counselor must disclose test results when they become available. Usually, a genetic counselor will review the possible results and the patient's reaction to each outcome prior to testing. A plan for communicating results either by telephone, mail, or in person is arranged. Finally, the genetic counselor facilitates an exploration of possible options following particular results. Communication, exploration of options, and support for the patient's decision follow the provision of results. Genetic counselors can continue to be resources to the family and referring professionals in such circumstances.

It is standard practice to provide written documentation of the session(s) to the patient and referring physician. This letter or report may also include diagrams or figures that illustrate the information shared with the family. Written communication serves as a record the patient and physician can refer to at a later time; it can also be used to assist in explaining the information with other family members.

PSYCHOLOGICAL ASSESSMENT AND COUNSELING Since most genetic-counseling relationships are short-term, the genetic counselor must assess the psychological state of the patient and family rather quickly and tailor the plan for counseling and testing to meet the patient's needs. A new diagnosis or possible diagnosis often presents a crisis to the patient; the genetic counselor must determine how to intervene in the time of crisis, providing the proper amount and type of information, or planning for a more comprehensive approach at a later date. After establishing a rapport with the patient and family, the genetic counselor elicits the patient's perceptions about the genetic condition, testing, and the genetic-counseling process. The genetic counselor identifies the anxieties, fears, concerns, and hopes of the patient, accomplishing this by assessing verbal and nonverbal cues, and speaking with the patient, family members, and, occasionally, the referring physician.

The diagnosis of a genetic condition, or the realization that a health problem exists, leads to many emotions and reactions for the patient. By providing anticipatory guidance for the possible outcomes of genetic counseling and testing, the genetic counselor assists the patient by exploring issues of loss, grief, and survivor guilt. The genetic counselor can also assist the patient in examining the meaning of the diagnosis or possible outcomes of testing in the context of religious, spiritual, ethical, and cultural beliefs. When a patient faces difficulty in coping with the diagnosis and its implications, genetic counselors will make appropriate referrals to mental-health professionals or to any type of resource that will provide support financially, medically, or emotionally.

SUPPORT FOR DECISION-MAKING AND ONGOING PATIENT SUPPORT   In many genetic-counseling relationships, one goal of the session or sessions is to assist a patient in informed decision making regarding reproductive options, pursuing genetic testing, or acting on a test result. The genetic counselor aims to facilitate decision-making by providing a forum for discussion of the patient's reactions to any and all possible outcomes for each choice. A supportive environment in which a patient or family does not feel judged by the genetic counselor for any option they choose is essential to successful genetic counseling. Once a decision is made, the genetic counselor will facilitate arrangements for the patient to act on the choice. For example, if an asymptomatic son of a man who died of hereditary nonpolyposis colon cancer elects to have predictive testing, the genetic counselor will make arrangements with an appropriate laboratory and arrange for follow-up counseling either in person or on the telephone. In many cases, the genetic counselor can help meet the support needs of patients by making referrals to peer-support volunteers or support groups on a local or national level. Often, patients who learn they have a family history of a genetic condition feel alone, not knowing anyone else with the disorder. While professionals can be supportive, many patients seek the true empathy that only an individual in the same situation can provide. The Alliance of Genetic Support Groups is an excellent resource for providing contacts for this type of support (*see* Table 9-1).

Genetic counselors refer patients to a variety of medical specialists who can provide long-term care or treatment for patients with genetic conditions affecting a variety of systems. Ideally, a multidisciplinary continuity clinic can provide integrated, comprehensive care for such patients. Genetic counselors often serve on these clinic teams; others are aware of such clinics on a local, regional, and national basis. For example, a patient diagnosed with Marfan syndrome would benefit from attending a clinic staffed by specialists in cardiology, genetics, ophthalmology, and medicine. Many institutions have a Craniofacial Clinic at which children are followed and treated by otolaryngologists, orthodontists, plastic surgeons, speech pathologists, and audiologists. When patients are eligible for research protocols for diagnosis, treatment, and management, genetic counselors are excellent resources for referral to such programs.

The experience of loss and related grief occurs with the diagnosis of many genetic conditions, whether or not the disorder leads to the death of an individual or a pregnancy loss. Parents of newborns diagnosed with a genetic condition often grieve the loss of the expected healthy child they had planned for and dreamed about. A woman who learns she has the Huntington disease gene grieves the loss of a healthy future. Genetic counselors maintain relationships by contacting patients by telephone or mail at the time of the anniversary of a diagnosis or at the time a birth would have occurred if a pregnancy loss had not taken place. Plans for follow-up visits are also often made. In some cases, the genetic counselor provides support when seeing a patient or family when there are subsequent pregnancies or when new information on a disorder or test becomes available.

GENETIC TRIAGE: THE GENETIC COUNSELOR/ PRIMARY CARE PROVIDER PARTNERSHIP

Since increasing numbers and types of disorders are being identified as genetic conditions, primary care providers are being faced with questions from patients regarding etiology, risk assessment, and management of genetic conditions. Most practicing physicians, physician assistants, and nurses have had little genetics education during their training or in postgraduate courses and therefore are unable to provide comprehensive genetic services. An important role for primary care providers is to identify patients at risk for genetic conditions and to make appropriate referrals to a genetics center. After eliciting a genetic family history, the primary care provider can consult with a genetics professional for risk assessment and identification of patients who may benefit from genetic counseling and/or testing. The primary care provider can prepare patients for the genetic-counseling process by providing anticipatory guidance, explaining what to expect from the genetics consultation. Genetic counselors maintain ongoing communication with the referring health professional and the patient, informing them of new developments when appropriate. Genetics professionals and the primary care provider will establish a cooperative plan for follow-up, medical management, and support for the patient as needed. For example, a 57-year-old, Ashkenazi Jewish woman, who was diagnosed with breast cancer at age 41, came for genetic-susceptibility testing, learning that she has the common BRCA1 mutation, 185delAG. Her unaffected daughter, age 32, came for risk assessment, genetic counseling, and testing. She was found to have the same mutation, indicating that she has an increased lifetime risk of developing breast cancer. The genetic counselor referred the young woman to her internist with recommendations for surveillance by mammography and clinical breast exam as determined by her physician. The team approach is one used by geneticists and genetic counselors since the beginning of the profession. Genetics professionals usually function as consultants to those who provide ongoing care to the patient.

PROFESSIONAL VALUES OF GENETIC COUNSELORS

The practice of genetic counseling grew out of the medical model, whereby information was provided to patients, followed by advice from the clinician about reproductive choices. This prescriptive advice reflected the clinician's perception of the genetic condition and the burden the disorder placed on an individual and his family. This view has been associated eugenic policies and practices of the early part of this century. However, the eugenic Nazi atrocities led clinical genetics in America away from directive, prescriptive practice. The birth of the genetic-counseling profession was concomitant with the women's movement, the self-help movement, and the reproductive-rights movement. Thus, genetic counselors developed a technique of nondirectiveness with regard to reproductive decision making and prenatal-diagnosis counseling that reflects a respect for patient autonomy. It became obvious that in a situation that involved reproductive decisions,

such as deciding whether or not to continue a pregnancy after a fetal diagnosis of Down syndrome, there was no one right choice for all couples. Therefore, genetic counselors strive to provide information, support, and counseling in a context that is unique for each family. By demonstrating empathy, respect, and unconditional positive regard for their patients, genetic counselors can guide patients and families in understanding their own values, in making decisions that are appropriate for them, and in helping them cope with their grief. Nondirectiveness does not imply that genetic counselors give information, refuse to answer the question posed by many patients, "What would you do in this situation?" and remove themselves from the relationship when difficult decisions need to be made. The role of the genetic counselor is to elicit beliefs, values, and feelings from patients so that they can understand for themselves which decision is best for them. When there is clearly a better option for a couple, genetic counselors are often faced with a dilemma: a conflict of the bioethical principles of respect for autonomy and beneficence. These types of dilemmas are difficult, if not impossible, to resolve since the principles are not assigned varying levels of importance.

Thus, when the National Society of Genetic Counselors (NSGC) considered the format for its Code of Ethics, it elected to draft the Code as an "ethic of care," since this approach emphasizes the interdependence of individuals and best reflects the values, principles, and beliefs of genetic counselors. The relationships are: genetic counselors themselves; genetic counselors and their clients; genetic counselors and their colleagues, and genetic counselors and society. The NSGC Code of Ethics provides guidance and a framework for approaching dilemmas that genetic counselors face in practice. It includes the value of respect for client autonomy as an important focus. Genetic counselors, therefore, function within the health care system as patient advocates who aim to empower patients and families to find solutions to problems and ways of coping that are optimal for them.

GENETIC-COUNSELOR EDUCATION AND TRAINING

In response to the development of amniocentesis for prenatal diagnosis and carrier screening for several recessive conditions, the first master's-level program in genetic counseling was established at Sarah Lawrence College in 1969. By 1977, there were six programs that collectively graduated about 50 genetic counselors per year. These programs had unique curricula designed by faculty at each university. In 1979 a conference was convened to explore the training, role, and function of the genetic counselor. This was the first organized effort to standardize curriculum and training. The recommendations from this meeting have provided the backbone of education for genetic counselors. Some curricular modifications have resulted from the development of new diagnostic technologies in the laboratory, in the clinic, and from genetic counseling research. As the role of the genetic counselor expanded into specialty areas, the curricula changed to address the educational and practice needs of the students. For example, as questions from health professionals and pregnant women regarding the risks of exposures in pregnancy to the fetus arose with increasing frequency, genetic counselors (with their knowledge of birth defects,

embryology, epidemiological literature, and methods for presenting risks in a meaningful way) led the way in developing and staffing Teratogen Information Services. Similarly, as academic clinical molecular genetics laboratories and commercial biotechnology companies developed, their directors recognized the need to have a "customer service representative" for referring physicians and patients. Again, genetic counselors have filled many of these positions because of their skill in bridging the gap between the laboratory and the clinic.

Throughout the 1980s, leaders in the field recommended course topics and approaches to clinical training, yet there were no requirements or guidelines for programs to adhere to. Today, 23 master's-degree-granting programs are accredited by the American Board of Genetic Counseling (ABGC). Approximately 130 new graduates enter the field each year. Graduates of accredited programs must demonstrate proficiency in a wide range of appropriately supervised cases in the form of a log book and letters of recommendation to be eligible to take the ABGC certification examination.*

Each program comprises didactic courses, clinical rotations, academic departmental activities such as case conferences, journal clubs, rounds, and clinical research (optional). Within this framework, each program is unique and reflects the approaches of the faculty and the nature and culture of the patient populations. Each program can guide students in developing these skills in any way it chooses: in the classroom, the clinic, or both. Instructional curricular content must include the following topics:

1. Principles and applications of human genetics and related sciences.
2. Principles and practice of clinical/medical genetics.
3. Methods of genetic testing.
4. Theory and application of interviewing and counseling.
5. Social, ethical, and legal issues.
6. Health care delivery systems/public health.
7. Teaching skills.
8. Research methods.

Curricula and program accreditation are based on each program's ability to support the development of 27 practice-based competencies in genetic counseling drafted by a consensus development team comprised of program directors and the ABGC Board of Directors. These competencies define what an entry-level genetic counselor should be able to do upon graduation from an accredited program. The 27 competencies fall into four skill categories: communication, critical thinking, interpersonal counseling and psychosocial assessment, and professional ethics and values. The competencies are published in the September 1996 issue of the *Journal of Genetic Counseling*.

Graduate programs undergo an accreditation process every 6 years. A written self-study document is reviewed by the ABGC Accreditation Committee and recommendations are made regarding areas to explore during the 2-day site visit. Administrative/institutional support, curricular content and design, clinical training, and student supports are several areas that are explored as part of the accreditation process. Programs are required to submit an annual report to document that the program is remaining in compliance with ABGC requirements.

---

*The 2-part national certification examination includes a general genetics examination taken by all geneticists (doctoral and masters level) and a separate specialty examination in genetic counseling.

The interdisciplinary academic training of genetic counselors is essential if patients' needs are to be met successfully. The integration of course work in genetics, psychology, communication, ethics, and medicine, with supervised clinical experience, is essential for effective practice in the clinic and in society.

10   Transgenic Mice as Models of Disease

T. Rajendra Kumar and Martin M. Matzuk

BACKGROUND

Efforts to manipulate the genome have been the constant pursuit of geneticists since the end of the 19th century. Methods to improve the quality of the species have been practiced and perfected by plant breeders. Induction of random mutations by UV-radiation and consequent screening for interesting phenotypes in bacteriophage or fruit flies have set forth a trend to identify the genetic basis of structural and functional malformations in these organisms. The advent of chromosomal mapping and gene cloning techniques and the availability of breeding data in many animal species have made it possible to selectively manipulate the genomes of species such as mice, rats, pigs, and cattle. This technology, called "transgenic animal" technology, has already revolutionized our current understanding of how organisms develop and how several physiological processes are regulated. In addition, transgenic models have increased our understanding of the genetic basis for many human diseases, including cancer. Although gene manipulation is theoretically possible in many species, the mouse has become the obvious choice for several reasons. Mice are relatively inexpensive to maintain and easy to breed, and an exhaustive store of information is already available on chromosomal mapping and linkage analysis of many genes in the mouse. In addition, micromanipulation of mouse embryos is technically easier and more feasible compared to that of other species.

The manner in which transgenic technology has been used until today and will be used in the future has implications for basic and clinical research. Using essentially the same principles, but with specific modifications in the approach, it is now possible to create mice with precise targeted genetic lesions or generate mice that express any gene product at a designated time and place. As a result, numerous strains of mice have been created to address diverse issues such as early development, organogenesis, growth and differentiation, and the molecular basis of many diseases. In the following sections, we will briefly discuss the principles of transgenic technology and illustrate the efficacy and power of this novel approach by drawing some important examples in several physiological systems.

PRINCIPLES OF TRANSGENIC TECHNOLOGY

Foreign DNA can be introduced into the chromosomal DNA of mice essentially in three ways. The first method, originally devel-

oped years ago, involves the infection of mouse embryos at different developing stages by retroviruses. Because of many technical constraints, this method presents problems for the routine production of transgenic mice. The second method, which has been the most widely used procedure, involves the direct microinjection of foreign DNA into the pronuclei of one-cell fertilized mouse embryos (Fig. 10-1). This results in the chromosomal integration of one or more copies of the injected foreign DNA ("transgene") at a random site, and all cells of the embryo including the extraembryonic tissues will carry the injected DNA, since the injected transgenes usually integrate into the genome prior to embryo cleavage. The injected embryos are then transferred back to foster pseudopregnant mothers, and the offspring eventually are screened for the introduced transgene by standard protocols involving either Southern blot or polymerase chain reaction. The offspring generated are termed founder mice, and lines are eventually generated from these founder mice and maintained for successive generations by breeding to determine the transmission of the stably integrated transgene to the progeny. Because a wealth of information is available on different promoter or regulatory sequences of many genes, it is possible to over- or underexpress a given gene in a cell- or tissue-specific manner. Specific promoters or regulatory sequences can be used to selectively express reporter genes, toxin genes, oncogenes, or antisense constructs, as well as wild-type and mutant genes, in transgenic mice. Promoters can be constitutive, inducible, or even conditionally regulated, depending on the situation. In instances in which cell transfection studies are not possible, transgenic mouse technology can be exploited as a powerful expression system. Promoters containing hormone-responsive elements, enhancers, silencers, and locus-controlling regions can be finely mapped and functionally dissected. By targeting coding sequences of commercially and pharmacologically important proteins using mammary gland-specific promoters, bulk purification of these products is also possible.

The third method for generating transgenic mice is based on a gene-targeting approach in embryonic stem (ES) cells (Fig. 10-2). ES cells are derived from the cells of the inner cell mass of the blastocyst. The ES cells are pluripotent and can contribute to all tissues of the embryo. ES cells can be genetically manipulated in vitro and so-called "gene-targeting" vectors can be used to manipulate DNA at specific loci. The locus to be manipulated can be deleted, and this deletion can span a region as small as a base pair to as large as several megabases. Different types of vectors (insertional or replacement) can be designed, depending on the
Figure 10-1   Production of transgenic mice.

situation. Typically, replacement vectors are used that have positive and negative selectable markers, and sequences homologous to the target gene flank the positive selectable marker. The targeting vector DNA is then introduced into ES cells in culture, and a simultaneous double-selection procedure is used to enrich for the correct homologous recombination event. The negative selection eliminates many of the cells with random integrations. Cell clones that survive the double selection are expanded, and the DNA from these clones is analyzed by the polymerase chain reaction or Southern blot analysis to identify clones that contain the correctly targeted recombinant allele. ES cells carrying the desired mutation are microinjected into 3.5-day-old blastocysts and implanted back into uteri of the foster mice. Most ES cell lines are derived from mice that have an agouti coat color, and the blastocysts are usually collected from mice that have either a white or black coat color. Therefore, when the genetically manipulated ES cells mix with the inner cell mass cells of the injected blastocysts, the offspring are chimeric because of the patchy appearance of these distinct coat colors. The chimeric mice are subsequently mated to wild-type mice to obtain germline transmission of the mutant allele. The heterozygous mice (i.e., mice carrying one copy of the mutant allele) are bred, if viable and fertile, to obtain homozygous null mice (i.e., mice with two mutant alleles). If the mutation is not lethal in embryos, then theoretically 25% of the offspring will be homozygous for the mutation, following a typical Mendelian inheritance pattern.

Recently, it has also been possible to generate "tissue-specific" knockout mice. The mutation in the gene of interest is achieved as described above in ES cells but with insertion of phage sequences called lox sites that flank (f) the region to be deleted. These "flox-mice" are then mated to another line of transgenic mice that harbor a transgene containing the phage Cre protein coding sequences,

driven by a cell/tissue-specific promoter. The Cre protein can excise the gene sequences between the lox sites and thus result in a tissue-specific gene deletion. This method has many advantages in situations where the regular mutation is embryonic lethal or the mice eventually develop multiple defects in several tissues. In this manner, the specific function of a gene product in a given cell type can be studied by loss of function in that cell without affecting its expression in other cell types of the mouse. Alternatively, it is also possible to "knock-in" or replace a different new gene into a locus and disrupt the actual gene at that locus. In the following sections, we will describe the successful application of transgenic technology to study whole-animal biology and the development of mouse models for many human diseases. We will illustrate the functional analysis of each physiological system with a few examples.

APPLICATIONS OF TRANSGENIC TECHNOLOGY

CELL-CYCLE CONTROL   The process of cell multiplication involves a complex series of regulatory steps. Each of these steps is either activated, inhibited, or blocked by several protein kinases, phosphatases, cyclin proteins, growth factors, proto-oncogenes, or tumor suppressor proteins. Gain of function and/or loss of function mutations in the genes encoding these regulatory proteins often will lead to important insights into the origin and/or development of many tumors.

p53 is an important tumor-suppressor protein. It is ubiquitously expressed in mouse and human tissues. Under normal physiological situations, p53 is phosphorylated by cdc2 kinase in a cell-cycle–dependent manner. Thus, activation leads to the binding to and inhibition of a yet unidentified cell-replication protein and prevents the cells from entering the S phase. Mutations and allelic loss of the *p53* gene have been associated with many human tumors. These genetic lesions are frequently observed in spontaneous human cancers. Mutations in p53 are associated with the inherited cancer-susceptibility Li-Fraumeni syndrome in humans. To study the function of p53 in an animal model, mice carrying mutations in one or both copies of the *p53* gene have been generated.

Surprisingly, p53-deficient mice develop normally. Therefore, p53 does not play an essential role in cell-cycle control during embryonic development. However, these mutant mice develop tumors at a very early age with 100% penetrance. The tumors are often derived from multiple cell lineages, suggesting that the loss of growth control is not cell-type-restricted. Mice heterozygous for the mutant *p53* allele also develop tumors, although it usually takes more time to develop these tumors. The analysis of tumors from the heterozygous mice demonstrates that the tumor cells usually lose the remaining wild-type *p53* allele. Heterozygous *p53* mutant mice are more susceptible to tumors when challenged with carcinogens, which supports a role of p53 in DNA damage-response pathways. Because p53-deficient mice are highly susceptible to a wide spectrum of tumors as diverse as sarcomas, lymphomas, choriocarcinomas, and gonadoblastomas, these mice are invaluable for testing suspected carcinogens and cancer therapeutic agents.

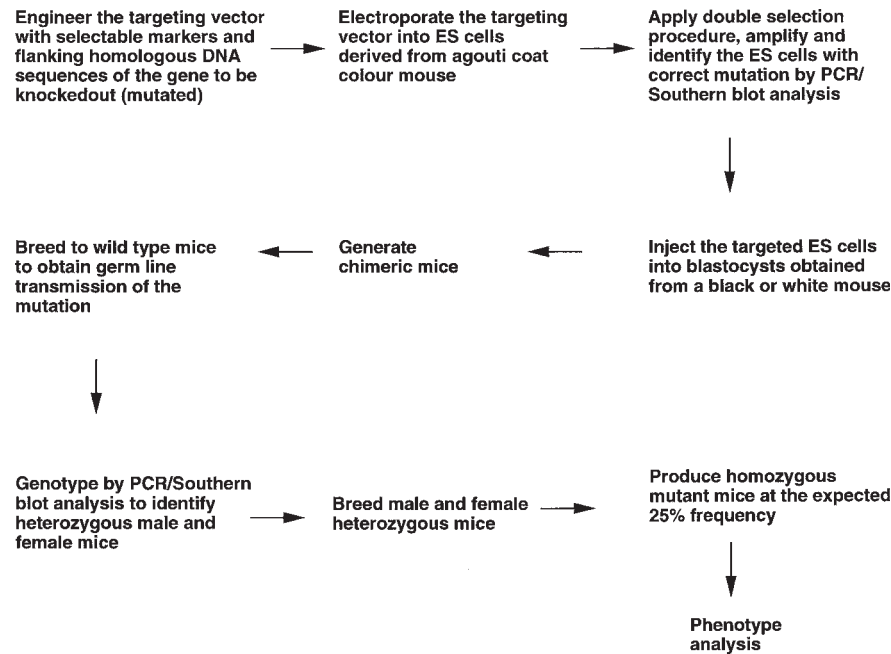
Several proteins are known to interact with p53 under different conditions in a given cell. One of the proto-oncogene products called Mdm2 (named after a gene located on a mouse double-minute chromosome present in 3T3 fibroblast cells) forms a complex with the p53 protein and inhibits the p53-mediated transregulation of gene expression. The human *Mdm2* gene is amplified in 30–40% of sarcomas and is overexpressed in many


Figure 10-2 Production of knockout mice.

leukemic cells. To understand the biological role of Mdm2 during development, null mice have been created. This mutation leads to lethality of the mice between embryonic day 4.5–7.5. In normal mice, both p53 and Mdm2 are ubiquitously expressed on embryonic days 6.0–6.5, and at this point in normal mouse development, there is a sudden increase in cell-cycle rate. To further resolve the issue of whether the embryonic lethality in Mdm2-deficient mice is a result of alterations in Mdm2-mediated gene expression or a loss in the ability of Mdm2 to downregulate p53 activity, double-homozygous mutants for both *Mdm2* and *p53* are generated by intercrossing the corresponding compound heterozygotes. Interestingly, absence of p53 rescues the embryonic lethality in Mdm2-deficient mice. These results indicate that Mdm2 functions normally in development primarily as a downregulator of p53 activity. *Mdm2/p53* double-mutant mice develop normally, are fertile, and they appear phenotypically similar to mice deficient in only p53.

The retinoblastoma susceptibility gene *(Rb)* is another tumor suppressor gene associated with a wide variety of tumor types, including retinoblastomas, sarcomas, and breast, prostate, and lung carcinomas. The inheritance of a mutant form of the *Rb* gene by an individual is associated with a 90% incidence of multifocal, bilateral retinoblastomas. Loss of heterozygosity has been observed at the *Rb* locus in these tumors, confirming that both copies of the *Rb* gene must be mutated for the development of retinoblastoma. Rb protein has been implicated to play key role(s) in cell-cycle control, and the gene is ubiquitously expressed in different cell types. However, homozygous mice with mutations in both *Rb* genes develop to mid-gestation but exhibit defects in the hematopoietic system and central and peripheral nervous systems leading to embryonic lethality. In contrast, heterozygous mice, like humans, exhibit a dramatic predisposition to tumor development with 100% penetrance by 18 months of age. However, the mice do not develop retinoblastoma, indicating that there are species differences in the susceptibility of differentiated cell types to loss of function mutations in *Rb*. Instead, these heterozygous mice develop multifocal tumors of the intermediate lobe of the pituitary gland and demonstrate elevated serum levels of α-melanocyte-stimulating hormone.

It is now feasible to consider using mice with specific genetic mutations as an assay system for the identification of tumor-suppressor genes because the effects of such targeted mutations in either known or unknown genes can be directly tested in vivo. For example, using this principle, inhibin has been shown to be the first secreted tumor-suppressor protein with specificity restricted only to the gonads and adrenals. Inhibins are heterodimers (α:β), which belong to the transforming growth factor (TGF)-β superfamily. They share the β-subunits (βA- or βB-subunits) with activins. Inhibins were originally discovered as Sertoli and granulosa cell products that had FSH-suppressing activity. These peptides are also expressed in other tissues outside the reproductive tract. Mice deficient in the α-subunit of inhibin are viable, indicating that inhibin is not essential for embryonic development. However, between 5 and 20 weeks, both male and female mice deficient in inhibin develop hemorrhagic and bilateral gonadal sex cord-stromal tumors with nearly 100% penetrance. As the tumors progress, they secrete high levels of activin, leading to a human-cancer cachexia-like wasting syndrome in the mice with hepatocellular necrosis and weight loss leading to eventual death. In contrast, gonadectomized, inhibin-deficient mice survive beyond 20 weeks but develop adrenal cortical tumors and also die of a similar wasting syndrome. These knockout mouse studies have provided an excellent opportunity to examine similar human gonadal tumors for mutations in the inhibin α-subunit gene, which was not previously envisioned.

DEVELOPMENTAL BIOLOGY Highly programmed molecular events triggered by the process of fertilization between the mammalian sperm and egg lead to distinct layers of cells and pattern formation in the embryo. The changing topography of the body axis during normal development eventually results in organogenesis. Mutations affecting critical events associated with early

embryogenesis may result in severe deformities of the developing embryo at distinct steps or even embryonic lethality. Several human mutations affecting the fetus have been described, and many interesting lines of mutant mice have been generated with the aim of dissecting the critical molecular events during early embryogenesis. Numerous genetic manipulation studies on fruit flies, zebrafish, and *C. elegans* have paved the way to identify homeobox genes and other related pattern-regulating genes. Many of these genes encode transcription factors involved in organogenesis, body axis determination, and distinct layer formation. The corresponding mouse homologs have been identified, and mice with mutations in these genes have been created and characterized. In some cases, these critical factors have been ectopically expressed to follow the cell fate and consequences of this aberrant expression.

Cleft palate is a commonly occurring craniofacial developmental disorder in humans. It has been possible to identify some of the critical factors during craniofacial development by generating different strains of mutant mice. For example, the majority of the mice that are deficient in activin βA, a member of TGF-β family, develop cleft palate, tooth defects, and lack of whiskers. Some of the mice that do not have cleft secondary palate exhibit either incomplete or complete failure of hard-palate formation. As a result, these mice cannot nurse and die perinatally. Similarly, mice deficient in follistatin, an activin-binding protein, also exhibit cleft palate and have hard-palate defects. In addition, mice that are deficient in a transcription factor MSX-1 display similar phenotypic characteristics. Thus, using transgenic mice, one can verify the in vitro observations in an in vivo context and also draw conclusions on the involvement of several factors in a common pathway controlling a physiological process.

Several lines of transgenic mice have also been created to study embryonic formation of limbs, notochord, different brain regions, musculoskeletal structures, and body-axis. Mice with mutations in the presumptive "mesoderm-inducers" have also been generated. It has been possible to dissect out the early developmental events in the formation of virtually every organ system using transgenic mice. A few examples are given below.

The *Wnt*-1 (*int*-1) proto-oncogene, which encodes a putative signaling molecule, is expressed exclusively in the developing central nervous system (CNS) and adult testes. To test the presumptive function of Wnt-1 in mammalian neural-tube organization and patterning role in CNS development, Wnt-1 null mice have been generated. These mice develop to term but die within 24 h after birth as a result of abnormal brain development. Most of the neural tube and nonneural tissues appear normal. However, as early as embryonic day 14.5, a substantial portion of the midbrain fails to develop. This includes a large contiguous domain, comprising approximately the caudal two-thirds of the midbrain, the normal midbrain-metencephalic junction, and rostral metencephalon. Thus, for the first time, using an in vivo approach, it has been established that Wnt-1 acts as a determinant for the development of a specific region of the CNS.

Defining and understanding the nature of vertebrate organizers in molecular terms have been among the fundamental issues in embryology. Toward this end, several putative DNA transcription factors that are expressed in the organizer region have been identified in *Xenopus*, chick, and mouse. The Lim 1 transcription factor is the mouse homolog of xlim-1 in *Xenopus*, which is expressed in the node, the developing kidney, and portions of the CNS. Lim-

1-deficient mice lack head structures anterior to the optic vesicle but develop the remaining body axis normally. The mutant embryos lack forebrain and midbrain because of the absence of an organized node, head process, and prechordal mesoderm by embryonic day 7.5. Some mutant embryos develop a partial anterior secondary axis as a result of a disrupted early organizing region. By embryonic day 10.5, most of the embryos die but a few "headless" pups (4/1000) are delivered stillborn. These mutant mice also lack kidneys and gonads. Thus, using knockout mouse technology, the requirement of Lim-1 in head-organizer formation has been clearly confirmed.

Combinatorial interactions between products of clusters of Hox genes direct regional development in the embryo. Hox genes encode transcriptional regulators that contain sequence-specific DNA binding motifs called homeodomains. Mutations in most of these genes often result in homeotic transformations. In the mouse, four clusters of Hox genes exist that are homologous to the *Drosophila* homeotic complex. Both gain-of-function and loss-of-function mutations in these genes have been created in transgenic mice. These experiments have demonstrated that Hox genes act as key selector genes and have led to the "Hox code"-hypothesis, in which several Hox genes control the specification of regional identity (i.e., they control the formation of the anteroposterior body axis and secondary axis of the limb). By either overexpression or deletion of a particular set(s) of Hox genes, it has been possible to specify and demarcate the boundaries of expression of each gene during development and determine the consequences of such a perturbation.

One of the models developed to establish the specific role of a *Hox* gene in a specific cluster has been to introduce *Hoxb-4* mutations into the mouse germline. Hox genes are organized in tightly linked clusters with poorly understood and complex mechanisms of transcriptional regulation. Because the conventional "replacement" gene-targeting strategy introduces exogenous sequences that may affect transcription of the *Hox* gene cluster and disrupt normal regulation at several important genetic loci, genetic subtle mutations have been engineered into the *Hoxb-4* locus. Hoxb-4 is a member of the Hoxb cluster on mouse chromosome 11. Hoxb-4 is first expressed at embryonic day 8.5 from the posterior end of the prospective spinal cord and eventually the anterior limit at the boundary between rhombomeres 6 and 7 in the hindbrain. In addition, Hoxb-4 is widely expressed in tissues including spinal ganglia, the nodose ganglion of cranial nerve X, prevertebrae up to the second cervical vertebra or axis (C2), and in mesodermal components of lung, kidney, and gut. Mutant mice that harbor a disrupted first exon of *Hoxb-4* show two obvious skeletal changes—a partial homeotic transformation of C2 from axis to atlas and a defective morphogenesis of the sternum. These phenotypes are variable in penetrance and expressivity depending on the genetic background. Mice generated from ES cells that are engineered to have a premature stop codon in the second exon, by an insertion of a oligonucleotide using the "hit-and-run" method, also show partial homeotic transformation of axis to atlas; these mice, however, do not show abnormalities in sternum. Whereas only a portion of the first-category mice survive to adulthood, mice that carry the second type of mutation are viable, healthy, and fertile. These experiments illustrate that ES cell technology can be effectively used to introduce subtle mutations into the mouse genome, and this can be used as an assay system to study their effects on functions of complex clusters of *Hox* genes. Selected

genetic crosses between individual mutant mice belonging to individual clusters give important clues to the combinatorial interactions that operate among these key regulatory molecules.

MUSCLE BIOLOGY A distinct set of transcription factors called myogenic basic helix-loop-helix (HLH) factors have been implicated in the regulation of skeletal-muscle differentiation. These include MyoD, Myogenin, Myf-5, and Myf-6/MRF-4. Each of these factors, when ectopically expressed in nonmuscle cells, can activate the skeletal-muscle differentiation program. Each factor can induce other factors, including a number of skeletal muscle-specific genes. Null mutations in each of these factors have been introduced into the germline of mice. Further, mice with multiple genetic lesions in these factors have also been obtained by breeding. It has been possible to formulate a hierarchical network of interactions involved in the program of muscle differentiation based on the functional analyses on these mutant mice.

Mice deficient in MyoD are viable and show no skeletal-muscle abnormalities. The inactivation of this gene causes a twofold increase in *Myf5* mRNA expression, whereas *myogenin* and *MRF4* levels are not altered. Myf-5-deficient mice also develop normal skeletal muscle, but die at birth because of the absence of the distal parts of the ribs, which leads to breathing problems. Double-mutant mice that lack both MyoD and Myf5 produce no detectable skeletal-muscle-specific markers (skeletal-actin, troponin T, and so on) and appear to lack skeletal myoblasts, suggesting that both of these factors function similarly in myoblast formation. Mice lacking myogenin have normal numbers of skeletal myoblasts at birth, but show a severe reduction of skeletal-muscle fibers. Both MyoD and Myf5 are expressed in undifferentiated myogenic cells, suggesting that they act earlier in development than myogenin. MRF4-deficient mice show only a slight reduction in a subset of muscle-specific genes. Consistent with the in vitro observations that MRF4 downregulates the expression of myogenin, myogenin levels are elevated in adult skeletal muscle from MRF4-deficient mice. Surprisingly, MRF4-null mice exhibit multiple rib abnormalities, possibly through an indirect mechanism affecting the rib primordia.

Duchenne muscular dystrophy (DMD) is an X-linked recessive disease in humans caused by defective expression of dystrophin. Progressive skeletal-muscle weakness and wheelchair confinement are the most obvious symptoms of DMD. Most patients die of respiratory failure resulting from progressive atrophy of the diaphragm. There is a naturally occurring mutant mouse strain called the *mdx* mouse that has been identified. This mouse has a point mutation that eliminates the expression of the 427-kDa muscle and brain isoforms of dystrophin. These *mdx* mice do not display muscle weakness or impaired movement, but the diaphragm muscles show progressive myofibre degeneration and fibrosis similar to the human condition. Transgenic mouse technology has demonstrated the feasibility of gene therapy for DMD. High-level and tissue-specific expression of a full-length murine dystrophin was achieved in transgenic mice by using the regulatory regions of the mouse muscle creatinine kinase gene, and the transgene was introduced into the *mdx* genetic background by crossbreeding. The transgene positive *mdx* mice show complete correction of the dystrophic pathology in skeletal muscles and the diaphragm as assessed by both functional and immunohistochemical tests. It is now feasible to generate viral vectors that encode the full-length human dystrophin to treat and/or cure human patients with DMD.

HEMATOLOGY/IMMUNOLOGY The most thoroughly studied aspects of mammalian physiology using transgenic technology are perhaps the immune and hematopoietic systems. Both by conventional microinjection techniques and using ES cell technology, mutant mice have been generated that either overexpress or lack cell-specific transcription factors, immune cell-specific light chains, the recombination-associated proteins, receptors for antibodies, MHC antigens, and immune cell-specific growth factors (lymphokines/ cytokines). Because many human disorders involve aberrations in hematopoietic/immune systems, these mice serve as excellent models to understand and treat these human disorders. Mice that lack an important component of these systems often are more prone to many microbial diseases and are often sensitive to immediate and/or delayed hypersensitivity reactions. These transgenic mice can be effectively used to screen for the efficacy of various anti-inflammatory drugs and other chemotherapeutic products and are also useful models in transplantation biology.

β2-microglobulin is a 12-kDa polypeptide and is associated with the heavy chain of the polymorphic MHC class I proteins encoded by the H2-K, H2-L/D, and Qa/Tla loci. One of the first mouse models generated using ES cell technology involved the targeted disruption of the β2-microglobulin gene. Mice deficient in β2-*M* microglobulin were generated to precisely understand its biological function. These mice are normal and fertile but have no mature CD4$^-$CD8$^+$ T cells in either the thymus or peripheral lymphoid organs and are defective in CD4$^-$CD8$^+$ T-cell-mediated cytotoxicity. Although it was widely believed that γδ T cells interact with class-I molecules, this subset of cells develops normally in these mutant mice.

TGF-βs are homodimeric peptides that control a wide variety of cellular processes such as cell proliferation, differentiation, embryonic development, extracellular matrix formation, bone development, wound healing and hematopoiesis, and immune and inflammatory cell response. Three distinct TGF-β genes (*TGF-b1*, *-b2*, and *-b3*) have been identified in mammals. The three mammalian TGF-βs are structurally highly similar (75% identity at the amino acid level) and are often coexpressed and colocalized in a spatiotemporal manner. Many additional functions are also attributed to TGF-βs based on in vitro observations. Obviously, to delineate the individual functions of these peptides, gene-targeting approaches have begun to be employed. Approximately 50% of TGF-β1 null mice show no gross developmental abnormalities. By 3–4 weeks of age, however, these viable mutant mice succumb to a wasting syndrome and die. All mutant mice exhibit a marked but variable degree of mixed inflammatory cell infiltration and tissue necrosis in multiple organs. Many of these lesions resemble those found in human autoimmune disorders, graft vs host diseases, and some viral diseases, and suggest that the TGF-β1–deficient mice are an important model to study these diseases.

Gene-targeting approaches have also recently helped to understand the molecular basis of human inflammatory bowel disease (IBD). These studies have led to the unexpected discovery that mice with deletions in genes encoding specific cytokines and T-cell receptor subunits develop chronic intestinal inflammation. In humans, IBD manifests as a chronic, noninfectious, inflammation limited to the large bowel, known as ulcerative colitis, or as a granulomatous inflammation anywhere along the gastrointestinal tract, known as Crohn's disease. Several lines of evidence suggest that human patients with IBD are hyperresponsive to nor-

mal gut constituents. Mutant mice that are deficient in T-cell receptor (TCR)-α, TCR-β, both TCR-β/δ, or class II major histocompatibility complex all develop chronic intestinal inflammation. This intestinal disorder resembles ulcerative colitis but without ulceration or bleeding. These mice have normal number of B cells but lack class II-MHC-restricted CD4+ αβ T cells. It was hypothesized that, in the absence of a tolerance to dietary or microbial antigens, an autoimmune attack on the intestinal epithelium results in the inflammatory response. This suggests that the αβ T-cell-mediated suppression of B cells does not occur in these mice.

Interleukins are cytokines of the immune system. Interleukin-2 (IL-2) is produced by activated T cells. It is a key regulator of immune and inflammatory responses. T-cell proliferation in vitro, differentiation of B cells, activation of macrophages, and NK cells are all dependent on IL-2 signaling. IL-2–deficient mice at 4 weeks of age develop normal thymus glands, with unaltered thymocyte and peripheral T-cell subset composition. The in vitro responses to T-cell mitogens on isolated T cells from these mice are reduced. The differentiation of B cells is affected in these mice, with a drastic increase of serum levels of immunoglobulin (Ig) G1 and IgE. IL-2–deficient mice beyond 6 weeks of age develop an IBD similar to ulcerative colitis in humans. These mice develop ulcerations and bloody diarrhea, and the mucosa and submucosal tissue of the large bowel shows pronounced thickening. Crypt abscesses are found, and the epithelial layer shows loss of goblet cells. Similar to IL-2–deficient mice, mice with a gene deletion in *IL-10* also develop mucosal inflammation. However, the inflammation in these mice is restricted to the villi. The crypt is associated with pseudopolyps and villous atrophy. These mice show elevated levels of interferon-γ. The intestinal disease in these mice may result from the absence of a suppressive effect of IL-10 on macrophage production of inflammatory cytokines. However, these knockout mouse models are not identical to patients with IBD, because IBD patients have T cells and produce IL-2 and IL-10. However, the mouse models elucidate that T-cell abnormalities could be the cause of many forms of intestinal inflammation. These mice may also prove useful in testing the involvement of other genetic and nongenetic factors in the etiology of human IBD.

PULMONARY BIOLOGY   Transgenic mouse technology has successfully been used in four major aspects of pulmonary biology research. First, the molecular mechanisms controlling epithelial-cell gene expression have been determined. Second, the cellular interactions that contribute to lung morphogenesis and maturation have been elucidated. Third, models that may be clinically relevant for developing new strategies for therapy have been developed. Fourth, functional analysis of genes by targeted expression or mutation and their consequences in lung growth and development has been undertaken.

The respiratory-cell epithelium produces distinct gene products, including surfactant proteins A, B, and C (SP-A, B, C), clara cell secretory protein (CCSP) or uteroglobulin. The most exhaustively studied genes are *SP-C* and *CCSP*. Expression studies using transgenic mice have identified that a 3.7-kb human SP-C promoter contained the necessary elements to drive a chloramiphenicol acetyltransferase reporter gene correctly to bronchiolar and alveolar respiratory epithelial cells. The same promoter has been used to express diphtheria toxin-A chain in transgenic mice. These mice die immediately after birth as a result of cytotoxic lesions of the respiratory epithelium induced by the diphtheria toxin expression. Similarly, to study lung epithelial-mesenchymal interactions in

vivo, transgenic mice have been created that express human TGF-α under the control of the 3.7-kb *SP-C* promoter sequences. These mice develop marked pulmonary fibrosis, exhibit increased collagen deposition, and demonstrate disruption of elastin fibers. Two other mutant strains of mice have been created with lung-specific promoter sequences. In one case, a dominant negative FGF-receptor mutant is expressed in transgenic mice, and in the second case, SV40 large T-antigen expression is directed from the 5' flanking sequences of the uteroglobin gene. While the mice expressing the former transgene die of respiratory failure similar to the 3.7-kb SP-C diphtheria toxin-A-bearing mice, the latter mice die because of the development of pulmonary adenocarcinoma. These models are highly useful for the study of molecular pathogenesis and therapy for adenocarcinoma of the lung in humans.

Transgenic mice have also been created to study the human disease cystic fibrosis. Cystic fibrosis is the most common fatal autosomal-recessive disorder, affecting about 1 in 2500 newborns. The disease is characterized by defective chloride transport in epithelial cells leading to excess mucus secretion. Meconium ileus, or intestinal blockage, is also a diagnostic feature of the disease. Associated defects include pancreatic insufficiency, malabsorption in the gut, chronic opportunistic lung infections, and reproductive tract defects. To develop mouse models, both insertional mutagenesis, which disrupts exon 10 of the *CF* gene, and a replacement-type vector to delete the same exon, have been employed. The cystic fibrosis transmembrane regulator *(CFTR)* mutant mice demonstrate many similarities in their pathology to human patients. The majority of mutant mice die from intestinal perforation and peritonitis following intestinal blockage. This is primarily caused by dehydrated secretions in the crypts of the intestine. The pancreatic effects seen in humans are not recapitulated in mice, however. Pathological changes in the respiratory tract of mutant mice mimic those in humans-goblet cell number increases, gland ducts in the nasal and proximal trachea dilate, and destructive changes in the upper-airway epithelia occur. Interestingly, there are no reproductive defects in male mice that survive to the adult stage, but female mice show infertility.

Mice deficient in N-*myc* proto-oncogene exhibit markedly slow growth rates in embryonic lungs, resulting in hypoplastic lungs at birth. Targeted disruption of a novel homeobox gene, *Gsh*-4, similarly results in neonatal respiratory failure in the mutant mice. The expression of *Gsh*-4 mRNA is confined only to the CNS, suggesting that the mice die as a result of a respiratory-center failure in the brain at birth. Both of these mouse models have provided previously unanticipated results demonstrating the power and the advantage of transgenic mouse technology to establish novel functions of known gene products.

CARDIOVASCULAR BIOLOGY   Hypertension and atherosclerosis are the most common human disorders. Many transgenic animal models have been developed to study cardiovascular function. Cardiovascular function is dependent on a multitude of hormones, regulatory peptides, and cell-signaling pathways, in addition to the genetic background. Only a few candidate genes have been identified thus far, and many quantitative trait analyses are being performed to identify loci that control cholesterol levels in mice.

Antidiuretic hormone (ADH) is a nona-peptide synthesized in the hypothalamus as a precursor and later transported to and stored in the posterior pituitary. The major endocrine function of ADH is to increase reabsorption of water in collecting ducts of the kidney. ADH also increases blood pressure by constricting the arterioles.

Absence of ADH results in diabetic insipidus, a common human disease with problems of water retention. Surprisingly, transgenic mice that chronically express a preproarginine vasopression, by using a metallothionein promoter, have a mild nephrogenic diabetes insipidus.

Atrial natriuretic peptide (ANP) is released from the heart in response to cardiac atrial stretch. This peptide is also involved in sodium balance. It is highly concentrated in the preoptic and median eminence areas within the CNS. A 10-fold overexpression of ANP by using a *transthyretin* promoter in transgenic mice resulted in lowered blood pressure without affecting the electrolyte balance. ANP has been implicated to mediate its natriuretic and vasorelaxant effects through the guanylyl cyclase-A (GC-A) receptor. Approximately half of all humans with essential hypertension are resistant to salt. However, a gene defect for this phenotype has not been described. Recently, GC-A gene knockout mice have been generated. As a result of this mutation, these mice have chronic elevations in blood pressure when placed on a normal diet, and even in response to either minimal or high-salt diets, the blood pressure remains elevated and unchanged. Aldosterone and ANP concentrations are not affected in these mice. Therefore, mice with GC-A mutations can be useful models to study some salt-resistant forms of essential hypertension in humans.

The renin-angiotensin system is a major regulator of blood pressure and sodium and volume homeostasis. Transgenic mice that overexpress the rat or human renin or angiotensin genes develop high blood-pressure levels. Recently, knockout mice have been generated to systematically address the issues of hypertension in relation to the angiotensin system. Mice carrying one, two, three, or four functional copies of the murine *angiotensinogen* gene at its normal chromosomal location have been created by gene targeting. These mice demonstrate plasma angiotensinogen levels corresponding to the number of gene copies they carry (i.e., mice with four copies show 145% elevated levels compared to one-copy animals). Accordingly, the blood pressures also show significant and linear increases in each of these mice. These elegant experiments have established a direct causal relationship between angiotensinogen genotypes and blood pressure.

Atherosclerosis and other lipid-associated disorders are very common in humans. There are four major types of plasma lipoproteins—chylomicrons, very low-density lipoproteins (VLDL), intermediate density, and low-density lipoproteins (IDL and LDL), and high-density lipoproteins (HDL). These are synthesized either in liver or intestine. The lipid-free protein components of plasma lipoproteins are termed apolipoproteins. These are represented by five major types (A, B, C, D, and E), and some of them also can be categorized further into subtypes, for example, A-I, II, IV and C-I, II, III. The coordinated network of interactions between these complexes and the corresponding receptors regulates cholesterol homeostasis in blood.

To mimic human atherosclerosis in mice, several candidate genes have been either overexpressed or knocked-out in transgenic mice. Apolipoproteins A-I (apo A-I) is the major protein associated with HDL. It is synthesized in the liver and small intestine. Apo A-I serves as a cofactor for the enzyme lecithin-cholesterol acetyltransferase that catalyzes cholesterol ester formation. Human individuals deficient in apo A-I because of various types of mutations are more prone to developing atherosclerosis. The human *apo AI* transgene has been genetically transferred into the atherosclerosis-susceptible inbred mouse strain C57BL/6. This results in elevated levels of apo A-1 and HDL and correction of atherosclerosis. Mice that are deficient in apo A-1 have low levels of HDL cholesterol, but interestingly, do not develop atherosclerosis when supplemented with an atherogenic diet. This suggests that low levels of HDL may only predispose, but low HDL does not by itself, accelerate atherosclerosis. Transgenic mice that overexpress apo E do not show atherosclerotic plaques, even when fed a high-fat diet. In contrast, apo E-deficient mice accumulate VLDL and remnant particles in plasma. Young mice lacking apo E that are fed a low-fat diet develop atherosclerosis similar to that seen in humans. Transgenic mice that overexpress dominant apo E mutants have also been generated. These types of mutations are associated with a dominant form of type III hyperlipoproteinemia in humans. Mice overexpressing these mutant forms of apo E develop hypertriglyceridemia and hypercholesterolemia. Finally, the "familial hypercholesterolemic mouse" has been developed by knocking-out the LDL-receptor gene. These mice have elevated cholesterol levels and demonstrate delayed plasma clearance of VLDL and LDL. When placed on an atherogenic diet for prolonged time, the mice develop extensive fibroproliferative atherosclerosis and thus are a useful model to study human disease. In contrast, high levels of LDL-receptor expression in transgenic mice results in eight times faster clearance of blood LDL than normal. This has exciting possibilities of genetically correcting some human familial hypercholesterolemia syndromes caused by LDL-receptor defects.

Mutant mice with gene deletions in the endothelial receptor tyrosine kinase *tek* die in utero. These mice have defects in the integrity of endothelium and show abnormalities in heart development. These in vivo studies have identified that the tek signaling pathway plays a critical role in the differentiation, proliferation, and survival of endothelial cells in the mouse embryo. Vascular-system defects are the major phenotypic characteristics in mutant mice that lack ras GTPase-activating protein. The ras family consists of small guanine-nucleotide-binding proteins that are known to participate in normal- and oncogenic-signaling pathways. Four GTPase-activating proteins (GAPs) specific for ras proteins have been identified. These function as negative modulators of ras activity. One of the proteins, p120-ras GAP, interacts with various proteins, including tyrosine kinases, through its src-homology 2 (SH2)-binding domains. Mutant mice that lack this important biological signaling protein die by embryonic day 10.5. These embryos have a reduced number of somites and show a failure in reorganization of endothelial cells into a vascular network. The mutant embryos also exhibit a thinning of the dorsal aorta and aberrant ventral branches. In later stage mutants, local ruptures in the embryonic vasculature result in leakage of blood into the body cavity. At this stage, the pericardium is distended. These mutant mice have provided important insights into the understanding of the molecular mechanisms involving the interactions between SH signaling proteins and downstream targets of tyrosine kinases.

RENAL BIOLOGY Kidney development requires the coordinated differentiation of two distinct tissues, the ductal epithelium and the nephrogenic mesenchyme. Both of these tissues are derivatives of the early embryonic-intermediate mesoderm. The ductal epithelium gives rise to the genital tracts, ureters, and collecting duct system. The mesenchymal components undergo epithelial transformation to form nephrons, the functional unit of the kidney. The nephron consists of the renal corpuscle and proximal and distal tubules, which are derived from the metanephric blastema.

Mutations in genes expressed during kidney development have been created using transgenic mice technology. The phenotypes of these mutant mice, in many cases, resemble many of the well-known human renal disorders. The most striking phenotype of the Wilms' tumor *(WT)*-1 gene knockout mouse is the absence of kidneys. WT-1 encodes a protein with a proline/glutamine rich N-terminal domain and with four Cys-His zinc fingers at the C-terminal domain. Germline mutations in *WT-1* gene are associated with human urogenital malformations and a childhood kidney tumor called Wilms' tumor. Mutant mice that are deficient in WT-1 protein die at embryonic day 11.5. At this stage, the metanephric blastema cells undergo cell death, and the embryos show a failure in ureteric bud growth and an absence of the inductive events, which lead to the formation of a definitive kidney. Whereas human individuals with the WAGR (Wilms' tumor, aniridia, genitourinary, and mental retardation) syndrome, with retention of one functional copy of the *WT-1* gene, are predisposed to develop kidney tumors, *WT-1* heterozygous mutant mice are normal. This situation is reminiscent of the absence of retinoblastomas in *Rb*-heterozygous mice as described above.

Abnormal kidney development is also seen in mutant mice that lack either the ligand, platelet-derived growth factor (PDGF) B or its cognate receptor PDGFβ-R. In both cases, the kidney glomerular tufts do not form because of the absence of mesangial cells, and there are also cardiovascular defects. Failure of kidney mesenchymal-epithelial interactions is also obvious in bone morphogenetic protein-7 (BMP-7) mutant mice. BMP-7 is a member of the TGF-β superfamily. BMP-7 is expressed in the kidney at the time of the earliest inductive event. BMP-7–deficient mice die within 48 h of birth as a result of small dysgenic kidneys with hydroureters. The kidneys show a severe reduction in the number of glomeruli, lack identifiable metanephric mesenchyme, and do not show any evidence of glomerular formation in the cortical region. At embryonic day 14.5, all mesenchymal derivatives are absent in the mutant embryos. The expression of the early markers in kidney development, for example, WT-1 and Pax-2, are either reduced or completely absent in BMP-7–deficient embryos. These studies have thus identified BMP-7 as an early glomerular inducer. The BMP-7 mutant mice may also be a useful animal model to dissect the genetic pathway for several human genetic diseases accompanied by impairment of glomerular formation.

Recently, a prostaglandin synthase-2 gene knockout mouse model has been created that accurately mimics the human congenital renal disease called oligomeganephronia. This condition is characterized by small kidneys with reduced number of nephrons. The glomeruli and tubules are hypertrophied, and the kidneys eventually develop focal segmental glomerular sclerosis. These mice will be important models for studying human oligomeganephronia.

Transgenic mice have been generated using glomeruli-specific promoters driving the expression of SV40 T antigen. These mice develop tumors of the glomeruli, and cell lines derived from these tumors are useful for studying renal-cell biology in vitro. Transgenic mice that express a constitutively activated allele of the human c-erbB2 growth factor receptor gene under the regulatory control of a MMTV-LTR promoter develop hyperplastic lesions in kidney, in addition to defects in other organs. In the kidney, multifocal, severe hyperplasia of renal tubules appear that may lead to microcyst formation. Within the tubules, the epithelial cells show atypical proliferation into the intraluminal compartment. The morphology of these cells also shows dramatic changes, with increased cell volume and enlarged nuclei.

Renal cysts also appear in transgenic mice that chronically overexpress TGF-α under the control of a metallotheionein (MT) promoter. TGF-α is a member of the epidermal growth factor (EGF) family of proteins. Like EGF, TGF-α binds to the EGF receptor and elicits its cellular function. In human autosomal-dominant polycystic kidney disease, EGF and its stimulation have been implicated to cause this renal pathology, and thus the MT–TGF-α transgenic mice may be mimicking the human pathology.

NEUROBIOLOGY   One of the challenging areas of research in present-day modern biology is to understand the development of the mammalian nervous system. Many naturally occurring mutant mice provide excellent models to study human disorders associated with this complex system. The identification of many neuronal cell-specific genes that encode receptors, neurotransmitters, growth factors, surface antigens, and structural proteins has resulted in generation of a vast array of transgenic and knockout mice strains. These aid in understanding many neurological diseases like Prion disease, Alzheimer's disease, poliomyelitis, many myelination disorders, leukodystrophy, Amylotropic lateral sclerosis, peripheral neuropathy, Down's syndrome, Parkinsonism, and many others. Transgenic mice that express viral oncogenes in specific neural-cell types are excellent sources of generating immortalized cell lines. In addition, the development of mouse models has made it possible to probe into the early developmental aspects of the nervous system. Generation of transgenic and knockout mice for neurotrophins and their receptors has helped to obtain a clearer picture of the factors necessary for survival of many types of neurons. Transgenic and mutant mice are also currently being extensively used to explore the genetic basis of complex behavioral patterns and cognitive functions such as learning and memory. Numerous mouse models are already available for understanding the development and function of special sense organs; for example, the eye, ear, and skin. Transgenic-mouse models that mimic many human neurodegenerative disorders have been developed. We will give examples of mouse models for neurodegenerative disorders in the following section.

Amyotrophic lateral sclerosis (ALS) in humans is a degenerative disease of motor neurons. It is characterized by accumulation of neurofilaments in the perikarya and proximal axons. Neurofilaments (NF) belong to the intermediate filament family, are approximately 10 nm in diameter, and show polymorphism depending on the cell type. Transgenic mice that overexpress the human NF-heavy-subunit gene *(NF-H)* show neuropathological symptoms close to those seen in human patients. These include neuronal and axonal swellings of α motoneurons and dorsal root ganglion cells, distal axonopathy, and secondary muscular atrophy. The L5 ventral roots from NF-H transgenic mice at old age reveal massive degeneration of large axons derived from spinal motor neurons. Metabolic labeling experiments and ultrastructural analyses on these mice have provided valuable insights into the mechanism of neurodegeneration resulting from disorganized neurofilaments. Most importantly, there are dramatic defects in axonal transport of neurofilaments, tubulin, and actin. Ultrastructural analysis on these mice indicate significant reduction of mitochondria in the degenerating axons. Because this affects the energy metabolism, neuropathy may result in these mice. Similar phenotypic characteristics are also apparent in some human familial ALS cases induced by mutations in the superoxide dismutase gene *SOD-1* and in transgenic mice that express a mutant form of

human *SOD-1*. The NF-H transgenic-mouse model, therefore, provides an important assay system to test drugs that are capable of downregulating neurofilament expression and consequently help to devise therapeutic approaches to treat human ALS.

Huntington's disease (HD) is a dominant neurodegenerative disorder. Typical symptoms of the disease include chorea, psychiatric alterations, and intellectual decline. The disease results from the presence of an expanded stretch of CAG trinucleotides (37–40 U) in one copy of the gene encoding huntingtin. It is a ~350-kDa cytoplasmic protein with unknown biological function, found in fetal and adult peripheral tissues and nervous system. Because the CAG repeat, when translated, elongates the N-terminus of huntingtin protein by a polyglutamine segment, it may reduce the normal activity of the protein. However, humans with one copy of the normal gene inactivated because of translocations do not develop HD. Similarly, a loss of function or a gain of function mutation in huntingtin *(Hdh)* leading to HD may also exist. To assess these possibilities, the mouse *Hdh* gene has been inactivated by gene targeting. Heterozygous mice are viable, fertile, and display no phenotypic abnormalities, similar to individuals with translocations. The homozygous *Hdh* mouse embryos implant normally, exhibit abnormal gastrulation at embryonic day 7.5, and resorb by day 8.5. These results suggest that Hdh is critical for embryonic development in mice, before the emergence of neural tube, presumably between embryonic days 8.0 and 8.5. Because the Hdh inactivation does not lead to the development of Hd neuropathology, this suggests that the human disease involves a gain of function. These experiments now open up the possibility of generating an accurate model of HD by producing transgenic mice that carry the Hdh with an expanded polyglutamine segment. A similar strategy has recently been adopted by generating a mouse model for another neurodegenerative disorder, called spinocerebellar ataxia-1 (SCA-1). SCA-1 is an autosomal-dominant inherited adult-onset human neurologic disorder characterized by loss of Purkinje cells in the cerebellar cortex and neurodegeneration within the brain stem and spinocerebellar tracts. Both the human and mouse *SCA1* genes have been isolated and genetically mapped. Whereas the human gene normally has 6–40 CAG repeat units, the mouse homolog has only two CAGs. The human gene encodes a protein called ataxin-1 with 792–826 amino acids, depending on the number of glutamine residues. It is expressed in a variety of both neuronal and nonneuronal cell types and can be localized to nucleus and cytoplasm, respectively. In contrast, in cerebellar Purkinje cells, ataxin-1 has both nuclear and cytoplasmic localization. To study the intergenerational stability of trinucleotide repeats in mice, the human *SCA-1* gene with normal or an expanded CAG tract containing 30 or 82 repeats, respectively, has been introduced into the mouse germline under the regulatory control of Purkinje cell-specific gene *Pcp2* sequences. Several lines of heterozygous mice carrying the human transgene have been obtained. Some lines are bred to homozygosity. Transgenic mice that carry the normal human *SCA1* allele are neurologically normal even after 1 year of age, indicating intact Purkinje cell function. In contrast, as early as 8–10 weeks of age, transgenic mice that carry the expanded repeats show slightly reduced cage activity, a gentle swaying of the head while walking, and early signs of general incoordination. By 16–30 weeks, these mice become clearly ataxic when walking. The onset of the neurological abnormalities and ataxia phenotype vary in independent 82-repeat-transgenic lines, without any correlation to the mRNA

levels of the transgene. Those lines of mice that show earliest onset of ataxia tend to have the most severe neuropathologic disease. Typical phenotypic characteristics include significant loss of Purkinje cell population, with Bergmann glial proliferation, and shrinkage and gliosis of the molecular layer. These mice also show numerous ectopic Purkinje cells in the molecular layer, sometimes in the granular layer, and abnormal dendritic arrays. Heterozygous 82-repeat-transgenic mice do not show ataxia symptoms but display only mild cerebellar pathology. These mice do not show loss of Purkinje cells or gliosis, but exhibit only occasional Purkinje cells in both the molecular and granular layers. In humans, CAG repeats in the expanded range are subject to intergenerational instability, but those in the unexpanded range are stable. Eighty-two CAG repeat-containing *SCA-1* transgenic mice show no variation in repeat length with parent-to-offspring transmission. These results suggest that the mechanisms of DNA repair, replication, and the higher order structure of chromatin may be important factors in determining the CAG repeat instability in humans. Irrespective of the molecular mechanisms that control CAG repeat instability, this in vivo transgenic approach has successfully resulted in the generation of a mouse model that phenocopies the human SCA-1 disorder. These mice may also be amenable for further manipulation to devise therapeutic strategies and for targeting SCA-1 transgene expression to different tissues within the CNS. In addition, loss of function mutations can be engineered into the murine SCA-1 locus to explore its biological function during normal development of the mouse.

Po is a cell-adhesion protein that belongs to the immunoglobulin (Ig) superfamily of recognition molecules. It contains only one variable-like Ig-related extracellular domain. Members of this family have been implicated in cell migration, axon outgrowth, fasciculation, and myelination. The other mammalian members of this neural-cell-adhesion molecule superfamily include neural-cell-adhesion molecule (N-CAM) proteins, L1, and MAG. Each of these molecules can exhibit both homophilic or heterophilic interactions, and their signal transduction pathway includes regulation of cytoskeletal and second-messenger systems. Po is uniquely expressed by myelinating Schwann cells of the peripheral nervous system during the first 3 weeks after birth and accounts for almost 60% of the protein in the peripheral myelin sheath. These characteristic features have been taken into consideration in generating the Po-deficient mouse model. The mutant mice exhibit lack of normal motor coordination, tremors, and occasional convulsions. The peripheral nerve axons show severe hypomyelination and degeneration. Many of the molecules involved in myelination are abnormally regulated in Schwann cells of the mutant mice. These results suggest that Po is essential for the normal spiraling, compaction, and maintenance of the peripheral myelin sheath and for the continued integrity of associated axons. In addition, these Po mutant mice may help to decipher the molecular mechanisms of genetically transmitted peripheral neuropathies in humans.

Although the above-mentioned mouse models mimic human neurodegenerative disorders, the initial efforts to develop a useful transgenic mouse model for the fatal Alzheimer's disease have not been successful. However, several attempts have been made to develop such a mouse model. Alzheimer's disease (AD) is an irreversible neurodegenerative disorder that affects the human CNS. The disease is characterized by massive deposition of fibrillary aggregates, intracellularly as neurofibrillary tangles, extracellularly as amyloid plaques. Patients with Down's syndrome

also show similar pathological symptoms. Principally, the plaques are deposited in parenchyma of amygdala, hippocampus, and neocortex. The human β-amyloid protein (Aβ) is derived from the amyloid precursor protein (APP), encoded by at least 18 exons located on chromosome 21. Four distinct transcripts of APP premRNAs are generated by alternate splicing. The rationale for developing an APP overexpressing mouse model is based on the fact that AD may be initiated or accelerated by high levels of APP. In addition, high levels of APP have been observed in Down's syndrome patients. Unfortunately, most of the transgenic mice that harbor several copies of human APP cDNA do not show any pathological symptoms of AD. Only in one case, in which the expression of a human APP cDNA is driven by a mouse metallothionein promoter, have behavioral changes been noticed.

Because in many instances, the introduction of foreign cDNA does not result in high levels of transgene expression, a different strategy has been used to derive APP transgenic mice. A yeast artificial chromosome (YAC) containing 400-kb human APP gene and approximately 250 kb of flanking sequences has been transfected into mouse ES cells. These cells have been used to generate transgenic mice that retain the APP-YAC transgene with stable integration and transmission. These mice show high levels of human APP mRNA and protein in brain and peripheral tissues. In particular, human APP is expressed in cell bodies of neurons in the hippocampus, neocortex, and cerebellum in a 3-month-old APP YAC transgenic mouse. Surprisingly, this mouse also does not show any AD-type pathology.

While transgenic mice that express human APP cDNAs or gene (through YAC) do not show any AD symptoms, recently two other mouse models have been generated to understand the AD pathology and to explore the normal function of APP in mouse. The first model is a transgenic-mouse model in which the mouse Aβ expression is restricted to only neuronal cells by using 1.8 kb of 5' flanking sequences from the mouse neurofilament-light (NF-L) gene. This promoter is transcriptionally active throughout adult life. Several independent lines overexpressing this NF-L–transgene have been generated. Although transgene expression is also seen in peripheral tissues, only brains from these mice show pathological changes. Similarly, in humans, even though Aβ deposits are seen in skin and intestine without much clinical consequence, the CNS is the main target of the APP toxicity. At least three independent lines of transgenic mice show extensive neuronal degeneration. *In situ* hybridization analysis suggests that apoptosis is the predominant cause for this degeneration. These mice also show reactive gliosis. Over 50% of the transgenic mice die by 12 months of age. However, the mice do not show neurofibrillary tangles and senile plaques characteristic of human AD. It may be possible that factors required for plaque formation in humans may be absent in mice. Nevertheless, this model is important in understanding the APP toxicity and the mechanisms of apoptosis that lead to neuronal-cell death and degeneration.

Lastly, to understand the physiological function of APP, the mouse *APP* gene was disrupted by insertion of a premature stop codon in exon 2 in ES cells, and mutant mice have been generated from these ES cells. Homozygous mutant mice continue to express the *APP* mRNA in brain and other tissues, although at 5- to 10-fold lower levels than wild-type mice. This could possibly result from skipping of the disrupted exon during splicing. A shortened β-APP–specific protein has also been detected in low levels in different regions of brain. These mutant mice show severe impairment of spatial learning and exploratory behavior. Most strikingly, these mice show an increased incidence of agenesis of the corpus callosum. Although the original goal of generating a true APP null mouse has not been produced here, this model does help to understand the normal physiological function of APP during mouse development.

ENDOCRINOLOGY Mouse models for human hypothalamic-pituitary disorders, thyroid disorders, pancreas disorders, and adrenal disorders have, in general, been useful for analysis of the endocrine function in mammals. Transgenic mice that overexpress either growth hormone (GH) or growth hormone-releasing hormone (GHRH) are excellent models for both acromegaly and hyperprolactinemia, common endocrine disorders in humans. MT-GH transgenic mice are historically one of the earliest mouse models developed and were used to correct a genetic defect in the dwarf *little* mouse. The little mouse, a naturally occurring mouse strain, shows a deficiency of GH, which causes its short stature. Several MT-GH fusion genes have been injected to generate transgenic mice that overexpress growth-hormone mRNA in several tissues and consequently elevated serum-GH levels. These mice show accelerated growth rates. When the transgene is introduced into the "little" background, the phenotype is rescued, and fertility is also restored.

Using cell ablation techniques in transgenic mice, the development of somatotropes, lactotropes, and thyrotropes can be suppressed. These experiments have clarified the lineage relationships and identification of common progenitor cells for these types of anterior pituitary cells. A similar strategy has also been helpful to study proopiomelanocortin (POMC) producing corticotropes and melanotropes. Transgenic mice that express the SV-40 T antigen oncogene, driven by a human α-glycoprotein hormone or a rat POMC promoter sequences, develop anterior and intermediate lobe of pituitary tumors, respectively, and have provided novel cell lines to study the function of these cell types.

Transgenic mouse models for analyzing the etiology of human type-I diabetes have been useful in the validation of the current hypothesis on the human disorder. Essentially different types of transgenes have been targeted to β cells of the pancreas to selectively destroy these cells. Transgenic mice in which the autoimmune response is evoked in pancreatic β cells by induction of MHC antigens develop diabetes accompanied by a selective loss of these cells. To mimic the typical autoimmune response in β cells, transgenic mice have been created that express a viral protein in pancreatic islet cells. Because the virus shares some antigenic epitopes common to mouse proteins, the immune response generated against the viral proteins also destroys the β cells. As a result, these mice develop diabetes. Although this model is useful in understanding the pathogenesis of human type-I diabetes, it differs from the human disease in two aspects. First, the presence of virus is required to elicit the response in mice, whereas in humans, the autoimmunity is maintained by endogenous β-cell-specific proteins. Second, the β cells are destroyed at a rapid rate in the mouse model unlike in the human situation, where the disease process is rather prolonged. Finally, transgenic mice that express a rat-insulin promoter-SV40 oncogene sequences develop heritable pancreatic β-cell tumors. They have β-cell hyperplasia and elevated serum insulin levels. The α and δ cells of the islets of Langerhans are disordered, and their number is drastically reduced in the pancreatic tumor tissue. These mice develop highly vascularized solid pancreatic tumors that cause

premature death of the mice around 9–12 weeks of age. This animal model has become invaluable in studying the biogenesis of islet cells, cell–cell interactions within the endocrine pancreas, and understanding of the pathobiology of human insulinomas.

The three pituitary glycoprotein hormones—namely, luteinizing hormone (LH), follicle stimulating hormone (FSH), and thyroid stimulating hormone (TSH)—are heterodimeric proteins. They share a common α-subunit that is noncovalently linked to a hormone-specific β-subunit. Whereas LH and FSH control gonadal functions, TSH regulates thyroid function. Mice deficient in the glycoprotein hormone α-subunit (α-GSU) have been generated by gene targeting in ES cells. These mice are viable, but exhibit growth insufficiency and are hypothyroid and hypogonadal. The thyroids are hypoplastic and contain small disorganized follicles. The animals are infertile and show lack of some secondary sexual characteristics, although the sex organs differentiate normally. Within the pituitary, the thyrotropes exhibit hypertrophy and intensely stain for TSH-β subunit antibody. The gonadotrope cell population is normal, whereas both somatotropes (GH expressing cells) and lactotropes (prolactin-expressing cells) are reduced and absent, respectively. Absence of α-GSU does not affect the distribution and appearance of gonadotropin-releasing-hormone (GnRH) neurons that migrate to different regions of the hypothalamus. Experiments with these mice have thus established the physiological functions of these important trophic hormones in mammalian growth and differentiation.

REPRODUCTIVE BIOLOGY The hypothalamic-pituitary-gonadal axis, commonly known as the reproductive axis, is regulated by a complex network of interactions between neuropeptides, trophic hormones, gonadal steroids, and peptides and growth factors. Distinct genes encoding several critical factors are activated during the establishment of the primitive reproductive axis, functional maturation of the gonads, and maintenance of their differentiated function. Disruption of any key step may lead to aberrant reproductive function and may even cause sterility as demonstrated in the analysis of several transgenic and knockout mice. Still, many mouse models are currently being generated to understand human infertility and associated disorders to test and design novel strategies for contraception. These many transgenic models have been extensively summarized elsewhere, and we will only discuss a few models related to sex determination.

Mammalian sex differentiation is dependent on interactions between several factors. The early molecular events that dictate the choice between the pathways of male and female sex-organ development in mammalian early embryo are poorly understood, including those in humans. Several genetic lesions have been characterized in humans that affect this complex pathway. Successful application of the transgenic-mouse technology in recent years has given important clues toward identifying functions of regulatory molecules that control the sexual-differentiation process. Most important among these are transcription factors including WT-1 (described in an earlier section) and steroidogenic factor-1 (SF-1), SRY, and Mullerian inhibiting substance (MIS), a member of the TGF-β superfamily. Gene deletions of WT-1 or SF-1 by homologous recombination in ES cells and generation of knockout mice show drastic phenotypes. Absence of either WT-1 or SF-1 results in failure of development of the gonads. Transgenic mice that express SRY, a testis-determining gene, demonstrate testis formation in XX females. The function of MIS in mammalian reproductive development has been elucidated both by gain-of-function transgenic mice that chronically overexpress MIS and by an MIS knockout mouse model. Absence of MIS in males prevents regression of the Mullerian duct, and therefore male mice develop uteri and testicular Leydig cell hyperplasia.

METABOLIC DISORDERS Metabolic defects most often result from an accumulation of a substrate because of absence or reduced activity of an enzyme, often causing formation of a toxic side product or absence of an important product for a subsequent enzyme reaction. Such defects can cause life-threatening problems during childhood or adulthood. There are many transgenic-mouse models available to investigate the pathogenesis and to evaluate therapeutic approaches for such human diseases. Some of the transgenic mice that are useful models in understanding these human metabolic disorders are discussed below.

The Lesch-Nyhan syndrome in human males is a rare neurological and behavioral disorder. The disorder is caused by an inherited deficiency in the level of activity of the X-chromosome–linked purine salvage enzyme hypoxanthine-guanosine phosphoribosyl transferase (HPRT). Hemizygous mutant male mice have been generated that carry a mutation in the HPRT gene. Interestingly, these mice are viable and normal. No gross neurological symptoms have been apparent in male mice. Even though these mutant mice do not show any metabolic, neurological, or behavioral symptoms characteristic of the human syndrome, the basic principles of gene-targeting technique were originally developed during the creation of this animal model.

Urate oxidase, or uricase, is a purine metabolic enzyme. The enzyme catalyzes the conversion of uric acid to allantoin in most mammals. In humans and other primates during evolution, deleterious mutations in the urate oxidase gene resulted in the loss of this enzyme. Therefore, the sparingly soluble uric acid is the end product of purine metabolism in humans, instead of a more soluble allantoin. Because humans lack urate oxidase, they are predisposed to metabolic disorders, such as gouty arthritis and renal stone formation, as a result of elevated uric acid levels. To understand the biological function of urate oxidase in lower mammals and to develop an animal model for human hyperuricemia, knockout mice have been created by gene-targeting techniques. Approximately 65% of mice deficient in urate oxidase die at 3–4 weeks of age. Both serum and urinary uric acid levels are elevated 10- and 5-fold higher, respectively, in mutant mice compared to wild-type control mice. Consistent with the biochemical action of the enzyme, mutant mice show a decrease in urinary allantoin content. Urate oxidase-deficient mice show small cortical cysts and white yellow deposits of uric acid in both kidney cortex and medulla as early as 6 days after birth. With the progression of the deposition, the mice show kidney tubular degeneration leading to severe hydronephrosis at 5 weeks. This eventually results in glomerular atrophy and occurrence of chronic inflammation within the kidney interstitium, similar to acute hyperuricemia nephropathy in humans. Similar to human patients, urate oxidase-deficient mice, when treated with allopurinol, an inhibitor of xanthine oxidase, show dose-dependent reduction in serum uric acid levels. Although urate oxidase is absent in humans, most humans do not develop hyperuricemia at a young age and do not show increased mortality, unless in conjunction with other environmental and genetic factors. However, generation and analysis of urate oxidase knockout mice resolved the long-standing debate on the biological function of urate oxidase in mice and other lower mammals that retain it.

DERMATOPATHOLOGY   The application of transgenic technology to skin research has resulted in many advances in our understanding of skin development and function. The skin is a complex organ system. It consists of two different layers, epidermis and dermis, derived from ectoderm and mesoderm, respectively. Cells of the outermost layer of the epidermis, called periderm, continually undergo keratinization and are replenished by cells arising from the basal layer that lies beneath. The fully developed epidermis consists of five distinct layers—stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum, and stratum germinativum. The epithelial cells of the epidermis are called keratinocytes. They produce important proteins that regulate the epidermal–dermal interactions.

The epidermis has been the major target for several gene-manipulation studies. The epidermis exerts its protective function through an extensive cytoskeletal network. The major structural components of this network are called keratins. Keratins are members of the intermediate filament (IF) superfamily. They are α-helical proteins that can assemble into 10-nm filaments. Based on amino acid sequence, keratins can be subdivided into two groups—the acidic, type I, keratins and the basic, type II, keratins. Type I keratins include K9–K20 and are in the molecular-weight range of 64–40 kDa, whereas type II keratins include K1–K8 and weigh 67–53 kDa. Heteropolymeric combinations of type I and type II can result in the formation of 10-nm filaments. Proliferating basal cells express K5 and K14 mRNAs, and they differentiate in the first suprabasal layer, inducing the expression of K1 and K10. During the wound-healing process and in cultured epidermal cells, K6 and K16 are induced. Many of the human and mouse keratin genes and other epidermal-specific genes have been isolated and characterized in detail. This structural analysis has led to the design of many transgenic and knockout mice to understand cutaneous development and functions including hair development and skin cancer.

Epidermolytic hyperkeratosis (EHK) in humans is a dominantly inherited disorder of keratin, characterized by hyperplasia of the stratum corneum. Mutations in highly conserved regions of K1 and K10 genes have been identified in patients with EHK. Transgenic mice expressing a mutant form of K1 have been generated. Most of the homozygous mice with two copies of the mutant transgene die within 24–36 h after birth resulting from progression of skin erosions. Similar to EHK patients, the spinous layer shows many clear cells that have clumping of keratin filaments around the nucleus. Mice that survive to the juvenile and adult stage do not show suprabasal epidermal splitting (blistering) in their back skin, but their footpad epithelium, which lacks hair follicles, show cell lysis and splitting in the spinous layer, similar to human EHK disorder. Hyperkeratosis is also seen in mice deficient in follistatin, an activin-binding protein. Both granular and stratum corneum layers show increased thickness in these follistatin-mutant mice.

Psoriasis is a hyperproliferative inflammatory skin disorder in humans. Approximately 2% of the world's population is affected by this skin disorder. Transgenic mice that express either human integrin β1-subunit or heterodimers of β1- and α2- or β1- and α5-subunits in the suprabasal layers of epidermis exhibit a phenotype that resembles the human disorder. Integrins are extracellular matrix receptor proteins; three types are expressed by epidermal keratinocytes. They share a common β-subunit. The α2β1 complex is a collagen receptor, and the α3β1 is a laminin receptor; both of these are expressed in normal epidermis. The α5β1 is the keratinocyte fibronectin receptor and is upregulated during wound-healing, in psoriasis, and in cultured keratinocytes. Normally, integrin expression is confined to the keratinocytes in the basal layer of the epidermis. Since their expression is often seen in suprabasal layers during wound-healing and in psoriasis, integrin subunits are targeted to this layer in transgenic mice, using a suprabasal layer cell specific promoter called involucrin. Several lines of mice have been obtained that express each of the integrin subunits, α2, α5, and β1, separately. Subsequently, β1 transgene-bearing mice have been mated to α2 or α5 mice to generate mice that express the heterodimers. A majority of the α5, β1, and α5β1 transgenic mice have defects in eyelid closure, hair, and whisker development. The eyelids noticeably fail to fuse prior to birth, and often an inflammatory exudate in the cornea and eyelid is apparent. The hair of the coat does not display a uniform orientation, with disorganized follicles, and the whiskers are short and curly. These phenotypic features are characteristic of those seen in many other mutant mice in which the growth factor signaling is disrupted. For example, activin/inhibin βB knockout mice display eyelid-closure defects. Similarly, TGF-α and EGF receptor-deficient mice and BMP-2, BMP-4 overexpression transgenic mice exhibit abnormal skin development. In mice deficient in activin βA-subunit, the whisker follicles differentiate in a delayed manner, with abnormal hair papilla and irregularly positioned cells at the base of the hair bulb. These observations are all consistent with the fact that growth factors regulate integrin levels in keratinocytes and may explain the consequences of perturbances in integrin expression during embryonic development. The β1 alone or β1α2 or β1α5 integrin–transgenic mice also show the typical features of psoriasis (i.e., increased keratinocyte proliferation, abnormal differentiation, increased dermal mitoses, capillary dilation, and an influx of CD4+ and CD8+ T-lymphocytes). The abnormal keratinocyte development and inflammation in these mice result in flaking of the epidermis on the chin, behind the ears, reddening of skin and paws, and pustule formation on dorsal-skin surface. Consistent with the belief that psoriasis in humans is influenced by several genetic and environmental factors, all transgenic mice that express the integrin subunits do not show the symptoms. Thus, the transgenic technology has provided important answers to the understanding of the etiology of psoriasis. These mice have a potential as important models in the treatment of psoriasis using immunosuppressive agents.

Recently, gene-targeting approaches have been used to create knockout mice to mimic the human disease xeroderma pigmentosum (XP). XP is a rare autosomal disease in humans, resulting from a defective nucleotide excision repair process. It is characterized by hypersensitivity of the skin to sunlight and a very high risk of skin-cancer incidence in body parts exposed to sunlight. There are eight complementation groups in XP (A–G and a variant form). Mice deficient in XPC are viable and fertile and do not exhibit an increased susceptibility to spontaneous tumor generation. However, following 10 d of UV exposure, the ears of the mutant mice exhibit marked atrophy. By 20 weeks of exposure, they develop skin cancers of different types. Most of these belong to the squamous-cell carcinoma category. These mice also show epidermal hyperplasia with focal areas of hyperkeratosis and varying degrees of dysplasia, acantholysis, and/or dyskeratosis. The UV treatment of the mutant mice also results in keratitis and corneal ulceration of the eye. The spectrum of these phenotypic features are characteristic of human XPC. Similar to XPC-deficient mice, mice deficient in XPA also are viable and fertile and are highly susceptible to chemical and UV-induced skin carcinogenesis. These mice also develop squa-

mous-cell carcinoma and eye defects. These knockout mouse models are useful in two ways. First, they can be used to understand XP disorders, and cells from these mice can be used to study the molecular mechanisms of nucleotide excision. Second, sensitive short-term in vivo carcinogenicity of genotoxic agents can be tested using these excision repair enzyme-deficient mice.

CONCLUSIONS AND FUTURE DIRECTIONS

Transgenic animal technology has become highly popular in recent years. The primary reasons are because this is an in vivo manipulative approach, and the specificity with which a target gene can be expressed makes it an extremely powerful approach. Virtually every physiological system has been and will continue to be investigated from a developmental and functional perspective (i.e., both physiological and pathological). In many instances, the clinical data and the naturally occurring mutant strains of mice complement the efforts on gene-manipulation research.

What can we envision in future with this technology? Animal species such as goat and cattle can routinely be used as bioreactors to produce pharmacological products in high quantities. The functional redundancies or specificities between close members of a superfamily can be resolved by breeding and generating mice with combinations of mutations in distinct or unrelated pathways. Large-scale deletions that mimick many human chromosomal haploidy situations can be created in mice, and thus sets of genes on a specific chromosome can be identified structurally and functionally. The "cre-lox" system will be used in many cases to generate tissue-specific knockout mice. Many mouse models will be generated to address the genetic basis for the complex issues of behavior, learning, and memory. The potential possibilities of generating ES cells from species other than mouse and rat can be anticipated. The rapid pace with which the genome-mapping data are being accumulated in parallel will set a continued pace to identify and define the biological functions of many newly discovered genes. The final goal is to generate cheap, convenient, and easily manipulative animal models that exactly reflect many human-disease conditions. Both human health and health-care management will thus benefit richly from this fascinating technology.

11 Molecular Cardiology

An Overview

ANTHONY ROSENZWEIG

Not too long ago a textbook section entitled "Molecular Cardiology" would have seemed curiously paradoxical and impractical. Molecular biology appeared to have little to do with either clinical cardiology or even its scientific foundations. Classical large animal physiology experiments provided insights that were readily extrapolated from the laboratory to the bedside. In contrast, the clinical relevance of molecular biology seemed remote. This perception is changing because of the substantial progress made in applying the tools of molecular biology to cardiovascular biology and medicine.

An imperfect measure of these changes is reflected in the number of papers published in these fields over the past 30 years. Acknowledging that the number of papers published in all fields has burgeoned, some insight may be gained from comparing the relative changes in publications related to cardiology, molecular biology, or the intersection of these disciplines (Fig. 11-1). As one might expect, the number of publications in molecular biology has increased over 30-fold during this period, which has witnessed the genesis of many important technologies under this general umbrella. The number of papers in cardiology has also increased over this period by approximately fivefold. However, the number of papers over the past 30 years within what might be termed "molecular cardiology" has increased nearly 75-fold, perhaps reflecting the growing realization of valuable connections between these two fields.

Molecular biology provides a set of powerful tools that can be brought to bear on clinical and scientific problems. These tools are rapidly elucidating the molecular basis of many clinical phenomena. One example highlighted by Dr. Michel in Chapter 15 is the identification and molecular cloning of the enzymes responsible for production of endothelium-dependent relaxing factor (EDRF), now recognized as nitric oxide (NO). Absence or dysfunction of endothelial cells results in less NO production. This is recognized in the catheterization laboratory as a paradoxical vasoconstrictive response to acetylcholine that dilates normal vessels through an endothelium-dependent mechanism. Such an abnormality is seen both in atherosclerotic vessels and patients with risk factors for atherosclerosis even in the absence of angiographically demonstrable lesions. Identification of the nitric oxide synthase (NOS) genes responsible for NO production has permitted a demonstration of their role in vascular tone homeostasis. Such studies form the essential foundation for future analysis of the role of NOS and other regulators of vascular tone in a variety of cardiovascular conditions, including hypertension and atherosclerosis.

Molecular technologies that are particularly relevant to the clinical arena include molecular genetics, generation of genetic animal models, and somatic gene transfer. The exponential increase in available genetic markers has dramatically hastened analysis of monogenic disorders. Genetic analysis of such disorders is of immediate interest to clinicians because of its the potential to provide both diagnostic and prognostic insights. These themes are echoed repeatedly throughout this section in chapters on congenital heart disease, cardiomyopathies, arrhythmia, and hypertension. In Chapter 12, Dr. Chin reviews the growing list of genetic defects linked to congenital heart disease. Furthermore, he illustrates the importance of animal models for understanding the molecular basis of cardiac development, especially in relationship to congenital heart disease. Although standard genetic models are limited for congenital heart disease, there is great potential in the study of mutant zebrafish. Clinicians are occasionally skeptical of such studies both because the animals studied seem so far from clinical experience and because even human monogenic conditions represent only a small subset of a broad clinical spectrum of sporadic and polygenic disorders. However, both genetic animal models and mendelian conditions provide a rare window of opportunity for observations that can have much broader relevance. In addition, identification of disease-causing mutations can illuminate unanticipated molecular functions or interactions. Admittedly most of the cardiovascular diseases encountered routinely by clinicians result in fact from a complex interaction between multiple genetic loci and superimposed environmental influences. Using hypertension as an example, Drs. Koike and Jacob (Chapter 16) illustrate evolving approaches to understanding the genetic bases of polygenic disorders. Surprisingly, little is known about the genetic basis of most coronary artery disease, despite the prevalence of the phenotype. It is likely that approaches similar to those described by Drs. Koike and Jacob will shed light on the genetic bases of this problem as well.

Somatic gene transfer is of interest not only as a potential experimental tool for the development of local overexpression models, but also as a vehicle for somatic gene therapy. Gene therapy within the cardiovascular system has been broadly defined to include not only replacement of a defective gene but also overexpression of a beneficial gene product. This approach to gene therapy within the cardiovascular system differs from gene
Figure 11-1 Relative number of papers published 1966–1995. The MEDLINE database was searched using BRS Colleague to identify papers published between January 1966 and December 1995. Papers were identified as relating broadly to cardiology (contain the word "heart" or the root "cardi-"), molecular biology (contain the word-root "gene-" or "molecul-"), or molecular cardiology (falling into both categories). For each group, the number of papers was normalized to the initial reference period (1966–1970), which is arbitrarily assigned the value 1. The number of papers in subsequent 5-year periods is displayed relative to this initial reference period. ■, cardiology; ◆, molecular, ●, molecular cardiology.

Figure 11-2 Absolute number of papers published 1966–1995. The MEDLINE database was searched as described for Fig. 11-1. Here the absolute number of papers published in each 5-year period is shown graphically for each of the three categories as defined previously. ■, cardiology; ◆, molecular; ●, molecular cardiology.

replacement therapy in other disciplines in several important ways. Access to the target tissue is often more difficult than in other systems, and may require specific catheter delivery systems. In addition, the target cells for gene transfer within the cardiovascular system (endothelial cells, vascular smooth muscle cells, or cardiomyocytes) replicate either slowly or not at all and are notoriously resistant to gene transfer techniques. These limitations have sparked interest in viral vectors to achieve acceptable efficiencies in vivo. On the positive side, gene therapy for several potential cardiovascular applications (such as restenosis) has the advantage that transient expression of beneficial gene products may be sufficient to mediate significant clinical benefit. Drs. Vassalli and Dichek discusses the status of cardiovascular gene therapy in Chapter 18.

The potential power of molecular approaches to clinical cardiology is perhaps best illustrated in the evolving story of hypertrophic cardiomyopathy, recounted by Dr. Seidman et al. in Chapter 13. This clinically important, often familial condition has been recognized for approximately 30 years. However, the fundamental etiologies remained obscure. The Seidman laboratory first established genetic linkage for this condition in several large affected families. They then went on to identify disease-causing mutations in multiple genes, including cardiac myosin, troponin T, and tropomyosin. This work has had important implications for our understanding of hypertrophic cardiomyopathy and basic muscle biology. The clinical prognosis of patients with this condition is dramatically affected by the specific mutation they carry. As one might expect, more conservative mutations, in general, carry a better prognosis than more radical alterations. In addition, these genes all participate in forming the sarcomere, and elucidat-

ing the genetic abnormalities responsible for the clinical phenotype will likely continue to provide insights into their molecular functions and interactions.
The genetic analysis of the long QT syndrome (LQTS) discussed by Dr. London in Chapter 17 is a similar evolving success story, which also illustrates the potential synergism between basic and clinically focused research. The LQTS is an uncommon but life-threatening condition. Afflicted individuals suffer high rates of syncope and sudden cardiac death. The condition is clinically and genetically heterogeneous. Genetic pedigree analysis has implicated three ion channel genes in the condition. Simultaneously, basic investigation has substantially advanced our understanding of the contribution of these channels to the cardiac action potential. We are just beginning to realize the substantial promise of synergism between these fields. For example, one recent report suggests it may become feasible to tailor pharmacological therapy to the individual LQTS genotype. Specifically, patients in whom LQTS is due to delayed inactivation of the sodium channel benefit from mexiletene, which decreases inward sodium current. In contrast, in patients in whom LQTS is due to reduced function of a potassium channel, no benefit is seen with mexiletene. It should be noted that this particular potassium channel was initially cloned as a homolog of a mutant drosophila gene not then known to be relevant to cardiovascular disease. Further evidence that the dividends of basic research are far-reaching and difficult to predict.

The ability to manipulate putative disease-causing genes in the germline of mice allows such genetic analysis to be brought full-circle, and provides an invaluable animal model for analysis of pathophysiology and potential therapeutic interventions. Altering cardiac expression of ion channels in mice through germline manipulation has improved our understanding of the molecular basis of the cardiac action potential and offers promise of animal models of arrhythmia in general as well as LQTS in particular.

This may well become the paradigm for future investigation in molecular medicine: genetic analysis of human conditions providing the basis for development of genetically manipulated animal models. Those models, in turn, provide a unique opportunity to

return to the fundamental physiologic focus with which cardiovascular investigation began. The dog lab of the past may be supervened by the mouse lab of the future to allow analysis of physiology and pathophysiology with full advantage of the power of modern genetics. Moreover, such models will likely become the optimum testing ground for pharmacological or genetic therapies.

It is clear that clinical cardiology has only begun to feel the impact of these advances in molecular biology. Although, as pointed out earlier, there has been a dramatic increase in the relative number of papers published in "molecular cardiology," these papers still constitute an exceedingly small minority of the absolute number of papers published in either cardiology or molecular biology as a whole (Fig. 11-2). The transformation has only begun. It is likely that the most dramatic changes lie ahead. The chapters in this section provide a glimpse of a revolution very much in progress, but whose repercussions have yet to fully impact clinical cardiology.

12 Congenital Heart Disease

Alvin J. Chin

BACKGROUND

Sufficient progress has occurred in identifying, characterizing, and surgically repairing physiologically important congenital cardiac defects (which occur at the rate of 20,000/yr in the United States) that 85% of these infants can now expect to survive to adulthood. Since only the most severe structural malformations thwart current management schemes, prevention and early *in utero* detection are the remaining strategies to further reduce the impact of heart malformation on the health of infants and children; however, any prevention approach would depend largely on knowing the percentage of congenital heart defects that are genetic. For example, if the vast majority of congenital heart anomalies are due to intrauterine insults (infectious agents, toxins, mechanical stress, and so on) to the embryo during the first 30 days of gestation, then a prevention strategy would be ineffective; since most pregnancies are already monitored by ultrasound at least once for accurate dating, perhaps adding a "cardiac surveillance" portion to the imaging protocol would suffice to increase the chance of prenatal identification. However, evidence has begun to accumulate for the hypothesis that the majority of congenital heart malformations are due to gene alterations. Therefore, the scientific challenge of the next several decades will be to unravel the sequence of molecular decisions that result in the construction of the heart and blood vessels from the first embryonic tissue layers. Although more than 50 genes have already been reported to be involved in cardiovascular morphogenesis (Table 12-1), the way they function to form the heart and great vessels correctly (in space and time) remains obscure. Both forward and reverse genetic approaches are being tried, and a variety of organisms are being scrutinized since the underlying mechanisms of patterning appear to be widely shared among vertebrates. Murine cardiac development is difficult to study in vivo without new imaging techniques because of the relatively inaccessible embryo. Furthermore, a systematic screen of the mouse genome for embryonic lethal mutations affecting organogenesis is impractical. Other vertebrates such as the chick *Gallus gallus* and the African clawed frog *Xenopus laevis* have long generation times. The teleost fish *Danio* (formerly *Brachydanio*) *rerio* (zebrafish) has emerged as a model system because of its prolific egg production, rapid (90-d) generation time, optically transparent embryo, and extremely rapid heart development (48 h). Despite the advantages of the zebrafish system for mutational analysis, there are some aspects of cardiovascular construction, namely

septation and pulmonary artery formation, that must be studied in higher vertebrates.

This overview will discuss the anatomical malformations that make up the vast majority of cases of human congenital heart disease but will specifically exclude heritable cardiomyopathies (Chapter 13), long QT syndrome (Chapter 17), and Marfan syndrome, and will only briefly mention diGeorge syndrome, since this is also covered in Chapter 120.

CLINICAL FEATURES

The majority of human newborns with hemodynamically significant heart defects present in the first 2 weeks of life with one of four physiological arrangements: obstruction to pulmonary arterial circulation, obstruction to systemic arterial circulation, inadequate mixing between pulmonary and systemic circulations, or pulmonary venous obstruction. Because of the two-connected-pumps-working-in-parallel construction of fetal cardiac circulation (Fig. 12-1), these four types of hemodynamic aberration are well-tolerated for a 40-week gestation. An obstruction to either the pulmonary or aortic flow is reliably compensated for by blood flow shifting to the contralateral side of the heart. Transposition of the great arteries with intact ventricular septum does not have antenatal hemodynamic consequences since it merely constitutes a different variety of two-connected-pumps-working-in-parallel configuration. Finally, anomalous pulmonary venous connection with pulmonary venous obstruction does not substantially alter prenatal hemodynamics because very little blood flow is normally allowed into the lungs *in utero*.

The four physiological derangements are unmasked when the circulation is acutely changed at birth to a two-unconnected pumps-working-in-series arrangement, with lungs but without placenta (Fig. 12-1). The rapidity of presentation is critically dependent on the time course of foramen ovale closure or ductal closure or both. Obstruction to pulmonary arterial circulation (Fig. 12-2A,B) manifests as cyanosis. Obstruction to systemic arterial circulation manifests as "low output syndrome." Inadequate mixing between the pulmonary and systemic circulations also appears as cyanosis. Pulmonary venous obstruction (Fig. 12-2C) initially manifests as tachypnea out of proportion to arterial desaturation.

Although these four hemodynamic subsets account for virtually all cases of heart defect appearing early, severe cases of the rare malformation "absent pulmonary valve syndrome," whose cardinal feature is ventilatory failure due to airway impingement by adjacent markedly dilated pulmonary arteries, may also show up on the first day of life.

	Drosophila	*Xenopus*	*Mus*
Transcription factors			
NK		*XNkx2.3* in pharyngeal endoderm and cardiac mesoderm @ stage 16	
	tinman: no heart or gut muscle precursors	*XNkx2.5*(similar to *XNkx2.3*)	*Nkx2.5* in myocardial progenitors@7.5 d, in myocardium@8.5 d, also in sinus venosus @9.0 d, venosus@9.0 d, but not in aorta; *Nkx2.5* knockout@8.5 d shows no looping, cushions, trabeculae carnae
Hox			a-2 in aorta @ 9.75 d, in vasculature @11.5 d; knockout does not have heart phenotype
			a-3 in atrium and aortic trunk@12.5 d; a-3 knockout has defective aortic and pulmonary valves, thin aortic wall, atrial and left ventricular hypertrophy, dilatation of systemic veins
Sox			Sox-4 knockout die @ 14 d from dysplasia of both semilunar valves; there is also a defect in septation of the outflow of the heart
GATA			*GATA-4* in caudal end of heart tube @8.0 d, in endocardium and myocardium (stopping at distal outflow tract) @ 9.0 d, in endocardial cushions and myocardium @10 d; knockout dies by 9.5 d, showing cardia bifida and absence of the pericardial coelom, defects rescuable by wild-type endoderm
		XGATA-5 in ventral cardiac mesoderm @stage 18, by stage 34, only in endocardium	*GATA-5* in precardiac mesoderm @7.0 d, in atrium and ventricle @ 9.5 d, in only atrial endocardium @ 12.5 d
MADS	*Dmef2* in all cardiac cells @ 5.5 h; lies directly downstream of *t*inman		*GATA-6* in precardiac mesoderm and primitive streak @ 7.0 d, in atrium and ventricle @ 9.5 d, throughout atrial and ventricular endocardium and myocardium @ 12.5 d
			Mef2a in heart @ 8.5 d
			Mef2c in heart primordia@7.5 d, in sinus venosus @8.0 d, in atrium and ventricle @ 8.5 d; knockout dies by 10.5 d
			Mef2d in heart @ 8.5 d
			No looping occurs; the right ventricle and sinus venosus fail to form
bHLH			*dHAND*; knockout dies @ 10.5 d, showing hypoplastic right ventricle and outflow tract but a dilated aortic sac
			eHAND in outflow tract and left ventricle @ 8.0 d
	twist activates *tinman*	*Xtwist* in cephalic neural crest @ stage 16	*M-twist* in first branchial arch @ 8.0 d, in atrioventricular canal endocardial cushion @ 10.0 d; knockout does not have heart phenotype
HLH			Id in ventral, aortae, aortic arch, and dorsal aortae @9.0 d; in atrioventricular cushions and outflow tract ridges @ 10.0 d
Myc			1/3 of c-*myc* knockouts show enlarged heart and pericardial effusion; die by 10.5 d
			N-*Myc* in heart @ 9.5 d in only compact layer of ventricular myocardium @10.5 d; knockout shows reduction in compact layer of ventricular myocardium
MFH-1			Knockout shows type B interruption of left aortic arch in 10/12 and perinatal death
Pax			Homozygous splotch[2H] show truncus arteriosus @ 13.5 d approximately 50% of the time

Table 12-1 *(continued)*

Gene family	Drosophila	Xenopus	Mus
Transcription factors			
Zfh-1	In dorsal vessel cardio-blasts @ stages 11–15; mutant manifests breaks in anterior region of heart and kink in heart shape		
Evi			In truncal and conal ridges and valves @12.5 d
Secreted proteins			
TGF-β			β1 in yolk-sac blood islands and heart mesoderm @ 7.0 d, in endocardium @8.0 d, only in endocardial cushions (both atrioventricular canal and outflow tract) @9.5 d. Knockout does not have heart phenotype (due to transplacental passage of maternal TGF-β1) unless mother is TGF-β1 null. In the latter case, knockout shows poorly formed ventricular lumina and disorganized valves and ventricular myocardium; half die @ 10.5 d due to defective yolk sac vasculogenesis, endothelial differentiation, and hematopoiesis. β2 in sinus venosus @ 8.0 d, in outflow tract and aortic sac @ 8.5 d, in atrioventricular canal and proximal outflow tract myocardium @ 9.5 d β3 in pericardium @ 9.0 d
Vg-1		Injection of mRNA into right-dorsal blastomere randomizes heart looping	
DVR	*dpp* required for activation of dorsal mesoderm genes	*Xbmp4* overexpression ventralizes mesoderm; inhibition dorsalizes mesoderm	*bmp2* in atrial myocardium @9.5 d (low levels in truncus and dorsal aortae), in myocardium of atrioventricular canal (not truncus) @10.5 d *bmp4* in myocardium @8.5 d, more localized to atrioventricular canal region @ 9.0 d, more localized to truncus (aorta) @10.5 d; knockout: heart phenotype varies, depending on genetic background, dies between 7.5 and 10.5 d
Wnt	*wg*^{ts} shifted to nonpermissive temperature @3–5h: ↓#pericardial and cardial cells		
VEGF			In myocardium @ 8.5 d; heterozygotes die @ 11.0 d showing no blood vessels
Neuregulin			In endocardium @ 10.5 d; knockout shows absent ventricular trabeculae and distorted endocardial cushions
Nodal		Xnr-1 in left lateral plate mesoderm @ stage 19	Mouse nodal is in left side of node @ 4-somite stage and in left lateral plate mesoderm @ 5-somite stage
Extracellular proteins			
Tenascin	*odd Oz* in cardioblasts @9.5 h; encodes tenascin like protein		Tenascin-X is in epicardial layer of sinus venosus and atrium @ 12.0 d
Fibronectin			In mesoderm during primitive streak stage, in endocardium @ 5-somite stage; knockout may not develop a heart, depending on genetic background (heart primordia not fused @ 8.5 d)
Laminin	Heart is "broken" (dissociation of pericardial cells)		Knockout does not have heart phenotype
Receptors			
Receptor for PDGF			In dorsal aortae @9.5 d; in ventricular trabeculae, cushions, and pericardium @ 11.5 d; in valves @ 15 d; *Patch* mutation (deletion for PDGFRα) homozygotes show truncus arteriosus, and >50% die by 9.5 d

(continued)

Note: In the Wnt row, "wg^ts" uses a non-mathematical superscript notation for the temperature-sensitive allele.

Table 12-1 *(continued)*
Genes Involved in Cardiovascular Morphogenesis

Gene family	*Temporal and spatial expression of mRNA/phenotype of knockout homozygote/overexpression (mRNA injection) data*		
	Drosophila	*Xenopus*	*Mus*
Receptors for neuregulin			*ErbB4* knockout dies @ 10.5 d and shows absent ventricular trabeculae. *ErbB2* knockout dies @ 10.5 d and shows absent ventricular trabeculae
Receptors for TGF-β–like ligands		Injection of truncated activin receptor type IIB mRNA into left-dorsal blastomere (16-cell stage) randomizes heart looping	Activin receptor type II B knockout dies perinatally, showing randomized heart position (and double-outlet right ventricle, right atrial appendage isomerism, and other anolmalies)
VEGF receptors			*flk-1* in heart mesoderm @ 7.0 d, in yolk-sac blood islands @ 8.0 d, in vasculature and endocardium @ 8.5 d; knockout shows no yolk sac blood islands, endocardium, or blood vessels; dies by 9.5 d
			flt-1 knockout forms endothelial cells but cannot assemble blood vessels, shows disorganized endocardium, and dies by 9.0 d
			tie-1 in vasculature and endocardium @ 8.5 d; knockout shows edema (followed by hemorrhage) due to leaky blood vessels; dies @ birth
			tie-2 (also called *tek*) in yolk sac blood islands @ 8.0 d, in vasculature and endocardium @ 8.5 d; knockout shows malformation of vascular network including coronary vessels; dies by 10.5 d showing disorganized dorsal aorta and heart trabeculae
Integrins			α1
			α4 knockout shows no epicardium or coronary vessels and dies @ <15.5 d
			α5 knockout does develop a heart; dies by 11 d (abnormal blood vessel formation)
			α6 in myocardium@8.5 d; in endothelial cells of atrioventricular canal @ 11.5 d av in heart @ 8.5 d
Ig superfamily N-CAM			
PECAM-1			In endothelium of dorsal aorta, endocardium of conotruncus and ventricle@8.5 d
VCAM-1			Knockout has no epicardium and shows reduction in compact layer of ventricular myocardium and ventricular septum, and dies @12.5 d
Retinoic acid receptors RXR			α-/-: shows reduction in compact layer of ventricular myocardium and ventricular septum and dies @9.5 d
			RXRα-/-/RARα-/-: shows reduction in compact layer of ventricular myocardium, truncus arteriosus; aberrant right subclavian artery
			RXRα-/-/RARγ-/-: shows reduction in compact layer of ventricular myocardium, truncus arteriosus; proximal aorticopulmonary window; isol rpa
RAR			α1β2: TOF, right arch, aberrant left subclavian artery; truncus arteriosus
			αβ2+/–: truncus arteriosus, right arch; double arch, isol rpa and lpa
			αβ2: truncus arteriosus, right arch, absent lpa; left arch, aberrant right subclavian artery; right cervical arch, aberrant left subclavian artery; left cervical arch, aberrant right subclavian artery
			α1γα2+/–:TOF, aberrant right subclavian artery; double-outlet right ventricle
			αγ: truncus arteriosus, right arch, isolated lpa

Table 12-1 (continued)

Gene family	Drosophila	Xenopus	Mus
Channels			
connexin 43			cx43 in ventricle @ 9.5 d; knockout shows cyanosis, dies shortly after birth, with severe subpulmonary stenosis
Other			
NF-1			Knockout dies @ 13.5 d, shows double-outlet right ventricle with obstruction of both outflow tracts
ET-1			Knockout shows ventricular septal defect in approximately 50%
l-r dynein			iv homozygote shows heterotaxy

bHLH, basic helix-loop-helix; bmp, bone morphogenetic protein; cx, connexin; dpp, decapentaplegic; DVR, decapentaplegic-Vg1-related; Evi, ecotropic viral integration site-1; flk, fetal liver kinase; flt, fms-like tyrosine kinase; Hox, homeobox; Id, inhibitor of differentiation; Ig, immunoglobulin; isol, isolation of the; lpa, left pulmonary artery; MADS, MCM1, Agamous, Deficiens, Serum Response Factor; Mef, Myocyte enhancer factor; N-CAM, neural cell adhesion molecule; PDGF, platelet-derived growth factor; PDGFR, platelet-derived growth factor receptor; PECAM, platelet endothelial cell adhesion molecule; rpa, right pulmonary artery; TGF-β, transforming growth factor-β; TOF, tetralogy of Fallot; ts, temperature-sensitive; VCAM, vascular cell adhesion molecule; VEGF, vascular endothelial growth factor; wg, wingless.

Figure 12-1 (Left) Fetal circulation in the human. Oxygenated blood travels from the placenta to the fetus via the umbilical vein and then the ductus venosus. After combining with deoxygenated inferior vena caval blood, it preferentially streams across the foramen ovale into the left heart and eventually supplies the ascending aorta. Deoxygenated superior vena caval blood preferentially fills the right heart and supplies the descending aorta via the ductus arteriosus. Since they do not function as the gas exchange site, the lungs are not inflated in utero and receive very little blood flow. The two sides of the heart function as parallel pumps, communicating at the level of the atria (foramen ovale) and the great arteries (ductus arteriosus). (Right) Neonatal circulation in the human. The lungs inflate, assume their gas exchange function, and begin to receive more blood flow. Ductus venosus and ductus arteriosus constrict in the first few days. The two sides of the heart function as pumps-in-series now; any blood passing through the right heart must eventually also pass through the left heart. (See color insert following p. 684.)

A few types of malformation show up after 2 weeks of age. Isolated large septation defects resulting in left-to-right shunt physiology typically do not present in the first 2 weeks of age because the magnitude of the left-to-right shunt depends mostly on the pulmonary vascular resistance, the latter parameter falling to its adult value gradually over the first 6 months. The uncommon condition of anomalous origin of the left coronary artery from the pulmonary artery, which results in gradual-onset myocardial ischemia, also manifests after the neonatal period since the reduction in perfusion of the left ventricle is closely linked to the fall in pulmonary vascular resistance.

DIAGNOSIS

Although the screening protocol includes physical examination, arterial blood gas, electrocardiogram, and chest roentgenogram, currently the principal tool for detailed characterization of both morphology and hemodynamics in the human newborn is ultrasound imaging. With progressive refinement over the last 15 years, its accuracy in assessing anatomy and circulatory physiology in the newborn and young infant now approaches that of cardiac catheterization.

Taking a detailed family history and surveying the patient for even subtle extracardiac anomalies is an increasingly important part of the initial workup. For the detection of deletions, translocations, or duplications, fluorescence in situ hybridization (FISH) will become standard as more probes become widely available.

GENETIC BASIS OF DISEASE

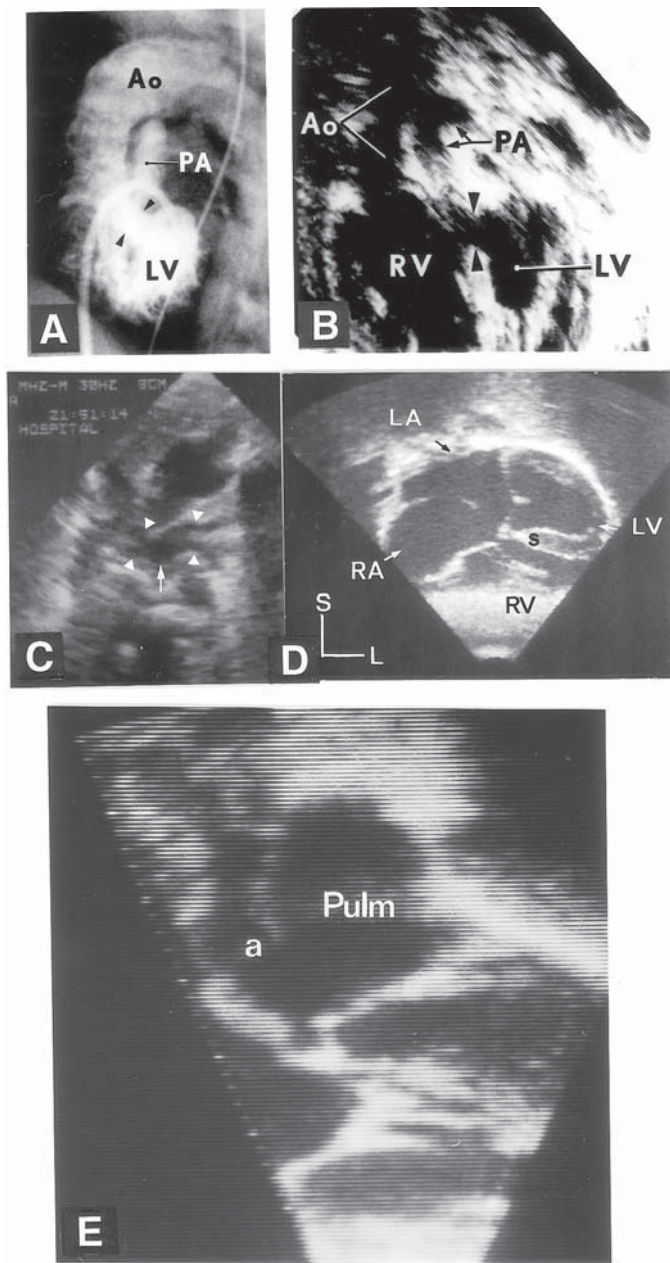
Until recently, the prevailing view of the etiology of congenital heart disease was that 8% of defects were single-gene defects, 2% due to teratogens, and 90% were "multifactorial." Three recent classes of observation argue that this view is incorrect. First, as the number of adult survivors of congenital heart disease in the US exceeds 600,000, surveys of the F1 generation reveal a much higher incidence of congenital heart malformation than previously reported. Second, an increasing number of genes responsible for syndromes involving the heart are being identified by positional cloning, a technique based on identifying a DNA marker with which a phenotype cosegregates (Table 12-2). Third, mutations producing phenotypes similar to human congenital heart disease are being identified in several lower vertebrates. In mice, the technique of targeted gene disruption has uncovered models for diGeorge syndrome (Hox a-3 knockout) and subpulmonary stenosis (connexin 43 knockout). Spontaneous mutations in the iv and


Figure 12-2 **(A,B)** Double-outlet right ventricle with severe subpulmonary stenosis, angiographic and echocardiographic sagittal views, respectively. The ductus arteriosus has already closed. **(C)** Suprasternal frontal echocardiogram showing the pulmonary venous confluence (arrow) in an infant with obstructed total anomalous pulmonary venous connection. The arrowheads point to the individual pulmonary veins. **(D)** Subcostal 4-chamber view of complete common atrioventricular canal. s = muscular ventricular septum. **(E)** Subcostal frontal view of an infant with truncus arteriosus as well as interrupted aortic arch. Note how the truncal root has been separated unequally such that the ascending aortic (a) component is very small compared to the pulmonary arterial (Pulm) component. Other abbreviations: Ao, aorta; L, left; LA, left atrium; LV, left ventricle; PA, pulmonary root; RA, right atrium; RV, right ventricle; S, superior.

pax-3 genes produce models for heterotaxy and truncus arteriosus, respectively. In zebrafish, saturation mutagenesis screens carried out in two laboratories (C. Nüsslein-Volhard at the Max-Planck-

Institut, Tübingen, Germany and W. Driever at Massachusetts General Hospital, Boston, MA) have revealed mutants lacking endocardium or valves, manifesting tachyarrhythmias, and demonstrating underdevelopment of particular chambers.

Reverse genetics in the human has been very successful in the last decade as exemplified by the mapping of several familiar disorders to specific chromosomal regions.

Familial supravalvar aortic stenosis (SVAS), an autosomal dominant disorder affecting many large arteries (particularly the pulmonary arteries and the ascending aorta), was found to be coinherited with a DNA polymorphism at 7q11.23. Analysis of a SVAS family in which a balanced translocation involving chromosome 7 cosegregated with the phenotype showed that the elastin gene was disrupted. Another SVAS family manifested a large deletion in the elastin gene. In addition, SVAS also occurs as part of Williams syndrome (supravalvar aortic or pulmonary stenosis, stenoses of other systemic arteries, elfin facies, precocious verbal ability, hypersensitivity to sounds, poor visual-motor integration). Hemizygosity at the elastin locus is present in both sporadic and familial Williams syndrome. Finally, Williams syndrome patients have a very large deletion extending beyond the elastin gene, raising the possibility of a contiguous gene syndrome. This concept has been proposed for diGeorge and Shprintzen (velocardiofacial) syndromes, part of the CATCH 22 (Cardiac defects, Abnormal facies, Thymic hypoplasia, Cleft palate, and Hypocalcemia from chromosome 22 deletions) spectrum (*see* Chapter 120).

Approximately 85% of complete atrioventricular canal patients exhibit Down syndrome. In the complete form of common atrioventricular canal, the atria and ventricles are incompletely septated (Fig. 12-2D); in addition, the atria drain into the ventricles via a single (common) atrioventricular valve with typically five leaflets. Through studies of families with various partial 21 trisomies, a critical region of 9 Mb for atrioventricular canal defects has been identified (21q22.2-21q22.3).

Holt-Oram syndrome (an autosomal dominant condition with forelimb anomalies, ostium secundum atrial septal defects, and atrioventricular block), which mapped to 12q2 in two large families, results from mutations in the human Tbx5 gene.

Although the association of both IAA type B and truncus arteriosus (Fig. 12-2E) with diGeorge syndrome has long been known, the finding that chromosome 22 deletions occurred in many diGeorge patients suggested the hypothesis that a specific gene defect could control arch formation and/or outflow tract development. Chapter 120 discusses the hunt for the diGeorge syndrome gene(s) in much greater detail; although the cloning of a balanced translocation between chromosomes 2 and 22 in a patient with "partial" diGeorge syndrome suggests that the section of DNA disrupted by the translocation breakpoint is responsible for much of the diGeorge phenotype, it may not be responsible for the heart disease (the affected individual had only aortic coarctation and no intracardiac malformation).

The further discovery that many nonsyndromic patients with interrupted aortic arch, truncus arteriosus, and tetralogy of Fallot have chromosome 22 microdeletions has instigated an effort to reclassify our patient populations genetically or developmentally. Because of its noninvasive nature, ultrasound imaging will emerge as the dominant postnatal screening method to construct the large pedigrees that form the substrate for investigation.

Table 12-2
Developmental Classification Scheme

Phenotype in H. sapiens	Gene product	Chromosomal locus in H. sapiens
Heart malposition		
Ectopia cordis		
Heterotaxy syndrome		(Familial variant—Xq24-q27.1)
Isolated dextrocardia		
Looping		
L-loop		
Supero-infero ventricles		
Ascending aorta/aortic arch/pulmonary artery (obstruction, interruption, dilatation, arch sidedness)		
Peripheral pulmonic stenosis (Alagille syndrome)	Jagged1	20p12
Coarctation (Turner syndrome)		Monosomy X
Familial supravalvar aortic stenosis and Williams syndrome	Elastin	7q11.23 deletion
Aortic dilation (Marfan syndrome)	Fibrillin-1	15q21.1
Aortic dilation (Ehler-Danlos syndrome, type IV)	Type III collagen	2q31
Arch interruption, right arch, anomalous origin of arch vessels (diGeorge syndrome)		
Conotruncus (outflow valve development, alignment, septation)		
Truncus arteriosus, TOF (malalignment VSD with subpulmonary stenosis), TOF with pulmonary atresia, TOF with isol rpa or lpa, double-outlet RV, malalignment VSD with subaortic stenosis (diGeorge syndrome)		22q11.2 deletion
Double-outlet RV, TOF	Trisomy 18	
Transposition of the great arteries		
Double-outlet left ventricle		
Anatomically corrected malposition of the great arteries		
Valvar aortic stenosis		
Valvar pulmonary stenosis (Noonan syndrome)		
Atrioventricular canal (valve development, septation)		
Complete AV canal, partial AV canal (Down syndrome)		Trisomy 21q22
Mitral and tricuspid prolapse (Marfan syndrome)	Fibrillin-1	15q21.1
Mitral and tricuspid dysplasia		Trisomy 18
Single ventricle		
Ventricles (septation, dysplasia, hypoplasia)		
Tricuspid atresia		
Ebstein's anomaly (RV dysplasia)		
Spongy myocardium		
Muscular VSDs		
Atria, systemic veins, pulmonary veins (septation, alignment)		
Sinus venosus type "ASDs"		
Ostium secundum ASDs (Holt-Oram syndrome)	Tbx5	12q2
Anomalous systemic venous connection		
Anomalous pulmonary venous connection		
Hypoplastic left heart syndrome		

ASD, atrial septal defect; isol, isolation of the; lpa, left pulmonary artery; rpa, right pulmonary artery; RV, right ventricle; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

Although the physiologically based schema mentioned in the Clinical Features section works quite well for the clinician, a developmentally oriented classification of defects (taking advantage of the fact that all vertebrate hearts appear to go through a straight heart tube stage) may be more appropriate for the molecular biologist (Table 12-2): heart malposition (i.e., abnormal positioning of the heart vis-à-vis the ventral-dorsal, rostral-caudal, and left-right body axes), looping, ascending aorta/aortic arch/pulmonary artery, conotruncus, atrioventricular canal, ventricles, and atria/systemic veins/pulmonary veins. Notice that situs inversus totalis is not listed since these rare

individuals are a left-right mirror-image of normal and do not necessarily have any heart disease.

Since few gene products have yet been identified, the way gene alterations contribute to pathology is still obscure. For example, how a reduced level of elastin results in the gradual development of supravalvar aortic stenosis is unclear. One hypothesis is that recurring damage to the endothelium of relatively inelastic arteries provokes intimal proliferation followed by fibrosis. Consistent with this hypothesis is the clinical observation that pulmonary arterial stenoses tend not to progress (the normal pulmonary vascular resistance decline results in gradual lowering of right ventricular pressure after birth, presumably lowering the shear forces on the main pulmonary branches).
Figure 12-3 Sagittal echocardiographic view of a modified Fontan repair. The superior (s) and inferior vena caval (i) flows have been rerouted directly into the proximal right pulmonary artery (open circle).

The anomalies in the CATCH 22 phenotype are in structures to which migrating neural crest cells contribute, so it is understandable that much attention is being focused on genes known to be important in cell–cell signaling and cell movement. However, other work centering on transcription factors that may function as master controls is also important. Vertebrate homologs to the *Drosophila* homeodomain-containing gene *tinman* (without which the fly does not form a heart) have been cloned recently, showing that control of cardiac formation is likely to have been conserved over 600 million years.

MANAGEMENT/TREATMENT

The vast majority of congenital heart malformations have now become rather straightforward to correct surgically. Even the varieties with hypoplasia of one or the other ventricle can be palliated well with a modified Fontan operation, in which the systemic venous circulation is rerouted directly into the pulmonary arteries (Fig. 12-3); the remaining questions for cardiologists and cardiovascular surgeons center around the prevention of arrhythmic and effusive complications and the search for ways of manipulating neonatal pulmonary vascular impedance so that the Fontan operation would not need to be staged as it is now.

Assessment of the quality of the surgical repair is no longer done 6 or 12 months postoperatively but rather in the operating room or shortly before hospital discharge. Long-term follow-up is typically done using noninvasive techniques such as ultrasound, magnetic resonance scanning, and exercise testing.

The only ways of further lowering the morbidity of congenital heart defects are prevention (by genotyping and counseling), termination *in utero* upon phenotype recognition, and better prenatal or postnatal screening. While the second may be practiced in some countries, for religious and ethical reasons it is doubtful whether it will ever be widely implemented in the US. The third way has so far not proved cost-effective. Hence, efforts will likely be concentrated on the first approach. As a prerequisite, more work needs to be done to understand the construction of the heart and vessels at the molecular level.

FUTURE DIRECTIONS

Some of the questions that biologists hope to answer are:

1. How do the myocardial, endocardial, and vascular endothelial lineages become specified?
2. How is the heart tube "patterned" and situated? (Do the same families of molecules responsible for body axis patterning get reused in the patterning of organs?)
3. How are the cardiac valves formed?
4. How is the conduction system formed? Humans with abnormal lateralization or looping have anomalous conduction systems.
5. Given that in mammalian hearts two atria and two ventricles function in parallel and develop in tandem *in utero*, how is growth of the left heart exquisitely matched to that of the right heart throughout gestation?
6. How are mechanisms constructed during embryonic development that allow heart rate and contractility to be modulated by both the nervous system and circulating hormones?
7. How are myocardial cells maintained in a state of terminal differentiation?

A variety of organisms will yield answers to these questions.

Although laboratories studying the mouse system will continue to create knockouts including double and triple knockouts, mice carrying specific mutations rather than null mutants may be more illuminating. Furthermore, tissue-specific mutations will also become feasible. Zebrafish labs will continue to analyze more than 100 recessive mutations affecting cardiovascular development that have been isolated in the Tübingen and Boston saturation mutagenesis screens. Cloning the genes affected in these mutants will be facilitated by the completion of a genetic map. Finally, positional cloning will continue to be utilized for large human families with single-gene disorders.

13 Inherited Cardiomyopathies

Christine E. Seidman, Calum MacRae, and J. G. Seidman

INTRODUCTION

The cardiomyopathies are primary disorders of the myocardium that traditionally are classified as hypertrophic, dilated, or restrictive. Although these descriptors reflect a common anatomy and/or the pathophysiology exhibited by affected individuals, the natural history of these disorders often encompasses more than one subclassification. That is, some individuals with hypertrophic cardiomyopathy exhibit little myocardial hypertrophy; others develop increased cardiac chamber size with clinical manifestations that typify idiopathic dilated cardiomyopathy. Similarly, myocyte hypertrophy is a common histopathologic manifestation of dilated cardiomyopathy. To understand the molecular signals that cause cardiac remodeling, researchers have sought to elucidate the genetic bases for hypertrophic, dilated, and restrictive cardiomyopathies. These studies may help to define pathways of cardiac remodeling that also occur in response to common cardiovascular pathologies.

Application of molecular genetic approaches to the study of inherited cardiomyopathies has yielded much progress. This approach requires the identification of affected families with multiple affected individuals. As a first step, linkage studies are performed to identify the chromosome location (or loci) of the disease gene. Subsequent analyses of candidate genes that map to the defined region and/or positional cloning of novel genes enables identification of mutations that cause the pathology. Molecular genetic studies have been particularly productive in elucidating many gene defects that cause hypertrophic cardiomyopathy. Although disease genes have yet to be identified that cause dilated cardiomyopathies inherited as a dominant trait, an ever-increasing number of loci responsible for these disorders have been mapped in the genome. Further, the molecular etiologies of several X-linked dilated cardiomyopathies have been elucidated. Unfortunately, application of molecular genetics to the restrictive cardiomyopathies remains limited, probably because these disorders occur infrequently and familial cases are extremely rare. Because neither the disease genes nor loci that cause restrictive cardiomyopathies are known, this disorder will not be reviewed further.

Elucidation of the genetic basis of inherited cardiomyopathies has refined classification of hypertrophic and dilated cardiomyopathies into distinct gene (or locus) defects. While compilation of the complete spectrum of genetic etiologies that cause these cardiomyopathies remains an ongoing effort, the data reviewed in this chapter and future progress will have significant relevance to patient diagnosis and management. Identification of cardiomyopathy genes allows characterization of a preclinical stage in these disorders. This provides a new perspective on the natural history of the cardiomyopathies that may ultimately foster early intervention. More immediately, individuals at risk for inherited cardiomyopathies can be recognized, and appropriate longitudinal evaluation can be initiated. Genetic studies have also clarified the relationship of sporadic and familial disease in some cardiomyopathies. Because sporadic disease can be due to *de novo* mutations in genes that cause familial disease, assessment of risk and genetic counseling of individuals with sporadic disease can be guided by the experiences of individuals with known familial disease. Perhaps most importantly, these studies have demonstrated substantial genetic heterogeneity in the cardiomyopathies; distinct genetic etiologies appear to account in part for the variable clinical phenotypes of dilated and hypertrophic cardiomyopathies. In dominant hypertrophic cardiomyopathy, genotype has been shown to influence clinical outcome. When the genetic basis for cardiomyopathies is more fully solved, our understanding of the complex relationship between genotype and phenotype will undoubtedly improve management of these disorders.

HYPERTROPHIC CARDIOMYOPATHY: A DISEASE OF THE SARCOMERE

CLINICAL STUDIES Hypertrophic cardiomyopathy is a disorder characterized by an increase in cardiac mass accompanied by myocyte and myofibrillar disarray. Outmoded clinical terms such as asymmetric septal hypertrophy (ASH), idiopathic subaortic hypertrophic stenosis (IHSS), and hypertrophic obstructive cardiomyopathy described the marked increase in myocardial septal mass found in some patients. However the widespread use of two-dimensional echocardiograms, family studies, and recent genetic research have demonstrated considerable variation in the location, symmetry, and extent of hypertrophy in affected individuals. Clinical diagnosis is generally based on finding unexplained left ventricular wall thickness greater than 13 mm at any location. Hypertrophic cardiomyopathy can occur without symptoms, but most individuals experience dypsnea, angina, and palpitations. Presyncopal symptoms are of particular concern because of the increased risk for sudden death in some affected individuals. Arrhythmias, embolic events, and congestive heart failure contribute to the premature morbidity and mortality of this disorder.

Table 13-1
Features of Familial Hypertrophic Cardiomyopathy Loci

Locus	Gene	Penetrance	Prognosis
1q32	Cardiac troponin T	Incomplete	Poor
7q3	Unknown	Variable for WPW	Unknown
11q1	Cardiac myosin binding protein C	Incomplete	Limited data; generally good
14q1	β Cardiac myosin heavy chain	Usually complete	Variable; Mutation-dependent
15q2	α Tropomyosin	Usually complete	Limited data

Family studies have demonstrated hypertrophic cardiomyopathy to be a heritable disorder that is transmitted as autosomal dominant trait or as a sporadic disease. Hypertrophic cardiomyopathy is not a rare condition; a recent report of more than 7000 two-dimensional echocardiograms of young individuals in the United States (obtained to screen for coronary artery disease) demonstrated the disorder in 0.2% of this population. No racial nor ethnic groups are predisposed to the condition.

GENETIC STUDIES   Molecular genetic analyses of familial hypertrophic cardiomyopathy (FHC) have identified disease loci (Table 13-1) on five chromosomes. To date, four disease genes have been identified: cardiac troponin T (chromosome 1), cardiac myosin binding protein C (chromosome 11), β cardiac myosin heavy chain (chromosome 14), and α tropomyosin. Collectively these genes account for approximately 60–70% of all FHC, thus indicating that other disease genes are yet to be identified. Only one other FHC locus has been mapped to chromosome 7; in one family, a mutation in this locus causes both FHC and Wolff-Parkinson-White syndrome (WPW).

More than 30 different mutations in the β cardiac myosin heavy-chain gene have been demonstrated to cause FHC. All are point mutations that alter one amino acid residue in the globular head or head-rod junction of the myosin heavy chain. In some instances, affected members from unrelated families have identical mutations. However, genetic (haplotype) analyses indicate that most mutations arose as an independent event; there is little evidence for a mutation founder effect in FHC. In addition to causing familial disease, *de novo* mutations in the β cardiac myosin heavy-chain gene have been demonstrated to cause sporadic hypertrophic cardiomyopathy.

While there is clinical variation in the phenotype associated with β cardiac myosin heavy-chain gene mutations, these defects are usually quite penetrant by adulthood. That is, although children may not exhibit signs or symptoms of disease, demonstrable hypertrophy (detected by two-dimensional echocardiograms) is typically evident in gene carriers by age 20. Figure 13-1 shows the parasternal long axis view of a two-dimensional echocardiogram from an 18-year-old with FHC caused by a missense (Arg453Cys) mutation in exon 14; there is significant interventricular septal and posterior ventricular wall hypertrophy. Marked myocardial hypertrophy characterizes many β cardiac myosin heavy-chain mutations; analyses of affected individuals from six families with different myosin mutations found a mean maximal left ventricular wall thickness = 23.7 ± 7.7 mm. Despite nearly complete disease penetrance and significant hypertrophy that is associated with β cardiac myosin heavy-chain gene mutations, survival varies considerably and is, in part, mutation-specific. That is, individuals with the Arg403Gln mutation have markedly shortened life expectancies (average age of death = 45 years), whereas survival is near normal in individuals carrying the Val606Met mutation. The change (or absence) of amino acid charge appears to influence
Figure 13-1   The echocardiographic findings of hypertrophic cardiomyopathy. Parasternal long axis view of the heart shows significant hypertrophy of the interventricular septum (IVS) and posterior ventricular wall. Cavity size of the left ventricle (LV) is normal, but the left atrium (LA) is enlarged. The aorta (Ao) is indicated.

outcome in FHC. In general, conservative mutations are associated with a better prognosis than nonconservative mutations. A mouse model of FHC has been created using the Arg403Gln mutation. Homozygous mice die soon after birth, but cardiac histopathology and dysfunction in heterozygotes resemble human FHC. This model may be useful to help define the natural history and pathophysiology of FHC. Although more data is required to provide a complete profile of the phenotypes associated with each myosin mutation, preliminary data clearly indicate that genotype may assist in risk stratification of premature death in FHC.

β Cardiac myosin heavy chains are abundantly expressed in the adult ventricle and at much lower levels in slow twitch skeletal muscles. Expression of this isoform outside of the heart has prompted evaluation of skeletal muscle structure and function in FHC patients. Intriguingly, there is histologic evidence of central core disease (*see* Chapter 104) in some patients with β cardiac myosin heavy-chain gene mutations, although a clinically significant skeletal myopathy has not been observed.

Mutations in cardiac troponin T account for approximately 15% of all FHC. Unlike FHC mutations in myosin, these gene defects include small deletions and mutations in splice signals, in addition

to missense mutations. The FHC phenotype produced by each of these mutations is, however, strikingly similar. Affected individuals have substantially less cardiac hypertrophy than that observed with myosin mutations; mean maximal left ventricular wall thickness $=16.7 \pm 5.5$ mm for cardiac troponin T mutations ($p < 0.001$; [5]). The hypertrophy found in some adult individuals with cardiac troponin T mutations is less than standard criteria for diagnosis. Despite this reduced penetrance, all reported cardiac troponin T mutations are associated with markedly reduced survival.

α Tropomyosin gene mutations are a rare cause of FHC; less than 5% of cases are caused by these gene defects. Because of their infrequent occurrence, less information is available regarding the correlation between genotype and phenotype. However these mutations are biologically interesting, because unlike all other FHC genes, α tropomyosin is widely expressed outside of the heart. The mechanism by which a cardiac-specific phenotype is produced by these mutations is unknown. Because some FHC mutations in α tropomyosin occur in regions that interact with troponin T, the tissue-specific isoform cardiac troponin T may restrict dysfunction to the myocardium. Alternatively, FHC mutations in α tropomyosin may perturb a function that is unique and/or critical to cardiac myocytes.

Recent studies have demonstrated that cardiac myosin binding protein-C mutations cause FHC. This polypeptide participates in thick filament assembly by binding myosin heavy chain and titin. In addition, the protein appears to modulate myosin ATPase activity and participates in adrenergic regulation of cardiac contraction. Three FHC mutations have been reported in cardiac myosin binding protein-C: two of these alter splice signals; the third mutation is a six amino acid insertion. The location of these mutations predict that each will perturb the ability of the peptide to bind myosin. Despite the limited number of known FHC mutations in cardiac myosin binding protein-C, linkage studies suggest that this locus contributes 10–15% of all FHC cases. Available clinical data suggests that cardiac myosin binding protein-C mutations are associated with reduced disease penetrance and better prognosis than that observed with cardiac troponin T and some myosin mutations.

SIGNIFICANCE OF GENETIC STUDIES Molecular genetic analyses of FHC have demonstrated mutations in β cardiac myosin heavy chain, α tropomyosin, cardiac troponin T, and cardiac myosin binding protein-C, thus defining this as a disease of the sarcomere. This result has implications for further basic research and clinical studies of cardiac hypertrophy. First, because four disease genes encode sarcomere proteins, it is likely that FHC genes yet to be identified will similarly encode proteins involved in cardiac contraction. Second, because most mutations are missense or alter splice signals, they are likely to encode stable proteins that are incorporated into the multimeric components of the sarcomere. These dysfunctional components presumably produce a dominant negative effect on the myocardial sarcomere. Third, the dysfunctional sarcomere must trigger intracellular signals that result in the clinical features of FHC.

There are several clinical ramifications of these data. First, based on genotype, a preclinical phenotype has been identified in children at risk. Although two-dimensional echocardiograms of young children with an FHC mutation are typically normal, their electrocardiograms usually demonstrate minor abnormalities. Second, disease penetrance appears to be dependent on both age and mutation type. Cardiac hypertrophy in affected adults is quite variable and can be subtle. Despite its name, FHC can occur with little hypertrophy. Third, genotype can provide prognostic information in FHC.

Definition of the precise mutation that causes FHC in an affected individual remains a difficult task. The FHC genes currently identified appear to encompass only 70% of cases. Further, because most mutations appear to be family-specific, there is considerable cost and complexity in mutation identification. While this remains a research tool at present, the rapid advances in DNA technologies are likely to make genotyping of FHC patients a useful clinical test in the near future.

HYPERTROPHIC CARDIOMYOPATHIES OF CHILDHOOD

CLINICAL STUDIES Recent clinical studies estimate that 30% of cardiomyopathy in children may be familial. The clinical presentations of these pediatric disorders differs significantly from the hypertrophic cardiomyopathies discussed in prior sections. That is, FHC that is caused by sarcomere gene mutations generally does not present until after childhood. Accurate clinical diagnosis of FHC in children at risk can actually be quite difficult until after the growth spurt of puberty. Similarly, many familial dilated cardiomyopathies are rare in childhood, and the age of onset of those associated with conduction system disease is generally after the third decade. In addition to syndromic disorders that are not discussed, molecular genetic studies of pediatric cardiomyopathies have identified defects of mitochondrial genes (*see* Chapter 103), and mutations in nuclear genes involved in fatty acid β-oxidation. Recent progress in understanding autosomal cardiomyopathies caused by mutations encoding proteins involved in fatty acid β-oxidation is reviewed here.

Patterns of inheritance, age of onset, and natural history of infantile cardiomyopathies have demonstrated significant differences from clinically related adult disorders. The clinical genetics of these pediatric disorders demonstrates autosomal recessive transmission. Affected children have two mutated alleles of genes encoding proteins involved in cardiac energy metabolism. Their heterozygous parents, with one normal and one mutated allele, are clinically well. The cardiomyopathies produced by these mutations are often hypertrophic, but cardiac dilation also occurs. The hemodynamic consequences of infantile hypertrophic cardiomyopathy are different from that of FHC. Infantile hypertrophic cardiomyopathies typically cause impaired systolic function, which usually occurs late in the natural history of FHC. In contrast, the dilated phenotype is not dissimilar from that of affected adults. Endomyocardial biopsy is useful in diagnosing infantile cardiomyopathies: lipid-laden cytoplasmic inclusion bodies help to define those disorders due to defects in energy metabolism.

The natural history of these cardiomyopathies can include heart failure, pulmonary edema, arrhythmias, and sudden death. As in FHC, sudden death may be the presenting manifestation of the disorder. However, symptoms and episodic cardiac dysfunction are generally precipitated by fasting states, such as childhood illnesses. Although these recessive cardiomyopathies can be severe and progressive, careful management of these children enables them to become clinically well and less susceptible to cardiac episodes. The biochemical basis for the age-dependent improved outcome is unknown.

GENETIC STUDIES Molecular genetic analyses of infantile cardiomyopathies have identified several defects in transport proteins or enzymes involved in fatty acid β-oxidation, the major source of energy in the myocardium during periods of hypoglyce-

mia. Carnitine is a required cofactor for entry of long-chain fatty acids into mitochondria and carnitine deficiency blocks metabolism of these fatty acids and ketones. Carnitine deficiency results from mutations in several genes including a transporter for intracellular uptake, carnitine-acylcarnitine shuttling (for translocation of carnitine into mitochondria [12]), and carnitine palmitoyltransferase II, which catalyzes carnitine derivatives into acyl-CoA (chromosome 1p32). Although limited numbers of mutations have been identified in each of these genes, recognition of these defects enables therapy. In some instances, pharmacologic doses of carnitine may provide clinical improvement.

The cardiac substrates for mitochondrial β-oxidation are fatty acids of variable chain lengths. Four acyl-CoA dehydrogenases (CAD) selectively act on very-long-chain, long-chain, medium-chain, and short-chain fatty acids. Mutations in the genes encoding very-long-chain, long-chain (chromosome 7), and medium-chain acyl-CoA (chromosome 1p) dehydrogenases result in cardiomyopathies. Estimates of the incidence of these mutations in the general population range from 1 in 10,000 to 1 in 15,000.

Several different types of mutations have been identified in each dehydrogenase, including splice signal, insertion, and missense mutations. Mutations in the medium chain acyl-CoA dehydrogenase are most common at nucleotide residue 985. An A-to-G transition at this site accounts for approximately 90% of individuals with medium chain acyl-CoA dehydrogenase deficiency. Haplotype analyses provide data strongly suggesting a founder effect.

SIGNIFICANCE OF GENETIC STUDIES Molecular genetic studies have demonstrated that childhood hypertrophic cardiomyopathy results from energy deprivation. This hypothesis is furthered by analyses of mitochondrial respiratory gene mutations; these similarly cause cardiomyopathies. The mechanisms by which defects in energy result in cardiac hypertrophy is unknown. However, these studies clearly demonstrate that energy deprivation causes cardiac remodeling and dysfunction. It is particularly intriguing that these mutations can produce both the hypertrophic and dilated phenotype; there may be common signals in these different cardiac remodeling pathways. Understanding the biochemical consequences of these metabolic defects may help to elucidate important mechanisms in other non heritable forms of cardiac remodeling.

Genetic studies of fatty acid β-oxidation mutations have improved clinical management of patients with these defects. First, definition of the molecular bases for these disorders has enabled presymptomatic diagnosis of children at risk. This is particularly important because of the impact that dietary therapy can have on survival. Further, these studies define a novel basis for cardiac arrhythmias. Defects in these pathways have been shown to increase intracellular long-chain fatty acylcarnitines, which are toxic to mitochondria and may induce ventricular arrhythmias that contribute to sudden death. In addition to usual therapeutics to manage life-threatening arrhythmias, understanding the biochemical defect has provided effective approaches to restore energy supplies to the heart, thereby reducing sudden cardiac death in affected children.

DILATED CARDIOMYOPATHIES

CLINICAL STUDIES Dilated cardiomyopathy is characterized by cardiac chamber dilatation and contractile dysfunction. A large number of acquired and inherited disorders can cause this phenotype, and estimated prevalence of dilated cardiomyopathy

approximates 37 per 100,000 individuals. In most cases the cause is unknown. Dilated cardiomyopathy is the most common indication of heart transplantation in the United States and accounts for up to one-third of severe heart failure in individuals 25–65 years old.

Although there has been significant progress in identifying the cellular changes that may contribute to the cardiac dysfunction of dilated cardiomyopathy, these studies have not provided a unifying pathophysiologic mechanism nor suggested a molecular mechanism. Findings include impaired sarcoplasmic reticulum calcium handling, atypical myocyte potassium currents and autoantibodies to myosin, adrenergic receptors, and other antigens. Animal models of dilated cardiomyopathy have also been studied including a natural occurring recessive hamster cardiomyopathy and murine models generated by autoimmunization with myosin or infection with cardiotropic enteroviruses. The relationship, if any, of these models to human disease is unknown.

Recent systematic screening of probands' families has suggested a genetic component to dilated cardiomyopathy. Over 25% of probands had first-degree relatives with evidence of dilated cardiomyopathy. In addition, up to 20% of first-degree relatives had evidence of ventricular enlargement without contractile dysfunction. Figure 13-2 shows the parasternal long axis view of a two-dimensional echocardiogram from a 14-year-old with family history of dilated cardiomyopathy; her study exhibited significant left atrial and ventricular chamber dilation. The precise relationship between this phenomenon and clinically significant dilated cardiomyopathy is currently unknown. These studies are supportive of two primary modes of inheritance in familial dilated cardiomyopathy: X-linked and autosomal-dominant.

Family studies of probands with dilated cardiomyopathy have demonstrated cardiac abnormalities in family members. Findings include atrial cardiomyopathy, atrioventricular block, hypertrophic cardiomyopathy, and ventricular tachycardia. This clinical diversity has implied that familial dilated cardiomyopathy is a genetically heterogeneous disorder. To elucidate the molecular bases for the many phenotypes observed in conjunction with cardiac dilatation, large families have been clinically evaluated and DNA isolated for linkage analysis. Unfortunately the majority of study families are small, in part due to the significant premature mortality associated with these disorders. The limited numbers of families appropriate for genetic studies has also hindered progress of gene identification. Autosomal-dominant dilated cardiomyopathy loci are often defined by analyses of a single family, which often has insufficient power to move from a genomic location to disease gene. Hence our knowledge of the genetic bases for dilated cardiomyopathies is currently limited to identification of disease loci.

GENETIC STUDIES Three X-linked syndromes with associated dilated cardiomyopathies have been mapped and disease-causing mutations identified. Cardiomyopathy can be found in patients with Duchenne/Becker muscular dystrophy and in some patients represents the dominant clinical phenotype. Deletions in the 5' muscle promoter of the dystrophin gene are associated with an "isolated" cardiac phenotype. Although muscle biopsies can demonstrate classical features of these dystrophies, these are often subclinical. A recently described mutation causing a premature stop codon has also been found in a family with no clinical skeletal myopathy. However, genetic analyses of the dystrophin promoter in patients with isolated idiopathic cardiomyopathy failed to detect any mutations, thereby suggesting that this is a rare cause of sporadic, adult onset dilated cardiomyopathy.
Figure 13-2   The echocardiographic findings of familial dilated cardiomyopathy. Parasternal long axis view of the heart shows normal wall thickness (compare interventricular septum [IVS] with hypertrophic septum in Fig. 13-1), but left ventricular (LV) chamber dilation. The left atrium (LA) is normal; the aorta (Ao) is indicated.

Emery-Driefuss muscular dystrophy causes progressive skeletal muscle dysfunction, contractures, and cardiomyopathy, typically associated with atrioventricular conduction abnormalities (*see* Chapter 94). Atrial paralysis, atrial fibrillation, and atrial flutter are common; symptoms often result from infra nodal conduction with slow junctional rhythms and atrioventricular block. The disorder has been mapped to the distal end of the X chromosome, and is therefore genetically (and clinically) distinct from the Duchenne/Becker muscular dystrophy locus. The genetic cause of this disorder has recently been identified (Emerin) through genetic mapping strategies. Although the function of the novel protein Emerin, remains unknown, it is localized to the nuclear membrane of muscle cells.

Barth's syndrome is a rare X-linked infantile disorder that is often lethal in childhood. Affected individuals exhibit a dilated cardiomyopathy, short stature, and neutropenia. Genetic mapping studies defined a locus that overlaps the Emery-Driefuss muscular dystrophy critical region. However, recent positional cloning have demonstrated these disorders to be due to different gene defects. Barth's syndrome is caused by mutations in a novel gene called tafazzin. Alternative splicing of this gene produces multiple transcripts that are expressed in a variety of tissues. Whether distinct mutations in tafazzins will correlate with clinical findings of this disease is unknown.

Dilated cardiomyopathies that are transmitted as an autosomal-dominant trait also provide evidence for clinical and genetic heterogeneity. The relationship of these to the X-linked disorders remains unknown, because at present no autosomal disease genes have been defined.

The first autosomal-dominant kindreds to be mapped were classified as conduction disease with dilated cardiomyopathy (Table 13-2). In one large kindred, affected individuals over the age of 30 years developed progressive conduction system disease

Table 13-2
Clinical Features of Dilated Cardiomyopathy Loci

Locus	Gene	Inheritance	Associated Phenotypes
1p1-1q1	Unknown	Dominant	Conduction system disease
1q24	Unknown	Dominant	None
3p2	Unknown	Dominant	Conduction system disease; CVA
9q13	Unknown	Dominant	None
Xp21	Dystrophin	X-linked	Variable involvement of skeletal muscles
Xq2	Tafazzin	X-linked	Short stature; neutropenia
Xq28	Emerin	X-linked	Skeletal muscle and conduction system disease

characterized by atrial arrythmias, atrial fibrillation, atrioventricular block. In conjunction with the conduction system disease, myocardial disease was evident and culminated in ventricular chamber dilation and congestive heart failure. Longitudinal studies have demonstrated some improvement with pacemaker implantation, but in other affected individuals disease progression continued. Genetic linkage studies mapped this disorder to the centromeric region of chromosome 1. A second family with autosomal-dominant conduction disease and dilated cardiomyopathy has been studied. Sinoatrial node dysfunction progressed to supraventricular tachyarrhythmias, and His-Purkinje system conduction delay and was accompanied by chamber dilation. Despite similarities to the clinical phenotype produced by the disease locus on chromosome 1, molecular genetic studies mapped the cardiomyopathy in this family to a distinct locus, on chromosome 3p25-p22.

Several kindreds with isolated dilated cardiomyopathy, unaccompanied by conduction system disease, have also been studied. Adult onset, dominant transmission of chamber dilation, and systolic dysfunction has been mapped to chromosome 9q13 in one family; dilated cardiomyopathy in two other unrelated families also appears to map here. A clinically similar disorder has been identified in anther family, but genetic mapping studies have defined linkage to chromosome 1q42.

SIGNIFICANCE OF GENETIC STUDIES   Although the clinical impact of these studies remains limited at present, they provide evidence of the power of genetic approaches to the study of inherited cardiovascular disease. Undoubtedly the disease genes at each of these dilated cardiomyopathy loci will be identified. These findings promise to provide substantive new insights into the complex relationship of the excitation, contraction coupling, and the mechanisms of cardiac failure. As with hypertrophic cardiomyopathy, identification of genes that cause inherited dilated cardiomyopathies can be expected to improve classification based on genetic subtypes, define the relationship of inherited dilated cardiomyopathies to isolated (idiopathic) cases, and improve risk stratification in affected individuals.

14 Coronary Atherosclerosis

ROBERT E. GERSZTEN AND ANTHONY ROSENZWEIG

BACKGROUND

Atherosclerotic coronary artery disease is a complex biological process resulting in the narrowing of arterial vessels supplying blood to the heart. This process can clinically remain silent, but it commonly gives rise to clinical signs and symptoms when the narrowing becomes sufficiently severe that blood flow is unable to meet the metabolic needs of the heart muscle. If this condition is transient without permanent myocardial cell damage, it is termed myocardial ischemia. If the condition is sufficient in severity and duration to cause irreversible, clinically detectable myocardial cell damage, it is termed myocardial infarction. The clinical symptoms associated with myocardial ischemia are termed angina pectoris. In myocardial ischemia, the blood flow is insufficient relative to the requirements of the myocardium. Therefore, ischemia can be influenced by both alterations in the coronary blood flow (supply) and changes in the metabolic state of the myocardium (demand). Many patients with coronary disease experience exertional symptoms in a consistent and predictable pattern termed chronic stable angina. A marked acceleration in the frequency, severity, or duration of angina, or a significant decrease in the level of exertion inducing angina, constitutes unstable angina and carries a substantial risk of progression to myocardial infarction. Together, unstable angina and myocardial infarction comprise the acute or unstable coronary syndromes. The biological basis for the transition from either no clinical symptoms or chronic stable angina to an unstable coronary syndrome is the subject of intense investigation and has important clinical implications.

First, we will review the clinical features of these two general presentations of patients with atherosclerotic coronary disease: the acute coronary syndromes and stable angina. Salient features of the history, physical exam, and diagnosis of each will be discussed. We then turn to the molecular pathophysiology of atherosclerosis and examine the putative role(s) of multiple constituents of the blood vessel wall in the development, progression, and stability of atherosclerotic plaques.

CLINICAL FEATURES

Atherosclerotic cardiovascular diseases constitute a major cause of morbidity and mortality among both men and women in the United States, accounting for 500,000 deaths each year, approximately half of which are sudden. Atherosclerosis is a chronic and complicated process in humans and develops over

many years. Large epidemiological studies and interventional trials have identified a number of contributory elements to the development of these lesions, including genetic predisposition, elevated lipid levels, diabetes, tobacco smoking, and hypertension. This has led to a significant decline in age-adjusted mortality rates for patients with cardiovascular disease over the past several decades. Over the past 25 years, important advances have been made in the treatment of severe coronary stenoses, including bypass surgery and subsequently percutaneous transluminal coronary catheter-based interventions. Since the mid 1980s, thrombolytic therapy has become a mainstay in our treatment of acute myocardial infarction. From this wealth of clinical experience, our theories about the pathogenesis of the atherosclerotic plaque and the propensity towards acute coronary syndromes (i.e., myocardial infarction and unstable angina) have also evolved.

Surprisingly, serial angiographic studies have demonstrated that it is often not the most angiographically severe lesions that become unstable clinically. This data suggest that nonobstructive lesions may progress rapidly to obstruction through plaque rupture and/or thrombosis. Furthermore, the angiographic appearance of a lesion is a poor predictor of its clinical behavior. Lessons learned from recent clinical trials with lipid lowering agents have been equally intriguing. While lipid reduction only modestly improves the angiographic severity of high grade atherosclerotic lesions, it substantially improves the risk of acute coronary events, such as unstable angina or myocardial infarction. Our clinical experience has therefore served as the impetus to better understand the fundamental mechanisms of lesion biology.

DIAGNOSIS OF UNSTABLE CORONARY SYNDROMES

HISTORY The hallmark of the unstable coronary syndromes is rapidly progressing exertional substernal chest pressure, often radiating to the jaw or left arm. However, the initial presentation may be symptoms at rest. The discomfort of acute myocardial infarction is qualitatively similar, although it is often more severe and prolonged. It is acute in onset and often associated with diaphoresis, dyspnea, and a sense of impending doom. Elderly and diabetic patients often have less typical symptoms. One must also consider underlying illnesses such as anemia or infection that may precipitate the presentation of coronary disease. Acute infarction is present in a minority of patients presenting with chest pain of presumed cardiac origin. Chest discomfort described as "pressure" or "burning" is most associated with acute infarction. Positional or pleuritic pain should prompt consideration of other

etiologies. It should be noted that approx 25% of myocardial infarctions are silent and associated with either no symptoms, or only mild and atypical symptoms. The prognosis of such silent infarctions appears similar to that of more classical presentations.

PHYSICAL EXAMINATION   Physical examination neither establishes nor excludes the diagnosis of acute myocardial infarction or unstable angina. It does, however, provide critical clinical information of practical importance in patient management. Evaluation of the vital signs is particularly important in patients with chest pain. The heart rate is usually normal or slightly elevated, though infarctions involving the diaphragmatic portion of the heart are often accompanied by bradycardia and nausea. An irregular rhythm should raise the suspicion of ventricular ectopy or atrial fibrillation. Hypotension in the setting of chest pain may be secondary to pump failure and is a particularly ominous finding. Mild hypertension is more commonly found with acute onset of symptoms. Tachypnea may be secondary to evolving congestive heart failure.

The jugular venous pulsation is usually normal. An elevated measurement may denote chronically elevated right-sided filling pressures but should raise the possibility of right ventricular involvement. The diagnosis of right ventricular infarction may also be suggested by a paradoxical rise in venous pressure with inspiration, known as the Kussmaul's sign.

Evaluation of the arterial pulse amplitude and duration provides important clues to possible valvular disease or associated, noncoronary arterial disease. The pulse contour also reflects the patient's cardiac output. This evaluation may be confounded in elderly patients by noncompliant arteries in that the pulse amplitude may appear normal despite a significantly reduced cardiac output. The status of peripheral arteries, as well as the quality of the lower extremity veins, should be carefully assessed prior to consideration of interventions such as cardiac catheterization, angioplasty, intra-aortic balloon counterpulsation, or bypass surgery.

The possible auscultatory findings in atherosclerotic heart disease are protean. An S4 heart sound is common, often a reflection of long-standing diastolic dysfunction secondary to hypertension. On the other hand, a third heart sound reflects significant systolic impairment. Cardiac murmurs may be fixed or transient, emphasizing the importance of serial examinations. Both stable and unstable symptoms may be precipitated or exacerbated by underlying valvular heart disease such as aortic stenosis. The murmur of papillary muscle dysfunction is often transient while mechanical complications such as ventricular septal defect may not occur until days into the hospital stay. A pericardial friction rub often occurs several days after infarction. Evaluation of the lungs centers on the presence of rales consistent with congestive heart failure. In the acute coronary syndromes, the presence of pulmonary rales consistent with congestive heart failure, coupled with an S3 gallop, is a poor prognostic sign.

LABORATORY EVALUATION   The classic electrocardiographic pattern of acute myocardial infarction includes ST-segment elevation in multiple leads reflecting a coronary distribution, followed by evolution of T-wave inversion and significant Q waves in these same leads, reflecting a Q-wave myocardial infarction. However, patients with infarction can also present with ST-segment depression or T-wave inversion alone without evolution of Q waves, termed non–Q-wave myocardial infarction. The correlation of these electrocardiographic findings with pathologic findings of transmural or subendocardial infarction is sufficiently

imprecise to favor exclusive use of the electrocardiographic descriptors in clinical practice.

Serologic markers of myocardial necrosis remain the cornerstone in establishing the diagnosis of myocardial infarction. The serum creatine kinase (CK) and its myocardial-specific isozyme, CK-MB, are the most widely used tests. The degree of elevation in these markers correlates approximately with the amount of myocardium damaged but is influenced by many other factors. Elevated levels of serum transaminase and lactate dehydrogenase (LDH) with isoform reversal occurs later after infarction. Measurement of these levels generally adds little to clinical management and should not be routinely employed in evaluation of acute chest pain. Recent work has emphasized the utility of CK-subforms and myocardial-specific isoforms of troponin T and I, noting advantages in sensitivity in early diagnosis.

In evaluating acute coronary syndromes, studies by Dr. Lee Goldman and colleagues have been particularly instructive. His group integrated historical features to assess pretest probability, along with electrocardiographic findings, in a computer algorithm to predict myocardial infarction, and used this tool to prospectively analyze almost 5000 emergency room patients with chest pain. Of note, the incidence of acute myocardial infarction in the setting of a normal or near-normal electrocardiogram is approx 10%, but these patients are at lower risk for the life-threatening complications of infarction.

DIAGNOSIS OF STABLE ANGINA

HISTORY   Angina is classically described as a substernal chest pressure brought on by exertion and relieved by rest. Radiation of this discomfort (to the arm or jaw) and associated symptoms such as dyspnea or diaphoresis are common. Other precipitants include emotional stress, cold weather, or even large meals in some patients. Comorbid diseases such as anemia, thyrotoxicosis, or infection should be considered as possible contributors. Angina is most frequently the result of epicardial coronary stenoses that impair the coronary flow reserve. As the coronary flow reserve is decreased, the stress-induced myocardial ischemia typically results in anginal chest discomfort. Classical studies have shown that angina often correlates with coronary stenoses of 70% of the luminal cross section. Rest angina may develop with coronary stenoses of 90% or greater. Many patients with coronary artery disease have documented episodes of ischemia in the absence of anginal symptoms. The full implications and management of this silent ischemia remain controversial.

PHYSICAL EXAMINATION   As described above for acute myocardial infarction, the physical exam provides important insights into the status of the patient's cardiovascular system and general health. In particular, evidence of valvular heart disease, systolic and diastolic ventricular dysfunction, and peripheral vascular disease should be sought.

LABORATORY EVALUATION   Two goals form the rationale for further evaluation of patients with suspected coronary artery disease: the first is to establish (or refute) the diagnosis; the second is to acquire prognostic information in patients with coronary disease. This information can be extremely useful by identifying not only candidates for more aggressive management, but also those who do not need it.

As with all clinical testing, a positive or negative result must be interpreted in the context of the prior probability that a diagnosis such as ischemic heart disease exists in the patient or population

under study. Further testing is most useful when clinical evaluation places the prior probability of coronary disease in an intermediate level. If the prior probability of disease is extremely low, a positive test is most likely to be a false-positive and may precipitate a cascade of expensive and otherwise unnecessary further tests. If the prior probability is extremely high, a negative test is likely false-negative, and a positive test contributes little to the diagnosis. However, testing can be extremely useful even in patients with known coronary disease as a functional assessment and a prognostic rather than a diagnostic tool.

Evocative testing is necessary because, as previously indicated, ischemia connotes a relative deficiency of blood flow. Therefore, clinical or electrocardiographic evaluation of a well-compensated patient at rest is often unrevealing, even in the presence of significant coronary artery disease. Several objective methods of inducing and measuring myocardial ischemia are useful. Exercise testing while monitoring the patient's blood pressure and 12-lead ECG remains the most widely used approach. The patient must be able to exercise adequately, and the baseline ECG must be normal to rely on this test alone. Furthermore, drugs that alter the repolarization phase, such as digoxin, are a significant source of false-positive ECG changes. This incremental study is usually symptom limited, and the test is discontinued if there is evidence of chest discomfort, profound shortness of breath, a fall in systemic blood pressure of more than 15–20 mmHg, marked ECG changes, or ventricular arrhythmia. The total duration of exercise, the time to the onset of ischemic ST-segment change and chest discomfort, the total work performed (calculated by the heart rate-blood pressure product), the depth of the ST-segment depression, and the time needed for recovery to baseline all have important prognostic implications. When exercise is not possible, pharmacologic manipulations such as intravenous adenosine or dipyridamole can be useful but do not provide the same functional information as exercise testing. These compounds produce a dose-dependent myocardial hyperemia secondary to dilation of the coronary microvasculature. Coronary pressure distal to an epicardial stenosis declines in response to pharmacologic vasodilation, and this results in an impaired microvascular perfusion pressure. Therefore, in the setting of severe epicardial stenoses, these drugs cause an intramyocardial "steal" such that endocardial blood flow acutely declines while epicardial blood flow is either unchanged or increased. If no stenoses are present, both endocardial and epicardial blood flow will increase. Relative differences in blood flow can then be detected by radionuclide imaging. Of note, patients with bronchospastic pulmonary disease may not tolerate this form of pharmacologic testing. Dobutamine, a selective β-adrenergic agonist that produces a positive inotropic and chronotropic effect on the heart, has also been used to provide a pharmacologic stress.

Noninvasive assessment of myocardial perfusion is most commonly accomplished with radionuclide scintigraphy following the intravenous administration of a radioisotope such as thallium-201. Such radionuclide scintigraphy improves both the sensitivity and specificity of evocative testing. In addition, these techniques often allow differentiation between ischemic and infarcted zones. In the former, isotope uptake is initially reduced but normalizes over time. In the latter, uptake is persistently decreased. Newer agents using Technetium -99m have the advantage of higher energy and shorter half-life. The increased radionuclide dose improves image quality and is less subject to artifacts of soft-tissue attenuation. An indirect indication of coronary flow is provided by examination of systolic wall movement and thickening by echocardiography. Therefore, dobutamine-induced ischemia can be detected as transient left-ventricular dysfunction by 2D-echocardiography. The sensitivity and specificity of stress echocardiography are similar to that of thallium stress testing.

GENETIC BASIS OF DISEASE

Atherosclerosis is a complex phenotype that most commonly appears modulated by interactions between environmental factors and multiple genetic loci, only some of which have been identified. Genetic dyslipoproteinemias can substantially accelerate disease progression. Assessment of serum lipid levels should be included in the evaluation of all patients with coronary disease and therefore provides an initial screen for genetic dyslipoproteinemias as well. Similarly, understanding the genetic bases for other recognized clinical risk factors such as diabetes mellitus or hypertension will have an important impact on the development and progression of coronary disease. Some studies have suggested an association between the deletional allele of the angiotensin converting enzyme (ACE) gene and the risk of myocardial infarction. However, this was not confirmed in a prospective study of a large cohort of US physicians. Elevated serum levels of homocysteine can result from genetic defects in certain metabolic enzymes and is independently associated with ischemic heart disease. The epidemiological relationship of coronary artery disease and markers of thrombosis such as fibrinogen levels are also currently being investigated. However, the genetic basis of most ischemic heart disease remains elusive.

MOLECULAR PATHOPHYSIOLOGY Hypotheses concerning the molecular pathogenesis of ischemic heart disease seek to explain two related but distinct phenomena: the gradual development of obstructive atherosclerotic lesions responsible for stable angina and the rapid progression of these lesions to the acute coronary syndromes. Dr. Russell Ross and colleagues first proposed that atherosclerotic lesions develop as a "response to injury" of the vascular endothelium, and much of our current view of atherogenesis arises from these concepts. The work of Dr. Michael A. Gimbrone, Jr., Dr. Myron Cybulsky, and colleagues has suggested that atherogenesis may begin with endothelial activation or dysfunction rather than actual injury. This endothelial dysfunction may represent a common response to a wide variety of factors (Fig. 14-1). This work has also emphasized the dynamic role of the endothelium as the interface between circulating leukocytes and subintimal constituents of the vessel wall (Fig. 14-2). Activation of vascular endothelium may initiate a cascade of events leading to mononuclear leukocyte recruitment into the vessel wall with subsequent release of cytokines and growth factors contributing to smooth muscle cell migration and proliferation, as well as abnormalities of extracellular matrix formation. The precise molecular mechanisms involved in vivo are not completely understood.

Abrupt clinical change from stable angina (or no symptoms at all) to the unstable coronary syndromes appears to have its basis in acute plaque rupture. Exposure of the atherosclerotic fatty gruel to the blood serves as a substrate for the propagation of clot. Pathological studies have emphasized the importance of a central lipid core in the process of plaque fissuring and confirmed the role of thrombosis in unstable angina and myocardial infarction.

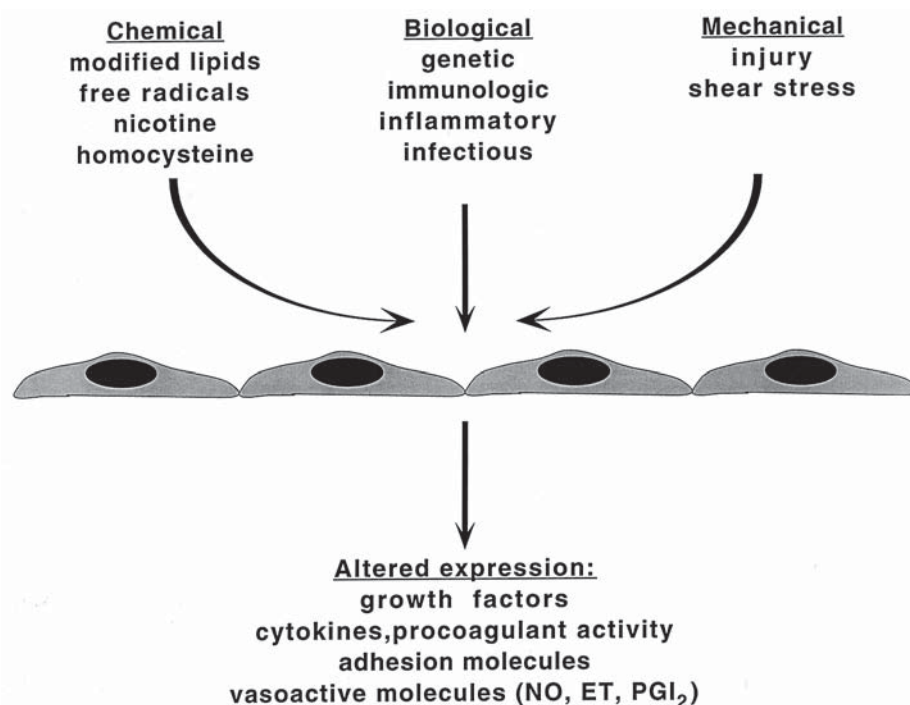
ROLE OF LIPIDS Autopsy studies have shown that fatty streaks frequently exist in the coronary arteries and aortae of chil-


Figure 14-1 The central role of vascular endothelium. Many different stimuli may induce a similar repertoire of dysfunctional endothelial responses that ultimately contribute to clinical atherosclerosis. The endothelium provides a potential pathophysiologic link between well-established clinical risks factors such as hypercholesterolemia, cigaret smoking, hypertension, and atherogenesis. The role of the endothelial effects of other agents such as homocysteine or viral infection, as well as inflammatory cascades, remains more controversial.
Figure 14-2 Leukocyte interactions with the vessel wall. An activated or dysfunctional endothelium may initiate a cascade of events that augment atherogenesis. These events include the recruitment of leukocytes through endothelial expression of cytokines and adhesion molecules, as well as alterations in smooth muscle cell function mediated by growth factors, cytokines, and vasoactive substances (indicated by arrows). Mononuclear cells and the foam cells they give rise to, as well as vascular smooth muscle cells, can also release growth factors and cytokines, further perpetuating this cycle.

dren in their teens. These lesions may constitute the earliest recognizable precursor of atherosclerotic plaques. The major lipid component of these lesions is oxidized LDL. In vitro experiments have shown that oxidized LDL stimulates the adherence of monocytes to vascular endothelium most likely through increased expression of endothelial adhesion molecules. Oxidized LDL also stimulates transcription and secretion of monocyte chemotactic protein-1 (MCP-1) by human aortic and smooth muscle cells in vitro. MCP-1

Prostaglandin	EC	SMC

is a powerful chemoattractant for monocytes and memory T cells in vitro, which are the predominant leukocytes populations present in atherosclerotic lesions. Lysophosphatidylcholine, which constitutes a significant fraction of oxidized LDL, is itself a chemoattractant for monocytes and also induces expression of the endothelial adhesion molecules vascular cell adhesion molecule-1 (VCAM-1) and intercellular adhesion molecule-1 (ICAM-1). In addition, oxidized LDL can stimulate platelet aggregation and promote procoagulant activity on the surface of macrophages by an increase in tissue thromboplastin activity and by stimulating the expression and secretion of tissue factor by monocytes or aortic endothelial cells. Finally, oxidized LDL may also contribute to the vasomotor dysfunction that can promote or exacerbate the atherosclerotic lesion. Therefore, in many patients with atherosclerosis, lipids (particularly oxidized lipids) likely constitute an early and persistent precipitant of endothelial activation and dysfunction.

CELLULAR COMPONENTS: SMOOTH MUSCLE CELLS

Abnormal growth of vascular smooth muscle cells (SMCs) is prominent in atherosclerosis. At least two phenotypes have been described of the smooth muscle cells that make up the vascular wall. This is based on examination of myosin filaments and details of the secretory protein apparatus. When cells are in a contractile phenotype, they respond to elements that promote vasoconstriction or vasodilation such as endothelin, angiotensin II, prostaglandin I$_2$, or nitric oxide. A second synthetic phenotype has also been identified. In this state, SMCs synthesize numerous growth factors and their receptors—cytokines, as well as matrix proteins. Multiple factors may be able to stimulate smooth muscle cell proliferation and migration from the vessel media through the internal elastic membrane. These activated smooth muscle cells, in turn, release substances that act in complex paracrine and autocrine manners, involving vascular endothelial and smooth muscle cells, as well as blood borne elements such as white cells and platelets (Table 14-1 and Fig. 14-2). A particularly dramatic example of this process occurs after mechanical injury of the vessel during angioplasty, but a similar process may contribute to atherogenesis. A central issue in the investigation of atherogenesis is to define the source(s) of the critical factors that initiate and perpetuate the shift in smooth

muscle cell phenotype. Peripheral leukocytes have been postulated to play a role in this process.

LEUKOCYTES Because of their early and consistent association with atherosclerotic lesions, mononuclear cells appear to be central to atherogenesis. The mononuclear cells in atherosclerotic lesions are predominantly monocytes and lymphocytes of the memory T-cell phenotype (CD45 RO$^+$). Monocyte-derived foam cells are a major component of atheroma, comprising as much as 60% of cells found in the necrotic lipid core and 10–20% of cells in the fibrous cap. Mononuclear cells serve as both as the progenitors of foam cells and as a potential source of growth factors and cytokines (Fig. 14-2). In turn, these chemical signals may mediate both intimal and smooth muscle hyperplasia and amplify recruitment of more leukocytes to the vessel wall. Even as atherosclerotic plaques increase in size, mononuclear leukocyte recruitment may continue to play an important role, particularly in the plaque borders. Furthermore, mononuclear cells may contribute to the plaque rupture underlying acute coronary syndromes, as suggested by correlative clinical studies of atherectomy specimens and autopsy series. When blood flow is restored after acute coronary occlusion, infiltrating leukocytes (particularly granulocytes) appear to be key mediators of reperfusion injury. Although considerable circumstantial evidence suggests a role of mononuclear cells in atherogenesis, their contribution remains unproven in vivo.

MOLECULAR SIGNALS

ADHESION MOLECULES Nevertheless, much work has focused on the molecular signals responsible for recruitment mononuclear leukocytes into the vessel wall. Recent findings have indeed pointed to a multistep sequence of events that guides the emigratory behavior of leukocytes in the vasculature. Leukocyte-endothelial interaction often begins with a relatively weak adhesive interaction manifested as leukocyte rolling, followed by firm adhesion to the vessel wall, and finally diapedesis. Local expression of adhesion molecules and cytokines by vascular cells appears to be an important determinant of this interaction.

Vascular cell adhesion molecule-1 (VCAM-1; CD106) is an intriguing candidate for a role in mononuclear cell recruitment in atherogenesis (Fig. 14-3). VCAM-1 was identified and cloned in rabbits by Dr. Myron Cybulsky and colleagues using an expression-cloning strategy designed to identify adhesion molecules potentially involved in the development of atherosclerotic lesions, so-called athero-ELAMs. VCAM-1 is an inducible 110-kDa member of the immunoglobulin superfamily (previously termed INCAM-110), which supports monocyte adhesion and is expressed by vascular endothelium and smooth muscle cells early in atherogenesis in the hypercholesterolemic rabbit model. VCAM-1 expression has been documented adjacent to infiltrating leukocytes in advanced human coronary atheroma. Expression of other adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1) has also been observed in association with atheroma in rabbit models and human plaques. However, this expression appears less specific and often extends into noninvolved endothelium. In addition, VCAM-1 (but not ICAM-1) could explain, at least in part, the specificity of mononuclear leukocyte recruitment since its counter-ligand, VLA-4, is expressed exclusively on these leukocytes. Furthermore, VCAM-1 (again in contrast to ICAM-1) has recently been demonstrated to support attachment of mononuclear leukocytes under flow without prior participation of selectin-mediated interactions.
Figure 14-3 Expression of VCAM-1 at sites of atherogenesis. In the left panel, the aorta of a hypercholesterolemic rabbit has been stained with Oil-Red-O to reveal characteristic sites of fat deposition and atherogenesis (darker red) involving areas of disturbed flow including the aortic arch and intercostal branch points. In the right panel, an autoradiograph of the same aorta using radiolabeled antibody to rabbit vascular cell adhesion molecule-1 (VCAM-1) demonstrates that these areas of fat deposition and atherogenesis correlate well with surface VCAM-1 expression. (Courtesy of Dr. Myron Cybulsky, Brigham and Women's Hospital, Boston, MA.) (*See* color insert following p. 684.)

Multiple clinically recognized modulators of atherogenesis also modulate expression of VCAM-1 in the appropriate direction. As noted above, VCAM-1 expression is inducible in vitro and in vivo by atherogenic lipids. Decreased nitric oxide activity increases VCAM-1 expression. VCAM-1 transcriptional induction is repressed by antioxidants, and this could explain the beneficial effects of these agents on atherogenesis in animal studies. The laboratory of Dr. Tucker Collins has demonstrated that the VCAM-1 promoter contains functional NF-κB binding sequences, which may represent a common pathway for activation of genes involved in the development of atherosclerosis. Intriguingly, aspirin, shown in many circumstances to have beneficial effects on the progression of ischemic vascular disease, inhibits VCAM-1 expression through an NF-κB pathway. Obviously, each of these manipulations produces multiple effects, and a causal role for VCAM-1 in atherogenesis remains speculative. Moreover, since VCAM-1 supports adhesion of both lymphocytes and monocytes, it alone cannot explain the predominance of monocytes in atherosclerotic plaque. One would predict an important contribution of other mol-ecules modulating either leukocyte recruitment or retention to fully explain the specificity of the populations observed.

CHEMOATTRACTANT CYTOKINES   In addition to cell surface expressed adhesion molecules such as VCAM-1, smaller secreted proteins may also play important roles in atherogenesis. The chemoattractant cytokines, also known as "chemokines," are proinflammatory cytokines that have been postulated to contribute to the recruitment of specific mononuclear leukocyte subpopulations into atherosclerotic plaques. Monocyte chemoattractant protein-1 (MCP-1) is a chemokine that acts specifically on monocytes and memory T cells, the two leukocyte populations most prevalent in atheroma. As noted above, expression of MCP-1 by vascular smooth muscle cells is induced in vitro by oxidized lipids. Furthermore, *in situ* studies have documented increased MCP-1 mRNA in vascular smooth muscle cells, mesenchymal intimal cells, and macrophages in atherosclerotic lesions, as compared to normal vessels. This chemokine may therefore play an important role in the local specific recruitment of monocytes and subsequent lesion formation. Chemokines are likely to augment leukocyte recruitment both by supplying a local chemoattractant signal and by enhancing the avidity of leukocyte counterligand binding to locally expressed adhesion molecules.

HEMODYNAMIC FORCES   It has long been clinically recognized that certain sites within the vasculature are more prone to development of atherosclerosis. These are often sites of disturbed flow, such as vessel branch points. Hemodynamic forces induce various functional changes in vascular endothelium, including morphological changes and alterations in the production of important product such as coagulation factors, fibrinolytic factors, growth factors and cytokines. However, only recently has a precise connection between hemodynamic forces and control of endothelial gene expression been elucidated. Work by Drs. Nitzan Resnick and Michael A. Gimbrone, Jr, has identified a *cis*-acting shear stress response element (SSRE) in the promoters of several genes, including PDGF-A and ICAM-1, which appears to mediate increased expression of ICAM-1 in cultured human endothelial cells subjected to a physiological range of laminar shear stress. The SSRE is a functional NF-κB binding site in vascular endothelial cells under these conditions. This SSRE may represent a common pathway by which mechanical forces influence gene expression. Other adhesion molecules such as VCAM-1 or E-selectin, whose promoters lack this motif, are not upregulated under these conditions. Identification of the molecular basis of upregulation of expression of VCAM-1 under more complex hemodynamic conditions may provide insights into the differential regulation of these genes and their role in atherogenesis.

MANAGEMENT/TREATMENT

In approaching an individual patient, several goals must be considered simultaneously. These include prevention of disease progression, control of symptoms, and optimization of prognosis. The tools available to achieve these goals include patient education, risk-factor modification, pharmacologic therapy, and mechanical interventions including surgical- and catheter-based approaches. All these considerations must be integrated into a coherent clinical approach, which, in practice, is often influenced dramatically by the acuity of the patient's clinical presentation.

Patient education and behavior modification form the cornerstone of primary and secondary prevention. Recent clinical trials have demonstrated that aggressive risk factor modification, par-

ticularly reduction in serum lipids, can have a dramatic clinical impact, even over a few years in populations with documented atherosclerotic coronary disease. Randomized trials have documented angiographic regression of plaques, establishing for the first time that regression is possible, in principle. However, even more intriguing is the observation that while the degree of regression has been modest, the improvement in clinical endpoints has been more dramatic. Reduction in serum lipids appears to have clinical benefits that are only imperfectly reflected in the angiographic appearance of lesions. These clinical benefits can be realized during a relatively brief (2–3 year) period of treatment, which underscores the importance of secondary prevention efforts. Although lifestyle modifications are emphasized as the first step in this process, it is often necessary to move to pharmacologic lipid-lowering therapies. The particular agent(s) employed is determined by the specifics of the patient's lipid profile.

Other therapies of proven clinical benefit in patients who have a prior history of myocardial infarction include aspirin, β-blockade, and angiotensin-converting enzyme inhibitors in patients with a reduced left-ventricular ejection fraction. These agents reduce the incidence of clinical cardiovascular events and mortality. For this reason, they should be considered in all patients after myocardial infarction, even if they are asymptomatic. Medications that may be useful in the chronic treatment of coronary patients but that have not been demonstrated to improve prognosis include calcium channel blockers and nitrates. In fact, in the setting of non–Q-wave infarction, the calcium channel blocker diltiazem had a deleterious effect on one year survival in patients manifesting congestive heart failure during the initial hospitalization. On the other hand, these medications may help control anginal symptoms, hypertension, or arrhythmias, but should not be routinely prescribed independent of a specific indication because of the lack of proven benefit in outcome.

Therapy for chronic stable angina includes both pharmacologic and mechanical interventions. The three classes of pharmacologic agents primarily employed are β-blockers, calcium channel blockers, and nitrates. As noted above, only the first has documented survival benefit in postinfarction patients, but all three have been demonstrated to improve exercise tolerance and can reduce ischemic symptoms—a valid goal in and of itself. Mechanical interventions encompass a variety of catheter-based approaches, such as percutaneous translumenal angioplasty (PTCA) and coronary artery bypass surgery (CABG). Early randomized trials established that CABG provides a survival benefit over medical therapy alone in patients with significant left main coronary disease or severe three-vessel coronary disease (particularly in the setting of compromised left ventricular function). In patients with one or two vessel coronary disease and mild symptoms, CABG does not confer a survival benefit. However, surgery eliminates or reduces anginal symptoms more effectively than medical therapy alone. Catheter-based interventions are also highly effective at reducing ischemic symptoms but are all plagued by a significant rate of restenosis. In addition, no survival benefit has been demonstrated for clinically stable patients using catheter-based interventions. Nevertheless, the number of these procedures performed each year continues to grow rapidly. Randomized comparisons of surgery and PTCA are currently underway.

In acute myocardial infarction, the immediate goal is restoration of adequate coronary flow as quickly as possible to minimize or avoid irreversible myocardial damage. Two general approaches are widely employed to achieve this goal: primary angioplasty and thrombolytic therapy. Several randomized trials have demonstrated additional clinical benefit to primary angioplasty, if it can be accomplished quickly by experienced interventionalists. However, in most communities this is not practical, and immediate administration of thrombolytic agents becomes preferable. The two most widely used are streptokinase (SK) and tissue plasminogen activator (tPA), both of which have been documented to improve survival and left ventricular function after infarction. The large GUSTO trial demonstrated a modest survival benefit of the substantially more expensive tPA as compared with SK. Whether this modest clinical benefit justifies the additional expense remains controversial. Interestingly, thrombolytic agents have not been beneficial in the treatment of unstable angina. However, therapy with heparin and aspirin—alone and in combination—reduces the rate of progression to frank infarction. Patients with unstable symptoms which cannot be controlled by heparin/aspirin and maximal anti-ischemic therapy should undergo early catheterization to define possible options for immediate mechanical intervention.

While heparin and aspirin remain the mainstay of antithrombotic therapy for unstable angina and non–Q-wave myocardial infarction, newer agents are currently being evaluated. Recently, basic investigation has pointed to the key role of the platelet glycoprotein IIb/IIIa receptor as the pivotal mediator of platelet aggregation. Platelet adhesion, the first step in the process of hemostasis, can be triggered endothelial dysfunction or injury and subsequent interaction of platelets with the subendothelial matrix. Adhesion molecules of the vessel wall, along with clotting proteins such as fibrinogen, interact with platelet-membrane glycoproteins—of which integrins such as IIb/IIIa play a key role. Currently, clinical trials are evaluating monoclonal antibodies directed at the IIb/IIIa receptor in the unstable coronary syndromes. Furthermore, lessons gleaned from the molecular biology of the thrombin receptor have spurred interest in the role of the naturally occurring leach anticoagulant hirudin in the clinical arena. Evaluation of the clinical role of hirudin, which binds thrombin with remarkable avidity, is currently underway. Molecular analysis of the human thrombin receptor has elucidated the role of a "hirudin-like" domain close to the site where thrombin cleaves its receptor. Future pharmaceuticals may include the creation of monoclonal antibodies or smaller synthetic molecules directed at this thrombin receptor domain, thus producing a direct receptor antagonist.

FUTURE DIRECTIONS

Several areas of investigation appear particularly fertile over the coming decade. Further genetic analysis of atherosclerosis as a complex trait will be imperative. Such studies should provide substantial insight into the significant proportion of clinical coronary risk that currently remains unattributable. Improved assessment of genetic risk for atherosclerosis would focus and facilitate efforts at primary prevention and intervention. Ultimately, the identification of the relative contribution of specific genes will also improve our understanding of the fundamental biology of atherogenesis.

Our understanding of atherogenesis may benefit more immediately from the ongoing development of genetically altered animal models. Germline manipulation of mice has already produced lines prone to atherosclerosis. These will continue to help define events in atherogenesis and to elucidate the modulating effects of other genes through crossbreeding experiments. Somatic gene transfer

will also help define the role of local vascular expression of individual molecules in disease pathogenesis, as well as the potential for therapeutic local gene delivery.

Finally, translation of these advances to the clinical arena will be vitally important. As described above, the tools available for assessing atherosclerosis in individual patients and for predicting the clinical behavior of individual lesions remain quite poor. One hopes that an improved understanding of genetic risks and lesion biology should enable us to develop better clinical markers. The ability to discriminate between biologically stable and unstable lesions would have far-reaching clinical implications. Two aspects of this problem are equally important: the identification of reliable markers of lesion behavior and the development of technologies for the practical detection of these markers in the clinical setting.

15 Endothelium-Derived Nitric Oxide and Control of Vascular Tone

Santiago Lamas and Thomas Michel

PHARMACOLOGIC AND ENDOGENOUS SOURCES OF NITRIC OXIDE

Endothelium-derived nitric oxide is a key determinant of vascular tone. Nitric oxide (NO) is a free radical gas, highly lipophilic and chemically reactive, and can be formed either by endogenous synthesis catalyzed by a family of nitric oxide synthase enzymes or consequent to the metabolism of organic nitrate vasodilator drugs. These drugs—which include such important cardiovascular agents as nitroglycerin, isosorbide dinitrate, and sodium nitroprusside—are metabolized to form NO by poorly understood enzymatic and nonenzymatic pathways.

NO has had an important role in cardiovascular therapeutics for more than a century: nitroglycerin and other organic nitrate compounds were first used in the treatment of angina pectoris in the late 19th century. Pharmacologists discovered in the 1950s that nitroglycerin and related organic nitrate drugs relax smooth muscle cells from diverse tissues, including the vasculature, gut, and lung. By the 1970s, nitroglycerin and the other organic nitrate vasodilators were discovered to be prodrugs that are metabolized in the body to form their biologically active metabolite, NO.

The NO formed from organic nitrate vasodilators leads to characteristic pharmacologic effects in diverse target tissues. An important molecular target of NO is the soluble isoform of guanylate cyclase, which is expressed in many tissues, including vascular smooth muscle cells, blood platelets, and cardiac myocytes. In vascular as well as nonvascular smooth muscle cells, guanylate cyclase activation, and the consequent rise in intracellular cyclic GMP (cGMP), leads to muscle relaxation. In blood platelets, elevated cGMP levels lead to an inhibition of platelet aggregation; guanylate cyclase activation in cardiac myocytes may attenuate myocardial contractility. The presence in these numerous tissues of molecular targets responding to NO metabolized from exogenously administered drugs suggested that endogenous pathways might exist that are modulated by NO-dependent signaling. Only in the past decade was the endogenous synthesis of NO documented in mammalian cells.

The discovery of the endogenous synthesis of NO represents the convergence of independent lines of investigation pursued variously by vascular pharmacologists, neuroscientists, and chemically inclined immunologists. In 1980, Furchgott and Zawadzki discovered that the vascular endothelium produces a labile molecule that relaxes smooth muscle, and termed this substance "endothelium-derived relaxing factor," or EDRF. In 1986, several groups discovered that EDRF is NO. In entirely independent studies in the mid-1980s, researchers investigating nitrate metabolism in inflammatory cells discovered that immunoactivated macrophages synthesize NO. High concentrations of macrophage-derived NO were shown to be toxic to cells, including tumor cells and bacteria, and it was proposed that NO synthesis by inflammatory cells represents a primitive immune response. A third line of investigations in the late 1980s led to the discovery that NO is synthesized by specific neuronal populations in the brain, and a role for NO in neurotransmission was proposed. In 1991 and 1992 several laboratories isolated a family of enzymes that make NO, termed NO synthases; during the past several years, three distinct nitric oxide synthases (NOS) were purified, cloned, and characterized at the molecular level. More than a century passed between the clinical use of NO in the form of organic nitrate vasodilators and the discovery of an endogenous pathway for NO synthesis in humans.

THE NITRIC OXIDE SYNTHASE GENE FAMILY

The different mammalian NOS were originally isolated from neuronal, immunocyte, and endothelial cell sources. One nomenclature for the three NO synthases, still in wide use, identifies the isoforms based on the cell types from which they were originally characterized (nNOS, iNOS, and ecNOS). However, it has since become clear that the different isoforms have a much wider tissue distribution than was originally appreciated; this has led to a numerical designation for the three isoforms, in order of their discovery (NOS1, NOS2, and NOS3, respectively). There are important differences in the physiologic roles subserved by the distinct NOS isoforms, as well as important differences for the same isoform as expressed in various tissues. The activity of the ecNOS isoform present in the vascular endothelium represents a key determinant of vascular tone under physiologic conditions.

The different NOS isoforms share a common overall catalytic scheme, as shown in Fig. 15-1. In ecNOS catalysis, as well as for the other enzyme isoforms, the amino acid L-arginine is oxidized to form NO plus L-citrulline in a complex reaction requiring molecular oxygen, as well as numerous redox cofactors.

Binding of the calcium-binding regulatory protein calmodulin is required for full NOS activation. The multitude of cofactors
Figure 15-1   NOS catalysis.

involved in NO formation provide for numerous potential points of regulation of the enzyme. Other forms of regulation occur at the level of the NOS genes themselves or the proteins once they have been synthesized. The different NOS isoforms can all be regulated by control of their genes (transcriptional regulation) or by alterations in the mRNA encoded by the gene (posttranscriptional regulation). A modification unique to ecNOS is *N*-myristoylation, in which the fatty acid myristic acid is added onto one end of the protein while it is being synthesized; ecNOS undergoes a second importantly regulated fatty acid modification termed palmitoylation. The fatty acid modifications of ecNOS are important determinants of the enzyme's targeting to specialized regions of the endothelial plasma membrane termed caveolae. All three NOS isoforms appear to be subject to regulation by reversible phosphorylation.

Other regulatory pathways influence NOS signaling, and may involve modulation of substrate availability or the metabolism of enzyme cofactors. For example, experiments in animal models and in humans have shown that dietary supplementation with the amino acid L-arginine, the NOS substrate, can influence atherogenesis. Another NOS substrate, molecular oxygen, may also play a role in regulation of NO-dependent relaxation: hypoxia may influence enzyme abundance and activity as well as NO metabolism. NO produced by the NOS enzymes themselves, as well as NO formed from pharmacologic sources, may also influence NOS activity and may relate to the mechanisms of pharmacologic tolerance to organic nitrate vasodilator drugs. The fate of NO once it is made may also be controlled by intracellular as well as extracellular pathways that importantly influence its biologic activity. These metabolic fates of NO may include binding to hemoglobin or other proteins, as well as interactions with reactive oxygen species, which may lead either to the degradation or stabilization of NO.

VASOACTIVE SUBSTANCES PRODUCED BY THE VASCULAR ENDOTHELIUM

The vascular endothelium is a specialized monolayer of cells that subserves numerous dynamically regulated functions in its role as the interface between blood components and the vascular wall. The endothelium is involved in the coordinated regulation of processes as diverse as thrombosis, smooth muscle mitogenesis, cell adhesion, and vascular tone. Furchgott and Zawadzki observed in 1980 that the vasodilatory effect exerted by acetylcholine was dependent on the presence of endothelial tissue, and deduced the existence of an EDRF, later shown to be NO. These and subsequent studies established the concept of the vascular endothelium as a major regulator of blood pressure homeostasis, and showed that NO represents the quantitatively most important endothelium-derived substance controlling vascular tone. Other endothelium-derived vasoactive mediators have been characterized, but appear to contribute less importantly to the dynamic regulation of vascular tone than does NO. Two extensively studied vasoactive endothelial products include prostacyclin and endothelin.

Prostacyclin was characterized in aortic strips as a substance capable of inhibiting platelet aggregation and promoting the relaxation of vascular smooth muscle. Prostacyclin, a dienoic bicyclic eicosanoid derived from arachidonic acid, is produced not only in endothelial cells, but is also synthesized within vascular smooth muscle cells and platelets, in which it contributes to the regulation of vascular tone and platelet aggregation. Prostacyclin synthesis from arachidonic acid is catalyzed by cyclooxygenase(s); after binding to its cognate G-protein–coupled cell-surface receptors, at least some of the physiologic effects of prostacyclin are mediated through activation of adenylate cyclase and the consequent increase in intracellular levels of cyclic AMP. Though prostacyclin may indeed play an important role in the regulation of platelet aggregation, this substance does not seem to be a major determinant of blood pressure under physiologic circumstances.

Endothelin is a peptide with powerful vasoconstrictor properties that was isolated and characterized as a novel product synthesized and secreted by cultured endothelial cells. Numerous lines of investigation have studied the synthesis, metabolism, and genetic regulation of endothelin. The role of endothelin in vascular homeostasis is less clearly established. Indeed, mice in which the endothelin-1 gene has been disrupted demonstrate a rather surprising phenotype. Inactivation of the gene encoding this vasoconstrictor peptide leads to significant developmental abnormalities and an unexpected vascular phenotype in which the endothelin-deficient mice are actually hypertensive. Despite numerous studies of the effects of endothelin in vitro, this substance has yet be definitively established as a major regulator of vascular tone in vivo.

By contrast, a variety of experimental approaches have shown that NO is a major determinant of vascular tone. Administration of arginine analogs that serve as competitive NOS inhibitors (e.g., N^G-monomethyl L-arginine) leads to an increase in blood pressure in experimental animals as well as human subjects. This observation suggests that tonic synthesis of NO plays an important role in vascular homeostasis. Proof for this hypothesis came from the analysis of mice in which the ecNOS gene had been genetically inactivated (by targeted gene disruption using homologous recombination in mouse embryo-derived stem cells). These ecNOS-deficient mice are fully viable but are hypertensive relative to their wild-type littermates, suggesting that compensatory mechanisms are unable to overcome the absence of endothelium-derived NO. Therefore, the ongoing synthesis of NO establishes a tonic state of vasodilation vital for vascular homeostasis.

The important role of ecNOS in blood pressure homeostasis has led to numerous investigations into the possible association of genetic defects in this enzyme with human hypertension. One report failed to find any convincing genetic linkage between the ecNOS gene and hypertension in a large population-based study. The genetic relationship between NOS and hypertension is likely to be complex. In other studies, the iNOS gene was discovered to map to a region in the rat genome linked to hypertension in SHR rats, but disease association or the relevance of this finding to human disease has yet to be established. A recent study found an association between polymorphisms in noncoding regions of the human ecNOS gene and atherosclerosis in cigaret smokers; the
Figure 15-2   NO signaling in vascular cells.

significance of this association remains to be established. A polymorphism in the ecNOS complementary DNA (cDNA) sequence, predictive of a conservative amino acid change, was found with higher frequency in a cohort of patients with vasospastic angina than in control patients, but the functional consequences of this genetic polymorphism have yet to be clarified.

REGULATION OF ECNOS IN THE VASCULAR WALL

The nitric oxide synthase in vascular endothelial cells (ecNOS) is activated by specific receptors and by increases in blood flow, and NO diffuses from the endothelium to inhibit platelet aggregation and to relax vascular smooth muscle (Fig. 15-2). Both cell surface receptors and increases in blood flow transiently activate ecNOS by increasing intracellular calcium. Perhaps the most important autacoid agonist for ecNOS activation is bradykinin. Bradykinin, a potent vasodilator peptide, is synthesized by cells in the vascular wall, and is degraded by angiotensin-converting enzyme, an enzyme that is expressed on the surface of endothelial cells. The clinically important angiotensin converting enzyme inhibitors (e.g., captopril, enalapril, lisinopril) exert at least some of their therapeutic effects by inhibiting the breakdown of bradykinin, which in turn promotes ecNOS activation leading to vasodilation. As a consequence of ecNOS activation, NO synthesized by ecNOS diffuses out of the endothelial cells, and relaxes smooth muscle and inhibits platelet aggregation by activating guanylate cyclase, thereby causing a rise in cGMP in these target cells.

The NO-dependent signaling scheme outlined in Fig. 15-2 appears to be affected in a variety of diseases. The ability of vascular endothelial cells to promote vasorelaxation is impaired ("endothelial dysfunction") in several important disease states, including hypertension, diabetes mellitus, atherosclerosis, hypercholesterolemia, and heart failure. Endothelial dysfunction may be an early marker of atherosclerosis and can be detected in patients before the onset of clinically apparent disease. Treatment of hypercholesterolemia by lipid-lowering drugs or diet appears to reverse endothelial dysfunction. Restoration of endothelium-dependent relaxation may also be seen after the oral administration of L-arginine, the amino acid substrate for NOS, to hypercholesterolemic rabbits or humans. The abundance of the endothelial NO synthase enzyme does not appear to be decreased in these disease states, and may even be increased. It seems likely that abnormalities in the activation of ecNOS or in the metabolism of NO are likely concomitants of endothelial dysfunction, but the molecular details remain obscure.

In addition to its acute effects on vascular tone, endothelium-derived NO may also serve to modulate the growth of vascular smooth muscle cells. For example, a recent report studied in vivo gene transfer of ecNOS to rat carotid arteries in which an intimal lesion was created by intravascular balloon injury. Gene therapy with ecNOS restored vascular NO activity in the injured vessel, and was associated with a marked attenuation of neointima formation, suggesting that NO is an endogenous inhibitor of neointimal proliferation.

NITRIC OXIDE AND PULMONARY HYPERTENSION

Structurally abnormal pulmonary endothelial cells have been documented in the lung vessels of patients with pulmonary hypertension. In these abnormal tissues, the expression of ecNOS appears to be markedly decreased; this was observed in patients with either primary or secondary pulmonary hypertension. It is not clear whether the abnormality in ecNOS is causal for these disorders, or whether reduced expression of ecNOS in pulmonary hypertension reflects a more general endothelial abnormality. Because NO is a gas, and its half-life in the systemic circulation is short, it was hypothesized that NO administered as an inhaled gas might selectively promote pulmonary vasodilation, with potential benefit to patients exhibiting pulmonary hypertension from a number of causes. Inhaled NO has been used to treat patients with the adult respiratory distress syndrome, as well as neonates with primary pulmonary hypertension of the newborn. Beneficial hemodynamic effects are observed in many such patients with pulmonary hypertension, in whom the inhaled NO indeed does selectively dilate the pulmonary vasculature, and because NO is rapidly inactivated in the bloodstream, there is little systemic hypotension. The efficacy and toxicity of longer-term therapy with inhaled NO is being studied in several ongoing clinical trials.

NO PRODUCTION AND SEPTIC SHOCK

A wide variety of cells possess the capacity to synthesize NO in response to immune activators. NO production by immuno-activated cells appears to have a beneficial function in host defense; however, the cellular synthesis of NO needs to be carefully regulated because of the potentially harmful cytotoxic and hypotensive effects of NO. Because NO is a reactive free radical molecule, high concentrations of NO can cause cytotoxic effects. The mechanisms underlying NO's cytotoxicity are multifactorial and include the inhibition of enzymes involved in DNA synthesis in addition to metabolic enzymes, as well as direct effects on cell lipids and DNA. In immunoactivated cells, the iNOS gene is induced, and the NO formed by these cells may play an important role in host defense against bacterial, viral, and protozoan infection. In contrast with cells that constitutively synthesize low levels of NO (such as vascular endothelial cells), immunoactivated cells are generally characterized by much higher levels of NO production. This reflects both the higher level of iNOS protein expression in many immunoactivated cells, as well as the fact that the iNOS protein remains persistently activated, whereas ecNOS (and nNOS) is only transiently activated in response to the short-lived increases in intracellular calcium consequent to receptor activation. The resulting NO production may produce profound hypotension and, not uncommonly, may lead to a fatal outcome. In addition to direct effects of NO on the vasculature to produce vaso-

relaxation, NO (generated by iNOS induced within the myocytes) may have a direct effect on myocardial contractility. Thus, inappropriate or unregulated NO synthesis may have deleterious effects, either because of direct cytotoxic effects or as a result of NO-induced hypotension.

The delicate balance of NO production in host defense is exemplified in studies of mice in which the iNOS gene has been genetically inactivated. These iNOS-deficient mice show a lower mortality from sepsis-induced hypotension, but are less able to resist infection compared with wild-type mice.

In pathologic states, such as sepsis, smooth muscle cells themselves may activate the iNOS gene in response to cytokines such as TNF-α (tumor necrosis factor-α, generated by immunoactivated cells) or in response to bacterial endotoxin. This leads to excessive NO formation in the smooth muscle cells, and the consequent vasorelaxation can lead to hypotension or even shock, as discussed below. In addition to vascular smooth muscle cells, a wide variety of other cells and tissues express the iNOS gene after immunostimulation by cytokines or bacterial endotoxins. The acute mortality from septic shock derives in part from NO-induced hypotension, and several studies have tried to inhibit sepsis-induced NO production in both experimental and clinical settings. Administration of glucocorticoids does attenuate the genetic induction of iNOS; but, likely because of their pleiotropic effects, steroids do not appear to reduce mortality from sepsis and may in fact be deleterious. Recent experimental studies have administered different growth factors and cytokines in an effort to more selectively block iNOS induction. The greatest amount of clinical experience is in the use of agents that directly block NOS enzyme activity.

NOS inhibitors have been studied in case reports describing treatment of septic shock and are being investigated in ongoing clinical trials. The iNOS inhibitors that have been most widely investigated are analogs of arginine, the substrate for all three NOS isoforms. Infusion of these arginine analogs increases systemic blood pressure in normal humans, and there are anecdotal reports in which administration of arginine analogs stabilized blood pressure in profoundly hypotensive patients in septic shock. Unfortunately, the therapeutic window for the administration of arginine analogs appears to be rather narrow. Complete NOS blockade may result in unopposed vasoconstriction, ultimately leading to tissue ischemia and death. It would be ideal to inhibit just the iNOS because concomitant inhibition of ecNOS could lead to unopposed vasoconstriction and tissue ischemia. Numerous academic investigators and pharmaceutical companies are trying to develop NOS inhibitors that selectively block the iNOS isoform.

The past decade has witnessed the confluence of multiple lines of investigation that together establish the central homeostatic role of NO in control of vascular tone. Ongoing investigations into the structure of NOS isoforms, as well as studies of their cellular regulation, will likely lead to therapeutic advances in the treatment of hypertension and septic shock.

16 Hypertension

George Koike and Howard J. Jacob

INTRODUCTION

The explosion of genetic markers and analytical techniques in the field of molecular genetics makes the dissection of the genes conveying risk for multifactorial (multiple genes and gene–environment interaction) disorders, such as essential hypertension, possible. This chapter will discuss the application of molecular genetic techniques to the genetic dissection of hypertension. It is important to note that, although the topic discussed in this chapter is hypertension, the approaches and techniques described are applicable to other multifactorial disorders, such as diabetes mellitus, renal failure, and myocardial infarction.

Essential hypertension, defined by an increased blood pressure that exceeds an epidemiologically significant threshold, is a major risk factor for cardiovascular disease as well as a major cause of heart failure, renal failure, and stroke. Although hypertension is a qualitative trait (either a patient has it or not), blood pressure is a continuous trait that exhibits a normal distribution or a quantitative trait in the population. As illustrated in Fig. 16-1 from the Hypertension Detection and Follow-Up Program (HDFP), the threshold level has continued to decrease as the epidemiological significance of a new threshold becomes apparent. If the threshold is inaccurate, its use may reduce statistical power and may introduce bias.

In recent years, there have been several genetic studies using a variety of study designs, most typically association studies (case control studies). These studies have focused on a limited number of candidate genes. The majority of the results from these studies are conflicting (Table 16-1). This may be owing to the difference of study method, phenotyping method (what kind of criteria is used to define hypertensives, what kind of protocol is used to measure blood pressure), number of subjects, gender, and genetic background. These issues are very important and must be considered when designing a genetic study properly. Clinicians/scientists have to be careful to evaluate each study. Currently, there is only one gene, angiotensinogen, that has met relatively stringent criteria, including replication in independent studies by more than one group. However, not all studies with angiotensinogen have been confirmatory, and the causal mutation of this gene has not been identified, leaving open the possibility that this is not the causal gene, but rather near the causal gene or linked to the causal gene.

The goal of this chapter is:

1. To outline how molecular genetic techniques can be brought to bear on hypertension.
2. To illustrate how study design and phenotyping play an essential role in discovering genetic underpinnings of human hypertension.
3. To extend results from studies of experimental animal models.

GENETIC STUDIES FOR HYPERTENSION IN HUMANS

EVIDENCE FOR A GENETIC BASIS Epidemiological studies for many years have revealed that hypertension clusters in families, which could be the result of sharing genes, sharing the same environment, or both. Segregation analyses (which tests for a genetic transmission pattern of disease within a pedigree) suggest that there is a fairly strong genetic component to this disease. The best studies for estimating heritability of a disease are those involving monozygotic and dizygotic twins. Since twins of both classifications share the same womb, there is a control for maternal environment. However, dizygotic twins share 50% of their genomes (same as any other sibling), whereas monozygotic twins are genetically identical. If the monozygotic rate of disease is significantly higher than the dizygotic one, there is a strong genetic component. In monozygotic twins, the chance of a twin developing hypertension if his or her sibling has hypertension is 58%, whereas in dizygotic twins, the risk of developing hypertension if his or her sibling has hypertension is 19%. These data are interpreted as follows: Since the risk to a monozygotic twin is three times higher than for the dizygotic twin, there is a strong genetic component. Interestingly, it is remarkable that even in monozygotic twins, hypertension and other diseases are not fully penetrant (a subject has the genetic predisposition, but does not develop the disease). The reasons for the diseases not being fully penetrant are still unknown, but the most common explanation is that environmental interaction may be required for disease expression. However, it is not hard to see how incomplete penetrance further increases the difficulty in determining the genetic cause of hypertension.

Although genetic and epidemiological studies demonstrated that hypertension has a genetic component, a problem with determining the genetic basis of hypertension is that it results from multiple genes (polygenic nature) and is very common, ranging from a prevalence of 20–40% in humans. The combination of multiple genes and a very common disease translates to most humans carrying at least one hypertensive gene, which means nor-
Figure 16-1 Frequency distribution of diastolic blood pressure at home screen of 158,906 persons, 30–69 years of age, HDFP (1974). H. D. a. F.-U. P. C. Group Circ Res 1997.

Table 16-1
Genetic Studies of "Hypertensive loci" in Humans

Candidate genes	Study design	Segregation with High blood pressure
Renin	Case control	No
ACE	Case control	Yes
	Affected sib-pairs	No
	Four corners	No
Angiotensinogen	Affected sib-pairs	Yes
	Case control	No
S_A	Case control	Yes
	Case control	No

motensive family members will carry hypertensive genes that are shared with hypertensive family members. This problem is further exacerbated by the relatively late age of onset. Will the normotensive subject always be normotensive?

BLOOD PRESSURE AS A PROTOTYPICAL QUANTITATIVE TRAIT   Hypertension is a clinically and epidemiologically defined disease. However, as shown in Fig. 16-1, blood pressure shows a normal distribution. There are two key words for the basic principals of the trait (phenotype), "qualitative" and "quantitative." The qualitative trait is a discontinuous variation. For example, Mendel's peas were either green or yellow: the coats of the peas were either smooth or wrinkled. The qualitative trait could be easily followed from one generation to the next with a defined mode of inheritance (additive, dominant, or recessive). In contrast, the quantitative trait is a continuous variation, in which the difference of the phenotype slowly integrates. The quantitative trait is usually described from one extreme to the other. Height and weight are typical examples of a quantitative trait. As described in Fig. 16-1, the distribution of the blood pressure shows from low (normotensive) to high (hypertensive) continuously, and blood pressure is a prototypical quantitative trait. This concept of quantitative genetics has been applied to the agriculturally important crops and experimental models, and several trait-causing genes have been mapped. In a last decade, this has also been applied to several complex traits in humans. Genetic studies for hypertension have used clinical thresholds to defined hypertension as a qualitative trait. To study hypertension as a quantitative trait, it is essential to collect "natural" blood pressure. However, in most cases, patients have been on medication for hypertension, preventing the use of blood pressure as a quantitative trait. Even if medication is removed, there is no guarantee that blood pressure measured is identical to what would have been found if the patients had not been treated. One solution to overcome this conflict is to study hypertension as a qualitative trait. This strategy worked for the human insulin-dependent diabetes mellitus (IDDM) study and human non–insulin-dependent diabetes mellitus (NIDDM) study (see Chapter 47). However, if the threshold to defining disease that

has quantitative trait is inaccurate, its use may reduce statistical power and may introduce bias.

DETERMINING THE GENETIC BASIS OF HYPERTENSION   Prior to 1980, genetic dissection of hypertension or any other diseases in human was practically impossible owing to a paucity of genetic markers. In 1980, Botstein and colleagues demonstrated that sequence variation can be used as a genetic marker. Recent progress of the human genome project has provided several tools, such as genetic markers, genetic linkage maps, expressed sequence tag sites (ESTs), large insert libraries (yeast artificial chromosome [YAC], and bacterial artificial chromosome [BAC]), and radiation hybrids, enabling investigators to carry out gene hunting for genetic disorders. Using these tools, causal genes for many genetic disorders, such as familial hypertrophic cardiomyopathy (see Chapter 13), Huntington's disease (see Chapter 97), and Liddle's syndrome, have been identified. However, all these diseases have been caused by one gene exhibiting simple Mendelian genetics. To date multifactorial diseases, such as hypertension, have remained elusive.

With the tools required for genetic dissection largely in place, genetic studies into the etiology of hypertension have become quite common. In general, these studies can be broken into two different study designs, as well as by how the subjects were ascertained. It is essential that the clinician/scientist interested in these studies understand the study designs used for dissecting the genetic basis of hypertension.

The study designs can be divided into two different ways: candidate gene approach and total genome scan.

Candidate Gene Approach   This strategy focuses on a single gene of interest and has been the most widely applied to the study of human hypertension, as well as other disorders. Generally, to perform candidate gene approach, targeted genes have been picked because they have been known to play a role in blood pressure regulation. For example, since the renin-angiotensin system has been known to play an important role in blood pressure regulation, renin and angiotensin-converting enzyme (ACE) have been favorite targets for studying human hypertension. Furthermore, this study design has frequently been combined with the easiest population ascertainment scheme, association study. (Please see Association Study below for details.) The concept of this strategy is to find an association between the sequence (allele) difference of a candidate gene and phenotype of interest, in this case, blood pressure. This strategy works well for simple Mendelian diseases. However, since hypertension is a polygenic (polygeneity: simultaneous abnormalities of multiple genes cause one phenotype [hypertension] and genetically heterogeneous [genetic heterogeneity]:

Table 16-2
Comparison of Genetic Studies

Linkage analysis (pedigree analysis)
  Advantages
    Suitable for total genome scan
    Suitable for simple Mendelian traits
    No need to collect a control population
    May be useful for multifactorial disorders when isolated population is studied
  Disadvantages
    Difficult to collect large informative pedigrees
    Difficult to obtain enough statistical power for complex traits
Allele-sharing method
  Advantages
    Suitable for total genome scan
    Suitable for multifactorial traits
    No need to collect a control population if the information of allele frequency in general population is available
  Disadvantages
    Difficult to collect population
  Affected sib-pairs study
  Advantage
    More statistical power with parent's information (IBD information)
  Disadvantage
    Same as above
  Affected pedigree member study
  Advantage
    More statistical power with the more information of IBS to infer IBD
  Disadvantage
    Difficult to collect relatives in addition to sib-ships
  Discordant sib-pairs study
  Advantages
    To save genotyping effort (requires fewer genotypes and fewer patients to be ascertained)
    To use same population for several different traits of interest
  Disadvantage
    Need to collect a large number of sib-ships, affected and unaffected; especially difficult to collect unaffected sib-ships
    Discordant unaffected sibs need to be defined based on the distribution within the population
Association study (case control study)
  Advantages
    Suitable for candidate gene approaches
    Easiest for subjects ascertainment
  Disadvantages
    Need a large number of population
    Need a control population
    Difficult to obtain enough statistical power
    High probability of false linkage without the correct control population

abnormalities in any one of several genes cause one identical phenotype [hypertension]) disease and a lot of genes have been considered as candidates, with current technology it is not an efficient way to study hypertension owing to hundreds of combinations of candidate genes within the population.

Total Genome Scan Strategy This strategy, reported in 1986 by Lander and Botstein, has become more favored as the number of genetic markers have increased. The concept of this strategy is that once a complete genetic linkage map is available, the total genome could be scanned simultaneously to find genetic markers that cosegregate (is genetically linked) with phenotypes that have a genetic basis; in this case, blood pressure. This approach is more systematic compared to the candidate gene approach. Therefore, this strategy is suitable to studying a polygenic and genetically heterogeneous disease, such as hypertension. Using this strategy, the region or genetic locus containing a gene responsible for a disease could be mapped without any *a priori* knowledge, having a great potential to identify novel genes.

Study designs and the methods to collect study population (patient ascertainment) available for genetic dissection of multifactorial traits in humans, such as hypertension, can be broken down roughly into three methods:

1. Linkage analysis (pedigree analysis).
2. Allele-sharing method (affected sib-pairs study, discordant sib-pairs study, affected pedigree member study).
3. Association study (case control study).

A brief comparison of these studies is summarized below and in Table 16-2. For more detailed information, several reviews are available.

Linkage Analysis Linkage analysis involves proposing a model to explain the inheritance pattern of phenotypes and genotypes observed in a pedigree. For simple Mendelian traits, this model is straightforward and powerful. Among hypertension-related diseases, identification of the genes for Liddle's syndrome and

glucocorticoid-remediable aldosteronism provides typical examples. On the other hand, for multifactorial traits, such as essential hypertension, this model could become more complicated and less powerful owing to the difficulty of phenotyping (difficult to define disease state, especially with late-onset traits among generations) and the loss of transmission of the linkage among generations. Since hypertension is polygenic and common, unaffected pedigree members will carry some of the genes, but not express the disease. This situation is the biggest limitation to studying hypertension with this strategy. One solution would be to divide hypertension patients into multiple subgroups based on phenotype. Unfortunately, we do not have any agreed upon clinical end points to accomplish this. It may be possible to apply this strategy to an isolated population, such as Chicoutimi-Saguenay-Lac St. Jean French-Canadian population. Isolated populations frequently exhibit a founder effect, meaning that only a few disease genes are segregating in the population. Therefore, the disease has less heterogeneity, improving the likelihood that hypertension is a single disease. For this strategy, multiple consecutive generations (generally at least three) in a pedigree are required to specify the correct model to obtain a enough statistical power. Without the information of multiple consecutive generations, linkage analysis could not be carried out. However, it is highly likely that a model for a pedigree assumed with this limited information could be wrong, resulting in missing true linkage and sometimes accepting false linkage.

Allele-Sharing Method The allele-sharing method can obviate many of these restrictions in the dissection of polygenic traits. Affected sib-pairs, affected pedigree member (APM), and discordant sib-pairs studies are included in this method. Prior information regarding the mode of inheritance, penetrance of the disease, or other assumptions is not required. Analysis is based on significant sharing of alleles between affected relatives at the disease loci. Both the candidate gene approach and the total genome scan strategy can be applied with this method. Affected sib-pairs study compares the number of alleles shared between sib-ships. On average (with fully informative markers), sib-ships are expected to share an allele 50% of the time. However, if a disease-causing gene resides near a genetic marker, then affected sib-pairs will exhibit allele sharing significantly different from 50%. In practice, if parental genotypes are not known, shared alleles are identical-by-state (IBS), because one does not know if the parents shared the same allele. If parental genotypes are known, the allele sharing is identical-by-descent (IBD) (with a fully informative marker). Consequently, multiplex families provide more genetic power than simply looking at affected sib-pairs. In contrast, APM study requires affected relatives (uncles, aunts, cousins, and so forth) and in some cases is more informative than the affected sib-pairs study. Recently, discordant sib-pairs study design has been described and is based on most of the linkage information being derived from both extremes of the traits of population. For this strategy, affected sibs and unaffected sibs are collected to reflect the extremes of the general population in contrast to the other studies. Therefore, fewer patients need to be ascertained and genotyped. Unfortunately, ascertainment is based on the unaffected individuals being at the extreme of the population. Consequently, this study design requires population data and selective ascertainment.

Two examples of using allele-sharing method in human are the identification of the region of the human genome linked to NIDDM by Hanis et al. and of several regions linked to IDDM by Davies et al. (*see* Chapter 47).

Association Study Association study is the most common strategy used to carry out genetic study for hypertension, and does not require familial inheritance patterns of diseases at all. This study design is based on a comparison of unrelated affected and unaffected individuals from a given population, and to test whether a particular allele is observed at higher frequency among affected than unaffected individuals. Therefore, criteria to collect individuals are less stringent (subjects could be collected randomly) than other studies discussed above. An essential component is the selection of the unaffecteds (controls) and to study a large number of subjects followed by ascertaining a second population set for confirmation. Otherwise, the chance of a false linkage is high. This approach has widely been applied. For example, association studies for ACE insertion/deletion (I/D) polymorphism, and several diseases, such as myocardial infarction, hypertrophic cardiomyopathy, left ventricular hypertrophy, and hypertension have been carried out. However, replications of these findings have been limited and may be owing to the following reasons:

1. The criteria to collect human subjects (affecteds and unaffecteds) may differ among studies.
2. The number of subjects is relatively small.
3. The two-allele system (D allele and I allele) for ACE does not provide enough information, since it is highly possible that these alleles may be commonly observed among subjects.
4. It is extremely unlikely that this sequence variance represents a biologically relevant mutation.
5. Most of the studies are the retrospective that potentially introduces biased data set. For example, in the first paper demonstrating an association of myocardial infarction (MI) and ACE polymorphism, the subjects studied were the survivors from the initial MI. This study did not include the subjects who died at the initial MI.

Each one of these decreases the statistical power to analyze the data set. If these criteria are well-covered, this approach is a powerful method to perform genetic dissection of multifactorial disease, such as the association between apolipoprotein E and Alzheimer's disease. This study involved the use of the multiple-allele system and relatively large population, and has been replicated numerous times.

How then does one design a study that has enough power to detect genes responsible for hypertension against a backdrop of multiple genes, moderate penetrance, environmental interaction, and when many of the causal genes are frequent in the general population? Despite the recent advances in molecular genetics (because of the success of the international human genome project), only one locus, the angiotensinogen gene locus, has been shown to segregate with essential hypertension in several studies and several study designs (although not all studies find a positive association). Major limitations in human studies are as follows:

1. To collect the large number of samples in a well-controlled study with accurate phenotyping remains a daunting challenge.
2. Genetic heterogeneity (several genes or gene combinations are able to cause the same phenotype).
3. Polygeneity (multiple genes are necessary to express the phenotype).

4. Environmental factors (for example, it is well-known that stress and salt in some people are able to increase blood pressure).
5. Statistical concerns and challenges in evaluating collected data, particularly with respect to studying hypertension as a quantitative trait.

These limitations have restricted the genetic dissection of hypertension in humans to the candidate gene approach instead of scanning the total genome, although they are now under way in several laboratories around the world. One solution that we have taken is to attack the genetic basis of hypertension using two approaches, allele-sharing methods and studies of experimental animal models.

As described *above*, we are still facing several difficulties that have to be overcome. Therefore, the points that we have to be careful to evaluate in genetic studies, especially in human, are as follows: (1) Is positive result real or not? (2) Negative result does simply not mean there is no linkage. If the study is carried out with enough genetic power, there may potentially be a linkage identified, or the gene may play a role in another population or ethnic group.

GENETIC STUDIES FOR HYPERTENSION IN EXPERIMENTAL ANIMAL MODELS

Another approach to carrying out the genetic study for hypertension is the genetic analysis of large crosses in experimental animal models, particularly in rat. Experimental animal models offer several advantages for genetic research:

1. They are inbred (maternal and paternal chromosomes are identical), thereby solving the problem of heterogeneity.
2. Mating can be controlled and optimized.
3. Large numbers of progeny can be generated.
4. Invasive phenotyping protocol can be used.

These attributes of inbred animals are allowing dissection of various genes affecting multifactorial traits, such as hypertension. The coding region of the rat genome is more than 90% similar to the human genome. Therefore, once disease genes are identified in animal models, these genes can then be studied in the regions of conserved gene order between human and model genomes. Not all genes discovered in this manner are expected to play a role in the human disease; however, historically, more complete understanding of the physiology in model animals has aided understanding of human biology. Of course, genetic dissection of human hypertension has made progress recently, and the physiology and pathophysiology of the experimental animal models are not identical with human. For example, in the case of humans and rat (experimental animal model for hypertension), cardiovascular parameters, such as blood pressure and heart rate, and onset age of hypertension are different. However, recent progress in the human cannot account for the etiology of hypertension completely. Therefore, the complementary investigations in both humans and experimental animal models should continue toward our complete understanding of genetic causes for hypertension and other multifactorial diseases (e.g., diabetes and renal failure). In the last 30 years, several experimental animal models of hypertension have been used to study the etiology of hypertension and the blood pressure regulation. Among several experimental animal models, the rat has been extensively characterized in physiology. Most importantly, several hypertensive and normotensive rat strains are available as inbred strains. Table 16-3 lists major hypertensive and

Table 16-3
Major Hypertensive and Normotensive Inbred Rat Strains

Hypertensive rat
Dahl salt-susceptible rat (SS/Jr): Model for salt-sensitive hypertension
Fawn-Hooded hypertensive rat (FHH): Model for hypertension and renal failure
Genetically hypertensive rat (GH): Model for hypertension and cardiac hypertrophy
Lyon hypertensive rat (LH): Model for hypertension
Milan hypertensive rat (MHS): Model for mild hypertension
Sabra hypertensive rat (SBH): Model for DOCA salt-sensitive hypertension
Spontaneously hypertensive rat (SHR): Model for hypertension
Stroke-prone spontaneously hypertensive rat (SHRSP): Model for hypertension, stroke and cardiovascular diseases

Normotensive rat
AxC irish rat (ACI)
Brown Norway rat (BN)
Dahl salt-resistant rat (SR/Jr)
Donryu rat (DRY)
Fischer rat (F344)
Lewis rat (LEW)
Lyon normotensive rat (LN)
Milan normotensive rat (MNS)
Wistar-Kyoto rat (WKY)

normotensive inbred rat strains. As described in this table, each hypertensive strains has a unique character(s).

Based on genetic infrastructure, the mouse is the best-characterized experimental model. However, there is only one mouse strain that develops severe hypertension, and the physiology of the mouse cardiovascular system is very rudimentary. Even though the rat genetic infrastructure is less developed than the mouse, a tremendous effort has been made to understand the physiology of hypertension using this species. For example, there have been more than 2000 reports that have used the spontaneously hypertensive rat (SHR), a genetically hypertensive rat, with most of these reporting differences between the SHR and a normotensive control, typically the Wistar-Kyoto rat (WKY). Similar studies have been carried out using various genetically hypertensive rats. However, these studies focused on simple differences in physiological characteristics between the strains without genetics.

Clearly experimental animal models have some physiological and pathophysiological differences with human, so how useful will these models be? The issue of relevancy to the human pathobiology is frequently associated with there being a 100% correlation between human and experimental animal models. It would be extremely unlikely that the rat strains developed by simply selecting for animals with the highest blood pressure would be identical to human hypertension. It would be equally unlikely that any human pedigree or small set of affected sib-pairs would represent all patients with hypertension. In fact, the very definition of hypertension remains limited to the clinical presentation and various attributes found in some patients with hypertension. In practice, however, it is very likely that some genes found in animal models will be concordant with human disease, but in all cases, the information learned is important in understanding the etiology of hypertension. For example, Cicila et al. reported that 11-β hydroxylase is responsible for mineralocorticoid hypertension in the SS/Jr. These data appear to confirm the study by Lifton et al. (1992),

which found that an unequal crossover between 11-β hydroxylase and aldosynthase resulted in glucocorticoid-remediable aldosteronism. A recent genome-wide scan of humans for IDDM located two quantitative trait loci (QTLs) in homologous regions with the NOD mouse, confirming that total genome search in animal models may provide insight. We believe that using the rat QTLs as genetic pointers to highlight the regions of the human genome to genotype with markers at 1-cM intervals will increase our chances of locating novel and important regions involved in hypertension.

Our laboratory has been building the infrastructure, genetic markers, and genetic map for the rat. We and others have used this infrastructure to carry out genetic dissection of multifactorial traits, such as hypertension, renal failure, type I and II diabetes mellitus, and cardiac hypertrophy using the rat as an animal model. In this chapter, we would like to focus on how these data can be used to study hypertension in human.

RECENT PROGRESS IN RAT   Over the last few years, investigators have begun to use molecular genetic techniques to find genes responsible for hypertension using rats. Initial studies began with "candidate gene" studies hypothesizing that the gene is a cause of hypertension. Previously, Dr. John Rapp set four criteria to define a causal gene:

1. A biochemical and/or physiological difference between two strains (people) must be established.
2. The locus or loci must segregate in a Mendelian fashion.
3. The locus or loci identified must account for a significant portion of the blood pressure.
4. There must be some logical link between the locus or loci and its control of blood pressure.

More recently, the definition of a candidate gene has expanded to include an unknown gene within an interval that cosegregates with hypertension, and these genes are "positional candidate genes."

Complete genome scans in the rat models of hypertension have become more popular as the number of markers available for the rat genome have increased. These studies involve genotyping a large number of genetic markers and observing if any of these markers cosegregate with any of the recorded phenotypes, offering the possibility of locating previously unknown genes responsible for hypertension. A glance at Table 16-4, listing the loci found in several studies, shows that many of the genetic regions that cosegregate with high blood pressure contain a candidate gene. Several key points are evident from Table 16-4. First, there appears to be a "hypertension-causing" gene on practically every rat chromosome. One might conclude that genetic dissection does not appear to be simplifying the process of determining the causal genes for high blood pressure. However, the blood pressure regulatory pathway is very complex and contains a large number of potential sites, which, if disrupted, could result in high blood pressure. It is quite likely that this list will expand as the genetic map of the rat improves and the number of crosses studied increases. Second, when studying this table, it is apparent that different crosses utilizing one or both of the same strains may or may not have the same QTL(s) cosegregating with blood pressure. A limitation of all genetic dissection is that it can only identify differences between strains or people. It cannot identify genes in common between two strains, even if those genes are also critical to the development of hypertension.

This table also details, quite surprisingly, that very few studies (except for those in the recombinant inbred strains) have identified QTLs associated with baseline blood pressure, despite a spread of more than 2 SD between the blood pressure of the two parental strains. Why so few QTLs have been identified for baseline blood pressures remains to be determined. A logical hypothesis is that the critically important system of blood pressure regulation involves a large number of genes, some involved in increasing low blood pressure and others involved in reducing blood pressure. If this hypothesis is correct, there may be several genes involved in hypertension in any one cross, each one contributing only a few mmHg to the overall blood pressure. In this case, a very large number of animals will be required before "linkage" can be determined. Therefore, it may be necessary to induce various stresses to the cardiovascular system in order to uncover which regulatory mechanism of the blood pressure system cannot respond. This may also explain why most of the studies have identified linkage to a particular QTL after inducing a salt-load stress.

In sum, the initial studies utilizing a genetic dissection approach have located several regions in the rat genome that play a role in hypertension; however, several points need to be emphasized. Many of the initial studies have not utilized a complete genetic linkage map and may have missed additional QTLs. Also many of the crosses studied are quite small (<200 animals) and lack enough power to identify additional QTLs.

Newly identified QTLs have become synonymous with candidate genes in or near the QTL. This association with any candidate is likely to be premature and may cause future research to focus on the candidate, rather than identifying previously unknown genes in the region that may also be involved with blood pressure regulation. If the initial candidate does not prove to be causative in additional studies, the initial finding may be discounted based on studying the wrong candidate. For example, renin is a candidate gene because it is important in blood pressure regulation, and it also has been shown to cosegregate with high blood pressure. However, there is no direct evidence that the renin gene is a causal gene for hypertension in the original cross.

Based on previous rat studies in Table 16-4, another aspect that we have to pay attention to is genetic background. The influence of genetic background on the expression of hypertension has been largely ignored. Studies using the same hypertensive strain crossed with different normotensive strains showed different results (each study identified different loci), suggesting that the gene(s) derived from normotensive strain may play a role in the development of hypertension. This may also be a result of differences in phenotypes. Presently, the only method to control for these effects is to use a 2×2 study design, where two different hypertensive strains are crossed with the same normotensive strain, which has not been reported.

The effect of gender on blood pressure also has been largely overlooked, since most cross-structures reported have used a single-cross approach (typically the male hypertensive animal crossed with a female normotensive animal) and most studies have only focused on males. The use of single cross and/or the use of male animal prevents determining if a phenotypic difference between the male and female animals is the result of a sex-linked (gene carried on the sex chromosomes X or Y) gene or genes, or the sex-specific (the result of hormonal differences or other factors that distinguish the two sexes).

LESSONS FROM RAT STUDIES   In addition to identifying loci responsible for blood pressure regulation, results from our rat studies revealed significantly important aspects regarding gender

[a]Candidate genes: α2b adrenergic receptor (ADRFLP); angiotensin-converting enzyme locus (ACE); arginine vasopressin (AVP); calmodulin-dependent protein kinase II-Δ locus (CAMK); cytochrome P450 (P450); endothelin-2 locus (ET2); endothelin-3 locus (ET3); guanylyl cyclase A/atrial natriuretic peptide receptor locus (GCA); heat-shock protein locus (HSP); inducible nitric oxide synthase locus (iNOS); metallothionein-1 pseudogene-A (MT1PA); metallothionein-1 (MT1PB); Na$^+$K$^+$ATPase α locus (NaKα1); nerve growth factor locus (NGF); neuropeptide Y locus (NPY); substance P receptor locus (SPR); the testis-specific histon locus (HITH); no known candidate gene reported (?).

Phenotypes: blood pressure (BP); diastolic blood pressure (DBP); mean arterial pressure (MAP); pulse pressure (PP); systolic blood pressure (SBP).

Strains of rats: donryu (DRY); genetically hypertensive (GH); Lyon hypertensive (LH); Lyon normotensive (LN); Milan normotensive strain (MNS); spontaneously hypertensive rat (SHR); stroke prone SHR (SHRSP); Dahl salt-susceptible rat (SS/Jr); Dahl salt-resistant rat (SR/Jr).

[b]RI, recombinant inbred strains. This methodology, although not as powerful as a cross-study, does offer some insight. A problem with this approach is that the same phenotyping information is "scanned" repeatedly, increasing the chance of false linkage, and the segregation of genes is fixed in only 28 strains.

differences and phenotyping that may also be critical for human genetic studies. In this section, we discuss how these issues potentially relate to genetic studies of human hypertension.

Gender Effect The difference in blood pressure levels between males and females and the putative regulatory mechanisms involved have been extensively addressed in the literature. Even though the sex effects have been reported by several investigators, controversy over the existence of sex-linked (the result of

gene[s] on the X or Y chromosome) and/or sex-specific (differences because of sex: the result of hormonal differences or other factors that distinguish the two sexes) effects remains. Previously, Tanase et al. used several estimates of heritability to carry out genetic analysis of hypertension in three crosses (Table 16-5). The progenies of these crosses were phenotyped over many weeks. Several interesting points arise from this study. One of them is that an estimate of the number of loci is different between male and

Table 16-5
Number of Genetic Loci Estimated to be Responsible for Blood Pressure at Different Sexes and Ages[a]

	Week										
Cross	5	7	9	11	13	15	17	19	20	25	30

Female						2.7			3.1		

[a]WI, Wistar/Imamichi; WKY, Wistar/Kyoto; WM, Wistar/Mishima.

female in the same cross at the same time-point, indicating the gender difference responsible for hypertension. Recently, differences between sexes also observed in the SHRSP/Hei X WKY/Hei and the GH X BN cross suggest that there maybe sex-specific (not sex-linked) QTLs influencing blood pressure. An example for sex-linked effect is the Y chromosome effect on blood pressure. In 1990, Ely and Turner reported a Y chromosome effect that accounted for a significant proportion of the genetic variance in blood pressure. The notion of a hypertensive gene on the Y chromosome is consistent with producing all hypertensive progeny in the fourth generation after initiating the selection for hypertension when deriving the original SHR. They have generated a set of congenic animals where a Y chromosome from the WKY was placed on an SHR background (SHR-Y^{WKY}) and a Y chromosome from the SHR was placed on a WKY background (WKY-Y^{SHR}). These congenic rats' blood pressures were measured and compared to the parental strains. The SHR-Y^{WKY} has a lower pressure than the SHR, and the WKY-Y^{SHR} has a higher blood pressure than the WKY.

To address the gender effect, a study design, reciprocal cross-setup, allows one to investigate if there are any sex-linked genes, sex-specific genes, or epigenetic factors (imprinting, mitochondrial genes) in a cross. Reciprocal crossdesign is to setup two different grandparents combination; hypertensive male × normotensive female, and normotensive male × hypertensive female, resulting in maximum power to carry the genetic study to elucidate gender effect and potentially reveal any epigenetic effects (mitochondrial or imprinting). However, the majority of previous rat studies used only single grandparent setup (generally hypertensive male × normotensive female), not able to see sex-linked genes or epigenetics. Our study addressing these effects is being analyzed, but this stage is too early to show our conclusion. Nevertheless, we are confident that our studies will be very useful in understanding sex-linked, gender, and epigenetic effects on blood pressure regulation and provide us with clues for searching for genes in affected sib-pairs and case control studies.

Phenotyping Window Effects   It is important to realize that rat genetic studies described in this chapter can distinguish differences between the only two strains studied. (This is an advantage to use animal models instead of human.) Because the selection of strains determines the number of genes segregating within the cross, it is meaningless to talk about the number of genes responsible for hypertension without specifying the strains studied. The

number of genes responsible for phenotype can theoretically be estimated. For example, again using the study of Tanase et al. described in Table 16-5, another interesting point is that the estimated number of loci are changing at the different time-points and are different between male and female in the same cross at the same time-point. Recently, we identified two genes, *Rf-1* and *Rf-2*, responsible for renal failure using the FHH × ACI cross. In this study, we only used male population, because females did not develop renal failure at the age of 6–9 months, but males do develop renal failure. However, when we let the females live to 2 years of age, they developed renal failure, and we could identify *Rf-1* with the female population. In this case, age of onset for renal failure is completely different. These two studies imply the following question: Are phenotypes collected at a correct time-point? Especially when a gender-mixed population is studied, investigators have to be careful to set a phenotyping time-point.

In humans, women generally develop hypertension later than men (in early adulthood until late middle age, the rise in men's blood pressure is bigger than women's), indicating that phenotyping time-point should be different between males and females. Therefore, this "phenotyping window effect" has to be considered, leading one to ask; "Are gender-matched, age-matched study designs appropriate?" Otherwise, human genetic studies with gender-mixed populations and age-matched controls may not be appropriate because of this "phenotyping window effect."

Phenotyping Is Critical   There are a variety of methods to measure blood pressure of the rat, such as direct catheter measurement, tail-cuff method, and telemetry method. One of our studies using F_2 intercross of GH X BN measured blood pressure by two different methods, direct catheter measurement and tail-cuff method. Even if we could measure blood pressure under the same conditions by different methods, the same QTLs should be detected if the methodology has no effect. However, we could detect QTLs on chromosome 2, 6 and 18 by tail-cuff method, and only on chromosome 6 by the direct catheter method, suggesting these two phenotypes represented different blood pressure phenotypes. It is obvious that these two methods are totally different. The tail-cuff method is a stressful method for the rat (stress induces blood pressure increase) because of the use of anesthesia, heating, and tail-cuff itself in contrast to the direct catheter method, which is less stressful. This could explain why several studies identified different QTLs with the use of the same rat strains. Consequently, determination of blood pressure in human is not as easy as it

Table 16-6
Cosegregation of Hypertensive Loci in the Human and Rat Genome

Hypertensive loci	Species	Cosegregation with high blood pressure	
Renin	Rat	Yes:	SS/Jr × SR/Jr
			SHR × WKY

		No:	

appears, since the following factors are likely to influence the level of blood pressure:

1. Type of method.
2. When.
3. How many times.
4. Which position, and so forth.

CLINICAL IMPLICATIONS OF THE RAT STUDIES In Table 16-6, a comparison of the recent studies between human and rat is summarized. Of course, we are not simply able to compare human and rat studies because of the difference in the experimental design. Table 16-6 can be interpreted several ways. Optimistically, we could say that the ACE locus and the S_A locus, found to be important in the rat for the increase in blood pressure after a salt-load, play a role in human hypertension. However, we could say just the opposite, which the majority of investigators would support based on the strength of each study's design. We take these data at face value to mean that the genetic dissection of hypertension in the rat and human will at times lead to conflicting results. These differences come from several sources. For human study, etiological heterogeneity and study designs are the major reasons for the conflicts, as Lander and Schork recently observed. For the rat studies (Table 16-4), genetic background effects are a major problem that should prevent investigators from making sweeping conclusions, but do not. Even when using the rat, the number of the rats in some studies is relatively small and may not have enough power to identify QTLs, which control a small portion of the variance.

Given these difficulties in the rat studies and the successes of molecular genetics in dissection hypertension in humans, many investigators may ask next the following simple questions: Is there still a role for experimental animal models? Will the genes important in determining hypertension in animal models also be important in humans? Data outlined in Table 16-6 suggest that the rat genes may not be important for human hypertension. Furthermore, a study by Hübner et al. reported that angiotensinogen, the only known gene responsible for hypertension in humans, does not cosegregate with hypertension in the SHRSP/Hei x WKY/Hei.

However, we must consider several points. First, as discussed earlier, the data connecting the QTL with any candidate genes are largely circumstantial. Additionally, most of the genetic "hypertensive" loci have not yet been tested as candidate regions in affected sib-pair studies or in various ethnic groups. Second, the negative study with angiotensinogen in a single cross has very little meaning, since genetic studies can only distinguish differences between the two strains studied, and a negative finding can have several causes and is not definitive for the candidate gene in a more general context.

After finding a gene responsible for hypertension in either human or experimental animal models, the next step in the research would be to investigate its molecular mechanism and physiology. Because of the difficulty of carrying out a physiological study in humans, experimental animal models have been studied instead. These studies have been providing us with the detailed physiology for the understanding of the pathogenesis of hypertension. Even a novel gene responsible for hypertension is found based on human genetic study, experimental animal models will remain one of the best ways to understand the detailed physiology and gene functions.

SUMMARY

Despite the recent progress of molecular genetics, there are several challenges to dissect the genetic basis of human essential hypertension using human subjects. Although there is an argument regarding whether the experimental animal models could represent humans, there is no question that this is one of the powerful approaches to performing genetic study. Genetic analysis using experimental animal models (rat for hypertension) provides: (1) understanding of the multifactorial basis of hypertension (e.g., genetic basis, environmental factors, and gene–gene interaction) and (2) the direction of the regions of the human genome to be studied before the genes are identified, thereby revealing clues about the genetic basis of human hypertension. The detailed physiology known about the animal models (this is also another advantage for the animal models) combined with this new genetic information is likely to provide more complete understanding of

the pathogenesis of hypertension. Taking this advantage, clinical diagnosis of essential hypertension will be divided into more detailed subcategories (no longer essential hypertension with unknown etiology), resulting in increasing the efficiency of drug therapy and potentially in future gene therapy.

17 Cardiac Arrhythmias

BARRY LONDON

BACKGROUND

Modern experimental electrophysiology began earlier this century with the explanation of the basis of the action potential by Hodgkin and Huxley in the squid giant axon, and clinical cardiac electrophysiology with the development of the electrocardiogram by Einthoven. The fields continued to diverge in two rather independent directions. The development of intracellular electrodes, the voltage clamp, and the single-channel patch clamp revealed the subcellular events that underlie cardiac excitability and automaticity. Meanwhile, arrhythmia mapping, devices, and clinical trials have defined the mechanisms of the more common human arrhythmias and assessed the efficacy of therapeutic interventions. The advent of molecular biology has been invaluable to the understanding of channel biophysics during the last decade; the relation of single-channel properties to clinically relevant electrophysiology has lagged behind. The promise of molecular electrophysiology as a unifying element in the field is only now becoming apparent.

The genetic basis of one condition, the autosomal dominant long QT syndrome, has recently been revealed through positional cloning. I will discuss the molecular genetics, pathophysiology, and implications of these findings in considerable detail. It is important to realize, however, that arrhythmias remain a major cause of cardiovascular morbidity and mortality, and that the vast majority of arrhythmias result not from Mendelian genetic defects but from more common ischemic or cardiomyopathic disorders. Molecular mechanisms undoubtedly predispose these more common disorders to cardiac arrhythmias; they are unlikely to yield their secrets as rapidly as the genetic disorders. I will highlight some of the avenues of future research that are most likely to yield results.

THE LONG QT SYNDROME

CLINICAL SYNDROME   Romano and Ward described the autosomal dominant form of the long QT syndrome in the early 1960s. The condition is rare, and while the exact gene frequency is not known, it is one of the more common causes of sudden cardiac death among otherwise healthy adolescents and young adults (along with hypertrophic cardiomyopathy and myocarditis). It is characterized by recurrent presyncope and syncope, unexplained seizures, and sudden death. Symptoms often begin near adolescence and are preceded by emotional events such as surprise and fear. The electrocardiographic manifestation of the

disease is a prolonged QT interval and an abnormal T-wave morphology on the surface EKG, although the QT interval has considerable variability and some symptomatic affected individuals have QT intervals within the normal range. The most common arrhythmia is *torsade de pointes*, or polymorphic ventricular tachycardia with a rotating axis (Fig. 17-1). The symptoms often respond to treatment with β blockers, although some patients are refractory and require sympathectomy.

An autosomal recessive long QT syndrome was reported by Jervell and Lange-Nielsen and is associated with congenital deafness. Other conditions also prolong the QT interval and lead to similar arrhythmias. Causes of these "acquired long QT syndromes" include medications (particularly Type IA antiarrhythmics but also certain antibiotics and antihistamines), ischemia, metabolic disorders, and neurologic disorders.

MOLECULAR BASIS OF THE DISEASE   Ion-channel defects were considered likely candidates for this disease, whose hallmark is a prolonged QT interval. A sodium or calcium channel that fails to inactivate properly could delay repolarization by producing an inward leak current. This would explain the dominant nature of the disease. A defective potassium channel could also cause the syndrome by interfering with the outward currents, which repolarize heart cells following each action potential (Fig. 17-2). The dominant nature of the syndrome might be explained by insufficient outward repolarizing current owing to the presence of only one functional copy of the gene; the large number of potassium channel subunits expressed in the heart makes this seem somewhat unlikely. Alternately, the syndrome's dominant nature could be explained by taking into account that four potassium channel α-subunits (with or without assorted β-subunits) are required to form functional channels. A single defective gene product could homomultimerize or heteromultimerize with normal subunits (translated from the normal copy of that gene or from related genes) and produce a large number of the nonfunctional potassium channels through a dominant negative mechanism (Fig. 17-3).

Dr. Mark Keating mapped the gene of one large family to the H-ras locus on chromosome 11p15.5. His group and others quickly mapped additional families to that locus and to unrelated loci on other chromosomes; mutations of at least four genes cause the long QT syndrome. In 1995, Dr. Keating's laboratory identified three of these genes. Multiple mutations of two potassium channels (HERG and KVLQT1) and one sodium channel (SCNA5) cause the long QT syndrome. HERG and SCNA5 were identified by a candidate gene approach; KVLQT1 was identified by exon trapping of potassium channel-like elements from cloned genomic

Figure 17-1 Electrocardiographic manifestations of the long QT syndrome. (Top) EKG of a child with the Romano-Ward autosomal dominant long QT syndrome. (Bottom) Lead II rhythm strip demonstrating *torsade de pointes*. (Figure courtesy of Carol A. Satler, Children's Hospital, Boston, MA.)

DNA. In vitro studies of SCNA5 mutants confirm a disruption of inactivation, and in vitro studies of HERG suggest that mutations affect the inwardly rectifying potassium current I_{Kr} in the heart. This inward rectification arises from a voltage-dependent inactivation process that reduces conductance at positive voltages. The inactivation resembles C-type or the slow inactivation mechanism of other K^+ channels. The exact mechanism by which potassium channel mutations cause disease is currently a subject of intense investigation.

Of interest, neither HERG nor KVLQT1 was known to be important to the function of the heart prior to their identification as causes of the long QT syndrome by positional cloning. This is the case despite the prior cloning of more than 30 potassium channel genes, of which at least 10 are expressed in the heart. In addition, the fact that markedly different underlying channel disorders produce indistinguishable phenotypes underscores the importance of the balance between depolarizing and repolarizing forces in the heart.

MANAGEMENT AND TREATMENT The mapping of the long QT syndrome and the identification of the responsible genes allow prenatal and presymptomatic testing for many families with this disorder. In addition, knowledge of the underlying channel pathology will allow testing of channel-specific therapies: sodium channel blockers such as mexilitine for patients with the SCNA5 defect, and manipulation of serum potassium levels for patients with potassium channel defects. Preliminary studies by Dr. Peter Schwartz and colleagues have shown QT-interval shortening in

response to mexilitine in patients with SCNA5 sodium channel mutations but not in patients with HERG potassium channel mutations.

The long QT syndrome story remains incomplete. Other genes remain to be cloned. The molecular causes of the acquired forms are unknown; it is possible that defects of other channels may prolong the QT interval only in the presence of certain drugs. The exact mechanisms by which mutations lead to disease are not entirely understood. The efficacy of gene-specific treatments on symptoms and survival remains to be shown. The work of the last several years is a major advance, however, in the understanding not only of the cause of this rare syndrome but also of the relationships in vivo between ion channels, currents, and clinical cardiac electrophysiology.

OTHER ARRHYTHMIAS

CLINICAL SYNDROMES Certain arrhythmias are poorly understood but effectively treated. Bypass tract-mediated (Wolf-Parkinson-White syndrome) and AV node re-entrant tachycardias usually respond well to either radiofrequency ablation or medication. Bradyarrhythmias most commonly result from idiopathic deterioration of the conduction system; electronic pacemakers are usually safe and effective.

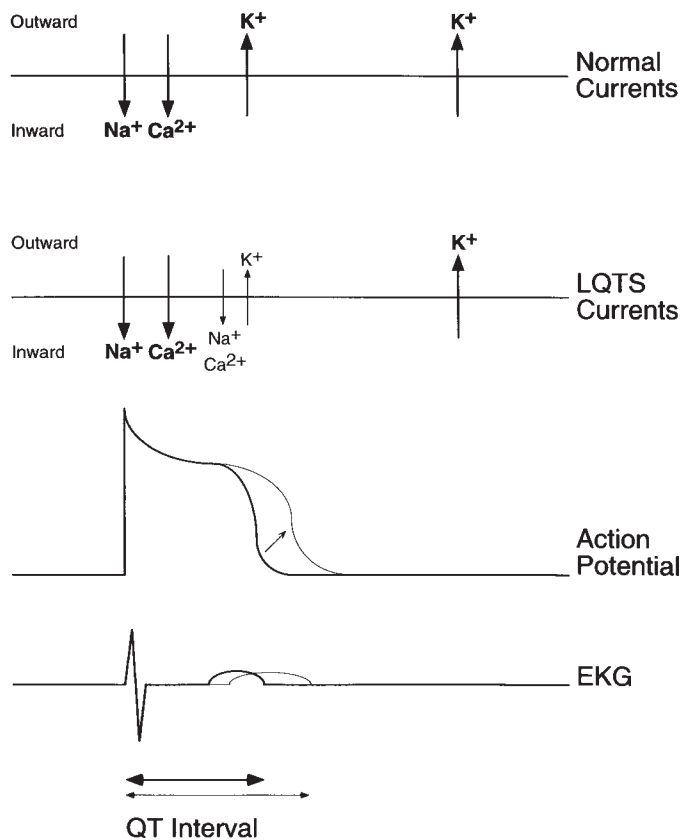
Most cardiac arrhythmias, however, occur in adults and in the presence of other heart disease. Atrial tachyarrhythmias such as atrial fibrillation and flutter usually result from conditions that


Figure 17-2 Ionic basis of the long QT syndrome. Schematic representation of transmembrane ionic currents (top), intracellular potential (middle), and surface electrocardiogram (bottom) of a normal individual contrasted with one having the long QT syndrome (LQTS). A prolonged inward sodium (Na$^+$) current, a prolonged inward calcium (Ca^{2+}) current, or insufficient repolarizing potassium (K$^+$) current can prolong the cellular action potential (arrow) and the QT interval.

Figure 17-3 Molecular basis of the long QT syndrome. Schematic representation of the mechanisms by which channel mutations (designated by X) can cause increased inward currents (left) or decreased outward currents (right). Note that sodium and calcium channels have a single α-subunit with four homologous domains, whereas potassium channels have four α-subunits, all of which multimerize to form tetramers. Mutations of one sodium or calcium channel gene could produce dysfunctional channels to allow increased inward current and cause the disease. Mutations of a single potassium channel gene could decrease the number of functional channel tetramers and cause disease either by decreasing the pool of normal α-subunits or by multimerizing with normal subunits to form nonfunctional channels.

mechanically stretch the atria, including hypertension and valvular heart disease. Ventricular tachyarrhythmias accompany acute myocardial ischemia and infarction, occur postinfarction in the scarred ventricle, and are also common in myocarditis and idiopathic dilated cardiomyopathies. Re-entry through intraventricular electrical circuits is often documented by electrophysiological (EP) studies. Treatment for these conditions remains limited, as sudden death can be the presenting symptom, the long-term efficacy of drug therapy is often poor, and devices carry the problems of high cost and limitation of lifestyle.

MOLECULAR BASIS OF THE DISEASES Atrial and ventricular arrhythmias accompany a vast array of diseases. Most are considered "structural," and little is known about them at the molecular level. In human cardiomyopathies, for example, the action potential is prolonged and a decrease of outward potassium currents has been noted. It is likely that molecular changes in ion channel and/or ion pump expression accompany and predispose to these diseases.

Molecular changes may predispose to disease in ways other than mutated channel proteins (the mechanism responsible for the long QT syndrome). Gene polymorphisms could contribute to familial inheritance in some of these cardiac disorders. Ion-channel gene promoters contain binding sites for regulatory molecules including glucocorticoids and cyclic AMP; these mediators are altered in disease and are proven to modify channel expression in vitro. In addition, electrical coupling of adjacent myocytes through gap junctions is tightly regulated and clearly plays a major role in the genesis and maintenance of arrhythmias.

FUTURE DIRECTIONS

ANIMAL MODELS One promising direction involves the use of animals to study the function of channel genes in vivo and to design interventions on arrhythmias. As one example, recombinant adenoviral vectors have been used to express potassium channels and shorten the action potential in heart cells of rats and dogs. Clearly gene therapy for arrhythmias remains far away, and much progress would need to be made both technically (e.g., obtaining sufficiently uniform gene transfer to prevent electrical inhomogeneities) and in understanding the complex interactions among the many cell systems tied to ion fluxes (*see* Chapter 18). The usefulness of this technique to dissect those elements important for normal cardiac function and for arrhythmias is more immediately apparent.

The recent ability to manipulate the mouse genome using transgenic and knockout techniques also provides a novel avenue for research. Our laboratory and others have used gene targeting to disrupt ion channels thought to be important in the heart. These methods should allow the engineering of a mouse model of human genetic diseases such as the long QT syndrome. Of equal importance, however, will be the information obtained regarding the relationship of individual gene products to the function of the heart as an electrical entity.

FROM ION CHANNEL TO ARRHYTHMIA A great many ion channels, pumps, and exchangers have been cloned during the past decade and studied in vitro using isolated membranes, vesicles, *Xenopus* oocytes, and cultured cells. These proteins form the basis of the currents that depolarize and repolarize the heart. A

complete catalog of their identity, a model of their structure, and an understanding of the biophysical mechanisms by which they open, close, inactivate, interact, and distinguish between different ions are rapidly becoming reality. The regulation of gene expression, the role of posttranslational modifications, and the relationship of individual genes to the cardiac currents, to the action potential, to the EKG, and to arrhythmias will not be solved in the near future. Establishing the link between these basic and clinical parameters is essential, however, if the molecular analysis of cardiac electrophysiology is to have maximal impact in the understanding and treatment of arrhythmias. Future possibilities include (but are not limited to) rational drug design, arrhythmia prediction, arrhythmia prevention, and gene-directed therapies. The recent advances related to the long QT syndrome highlight the possibilities.

18 Cardiovascular Gene Therapy

GIUSEPPE VASSALLI AND DAVID A. DICHEK

INTRODUCTION

Recombinant DNA technology has provided invaluable tools for understanding the molecular basis of cardiovascular diseases. Elucidation of the underlying molecular genetic mechanisms of cardiovascular disease has led to the emergence of gene therapy as an appealing therapeutic approach. Gene therapy involves the introduction and expression of recombinant DNA in order to ameliorate or cure a disease condition. Despite the extensive publicity devoted to gene therapy, it must be emphasized that this field is still very much in its infancy, and fundamental questions regarding efficacy, safety, and clinical benefit remain unanswered. Initial clinical trials in cardiovascular gene therapy are at an early stage, and the place of gene therapy within the armamentarium of cardiovascular therapeutics remains uncertain. This chapter is devoted principally to a review of the theoretical basis for cardiovascular gene therapy, as established by in vitro and preclinical animal experiments. In addition, the two currently approved human cardiovascular gene-therapy trials (familial hypercholesterolemia [FH; MIM # 14389] and peripheral arterial disease) are discussed, and the likely future directions of the field are summarized.

CARDIOVASCULAR DISEASES POTENTIALLY AMENABLE TO GENE THERAPY

MONOGENIC DISEASES Cardiovascular diseases potentially amenable to gene therapy are summarized in Table 18-1. The potential of gene therapy is most obvious in those rare cases of cardiovascular disease due to a defect in a single gene. Specific examples of monogenic cardiovascular disease include the cardiomyopathy associated with Duchenne muscular dystrophy (DMD; MIM # 31020), an X-linked genetic disease caused by a defect in the gene that encodes dystrophin (*see* Chapter 94) and atherosclerotic disease resulting from homozygous FH, an autosomal dominant disease with a gene dosage effect, caused by low-density lipoprotein (LDL) receptor deficiency. Both DMD and homozygous FH are caused by the absence of normal alleles (i.e., lack of one normal allele for DMD and lack of two normal alleles for the homozygous form of FH). If heterozygotes are either asymptomatic (as in DMD) or have a less severe form of the disease (as in FH), then homozygotes might be treated by introduction of a normal allele. However, not all cardiovascular diseases arising from monogenic defects are clearly treatable by introduction of a normal allele. Hypertrophic cardiomyopathy (HCM), caused frequently by dominant mutations in the gene encoding the β-myosin heavy chain (*see* Chapter 13), cannot be treated with current gene therapy technology because the heterozygotes may have a severe disease phenotype despite the presence of a normal allele. Gene therapy for this type of dominant mutation would require replacement of the mutated allele, not simply addition of a normal allele. The technology for widespread gene replacement in vivo does not yet exist.

POLYGENIC DISEASES Complex cardiovascular disease processes such as atherosclerosis (*see* Chapter 14), thrombosis, and hypertension (*see* Chapter 16) have a polygenic basis and are also subject to significant modulation by environmental factors. Nevertheless, several gene therapy approaches to polygenic cardiovascular diseases have been described, each of which is based on delivery of a normal allele of a single gene (Fig. 18-1). In each of these gene therapy strategies, delivery and expression of the chosen therapeutic gene are intended to drive specific metabolic pathways for which the therapeutic gene product is rate-limiting. The metabolic pathways that are driven by the introduced gene act to reverse the pathophysiology of the targeted disease. Thus, delivery of a single gene may be an effective therapy for complex disease processes. This approach to gene therapy is strikingly similar to traditional pharmacotherapy, in which a therapeutic drug (e.g., a diuretic for essential hypertension or coumadin for atrial thrombosis) is given to counteract a disease process rather than to correct the underlying cause.

Specific single-gene therapies for the polygenic diseases of atherosclerosis, thrombosis, and hypertension have each been tested in animal models. Gene therapy for primary atherosclerosis has focused primarily on manipulation of lipid metabolism. For example, transfer of the gene that encodes 7α-hydroxylase (which catalyzes the rate-limiting step in bile acid synthesis) into the livers of hamsters reduced plasma LDL to nearly undetectable levels. Transfer of the genes that encode either tissue-type or urokinase plasminogen activator into baboon endothelial cells decreased thrombus deposition in ex vivo arteriovenous shunts. Finally, transfer of the gene that expresses human tissue kallikrein reduced blood pressure in spontaneously hypertensive rats. In each of these studies, the overexpression of a single normal allele in animals not known to have a specific genetic defect produced a potentially therapeutic effect.

Table 18-1
Cardiovascular Diseases Potentially Amenable to Gene Therapy

Disease	*Therapeutic gene(s)*	*Anticipated mechanism*[a]	*Results*
Familial hypercholesterolemia (LDL receptor defective or absent)	LDL receptor	LDL clearance	Ex vivo gene transfer in humans: 6–23% decrease in LDL cholesterol in three of five patients
Hyperlipidemia with no specific genetic defect	LDL receptor	LDL clearance	In vivo gene transfer into normal mice: decrease in LDL cholesterol
	7α-Hydroxylase	Biliary elimination of cholesterol	In vivo gene transfer into hamsters: reduction in LDL cholesterol
	Apolipoprotein A-I	Increase in HDL	In vivo gene transfer of human apolipoprotein A-I into mice: 35% increase in HDL
Hypertension	Tissue kallikrein	Vasodilation	Prolonged (6 weeks) blood pressure reduction in spontaneously hypertensive rats
Peripheral artery disease	VEGF	Angiogenesis	Gene transfer into patients with stage IV peripheral artery disease (in progress)
Occlusive arterial disease	Constitutively active retinoblastoma gene, hirudin, thymidine kinase, NO synthase	Cytostatic, cytotoxic, inhibition of smooth muscle cell proliferation	In vivo gene transfer into injured rat carotid or pig femoral arteries: 35–70% reduction in neointima formation
Thrombosis	Prostaglandin H synthase	Prostacyclin production	In vivo gene transfer into pig carotid arteries: decreased thrombosis
	t-PA and glycosyl-phosphatidylinositol-anchored urokinase	Fibrinolysis	Ex vivo gene transfer into endothelial cells seeded onto vascular grafts in baboons: reduction in platelet deposition and fibrin accumulation
Hypertrophic cardiomyopathy	Gene replacement of mutated with normal allele of myosin heavy chain	Normalized function of cardiac myosin	None; currently technically unfeasible

[a]The anticipated mechanism has not always been experimentally verified in individual studies.

Figure 18-1   Gene therapy approaches to polygenic cardiovascular diseases. Environmental and hereditary factors are involved in the development of polygenic diseases such as hypertension, hypercholesterolemia, and thrombosis. These diseases can be potentially corrected by transfer of one therapeutic gene.

METHODS OF CARDIOVASCULAR GENE TRANSFER

To achieve delivery of a recombinant gene product in vivo, the following steps must occur:

1. Recombinant DNA sequences must be introduced into the nucleus.
2. The DNA must be transcribed into RNA.
3. The RNA must be translated into a functional protein.

Figure 18-2 Methods in gene therapy. **(A)** Ex vivo gene transfer. This approach has been used to deliver the gene that encodes the LDL receptor to the liver in patients with familial hypercholesterolemia. Following partial hepatectomy, hepatocytes are transduced in vitro using a retrovirus vector, and recombinant DNA is integrated into the hepatocyte genome. Finally, transduced hepatocytes are reinfused into the portal vein and target the liver. **(B)** In vivo gene transfer. This approach has been used to deliver the gene that encodes vascular endothelial growth factor (VEGF) to peripheral arteries.

Steps 2 and 3 must occur in vivo; however, step 1, gene delivery, may be accomplished either in vivo or ex vivo. Stated differently, therapeutic genes may be delivered to cells within an intact animal (or human) tissue or, alternatively, cells may be removed from the targeted tissue, subjected to gene transfer ex vivo, and then reimplanted within the tissue from which they were derived. These two strategies are referred to as "in vivo" and "ex vivo" gene therapy, respectively, and have each been used in cardiovascular gene therapy studies (Fig. 18-2). Each strategy possesses advantages and disadvantages, which we will discuss herein.

EX VIVO GENE THERAPY In ex vivo gene therapy, cells are removed from an animal, maintained in culture, targeted with a therapeutic gene, and then reintroduced into the donor animal. The role of the reintroduced cells is uniquely to deliver a recombinant gene product. The cells are not required to reconstitute a particular organ or tissue; therefore, the excised cells may be reimplanted in a location different from their site of excision. For example, hepatocytes harvested from one liver lobe and genetically modified ex vivo may be reinfused throughout the donor liver. Endothelial cells harvested from a donor vein may be reimplanted in the arterial circulation.

The primary advantages of ex vivo gene therapy are:

1. Gene delivery is performed under controlled, optimized conditions in which the efficiency of gene transfer into the targeted cells may be very high.
2. Gene delivery may be restricted to one specific cell type in which expression is optimized by careful design of a cell-type-specific transgene construct.
3. The potential for an immune response to the gene transfer vector is minimized by performing gene delivery in a setting remote from the host immune system (i.e., a tissue culture dish).

The disadvantages of ex vivo gene transfer derive primarily from technical considerations:

1. Except in rare cases of monozygotic siblings, the requirements of histocompatibility mandate that the excised cells be reintroduced only into the donor individual. Thus, every animal (or human) receiving ex vivo gene therapy must undergo two invasive procedures: cell harvest and cell reintroduction.
2. Cell culture and ex vivo gene transfer must be performed under strict aseptic conditions to avoid the introduction of pathogenic microorganisms at the time of cell reimplantation.
3. The requirement that cells be removed and reinfused in ex vivo gene therapy imposes limitations on the type and number of cells that can be used.

The cells must be nonessential, and their removal and reimplantation must be practical. Thus, ex vivo cardiovascular gene therapy may be attempted with hepatocytes derived from partial hepatectomy and with endothelial and smooth muscle cells derived from excised, nonessential vessels. However, the ex vivo approach is not feasible with other cell types (e.g., cardiac myocytes).

IN VIVO GENE THERAPY The advantages and disadvantages of in vivo gene therapy are the reverse of those of ex vivo gene delivery. Advantages of in vivo gene therapy include:

1. Only one invasive procedure is required (i.e., injection of the gene vector).
2. Laborious and technically demanding steps of cell harvesting and reimplantation are eliminated.
3. Any cell within an intact tissue or organ is theoretically a target for in vivo gene therapy.

Table 18-2
Major Advantages and Disadvantages of Currently Available In Vivo Gene-Transfer Techniques

Method	Advantages	Disadvantages
Naked DNA	Not a known pathogen No integration into host genome[a] Permits large DNA inserts Easy to manipulate	Low efficiency
Liposomes	Not a known pathogen Wide range of target cells Permits large DNA inserts Commercially available	Low efficiency
Adenovirus	High efficiency Transduces nonreplicating cells No integration into host genome[a]	Derived from potential pathogen DNA insert size limited (≤8 kb) Direct toxicity Short duration of expression Inflammatory response Complex construction
Retrovirus	Stable, long-term gene expression To date, safe in human use	Low efficiency Potential reversion to replication competence Transduces replicating cells only Integration into host genome[a]

[a]Integration into host genome might be favorable with respect to the duration of transgene expression; however, there is a theoretical risk of insertional mutagenesis.

The disadvantages of in vivo gene therapy are:

1. Gene delivery to remote, technically difficult locations may be required; for example within the myocardium or in the presence of flowing blood in a narrow end artery supplying an ischemic territory. In clinical settings such as these, the gene transfer vector may be washed away or undesirable clinical consequences (ischemia, infarction) may intervene prior to successful gene delivery.
2. Systemic release of the vector is unavoidable; therefore, the target cells for in vivo gene delivery are likely to be a heterogeneous population in which optimization of expression is difficult.
3. There is an obligatory exposure of the gene delivery vector to the immune system. This exposure may produce an immune response that causes rejection of the transduced cells or abrogation of gene delivery if the recipient organism is already immune to the gene transfer vector.

Despite these disadvantages, the practical advantages of in vivo versus ex vivo gene transfer are overwhelming. If cardiovascular gene therapy is ever to become practical as well as economically feasible, it will likely be with in vivo gene transfer technology.

VECTORS FOR CARDIOVASCULAR GENE THERAPY

In general, the uptake of foreign genetic material (naked DNA or RNA) by mammalian cells is an inefficient process. This inefficiency makes sense teleologically, as there is little advantage for a cell to allow its highly regulated and evolved genetic program to be altered at random by pieces of DNA or RNA that land on its membrane. While there are notable exceptions, in order to introduce genetic material into mammalian cells with reasonable efficiency, it has generally been necessary for investigators to associate the genetic material with a "vector" that can mediate entry, nuclear transport and, in some cases, chromosomal integration. Vectors for mammalian gene therapy belong to two general categories: nonviral vectors, which mediate gene transfer largely by physical means; and viral vectors, which make use of viral proteins and nucleic acids to mediate efficient gene transfer (Table 18-2).

NAKED DNA AND NONVIRAL VECTORS   Nonviral means of gene transfer include naked DNA, liposomes, protein-polylysine complexes, and microparticle bombardment. The principal theoretical advantage of nonviral gene transfer is that the components can be prepared as standardized pharmaceutical reagents. This standardization might maximize reproducibility and minimize toxicity. Individual investigators have reported both promising animal data and plans for clinical trials in humans using naked DNA for cardiovascular gene therapy. However, the efficiency of gene transfer with nonviral vectors is low when compared to that obtainable with viral vectors, and in no case have nonviral gene transfer approaches achieved long-term, stable expression in the cardiovascular system.

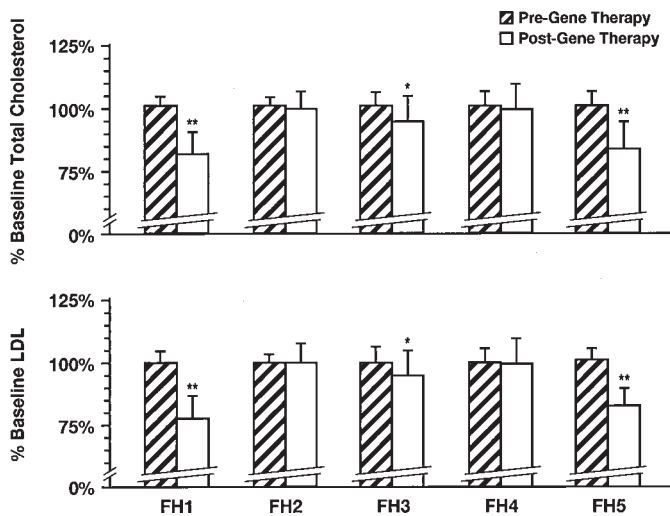
VIRAL VECTORS   Both retroviral and adenoviral vectors are currently in use for cardiovascular gene therapy in animal models. Retroviral vectors are able to mediate integration of recombinant DNA into the target cell chromosome, permitting long-term expression of transgenes and ensuring transmission of inserted DNA to the progeny of transduced cells. Use of retroviral vectors in cardiovascular gene therapy has been limited, however, by their inability to achieve reasonable levels of gene transfer in vivo. The estimated efficiency of in vivo retrovirus-mediated arterial gene transfer is 0.01% or less. In contrast, adenovirus vectors are capable of high efficiency in vivo gene transfer: About 35% of smooth muscle cells in a local segment of injured artery and about 90% of hepatocytes express recombinant genes following in vivo gene transfer in animal models. The clinical use of adenovirus vectors is limited, however, by their toxicity and immunogenicity. Despite the promise demonstrated by adenovirus vectors in animal models of cardiovascular disease, it is likely that significant improvements in adenovirus vector design will be required prior to their widespread use in humans.


Figure 18-3 Cholesterol and LDL levels before (hatched box) and after (white box) retrovirus-mediated ex vivo transfer of the LDL receptor gene in five patients with familial hypercholesterolemia (FH). A significant decrease in these two parameters was observed in three out of five patients (*p = 0.05, **p < 0.01 vs before gene therapy). (Reproduced with permission from Grossman et al.)

CARDIOVASCULAR GENE THERAPY: CURRENT STATUS AND FUTURE DIRECTIONS

ATHEROSCLEROSIS RESULTING FROM HYPERLIPIDEMIA Because plasma LDL cholesterol is a genetically determined, major modifiable risk factor for the development and progression of atherosclerotic cardiovascular disease, it is logical that gene therapy approaches have focused on lowering plasma LDL cholesterol. An extensive set of in vitro data with cultured hepatocytes and preclinical experiments with both rabbits and primates led Grossman et al. to develop and implement an ex vivo clinical gene therapy protocol for homozygous FH (Fig. 18-3). Treatment of five FH patients revealed that introduction of a normal LDL receptor allele was capable of increasing LDL catabolism and lowering LDL cholesterol in individual patients; however, in no case was LDL lowered to such an extent that any of the patients' cardiovascular disease risk was appreciably diminished. Moreover, the response of the patients was heterogeneous, with two of five showing no change in plasma LDL levels following gene therapy. The authors acknowledged that their inability to reconstitute more than a small fraction of the liver with genetically modified cells placed a severe limitation on this approach, forcing them to forego further clinical trials and refocus their attention on the more basic issue of effecting higher levels of hepatic gene transfer.

Additional approaches to gene therapy of hyperlipidemia include adenovirus-vector-mediated overexpression of apolipoprotein A-I to raise plasma high-density lipoprotein (HDL) levels (which are negatively correlated with the development of cardiovascular disease) and hepatic overexpression of 7α-hydroxylase, to expedite hepatocyte catabolism of cholesterol to bile acid with subsequent elimination via the gastrointestinal tract. While both of these approaches have appeared powerful and feasible in animal studies, the key questions of efficiency and safety that have been raised in human studies with retrovirus vectors and in animal studies with adenovirus vectors will require resolution, prior to the commencement of clinical studies with these potentially therapeutic genes.

RESTENOSIS FOLLOWING ANGIOPLASTY The initial success of percutaneous transluminal coronary angioplasty in enlarging the lumen of stenotic coronary arteries is reversed by recurrent stenosis ("restenosis") in 30–50% of patients. Demonstration of successful in vivo gene transfer into injured mammalian arteries with both viral and nonviral gene transfer systems, along with the availability of animal models of local arterial injury, have stimulated several groups to propose gene therapy approaches to prevent restenosis. Transfer of cytotoxic genes, such as herpesvirus thymidine kinase, or cytostatic genes, such as a mutant retinoblastoma protein, into injured arteries results in decreased neointima formation in animal models. Alternatively, transfer of "protective" genes, such as nitric oxide synthase or hirudin, at the time of arterial injury results in a similar reduction in neointima formation. None of these animal studies, however, has demonstrated a decrease in arterial stenosis following gene delivery.

The success of gene transfer in limiting neointima formation in animal models has suggested to some that a gene therapy trial for restenosis in humans is imminent. Indeed, restenosis appears to be a reasonable candidate for gene therapy in that it is a focal disease for which there is currently no accepted therapy. There are, nevertheless, important caveats that should be considered prior to the initiation of human trials:

1. The pathophysiology of human restenosis is almost certainly different from that found in animal models of arterial injury; cell proliferation (the target of several gene therapy approaches) may not play a significant role in human restenosis.
2. Local gene delivery in the human coronary circulation is far more challenging than in an isolated peripheral animal artery. In contrast to the animal experiments with isolated peripheral arteries, it is currently unfeasible to isolate a human coronary artery lumen (with both proximal and distal occlusion as well as prevention of leakage via side branches) and maintain an elevated infusion pressure during 20 min of gene delivery. Thus, without significant technical improvements, gene transfer efficiency in human coronaries will almost certainly be lower, and systemic gene delivery will be far higher, than in animal models (Fig. 18-4).
3. Direct vascular toxicity and proinflammatory effects of adenovirus may counteract any salutary effects of expressed transgenes. As 50–70% of angioplasty patients are cured of their disease without gene therapy, it would appear that careful consideration of pros and cons as well as resolution of the above major clinical issues should precede human trials.

PERIPHERAL ARTERY DISEASE The identification and cloning of genes that control the development and growth of blood vessels has inspired several investigators to propose gene therapy for deficient peripheral circulation. According to this paradigm, delivery of a gene to the wall of an artery supplying an ischemic territory will result in the release of angiogenic peptides into the distal circulation. These peptides will, in turn, stimulate the growth of blood vessels that relieve the peripheral ischemia. A human clinical trial has been initiated to treat severe peripheral arterial disease by delivery of the gene encoding vascular endothelial
Figure 18-4 In vivo arterial gene transfer. **(A)** Surgical approach. Side branches are ligated, and the target segment vessel is clamped proximally and distally. Infusion is performed under direct vision, and the vessel wall is maintained in a distended state by the infusion pressure. Systemic spread of the recombinant gene is limited. **(B)** Potential percutaneous approach. The recombinant gene is delivered through a double-balloon catheter. Systemic leakage via the side branches cannot be avoided, and distension cannot be maintained. In addition, collateral flow (dotted arrows) may enter the occluded artery and dilute the vector solution. Gene delivery will likely be decreased and systemic exposure increased compared to the surgical approach. The use of double-balloon catheters for arterial gene delivery has, to date, largely been accomplished via a surgical approach using direct vision and ligation of branch vessels, as in (A).

growth factor (VEGF) to the iliofemoral artery wall. If effective in engendering the growth of physiologically significant collateral vessels, it is anticipated that this protocol will result in the salvage of severely ischemic limbs. Furthermore, any success encountered in the peripheral circulation will certainly inspire efforts to direct gene therapy toward the enhancement of coronary collaterals to relieve myocardial ischemia.

HYPERTENSION A recent animal study demonstrated the feasibility of gene therapy for hypertension. Intravenous injection of a naked DNA construct expressing human tissue kallikrein reduced systolic blood pressure for 6 weeks in spontaneously hypertensive rats (Fig. 18-5). The authors did not present any results obtained by using a gene transfer vector, such as retrovirus, that may have provided longer-lasting gene expression. Thus, it remains possible that, with a more stable gene transfer system, the hypotensive effect would have persisted even longer. These findings therefore raise the exciting possibility that human hypertension, a lifelong disease treated with a lifetime of expensive and inconvenient medication, might someday be treated by the transfer and stable expression of a single gene. The promise and attraction of gene therapy lie precisely herein: the potential that the delivery of a single gene could reprogram and correct systemic physiology for the lifetime of a patient. Just as the inheritance of a single dominant disease allele can produce a lifetime of disease, a single dominant therapeutic allele might prevent a lifetime of disease. The power of gene therapy and the potential that it might someday revolutionize medical care is perhaps most evident in the context of such common diseases as hypertension.

Prior to the initiation of therapeutic trials of gene therapy for hypertension, it will be important to address several issues:

1. The applicability of studies in specific animal models to the pathophysiology of hypertension in humans.
2. The requirement for long-term stable expression in a significant number of cells.
3. The need to develop practical means for the adjustment or reversal of antihypertensive gene therapy, should the effect of the inserted gene prove detrimental over time.

THROMBOSIS Gene therapy for thrombosis has focused on the thrombotic problems of intravascular prosthetic devices such as grafts and stents. Because these devices are acellular and cannot be targeted by in vivo gene transfer, an ex vivo, cell-based gene therapy strategy is obligatory. According to this strategy, endothelial cells may be harvested from a superficial vein and transduced with genes that express either tissue plasminogen activator (t-PA) or urokinase. These fibrinolytically "enhanced" cells would then be seeded onto the surface of prosthetic devices prior to device implantation. When these cells are implanted in vivo, increased expression of t-PA or urokinase might prevent device thrombosis. With this approach, overexpression of plasminogen activators from seeded endothelial cells decreased thrombus deposition onto a synthetic baboon arteriovenous shunt (Fig. 18-6). The antithrombotic effect was unaccompanied by evidence of systemic fibrinolysis, proving the concept that genetic manipulation of endothelial cells can decrease local thrombosis without creating a systemic fibrino(geno)lytic state. While theoretically promising, these data are derived from very short-term experiments (1 h), whereas the clinical problem they address (device thrombosis) may extend over years. The clinical applicability of the seeding of vascular devices with genetically "enhanced" cells will depend on the generation of data that demonstrate that these cells or their
Figure 18-5 Systolic blood pressure of spontaneously hypertensive rats after intravenous injection of plasmid DNA. Rats received injections of control plasmid DNA (open circles), plasmid DNA expressing a human tissue kallikrein cDNA under the control of the Rous sarcoma virus 3'-long terminal repeat promoter (RSV-cHK; solid circles), or plasmid DNA expressing a human tissue kallikrein cDNA under the control of a metal response element-containing (MRE) promoter (MRE-pHK; open squares). Blood pressure values are expressed as mean ± SEM ($n = 6$). Bars represent standard deviation. *$p < 0.05$ vs control. Blood pressure differences were no longer significant at 7 weeks (not shown). (Reproduced with permission from Wang et al.)

Figure 18-6 Deposition of In-labeled platelets on thrombus tails propagated downstream from grafts seeded at equivalent densities with either untransduced or transduced endothelial cells and exposed to flowing blood in a baboon ex vivo arteriovenous shunt. Platelet deposition is shown in real time for untransduced endothelial cells (open circles; $n = 13$), endothelial cells transduced with a retroviral vector expressing human tissue plasminogen activator (t-PA; closed circles; $n = 8$), and a retroviral vector expressing glycosylphosphatidylinositol (GPI)-anchored human urokinase plasminogen activator (a-uPA; closed squares; $n = 5$). Bars represent SEM. (Reproduced with permission from Dichek et al.)

progeny survive for prolonged periods of time following introduction in vivo. Such data have not yet been forthcoming, despite substantial experimental efforts in animal models. Furthermore, the logistical issues mentioned above surrounding ex vivo manipulation of autologous cells are particularly daunting in this clinical setting, given the extreme importance of avoiding microbial contamination of a prosthetic device.

CONCLUSIONS

A variety of mono- and polygenic cardiovascular diseases are potentially treatable with gene therapy. Initial animal studies have confirmed that genes with potentially therapeutic effects within the cardiovascular system may be introduced in vivo. Nevertheless, practical concerns relating to the achievement of safe, efficient, and long-lasting gene therapy continue to dominate the field. To become useful therapeutic approaches, gene transfer techniques must, in general, achieve high efficiency, prolonged gene expression, and tissue-specific targeting, without the induction of systemic immunity. Each of these goals represents a substantial technical challenge. In addition, as we progress beyond the initial excitement associated with overcoming these technical hurdles, gene therapy must ultimately prove its safety as well as its efficacy in relation to more traditional therapeutic interventions. Only then will gene therapy gain acceptance as a treatment for cardiovascular disease.

19 Hematopoiesis

Growth Factors and Mechanisms of Regulation

Andrew Haynes and Nigel Russell

INTRODUCTION

The bone marrow of a normal individual represents 5% of the total body weight. Hematopoietic cells first appear in the yolk sac, and migrate first to the liver and finally to the marrow, so that, by 5 months *in utero*, the marrow is the major source of hematopoietic cells. At birth, all bones contain hematopoietic marrow, but in adults, fatty replacement restricts active hematopoiesis to the axial skeleton, upper humeri, and femora. To sustain a healthy peripheral circulation, the bone marrow turns over a trillion cells every day, producing 70 billion neutrophils and 200 billion red cells. The marrow contains a spectrum of cells within each lineage, ranging from immature precursors to mature cells. The latter represent storage compartments released at times of increased demand; 10 times the circulating number of neutrophils are stored in the marrow, whereas the stored and circulating numbers of reticulocytes for red cells are equal. As a consequence in normal marrow, some 50–60% of cells are dedicated to myelopoiesis.

STRUCTURAL ORGANIZATION OF THE BONE MARROW

Bone marrow occupies the intertrabecular spaces inside the marrow cavity of trabecular bone. A framework of reticular cells and collagen supports hematopoietic tissue and vascular channels. Stromal cells, adipocytes, and macrophages provide the necessary microenvironment for hematopoietic cells. Thin-walled vascular sinuses drain blood from the periphery to the center of the marrow cavity. Hematopoietic elements are organized in a perivascular distribution. Discrete islands of erythropoietic cells often with a central macrophage are located near vascular sinuses. The macrophages present growth factors and phagocytose extruded nuclei. Megakaryocytes that produce platelets are also located adjacent to vascular sinuses. In contrast, immature white cell precursors are found next to the bony trabeculae, but as cells differentiate, they become motile; mature cells migrate to the vascular sinuses.

STEM CELLS   Hematopoietic activity is sustained by the presence of pleuripotent stem cells which are capable of differentiation to form all of the mature elements of the blood (Fig. 19-1). The existence of such cells was postulated after the demonstration that bone marrow infusion could rescue lethally irradiated mice. The spleens of such animals contained colonies of hematopoietic cells,

and the seminal work of Till and McCulloch provided evidence for the existence of self-renewing pleuripotent cells that are capable of sustaining long-term stable hematopoiesis. Single-cell cultures of murine fetal liver stem cells give rise to colonies containing mature lymphoid and myeloid cells, supporting the presence of a pleuripotent stem cell. The pleuripotent stem cells give rise to more differentiated lineage-committed stem cells that, in turn, differentiate into mature end-stage cells. The stem-cell content of human bone marrow can be inferred from the in vitro growth of colonies that produce mature cells in semi-solid media. These colonies arise from lineage-restricted committed stem cells, and those forming myeloid cells (CFU-GM), erythroid cells (CFU-E and BFU-E), and megakaryocytes (CFU-Meg) have been described. It is estimated that 0.1–0.3% of the cells in human marrow are committed stem cells.

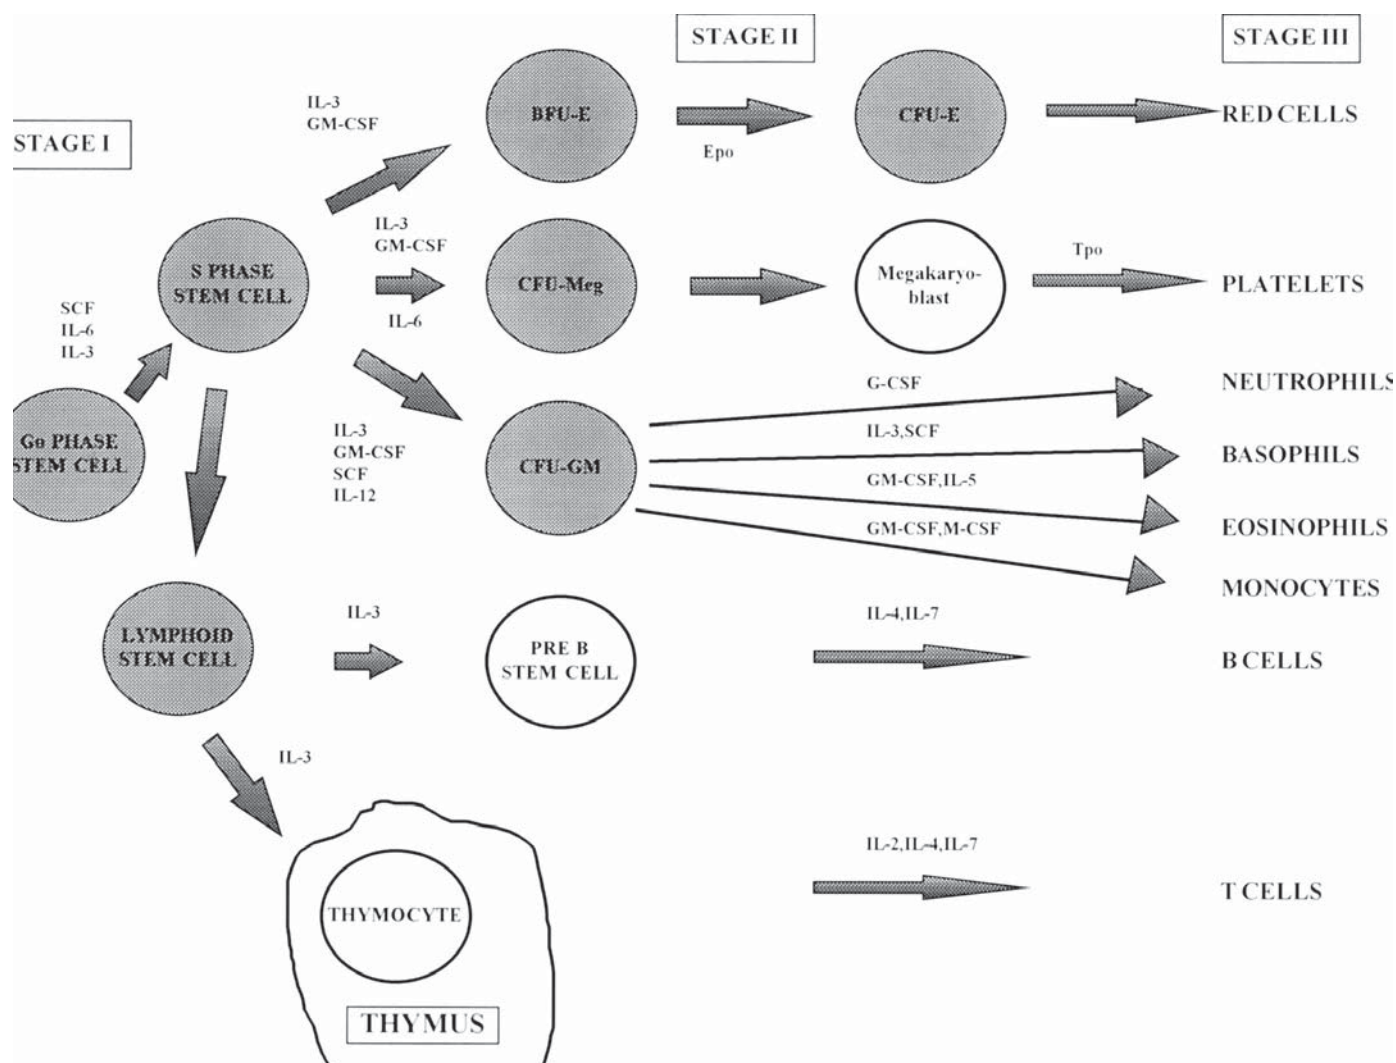
PLEURIPOTENT STEM CELLS   These most primitive stem cells have been isolated from the lymphocyte fraction of marrow, and at any given time, less than 5% are in active cell cycle. Stable long-term hematopoiesis therefore requires a balance between expansion and differentiation of the pleuripotent stem cell pool. It is estimated that 1 in 10^6 marrow cells are pleuripotent stem cells; hence, the total population of $1–2 \times 10^6$ such cells produces greater than 10^{11} cells each day. Assays for human primitive stem cells have been developed, such as the long-term culture initiating cell (LTCIC) assay. Plastic adherence can also be used to separate long-term culture repopulating cells from more committed stem cells. Civin et al. described the expression of a specific antigen—now designated CD34—on the surface of 1–3% of bone marrow mononuclear cells. This fraction of marrow cells contains committed stem cells but is also capable of stable long-term reconstitution of hematopoiesis in humans after myeloablative doses of chemoradiotherapy. Furthermore, marking by transfection of the Neomycin resistance gene has confirmed its ability to cause long-term production of all lineages, hence the presence of pleuripotent stem cells within the CD34-positive fraction. Expression of the CD34 antigen is stage-specific and lost upon maturation. Further characterization of CD34-positive cells can be made by studying their expression of surface antigens. Cells expressing high levels of CD34 (CD34^{bright}) are the most primitive. Analysis of the expression of CD38, Thy-1, CD45 isoforms and the uptake of the dye Rhodamine 123 has identified a subpopulation of CD34 cells that are CD34^{bright}, Thy-1$^+$, CD38$^-$, CD45RO$^+$, and Rhodamine 123^{dull}. These cells can establish LTCIC capable of self-renewal in


Figure 19-1   Hierarchy of stem-cell development. At stage I, the pleuripotent stem cell is capable of differentiation to form all of the mature elements in the blood under the influence of appropriate growth factors. At stage II, stem cells become lineage-committed and differentiate only to form particular mature elements (stage III). Shaded cells express CD34 antigen; expression is lost at stage II of differentiation. SCF, stem-cell factor; IL, interleukin; GMCSF, granulocyte macrophage colony-stimulating factor; G-CSF, granulocyte colony-stimulating factor; M-CSF, macrophage colony-stimulating factor; Epo, erythropoietin; Tpo, thrombopoietin.

vitro and represent less than 10% of the CD34-positive cell fraction. The gene for the CD34 antigen is present on chromosome 1 at 1q32 and encodes for a 110-kDa glycoprotein. The function of CD34 remains unknown; it may play a role in cell adhesion, with its expression upregulated after intracellular phosphorylation by protein kinase C.

GROWTH FACTORS

The survival, proliferation, and differentiation of normal progenitor cells in vitro is dependent on the presence of growth factors or colony-stimulating factors. A growing family of such factors is emerging with their evolutionary significance underlined by interspecies homology, homology between different factors in the same species, and the common use of certain receptors and signaling mechanisms by different factors. Growth factors prevent apoptosis in stem cells, and their crucial role in normal hematopoiesis is highlighted by genetic studies in mice. Murine production of stem-cell factor (SCF) and its receptor, c-kit, occur at the

Steel (Sl) and *W* loci, respectively. Homozygous deletion of these loci results in animals with diminished erythropoiesis and mast cell production. In the O*p* mouse, a stop codon in the macrophage colony-stimulating factor (M-CSF) gene results in osteopetrosis and decreased macrophage production.

It is beyond the scope of this chapter to give a detailed account of all of the growth factors contributing to hematopoiesis. An overview of stem-cell hierarchy and the important growth factors is presented in Fig. 19-1. We intend to focus on a number of growth factors that illustrate common mechanisms and that have achieved a place in the management of clinical problems (Table 19-1).

Some factors play a crucial role in the basal production of specific lineages; for example, antibodies against Epo or G-CSF produce anemia and neutropenia, respectively, when injected into animals. Other factors, such as GM-CSF and IL-3, exert actions on a variety of lineages. More than one growth factor appears to exert actions on a particular lineage, and the reasons for this apparent redundancy may be several:

Table 19-1
Human Growth Factors

	Human chromosome location	Product, kDa	Origin	Receptor	Action
G-CSF	17q21–q22	19–25	Monocytes Macrophages	Low-affinity monomer (130 kDa) High-affinity oligomer	Proliferation and differentiation of neutrophils upregulates activity of mature neutrophils
Epo	7q	18–32	Kidney Fetal liver	507-Amino acid polypeptide	Proliferation and differentiation of intermediate stage erythroid progenitors
Tpo	3q26–q27	76	Liver Kidney Spleen Marrow	Product of the c-mp1 proto-oncogene	Proliferation and differentiation of megakaryocyte precursors
GM-CSF	5q23–q31	22	Macrophages Endothelium T cells Fibroblasts Mast cells	Low affinity α-subunit (85 kDa) β-subunit (120 kDa) common to IL-3/5 receptors	Growth and differentiation of granulocyte and macrophage committed stem cells upregulates macrophage, neutrophil, eosinophil, and endothelial cell function
IL-3	5q23–q31	28	T cells Mast cells	Low affinity α-subunit (70 kDa) β-subunit (120 kDa) common to IL-3/5 receptors	Proliferation and differentiation of early precursors in multiple lineages
SCF	12q22–q24	20–35	Marrow stroma Fibroblasts	145-kDa Transmembrane protein	Proliferation and differentiation of multiple lineages

G-CSF, granulocyte colony-stimulating factor; Epo, erythropoietin; Tpo, thrombopoietin; GM-CSF, granulocyte macrophage colony-stimulating factor; IL-3, interleukin-3; SCF, stem-cell factor.

1. Sequential action: Regulators may act at specific phases in the differentiation sequence of specific lineages. For example, Epo acts on more mature erythroid precursors, whereas IL-3 and SCF act on early progenitors.
2. Recruitment: Purified stem cells require a combination of two or more growth factors for proliferation, for example, SCF plus IL-3 or IL-6. Stem-cell factor alone maintains the survival of stem cells but induces little division, unless a second regulator is present. This need for simultaneous signaling by two receptors is an example of recruitment.
3. Synergy: Enhancement of proliferation by combinations of growth factors such as SCF plus G/GM-CSF results, not in an increased number of colonies formed, but a 10- to 20-fold increase in the number of cells per colony, compared to either growth factor alone.

These processes of sequential action, recruitment and synergy overlap in normal development. The injection of G-CSF not only increases circulating neutrophil numbers, but it also increases the levels of progenitor cells of all lineages in the peripheral blood. The failure to produce mature cells in other lineages results from the absence of the relevant factors, emphasizing the need for synergy and sequential action. If G-CSF is injected into mice bearing the *Steel* or *W* loci mutations that abrogate responses to SCF, a much smaller rise in circulating neutrophils and progenitors is observed, emphasizing the need for recruitment.

REGULATION OF GROWTH FACTOR PRODUCTION

Regulation of expression of growth factors lie predominantly at the posttranscriptional level that involves mRNA stabilization. The genes encoding growth factors belong to the family of early response genes (ERGs) which are characterized by a rapid and transient activation of transcription. ERG mRNAs are usually short-lived with half-lives of 10–30 min, compared to those of most mammalian mRNAs, which typically survive for hours or days. ERG mRNAs are characterized by the presence of multiple copies of the sequence motif AUUUA in the 3' untranslated region (UTRs); this sequence appears to function as a potent mRNA destabilizing determinant.

For instance, the mRNA encoding G-CSF has a half-life of less than 15 min owing to rapid degradation of the mRNA by cytoplasmic RNase. In contrast, although the mRNAs of other cytokines (such as GM-CSF, IL-1, and IL-6) also contain poly-AUUUA sequence, these mRNAs are stabilized by IL-1 and thus allowed to accumulate. In normal cells, G-CSF gene expression is transient, with levels diminishing after 8–12 h, even in the face of continued simulation. In solid tumors, aberrant production of G-CSF in association with abnormal mRNA accumulation, may be responsible for a "leukemoid reaction" with marked increase in circulating neutrophils.

At the transcriptional level, two upstream regulatory elements important in transcription have been identified: an octamer sequence (ATTTGCAT) 110 bp upstream of the TATA box, a decanucleotide sequence (GAGATTCCCC) 180 bp upstream of the transcription start-site, which is conserved between species. Similar sequences are present in the GM-CSF and IL-3 genes.

GROWTH FACTOR RECEPTORS

Growth factors exert their actions via interaction with receptors; different receptor families specific to groups of growth factors have been recognized on the basis of their molecular structure (Fig. 19-2).

Receptors with intrinsic tyrosine kinase activity stimulated by ligand binding, are distinguished by a single membrane spanning
Figure 19-2 Molecular structure of human growth factor receptors. Two families are recognized: those with intrinsic tyrosine kinase activity and those without, which are members of the cytokine receptor superfamily. Trp-Ser-X-Trp-Ser motif, thick black bar; conserved cysteine residues, double thin black bar; conserved box 1/2 domains, single thin black bar.

domain and five immunoglobulin-like extracellular domains that identify them as part of the immunoglobulin superfamily. Examples include the SCF and M-CSF receptors.

Receptors with common motifs in their extracellular domains identify them as part of the cytokine receptor superfamily. Examples include Il-2/3/4/5/6/7, G-CSF, GM-CSF, Epo, and Tpo receptors. The extracellular motifs include four conserved cysteine residues and a conserved five amino acid sequence of Trp-Ser-X-Trp-Ser where X can be any amino acid. The latter domain is present in complement proteins, thrombospondin and properdin, where it mediates protein–protein interaction. These receptors have some sequence homology in their cytoplasmic membrane proximal regions termed the box 1 and 2 domains that are important for signaling.

In the cytokine receptor superfamily, some members are single chain such as the Epo or G-CSF receptors whereas others have two or more subunits such as the GM-CSF or IL-3 receptors (Fig. 19-2). A better understanding of the structure of these receptors has helped to explain some of the observed effects of and the cellular events triggered by growth factors.

ERYTHROPOIETIN RECEPTOR   The gene for the human Epo receptor is on chromosome 19p and encodes a 507-amino acid, 68-kDa, single polypeptide chain protein with a single transmembrane domain. The cytokine superfamily motifs divide the extracellular portion of the receptor into two subdomains linked by disulfide bonds; the regions of this structure crucial for particular functions have been studied in vitro by site-directed mutagenesis.

1. Mutations affecting the Trp-Ser-X-Trp-Ser motif result in sequestration of the protein in the endoplasmic reticulum and failure of expression.

2. The cytoplasmic portion of the receptor consists of 236 amino acids with the two regions, box 1 and box 2, which share sequence homology with other cytokine receptors. Mutations truncating the carboxyl terminus and removing the box 1 and 2 domains abolish growth-signaling, establishing the importance of the membrane proximal domains in this process.

3. A mutation changing Arg^{129} to cysteine in the extracellular domain results in receptor dimerization and constitutive signaling not dependent on the presence of Epo. This indicates a requirement for the normal receptor to oligomerize to permit growth signaling.

4. A mutation truncating 70 amino acids at the carboxy terminal of the cytoplasmic domain results in abnormal signaling and produces familial erythrocytosis in humans. This area is important for limiting signaling after stimulation.

GRANULOCYTE COLONY-STIMULATING FACTOR RECEPTOR   This is a 100- to 120-kDa single polypeptide chain protein that is a member of the cytokine receptor superfamily. The monomeric protein has low affinity for G-CSF but forms a high affinity receptor after oligomerization. In addition to the cytokine family motifs, the extracellular domain also has three fibronectin-like repeats. The first 57 amino acids of the cytoplasmic domain contain the box 1 and 2 sequences that are required for growth signaling. A murine knockout of the transcription factor, CAAT enhancer-binding protein (C/EBP) α, causes loss of G-CSF receptor expression and a block in neutrophil development.

GRANULOCYTE–MACROPHAGE COLONY STIMULATING FACTOR AND IL-3   Both of these growth factors have actions on a wide range of hematopoietic cells. Binding of GM-CSF to its receptor is completed by IL-3 and vice versa; this cross-competition is explained by the molecular structure of their

receptors. Ligand binding occurs with low affinity to a specific α-chain, which for GM-CSF and IL-3 are encoded by genes in the pseudoautosomal regions of the X and Y chromosomes. Both receptors share a common 120-kDa β chain encoded by a gene on chromosome 22q12-13 that is necessary for signaling. The αβ chain heterodimer displays high affinity specific binding. Transfection of the cell line NIH-3T3 with GM-CSF α, IL-3 α, and common β-subunits has confirmed that the basis for cross-competition is competition among specific α-subunits for the common β-subunit. The extracellular domains of both chains carry the motifs associated with the cytokine receptor superfamily. The membrane proximal portion of the β-subunit has box 1 and 2 domains, and truncated mutations that retain the 60 amino acids containing these domains still induce growth signals. The cytoplasmic domains of the α chains are also required for signaling, indicating that an intact αβ heterodimer is required for this process.

STEM-CELL FACTOR RECEPTOR   This 145-kDa product of the c-*kit* proto-oncogene is a transmembrane glycoprotein. Receptor–ligand interaction is associated with oligomerization and activation of endogenous tyrosine kinase activity that is essential for signaling.

The response of a given hematopoietic precursor will thus depend on the nature of the receptor units expressed by that cell and their relative numbers. This may explain some of the pleiotropic actions of human growth factors.

RECEPTOR SIGNALING MECHANISMS

TYROSINE PHOSPHORYLATION   The intrinsic protein tyrosine kinase activity of the SCF and M-CSF receptors is essential for signal transduction. Similarly, a number of common proteins are tyrosine phosphorylated after stimulation by IL-3, GM-CSF, and Epo. In the Epo receptor, deletion of 20 amino acids (numbers 280–301) in the conserved region of the cytoplasmic domain inactivates growth promotion, tyrosine phosphorylation, and early gene induction. Finally, tyrosine kinase inhibitors prevent the action of growth factors. These lines of evidence suggest that although members of the cytokine receptor superfamily do not have intrinsic tyrosine kinase activity, an associated activity is essential for receptor signaling. Tyrosine kinase activity is rapidly induced after stimulation of these receptors at 4°C, suggesting that the kinase activity must be closely associated to the receptor, if not an integral part of its structure.

A family of cytoplasmic tyrosine kinases, the Janus or Jak kinases, are associated with activated growth factor receptors (Table 19-2). The four members of this family contain two kinase domains, the carboxy-terminal one being a protein tyrosine kinase. The region of the box 1 and 2 domains in the cytoplasmic tail of cytokine receptor superfamily members is required for receptor association with Jaks. This association may be constitutive e.g., Epo receptor or occurs only after ligand binding, e.g., IL-3 receptor. Oligomerization of the receptors brings the associated Jak kinases into sufficient proximity to allow crossphosphorylation and activation of their protein tyrosine kinase domains. A single chain may associate with a single Jak, e.g., Epo receptor and Jak 2 or with multiple Jaks, e.g., G-CSF receptor and Jaks 1 and 2. These observations explain many of the structural requirements of growth factor receptors necessary for signaling to occur.

PATHWAYS ACTIVATED BY TYROSINE PHOSPHORYLATION   Receptor autophosphorylation by Jaks creates crucial docking sites for a number of important proteins that propagate the growth signal (Fig. 19-3).

Table 19-2
The Janus Kinase Family
and Hematopoietic Growth Factor Receptors

|	Size	Chromosome	Receptors linked to
JAK-1	135	1p31.3	IL-2, -3, -4, -5, -6, -7, -11 G-CSF GM-CSF IFN-α/β/γ
JAK-2	130	10p23–24	IL-2, -3, -4, -5, -6, -7, -11, -12 Epo G-CSF GM-CSF
Tyk-2	140	19p13.2	IL–6, -11, -12 IFN-α/β/γ

Figure 19-3   Signal transduction mechanisms used by growth factor receptors. The PTK activity intrinsic to or associated with the growth factor receptor activates a series of phosphorylation cascades. PI-3-kinase phosphorylates inositol phosphates, whereas activation of the Ras pathway stimulates the intrinsic GTPase activity of this GTP-binding protein. The latter induces a further phosphorylation cascade that culminates in early gene induction. The Jak kinases have tyrosine phosphorylation activity and rapidly associate with activated growth factor receptors. These molecules phosphorylate a second family of molecules, termed Stats, which then acquire DNA binding properties. PTK, protein tyrosine kinase; Jak, Janus kinase; STAT, signal transducer and activator of transcription; GF, growth factor.

Ras Pathway Activation   Receptor associated Jaks activate the protein SHC that, in turn, associates with the adaptor protein Grb 2. The latter associates with SOS, a GDP-GTP exchange factor that controls the intrinsic GTPase activity of a small molecular-weight membrane associated GTP-binding protein termed Ras.

Phosphorylated Ras activates a phosphorylation cascade that activates Raf-1 and MAP kinase, which in turn leads to early gene induction.

Phosphatidyl Inositol 3 Kinase (PI-3 Kinase) Activation The box 1 and 2 domains of the cytoplasmic tail of receptors can bind the p85 subunit of PI-3 kinase, increasing its activity. This kinase phosphorylates inositol phosphates that are known to play a role in signal transduction for non–growth factor receptors.

Vav Activation The vav gene is only expressed in hematopoietic cells and is tyrosine phosphorylated by a number of growth factors. Expression of antisense vav in hematological malignancies reduces CFU-GM colony formation and BFU-E activity. However, function of this gene remains incompletely understood.

Signal Transducer and Activator of Transcription (Stat) Activation This novel family of proteins acquire DNA-binding properties after tyrosine phosphorylation and oligomerization. These proteins were identified as important links in mediating signal transduction between interferon receptors and interferon responsive genes. Stats share sequence homology and coprecipitate with Jaks after growth factor stimulation. A growing family of Stats has been identified that appear to be important in initiating altered gene transcription after growth factor signaling (Fig. 19-3).

Hematopoietic Cell Phosphatase (HCP) Activation This protein contains a carboxy-terminal tyrosine phosphatase domain that binds to the tyrosine phosphorylated carboxy-terminal domains of the Epo, SCF, and IL-3 receptors. Its expression is restricted to hematopoietic cells. The importance of this factor for limiting the action of growth factors has been confirmed by study of "motheaten" mice. These animals have a mutation that deletes HCP and is rapidly lethal in the homozygous state owing to accumulation of activated macrophages in the lung. It is associated with increased sensitivity to Epo. Similarly, the familial erythrocytosis seen with mutations that remove 70 amino acids at the carboxy-terminal of the human Epo receptor is a result of loss of the phosphorylation residue recognized by HCP and continued signaling after receptor stimulation.

Gene Transcription Growth factor tyrosine phosphorylation is associated with upregulation of c-*myc*, which, in turn, upregulates expression of the enzyme ornithine decarboxylase (ODC). Inhibition of this enzyme blocks growth factor stimulation.

Other genes upregulated by growth factors include c-*fos*, c-*jun*, and *pim*-1. The latter is expressed only in hematopoietic cells and produces a serine-threonine kinase that may influence cell-cycle control.

CLINICAL APPLICATION OF GROWTH FACTORS Our expanding knowledge of the mechanism of action of human hematopoietic growth factors is shedding light on the pathophysiology of a number of disease states. Furthermore, in the decade since the cDNAs for G and GM-CSF were identified, recombinant human growth factors have become established in therapeutic use. In the next section, we will outline some of the clinical consequences arising from our understanding of the basic science of hematopoietic growth factors.

GRANULOCYTE COLONY-STIMULATING FACTOR (G-CSF) Recombinant human G-CSF expressed from bacterial or yeast cells is available for clinical use. After subcutaneous or intravenous injection of 2.5–10 µg/kg of these products, up to a 10-fold rise in the peripheral neutrophil count, beginning with the first dose and sustained for the duration of therapy, is seen. In concert with this, up to a 100-fold increase in circulating progenitors of all lineages is seen during treatment. These observations have led to a number of clinical applications.

Minimizing Chemotherapy-Induced Neutropenia The use of myelosuppressive chemotherapy to treat hematological malignancies and solid tumors is associated with a period of neutropenia. Septicemia from endogenous organisms colonizing the gut is a cause of patient morbidity and mortality during periods of neutropenia. The risk of such sepsis is directly related to the duration and degree of neutropenia. By administering G-CSF after the chemotherapy, the depth and duration of neutropenia can be reduced. Trials have shown that for a number of diseases, including lymphoma and acute leukemia, as well as solid tumors, G-CSF support during chemotherapy reduces the number of infections, hence patient morbidity. These trials have not demonstrated definitive benefits for treatment outcome. Other growth factors, such as GM-CSF or IL-3, have no superior efficacy to G-CSF but are associated with more side effects.

Maximizing Dose Intensity of Chemotherapy By minimizing the duration of neutropenia induced by chemotherapy, the interval between courses of treatment can be shortened with an increase in the delivered dose intensity. Using G-CSF, it has been possible to reduce the duration between courses, but thrombocytopenia remains a limitation. Only modest increases in dose intensity can be achieved by this approach, and major clinical benefit has not resulted. With the isolation of Tpo, new approaches to prevent dose-limiting thrombocytopenia may be feasible. Animal studies have demonstrated the ability of Tpo to decrease the depth and duration of thrombocytopenia and its safe combination with G-CSF.

High-Dose Therapy and Transplantation Independent observers have documented the "mobilization" of stem cells from the bone marrow into the peripheral blood after G-CSF treatment or upon recovery from myelosuppressive chemotherapy. The combination of both treatments is synergistic for this effect. Stem cells can be harvested from the peripheral blood mononuclear fraction by leukapheresis. Such collections contain CD34-positive stem cells and can be used for bone marrow rescue after high-dose therapy (Fig. 19-4). The aim of such treatment is to give maximum dose intensity to eliminate the disease and use peripheral blood stem cells (PBSC) to rescue the patient from the resultant myeloablation. The PBSC may be collected from the patient and used for a later autologous procedure or from a sibling donor in an allogeneic transplant. Gene-marking studies have documented the ability of PBSC to restore long-term stable hematopoiesis in this setting, hence the presence of pleuripotent stem cells in these collections. The stem-cell content of PBSC can be inferred from the numbers of CD34-positive cells collected. Patients receiving greater than 2.5×10^6 CD34-positive cells per kilogram body weight engraft rapidly after autologous PBSC transplants. This engraftment is more rapid than that seen with bone marrow rescue as the source of stem cells and is accounted for by the number of CD34 positive cells, which is up to 10-fold higher in PBSC collections. The number of natural killer (NK) cells is up to 20-fold greater in PBSC and the distribution of lymphocyte subsets differs. For these reasons, the use of PBSC for allogeneic transplantation may offer enhanced immunological reactions against malignant cells, the so-called "graft vs leukemia" effect and speedier immune reconstitution with a reduction in the risk of infection. For hematological diseases that affect the bone marrow, PBSC may provide
A AUTOLOGOUS TRANSPLANT

CHEMOTHERAPY

- Cryopreserve mononuclear cells
- At a later date treat patient with high dose chemo-radiotherapy
- Return mononuclear cells (PBSC) after last chemotherapy cleared from body
- 10-14 days later marrow regeneration occurs

B ALLOGENEIC TRANSPLANT

- 15-28 days later marrow regeneration from donor stem cells occurs

Figure 19-4   Use of G-CSF to obtain stem cells for (**A**) autologous and (**B**) allogeneic transplantation.

a source of autologous rescue that is less contaminated with tumor cells than bone marrow. In practice, however, tumor-cell contamination has been documented and may relate to the degree of marrow contamination at the time of mobilization.

The use of PBSC has now virtually replaced marrow in autologous rescue after high-dose therapy, and we expect their use for allogeneic transplantation to expand. These procedures are still associated with a period of absolute neutropenia and thrombocytopenia; the use of growth factors to further reduce these remains to be explored. Combinations of other growth factors such as SCF or IL-3 with G-CSF are being explored for synergy in mobilizing CD34 positive stem cells for collection.

Congenital Neutropenia   Congenital neutropenias are a spectrum of disorders with various etiologies. Kostmann's syndrome is one example in which severe neutropenia at birth is associated with maturation arrest at the promyelocyte/myelocyte stage of development in the marrow. Inheritance may be autosomal dominant or recessive. These babies experience severe pyogenic infection and historically have a median survival of approximately 3 years. Circulating levels of G-CSF are raised in Kostmann's syndrome, with normal expression and affinity of G-CSF receptors. Studies on G-CSF receptor structure have largely been normal, but abnormal protein phosphorylation has been described raising the possibility of a downstream signal transduction block. The majority of these patients respond to G-CSF

therapy with a rise in their neutrophil counts, a reduction in infections, and improvements in survival. Prior to the use of G-CSF, some of these patients developed myelodysplasia and acute myeloid leukemia. Many patients have now been treated with G-CSF for several years, and an increased incidence of this progression to acute leukemia has been documented in such patients. This is probably a result of increased survival highlighting this feature of the natural history of Kostmann's syndrome. Patients developing leukemia usually have an antecedent monosomy 7 cytogenetic abnormality, and one report detailed the presence of mutations in the G-CSF receptor in this group. The latter may also account for the rare cases that are refractory to G-CSF therapy.

Neonatal Sepsis   Newborn babies have immature host defense systems that predispose them to increased mortality during bacterial sepsis. Depletion of storage pool neutrophils associated with neutropenia during neonatal sepsis is associated with a poor prognosis that can be improved by granulocyte transfusions. Studies have documented decreased production by effector cells of a number of growth factors in neonates, including G-CSF, GM-CSF, IL-3, and IL-6. Other studies have documented the safety of administration of G- and GM-CSF in this setting, with increases in peripheral neutrophil counts. Trials are pending to show the clinical benefits of such treatment.

ERYTHROPOIETIN   Renal Failure   Erythropoietin was the first human growth factor to be available for clinical use. The

first patient group targeted for therapy were patients with renal failure. Since Epo is made by peritubular cells in the kidney, nephron loss is associated with decreased Epo production. Patients with renal failure thus have a hypoproliferative anemia with low Epo levels for the degree of anemia. The anemia is responsible for much of the morbidity of renal failure with poor exercise tolerance and exacerbation of the symptoms of ischemic heart disease, which is not uncommon in this patient group. Greater than 95% of renal patients treated with recombinant Epo will improve their hemoglobin and derive clinical benefit. Other benefits include improvement in cardiovascular parameters, such as reduction in left ventricular hypertrophy and normalization of the bleeding time. The increased blood viscosity may exacerbate hypertension, and an increased incidence of shunt thrombosis has been reported. Iron stores must be adequate prior to starting Epo, and supplementation may be necessary.

Chronic Disease   Some, but not all, patients with chronic disease such as malignancy or rheumatoid arthritis have a hypoproliferative anemia associated with Epo levels that are reduced for the degree of anemia. These patients have been documented to respond to pharmacological doses of Epo with an increase in hemoglobin and improvement in morbidity.

Premature Neonates   Some premature neonates experience a hypoproliferative anemia 2–12 weeks postnatally. Erythropoietin levels are detectable in cord blood of babies born from 25 weeks gestation but show an increase after 32 weeks. Levels of SCF and IL-6 had no relationship to gestation, and those of GM-CSF and IL-3 were undetectable. In a randomized study, recombinant Epo reversed the anemia of prematurity in about 30% of premature infants, suggesting low levels of Epo may be a contributory factor.

Diamond Blackfan Anemia   This is a rare congenital pure red cell aplasia, presenting with macrocytic anemia in infancy. The disease behaves heterogeneously with regard to associated dysmorphic features, inheritance, and clinical course. These patients have appropriate Epo levels, and no clinical response to treatment with recombinant Epo has been demonstrated. Over 70% of patients respond to steroid therapy, and the majority are steroid dependent. Some become refractory to treatment, and, ultimately, some 40% will be transfusion dependent. Levels of stem-cell factor and the expression of c-*kit*, the SCF receptor, are normal. In vitro erythroid colony formation is reduced but shows some response to IL-3. Clinically, IL-3 has produced responses in approximately 10% of patients, some achieving steroid independence for several years. All of the responders had at some point been steroid responsive. At least a third of patients had side effects, including fever, fluid retention, and local reactions at injection sites. Further studies to better define the molecular lesions in these patients are pending.

CONCLUSION

Our understanding of the molecular factors that stimulate and regulate hematopoiesis is a good example of the impact basic scientific knowledge can have on the practice of clinical medicine.

New factors, both stimulatory and inhibitory, continue to be defined, offering insights into the pathogenesis of inherited and acquired disease and the potential for novel therapeutic strategies.

20 Disorders of Hemoglobin Structure and Synthesis

Swee Lay Thein and Jacques Rochette

INTRODUCTION

All human hemoglobins have a tetrameric structure, consisting of two identical α-like (α or ζ) and two β-like (ε, γ, δ, or β) globin chains, each linked to a heme group.

Human hemoglobin production is characterized by two "switches," production of embryonic hemoglobin switches after the first 2 months of gestation to the production of fetal hemoglobin and then just before birth to adult hemoglobin (Fig. 20-1). These different types of hemoglobin have been adapted to the changes in physiological requirements that occur during development. Fetal hemoglobin (Hb F) exhibits a higher oxygen affinity than the adult hemoglobins in vivo; the higher oxygen affinity of Hb F relative to adult hemoglobin facilitates the transfer of oxygen across the placenta from the maternal circulation to the fetal circulation.

The α- and β-like globin chains are encoded by genetically distinct loci on the tip of chromosome 16p and chromosome 11p15.5, respectively (Fig. 20-1). In both clusters, the genes are arranged 5'→3' in the order in which they are expressed during development. While the α-like genes undergo a single developmental switch (embryonic → fetal/adult), the β-like genes undergo two switches (embryonic → fetal → adult).

Expression of the individual genes within each cluster is controlled by complex interactions between regulatory sequences within each gene, and regulatory elements upstream of the cluster. In the β cluster, the upstream element is referred to as the β locus control region (β-LCR) and a corresponding element in the α cluster is referred to as HS-40 (Fig. 20-1). The products of the two gene clusters are expressed in equal amounts, maintaining a balance in globin chain production throughout development.

Much interest has focused on the mechanisms by which the globin genes are expressed in a tissue- and developmental-stage–specific manner. Tissue-specific expression may be explained by the presence of the binding sites for two proteins, GATA-1 and NF-E2, in the upstream regulatory elements and the local promoter of the globin genes. GATA-1 and NF-E2 are specifically expressed in erythroid cells, and it seems likely that these two *trans*-acting factors form part of a network of factors that commit hemopoietic stem cells to erythroid differentiation. The mecha-

nisms by which developmental regulation is controlled are less clear; autonomous control of the embryonic ε and ζ genes and the γ genes implicates negatively acting factors, referred to as silencers. So far, the best-defined example of a developmental–stage-specific regulatory factor is the erythroid Krüppel-like factor (EKLF) that appears to be essential for the final steps of definitive erythropoiesis, at least in mice.

The vast majority of hemoglobin disorders are inherited and can be classified into those that are characterized by a quantitative deficiency of one or more of the globin chains of hemoglobin (thalassemias); those in which there is a structural change in a globin chain (hemoglobin variants) and the thalassemic hemoglobinopathies in which a structurally abnormal hemoglobin produces the phenotype of thalassemia. The acquired abnormalities can also be classified into those characterized by a reduced synthesis of the globin chains (e.g., acquired Hb H disease) and those that alter the structure and function of hemoglobin so that oxygen transport is affected (e.g., carboxyhemoglobinemia, methemoglobinemia).

THE THALASSEMIAS

BACKGROUND Thalassemia was first recognized by Cooley and Lee in 1925 as a form of severe anemia that is associated with splenomegaly and bone changes in children. The term thalassemia is derived from the Greek θαλασσα (the sea), because many of the early cases came from the Mediterranean region. However, it is now clear that the disorder is not only limited to the Mediterranean region, but it occurs also throughout the world, prevalent in the tropical and subtropical regions including the Middle East, parts of Africa, the Indian subcontinent, and Southeast Asia. It appears that heterozygotes for thalassemia are protected from the severe effects of *falciparum* malaria, and natural selection has increased and maintained their gene frequencies in these malarious regions.

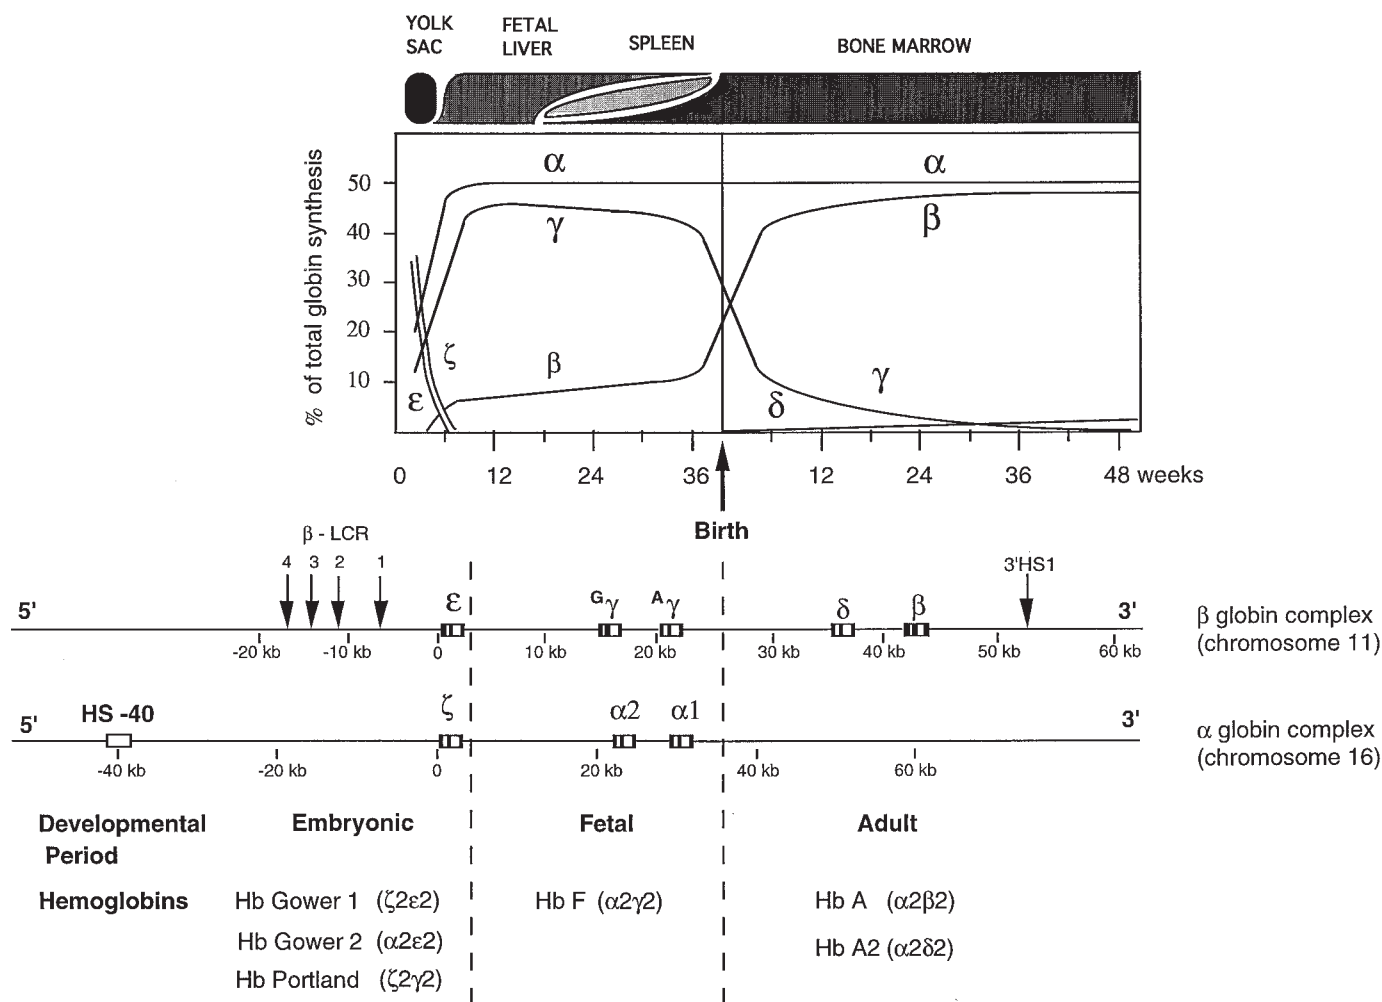
The thalassemias can be classified according to the type of globin chain(s) that is produced in reduced amounts (i.e., α-, β-, δβ-, γδβ-, δ-, γ-, and εγδβ-thalassemias). The two major categories are the α- and β-thalassemias, whereas the rare forms include the γ-, δ-, and εγδβ-thalassemias. Hereditary persistence of fetal hemoglobin (HPFH) syndromes refer to the group of disorders in which the switch from fetal to adult hemoglobin production is incomplete, and the fetal hemoglobin levels are elevated in otherwise normal individuals. Because of their concomitant increased Hb F levels, the δβ- and γδβ-thalassemias are often


Figure 20-1   Sequence of human hemoglobin synthesis *(above)* and the organization of the globin gene clusters on chromosome 11p and 16p *(below)* with the types of hemoglobin synthesized during the different developmental periods. Solid arrows represent the erythroid-specific deoxyribonuclease I hypersensitive sites (HSs) in the β cluster. HSs 1–4 upstream of the β cluster form the β-LCR; the 3'HS1 site is a downstream enhancer. HS –40 form the equivalent of the β-LCR in the α-globin complex.

considered with the HPFH syndromes. In many populations, the α- and β-thalassemias coexist with a variety of different structural hemoglobin variants. In these populations, it is quite common to inherit a combination of genes; these complex interactions give rise to an extremely wide spectrum of clinical phenotypes that together constitute the thalassemia syndromes. It has been estimated that about 300,000 individuals severely affected with thalassemia are born each year, posing a heavy burden on health services. Mass migration of populations from high prevalence areas has resulted in the hemoglobin disorders being increasingly observed in parts of the world where they were not previously recognized.

THE β-THALASSEMIAS   Clinical Features   The clinical features of β-thalassemia range from the major forms to a completely silent carrier state.

Infants affected with β-thalassemia major are well at birth. Anemia usually develops during the first few months of life, when adult hemoglobin synthesis becomes established. There are no specific clinical signs, and further clinical manifestations of the disease depend on whether the child is maintained on an adequate transfusion regime.

The inadequately transfused child develops the typical features of Cooley's anemia. They show marked retardation of growth and development with progressive hepatosplenomegaly. A typical "thalassemia" facies develops with frontal bossing, prominent cheek bones, and protruding upper jaw as a result of extension of the marrow in the skull and facial bones. Radiography of the skull shows the typical "hair-on-end" appearance. The long bones and phalanges become rarefied from marrow expansion and show a lacy trabecular pattern on radiography. These changes may be associated with repeated pathological fractures. Occasionally, the expanding marrow extends from the rib or vertebrae and forms large paraspinal extramedullary masses. The massive marrow expansion causes a hypermetabolic state that is accompanied by intermittent fevers and weight loss. Gall stones and leg ulcers are common complications. Without any transfusion, death occurs within the first 2 years. "Palliative" transfusion allows the child to live somewhat longer, but the bony deformities remain unchanged; the child normally succumbs to an overwhelming infection. If these children survive to puberty, they develop complications of iron overload. Iron accumulation results from an increased rate of gastrointestinal absorption, as well as that derived from the blood transfusions.

When transfused adequately to maintain a hemoglobin level of >11 g/dL, these children grow and develop normally until early puberty, when they begin to show signs of progressive hepatic, cardiac, and endocrine disturbances, including liver failure, diabetes, hypoparathyroidism, and delayed or absent secondary sexual development. These changes are owing largely to tissue siderosis from the progressive accumulation of iron derived from transfusions. Unless iron overload is controlled by regular chelation therapy, death results in the second or third decade, from acute or intractable congestive cardiac failure.

Individuals with β-thalassemia minor are typically asymptomatic. Splenomegaly is rare.

Diagnosis   Untransfused hemoglobin levels in β-thalassemia major can be as low as 2–3 g/dL. The red cells show severe hypochromia, marked anisopoikilocytosis, target cell formation, and basophilic stippling. Poorly hemoglobinized nucleated red cells are frequently found in the peripheral blood and may reach very high levels after splenectomy. Despite the severe anemia, the reticulocyte count is usually not very high because of the massive destruction of erythroid precursor cells in the bone marrow (i.e., ineffective erythropoiesis). The bone marrow shows marked erythroid hyperplasia, characterized by poorly hemoglobinized normoblasts. Ragged inclusions (α-chain aggregates) in the normoblasts are revealed under phase microscopy or after supravital staining (e.g., methyl violet). Increased iron deposition is also seen in the bone marrow; the majority of the iron granules are randomly distributed. Biochemical evidence of hemolysis and progressive iron loading are observed. Other biochemical changes may include evidence of diabetes and endocrine dysfunction, such as parathyroid insufficiency.

The findings on Hb electrophoresis vary with the β-thalassemia genotype and is informative only in the previously untransfused patient. In homozygous $β^o$-thalassemia, Hb A is completely absent, and the hemoglobin consists of F and A_2 only. In $β^+$-thalassemia (homozygous or compound heterozygous), a variable amount of Hb A is present. The Hb F is usually elevated and vary from 10 to 90% of the total hemoglobin. The Hb A_2 level is of no diagnostic value. In vitro globin chain biosynthesis of peripheral blood reticulocytes or bone marrow shows globin chain imbalance with a marked excess of α- over β- and γ-chain production. In $β^o$-thalassemia, there is a complete absence of β-chain synthesis.

The heterozygous state for β-thalassemia ($β^o$ or $β^+$) is remarkably uniform hematologically. If present, anemia is mild, and the diagnosis is based on a low MCV and MCH, accompanied by an increased proportion of Hb A_2, from 3.5 to 5.5%, with the exception of a subgroup that has a normal level of Hb A_2. Globin chain biosynthesis shows α chains in excess of about twofold.

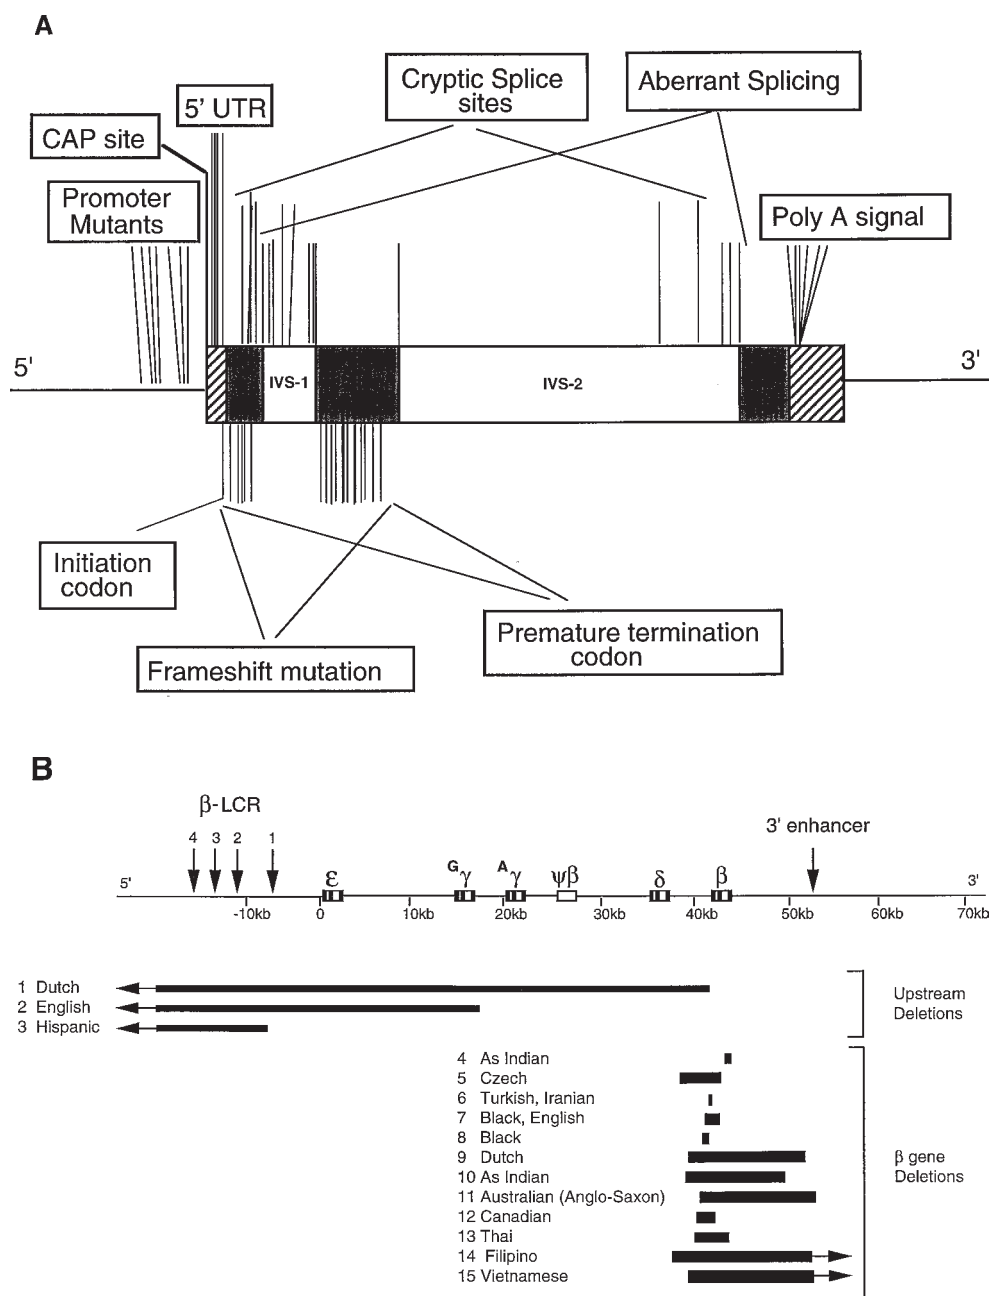
Normal A_2 heterozygous β-thalassemia may be difficult to distinguish hematologically from heterozygous α-thalassemia, since both cases are characterized by hypochromic microcytic red cells and a normal Hb A_2 level. The distinction is made by globin chain biosynthesis and DNA analysis. Type I normal A_2 β-thalassemia is "silent," in that the red cell indices are almost normal, and the phenotype is caused by very mild mutations that cause only a minimal deficit in β-chain production (e.g., C-T mutation in position –101 of the β gene). Other cases (type 2 normal Hb A_2 β-thalassemia) are a result of the coinheritance of δ-thalassemia *in cis* or *in trans* to the β-thalassemia gene.

DNA analysis frequently shows the β-globin cluster to be intact and point mutations within the β gene or its immediate flanking regions.

Genetic Basis of Disease   The β-thalassemias are considered to be autosomal recessive disorders, because individuals who have inherited one abnormal β gene (carrier) are asymptomatic and the inheritance of two abnormal β-globin genes is required to produce a clinically detectable phenotype. Molecular analysis of the β-thalassemia genes has demonstrated a striking heterogeneity. Although >150 β-thalassemia alleles have been characterized, population studies indicate that probably only 20 β-thalassemia alleles account for >80% of the β-thalassemia mutations in the whole world. This is because in each of the high-frequency areas, only a few (four to six) mutations are common, with a varying number of rare ones; each of these populations has its own unique group of mutations. This is particularly relevant to prenatal diagnosis, because direct detection of these mutations by DNA analysis becomes feasible.

The vast majority of β-thalassemia mutations are single-base substitutions, small insertions or deletions of one to two bases involving the critical sequences that control the various stages of gene expression (Fig. 20-2A). Approximately half of these mutations completely inactivate the β gene and cause a phenotype of $β^o$-thalassemia. Mutations that allow the production of some β globin lead to the phenotype of $β^+$-thalassemia. Mutations affecting the conserved sequences in the 5' promoter (i.e., TATA box, proximal CACCC and distal CACCC box), typically cause a 70–80% reduction in promoter activity and are often very mild. Mutations affecting the polyadenylation signal (AATAAA) at the 3' end also generally result in a mild $β^+$-thalassemia phenotype.

Studies show that the different inphase termination mutants exhibit a "positional" effect. Frameshifts and nonsense mutations that result in premature termination early in the sequence (in exon 1 and 2) are associated with minimal amounts of mutant β mRNA. In such cases, no β chain is produced from the mutant allele, and only half the normal β globin is present, resulting in a phenotype of typical heterozygous β-thalassemia. In contrast, mutations that produce inphase terminations later in the β sequence—in exon 3— are associated with substantial amounts of mutant β-mRNA. Such mutations, even when present in a single copy, result in a moderately severe anemia and are said to be "dominantly inherited." Small amounts of truncated β-variant chains have been isolated in one case (heterozygous β codon 121). However, these truncated β chains are nonfunctional and not able to form viable tetramers, resulting in ineffective erythropoiesis and clinical disease, even in the heterozygous state.

β-thalassemia is rarely caused by deletions (Fig. 20-2B). Of these, only the 619-bp deletion at the 3' end of the β gene is common, but even that is restricted to the Sind populations of India and Pakistan, where it constitutes approximately 30% of the β-thalassemia alleles. The other deletions, although extremely rare, are of particular phenotypic interest, because they are associated with an unusually high level of Hb A_2 in heterozygotes. The mechanism underlying the markedly elevated levels of Hb A_2 and the variable increases in Hb F in heterozygotes for these deletions is related to the removal of the 5' promoter region of the β-globin gene that removes competition for the upstream β-LCR, leading to an increased interaction of the LCR with the γ and δ genes *in cis*, thus enhancing their expression. Even more rare are three upstream deletions that remove all or part of the β-LCR, but leave the β gene itself intact, yet cause β-thalassemia. Because of the vast number of different β-thalassemia mutations, many patients with thalassemia major are compound heterozygotes for two different molecular lesions.


A

B

Figure 20-2 **(A)** Point mutations causing β-thalassemia. The β-globin gene is represented by 3 exons (gray) interrupted by 2 introns with the 5' and 3' untranslated regions (UTRs, striped boxes). The vertical lines represent the sites of the different mutations that can be found in the UTRs, exons and introns. **(B)** Deletions causing β-thalassemia. Two groups of deletions are shown: (1) group of upstream deletions which remove extensive regions (30–100 kb) of the 5' end of the β cluster but leave the β gene intact; (2) deletions that remove part or all of the β gene. These range from 290 bp to >45 kb in size. The 619-bp deletion (number 4) removes the 3' end of the β gene but leaves the 5' end intact, whereas the other deletions remove, in common, the 5' promoter region of the β gene, including sequences from positions –125 to +78 (relative to the β mRNA cap site).

Pathophysiology The molecular defects in β-thalassemias result in absent or reduced β-chain production, whereas α-chain synthesis proceeds at a normal rate. This imbalance in globin synthesis in β-thalassemia gives rise to excess α chains (Fig. 20-3A), which are extremely unstable and precipitate in the red cell precursors, forming inclusion bodies. These inclusions interfere with the red cell maturation and are responsible for the intramedullary destruction of the erythroid precursors, hence, the ineffective erythropoiesis that characterizes all β-thalassemias. The anemia of β-thalassemia results from a combination of underproduction of

hemoglobin and ineffective erythropoiesis and is ultimately related to the degree of imbalance between the α- and non–α-globin chains.

HB E/β-THALASSEMIA Throughout Southeast Asia and the Indian subcontinent, it is not uncommon to encounter individuals who are compound heterozygotes for Hb E and β-thalassemia. Because Hb E is also insufficiently synthesized, the compound heterozygous state results in a clinical picture closely resembling homozygous β-thalassemia, ranging from severe anemia and transfusion dependency to thalassemia intermedia. The diagnosis of Hb E/β-thalassemia is confirmed by finding Hb E and F on hemoglo-

bin electrophoresis and by demonstrating Hb E trait in one parent and β-thalassemia trait in the other.

THE δβ-, γδβ-THALASSEMIAS AND HPFH SYNDROMES This group of disorders is characterized by a reduced synthesis of β- and δ-globin chains and a variable increase in γ-chain production. They are remarkably heterogeneous at the molecular level. In some cases, they result from extensive deletions of the β-gene cluster, removing the β- and δ- or β-, δ- and γ-globin genes, whereas in others, they result from point mutations in the γ-globin promoters (HPFH). Occasionally, δβ-thalassemia results from unequal crossing over between the δ- and β-genes producing a δβ-fusion gene. The δβ-fusion chains combine with α chains to form Hb Lepore $(\alpha_2(\delta\beta)_2)$. In a subgroup of HPFH, heterocellular HPFH, the β cluster—including the γ-globin genes—is intact. The distinction between HPFH and δβ-thalassemia is subtle and made on both clinical and hematological grounds.

HPFH is characterized in heterozygotes by levels of Hb F of up to 30% with normal red cell indices and near normal hematocrit levels, whereas heterozygotes for δβ-thalassemia tend to have elevated levels of Hb F that are lower (up to 20%) with mild anemia and hypochromic microcytic red cells. The importance of this group of conditions lie in their interaction with β-thalassemia. Compound heterozygotes for HPFH and β-thalassemia tend to have a mild disease compared to β-thalassemia homozygotes, whereas compound heterozygotes for δβ- and β-thalassemia exhibit a wide spectrum in disease severity, ranging from mild anemia to thalassemia major.

INTERMEDIATE FORMS OF β-THALASSEMIA Thalassemia intermedia is an ill-defined clinical term used to describe patients with phenotypes that are more severe than the asymptomatic thalassemia trait but milder than the transfusion-dependent thalassemia major. The criteria on which the diagnosis is based is that patients present later in life relative to thalassemia major and that they are capable of maintaining a reasonable level of hemoglobin (≥ 6 g/dL) without transfusion. At the severe end of the spectrum, patients present between the ages of 2 and 6 years; although they are just capable of surviving without blood transfusion, it is clear that growth and development are retarded. Many will show the skeletal and facial changes and progressive splenomegaly, as seen in untreated thalassemia major. As they become older, they develop iron-overload because of increased gastrointestinal absorption of iron. At the other end of the spectrum, patients are completely asymptomatic until adulthood and are transfusion-independent with hemoglobin levels of 10–12 g/dL. Such patients are diagnosed either during episodes of infection, when they become anemic, or by a chance hematological examination. There is usually some degree of splenomegaly. Table 20-1 lists some of the molecular interactions associated with the phenotype of thalassemia intermedia.

Because of the extreme variability of these disorders, these patients should be regularly followed from early childhood and the growth charts and iron accumulation carefully monitored.

THE α-THALASSEMIAS The geographical distribution of α-thalassemia is very similar to that of β-thalassemia. Although the α-thalassemias are more common, they pose less of a public health problem because the severe homozygous states cause death *in utero*, and the milder forms that survive into adulthood do not cause a major disability.

Clinical Features The clinical disorders resulting from α-thalassemia range from death *in utero* (Hemoglobin Bart's hydrops syndrome) to a completely silent carrier state.

Hb Bart's hydrops is a frequent cause of stillbirths in Southeast Asia. Affected infants are usually stillborn with gross pallor, generalized edema, and massive hepatosplenomegaly. The placenta is enlarged and friable, frequently causing obstetric difficulties. The intermediate form of α-thalassemia is Hb H disease, commonly seen in the Mediterranean, Middle East, and Southeast Asia. A spectrum of disease severity is also encountered in Hb H disease. Generally, these individuals have a moderately severe anemia and splenomegaly but are usually transfusion-independent, except during episodes of hemolysis associated with infection. The skeletal deformities and growth retardation characteristic of β-thalassemia are not common.

Diagnosis Diagnosis is based on the hemoglobin level, red cell indices, examination of the peripheral blood smear, and hemoglobin analysis. Infants with Hb Bart's hydrops are severely ane-

Table 20-1

          X-linked, 6q-linked.
2. Compound heterozygotes for β-thalassemia and deletion forms of HPFH or δβ-thalassemia.
3. Compound heterozygotes for β-thalassemia and β-chain variants (e.g., Hb E/β-thalassemia).
4. Heterozygotes for β-thalassemia.
    a. Coinheritance of extra α-globin genes.
       (ααα/αα or ααα/ααα)
    b. Dominantly inherited forms of β-thalassemia (including some thalassemic hemoglobinopathies).

mic with hemoglobin levels of 6–8 g/dL. The blood film shows severe thalassemic changes with numerous hypochromic nucleated red cells. There is no Hb A or F, the hemoglobin consists mainly of Hb Bart's (γ_4 tetramers), with small amounts of embryonic hemoglobin and Hb H (β_4 tetramers). Biosynthetic studies confirm the complete absence of α chains. Patients with Hb H disease run an hemoglobin level of 7–10 g/dL, with moderate reticulocytosis. Again, typical thalassemic changes are seen in the blood film. On incubation of the red cells with brilliant cresyl blue, numerous inclusion bodies are generated by precipitation of the Hb H, forming typical "golf balls." Hemoglobin analysis shows 5–40% Hb H, with the major component being Hb A and a normal or reduced level of Hb A_2. Sometimes, there is also a small amount of Hb Bart's. Carriers for α-thalassemia may be slightly anemic with hypochromic microcytic red cells or "silent," with minimal hematologic changes. The Hb electrophoretic pattern is normal, and globin biosynthetic studies show a deficit of α-chain production.

Diagnosis of α-thalassemia is confirmed by DNA analysis, which commonly reveals deletions of the α-gene cluster, removing one or both α genes. Less commonly, the α genes are present and DNA sequence analysis reveals point changes within the α2 gene or its immediate flanking regions.

Genetic Basis of Disease   Normal individuals (αα/αα) have two α-globin genes, α2 and α1, on each chromosome 16. The α-thalassemia syndromes result from underproduction of α chains and are frequently caused by deletions that remove one of the linked α genes ($-\alpha^{3.7}/\alpha\alpha$ or $-\alpha^{4.2}/\alpha\alpha$). Extensive deletions that remove both the linked α2 and α1 genes tend to be geographically isolated, and so are often referred to by their geographical origin for example, —^{SEA}/αα. More rarely, upstream deletions that remove the HS −40 region but leave the α genes themselves intact can also cause α-thalassemia.

Loss of one functioning α gene (αα/−α) is almost completely silent with normal or only slightly hypochromic red cells. Loss of two α genes (—/αα or −α/−α) produces a mild hypochromic microcytic anemia. Individuals who have inherited only one α gene (—/−α) have Hb H disease, whereas inheritance of no α genes (—/—) gives rise to a lethal, intrauterine hemolytic anemia termed the Hb Barts hydrops fetalis syndrome. Deficiency of α chains

gives rise to an excess of γ chains (in fetal life) or β chains (in adult life) that form γ_4-tetramers (Hb Barts) and β_4-tetramers (Hb H). The presence of Hb Barts or Hb H is thus diagnostic of α-thalassemia. Anemia results from a combination of the underproduction of hemoglobin and hemolysis owing to the intracellular precipitation of Hb Barts and Hb H, and is ultimately directly related to the degree of α-chain deficiency.

Less commonly, α-thalassemia results from point mutations involving the critical sequences that control the various stages of gene expression, as encountered in β-thalassemia. With the exception of one phenotypically mild α thalassemia mutant, all of these mutations affect the dominant α_2-globin gene. In general, the nondeletion α-thalassemia variants ($\alpha^T\alpha/\alpha\alpha$) give rise to a more severe reduction in α-chain synthesis than the single α-gene deletions ($-\alpha/\alpha\alpha$), the homozygous state ($\alpha^T\alpha/\alpha^T\alpha$) for such variants often result in Hb H disease. A common nondeletion α-thalassemia variant in Southeast Asia is Hb Constant Spring (Hb CS), which is caused by a single base substitution (TAA → CAA) in the α2 globin termination codon. This results in read through of the 3' untranslated sequence until another inphase termination codon is encountered 31 codons later. Homozygotes ($\alpha^{CS}\alpha/\alpha^{CS}\alpha$) or compound heterozygotes ($\alpha^{CS}\alpha/—$) for Hb CS have a less severe form of Hb H disease. Very low levels of this elongated α globin chain (5–8% of the total hemoglobin in homozygotes) are found; the defective α^{CS} chain production is a consequence of the instability of the α^{CS} mRNA. Three other variants (Hb Icaria, Hb Seal Rock, and Hb Koya Dora) involving different base substitutions in the α2 termination codon have been identified.

Pathophysiology   There is a fundamental difference in the pathophysiology of the α- and β-thalassemias (Fig. 20-3). Because γ_4 and β_4 tetramers are soluble, they do not precipitate to a significant degree in the bone marrow (i.e., erythropoiesis is more effective than in β-thalassemia). However, these β_4 tetramers do precipitate as the red cells age, forming inclusion bodies. Hemolysis occurs because of the red cell membrane damage and obstruction in the spleen.

α-THALASSEMIA WITH MENTAL RETARDATION (ATR) SYNDROMES   There are two distinct syndromes of α-thalassemia and mental retardation. One group, ATR-16, results from

Table 20-2
Clinical Disorders Caused by Structural Hemoglobin Variants

1. Sickle syndromes causing hemolysis and tissue damage.
   Hb S and interaction of Hb S with other Hb variants.
   (Hbs S/C, S/O-Arab, and S/D-Punjab) and β-thalassemia (S/β-thal).
2. Chronic hemolysis—unstable hemoglobin variants (congenital Heinz body anemia, CHBA).
   e.g., Hb Köln, Hb Bristol.
3. Congenital polycythemia—high oxygen affinity Hb variants.
4. Congenital cyanosis—Low oxygen affinity Hb variants.
   M hemoglobins.
5. Hypochromic microcytic anemia (thalassemic hemoglobinopathy).
   e.g., Hb E—β structural variant.
   Hb Constant Spring—α structural variant.
   Hyperunstable hemoglobin variants.
6. Drug-induced hemolysis (e.g., Hb Zurich).

extensive deletions of 1–2 Mb of the tip of chromosome 16, which remove the α-globin gene cluster. The mental retardation is associated with variable dysmorphic features and is thought to result from loss of a variable number of genes at the tip of chromosome 16p. ATR-X is characterized by more severe mental retardation, characteristic dysmorphic facies, and genital abnormalities. In these cases, the α-globin gene cluster is intact; the underlying mutation is a *trans*-acting abnormality encoded in the *XH2* gene on the X chromosome.

ACQUIRED HB H DISEASE Hb H disease is occasionally seen in individuals with a variety of hematological disorders within the myelodysplastic syndromes. These individuals are predominantly elderly males and hematologically normal before the onset of the disease. The α-globin gene cluster is intact, and the acquired α-thalassemia is likely to be caused by reduced α-gene transcription, but the nature of the specific defect remains completely unknown.

MANAGEMENT The thalassemias are a major health problem in many populations; because there is no definitive treatment, major efforts are concentrated on prevention.

Preventive programs in the past were based on education, population screening, heterozygote detection, and genetic counseling, but they were not entirely effective. Most countries now combine this approach with screening programs at antenatal clinics. When heterozygous mothers are detected, their partners are tested; if their partners are also carriers, the couples are offered prenatal diagnosis and selective termination of pregnancy.

Regular transfusion and iron chelation remain the cornerstones of treatment for severe β-thalassemia and are primarily palliative. Currently, the most useful chelating agent is desferrioxamine (Desferal). Unfortunately, Desferal is not only expensive, but it also has to be administered parenterally via an infusion pump. It is not surprising that noncompliance becomes a problem, particularly during adolescence. Considerable effort is directed towards the development of a safe and effective oral iron chelator. The most promising of these is deferiprone (L1); results of recent clinical trials suggest that although deferiprone is initially effective, there is a loss of efficacy in the long term. Another alternative that is currently being developed is a new formulation of depot desferrioxamine which can be given as a single bolus dose subcutaneously once a week. The development of hypersplenism as shown by the falling platelet and white-cell counts, and increasing blood transfusion requirements is an indication for splenectomy.

Bone marrow transplantation is the only form of treatment that can cure the severe forms of β-thalassemia, but it is dependent on the availability of an HLA-compatible related donor. Young well-chelated patients without evidence of liver disease are the best candidates, having 80% chance of cure.

With increasing knowledge of cell and molecular biology, a long-term aim would be the replacement of the defective β gene with its normal counterpart. Although, significant progress has been made in addressing the problems of gene transfer and expression, major biological problems remain. It has long been known that the severity of disease in β-thalassemia can be ameliorated by coinheritance of genetic factors that increase Hb F production. Thus, activation of the normal γ genes in patients with β-thalassemia represent a potentially important approach of therapy for this disorder. Several compounds, including 5-azacytidine, hydroxyurea, butyrate and butyrate analogs, have been tried, but, to date, none could achieve the therapeutic levels of Hb F needed without inducing significant toxic side effects.

STRUCTURAL HEMOGLOBIN VARIANTS

More than 600 structurally different hemoglobin variants have been described. Many of them are harmless and have been discovered in population surveys using electrophoretic analyses of human hemoglobin. Because only variants that alter the charge of the hemoglobin molecule are detectable in routine electrophoresis, this number is probably an underestimate. Diseases resulting from structural abnormalities of hemoglobin are shown in Table 20-2. In this section, only those abnormal hemoglobins of clinical importance are described.

SICKLE-CELL DISEASE

Background Sickle-cell anemia was first described by Herrick from Chicago in 1910, in a West Indian student. Peculiar elongated and sickle-shaped red blood cells were observed in the peripheral blood films and suggested the term sickle cell anemia. In 1949, Pauling et al. demonstrated that this sickling phenomenon was related to an abnormal hemoglobin present in all patients with sickle-cell anemia; this hemoglobin had an abnormally slow electrophoretic migration. Subsequently, in 1956, the sickle hemoglobin was chemically characterized by Ingram and was shown to differ from normal adult hemoglobin (Hb A, $\alpha_2\beta_2$) by the single substitution of glutamic acid to valine at position six in the β-

Table 20-3
The Major Sickling Disorders

	β Genotype	α Genotype	Hb Electrophoresis
Sickle-cell trait	β^A/β^S	$\alpha\alpha/\alpha\alpha$	Hb S approx 40%; Hb A 60%
Sickle-cell trait	β^A/β^S	$\alpha-/\alpha\alpha$ or $\alpha-/\alpha-$	Hb S 20–35%; Hb A 65–80
Sickle-cell Anemia	β^S/β^S	$\alpha\alpha/\alpha\alpha$	Hb S 80–100%; Hb F 0–20%
SC disease	β^S/β^C	$\alpha\alpha/\alpha\alpha$	Hb S 50%; Hb C 50%
SO-Arab disease	β^S/β^{OArab}	$\alpha\alpha/\alpha\alpha$	Hb S, HbO Arab[a]
SD-Punjab disease	$\beta^S/\beta^{D-Punjab}$	$\alpha\alpha/\alpha\alpha$	Hb S 50%; Hb D Punjab 50%[b]
Sβ^+ thal	β^S/β^{Th}	$\alpha\alpha/\alpha\alpha$	Hb S 50–80%; Hb F 0–20% Hb A 10–30%; Hb A$_2$ 3–6%
Sβ^o thal	β^S/β^{Th}	$\alpha\alpha/\alpha\alpha$	Hb S 75–100%; Hb F 0–20% Hb A$_2$ 3–6%
S HPFH	β^S/β^c	$\alpha\alpha/\alpha\alpha$	Hb S 70–80%; Hb F 20–30%; Hb A$_2$ decreased

[a]HbC, HbO-Arab, and HbE are not separated on routine alkaline electrophoresis.
[b]Quantitation based on agar gel electrophoresis.
[c]Deletion of β-globin cluster.

subunit. Since then, molecular characterization has shown that, apart from the homozygous state for the β^s gene, the syndrome of sickle-cell disease can also arise from the compound heterozygous state for HbS and other structural variants such as Hbs C and D and β-thalassemia (Table 20-3).

The sickling disorders occur predominantly in black African populations, but they are also prevalent throughout the Mediterranean, Middle East and parts of India. It appears that heterozygotes for the β^s gene are protected from the severe effects of *Plasmodium falciparum*, thus explaining the high gene frequencies in those malarious regions. The β^s gene in these diverse population groups is caused by the same molecular defect (β codon 6 GAG to GTG).

Recent investigations using β haplotypes constructed from the linked-groupings of DNA sequence polymorphisms in the β globin cluster have provided some insights into the origins and migration of the β^s gene. The β^s gene occurs on four different β haplotypes in Africa, known as the Senegal, Benin, Central African Republic (or Bantu), and the Cameroon types. In addition, it is associated with a different β haplotype in Saudi Arabian and Asian Indian sickle patients. The evidence suggests multiple independent origins of the β^s mutation, although gene conversion on regionally specific β haplotypes cannot be excluded.

Clinical Features Sickle-cell trait is a benign condition and generally does not cause any clinical disability. However, under certain extreme conditions such as severe pneumonia, flying in unpressurized aircraft, and exercise at high altitude, vaso-occlusive episodes can occur.

The clinical manifestations of sickle cell disease range from a chronic hemolytic anemia interspersed with painful crises to a completely asymptomatic state, detected only by chance on routine hematological examination. Most patients fall between these two extremes and are relatively asymptomatic, except for the occasional clinical crisis.

Sickle-cell anemia normally presents in infancy with attacks of painful dactylitis, the so-called "hand-foot syndrome," with swelling of the fingers and feet. At this stage, the infant is usually anemic with mild jaundice and the spleen palpable. Splenomegaly usually resolves owing to repeated infarctions of the spleen, the "autosplenectomy" manifested by typical postsplenectomy changes in the peripheral blood film. It is unusual to feel the spleen after the first decade of life. Typically, these children have a

chronic hemolytic anemia. The hemoglobin level varies between 6 and 8 g/dL, with a reticulocyte count of 10–20%, slight elevation of the serum bilirubin level, and increased urinary urobilinogen. Examination of the peripheral blood smear shows polychromasia and poikilocytosis, with a variable number of sickled erythrocytes.

The chronic hemolysis of sickle-cell anemia is punctuated by acute exacerbations of the illness termed sickling crises traditionally classified as vaso-occlusive, sequestration, aplastic, or hemolytic.

The most common are the vaso-occlusive crises, characterized by acute painful episodes caused by blockage of small vessels with sickled erythrocytes and tissue infarction. Commonly, the patient experiences a rapid onset of deep throbbing bone pain in the lumbosacral spine and limb bones, usually without physical findings but sometimes accompanied by local tenderness, warmth, and swelling. Marrow aspirated from areas of bone tenderness have revealed infarction of the marrow tissue. Occasionally, abdominal pain is the major symptom and can pose a difficult problem in differential diagnosis. The abdominal crisis is accompanied by distension and rigidity with loss of bowel sounds—findings typical of an acute surgical abdomen.

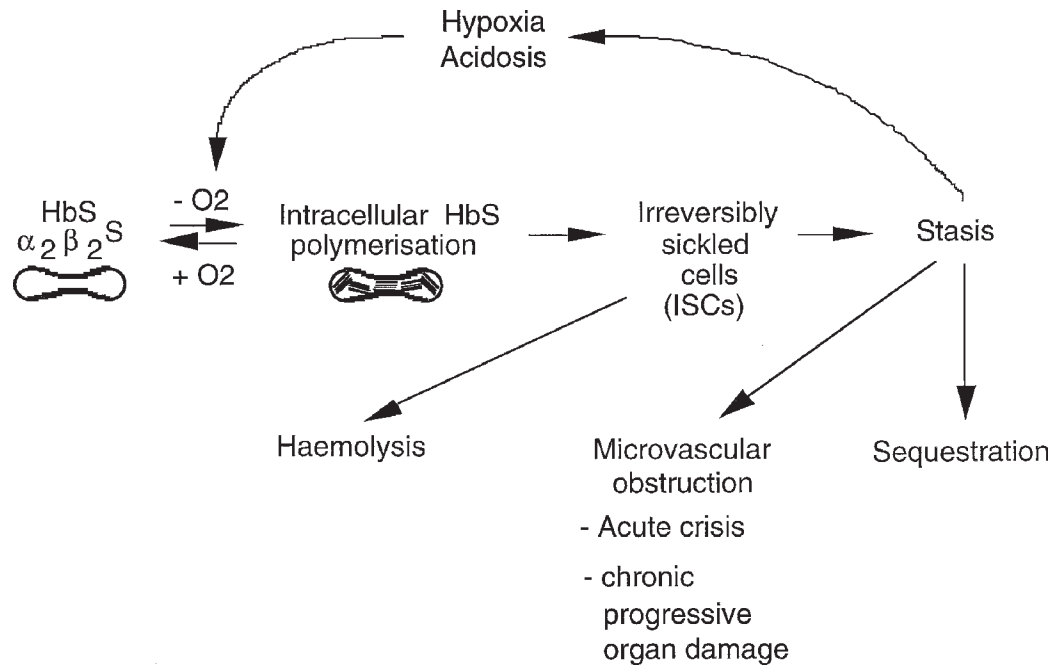
Vaso-occlusion in the lung, acute chest syndrome, is characterized by acute dyspnea and pleuritic pain and often accompanied by a significant fall in the hemocrit that may reflect sequestration of the sickled cells in the pulmonary vessels. The distinction from pulmonary infection is often very difficult, particularly as infection and infarction usually coexist. Acute chest syndrome is the most common cause of death after 2 years of age; the patient with acute chest syndrome is extremely vulnerable because hypoxia has a profound effect on sickling. Acute vaso-occlusion in the central nervous system (CNS) usually presents in childhood, either as fits, transient neurological symptoms resembling ischemia attacks, or with a fully developed stroke. Recurrent attacks are common, 70% of patients experience a recurrence within 3 years, and many are left with permanent motor and intellectual disabilities. Priapism is a distressing problem resulting from vaso-occlusion of the outflow vessels from the corpora cavernosa by sickled erythrocytes. This complication may present as multiple short-lived episodes ("stuttering" priapism) that may progress to "severe prolonged" priapism, lasting several days and leading to permanent sexual dysfunction.


Figure 20-4 Pathophysiology of sickle-cell disease. Initially, intracellular polymerization is reversible, but repeated cycles of polymerization-depolymerization in the circulating red cell results in membrane damage, and the cell becomes irreversibly sickled. This results in two main effects; first, sickled erythrocytes are mechanically fragile with a short intravascular life-span resulting in a chronic hemolytic anemia. Second, sickled erythrocytes are not so flexible, particularly in the microvasculature; they adhere abnormally to the vascular endothelium and form aggregates leading to vascular stasis, local hypoxia, and further sickling, complete vaso-occlusion and tissue infarction.

Temporary marrow aplasia can have a profound effect with reticulocytopenia and a very sudden drop in hematocrit. These aplastic crises appear to result from intercurrent infections, particularly owing to parvovirus B19 and often occur in epidemics, frequently involving more than one sibling in the same family.

Sequestration crises are the most serious of the acute crises and commonly involve the spleen in the first 2 years of life. Acute splenic sequestration is characterized by sudden rapid massive enlargement of the spleen that becomes engorged with sickled erythrocytes. As the crisis progresses, a large proportion of the circulating red cell mass may be trapped in the spleen, leading to profound anemia and death. Splenic sequestration shows a tendency to recur in the same individual. A similar type of sequestration may occur in the liver in adult life, causing a dramatic fall in the hematocrit.

Patients with sickle-cell disease are particularly susceptible to infection because of Streptococcus pneumonia, Salmonella, *Escherichia coli*, and Hemophilus influenza. Osteomyelitis is common and results from infection of bone infarcts. Pneumococcal pneumonia and overwhelming septicemia are particularly important causes of death in infancy and childhood because of hyposplenism.

Repeated vaso-occlusive events ultimately result in end-organ damage and almost any organ can be affected. The vertebral bodies and femoral heads are particularly prone to infarction. A vascular necrosis of the femoral head may lead to total disability, frequently requiring a total hip prosthesis. Virtually every patient with sickle-cell anemia has some form of renal impairment. Sickling of the erythrocytes is enhanced in the hypertonic, hypoxic, and acidotic environment of the renal medulla, leading to progressive infarction of the medullary papillae. There is progressive inability to concentrate urine, polyuria, nocturia, and enuresis, which is common in children. Eventually, the glomerular damage causes chronic renal failure, particularly in patients over 40 years of age. Because of chronic hemolysis, gallstones are very common and are seen in one-third of SS patients by 10 years of age. However, it is difficult to assess its clinical significance, because only a minority develop clear-cut cholecystitis. Recurrent chronic leg ulceration is common and can be a major handicap. The lesions normally occur just above the medial malleoli and seem to be more common in those patients with severe anemia. Proliferative retinopathy leading to progressive visual loss is an important ocular complication, although this is more common in Hb SC disease.

Diagnosis   Diagnosis is established by the combination of several tests: hemoglobin electrophoresis on cellulose acetate (pH 8.6) and agar (pH 6.2) and positive sickling or solubility tests. Diagnostic difficulties can often be resolved by family studies.

Genetic Basis and Molecular Pathophysiology of Disease
Sickle hemoglobin (Hb S, $\alpha_2\beta_2{}^S$) is produced by a single base substitution (G<u>A</u>G→G<u>T</u>G resulting in Glu to Val) in codon 6 of the β-subunit of hemoglobin. Fundamental to the sickle-cell pathophysiology is the insolubility of deoxy-Hb S in the red cells (Fig. 20-4). This leads to intracellular polymerization, which alters successively the cytoplasmic viscosity, the topography, and microrheology of the membranes, the ion fluxes, and the cell–cell interactions in their adherence to the vascular endothelium. The rate of polymerization varies exponentially with the intracellular hemoglobin concentration and composition (percentage of Hb S and non-S hemoglobin), as well as oxygen saturation. Oxygen binding to HbS has a dramatic effect on polymerization.

Sickling is influenced by a wide variety of inherited and acquired factors, both intracellular and extracellular. Abnormal endothelial adherence of the sickled erythrocytes is also influenced by cellular constituents such as von Willebrand factor, cytokines, and vascular tone.

Management   Currently, there is no specific treatment that is useful in sickle cell disease. Management consists of continuous general medical care and treatment of complications as they arise. In high-risk populations, neonatal screening programs should be established to identify babies with sickle-cell anemia as soon as possible. These babies should be given prophylactic penicillin, followed by polyvalent pneumococcal vaccine between the ages of 6 and 12 months.

Folate supplements should be given during pregnancy and in patients with severe anemia. Transfusions are not usually required except in special circumstances. Episodes of infection should be treated early and sudden exposure to cold and high altitudes avoided.

All but the mildest of crises should be managed in hospital. The patient should be examined for any underlying infection, kept warm and adequately hydrated, either orally or intravenously, and given appropriate antibiotics. Prompt and adequate relief of pain is of prime importance. In selected patients, exchange transfusion may be effective in preventing recurrent painful crises.

Most patients with sickle-cell anemia tolerate the relatively low levels of hemoglobin quite well, and blood transfusion is usually not required. However, a blood transfusion is indicated when there is a sharp fall in the hemoglobin because bone marrow failure (aplastic crisis) or increased hemolysis. A sequestration crisis requires very close surveillance, and urgent transfusion is usually indicated because of the prompt development of profound anemia. "Acute chest syndrome" and the "brain syndrome" should be treated by partial exchange transfusion to maintain a level of sickle hemoglobin of <30% of the total Hb.

Proliferative retinopathy may require photocoagulation or diathermy to reduce the risk of vitreous hemorrhage. Chronic leg ulcers may respond to conservative treatment, such as rest and elevation of the affected limb and zinc sulfate dressings. Occasionally, a regime of regular blood transfusions is helpful. Priapism occurs in approximately 40% of SS male patients. Preliminary data suggest that stilboesterol (5 mg daily) may be effective in preventing a major episode in patients with "stuttering" priapism. Initial management should be conservative and include sedation, adequate hydration and analgesia, and partial exchange transfusion to maintain the level of Hb S at <30%. Failure to respond after 24 hours requires immediate surgical intervention, rather than waiting in hope of resolution. Patients who develop a long-standing impotence may benefit from a penile prosthesis.

There is no special treatment during pregnancy except for close supervision and folate supplementation. Blood transfusions are not normally indicated, except for when there is a significant drop in hemoglobin level or recurrent crises. In such cases, a regular transfusion regime should be started to maintain the Hb S level below 30% throughout pregnancy and delivery. Although there is no evidence that oral contraceptives increase the risk of veno-occlusive episodes, it may be prudent to use a low estrogen preparation. Any surgical procedure should be undertaken with caution, and scrupulous care taken to avoid factors known to precipitate crisis, including hypoxia, dehydration, cold, acidosis, and circulatory stasis. Major surgical procedures may be best carried out after exchange transfusions.

Prenatal Diagnosis   Despite the advances in prenatal diagnosis, there has been little uptake of these services with little impact on the prevention of SS disease. The situation may be a reflection of the extreme clinical variability of disease and ineffective genetic counseling.

Anti-Sickling Therapy   Currently, treatment to prevent sickling follows three approaches; chemical inhibition of Hb S polymerization itself, reduction of mean cell hemoglobin concentration (MCHC), and pharmacological induction of fetal hemoglobin.

Numerous chemical antisickling agents have been promoted, but none can be regarded as safe and effective. The rationale of reducing MCHC by inducing hyponatremia thereby causing an osmotic swelling of red cells is sound, but it is too cumbersome and risky. Induction of Hb F as a form of therapy was initially based on clinical and epidemiological observations that showed that even slight elevations of fetal Hb have an ameliorating effect on the clinical severity. These observations were subsequently supported by biophysical studies. An increase in intracellular Hb F effectively reduces the concentration of Hb S and mixed hybrids of Hb S and Hb F ($\alpha_2\gamma\beta^s$) do not form polymers. Pharmacological agents used include 5-azacytidine, a potent inhibitor of DNA methylation, arabinosylcytosine (Ara-C), hydroxyurea, erythropoietin, and the butyrate analogs. Hydroxyurea is currently the agent of choice. It is relatively nontoxic, its myelosuppressive effects are reversible, and it is not known to induce secondary malignancies. A recent trial in the United States suggests that SS patients given daily hydroxyurea increase their Hb F levels and have fewer crises. Hydroxyurea has also been shown to be highly effective in a group of Greek sickle/β-thalassemia patients.

Bone Marrow Transplant   Bone marrow transplant may have a role in certain cases of sickle-cell disease. Until more is known about the natural history of the disease and the ability to predict the disease severity, bone marrow transplant as a form of curative treatment for all cases is not recommended.

OTHER SICKLING DISORDERS   These include mainly the compound heterozygous states for HbS, together with Hbs C, O-Arab, and D-Punjab, as well as the inheritance of the β^s gene with the different forms of thalassemia (Table 20-3).

Sickle/β-thalassemia is the most common sickling disorder in individuals of Mediterranean origin. The severity of disease ranges from a completely asymptomatic state to one similar to that seen in sickle-cell anemia. Much of this heterogeneity depends on the type of β-thalassemia mutation and the amount of Hb A produced. Because the majority of the β-thalassemia alleles in Africans causes a minimal deficit in β-chain production, sickle/β-thalassemia in Africans is generally milder than in the Mediterranean populations. The presence of β-thalassemia is indicated by the presence of hypochromic microcytic red cells, more than 50% of Hb S on electrophoresis and an elevated level of Hb A_2. Family studies are often crucial in distinguishing between the two disorders. Globin chain biosynthetic studies are also useful; in S/β-thalassemia, the β^S/α ratio is 0.5, whereas in SS disease, it is close to one.

OTHER HEMOGLOBIN VARIANTS   The other hemoglobin variants that are encountered commonly are Hbs C, E, and D (Table 20-4). Hb C is the second most common variant among individuals of African ancestry. Hb C is less soluble than Hb A and tends to crystallize within the red cells leading to their reduced deformability. The important interactions of Hb C are with Hb S (to produce Hb SC disease) and β-thalassemia. Individuals with Hb C/β°-thalassemia have a mild to moderate hemolytic anemia.

Hb E (β26 Glu—Lys) is the second most common hemoglobin variant in the world, occurring in a region extending from

Table 20-4
Common Hemoglobin Variants (Other than HbS)

Variant	Phenotype	Genotype	Diagnosis
HbC ($\alpha2\beta2^{6\ Glu\rightarrow Lys}$)[a]	Trait (asymptomatic) HbC Disease (mild to moderate hemolytic anemia)	β^A/β^C β^C/β^C	Hbs A, C, target cells, Hb C 100% target cells 100%
HbE ($\alpha2\beta2^{26\ Glu\rightarrow Lys}$)[a]	Trait (asymptomatic) HbE disease (asymptomatic mild anemia)	β^A/β^E β^E/β^E	Very mild hypochromic microcytosis, Hbs A, and E Hypochromic microcytosis Hb E 100%
HbD-Punjab[b] ($\alpha2\beta2^{121\ Glu\rightarrow Gln}$)	Trait, asymptomatic HbD disease (asymptomatic, very mild anemia)	$\beta^A/\beta^{D\text{-Punjab}}$ β^D/β^D	Hbs A and D Hb D approx 100%

[a]Hbs C and E are not separated from Hb A_2 on routine alkaline electrophoresis.
[b]HbD[Punjab] has the same electrophoretic mobility as HbS at alkaline pH.

Bangladesh through to China, including Southeast Asia. Gene frequencies of 50–70% have been recorded in parts of Thailand, Laos, and Kampuchea. The pathophysiology of Hb E is thought to result from a combination of inefficient synthesis of Hb E owing to activation of a cryptic site in exon 1 of the β-globin gene and reduced stability of Hb E itself. The overall reduction in splicing is the molecular basis for the mild β^+-thalassemia phenotype of Hb E. The importance of Hb E lies in the interaction with β-thalassemia (see Hb E/β-thalassemia).

THE UNSTABLE HEMOGLOBIN DISORDERS Structural changes in the globin subunits can lead to instability of the hemoglobin molecule, causing it to precipitate intracellularly, forming Heinz bodies and a chronic hemolytic anemia. This group of unstable hemoglobin disorders are generally referred to congenital Heinz body hemolytic anemia (CHBA); the true incidence of CHBA is not known. The majority follows an autosomal dominant pattern of inheritance; affected individuals are almost exclusively heterozygotes. In many families, only the proband is affected, suggesting that the mutation has arisen by a *de novo* mutation. Instability of the hemoglobin can be demonstrated by the presence of flocculent precipitates on heating a dilute hemoglobin solution at 50°C for 15 min or by the addition of isopropanol.

Most patients with CHBA do not require treatment. General supportive measures include folic acid supplements, prompt treatment of infection, and reduction of fever. Oxidant drugs should be avoided. Transfusions are indicated only rarely, such as during an aplastic crisis.

HEMOGLOBIN VARIANTS WITH ABNORMAL OXYGEN BINDING The hemoglobin tetramer exists in equilibrium between two quaternary conformations: R and T. When fully deoxygenated, hemoglobin assumes the "T" or "tense" state, in which it has a relatively low affinity for oxygen and relatively high affinity for allosteric effectors such as Bohr protons and 2,3-DPG. On the other hand, oxyhemoglobin exists in the "R" or "relaxed" state, in which it has a high affinity for oxygen and a low affinity for effectors. The transition between these two conformations requires "heme–heme interaction" which involves a series of structural changes. Thus, mutations that result in a structural alteration that affects the equilibrium between the R and T states would have a marked effect on hemoglobin binding of oxygen. Both high and low oxygen affinity variants have been described.

Individuals with high oxygen affinity hemoglobin variants have an increased red cell mass, as shown by the unusually high hemoglobin level or hematocrit. Diagnosis is made by excluding other causes for erythrocytosis and by demonstrating a left-shifted oxygen dissociation curve with a reduced p50 value and a normal 2,3-diphosphoglycerate (2,3'-DPG) value. High-affinity variants follow an autosomal dominant inheritance pattern; all affected individuals are heterozygotes. A positive family history is helpful, but occasionally, the variants rise from *de novo* mutations.

Far fewer hemoglobin variants with low oxygen affinity have been described, but they should always be considered in any patient with unexplained congenital cyanosis—the differential diagnosis being methemoglobinemia.

HEMOGLOBINS M A group of seven hemoglobin variants known as Hbs M is characterized by the presence of ferric atoms in either α or β chains, owing to amino acid substitutions in the heme pocket. The most common substitutions are tyrosine for the proximal (F8) or the distal (E7) histidine in either the β or α chain. As a result of these substitutions, these Hbs M are resistant to the reduction by methemoglobin reductase. These variants do not combine fully with oxygen.

The predominant clinical feature associated with Hbs M is a change in the coloration of skin and mucous membranes that can vary from brownish to slate gray. Cyanosis is a result of an excess of deoxyhemoglobin. Hbs M have a dominant form of inheritance; affected individuals are heterozygous and present early in life with cyanosis. Furthermore, if the cyanosis is present from birth, it is normally because of an α-chain variant, whereas β-chain Hb M produces cyanosis after the first few months of life, when adult hemoglobin synthesis becomes established.

The most reliable diagnostic test is based on examination of the hemolysate by recording spectrophotometry. The underlying molecular lesion is identified by DNA analysis of the globin genes.

THE THALASSEMIC HEMOGLOBINOPATHIES

This group of hemoglobin disorders includes structural hemoglobin mutants, presenting with a clinical phenotype that ranges from the mild forms of heterozygous thalassemia to that resembling thalassemia intermedia. Despite the extensive clinical heterogeneity, these patients have in common a typical hematological phenotype, including the thalassemic red cell morphology with hypochromic microcytic anemia and basophilic stippling; in some cases, chronic severe hemolytic anemia with splenomegaly is a feature. The molecular abnormalities are remarkably heterogeneous and include single amino acid mutations, amino acid dele-

Table 20-5
Molecular Abnormalities Observed
in Thalassemic Hemoglobinopathies

Unstable variants	e.g., Hb Suan Dok ($\alpha 2^{109\ Leu \rightarrow Arg}$)
Hyperunstable variants	e.g., Hb Quong Sze ($\alpha 2^{125\ Leu—Pro}$)
	Hb Showa Yakushiji ($\beta^{110\ Leu \rightarrow Pro}$)
Variants that cause abnormal splicing	e.g., Hb E ($\beta 26 Glu \rightarrow Lys$)
	Hb Knossos ($\beta^{27\ Ala \rightarrow Ser}$)
Variants with mutations in the termination codon	e.g., Hb Constant Spring ($\alpha 2^{142\ Term \rightarrow Gln}$)[a]
δ/β fusion globin subunits	e.g., Hb Lepore

[a]Hb Constant Spring is a particularly common form of nondeletion α-thalassemia in Thailand.

tions, elongated or truncated globin chains, and fusion globins (Table 20-5). In contrast to β-thalassemia, thalassemic hemoglobinopathies are often inherited as autosomal dominants.

21 Disorders of the Red Cell Membrane

JEAN DELAUNAY

BACKGROUND

The red cell membrane is composed of a lipid bilayer, studded with transmembrane proteins, and the membrane skeleton, also termed the erythrocyte skeleton. The latter is a bidimensional network that laminates the inner surface of the bilayer. Skeleton proteins are connected to transmembrane proteins through anchoring proteins (Fig. 21-1). The main features of the proteins of interest and their genes are enumerated in Table 21-1. A number of hereditary hemolytic anemias, usually associated with red cell shape abnormalities, stem from mutations affecting a variety of genes that encode membrane, skeletal, or anchoring proteins. We will focus on hereditary spherocytosis (HS), hereditary elliptocytosis (HE), and its aggravated form, hereditary pyropoikilocytosis (HPP).

CLINICAL FEATURES

The conditions mentioned above share in common icterus, anemia, and splenomegaly. Their severity can range from the absence of symptoms to death *in utero* (hydrops fetalis). Complications may occur, including gallstones and parvovirus infections (HS). HE/HPP is encountered in one out of 5000 Caucasian kindreds, and up to 1 out of 100 families in some black populations. The prevalence of HE/HPP coincides with some malarious regions. In comparison to HE/HPP, HS is relatively more common (with a frequency of approximately 1 in 2000 kindreds); it is uniformly distributed throughout all ethnic groups, although studies show that it seems to be absent among black people.

DIAGNOSIS

Routine laboratory data are based on the red cell indices, the levels of bilirubin, and haptoglobin, the reading of blood smears and the study of the osmotic fragility (its increase is a key sign in HS). More sophisticated techniques, such as ektacytometry or electron microscopy, may be used. Electrophoresis of membrane proteins on polyacrylamide gel in the presence of SDS (SDS-PAGE) (Fig. 21-2) and, if necessary, spectrin partial digests, often provides clues to the primarily altered proteins. Because the genes encoding these proteins have been cloned and sequenced and polymorphic sequences, including variable number of dinucleotide repeats (VNDRs) and variable number of tandem repeats (VNTRs) identified, it is possible to track these genes by linkage to these polymorphic sites using polymerase chain reaction (PCR). For further analysis, exons or portions of cDNA are PCR-amplified in

view of finding single strand conformational polymorphisms (SSCPs). Polymorphic fragments are then cloned and submitted to nucleotide sequencing.

GENETIC BASIS

HEREDITARY SPHEROCYTOSIS   Based on genomic lesions, it is possible to divide HS into 6 subsets.

HS Associated with ANK1 Gene Mutations   In 75% of the HS Caucasian kindreds, the disease stems from a mutation in the ANK1 gene, encoding erythroid ankyrin. The ankyrin gene contains 42 exons that are distributed over about 160 kb. Dominantly inherited HS cases are often owing to nonsense or frameshift mutations (heterozygous state). Upon SDS-PAGE, the lacking haploid set is mainly manifested by a reduction of ankyrin isoform "band 2.1." An elevated reticulocyte count is likely to mask this decrease because the reticulocyte part of band 2.1 has not yet been proteolyzed into components of lower molecular weights, a process applying to normal and pathological red cells (Fig. 21-2A). Mutations indifferently involve the three domains of ankyrin: domain "89 kDa" (carrying the binding site for band 3), domain "63 kDa" (binding site for β-spectrin), and domain "55 kDa" (regulatory domain). The reduction of ankyrin is accompanied by a nearly constant reduction in protein 4.2 although no direct contact between ankyrin and protein 4.2 has been demonstrated so far, and a less constant decrease of spectrin (Fig. 21-2A). When occurring near the 3' end of ANK1 gene, a truncated ankyrin molecule may be generated (Fig. 21-2B). Recessively transmitted HS cases imply the occurrence of two mutations *in trans* to one another (homozygous or compound heterozygous states). Ankyrin (band 2.1) is also reduced, but, again, a high reticulocyte count may mask this decrease. Only in a very few instances have the two changes been elucidated unambiguously, and some described changes possibly represent functionally neutral polymorphisms.

HS Associated with EPB3 Gene Mutations and Band 3 Deficiency   In 15–20% of HS families, the condition stems from mutations (heterozygous state), affecting the EPB3 gene that encodes band 3—that is, the erythroid anion exchanger 1 (AE1). Nonsense or frameshift mutations may occur in the cytoplasmic domain (positions 1–403), or the transmembrane (TM) domain of the molecule (positions 404–881) comprising 14 membrane-spanning segments. They result in the absence of one haploid set of band 3 (Fig. 21-3). SDS-PAGE shows a 20–40% decrease of band 3 and, in a secondary fashion, of protein 4.2, which binds to the cytoplasmic domain of band 3 (Figs. 21-2C and 21-3). The mode of inheritance is dominant; blood smears disclose occasional
Figure 21-1 Section of the erythrocyte membrane and skeleton. Only relevant proteins and some other major proteins are shown. Band 3, anion exchanger; GPC and GPD, glycophorins C and D, respectively; horizontal interactions, spectrin αβ dimers self-associate head-to-head to form an $\alpha_2\beta_2$ heterotetramer—each of the extremities of the tetramer interacts with actin and protein 4.1 (junctional complex). Vertical interactions: β-spectrin interacts with ankyrin that, in turn, interacts with the cytoplasmic domain of band 3; protein 4.2 also interacts with the latter. Protein 4.1, p55 and GPC (GPD) form another vertical (ternary) complex.

"pincered" red cells, the shape of which evokes mushrooms. Single amino acid substitutions at highly conserved positions in membrane spanning segments result in an identical picture, presumably because they impede band 3 incorporation into the membrane. The only known homozygous case of mutations of this category was lethal *in utero* (Alloisio et al., unpublished results); however, no generalization can be made at this time. Red blood cells from mice with targeted disruption of the band 3 gene spontaneously shed membrane vesicles and tubules, leading to severe spherocytosis. However, the synthesis of spectrin and skeletal architecture were nearly normal, suggesting that band 3 does not regulate membrane skeleton assembly, but it is necessary for membrane stability.

HS Associated with EPB3 Gene Mutations and the Absence of Protein 4.2   Quite rarely, homozygous state mutations lying in the cytoplasmic domain of band 3 leave the amount of band 3 virtually unchanged but yield a total, or at least a substantial lack of protein 4.2; only Western blots may reveal traces of this protein and some lower compounds that could be degradation products (Figs. 21-2D and 21-3). The inheritance pattern is strictly recessive; the mutations are thought to disrupt the binding site of band 3 cytoplasmic domain for protein 4.2.

HS Associated with ELP42 Gene Mutations and the Absence of Protein 4.2   Also rarely, homozygous or compound heterozygous state mutations affecting the ELP42 gene, encoding protein 4.2, result in the complete—or nearly complete—absence of protein 4.2 (Fig. 21-2E). Again, these conditions are recessively transmitted. The picture is that of an atypical form of HS: spherocytes are rare, and the osmotic fragility is little increased. Apart from one case—allele ELP42 Lisboa, carrying a frameshift mutation—single amino acid substitutions come into play and must disrupt the binding site for the cytoplasmic domain of band 3 or disturb the overall stability of protein 4.2.

HS Associated with SPTB Gene Mutations   Several mutations responsible for dominantly transmitted HS have been found in the SPTB gene, encoding erythroid β-spectrin. Usually, nonsense or frameshift mutations, scattered over the β chain except for

homologous segment β17 (in this case, the mutations would engender HE or HPP; *see below*, abolish the synthesis of one haploid set of β chain. Because the β-chain synthesis, though in excess, is limiting with respect to that of α chain, the lack of one haploid set of β-spectrin causes a deficit in spectrin $\alpha_2\beta_2$ tetramer. One mutation that defines spectrin Kissimmee carries a simple amino acid substitution and alters the binding capacity of β-spectrin for protein 4.1 and F-actin.

HS Associated with SPTA1 Gene Mutations   So far, mutations responsible for recessively transmitted HS have been encountered in the SPTA1 gene, encoding erythroid α-spectrin. They are frameshift mutations and occur *in trans* to one another. Because of the large excess of spectrin α-chain synthesis, heterozygosity is nonexpressed.

HEREDITARY ELLIPTOCYTOSIS AND HEREDITARY PYROPOIKILOCYTOSIS   HS/HPP Associated with SPTA1 and SPTB Gene Mutations   Numerous mutations responsible for HE/HPP have been found in SPTA1 and SPTP genes. Both spectrin chains are comprised of approximately 106 amino acid homologous or repeating segments: 22 in the α chain and 17 in the β chain. Each homologous segment contains three α-helical stretches—h3, h1, and h2—and is folded into conformational units with a shift of 26 amino acids. As a result, a conformational unit harbors helices 1 and 2 of a homologous segment and helix 3 of the following segment (Fig. 21-4). The HE/HPP mutations stand in or near α-spectrin, the self-association region—that is, the region at which two spectrin αβ dimers interact head-to-head through complementary binding sites to form an $\alpha_2\beta_2$ tetramer (Fig. 21-4). As a consequence, the self-association process is weakened. Most of the α mutations lie in helices 3 of homologous segment α1–α8. No mutations have been found in segment 6; however, it must be a matter of chance. Mutations in helices 2 are rare. The insertion of a leucine at position 154—helix 3, homologous segment α2— is endemic in West Central Africa. It followed population migrations to the Indies and North America and to both banks of the Mediterranean Basin. Mutation Saint Louis—helix 2, segment α2)—which is less frequent, may have had a similar history.

Many mutations of the β17 homologous segment (helix 2) yield a truncation of the β chain in one way or another and disclose a dominant inheritance pattern (Fig. 21-2F). Others are single amino acid substitutions, a cluster of which exists in helix 1 of segment β17. Silent in the heterozygous state, they produce a severe phenotype in the homozygous state.

Allele α^LELY   A salient feature concerns alleles of the SPTA1 gene (α^HE alleles). For a given mutation, some members disclose a mild HE phenotype or are symptomless, whereas other members are severely affected, often exhibiting HPP. It has long been assumed that this situation reflected the presence of a low expression allele *in trans* to the α^HE allele. That allele had to be widespread, for it manifested itself in nearly all families already carrying an α^HE allele. The key to the problem was the discovery of allele α^LELY (LELY: Low Expression LYon). Allele α^LELY appears to be uniformly distributed at a polymorphic frequency of 0.2–0.3 of all α alleles among all ethnic groups (Caucasians, blacks, Japanese, Chinese). It is invariably characterized by mutations at position 1817 (exon 40), at positions - 12 of introns 45 and 46 (however, the latter mutation is nonspecific). The mutation in intron 45 is associated with a partial skipping (50%) of exon 46 (18 nt) on α-spectrin transcript processing. Lack of exon 46 is thought to disrupt the binding site of the α-chain site (C-

Table 21-1
Main Features of the Considered Proteins and Their Genes

	Amino acids (actual mol wt)	Monomers per cell	Gene symbol and chromosomal location	Gene size (kb) and exon number	Size of mRNA, kb	Disease	Inheritance pattern[b] (autosomal)
Spectrin α chain	2429 (281)	242,000	SPTA 1; 1q22–q23	80; 52	8	HE	Dominant
						HS	Recessive
Spectrin β chain	2137 (246)	242,000	SPTB; 14q23–q24.2	> 100; 36	7.5	HE	Dominant or recessive
						HS	Dominant
Ankyrin	1880 (206)	124,000	ANK1; 8p11.2	> 120; 42	6.8–7.2	HS	Dominant or recessive
Band 3	911 (102)	1,200,000	EPB3; 17q12–q21	17; 20	4.7	HS	Dominant or recessive
Protein 4.1	588 (66)	~ 200,000	EL1; 1p33–p34.2	> 250; > 23	5.6	HE	Dominant
Protein 4.2	691 (77)	~ 200,000	ELP42; 15q15–q21	20; 13	2.4	HS[a]	Recessive

[a]Atypical form of HS.
[b]The inheritance pattern depends on complex factors in addition to the mere nature of the mutations.
Figure 21-2 A series of changes in the SDS-PAGE profile in HS and HE/HPP. (▶), primary decrease or absence; (▷), secondary decrease; (*), duplication (+ decrease). A and B: HS associated with ANK1 gene mutations. A: one allele (heterozygosity) carries an early frameshift mutation. It abolishes one haploid set of ankyrin and leads to the secondary reduction of spectrin and protein 4.2 (Morlé et al., unpublished results). B: one allele (heterozygosity) carries a nonsense mutation near the 3' end of the gene. It yields a truncated ankyrin molecule (Hayette et al., unpublished results). C and D: HS associated with EPB3 gene mutations. C: compound heterozygosity for two abnormal alleles generates a sharp reduction of band 3 and, secondarily, a noticeable decrease of protein 4.2 (Alloisio et al., unpublished results). D: compound heterozygosity for two other abnormal alleles yields a total absence of protein 4.2; one allele is of the same type as in C (abolishing one haploid set of band 3) and the other allele disrupts the binding site of band 3 cytoplasmic domain for protein 4.2 (Kanzaki et al., unpublished results). E: HS associated with a frameshift mutation in the ELP42 gene (homozygosity). F: HE associated with an exon skipping near the 3' end of SPTB transcript (heterozygosity), yielding a truncated β-spectrin molecule. G: HE associated with the abolition of the downstream initiation codon (homozygosity) of the EL1 gene. (Electrophoreses done by Ms. M.-A. Schreiner.)

terminal region) for a complementary site in the β chain (N-terminal region). As a consequence, the nucleation process, i.e., the onset of dimerization, becomes impossible, and all exon 46-lacking spectrin α chains are discarded. However, this remains innocuous, even in the homozygous state, because a large excess of α chains is normally synthesized. Half of the α^{LELY} products—those bearing exon 46—are sufficient to meet the needs of the erythrocyte. On the contrary, in the $\alpha^{HE}/\alpha^{LELY}$ situation, there is a twofold excess of α^{HE} chains compared to α^{LELY} chain having retained exon 46. An increased proportion of α^{HE}β dimers are assembled. Subsequently, those dimers prove unable to self-associate, hence the aggravation of the disease. Of course, some α^{HE} alleles, coined $\alpha^{HE-LELY}$ alleles, carry the LELY mutations in *cis* of a HE mutation. As one would anticipate, the expression of HE is attenuated.

4.1(-) Hereditary Elliptocytosis Among Caucasians, approximately 30% of HE results from defects involving protein 4.1, usually in the heterozygous state and rarely in the homozygous state (Fig. 21-2G). Protein 4.1 is a key element of the junctional complex (Fig. 21-1). Heterozygous 4.1(–) HE is symptomless and discloses numerous, smooth and well-elongated elliptocytes. Homozygous 4.1(–)HE achieves a picture of HPP. Owing to the size of EL1 gene (>250 kb) and of its introns, and also because of the extraordinary complexity of the alternative splicing characterizing protein 4.1 transcript, only two mutations have been elucidated at the gene level so far. One of them cancels the downstream initiation codon for translation—the only initiation codon used in the erythroid cells—whereas the other disrupts the binding site of protein 4.1 for spectrin and actin.
Figure 21-3 Location of mutations in band 3 (cDNA level) (recorded 8/31/95). The cytoplasmic domain (positions 1 to 403) and the membrane domain (404–881) with its transmembrane segments (circled numbers) are individualized. ●, single base mutations; ○, polymorphisms; x, frameshift or nonsense mutations; △, mutations abolishing the binding of protein 4.2.

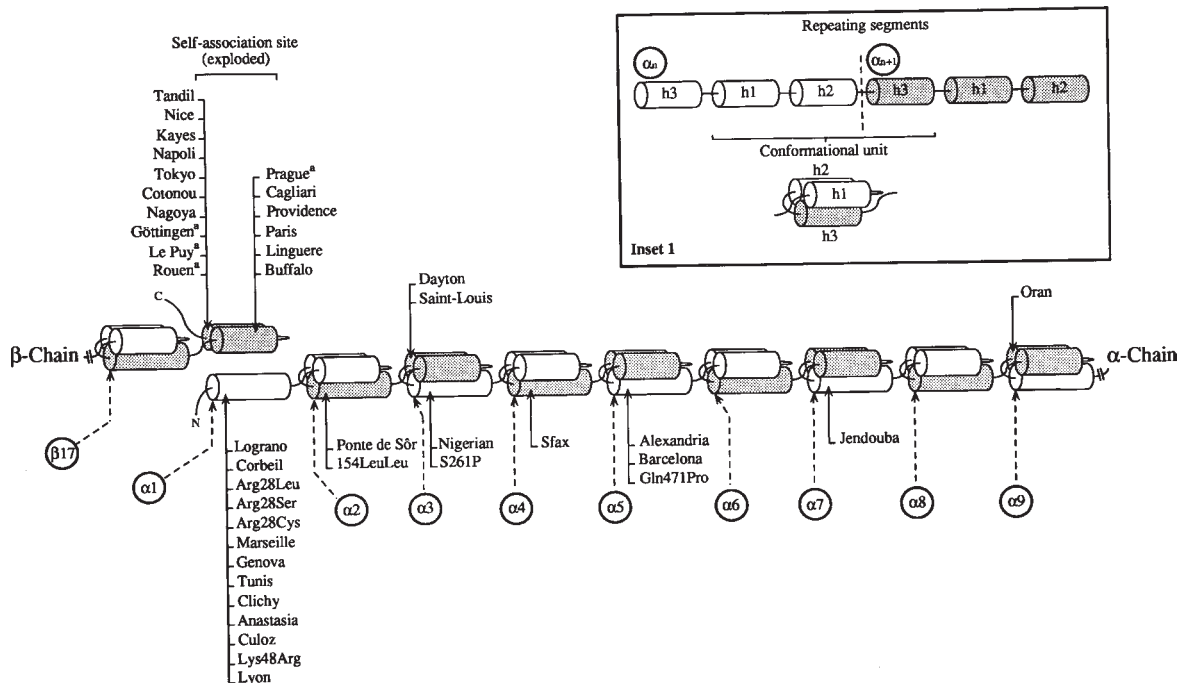

Figure 21-4 Clustering of mutations responsible for HE/HPP at/or in the vicinity of the self-association region (recorded 8/31/95). Circled numbers designate the homologous segments at the point where they begin. [a]: intronic mutations that yield skipping of SPTB gene exons 30 or 31. Inset: correspondence between the homologous (or repeating) segments (linear) and the conformation units (three-dimensional). Each conformational unit contains one helix with a color, h3, belonging to a homologous segment, and two white helices, h1 and h2, belonging to the preceding homologous segment. (Courtesy of Dr. P. Maillet.)

In homozygous 4.1(–)HE, the total absence of protein 4.1 causes a sharp reduction of transmembrane glycophorin C and the total absence of a third protein, called p55 (not shown). This reflects a triangular interaction between these proteins (a vertical interaction; see Fig. 21-1). On the other hand, the Leach phenotype, a rare blood group resulting from the primary absence of glycophorin C, is associated with elliptocytosis. Protein 4.1 is slightly diminished (hence the elliptocytosis) and p55 is, again, entirely missing.

MOLECULAR PATHOPHYSIOLOGY

Few studies have tried to bridge the abnormalities at the molecular and cellular levels. In a simple fashion, spherocytes stem from discocytes by "spleen conditioning," i.e., the removal of microvesicles (50–80 nm) that yield a reduction of the membrane surface area. It is intriguing that mutations in at least five distinct proteins result in the same cellular phenotype. Elliptocytes do not recover the discocyte shape following shear stress in large vessels. This lack of elastic deformability generates increased mechanical fragility. In severe cases, the cells shatter against the walls of major arteries, achieving pyropoikilocytosis. Again, it is remarkable that mutations in spectrin and protein 4.1 have a similar cellular phenotype.

TREATMENT

Molecular genetics has allowed reclassification HS and HE/HPP and provide a rational basis of diagnosis. Treatment is based on occasional or regular blood transfusions. Splenectomy is beneficial; it is nearly curative in HS. Identification of the causative mutation at the DNA level allows prenatal diagnosis when a mutation, that is severe or lethal in the homozygous state, occurs in consanguineous couples (Alloisio et al., unpublished data). The efficiency of prenatal and postnatal managements do not justify gene therapy.

FUTURE PROSPECTS

Beside the practical interest in describing mutations, many of the latter offer precious natural models. They allow far-reaching studies on gene expression and structure–function relationships within proteins.

22 Red Cell Enzymopathies

Lucio Luzzatto and Rosario Notaro

INTRODUCTION

The mature red cell is the product of a developmental pathway that brings the phenomenon of differentiation to an extreme. An orderly sequence of events produces synchronous changes, whereby the gradual accumulation of a huge amount of hemoglobin in the cytoplasm (to a final level of 340 g/L, i.e., about 5 mM) goes hand in hand with the gradual loss of cellular organelles and of biosynthetic abilities. In the end, the erythroid cell undergoes a process that has features of apoptosis, including nuclear pycnosis and actual loss of the nucleus. However, the final result is more altruistic than suicidal; the cytoplasmic body, instead of disintegrating, is now able to provide oxygen to all cells in the human organism for some remaining 120 days of the red cell life-span.

This unique behavior has important consequences, not only with respect to the physiology of red cells (which cannot be covered here), but also with respect to their pathophysiology. Specifically, the chemical machinery of intermediary metabolism is drastically curtailed in mature red cells (Fig. 22-1); for instance, because cytochrome-mediated oxidative phosphorylation has been lost with the loss of mitochondria, there is no backup to anaerobic glycolysis for the production of adenosine triphosphate (ATP). Also, because the capacity of making protein has been lost with the loss of ribosomes, the existing metabolic machinery is always at risk: if any component deteriorates, it cannot be replaced, as in most other cells. Another consequence of the relative simplicity of red cells is that they have a very limited range of ways to manifest distress under conditions of hardship: in essence, any sort of metabolic failure will eventually lead either to membrane damage or to failure of the cation pump. In the former, the cell will suffer direct mechanical breakdown; in the latter, it will undergo osmotic lysis. In either case, the life-span of the red cell is reduced, which is the definition of a hemolytic disorder. If the rate of red cell destruction exceeds the capacity of the bone marrow to produce more red cells, the hemolytic disorder will manifest as hemolytic anemia.

Inherited abnormalities of red cell enzymes (enzymopathies for short) are a distinct set of genetic disorders. Most of the enzymes involved are housekeeping enzymes that, by definition, are present in all cells. Therefore, it is of interest first of all to consider the possible consequences of the deficiency of any of them. On one hand, we might expect that a severe reduction in the activity of any housekeeping enzyme would have generalized clinical manifestations, because in principle, all organs would be affected. On the other hand, in many cells there might be "metabolic redundancy," whereby other enzymes provide the missing function in a surrogate capacity; or, if the deficiency is not total, an increase in the synthesis of the enzyme involved might provide the minimum of activity compatible with cell viability. Because both of these compensatory mechanisms are not available to red cells, they would be more severely affected than other cells. In practice, we observe a clinical picture somewhere within this spectrum for each individual enzymopathy. In the majority of cases the main problem is hemolytic anemia; in some cases, hemolytic anemia is associated with other clinical manifestations; and in others the latter—particularly neurological damage—may dominate the clinical picture.

In this chapter, we shall concentrate on those enzymopathies affecting red cell metabolism of which the molecular basis has been elucidated. We will not cover conditions in which an enzyme abnormality is expressed also in red cells, but the main clinical manifestations are elsewhere (e.g., the porphyrias, acatalasemia, galactosemia, the Lesch-Nyhan syndrome). For the sake of brevity, some enzymopathies will be discussed as a group, with details of individual enzymes given in additional notes and within the illustrative material.

ENZYMOPATHIES OF GLYCOLYSIS

PREVALENCE   All of these defects are rare to very rare (Table 22-1, pp. 200–201).

CLINICAL FEATURES   All of these defects cause hemolytic anemia with varying degrees of severity (the detailed description of the clinical features and of the pathophysiology of hemolytic anemia is not within the scope of this book). If the anemia is severe, it will usually present very early in life, sometimes with severe neonatal jaundice that may require exchange transfusion; if the anemia is less severe, it may present later in life, or it may even remain asymptomatic and be detected incidentally when a blood count is done for unrelated reasons. The spleen is often enlarged. When other systemic manifestations occur, they involve either the neuromuscular system, or the central nervous system (CNS)—sometimes entailing severe mental retardation—or both.

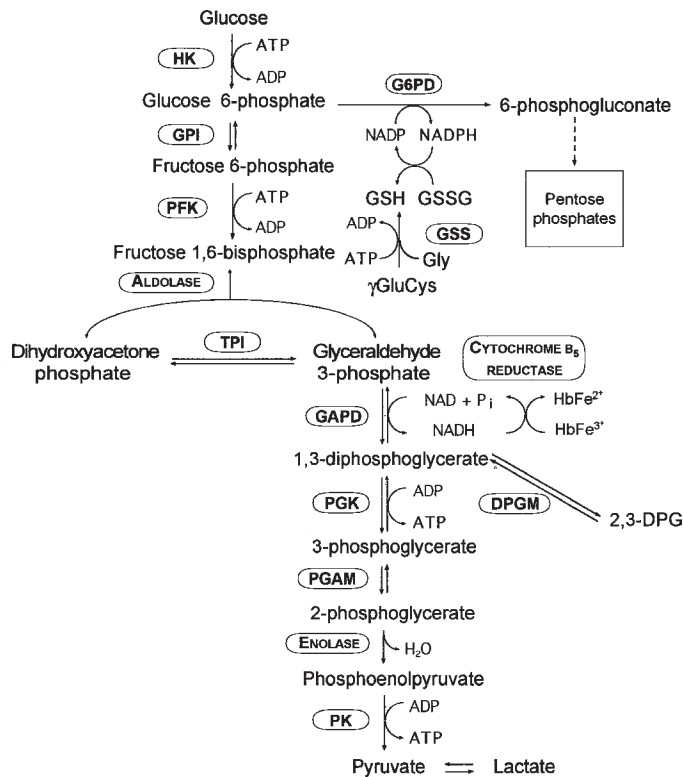
DIAGNOSIS   The diagnosis of hemolytic anemia is usually not difficult, based on the triad of normo-macrocytic anemia, reticulocytosis, and hyperbilirubinemia. Enzymopathies should be considered in the differential diagnosis of any chronic Coombs-negative hemolytic anemia. Once hemoglobinopathies have been ruled out, the field is narrowed down to membrane abnormalities and enzymopathies. Red cell morphology is usually conspicuously


Figure 22-1 Intermediary metabolism in red cells. The diagram shows the glycolytic pathway and related reactions (not the complete metabolic machinery of the red cells). Enzymes are enclosed in rounded boxes. Abbreviations are as in Table 1. Additional abbreviations: DPG, diphosphoglycerate; GSH, reduced Glutathione; GSSG, Glutathione; HbFe^{2+}, hemoglobin; HbFe^{3+}, methemoglobin; γGluCys, γ-Glutamylcysteine.

abnormal in membrane disorders, but conspicuously normal in glycolytic enzymopathies. A useful test is the so-called autohemolysis test, in which red cells are simply incubated at 37°C under defined conditions, and the percent lysis measured after 48 hours. With membrane abnormalities, an abnormal hemolysis takes place, but this can be limited or abolished by the addition of sufficient concentrations of glucose; with glycolytic enzyme abnormalities, this "glucose correction" is only partially or totally lacking. This test has been criticized because it is unspecific: however, in our hands, it can be used as a reliable screening for enzymopathies. If the test is abnormal, the final diagnosis must be done by assaying individual glycolytic enzymes by the appropriate spectrophotometric method. For the sake of economy, it makes sense to carry out these rather laborious tests in order of frequency of the various enzymopathies (i.e., first PK, then GPI, and so on; Table 22-1). If a particular molecular abnormality is already known in the family, of course one can test for that directly on the patient's DNA, bypassing the need for enzyme assays.

GENETIC BASIS   Because these conditions are all recessive, there are usually no affected members in the previous generations. However, inquiries for consanguinity should always be made, and there may be of course an affected sibling.

MOLECULAR PATHOPHYSIOLOGY   At the biochemical level, all glycolytic enzymopathies have something in common, because their main consequence is to reduce the capacity of the red cell to produce chemical energy in the form of ATP. As seen in

Table 22-1, the majority of mutations so far identified in the genes encoding glycolytic enzymes are of the missense type, causing single amino acid replacements. This is important, because in all these cases, the activity of the respective enzyme is reduced, but it is not completely lost. Thus, the residual activity can still support a decreased but nonzero flow through the glycolytic pathway: this explains how red cells survive in circulation, even though their life-span is reduced. As for the molecular basis for the reduction in enzyme activity, we must consider two basic mechanisms:

1. In the majority of cases, loss of activity is probably owing to a decreased stability of the protein. In such cases, we would predict that other cells might be much less affected than red cells, because the former can compensate for decreased stability through increased synthesis of the enzyme.
2. In some cases, the amino acid replacement may affect the active center of the enzyme. This, in turn, may affect either substrate binding (K_m) or the catalytic rate of the enzyme (k_{cat}), or both: in this case, other cells in which the rate of glycolysis is critical will be affected, as well as red cells.

MANAGEMENT   Currently, there is no specific treatment for these conditions. Patients with moderate anemia may require occasional blood transfusion when they experience exacerbations of the anemia because of increased rate of hemolysis, or because of decreased red cell production secondary to infection (the most extreme example being "aplastic crisis" from parvovirus infection). Very rarely, chronic anemia may be sufficiently severe to require regular blood transfusion treatment with associated iron chelation. In some patients, splenectomy has been beneficial. In severe cases, bone marrow transplantation would be a rational form of treatment for patients who have a suitable donor, provided there are no systemic manifestations other than hemolytic anemia, and provided it is carried out before there is organ damage (e.g., from iron overload).

ADDITIONAL NOTES ON INDIVIDUAL GLYCOLYTIC ENZYMOPATHIES

HEXOKINASE (HK)   Several isoenzymes of HK are known. The main isoenzyme in normal red cells is type 1. In the very rare cases of HK deficiency, this defect is only expressed in red cells, presumably because the other isoenzymes contribute sufficient HK activity in other cells. It is possible that even in red cells HK2 (normally present as a minor species) might help in damage limitation.

GLUCOSE 6-PHOSPHATE ISOMERASE (GPI)   Most mutations entail single amino acid replacements, compatible with some residual enzyme activity (Fig. 22-2, p. 202). The splicing defects near exon 16 and the stop codon mutation in exon 18 might still result in the production of some enzymatically active protein. The nonsense mutation in exon 4 might be lethal in the homozygous state, but it has been found, together with a missense mutation, in two brothers with HA who were genetic compounds for these GPI mutations.

PHOSPHOFRUCTOKINASE (PFK)   In many metabolic pathways, the first reaction is the one most exquisitely regulated (Fig. 22-3, p. 202). In the case of glycolysis in red cells it appears that PFK, the second kinase of the pathway, is more subject to regulation, particularly by ATP and adenosine monophosphate (AMP), which affect both k_{cat} and K_m^{F6P}. An interesting point of potential physiological significance is that this step is downstream of the pentose phosphate shunt; thus, the two pathways can be

regulated independently. Five isoenzymes encoded by two genes are present in red cells. In PFK deficiency, all the mutations have been in the M subunit (Table 22-1), which explains the basis for the myopathy (glycogenosis type VII). In all these cases, we presume that the contribution of the L_4 species of PFK will be unaffected, and hybrid tetramers may be partially active. This may explain why the HA associated with PFK deficiency is rather mild. Conversely, it is possible that L subunit mutations may exist, but they may not cause HA as long as the M subunit is normal.

ALDOLASE Aldolase A, present in red cells, is a different enzyme from that which, when deficient in liver, causes fructose intolerance. Very few families with this red cell enzymopathy have been reported, and in only two was the molecular defect identified. In one family it was a missense mutation, causing an amino acid replacement of glycine for aspartic acid at position 128, a change that was shown to cause marked instability of the enzyme. Two members of the family were homozygous for this mutation and had enzyme levels of about 5% of normal, showing convincingly that aldolase deficiency can cause HA.

TRIOSEPHOSPHATE ISOMERASE (TPI) This is a very rare but one of the most serious red cell enzymopathies, because HA is usually associated with severe involvement of the CNS (Fig. 22-4, p. 203). One might reasonably surmise that this is owing to the fact that a low level of TPI compromises some crucial metabolic step in the CNS; however, there is a single report in the literature of two brothers with TPI deficiency, one of whom died with severe mental retardation, whereas the other lives at the age of 22 with only hemolytic anemia. This intriguing observation would be consistent with the CNS manifestations requiring the coexistence of a mutation in some other unlinked gene. Another extraordinary finding has been that of the same missense mutations (105 Glu→Asp) in 17 unrelated families from distant parts of the world. In addition, this mutation is in strong linkage disequilibrium with several polymorphic sites.

DIPHOSPHOGLYCERATE MUTASE (DPGM) DPGM is the only enzyme in the table that is not housekeeping; on the contrary, it is probably erythroid-specific. It is important in controlling the level of DPG, which is a regulator of the hemoglobin–oxygen dissociation curve. With DPGM deficiency, the DPG level is reduced, with consequent decreased delivery of oxygen to tissues, functional hypoxia, and polycythemia.

PHOSPHOGLYCERATE KINASE (PGK) Like most other enzymes in the table, the X-linked gene encoding PGK is expressed in virtually all cells: a notable exception are sperm cells, in which a closely related autosomal PGK gene is expressed (Fig. 22-5, p. 203). Apart from HA, patients with PGK deficiency often have either CNS involvement, a myopathy, or both. Attempts have been made to correlate various combinations of clinical manifestations with the extent of enzyme instability produced in red cells and in muscle cells by individual mutations. However, the correlation does not always hold.

PYRUVATE KINASE (PK) PK deficiency is by far the most common glycolytic enzymopathy (Fig. 22-6, p. 204), and it is also that for which the largest number of mutant alleles has been reported (Table 22-1). In a recent survey of 30 patients (60 alleles), 19 different mutations were observed. A single mutant, 1529A (corresponding to 510 Arg→Gln in Fig. 22-6), accounted for 42% of the total. This mutation had been already found in several families, and it is in strong linkage disequilibrium with a polymorphic site elsewhere in the gene, consistent with a single ancient origin.

Although this might be an example of founder effect, it is also compatible with some selective advantage of this allele in heterozygotes, possibly related to a slightly increased DPG level in these subjects. Homozygotes are at a disadvantage because of HA, but this is often characteristically well-tolerated, as a markedly increased DPG favors oxygen supply to the tissues. One patient with PK deficiency is known to have successfully completed a marathon run (EC Gordon-Smith, personal communication). PK deficiency is also the only glycolytic enzymopathy for which a significant proportion of mutant alleles are of the "null" variety, by virtue of having nonsense or frameshift mutations. In most cases, residual activity can be provided by the other allele in genetic compounds. However, several patients have been identified who were homozygous for the frameshift mutation called Gipsy. In these patients, some residual activity may be contributed by the M isoenzyme, present at low abundance in red cells. A mouse model of PK deficiency has been described that exhibits splenomegaly and nonspherocytic hemolytic anemia. This strain may be useful as an experimental model of PK deficiency.

GLUCOSE 6-PHOSPHATE DEHYDROGENASE (G6PD) DEFICIENCY

EPIDEMIOLOGY G6PD deficiency is distributed worldwide. Areas of high prevalence are found in Africa, Southern Europe, the Middle East, South East Asia, and Oceania. In the Americas and in parts of Northern Europe, G6PD deficiency is also quite prevalent as a result of migrations that have taken place in relatively recent historical times. The overall geographic distribution of G6PD deficiency and its heterogeneity, together with clinical field studies and in vitro culture experiments, strongly support the view that this common genetic trait has been selected by *Plasmodium falciparum* malaria, by virtue of the fact that it confers a relative resistance against this highly lethal infection.

CLINICAL FEATURES Three types of clinical presentations are well characterized: acute hemolytic anemia, neonatal jaundice, and chronic nonspherocytic hemolytic anemia.

1. The vast majority of G6PD deficient people are asymptomatic most of the time, but they are at risk of developing acute hemolytic anemia (AHA), which may be triggered by drugs, infections, or fava beans. During a hemolytic attack, the hemoglobin may fall very little, or it may plummet to values as low as 40 g/L or less; however, even if severe, the anemia is usually self-limited and tends to resolve spontaneously. Depending on the proportion of red cells that have been destroyed (reflected in the severity of the anemia), the hemoglobin level may be back to normal in 3–6 weeks.

2. The risk of developing neonatal jaundice (NNJ) is much greater in G6PD deficient than in G6PD normal newborns. NNJ related to G6PD deficiency—unlike "classical" Rhesus-related NNJ—is very rarely present at birth; the clinical onset is usually between day 2 and day 3. The severity varies enormously from being subclinical, to overlapping with "physiological jaundice," to imposing the threat of kernicterus, if not treated. Prematurity, infection, and environmental factors (e.g., the use of naphthalene—camphor balls—used in baby bedding and clothing) are known aggravating factors.

Table 22-1
Synopsis of Red Cell Enzymopathies[a]

Enzyme	Isoenzyme[b] characteristic of red cells	Prevalence of enzyme deficiency	Main clinical features associated with enzyme deficiency[c]	Benefit from splenectomy[d]	Chromosomal localization	Number of exons
Hexokinase (HK)	1	Very rare	HA	Partial	10q22 (q11?)	18
Glucose 6-phosphate isomerase (GPI)		Rare	HA, NM, CNS	Partial	19q13.1	18
Phosphofructokinase (PFK)[h]	M	Very rare	HA, myopathy		1cen-q32	24
	L				21q22.3	22
Aldolase	A	Very rare	HA, myopathy		16q22–24	12
Triosephosphate isomerase (TPI)		Very rare	HA, CNS, NM,	None	12p13	7
Glyceraldehyde 3-phosphate dehydrogenase (GAPD)[k]		Very rare	HA		12p13.31–p13.1	9
Diphosphoglycerate mutase (DPGM)		Very rare	Polycythemia		7q31-q34	3
Phosphoglycerate kinase (PGK)	1	Very rare	HA, CNS, NM	Partial	Xq13	11
Monophosphoglycerate mutase (PGAM-B)	B				10q25.3	
Enolase[k]	1 (α)	Very rare	HA		1pter-p36.13	
Pyruvate kinase (PK)	R[m]	Rare	HA	Partial	1q21	12
Glucose 6-phosphate dehydrogenase (G6PD)	B	Common	HA	None	Xq28	13
Cytochrome-b_5 reductase		Rare	pseudocyanosis, CNS		22q13.31–qter	9
Adenylate kinase (AK)	1	Very rare	HA, CNS	Partial	9q34.1	7
γ-Glutamylcysteine synthetase (GLCLC)[k,q]		Very rare	HA		6p12	
Glutathione synthetase (GSS)		Very rare	HA, CNS		20q11.2	12
Glutathione peroxidase (GSH-Px)		Very rare[r]	?[r]		3q11–q12	

Enzyme	Number of amino acids[e]	5'UTR[j]	Missense	Nonsense	Number of known mutations[f] — Deletion–insertion In frame	Deletion–insertion With frameshift	Affecting splicing	Total
Hexokinase (HK)	917		1		3–0			4[g]
Glucose 6-phosphate isomerase (GPI)	558		19	2			2	23
Phosphofructokinase (PFK)[h]	780		7	1		1–0	6	15
	784							
Aldolase	364		2					2[i]
Triosephosphate isomerase (TPI)	249	1	9	2		1–0		13
Glyceraldehyde 3-phosphate dehydrogenase (GAPD)[k]	335							
Diphosphoglycerate mutase (DPGM)	259		1		1–0			2[l]
Phosphoglycerate kinase (PGK)	417		8		1–0		2	11
Monophosphoglycerate mutase (PGAM-B)	254							
Enolase[k]	434							
Pyruvate kinase (PK)	574[m]	1	65	7	2–2	7–3	9	96
Glucose 6-phosphate dehydrogenase (G6PD)	515		115[n]	1	6–0		1	123
Cytochrome-b_5 reductase	276[o]		7	2	2–0		2	13
Adenylate kinase (AK)	194		2	1				3[p]
γ-Glutamylcysteine synthetase (GLCLC)[k,q]	637							
Glutathione synthetase (GSS)	474		13		1–0	1–0	1	16
Glutathione peroxidase (GSH-Px)	201							

[a]We have listed all enzymes in the intermediary metabolism of red cells for which—to the best of our knowledge—the corresponding cDNA/gene has been cloned. There are other enzymes the deficiency of which may be associated with HA, but for which no molecular information is yet available: for instance pyrimidine 5'-nucleotidase.

[b]No entry in this column means that there are no known isoenzymes; therefore, it is assumed that the same enzyme type is present in all tissues.

[c]The following abbreviations have been used. CNS, central nervous system involvement; HA, hemolytic anemia; NM, neuromuscular manifestations.

[d]Data available only on some patients.

[e]Including N-terminal methionine, which is cleaved off in most or all cases.

[f]Each individual molecular change, if observed in more than one patient, has been counted only once.

[g]Two HK mutations were found in the same patient: 529 Leu→Ser and Δ162-193. Two large deletions were found in another patient: △ exons 3–14, Δ exons 5–8.

[h]PFK in normal red cells consists of a mixture of the five tetrameric species that can be formed from random association of the M (muscle) and L (liver) highly homologous subunits (i.e., M_4, M_3L, M_2L_2, ML_3, L_4).

[i]The only known aldolase mutations are 128 Asp→Gly and 206 Glu→Lys.

[j]5'UTR, 5' Untranslated region.

[k]Since no mutations have yet reported, there is no formal proof that HA associated with this enzyme deficiency is due to mutation of the corresponding gene.

[l]The only two DPGM mutations known were found in the same patient. They were: 89 Arg→Cys and Δ C205 (or 206). The deletion causes a frameshift resulting in an abnormal protein of 46 amino acids in which only the first 19 N-terminal amino acids are correct.

[m]The red cell form of PK called R is produced by the gene encoding the L (liver) subunit. Because a different promoter is used (*see* Fig. 22-5) the size of liver PK is 543 amino acids.

[n]The 115 missense mutations include two variants with normal activity, A and São Borja. Seven variants have 2 missense mutations each: these include G6PD Santamaria, G6PD Mount Sinai and the three variants that are called G6PD A—both of which have the mutation of G6PD A plus another mutation; G6PD Honiara and G6PD Bangkok. G6PD Vancouver variant has 3 different missense mutations (*see* Fig. 22-6).

[o]The cytoplasmic form of this enzyme, present in red cells, differs from the microsomal form present in other cells because, as a result of an alternative splicing pathway, it lacks the first 25 N-terminal amino acids. Therefore, in other cells, the size of the enzyme is 301 amino acids.

[p]The known AK mutations are: 128 Arg→Trp, 164 Tyr→Lys, and 107 Arg→Stop.

[q]γ-glutamylcysteine synthetase consist of two subunits, a catalytic subunit and a regulatory subunit; the data concerning the catalytic subunit are shown here.

[r]There is no clear evidence that inherited deficiency of glutathione peroxidase exists.
Figure 22-2 Diagram of mutations in the *GPI* gene. In this and in the following figures, the central vertical line represents the genomic structure, with exons shown as thick blocks and introns as thin lines. Exons are numbered. Long introns are signalled by a diagonal double line. Additional symbols are as follows: ■, translated exon region; ▨, untranslated exon region; △, deletion; Ins, insertion; ∫, splicing error. The *GPI* genomic gene spans approximately 40 kb. A question mark (?) next to a diagonal double line indicates that the exact length of the intron is unknown. *a*This variant has a mutation in the acceptor site that causes an aberrant splicing of exon 16. *b*This variant has a deletion of the last 2 nucleotides of exon 16 and of the first 2 nucleotides of intron 16, with possible abnormal splicing.

3. Chronic nonspherocytic hemolytic anemia (CNSHA). In contrast to the large majority of G6PD deficient subjects who have minimal and subclinical hemolysis in the steady state, a small minority of G6PD deficient individuals have chronic anemia of variable severity. This rare condition is rather similar to CNSHA associated with glycolytic enzymopathies *(see above)* and, again, it is of variable severity. However, it is characteristically exacerbated by the same agents that can cause acute hemolytic anemia in people with the ordinary type of G6PD deficiency.

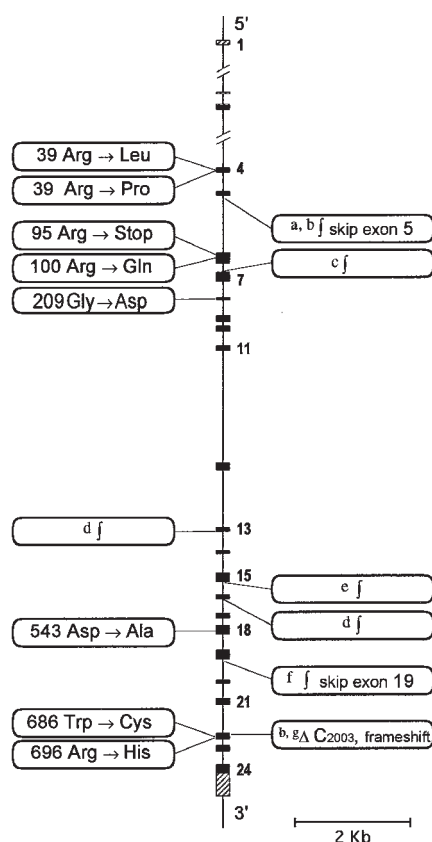
DIAGNOSIS   When there is anemia, it is usually normocytic and normochromic, and it may be from moderate to extremely severe. In AHA, the anemia results from intravascular hemolysis; and hence, it is associated with hemoglobinemia, hemoglobinuria, and low or absent plasma haptoglobin. The blood film shows anisocytosis, polychromasia, and other features associated with acute


Figure 22-3   Diagram of known mutations in the *PFK-M* gene. The *PFK-M* genomic gene spans approximately 30 kb. *a*This mutation at the donor site of intron 5 causes exon 5 to be skipped (in frame) and thus a protein lacking 26 amino acids is produced. *b*Each one of these two *PFK* mutations has been found recurrently in several Ashkenazi families. *c*This mutation at the acceptor site of intron 6 causes the production (thanks to the presence of two cryptic splice sites in exon 7) of two abnormal mRNA species, one lacking 5-bp and the other lacking 12-bp: the latter is more abundant and in frame, thus producing a protein lacking 4 amino acids. *d*The mutation in the donor site causes splicing to a cryptic site in the intron, resulting in the retention of some intronic sequence and a premature stop. *e*The mutation at the donor site of intron 15 causes splicing to a cryptic splicing site in exon 15 (in frame) and thus a protein lacking 25 amino acids is produced. *f*This mutation at the donor site of intron 19 causes exon 19 to be skipped (in frame), thus, a protein lacking 55 amino acids is produced. *g*This single basepair deletion causes a frameshift with a stop codon 47 nucleotides downstream and a truncated protein of 683 amino acids, with the last 16 C-terminal amino acids being incorrect. (For other symbols, *see* legend to Fig. 22-2.)

hemolysis, including spherocytes. In severe cases, the poikilocytosis is very marked, with presence of bizarre forms, numerous red cells that appear to have an uneven distribution of hemoglobin within them (hemighosts), and red cells that appear to have had parts of them bitten away ("bite cells," or "blister cells"). Supravital staining with methyl violet, if done promptly, reveals the presence of Heinz bodies, consisting of precipitates of denatured hemoglobin. In CNSHA, the morphology is less characteristic. The final diagnosis must rely on the direct demonstration of decreased activity of G6PD in red cells. In most cases, one of the commercially available "spot tests" is adequate, but the gold standard is, as for all other enzymes, a spectrophotometric assay.
Figure 22-4 Diagram of mutations in the *TPI* gene. The *TPI* genomic gene spans 3.2 kb. *a*Sequencing of this variant reveals of two single base change in the 5' untranslated region. It is not clear whether and how this causes enzyme deficiency. *b*The deletion of these two nucleotides causes a frameshift. (For other symbols, *see* legend to Fig. 22-2.)

Figure 22-5 Diagram of known mutations in the *PGK* gene. The *PGK* genomic gene spans approximately 23 kb. The methionine initiator is counted as residue zero. ●, hemolytic anemia; ◯, myopathy; *, CNS involvement. *a*This mutation in the donor site of intron 3 causes splicing to a cryptic site within intron 3 with the consequent insertion of 10 extra amino acids in the protein. *b*This mutation in exon 7 causes either a missense mutation and the alteration of the consensus donor splice sequence site with alternative splicing to a cryptic site in intron 7 and a premature stop. *c*The variant PGK-II, found at a polymorphic frequency in New Guinea, has normal activity. (For other symbols, *see* legend to Fig. 22-2.)

GENETIC BASIS   G6PD is a homodimeric molecule, and its single subunit is encoded by an X-linked gene (Table 22-1). Therefore, in areas with high prevalence of G6PD deficiency, male hemizygotes and female heterozygotes are common, but female homozygotes are rare. As a result of the phenomenon of X-chromosome inactivation in somatic cells, female heterozygotes are genetic mosaics, in whom approximately one-half of the red cells are normal and approximately one-half are G6PD deficient; however, sometimes the ratio is greatly imbalanced. Clinical manifestations in heterozygotes are milder than in hemizygotes and in homozygotes, roughly in proportion to the fraction of red cells that are G6PD deficient.

MOLECULAR PATHOPHYSIOLOGY   AHA associated with G6PD deficiency results from the action of an exogenous factor on intrinsically abnormal red cells. Although the sequence of events ending in hemolysis is not completely understood, it is clear that the exogenous agent taxes the capacity of the red cell to detoxify oxygen radicals, which is impaired by the short supply of NADPH in G6PD deficient red cells. Hence, the notion of oxidative hemolysis. AHA is seen with variants of G6PD that retain some 10% of the normal enzyme activity, or even less, if the kinetic parameters are favorable. By contrast, with some other variants the steady-state level of G6PD is so low that, even in the absence of any oxidant challenge, it becomes limiting for red cell survival. This is the case in the patients with CNSHA, who may have a red

cell life-span of between 10 and 50 days. Very numerous point mutations in the *G6PD* gene causing CNSHA have been identified (*see* Fig. 22-7). Although we cannot explain the reason for a severe clinical phenotype in every case, a cluster of mutations causing CNSHA in exons 10 and 11 corresponds closely to the region of the molecule where the two subunits interface. It is not surprising that amino acid replacements in this region will interfere with dimer formation or will cause marked instability of the dimer.

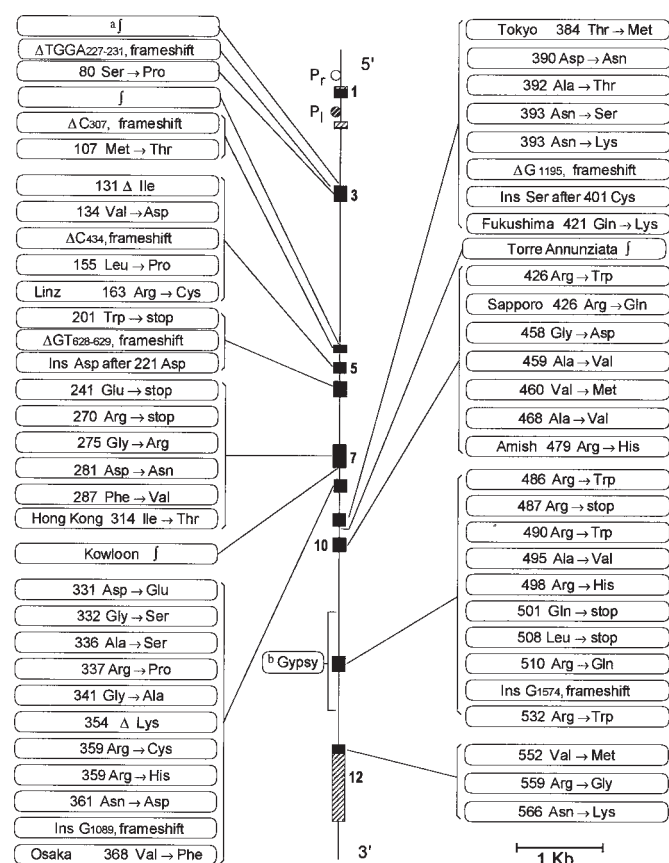
MANAGEMENT   The most common manifestations of G6PD deficiency, NNJ and AHA, are largely preventable or controllable by screening, surveillance, and avoidance of triggering factors, particularly fava beans, by G6PD deficient subjects. When a patient presents with AHA, and once the cause is diagnosed, no specific treatment may be needed if the episode is mild. However, at the other end of the spectrum—especially in children—AHA may be a medical emergency requiring an immediate blood transfusion. The management of NNJ does not differ from that of NNJ owing to causes other than G6PD deficiency. To prevent neurological damage, it may have to include phototherapy and/or exchange blood transfusion. The management of CNSHA is simi-


Figure 22-6 Diagram of mutations in the *PK* gene. The *PK* genomic gene spans 8.6 kb. The same gene encodes the R (red cell) and L (liver) form of PK. In the erythroid cell transcription starts from the upstream promoter (P$_r$ ◯); in the liver transcription starts from the downstream promoter (P$_l$ ⊘. Thus, exon I of erythroid *PK* mRNA is missing in liver *PK* mRNA. [a]The consequences of this mutation at the acceptor site of intron 2 on RNA processing are not known. [b]This deletion removes the entire exon 11 and parts of intron 10 and intron 11 (total 1149 bp); it also causes a frameshift. (For other symbols, *see* legend to Fig. 22-2.) For reasons of space not all mutations can be shown.

lar to that of CNSHA caused by glycolytic enzymopathies, but, in addition, it is important to avoid exposure to potentially hemolytic drugs. Again, although there is no evidence of selective red cell destruction in the spleen (e.g., as seen instead in hereditary spherocytosis), splenectomy has proven beneficial in severe cases.

GLUTATHIONE SYNTHETASE DEFICIENCY

Glutathione (GSH) is a ubiquitous tripeptide with a range of important biological functions. In red cells, the main function of GSH is protection against oxidative damage. GSH is produced from glutamic acid, cysteine, and glycine through the action first of γ-glutamylcysteine synthetase and then glutathione synthetase (GSS) (*see* Fig. 22-1). GSS deficiency is a rare autosomal recessive disorder resulting in very low levels of GSH in red cells. Clinically, GSS deficiency may present in two different clinical forms: a mild form that causes only a compensated hemolytic anemia, and a severe form that causes also 5-oxyprolinuria and neurological manifestations. Twelve unrelated patients with GSS deficiency have been studied for mutations in the *GSS* gene and 16

different mutations have been identified: three patients were homozygotes, six were compound heterozygotes, and in three only a missense mutation was found in heterozygosity (Fig. 22-8).

CYTOCHROME B$_5$ REDUCTASE DEFICIENCY

A small amount of methemoglobin is formed in red cells continuously as a by-product of the cyclic oxygenation and deoxygenation of hemoglobin. It is estimated that methemoglobin would accumulate in blood at the rate of about 2% per day, unless it was continuously reduced. Red cells have both a NADPH-dependent and a NADH-dependent mechanism for the reduction of methemoglobin, but several lines of evidence indicate that the latter is by far more important physiologically. Cytochrome-b$_5$ reductase (formerly called diaphorase) is the currently accepted name for the enzyme that reduces methemoglobin using NADH as the electron donor. Patients with cytochrome-b$_5$ reductase deficiency can be also described as having methemoglobinemia. However, because this is caused by an enzyme defect rather than to a hemoglobin abnormality (Hb M), the former term is preferable.

PREVALENCE Cytochrome-b$_5$ reductase deficiency is relatively common in Alaskan Eskimos, but it is a rare condition elsewhere.

CLINICAL FEATURES The main finding is cyanosis, because since this is a result of the presence of methemoglobin rather than deoxyhemoglobin, it is sometimes referred to as pseudocyanosis, but with the naked eye, the two are not easily distinguished. There may be also a mild erythrocytosis, resulting from the erythropoietin-drive associated with the reduced oxygenation of tissues. A subset of patients with cytochrome-b$_5$ reductase deficiency (i.e., designated as having type II disease) may have also mental retardation, which can be severe, and other neurological signs including microcephaly, opisthotonus, and athetoids movements.

DIAGNOSIS Usually a patient presenting with cyanosis is suspected to have congenital heart disease or acquired cardiac or pulmonary disease; the suspicion may be reinforced by the coexistence of erythrocytosis. When the appropriate investigations are negative, a test for methemoglobin will explain the (pseudo)-cyanosis. The differentiation of methemoglobinemia caused by cytochrome-b$_5$ reductase deficiency from that caused by Hb M is based on electrophoretic and spectral studies of hemoglobin. An enzyme assay or a therapeutic trial of methylene blue will clinch the diagnosis.

GENETIC BASIS Clinically affected individuals are homozygotes or genetic compounds; therefore, methemoglobinemia secondary to cytochrome-b$_5$ reductase deficiency exhibits an autosomal recessive pattern of inheritance. This is in contrast to methemoglobinemia associated with Hb M, in which the pattern of inheritance is autosomal dominant.

MOLECULAR PATHOPHYSIOLOGY Several point mutations have been identified in the cytochrome-b$_5$ reductase gene in patients with congenital methemoglobinemia (Fig. 22-9). Not surprisingly, patients with type II disease have mutations that are different from those found in patients with type I disease: indeed, they include amino acid deletions and splicing mutations. Presumably, the resulting abnormal molecules are more unstable, or compromised in catalytic efficiency; therefore, the level of enzyme activity becomes severely reduced, not only in red cells, but also in nerve cells. In the latter, the enzyme is thought to be involved in lipid synthesis.

Figure 22-7 Diagram of mutations in the *G6PD* gene. The *G6PD* genomic gene spans approximately 18 kb. ⬤, variant with normal enzymatic activity; ◯, variant that cause acute hemolytic anemia; ⬭, variant that cause chronic nonspherocytic hemolytic anemia (CNSHA). *a*This variant has, in addition to the mutation shown, also the mutation (454 Arg→Cys) of G6PD Andalus. *b*These variants have, in addition to the mutation shown, also the mutation (126 Asn→Asp) of G6PD A. *c*This variant has been reported to have three different mutations; two are unique (106 Ser→Lys and 182 Arg→Trp), whereas one is the mutation (198 Arg→Cys) of G6PD Coimbra. *d*The deletion of the last two nucleotides of intron 10 destroys the acceptor site with unknown effect on the processing of the transcript. (For other symbols, *see* legend to Fig. 22-2.) For reasons of space not all mutations can be shown.

MANAGEMENT Most patients with type I disease suffer little disability. However, if they are fair-skinned, their discoloration may create a cosmetic problem: this responds very well to the administration of methylene blue or ascorbic acid. The former activates the NADPH-dependent pathway of methemoglobin reduction; therefore, it is not effective if the patient happens to be also G6PD deficient. Unfortunately, no treatment is known for the neurological manifestations of type II disease. Knowledge of the molecular lesion makes it possible to offer prenatal diagnosis to a couples at risk for type II disease.

FUTURE DIRECTIONS

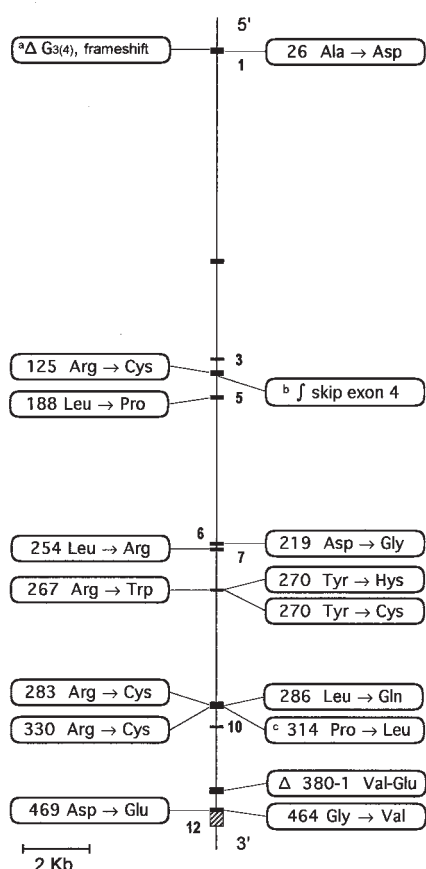
Red cells have been for decades a model system in the study of intermediary metabolism, and red cell enzymes have been a classical tool of biochemical genetics and of population genetics. With the cloning of most of the genes encoding red cell enzymes, it has been possible to validate many of the items predicted in earlier times: for instance, the prediction that most of the individuals affected with rare autosomal enzymopathies—barring inbreeding—would be genetic compounds rather than true homozygotes. From the point of view of genotype–phenotype correlations, the


Figure 22-8 Diagram of mutations in the *GSS* gene. The *GSS* genomic gene spans approximately 23 kb. [a]This single base deletion causes a frameshift. [b]The mutation in the donor site results in aberrant splicing, whereby exon 4 is skipped. [c]This varient has normal activity. (For other symbols, *see* legend to Fig. 22-2.)
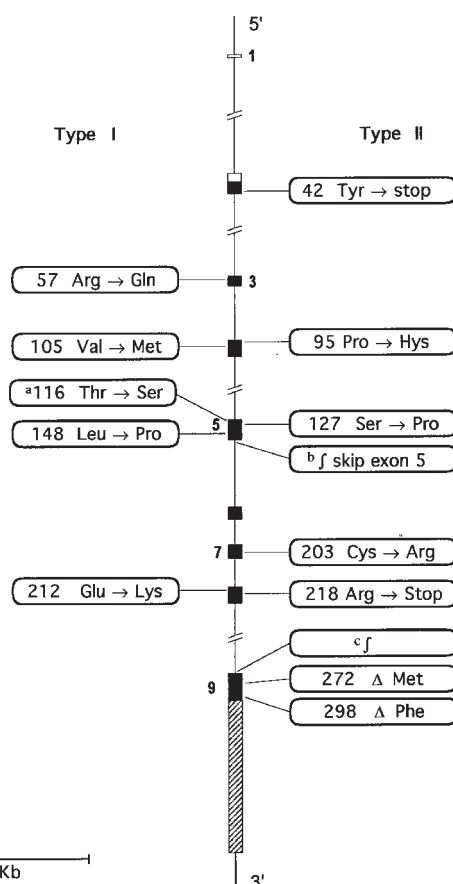

Figure 22-9 Diagram of known mutations in the *cytochrome b5 reductase* gene. The genomic gene spans approximately 31 kb. ▭, region of exon 1 and 2 encoding for transmembrane domain (25 aa), missing in the erythrocyte cytoplasmic form of the enzyme. The methionine initiator is counted as residue zero. There are two types of cytochrome-b5 reductase deficiency. In type I, the enzyme deficiency is limited to the red cell cytoplasmic form, and its main clinical manifestation is pseudocyanosis. In type II, the enzyme deficiency involves both the cytoplasmic and the microsomal forms of the enzyme, and all tissues are affected. In addition to pseudocyanosis, there is mental retardation and other neurological signs. It is likely that type I mutations affect mainly the stability of the enzyme, whereas type II mutations either produce no viable protein or compromise drastically its catalytic activity. [a]This variant, found at a polymorphic frequency in African American, has normal activity. [b]The mutation at the donor site of intron 5 causes the skipping of exon 5 and produces in red cells a truncated protein of 102 amino acids. [c]The consequences of this mutation at the acceptor site of intron 8 on the RNA are not exactly known, but the protein product is undetectable by immunological analysis. (For other symbols, *see* legend to Fig. 22-2.)

analysis of at what point mutations cause what degree of change in stability or in catalytic properties of each enzyme has only just begun. The universe of patients with enzymopathies constitutes a living spontaneous mutagenesis laboratory in which structure–function relationships are, so to speak, displayed in vivo. From the practical point of view, the molecular analysis has not yet had any impact on management, which is still unsatisfactory, but it does provide the option of prenatal diagnosis in cases where previous family history has led to identifying a specific enzymopathy. Because chronic hemolytic anemia is the main clinical problem associated with these enzymopathies (in the majority of cases), they are an ideal target for correction by gene transfer into hematopoietic stem cells. Indeed, since the deficiency of most of these enzymes is likely to be a disadvantage even before erythroid cell differentiation reaches the end point of the mature red cell, it is conceivable that phenotypic correction might be self-selecting, thus abrogating the need for bone marrow ablation in future gene therapy protocols.

23 Coagulation Disorders

Martina Daly, Anne Goodeve, Peter Winship, and Ian Peake

INTRODUCTION

Inherited disorders of the coagulation system have been recognized for many years, and their study formed the basis of laboratory experiments from which grew the concept of clotting factors and the coagulation cascade with its subsequent refinements. The genes encoding these factors have now also been identified and cloned (Table 23-1), and, in most cases, a series of causative mutations have been detected. The gene for von Willebrand factor (VWF) has also been identified and cloned. Although not a procoagulant factor, VWF plays an integral part in the primary hemostatic process, and its deficiency results in von Willebrands disease (VWD), the most common bleeding disorder. This chapter will concentrate on the genetic basis of the three most common disorders, hemophilia A (factor VIII deficiency), hemophilia B (factor IX deficiency), and VWD. Reference to rarer defects in other factors will also be made.

THE GENETIC BASIS OF HEMOPHILIA A

Hemophilia A is a recessively inherited X-linked disorder of coagulation factor VIII (FVIII) with an incidence of 1 in 5000 in the male population. The gene for FVIII was identified and cloned in 1984 and is found on the long arm of the X chromosome at Xq28.

Human FVIII is synthesized primarily in hepatocytes as an approximately 300-kDa single-chain polypeptide, having a repeated domain structure A1-A2-B-A3-C1-C2. Activation of FVIII occurs by thrombin cleavage at sites within the B-domain, giving rise to a heterodimer comprised of a constant sized light chain (A3-C1-C2) and a heavy chain (A1-A2). FVIII circulates in complex with VWF, an association that protects it from proteolytic degradation. Thrombin activation releases FVIII from VWF and allows it to function as a cofactor for FIXa in the conversion of FX to its activated form (FXa).

FACTOR VIII GENE STRUCTURE   The factor VIII gene is 186 kb in length and contains 26 exons. The FVIII mRNA is approximately 9 kb long and contains 7053 nucleotides of coding sequence. The mature factor VIII protein contains 2332 amino acids (Fig. 23-1).

Of particular interest is intron 22 of the gene that contains a CpG island from which two adjacent genes, F8A and F8B are encoded in opposite orientations. This was the first example in humans of genes being found wholly contained within another gene. The F8A gene is in the opposite orientation to the FVIII

gene, is intronless, and produces a mRNA transcript of 1.8 kb found in many tissues. F8B is transcribed in the same direction as FVIII. Its first exon, encoding eight amino acids, is within intron 22 and, in the mRNA, is spliced to exons 23–26 of the FVIII gene. The function of the F8A and F8B genes and their predicted protein products are not known. F8A lies within a 9.5-kb region of DNA (int22h) repeated two additional times approximately 400 kb telomeric to FVIII. The three homologous regions (int22h 1, 2 and 3) are identical in over 99.9% of their sequence, and each of the three F8A genes is transcribed.

DEFECTS IN THE FACTOR VIII GENE   Following the cloning of the FVIII gene in 1984, it became possible to begin analysis for mutations resulting in hemophilia A. Southern blotting analysis initially revealed a few patients with total or partial deletions or point mutations at specific restriction enzyme sites (e.g., C to T transitions at CpG sites identified by TaqI digestion—*see below*). The more sensitive techniques now applied to mutation detection are all based on amplification of DNA by the polymerase chain reaction (PCR), followed by mismatch detection methods (e.g., SSCP, DGGE, and so on) and DNA sequencing to characterize the mutations found. These techniques can be applied to genomic DNA or cDNA, produced by reverse transcription and PCR amplification (RT-PCR) from FVIII mRNA. The current hemophilia A database demonstrates the variety of mutations responsible for FVIII defects and is summarized in Table 23-2. The mutations reported have not been located by a systematic search/analysis of the gene and thus cannot be taken as a true representation of the relative incidence of the different mutations within the hemophilia A population. The table demonstrates that mutations can occur throughout the entire coding region of the FVIII gene, although no promoter or polyadenylation signal mutations have been identified to date. Twenty-five percent of single basepair substitutions occur at CpG dinucleotides; multiple mutations at these sites are frequent in the database and reinforce its "mutation hotspot" nature. Despite this, most of these mutations are "private," and are found in only one or a few unrelated families.

In contrast to the above, a novel type of mutation is now known to occur in the FVIII gene and accounts for nearly 50% of cases of severe hemophilia A. This DNA inversion is mediated by the three copies of int22h one located in intron 22 of FVIII, the other two 400 kb 5' and telomeric to the gene (Fig. 23-1). Homologous recombination appears to occur between the intron 22 copy (int22h-1) and either the distal (telomeric, int22h-3) or more proximal (int22h-2) copy, and this process occurs most readily at male meiosis when the X chromosome is largely unpaired. Recombina-

Table 23-1
Blood Coagulation Factor Genes

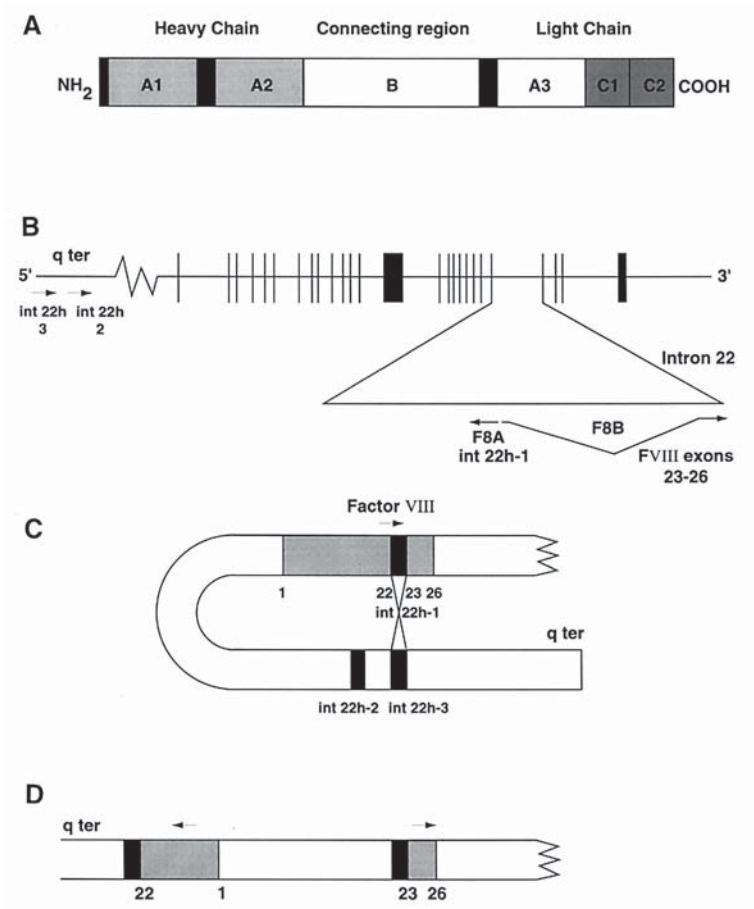
Clotting factor	Gene, kb	Location	mRNA, kb	Inheritance pattern
Fibrinogen (I)	α5.4		α2.2	Autosomal dominant or recessive
	β8.2	4q23–q23	β~2.5	
	γ8.4		γ~2.5	
Prothrombin (II)	20.2	11p	2	Autosomal recessive
Factor V	~80	1q21–q25	7	Autosomal recessive
Factor VII	13	13q34	~2.5	Autosomal recessive
Factor VIII	186	Xq28	8.8	X-linked recessive
Factor IX	34	Xq27.1	1.8	X-linked recessive
Factor X	25	13q34–qter	1.5	Autosomal recessive
Factor XI	23	4q32–q35	2	Autosomal recessive
Factor XII	12	5q33–qter	2-4	Autosomal recessive
Factor XIII	A160	A 6p24–25	A4	Autosomal recessive
	B28	B 1q31–32;1	B > 2	
von Willebrand Factor (VWF)	178	12p12–pter	9	Autosomal dominant or recessive


Figure 23-1 The factor VIII gene. (**A**) Structural domains of factor VIII. Triplicated A domains of 330 amino acids, the unique B domain of 980 amino acids and duplicated C domain of 150 amino acids, are shown. (**B**) Exon (vertical bar) and intron (horizontal line) structure of factor VIII gene. Intron 22 is shown expanded, the locations of F8A and F8B transcripts are shown and the three homologous regions int22h-1 within factor VIII, and -2 and -3 400 kb 5' and telomeric to factor VIII are indicated. (**C**) An intrachromosomal crossover event, mediated by homologous recombination between int22h-1 and -3 is shown. This results in the common distal form of factor VIII gene inversion shown in (**D**). (D) Following an inversion event, introns 1–22 of the factor VIII gene now lie 400 kb 5' and telomeric to exons 23–26 of the gene, in the opposite transcriptional orientation.

tion results in FVIII exons 1–22, in addition to adjacent DNA becoming inverted and relocated some 400 kb from its normal position, with exons 23–26 remaining in their original location. Therefore, intact FVIII transcript and protein cannot be produced.

Crossover with the most distal int22h sequence results in a type 1 inversion. This is the most common inversional event, accounting for 82% of all inversions and 35% of all patients with severe disease. Crossover involving the proximal int22h results in a type 2

[c]0.11 in Asians.
[d]Probe (Southern blot) method when PCR-based technique has not been reported.
[e]Dimorphic with two major forms differing by 50 bp.

inversion and occurs less frequently (15%). The number of copies of int22h outside the FVIII gene appears to be polymorphic, with some individuals having extra complete or partial copies that can result in rarer types of inversion (3A, 3B, or other variants). Inversions can be readily detected by Southern blotting following DNA digestion with BclI and using a probe for part of the int22h sequence. Overall, this inversion is the causative mutation in 43% of patients with severe disease and accounts for 20% of all cases of hemophilia A.

GENETIC SCREENING FOR HEMOPHILIA A　In families affected by hemophilia A, female relatives of patients wish to know their carrier status. This can be achieved either by tracking the defective FVIII gene through the family by using polymorphic genetic markers or by detection of the causative mutation. The latter procedure is the most technically demanding and expensive, unless the inversion mutation is present, but is the ideal approach.

Since mutation detection is not available in many laboratories, the approach most frequently adopted for noninversion families is that of gene tracking, using DNA polymorphism analysis. A number of intragenic restriction fragment length polymorphisms (RFLP) in the FVIII gene have been described. However, the CA dinucleotide repeat polymorphisms located in introns 13 and 22 are the most useful (*see* Table 23-3). Heterozygosity rates in females from different ethnic backgrounds vary from 30 to 90%.

The suggested strategy for hemophilia A analysis is thus to first determine whether the FVIII gene inversion is present. If not, then

dinucleotide repeats should be examined; if these are not informative, try RFLPs. Approximately 85% of families examined will be informative by using one of these intragenic polymorphisms. The probability of error caused by crossover at meiosis between a factor VIII gene mutation, and the intragenic polymorphism used to track its inheritance is <1%. For the families remaining uninformative, two extragenic markers at loci St14 and DX13 can be used with caution, since an approximate 5% crossover rate at meiosis has been reported between these loci and the FVIII gene locus. Overall, about 5% of families are uninformative for the FVIII gene inversion and the intragenic and extragenic polymorphisms outlined *above*. For these kindred, direct mutation analysis is the only option. Approximately, one-third of all cases of hemophilia have no prior family history of the disorder (sporadic hemophilia A). Prior to recognition of the FVIII gene inversion, 85% of mothers of these isolated cases were estimated to be true carriers of hemophilia, based on phenotypic analysis or by retrospective diagnosis following the birth of a second affected male child. A further proportion were thought to be mosaics for the mutation (i.e., it was present in only a proportion of their tissues). Since the recognition of the FVIII gene inversion and its ready detection, 96% of mothers of sporadic cases of hemophilia A caused by the inversion have been shown to carry the mutation. It should be noted that in families without the FVIII gene inversion and with no prior history of hemophilia, carrier diagnosis by linkage analysis is only able to exclude carrier status.

Prenatal diagnosis of hemophilia A is generally achieved by chorionic villus sampling (CVS) at 10–13 weeks' gestation. Karyotype analysis is performed to determine fetal sex and eliminate any chromosomal abnormalities. Fetal sex can also be determined by PCR. Chorionic villus DNA can be used for the detection of a previously identified familial mutation, or of a polymorphic allele in phase with hemophilia A in that particular family.

MOLECULAR PATHOPHYSIOLOGY OF HEMOPHILIA A
Patients with hemophilia A can either have levels of FVIII activity and protein reduced in parallel (crossreacting material negative [CRM⁻]) or have dysfunctional protein present at normal (CRM positive [CRM⁺]) or reduced (CRM reduced) level. The mutations found in CRM⁺ and CRM-reduced patients are important in understanding the functional significance of particular amino acids. Only the small proportion of mutations that result in FVIII protein production in vivo and in vitro enable the effect of the mutation on the protein to be elucidated. Thus, mutations at Arg 372 and Ser 373 that abolish thrombin cleavage in the heavy chain and at Arg 1689 that abolishes thrombin cleavage in the light chain result in CRM⁺ hemophilia A where FVIII cannot be activated.

VWF binds to FVIII in a region between Lys 1673 and Glu 1684. There are two sulfated tyrosines in this region—Tyr 1664 and Tyr 1680. Several unrelated instances of Tyr 1680 Phe have been reported that result in moderate CRM-reduced hemophilia A. Replacement of tyrosine by phenylalanine results in loss of high-affinity binding to VWF. Other mutations appear to create new glycosylation sites

Approximately one-third of all hemophilia A patients will develop inhibitors (antibodies) directed against FVIII, following replacement therapy with FVIII. A small number of these inhibitors are persistent, of high titer, and cause considerable problems in the management of bleeds. Inhibitor development appears to be related to some extent to the severity of the causative mutation, with, for example, patients having major gene deletions being

more likely to develop an inhibitor than those with a missense mutation. However, this is not the sole influence, and it is now clear that the patient's genetic background (HLA type) and the FVIII concentrate with which they are treated can also contribute to inhibitor development.

THE GENETIC BASIS OF HEMOPHILIA B

Hemophilia B (Christmas Disease), a sex-linked recessive blood coagulation disorder occurring at a frequency of approximately 1 in 30,000 males, is caused by reduced levels of biologically active coagulation factor IX in the plasma and is clinically indistinguishable from hemophilia A. The biochemical distinction between classical hemophilia and Christmas disease first became apparent in 1952, with the realization that one of two different components of the plasma could be reduced or absent in patients with "hemophilia." Laboratory clotting tests have subsequently been developed to permit the differential diagnosis of these two conditions. The clinical similarities between the two conditions can be rationalized, once it is appreciated that both factor VIII and factor IX participate at the same step in the middle phase of the blood coagulation cascade. Indeed, factor VIII acts as a cofactor in the enzymatic cleavage of coagulation factor X by the activated form of factor IX. Christmas disease patients can be broadly classified into one of two categories on the basis of biochemical tests for factor IX antigen (FIXAg) and factor IX clotting (FIXc) levels. Sixty percent of patients are termed CRM⁻ and show characteristically low circulating levels of biologically active factor IX. The remaining 40% of patients have lowered or near normal levels of circulating factor IX with a low biological activity and are therefore referred to as CRM⁺. Approximately 1% of patients have absolutely no detectable plasma factor IX and raise antibodies to the exogenous factor IX administered during replacement therapy.

FIX GENE STRUCTURE   FIX cDNA clones were isolated from both bovine and human cDNA libraries in the early 1980s and showed the full-length human cDNA to be 2.8 kb, including a 296p 5' noncoding and a 1.39-kb 3' noncoding region (Fig. 23-2). These clones were then used as hybridization probes to screen human genomic libraries, and the entire 34-kb factor IX gene was isolated as a series of clones. The human FIX gene has been assigned to Xq27.1. The gene has been shown to comprise eight exons, separated by seven intervening regions of variable length, and the entire 34-kb region of DNA has been sequenced.

DEFECTS IN THE FACTOR IX GENE   Recent advances in DNA technology and mutation detection methods combined with the relatively small size and low complexity of the factor IX locus mean that defining the causative mutation in each individual patient has become a possibility. An international database has been established, and the most recent data is summarized in Table 23-2. As with hemophilia A and the FVIII gene, a large number of different mutations have been found within the FIX gene in individuals with hemophilia B. Indeed, ongoing research programs directed towards establishing national databases listing the precise molecular defect in each individual with hemophilia B are being established in the United Kingdom, Sweden, and New Zealand. Once established, these will serve as a valuable resource, enabling precise mutation information to be made available in these countries to all families with a history of the disease *(see below)*.

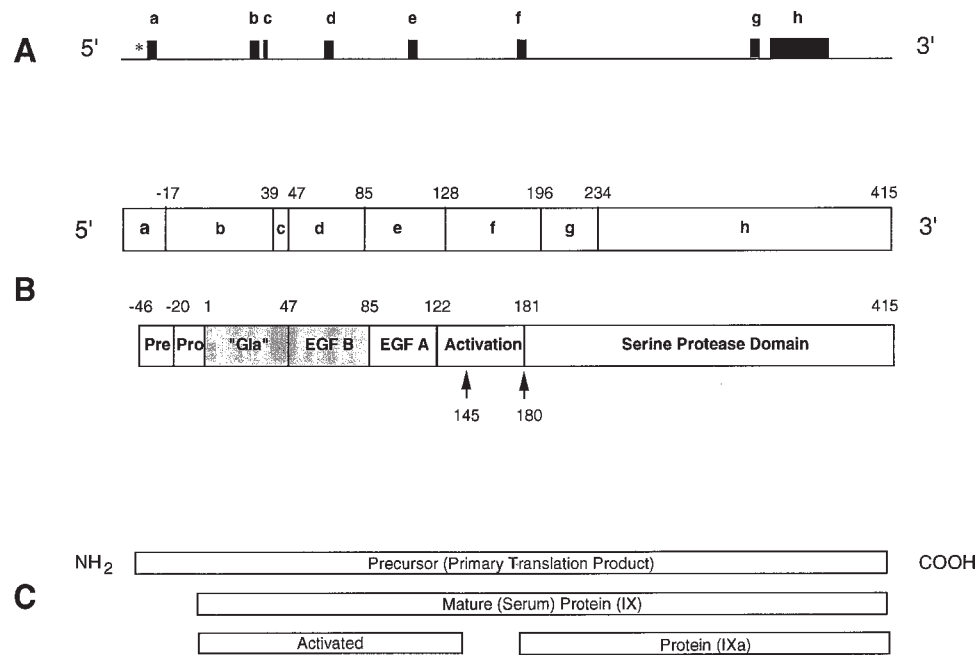
GENETIC SCREENING FOR HEMOPHILIA B   As with hemophilia A, the X-linked nature of hemophilia B inheritance and the resulting silent transmission of the condition through


Figure 23-2   Organization of the factor IX gene and protein. **(A)** Line diagram of the 34 kb factor IX gene locus showing the location of the 8 exons, a–h. *Promoter region of the gene. **(B)** Factor IX mRNA and protein domain structure *(below)* showing the close correspondence between the 8 exons and 7 protein domains are numbered relative to the 1st residue of the mature serum protein. The peptide bonds cleaved to produce the two chain activated form of factor IX (IXa) are shown by arrows. **(C)** Sequential processing of the precursor molecule to the mature serum protein is achieved by excision of the pre- and proleader sequences. The cysteine-bridged two-chain activated protein (IXa) is produced by removal of the activation peptide (amino acid residues 145–180) from the mature serum protein.

the female line to male offspring means that screening for female "carriers" and prenatal screening of potentially affected male fetuses forms the major focus of any genetic screening program.

Original carrier screening methods based on a combination of measured circulating factor IX protein levels and estimating prior risk by pedigree analysis were at best only 80% accurate. Accordingly, as with hemophilia A, this procedure has been largely superceded by the more reliable methods of linkage analysis with intragenic RFLP markers or direct detection of the genetic defect itself in a particular kindred.

Useful RFLPs have been characterized either within the factor IX structural gene itself or in the immediate 5' and 3' flanking sequences. (Table 23-3). The use of any of these polymorphic markers to "tag" the defective gene and follow it through the affected pedigree will, where diagnosis is possible, allow carrier status (or prenatal diagnosis) to be made with 99.9% certainty. Varying levels of overall heterozygosity for the polymorphisms are observed in different ethnic groups and range from approximately 95% in Caucasians to less than 50% in Chinese. However, approximately one third of hemophilia B cases arise in pedigrees with no prior history of the condition. As with hemophilia A and the FVIII gene, whether these represent genuine cases of *de novo* mutation in either the patient or his mother, or simply the silent transmission of an existing mutation through the female line for a number of generations, cannot be deduced without first knowing the exact nature of the molecular defect. Fortunately, the identification of causative mutations within the FIX gene in patients with hemophilia B is becoming increasingly possible *(see above)* and, in several laboratories, polymorphism-based family studies have been replaced by direct mutation analysis.

MOLECULAR PATHOPHYSIOLOGY OF HEMOPHILIA B

The eight exons, a–h, of the factor IX gene each encode, at least in part, distinct protein domains of the mature protein (Fig. 23-2). Hence, the first exon, a, contains the 5' noncoding region of the mRNA and also encodes the hydrophobic signal domain of the primary translation product (precursor molecule). Exon b encodes the hydrophilic pro sequence of the precursor molecule. The prepro 46-amino acid leader sequence must be cleaved to allow release of the blood-borne 415-amino acid single-chain mature glycoprotein from its site of synthesis in the liver. The bulk of exon b encodes the first domain of the mature factor IX molecule. The posttranslational γ-carboxylation of 12 glutamic acid residues in this domain is instrumental in the formation of calcium bridges between this protein domain of the molecule and the phospholipid surface at its site of action on the vascular endothelium. The third exon, c, encodes a hydrophobic stack domain that is essential for the interaction of factor IX with its cofactor factor VIII. Two domains with homology to epidermal growth factor (EGF) are encoded by exons d and e; the EGF-B domain (encoded by exon d) containing a high-affinity calcium binding site required for the expression of full biological activity. Cleavage of the activation domain (encoded by exon f) during the coagulation process yields the two chain-activated forms of the mature protein molecule. Finally, the seventh and eighth exons, g and h, encode the catalytic activity domain seen in all members of the vitamin K dependent serine protease family, of which factor IX is one example.

Inspection of the current 1998 worldwide database of 1713 hemophilia B mutations (summarized in Table 23-2) indicates that just over one-third (652) are unique molecular events and confirms the extreme genetic diversity of the condition alluded to in

Table 23-4
Diagnosis and Molecular Basis of von Willebrand's Disease

Type	Diagnostic criteria	Inheritance	Location of mutations
Type 1	Quantitative deficiency of VWF	Autosomal dominant or recessive	Generally unknown, no specific region
Type 2A	Qualitative defect of VWF Reduced platelet binding Lack of HMW VWF multimers	Autosomal dominant	A2 domain
Type 2B	Qualitative defect of VWF Decreased platelet binding	Autosomal dominant	A1 domain Cys509–Cys695 loop region
Type 2N	Qualitative defect of VWF Reduced FVIII binding	Autosomal recessive	FVIII binding domain D1-D3
Type 2M	Qualitative defect of VWF Reduced platelet binding Normal VWF multimer profile	Autosomal dominant	A1 domain
Type 3	Severe quantitative deficiency of VWF	Autosomal recessive	Throughout VWF gene Deletion, termination codon, and so on

an earlier section. As with many genetic disorders, any repeat mutations at specific residues in apparently unrelated patients are explicable on the basis of CpG dinucleotides acting as mutational "hot spots." Other commonly occurring mutations are accounted for by founder effects.

The study of naturally occurring mutations has helped define and confirm the proposed importance and functions of the domains described in the previous section. Hence, mutations at 9 of the 12 γ-carboxylated residues in the Gla domain and the CRM$^+$ phenotype of these patients confirms the functional importance of these residues and this domain (Fig. 23-2). Similarly, the identification of CRM$^+$ patients with mutations at critical residues in the high-affinity calcium binding EGF-B domain serve to highlight its functional significance (Fig. 23-2).

One of the most interesting insights into gene/protein structure function relationships to emerge from these studies is the identification of the Leyden subgroup of hemophilia B patients. These patients are characterized by classic symptoms of hemophilia B in early life but have only very mild—if any—symptoms in later years. This clinical recovery, apparently triggered by the onset of puberty in the affected individual, is accompanied by a corresponding rise in circulating plasma levels of FIXc and FIXAg. This subtype of hemophilia B has generated considerable interest and has led to the identification of a complex array of transcription factors responsible for the regulation of factor IX expression. A picture is emerging of a series of liver-specific transcription factor binding sites directing the tissue restricted mode of expression of factor IX. To date, all patients with the Leyden subtype have a mutation at one of these sites in the factor IX promoter region (Fig. 23-2). Although controversial, it has been postulated that the clinical recovery of these patients is partly triggered by a compensatory mechanism, whereby the increased levels of testosterone present following puberty interact with and activate an androgen response element in the FIX gene promoter.

THE DIAGNOSIS AND GENETIC BASIS OF VWD

VWD is the most common human inherited bleeding disorder, occurring in a mild form in up to 1% of some populations. It occurs as a result of quantitative and/or qualitative deficiency of VWF, a multifunctional plasma glycoprotein synthesized in vascular endothelial cells and megakaryocytes and found in plasma, platelets, and in the subendothelial cell vascular matrix. VWF exists in plasma and platelets as a series of high-molecular-weight multimers, ranging from 5×10^5 to 2×10^7 Dalton. The two major functions of VWF are to form a link between exposed subendothelium and platelets and to bind to and protect coagulation factor VIII from premature proteolytic inactivation in plasma. The former function is multimer dependent with the largest multimers an essential requirement. VWD diagnosis is made by quantitative analysis of plasma VWF as VWF antigen (VWFAg), or qualitative analysis of VWF multimeric profile (i.e., its ability to bind to platelet glycoprotein GPIb/IX [measured as VWF Ristocetin Cofactor Activity], to collagen and to factor VIII).

The clinical and genetic heterogeneity of VWD is reflected in its recently revised classification (Table 23-4). Types 1 and 3 VWD refer to partial quantitative and virtually complete quantitative deficiency of VWF respectively. Type 2 VWD refers to qualitative VWF deficiency and is subdivided into four further categories, depending on the physicochemical properties exhibited by the VWF: Types 2A and 2M VWD refer to variants having decreased platelet-binding function associated with the presence (type 2M) or absence (type 2A) of high mol wt VWF multimers. Type 2B VWD refers to those qualitative variants having increased affinity for the platelet VWF receptor, GpIb/IX, and type 2N VWD refers to variants with reduced binding affinity for factor VIII.

Considerable variability in the severity of clinical symptoms and penetrance has been documented in VWD families and combined dominant and recessive inheritance within the same kindred has been described. The latter most likely reflects the multimeric structure of VWF and the possibility for mutated subunits to interact with normal subunits in a "dominant-negative" manner. Type 1 disease is usually dominantly inherited, whereas the most severe type 3 disease is often a recessive disorder. Some type 2 variants (e.g., type 2B) show dominant inheritance, and others (e.g., type 2N) are characterized by recessive inheritance. Molecular genetic analysis has revealed that compound heterozygosity, particularly coinheritance of types 1 and 2N VWD (indicated type 1/2N) is a relatively common event with important consequences for diagnosis and genetic counseling.

VWF GENE STRUCTURE The VWF gene is located on chromosome 12 at p12-pter and comprises 52 exons spanning some 178 kb of genomic DNA. The gene is transcribed to yield an approximately 9-kb mRNA encoding the preproVWF signal peptide (22 aa), propeptide (741 aa), and mature subunit (2050 aa)

A VWF Gene
B VWF Functional domains
C Mutations in VWD
Figure 23-3 Schematic representation of the VWF gene encoding the prepro-VWF subunit. VWF gene exons (not drawn to scale) are represented by vertical lines in part A. The repeated domain structure of the prepro-VWF and sites of signal and propeptide cleavage are indicated in part B. The approximate location of regions involved in VWF structure and function are indicated by thick bars below the figure in part C. The locations of clusters of mutations in the D', A1, and A2 domains identified in patients with type 2 VWD are indicated in part C.

(Fig. 23-3). VWF contains four types of homologous regions (A,B,C, and D), which, in the complete translated nonprocessed peptide, are present in the order of D1-D2-D'-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2. During processing, the D1-D2 domains (the signal and propeptide regions) are cleaved to yield the mature subunit, which, as a dimer, forms the basis of the multimeric structure of VWF. Also present on chromosome 22 (q11.22–q11.23), is a partial highly homologous pseudogene corresponding to exons 23–34 of the VWF gene and showing only 3% divergence in sequence. The presence of the pseudogene, along with the size and complexity of the VWF gene have, until recently, hampered molecular genetic analysis in VWD kindred. However, sequencing of the pseudogene has allowed sequence differences between it and the VWF gene to be exploited in selective PCR-based analyses of those regions of the VWF gene encoding specific functional domains. This has led to an acceleration in understanding the molecular basis of VWD and the characterization of almost 100 specific VWF gene mutations correlating with distinct VWD subtypes. Numerous polymorphisms within the VWF gene have also been reported. Of particular importance in family studies are the multiallelic polymorphic tetranucleotide repeat regions found within intron 40 (Table 23-3).

MOLECULAR PATHOLOGY OF VWD   Recent progress made in understanding the molecular basis of different phenotypic variants of VWD will be summarized here. For more detailed descriptions of the mutations giving rise to VWD, the reader is referred to the database of point mutations, insertions and dele-

tions giving rise to VWD, first published in 1993 and now maintained and updated on the Internet.

Type 2 VWD   By stabilizing circulating FVIII and mediating platelet adhesion to sites of injury, VWF has two major roles in hemostasis. Structure–function studies using proteolytic fragments of VWF, synthetic peptides, and monoclonal antibodies have localized FVIII binding moieties in the N-terminal 272 amino acids of the mature VWF subunit (D'-D3 region). Although the GpIb binding domain has not been fully characterized, several peptide sequences in the A1 domain are involved. Normal platelet adhesion also requires the assembly of high-molecular-weight VWF multimers. Expression studies using deletion mutants of VWF have indicated that the C-terminal 151 amino acids are required for dimerization to take place, whereas, in addition to the propeptide, both the D' and D3 domains are required for multimer assembly. Therefore, investigation of the molecular basis of qualitative VWF deficiency has concentrated on the regions of the VWF gene encoding specific functional domains.

Type 2A VWD   Type 2A VWD is dominantly inherited and is characterized by lack of high mol wt VWF multimers and reduced binding to GPIb/IX on platelets. The increased concentration of a 176-kDa proteolytic fragment derived from the C-terminus of VWF in plasma from affected individuals suggested that the phenotype may well have been caused by a mutation causing increased susceptibility to proteolysis and focused attention on the corresponding region of the VWF gene (exon 28). This has led to the identification of a number of mutations in type 2A VWD, the

majority of which are clustered within the A2 domain. Expression of mutated type 2A alleles in mammalian cells has revealed two possible mechanisms for the lack of high-molecular-weight multimers in plasma. Certain mutations can lead to a defect in intracellular transport with the retention of large multimers in the endoplasmic reticulum, whereas others appear to cause increased sensitivity of the largest multimers to proteolysis after their appearance in plasma.

Type 2B VWD   VWF in plasma from patients with type 2B VWD shows an increased affinity for platelet GpIb/IX. This results in a preferential loss of high-molecular-weight VWF multimers from plasma. At least 13 different mutations have been identified in type 2B disease, the majority causing amino acid substitutions within the A1 domain loop, which is formed by disulfide bonding between cysteine residues 509 and 695. The integrity of this loop appears to be important in VWF binding to GpIb/IX. Expression of recombinant type 2B variants has established the causative nature of the mutations, since the expressed material has increased affinity for platelet GpIb/IX.

Type 2N VWD   VWF from individuals with type 2N VWD has reduced affinity for FVIII in the absence of other qualitative or quantitative abnormalities. The most immediate consequence of this is the reduction in plasma FVIII levels, which contributes to the bleeding episodes that are experienced by affected patients and sometimes results in misclassification as mild hemophilia A. However, unlike hemophilia A, type 2N VWD shows autosomal recessive inheritance. At least six type 2N mutations have been characterized, and all cause substitutions of specific amino acids located in the N-terminal region of VWF implicated in FVIII binding *(see above)*. Interestingly, one of these mutations—Arg91Gln—has an allele frequency of approximately 1% in the Dutch population.

Type 2M VWD   The sequence of events leading to initial platelet adhesion to the vascular subendothelium is believed to involve binding of VWF to subendothelial components, followed by a conformational change, which causes binding of VWF to platelet GpIb/IX. Type 2M mutations presumably prevent VWF from undergoing this conformational change, resulting in decreased platelet-dependent function; at the same time, this does not have any effect on multimer structure. The number of such type 2M variants is small, and two missense mutations causing amino acid substitutions in the A1 domain have been described.

Type 3 VWD   VWF gene analysis by Southern blotting in patients with recessively inherited type 3 VWD—virtually complete quantitative VWF deficiency—has revealed complete or partial deletions of the VWF gene in a few families. Several individuals in these families have developed alloantibody inhibitors to VWF following replacement therapy.

In addition to gene deletions, direct sequencing of the entire VWF gene from members of kindred with type 3 VWD has identified several frameshift, splice-site, and nonsense mutations, often leading to introduction of early termination codons and a lack of expression from defective alleles either at the mRNA or protein levels. Of particular interest is the frameshift mutation, caused by the deletion of a single cytosine from exon 18 and the subsequent introduction of an early termination codon. This was shown to be inherited in either homozygous or compound heterozygous form in 15/24 Swedish type 3 families, probably as a result of a founder effect within the population.

Type 1 VWD   Although type 1 VWD—partial quantitative VWF deficiency—accounts for approximately 70% of all VWD, its genetic basis is poorly understood. Considerable variability in the clinical and laboratory features of type 1 VWD can occur, even within the same family. Molecular genetic analysis of the VWF gene in a number of type 1 families showing heterogeneity of clinical symptoms and VWF profiles has revealed that clinically relevant VWD is often associated with compound heterozygosity for a null allele and a mutated allele. This causes a qualitative defect and indicates that inheritance is actually recessive rather than dominant with the severity of disease depending on the particular combination of mutations inherited. In addition, although heterozygous relatives of type 3 patients who have a quantitative null allele sometimes meet the criteria for type 1 VWD, they are generally asymptomatic, and perhaps they should not be classified as having type 1 VWD. Therefore, quantitative defects caused by the presence of a null allele appear to result in heterozygous carriers of type 3 VWD, rather than type 1 VWD.

Dominant inheritance of type 1 VWD, the molecular mechanism of which is still unknown, is the most common form. However, it is believed that type 1 patients may have functional VWF defects that interfere with the products of the normal allele, the so-called "dominant-negative" effect. The products of both normal and mutated alleles may therefore form dimers, but only normal homodimers form normal multimers that may then be secreted.

RARE COAGULATION DISORDERS

Inherited defects of fibrinogen, prothrombin, and factors V, VII, X, XI, XII, or XIII are rare and are invariably inherited in an autosomal recessive manner. Most give rise to mild to moderate bleeding disorders, although some abnormal fibrinogens can predispose the individual to thrombotic problems. The incidence of these defects is often 1 per 10^6 or more of the population, although factor XI deficiency is relatively common with 5–10% of the Ashkenazi Jewish population being heterozygous for a defective FXI gene and having reduced FXI levels. Four mutations have been described, and two mutations account for 98% of cases (a nonsense mutation; GAA to TAA in exon 5, or Phe 283 Leu). The relatively high frequency of these mutations in this population is undoubtedly because of founder effects, as is the high incidence of FX Fruili (Pro 344 Ser) found in the area of the same name in Northern Italy. This factor X defect results in decreased clotting activity in both the extrinsic and intrinsic systems, since it impairs the interaction of FX with other coagulation factors.

FV deficiency is rare, even though the structure and function of FV are similar to those of factor VIII. The higher frequency of FVIII deficiency may be because of the X-chromosome location of the factor VIII gene, or because true homozygous FV deficiency is lethal in utero. Indeed this has been recently confirmed in mice in which both FV genes have been "knocked out." The same may apply to other severe clotting-factor deficiencies, accounting for their low incidence in the general population.

MANAGEMENT AND TREATMENT OF COAGULATION FACTOR DEFICIENCIES

Specific factor replacement therapy is the goal of treatment for clotting-factor deficiencies, and an industry has grown up to provide optimum treatment for hemophilia A, B, and VWD, in particular. Factors purified from large pools of human blood have been the mainstay of treatment since the early 1970s, and high purity material extracted from plasma and purified by affinity

chromatography (i.e., ion exchange or monoclonal antibody-based) is now available in most parts of the developed world for treatment of hemophilia. It should be remembered, however, that hemophilia is either treated ineffectively or not at all in 80% of the world. Less purified plasma products that contain VWF can be used to treat VWD.

The use of material prepared from large donor pools (often over 20,000 donors) has led to the infection of large numbers of patients with blood-borne viruses, in particular HIV, hepatitis B and hepatitis C. Virus inactivation has been achieved but the possibility of "new" resistant viruses in the blood supply is always a concern. The cloning and expression of factor VIII and IX (and VWF) in mammalian cells has led not only to the production of recombinant products but also to the possibility of gene therapy. Recombinant factor VIII, free of all human protein apart from albumin added as a stabilizer, is now available for treatment, and recombinant factor IX and VWF have also been produced.

Gene therapy studies using viral (i.e., retrovirus, adenovirus) and nonviral vectors have been reported for several years, in particular using the factor IX gene as a model system. It has been amply shown that normal factor IX will be produced by many cell types when transfected with a suitable vector containing the necessary promoter sequences and the FIX cDNA. In vitro studies have been followed by ex vivo experiments in which transduced cells have been transplanted into a recipient and have continued to produce factor IX that can be detected in the blood. Adeno-associated virus (AAV) has been used to deliver persistent therapeutic levels of factor IX in mice. In vivo studies, particularly in the hemophilia B dog model, have also shown promise. By targeting the liver (injection of factor IX cDNA-containing vectors into the hepatic portal vein) Mark Kay and colleagues in Chapel Hill, NC, were able to show prolonged low level factor IX production using retroviral-based vectors and transient high-level production using adenoviral-based vectors. These experiments confirmed the essential properties of these two-vector systems, and also showed that antibodies produced in the dogs to adenoviral antigens after the first adenoviral vector administration prevented subsequent successful therapy.

Nonviral-based systems targeting specific receptors have several advantages over viral vectors. The insert size constraints associated with viral systems which mean, for example, that the complete factor VIII cDNA cannot be used in these systems are not a problem. Also, there are continuing concerns about the use of viruses, although modified and inactivated, originate from oncogenic or highly infective and destructive pathogens.

Gene therapy for hemophilia will no doubt be available in some form in the future. Before this happens, however, improvements in the level of expression, intracellular stability, and cell specificity of the vectors will be essential.

24 Thrombotic Disorders

Robin J. Olds, David A. Lane, and Swee Lay Thein

BACKGROUND

Normal intravascular fluidity is maintained by a balance between the procoagulant and the anticoagulant mechanisms. Small amounts of activated coagulation factors, like factors Xa and Va, are generated continuously, producing small amounts of thrombin. Therefore, natural anticoagulant mechanisms are required to counteract this procoagulant effect. The importance of the coagulation inhibitors was demonstrated in 1965, when Egeberg described a family with familial venous thrombotic disease that was associated with an inherited reduction in antithrombin (AT) activity in the plasma. There followed a systematic search for other proteins that participate in regulation of coagulation and in which inherited deficiency might predispose to thrombosis. Identification of deficiencies of protein C and protein S resulted. However, before 1993, specific inherited inhibitor deficiencies could be identified in only approximately 5% of patients presenting with an unexplained thrombosis. In 1994, resistance to activated protein C (aPC) was described; in the vast majority of cases, this is caused by a single defect (506 Arg to Gln) in the factor V (FV) gene. The FV 506 Arg→Gln mutation can be identified in up to 50% of patients with thrombophilia. An important conceptual development is the recognition that mutations of single inhibitor genes on their own predispose towards—but do not cause—thrombosis. Clinical thrombotic manifestations of disease require either interaction of two or more genes, or interaction of acquired and genetic factors. This chapter will concentrate on the two principal endogenous anticoagulant pathways—AT/heparin and the protein C/protein S/thrombomodulin, the inhibitor protein deficiencies involved with and the nature of genetic mutations responsible for these deficiencies.

CLINICAL FEATURES AND DIAGNOSIS

EPIDEMIOLOGY The prevalence of venous thrombosis in the population is not well documented and, in part, the notorious unreliability of diagnosis based solely on clinical findings has contributed to this. An approximate prevalence is 1 in 1000 of the general population. The frequency with which individuals with confirmed venous thrombosis have family histories of thrombosis is about 25%. Venous thromboembolism appears to be uncommon in certain populations, such as Asians and Africans. The incidence of specific deficiencies in patients with objectively confirmed episodes of venous thrombosis and in the general population is shown in Table 24-1.

PRESENTATION OF VENOUS THROMBOSIS Venous thrombosis is the most common mode of clinical presentation in individuals deficient for the various inhibitor protein deficiencies. The usual sites of thrombosis are the superficial or deep veins of the leg, including the iliac and femoral veins. Individuals may also present with pulmonary embolism. Less commonly, venous occlusion may occur at other sites, including pelvic, renal, cerebral, retinal, hepatic, portal, axillary, and mesenteric vessels and the inferior vena cava. While presentation with arterial thrombosis is much rarer than with venous thrombosis, there is emerging evidence that inhibitor deficiency may constitute a low but significant risk for myocardial infarction.

Most clinically affected individuals are heterozygous for the abnormal gene. Homozygous protein C and protein S deficiencies typically present shortly after birth with purpura fulminans, the result of widespread microvascular thrombosis, leading to extensive skin necrosis and severe disseminated intravascular coagulation. Homozygous AT deficiency is very rare, and the few reported individuals usually have deficiency caused by mutations altering heparin binding and suffer arterial events or severe and recurrent venous thromboembolic disease. Homozygous factor V gene mutation has been identified much more frequently, and the clinical consequences seem less severe than with the other homozygous deficiencies.

In all heterozygous deficiencies, the incidence of thrombosis is age related. It is unusual for an episode to occur before teenage years. Although events such as immobilization, hospitalization, or pregnancy may trigger a thrombosis, in approximately 50% of cases, no predisposing event can be identified. Incidence rates of thrombosis in affected individuals are difficult to ascertain from the literature, but for aPC resistance, about 25% of aPC resistant relatives of probands presenting with venous thrombosis will also suffer a thrombotic episode before the age of 50. The risk for homozygously affected individuals is higher, with about 40% suffering an event by the time they are in their thirties. In heterozygotes for aPC resistance, the risk of thrombosis is increased sevenfold, compared to the unaffected population, with a 30-fold increased risk in the subgroup of affected females taking oral contraceptives. The risk of thrombosis caused by a genetic defect in PS has recently been estimated as ~10-fold. A general impression, not yet adequately supported by quantitative population-based data, is that the risk of thrombosis for heterozygotes increases in the order FV 506 Arg to Gln/protein C/protein S/antithrombin deficiency.

Table 24-1
Incidence of Defects Associated with Venous Thrombosis

	Normal population	*Patients with DVT, %*
AT Deficiency	1:5000 to 1:350	2–5
PC Deficiency	1:16000 to 1:250–300	2–4
PS Deficiency	1:15000	~ 5
aPC resistance	1–5%	30–60
Fibrinogen defects	?	<1

LABORATORY ASSESSMENT   Standard laboratory assays—both functional and immunological—are used to measure AT, protein C, and protein S in those presenting with thrombosis. For protein S deficiency, both total and free protein S antigen are assayed, the free protein S being that fraction that is unbound to C4b binding protein. At present, there is an awareness that functional assays for protein S are far from satisfactory. Resistance to aPC is identified in the laboratory by using clotting assays from commercially available kits and followed up by DNA analysis for the factor V 506 Arg to Gln mutation. This defect can be identified by *Mnl*I restriction analysis of a specifically amplified FV gene sequence.

There is no consensus as to precisely which patients should be screened biochemically for defects predisposing to thrombosis. Guidelines suggested by the British Society for Hematology includes those suffering from venous thromboembolism before age 40–45 years, recurrent venous thrombosis or thrombophlebitis, thrombosis in an unusual site (e.g., mesenteric vein, cerebral vein) unexplained neonatal thrombosis, arterial thrombosis before age 30, patients with a clear family history of thrombosis, and patients with recurrent fetal loss.

GENETIC BASIS OF DISEASE AND MOLECULAR PATHOPHYSIOLOGY

PRINCIPLE ENDOGENOUS ANTICOAGULANT PATHWAYS   Figure 24-1 depicts the site of action of the major anticoagulant pathways that have been identified; AT/heparan sulfate, protein C/protein S/thrombomodulin and tissue factor pathway inhibitor (TFPI), and the fibrinolytic system. Additionally, several other proteins have minor anticoagulant activities, as indicated. The generation of the activated serine proteinase thrombin, factor IIa, is the crucial event in the coagulation pathway in that it promotes the formation of the fibrin clot. The anticoagulant proteins act at various strategic points to downregulate the coagulation cascade. Antithrombin directly inactivates the coagulation proteinases—reactions that can be accelerated by heparin-like molecules, such as heparan sulfate. Another anticoagulant mechanism involves thrombin as the trigger. Thrombin, when complexed to an endothelial cell surface protein, thrombomodulin, is able to activate protein C. aPC, in association with protein S as a cofactor, downregulates the coagulation cascade by inactivation of activated coagulation factors Va and VIIIa. Tissue factor pathway inhibitor also has anticoagulant activity, inhibiting tissue factor/factor VIIa/factor Xa. As yet, no clear association between TFPI deficiency and thrombosis has been recognized. This chapter will only consider the first two major pathways.

AT/HEPARAN SULFATE PATHWAY

Normal Structure and Function of AT   Plasma AT is a 58-kDa single-chain glycoprotein, primarily synthesized in the hepatocytes, where a 32 amino acid signal peptide is removed prior to export of the 432 residue mature protein. Six cysteines form three intramolecular disulfide bonds, 8 Cys—128 Cys, 21 Cys—95 Cys, and 247 Cys—430 Cys, and there are four glycosylation sites at Asn residues 96, 135, 155, and 192 (Fig. 24-2). AT shares sequence and structural homology with other members of a family of serine proteinase inhibitors (collectively referred to as the serpins), which include members such as α_1-antitrypsin and ovalbumin. AT structure conforms to the helical/β-sheet model with 30% helices (nine helices, denoted A–I) and 40% β-sheet (five sheets). The reactive site bond of AT is located towards the C-terminus of the protein between residues Arg393 and Ser394 (designated P_1-P_1') in a protruding reactive center loop that is exposed to attack by the proteinases.

The other important functional domain is the glycosaminoglycan binding region, which is involved in the interaction with heparin and endothelial cell surface heparan sulfate proteoglycans. This domain is remote from the reactive center and includes the amino-terminal end and helix D, a region that contains a relatively high density of positively charged amino acids. The two functional domains—reactive center and heparin binding site—are conformationally linked, so that induced perturbations of one may influence the function of the other. AT inhibits the activated serine proteinases by acting as a pseudosubstrate. The proteinases attack and attempt to cleave the reactive site bond, P_1-P_1' (393 Arg-394 Ser) of AT, which subsequently undergoes a major conformational change. This involves partial insertion of one end of the reactive site loop into the β-sheet as an extra strand (strand 4), trapping the proteinase in an irreversible 1:1 complex. The inactive AT-proteinase complex is subsequently rapidly removed from the circulation. The rate at which AT and thrombin interact is accelerated in the presence of heparin, or in vivo, by (heparin-like) heparan sulfate proteoglycans that are located on the surface of endothelial cells. Heparin is a heterogeneous mixture of oligosaccharides of varying chain length. A minimum of five specific saccharide units is required to enhance anticoagulant activity of AT against factor Xa, whereas at least 18 monosaccharides (including the specific pentasaccharide sequence) are required for effective enhancement of AT inhibition of thrombin. Endothelial surface heparan sulfate is structurally much more heterogeneous than heparin, but it is known to contain elements that enable binding of AT and facilitate enhanced proteinase inhibition.

AT Gene Structure   The *AT* gene is located on chromosome 1q23–q25 and is 13.8 kb in length with seven exons, encoding a signal peptide of 32 aa and a mature protein of 432 aa (Fig. 24-2). The complete nucleotide sequence of the AT has now been determined; of particular interest is the presence of nine full-length and one partial-length Alu repeat elements located within the introns of the AT gene. These repeats comprise 25% of the intron sequence, which is considerably higher than the estimated 5% of the human genome accounted for by Alu repeats. Two of the Alu repeats, Alu 5 and Alu 8 within intron 4, have tails composed of trinucleotide (ATT) repeats that are polymorphic in copy number.

Commonly identified control regions such as the TATA box, the CCAAT box, or GC elements are not found in the 5'-untranslated region of the gene. Two regions have been identified in the 5' end of the gene, which appear to act as regulatory elements
Figure 24-1 Plasma anticoagulant pathways. The events of coagulation are summarized by the large arrow, with initiation by tissue factor (TF)-factor VIIa. The three major anticoagulant pathways, involving AT, protein C-protein S-thrombomodulin, and tissue factor pathway inhibitor (TFPI), and their targets are indicated, as well as other proteins which have some antithrombin activity.
Figure 24-2 Structure of the AT gene and protein. **(A)** Genomic organization with the exons numbered according to convention. Arrows indicate the positions of 10 Alu repeat sequences within the introns. Sequence polymorphisms are marked: L, length dimorphism; P, *Pst*I site; N, *Nhe*I site; D, *Dde*I site; (ATT)n trinucleotide repeat length polymorphisms in the tails of Alu 5 and Alu 8. **(B)** AT protein (not to scale), showing residues involved in disulfide bonds and Asn-linked glycosylation sites.

and that apparently confers some tissue-specific control of expression. A single transcription start site is localized 72 bp 5' of the ATG initiation codon, whereas the 3' end of the gene contains the polyA sequence, AATAAA, located 49 bp 3' to the termination codon. The cleavage/polyadenylation site is located 24 bp downstream from the AATAAA sequence. In addition to the polymorphic tails of the Alu repeats in intron 4, the AT gene contains a number of sequence polymorphisms that include a 76 bp length polymorphism at the 5' end of the gene and four single base variations, three of which involve restriction enzyme cleavage sites (*see* Fig. 24-2). These polymorphisms have proven to be extremely useful in the construction of *AT* gene haplotypes for tracking particular *AT* alleles within families and for tracing the origin of repeated *AT* mutations.

AT Deficiency AT deficiency may be inherited or acquired. This short article will concentrate on the hereditary AT deficiencies.

The incidence of hereditary AT deficiency has been estimated at between 1 in 2000 and 1 in 5000 in the normal population. However, according to a recent survey of Scottish blood donors, the incidence may be much higher—1 in 350—with most of these individuals being clinically asymptomatic.

Inherited AT deficiency is associated with a venous thrombotic tendency that increases with increasing age, although there is still uncertainty regarding the prevalence of thromboembolism in affected individuals. The risk of thromboembolism varies with the type of molecular defects *(see below)*. Defects causing AT deficiency are distributed mainly in the coding regions of the gene. In the most recently published AT mutation database, a total of 256

mutations were reported, 143 of which were unique molecular events. AT deficiency is classified as two main types: type I and type II. Type I deficiency is characterized by a quantitative reduction of AT at both the antigen and functional level to approximately 50% of normal, whereas in type II deficiency the antigen level is near normal, but functional activity is reduced, indicating the presence of a dysfunctional variant.

Type I AT Deficiency   The database of mutations lists 113 cases, 92 of which are unique molecular events. The majority of cases are caused by single nucleotide changes and short insertions or deletions; most of these mutations result in premature translation termination codons. Mutations that potentially affect mRNA splicing have also been identified but, unlike protein C, only a small number of type I deficiencies are associated with missense mutations. Large deletions of the AT gene are detected in less than 10% of cases of type I deficiency; only 12 cases are listed in the database. In one of these that has been fully characterized, exon 5 and flanking intron sequences were deleted, the deletion having arisen by homologous recombination between Alu repeat elements located in introns 4 and 5 of the AT gene.

Type II AT Deficiency   Type II deficiency can be subdivided according to the properties of the variant AT into those with abnormalities primarily affecting heparin binding, those with impaired reactive site function and those with pleiotropic or multiple abnormalities that demonstrate disturbance of both heparin-binding and proteinase inhibition. Additionally, many of the latter variants are present at reduced concentration in the plasma.

Analysis of variants with reduced heparin affinity has contributed to the delineation of the heparin-binding site of the normal AT protein. Substitution of two classes of residue produce reduced heparin affinity: residues making direct contact with the heparin chains and residues that control access to or overall conformation of the heparin-binding surface. Substitutions affecting positively charged Arg residues at positions 24, 47 (in exon 2 of the AT gene) and 129 (in exon 3 of the AT gene) probably alter contact sites with the chains of negatively charged heparin oligosaccharides. Modeling of normal AT shows that these residues are clustered to form a positively charged surface, involving the A and D helices of the protein. Other substitutions affecting 41Pro, 99Leu, 116Ser, and 118Gln probably affect heparin affinity by altering conformation of the heparin-contact domain.

AT variants in which primary abnormality is defective reactive site function have mutations confined to two distinct regions of the protein, near the C terminus. The residues 393 Arg-394 Ser form the reactive site bond, P_1-P_1', of AT protein. Substitutions affecting 392Gly, 393Arg, and 394Ser all result in reduced inhibition of serine proteinases. Another group of reactive site variants have mutations affecting the P_{12} and P_{10} residues, 382Ala and 384Ala; in addition to being functionally inactive, these variants act as substrates for thrombin and are cleaved at their reactive sites by thrombin. An explanation for the substrate behavior can be derived by considering the structures of cleaved and uncleaved serpins. Following cleavage of the reactive site loop the P_1 and P_1' residues move to opposite poles of the protein, and the P_4-P_{14} residues of the reactive site α-helix insert as strand 4 into a now six-stranded β-sheet. Partial insertion of the reactive site loop into the β-sheet appears essential to stabilization of the serpin–proteinase complex. It is likely that insertion is inhibited by the bulkier side chains of the substituted P_{10}–P_{12} amino acids that are situated in the hinge

region, and failure or delay of strand insertion results in substrate rather than inhibitor activity.

AT variants with pleiotropic abnormalities have substitutions in residues 402–407 and 429, in or adjacent to strand 1C at the C terminal end of the protein. These variants demonstrate reduced heparin affinity, as well as impaired proteinase inhibition. The combination of these properties may be explained by a conformational disturbance transmitted to both the reactive site and the heparin-binding domains.

There is clinical benefit in defining the type of AT deficiency, as individuals with heterozygous type II deficiency resulting from AT variants with reduced heparin affinity alone have a substantially reduced risk of thrombosis when compared to other AT deficient individuals.

PROTEIN C/PROTEIN S/THROMBOMODULIN SYSTEM
Normal Structure and Function of Protein C and Protein S
Protein C (mol wt 62,000) is synthesized in the hepatocytes and is found in plasma principally as a two-chain molecule, generated by proteolysis at the 156Lys–157Arg bond (Fig. 24-3). The N-terminal end of the mature protein contains six residues that undergo posttranslational vitamin K-dependent modification to γ-carboxyglutamic acid (the Gla domain). This region is involved in the interaction of protein C with Ca^{2+} and phospholipid surfaces and is crucial for the anticoagulant activity of the inhibitor. Other structural motifs include two epidermal growth factor (EGF)-like domains, the activation domain and the catalytic domain. Thrombomodulin-bound thrombin activates protein C by cleavage of the 169Arg–170Lys bond, resulting in the release of a 12 amino acid activation peptide from the N-terminal end of the heavy chain. The catalytic domain shows considerable sequence similarity with other serine proteinases, containing the characteristic catalytic site formed by 211His, 257Asp, and 360Ser.

Protein S (mol wt 70,000) is synthesized as a precursor of 676 amino acids, with a leader sequence of 41 residues, by hepatocytes, endothelial cells, and megakaryocytes. Like protein C, protein S has a number of recognizable structural motifs, including a Gla domain, a thrombin-sensitive region, four EGF-like domains, and a large C-terminal region that has homology to sex hormone binding globulin (Fig. 24-4). Approximately 60% of protein S in the plasma is bound to C4b-binding protein, the complexed fraction not demonstrating anticoagulant cofactor activity; the noncomplexed fraction is known as free protein S. Precisely how protein S functions as an anticoagulant cofactor is unknown and is subject of ongoing investigation.

Protein C Deficiency   The structure of the protein C gene is shown in Fig. 24-3. The gene spans 12 kb and has been mapped to chromosome 2q13–q14. Protein C deficiency can also be classified into type I and II subtypes, with a similar definition as that for AT. In the recently reported mutation database, 315 cases are listed, with 334 mutations, comprising 160 unique molecular events. Most deficiencies are associated with point changes or short insertions or deletions affecting the coding region of the gene, mRNA splicing or the promoter region. Included in the database are 18 homozygotes and 17 compound heterozygotes. By far, the greatest number of cases, 243 total with 107 unique mutations, to have missense mutations, causing mainly type I deficiency. Why so many amino acid substitutions should give rise to type I (quantitative) deficiency is not clear, but it suggests that the primary amino acid sequence is crucial to the correct ternary structure and stability of the protein. Substitutions within the Gla domain, at the

propeptide cleavage site, the thrombin cleavage site (169Arg) and the 211His reactive site residue have been found in type II deficiency. An aspect of recent interest has been the origin of different clinical presentation in families with protein C deficiency. Several reports have implicated heterozygous protein C deficiency as a severe risk factor for thrombosis, with many family members
Figure 24-5   Structure of coagulation factor V protein. The protein is composed of three A domains, two C domains and a connecting region, the B domain. Thrombin cleavage at the indicated residues results in the two chain active factor V. Sites cleaved by activated protein C and resulting in inhibition of active factor V are also shown.

presenting with thrombosis: this has been termed "clinically dominant" deficiency. On the other hand, heterozygous members of families of clinically severely affected individuals with homozygous or compound heterozygous deficiency have been found to be largely free of thrombosis: this has been termed "clinically recessive" deficiency. Inspection of the protein C mutation database reveals that many cases of "dominant" and "recessive" deficiencies have the same genetic defects. An explanation for the difference in clinical presentation has been provided by the demonstration of the presence of an additional risk factor for thrombosis, factor V 506 Arg to Gln, in some of the families.

Protein S Deficiency   The protein S gene which spans more than 80 kb, is located on chromosome 3p11.1–p11.2 (Fig. 24-4). Protein S deficiency has been classified into three main types. Type I deficiency results from a reduction in total protein S antigen (and of free protein S antigen and activity). Type II deficiency is defined by the presence of a functionally abnormal variant protein S molecule (total protein S antigen, normal; free protein S antigen, normal; but protein S activity, reduced). Type III deficiency is defined by normal total protein S antigen, but reduced free protein S antigen and activity. Recent genetic study of a large kindred has shown that type I and III deficiencies are manifestations of the same underlying geneotype arising from age-related changes in total PS levels in plasma. It is suggested that the level of free PS is the best indicator of the risk of thrombosis associated with a gene defect.

A protein S pseudogene has been identified, in which exon I of the functional gene has been deleted but otherwise demonstrates only 3% nucleotide sequence divergence. Characterization of the defects underlying protein S deficiency has been complicated by the presence of this pseudogene, although it is possible to specifically amplify sequences from the functional gene only by judicious choice of oligonucleotide primers. A number of mutations have now been summarized in the protein S mutation database, 126 point mutations and 3 partial gene deletions. The mutations causing type I deficiency are distributed throughout the coding sequence, while those causing type III deficiency tend to be concentrated in the sex hormone binding globulin-like domain. However, a single amino acid substitution, 460 Ser (to Pro), accounts for the majority of these latter cases and doubts have been raised whether this mutation constitutes a risk factor for thrombosis. Only a small number of mutations have been shown to be associated with type II deficiency.

FACTOR V   Normal Structure and Function of Factor V
Factor V is a single chain glycoprotein (mol wt 300,000) that is

synthesized in the liver and in megakaryocytes. Factor V is activated by thrombin and factor Xa during coagulation activation, by cleavage at Arg709-Ser710, Arg1018-Thr1019, and Arg1545-Ser1546 (Fig. 24-5). Activation results in a heavy and light chain (mol wt 105,000 and 74,000, respectively) noncovalently linked by calcium ions. Factor Va is inactivated by cleavage of the heavy chain by aPC. Several sequential cleavages are known to occur, but of particular importance is cleavage adjacent to 506 Arg. If this cleavage site is blocked by mutation of the Arg, inactivation of factor Va is impaired. In this circumstance, the protein C/protein S/thrombomodulin anticoagulant pathway does not function effectively.

Resistance to aPC: factor V 506 Arg to Gln Mutation   The protein C/protein S/thrombomodulin pathway can be investigated by performing an APTT reaction in the presence and absence of aPC. The ratio of results forms the basis of commercial aPC resistance tests. An abnormality in this test is the single most common phenotypic abnormality detected in patients with venous thromboembolism and is also found in approximately 5% of the general population (Table 24-1). A single amino acid substitution within coagulation factor V, 506Arg to Gln, resulting from the nucleotide substitution 1691G to A, is the only genetic defect that has been reported to date and accounts for 95% of the cases of aPC resistance. Cleavage at the normal 506Arg by aPC is correlated with the loss of factor Va coagulant activity, and replacement of 506Arg with Gln slows cleavage so that coagulant activity is retained. It is worth noting that some reports suggest that the lupus anticoagulant–antiphospholipid syndrome may result in aPC resistance. Additionally, some cases originally identified by plasma assay as protein S deficient have been redefined as aPC-resistant.

MANAGEMENT

ACUTE VENOUS THROMBOEMBOLISM   Heparinization represents the first line of treatment of acute venous thrombosis with or without embolism, followed by maintenance on warfarin. Heparin may conveniently be administered by continuous intravenous infusion, to maintain the APTT 1.5–2.0 times above normal limits. Alternatively, heparin may be administered by intermittent injection, although control is more difficult. Thrombolytic therapy may be necessary in some cases of massive thromboembolism. It is convenient to begin warfarin at the same time as the heparin, although care must be taken when initiating warfarin therapy in protein C deficient individuals, because of the risk of warfarin-induced skin necrosis; this has also been reported in some cases of protein S deficiency. In this circumstance, oral anticoagulation

should be begun slowly and under full heparin cover. The degree of anticoagulation induced by warfarin is monitored by the International Normalized Ratio (INR); for a first episode of thrombosis or following pregnancy, the INR should be maintained within the 2.0–3.0 range, whereas the higher range of 3.0–4.0 is required for treatment of recurrent disease. The duration that treatment is required is not established, although a minimum of 3–6 months is reasonable, and many consider that two distinct clinical events merits lifelong prophylaxis. Protein C concentrates are used to treat the severe complications of homozygous deficiency, in addition to anticoagulation, and maintenance therapy with blood product may be required. AT concentrates are also available and may be used in the management of venous thromboembolism or at parturition in heterozygous deficient patients but are probably best reserved for those cases not responding to standard treatment, as no definitive clinical trials have been performed.

PREGNANCY Pregnancy represents an extremely high-risk situation, and its management is both difficult and complex. Individuals with previous history of thrombosis should be treated and the treatment may include oral warfarin or heparin. Warfarin may be teratogenic during the first trimester and is associated with an increased risk of fetal hemorrhage. Accordingly, care should be taken to change from oral anticoagulants to heparin as soon as pregnancy is confirmed, or preferably, when a pregnancy is planned. Heparin can be self-administered and continued until the second or early third trimesters. At this time, oral anticoagulants can be given until just before term. At the time of delivery, anticoagulants should be discontinued. It has been recommended that heparin plus oral anticoagulants be resumed 48–72 h after delivery and continued for 3 months postpartum. The reference list contains articles detailing therapeutic options in greater detail.

ASYMPTOMATIC INDIVIDUALS The management of asymptomatic individuals with an anticoagulant deficiency is problematic. Most would agree that the patient should be counseled as to the additional risk factors that may predispose to a thrombotic episode and that following diagnosis, family members should be investigated to identify affected—but asymptomatic—individuals. A retrospective survey of individuals with hereditary AT deficiency carried out in the Netherlands found no excess in the mortality rate, the authors concluding that anticoagulant prophylaxis for asymptomatic affected individuals was not indicated. This view must be tempered by clinical judgment, however, because of the marked variability of clinical presentation observed between different kindreds. Lifelong prophylaxis with anticoagulants is not justified in asymptomatic individuals, but prophylactic anticoagulation should be offered to deficient individuals in situations presenting a recognized risk of thrombosis, such as pregnancy and surgery. In view of its remarkably high incidence and ease of detection, it is being debated whether individuals in high-risk situations (e.g., before major surgery, pregnancy, and before starting oral contraception) should be routinely screened for aPC resistance.

FUTURE DIRECTIONS

Many individuals with deficiency of the naturally occurring anticoagulant mechanisms remain asymptomatic for much of their lives. In a proportion of individuals suffering thrombosis, no predisposing abnormality can be identified, suggesting that other genetic factors remain to be discovered. In addition to defects resulting in recognizable deficiency of the anticoagulant pathways,

it seems likely that genetic effects on "normal" levels of anticoagulant activity may also be important. This has been shown for protein C, where sequence differences in the promoter region of normal protein C genes significantly influence the plasma levels of the protein. It is clear that the phenotype of venous thrombosis develops from multiple interacting genetic and environmental factors; it may be that analysis of interacting genetic factors will improve the risk prediction for thrombotic events in affected families. Until recently, inhibitor deficiencies were of too low prevalence to enable properly controlled clinical trials of prophylaxis and treatment to be undertaken. The high prevalence of the factor V 506 Arg to Gln mutation has transformed the prospects for progress in this area. The challenge remains to identify additional genetic risk factors that predispose to thrombosis and that interact with known acquired/genetic factors. Recently, the 20210 G-to-A mutation in the prothrombin gene found in 1% of the population was shown to be a significant but weak risk factor for venous thrombosis and a significant risk factor for myocardial infarction in young women. Hyperhomocysteinemia has been shown to be associated with venous thrombosis, and some, but not all studies have implicated a mutation in the methylenetetrahydrofolate reductase gene (C to T at 677). Finally, thrombomodulin gene mutations are increasingly being found in association with venous and arterial thrombosis.

25 Paroxysmal Nocturnal Hemoglobinuria

Bruno Rotoli and Khedoudja Nafa

INTRODUCTION

Paroxysmal nocturnal hemoglobinuria (PNH) is a complex hematological disorder probably first described three centuries ago, and regarded as a mystery until the 1980s, when most of its pathophysiology was elucidated, followed by the 1990s, when the underlying molecular defect was finally unraveled. The original denomination, PNH, stresses only one component of the disease (i.e., a hyperhemolytic state). A more complete contemporary definition could read as follows: an acquired blood disorder characterized by the expansion of one or a few hematopoietic cell clones that are unable to produce the glycosyl-phosphatidyl inositol (GPI) anchor, against the background of a reduced bone marrow activity. Some landmarks in the history of understanding this disorder are listed in Table 25-1. Because of its complex pathophysiology, this disorder has been variously classified among hemolytic anemias, myelodysplasia, myeloproliferative disorders, or bone marrow failure syndromes; indeed, PNH has some features of each of these. Here we will briefly summarize clinical, diagnostic, and therapeutic features, and we will then review in some detail recent progress on the genetic and pathophysiological aspects of PNH.

CLINICAL FEATURES The disease is rare (prevalence about 1–2 per million), but it occurs throughout the world, with increased prevalence in parts of Asia (i.e., Thailand, China), where an unexplained higher incidence of aplastic anemia is also observed. PNH is characterized by chronic hemolytic anemia with erratic exacerbations, frequent leukopenia and thrombocytopenia, tendency to thrombosis and, to a lesser extent, tendency to infection. The clinical picture can be anything from mild to severe, severity being dictated by extreme pancytopenia (the PNH/aplastic anemia syndrome), hyperhemolysis, or recurrent thrombosis (hemolytic type). Although the disease is not malignant (progression to acute leukemia is very rare, and the frequency may have been overestimated), with a median survival of 10 years in large series, the course may be stormy and the quality of life poor.

DIAGNOSIS A mild jaundice without splenic enlargement, anemia with moderate reticulocytosis, raised serum LDH, episodes of dark urine, and hemosiderinuria are clues to the diagnosis. Until the late 1980s, the only confirmatory test was the Ham test (lysis of a portion of red cells in acidified serum); simpler but less specific tests are the sucrose and the sugar-water tests (red cell lysis in serum with reduced ionic strength). At present, flow cytometry studies on blood cells *(see below)* are more sensitive and more specific than hemolytic tests. More recently, with the discovery of the causative gene, molecular studies on DNA or mRNA from nucleated blood cells have become valuable diagnostic tools.

GENETIC BASIS

Although this disease has a well-recognized genetic cause, it is neither inherited nor transmitted to the progeny. Indeed, it is a clonal disorder arising from a somatic mutation in the phosphatidyl inositol glycan class A *(PIG-A)* gene of an early hematopoietic progenitor.

THE *PIG-A* GENE AND THE GPI-ANCHOR *PIG-A* is a housekeeping gene located on the short arm of the X chromosome (Xp22.1), the cDNA of which was first isolated by Kinoshita's group in 1993 through expression cloning and complementation of GPI-deficient cell lines. The organization of the genomic gene was established by Bessler in 1994 (Fig. 25-1). *PIG-A* is a conserved gene that encodes for a protein involved in the synthesis of the glycosyl-phosphatidyl inositol (GPI) anchor. This molecule is used by cells to bind a number of proteins without a transmembrane portion on the outer surface. The functional implications of the GPI-anchoring of proteins are not completely understood; they include ease of assemblage and of shedding, lateral mobility, capping, involvement in endo-, exo-, and potocytosis (a clathrin-independent form of endocytosis and recycling). There are examples of proteins existing in both a transmembrane and a GPI-linked configuration. The adhesion molecule LFA-3 (CD58) is encoded by a gene that may undergo alternative splicing, producing the two different configurations; FcγR-III (CD16) is encoded by two different genes, one of which provides the site for GPI-anchor attachment. The strongest evidence that this type of membrane anchorage is important in cell biology is its high conservation among eukaryotic cells (e.g., it is found in yeast and in trypanosomes). The protein encoded by *PIG-A*, in combination with at least two other proteins, is essential in the very first step of the complex GPI-anchor biosynthesis pathway (i.e., in the transfer of *N*-acetyl glucosamine to phosphatidyl inositol [Fig. 25-2]). By experimental mutagenesis, GPI-deficient cell lines showing defects in any of the various metabolic steps have been produced. However, the study of PNH has shown, perhaps surprisingly, that the same early step is impaired in all patients, and all patients have a mutation in the *PIG-A* gene. The favored explanation for this finding is that among the various genes involved in GPI-anchor synthesis, *PIG-A* may be the only one that is X-linked. As a result, a single mutation in that gene will produce an abnormal cell in either sex: males have

Table 25-1

AchE, acetylcholinesterase; NAP, neutrophil alkaline phosphatase; AF, decay accelerating factor (CD55).

only one allele and females have only one functional allele (as a result of X-chromosome inactivation). Although females have two *PIG-A* alleles, only one half of the mutations will occur in the functional X; thus, the risk of having the disease is the same in both genders. Since a defect causing a metabolic block is generally recessive, it is very unlikely (although not impossible) that a double mutation targeting both alleles of an autosomal gene in the same cell may occur in vivo.

PIG-A MUTATIONS IN PNH　Practically all types of mutations have been found in the *PIG-A* gene of PNH cells: small deletions or insertions with frameshift, nucleotide substitutions resulting in a stop codon, missense mutations causing amino acid substitution or new sites for alternative splicing, and large deletions. Most of the mutations occur in exon 2, which is the largest; however, no particular clustering of mutations has emerged, and almost all mutations are unique to each patient (*see* Fig. 25-1).

If we compare the type of mutations found in PNH with those found in another—this time inherited—X-linked disorder of a housekeeping gene (i.e., G-6PD deficiency) a clear discrepancy is apparent. In PNH, the vast majority of mutations lead to truncated proteins, whereas missense mutations are rare; in G-6PD deficiency almost all mutations are missense. Two considerations may be relevant to this discrepancy.

1. In hereditary disorders, a complete lack of a housekeeping gene product is probably lethal; thus, we only see mutations with residual activity. By contrast, if a mutation is somatically acquired, it will not affect organ development and, once occurred, it will affect the genetic make-up of only a small fraction of somatic cells.
2. If missense mutations in PNH are rare, this means that for a clonal expansion to take place, the gene damage must be serious.

Indeed, several of the missense mutations found in PNH patients are associated with a complete absence of GPI-linked proteins, indicating that they affected seriously either mRNA stability, protein function, or both.

MOLECULAR PATHOPHYSIOLOGY

The *PIG-A* mutation responsible for PNH arises in a multipotent hematopoietic stem cell, which is then capable of differentiating along several lineages: erythroid, myeloid, and megakaryocytic differentiation capabilities are almost always preserved, whereas lymphoid differentiation (along B- and/or T-lineages) is observed in only a minority of patients. As a consequence of the damage of the GPI-anchor synthesis pathway, all the affected cells in any state of maturation are deficient in all the GPI-linked molecules, and deficiency is often complete. Up to now, at least 19 different proteins sharing the GPI-anchoring system have been described on the surface of human blood cells (Fig. 25-3). Our understanding of their functional significance is rather limited; in some cases, the very study of PNH patients or cells has been an important source of information. CD59/MIRL and CD55/DAF are the most typical examples: we now know that they are two complement-regulatory proteins, the absence of which renders PNH erythrocytes extremely sensitive to complement activation, and this is translated in vivo into a hemolytic state and in vitro into a positive Ham or sucrose test. A low level of complement activation is probably a constant physiological phenomenon, which is greatly amplified during inflammatory or infectious diseases; thus, PNH erythrocytes are chronically lysed with paroxysmal exacerbations. It is still unclear why exacerbation occurs mainly during the night. In a functional hierarchy, CD59 plays the major role. This was discovered by studying rare inherited conditions in which a single molecule is lacking: a CD59-deficient patient had a PNH-like picture, whereas subjects deficient in CD55 on red cell membrane (those carrying the rare Inab blood group phenotype) are almost normal. Although CD59 and CD55 are deficient also on leukocytes, there is no evidence of reduced leukocyte lifespan in PNH patients, probably because nucleated cells have an additional transmembrane (i.e., non–GPI-linked) molecule (CD46) that protects them from complement activation. Sensitivity to complement is the best known, but not the only defect, of PNH cells. Table 25-2 lists other molecules that are deficient with the specific function of each of them, if known. The surface abnormalities of PNH cells can be
Figure 25-1 *PIG-A* gene structure and mutations. The genomic gene spans approximately 17 kb. Exons (thick blocks, numbered) and introns (thin lines) are represented in the central bar; untranslated exon regions are in gray. Three mRNA transcripts arising from alternative splicing were found by Bessler et al., who also described an unproductive pseudogene mapped to 12q21. All the mutations found so far are displayed. ⬭, small deletion or insertion, with frameshift and truncated protein; ⬭, nonsense mutation; ⬭, mutation causing altered splicing; ▭, vast deletion; ⬭, deletion, in frame; ⬭, missense mutation. *Mutations found in more than one patient. A small letter outside the box identifies multiple mutations found in a single patient. Only one polymorphism has been described so far (55C→T, 19 art→trp).

also used for diagnostic purposes. Flow cytometry using fluoresceinated antibodies against GPI-linked molecules (Fig. 25-4) is a very sensitive contemporary diagnostic tool, by which a PNH abnormality can be identified even at a very early stage. In addition, it makes it possible to pinpoint which cell lineages are involved and to what extent.

CLONAL DOES NOT NECESSARILY MEAN MONO-CLONAL The presence of more than one abnormal cell population in a single PNH patient was first inferred by functional studies. In 1966, Rosse and Dacie found in a single patient a proportion of red cells that were three- to fivefold more sensitive to complement (which they called PNH II cells) and a proportion that were 15- to
Figure 25-2 GPI-anchor biosynthesis. The anchor synthesis is a multistep (1–9) process that occurs in the endoplasmic reticulum (ER), starting in the cytoplasmic side, then flipping into the luminal side. It is then transferred *en bloc* on the C-terminal of the protein, which is cleaved of a short sequence of 20–30 amino acids led by a signal sequence called ω. While GPI-deficient cell lines obtained by experimental mutagenesis have shown defects in any step of the synthesis, all PNH patients studied so far are defective in the first step (⊣⊢⊢).

Figure 25-3 GPI-linked molecules on blood cell surface. For each cell type, molecules are listed in order of sensitivity for detecting deficient cells (in bold: highest sensitivity). (…), weak expression; *, also transmembrane; #, increased upon cell activation; ##, expressed only upon cell activation. (a) About 25% of early hematopoietic progenitors express CDw90, which is an analog of the murine Thy-1. (b) In our hands, CD59 was always present on PNH monocytes. We have omitted a few other molecules that may need better characterization (HRF,NB1, Group 8, Mo3, p50–8-). (Reprinted with permission from B. Rotoli et al., Blood Reviews, 1993;7:78.)

25-fold more sensitive (PNH III) as compared to normal red cells. In the early 1990s, the establishment of lymphoblastoid cell lines has confirmed this finding: in a number of cases, two cell lines differing in their cytofluorometric pattern were obtained. Finally, DNA analysis has shown two different *PIG-A* mutations in several patients (Fig. 25-1).

A mechanism that may explain the expansion of more than one clone carrying the same functional defect, but arising from different mutations, is positive selection. A theory based on this mechanism was developed for PNH in 1989 and termed the "relative advantage" or the "escape" hypothesis; it is supported by several pieces of circumstantial evidence and still requires a direct confirmation. According to the relative advantage theory, a mutation in the *PIG-A* gene might be a fairly common phenomenon, which has no biological consequences, because the mutated cell has no chance of expanding or even of survival. However, if normal hematopoiesis is inhibited by a primary cause, and if the inhibition mechanism is mediated by one or more proteins that are GPI-linked on the surface of progenitor cells, *PIG-A* mutated cells acquire a relative advantage and may undergo clonal expansion. Because only cells severely GPI-deficient may escape, this explains why serious molecular lesions (i.e., frameshift, stop codon, deletion) prevail over single amino acid substitutions. A recent observation from Germany indirectly supports this hypothesis: in a few patients with B-cell non-

Hodgkin lymphoma experimentally treated with Campath-1H (a monoclonal antibody that kills T lymphocytes using the GPI-linked protein CDw52) severely GPI-deficient T cells appeared; they were cloned and showed mutations in the *PIG-A* gene. On Campath-1H discontinuation, the GPI-deficient T cells gradually disappeared. In order to explore experimentally the growth of PNH hematopoietic stem cells, the mouse *PIG-A* gene was inactivated in embryonic stem (ES) cells using the conventional knockout gene targeting technique. In vitro preliminary studies demonstrated that *PIG-A* deficient ES cells were able to differentiate into mature cells of various hematopoietic lineages. However, when tested in vivo, in the few surviving chimeras the proportion of GPI-deficient blood cells was low at birth and decreased with aging, thus proving that there is no absolute growth advantage for PNH cells as compared to normal cells coexisting in the same organism. If the escape theory is confirmed, several implications must be borne in mind:

1. PNH patients always have two concomitant defects: (a) one (or a few) early hematopoietic progenitor cells carrying a *PIG-A* mutation; and (b) a bone marrow failure syndrome, the mechanism of which is permissive for the expansion of GPI-deficient cells. This would explain the frequent association of PNH with aplastic anemia (AA) and the increased incidence of PNH in countries where AA is more frequent.

Table 25-2
Functions of GPI-Linked Proteins on Blood Cells

Antigen	Alternative denomination	Function
CD14	LPS-LPB-r	Monocyte adhesion and activation
CD16b	FcγR-IIIb	Low affinity receptor for IgG
CD24		Ca^{2+} flux, triggers H_2O_2 production by PMN
CD48	BLAST-1	Counter-receptor for CD2
CD55	DAF	Accelerates C3 and C5 convertase decay
CD58	LFA-3	Counter-receptor for CD2
CD59	MIRL	Binds C8/C9, thus inhibiting MAC assembly
CD66b	CGM6 (CEA family member)	Granulocyte adhesion/activation
CD66c	NCA	Granulocyte adhesion/activation
CD73	5'-NT	Purine/pyrimidine ribo/deoxyribonucleoside phosphorilation
CD87	uPAR	Urokinase receptor
CDw52	Campath-1	Unknown
CDw90	Thy-1	Adhesion
CDw108		Unknown
CDw109	Platelet Gove/b alloantigen	Unknown
ACHE		Enzyme, unknown substrate on RBC
NAP		Enzyme, granulocyte function
JMH		Unknown

2. The PNH clones, although responsible for a number of clinical consequences, are not invasive; rather, they should be considered "salvage" clones, which positively mitigate the consequences of bone marrow failure.
3. The aim of treatment should be to recover normal hematopoiesis rather than to destroy or to repair the PNH clone(s).

TREATMENT

At present, the treatment of PNH patients is essentially supportive. Prevention and early treatment of concurrent infectious or inflammatory diseases may help in reducing the frequency and severity of paroxysmal exacerbations. Folate supplement and red cell transfusion are the basis for ameliorating anemia. Iron supplements—to balance the persistent urinary loss of iron in the form of hemosiderinuria—or iron chelation, if iron overload develops due to frequent transfusions, may be needed in selected patients. Anticoagulants are used to treat or to prevent thrombosis.

Bone marrow transplant is a curative approach for PNH patients with severe bone marrow failure, less than 45 years of age, and having a related HLA-identical donor. If the escape theory is correct, there is little room for futuristic approaches with cell therapy (insertion of molecules on the outer surface of blood cells) or with gene therapy (insertion of a functioning *PIG-A* gene in early hematopoietic progenitors) in PNH, since a repair of the damaged cell may result in cell destruction; in fact, in most PNH patients, a residual population of normal hematopoietic progenitors already exists, but it is unable to repopulate the bone marrow. Immunosuppression using antilymphocyte globulin and/or cyclosporin could be a valid alternative, aiming to treat the underlying bone marrow failure syndrome; it has been used in a few patients in recent years, with promising results.

Figure 25-4 Red blood cell flow cytometry analysis of CD59-defined antigen expression in a normal subject and two representative PNH patients. *x*-axis: log green fluorescence; *y*-axis; relative cell counts. (**A**) The unimodal distribution of CD59+ cells in the normal subject. (**B**) Two cell populations are present in this patient, one normally expressing and the other completely lacking CD59. (**C**) Three cell populations are distinguishable in this patient (normal, dim, and negative). (Reprinted with permission from P. Hillman et al. BrJ Haematol 1992;80:402.)

FUTURE DIRECTIONS

Although so many pathophysiological aspects of PNH have been unraveled, several important items still require clarification, such as:

1. The functional properties of the GPI-anchoring system in human cells.
2. The structure and the function of the protein encoded by *PIG-A*.
3. The exact role of each GPI-linked molecule on blood cell development and function.
4. The amount of transfer of GPI-linked molecules (if any) that takes place in vivo from one cell to another.
5. The hierarchy by which the various molecules are preferred in the cell for anchor attachment, when a reduced amount of anchor is produced.
6. The reason for the nocturnal exacerbation of hemolysis.

Also, a formal proof of the escape theory is needed. If it is confirmed, PNH could be regarded as a special type of nonneoplastic clonal disease, in which the expansion of the mutated cell is due to a survival advantage rather than to a growth advantage.

26 Leukemias

JEFFREY E. RUBNITZ AND CHING-HON PUI

INTRODUCTION

The acute and chronic leukemias arise from the uncontrolled clonal expansion of hematopoietic progenitor cells blocked in differentiation. The different types of leukemia represent distinct clinicopathologic entities that have characteristic biological and clinical properties and respond to specific therapies. The identification of specific molecular lesions helps us to understand the molecular mechanisms that contribute to leukemogenesis. Here we review the epidemiology, clinical features, and molecular genetics of acute lymphoblastic leukemia (ALL), acute myeloid leukemia (AML), chronic myelogenous leukemia (CML), and chronic lymphocytic leukemia (CLL).

EPIDEMIOLOGY

Acute leukemia is the most common malignancy in children, accounting for approximately one-third of all childhood cancers. ALL predominates during childhood, with 2000 new cases diagnosed in the United States each year, compared to 500 new cases of AML. CML accounts for less than 100 cases of pediatric leukemia each year, whereas CLL is extremely rare in children. The 4:1 ratio of ALL:AML is reversed in adults, with AML being more common and occurring in approximately 5000 adults each year. Chronic leukemias are also common in adults, with approximately 6000 cases of CML and 12,000 cases of CLL diagnosed each year in the United States.

Environmental and genetic factors are linked to an increase in the risk of leukemia. Exposure to ionizing radiation, toxic chemicals (e.g., benzene), and specific chemotherapeutic agents are all associated with a higher risk of acute leukemia. In particular, alkylating agents used to treat a primary malignancy can induce secondary AML that is characterized by a prior myelodysplastic syndrome and abnormalities of chromosomes 5 and 7. Also, exposure to topoisomerase II inhibitors, especially the epipodophyllotoxins teniposide and etoposide, can lead to the rapid development of secondary AML with rearrangements of the *MLL* gene.

Genetic diseases associated with chromosomal instability, such as Bloom's syndrome, Fanconi's anemia, and ataxia–telangiectasia, are also characterized by an increased risk of acute leukemia. Similarly, children with congenital immunodeficiencies, such as Wiskott-Aldrich syndrome, are predisposed to develop leukemia. The 10- to 20-fold increased risk of acute leukemia in patients with

trisomy 21 is further evidence for a role of genetic factors in the development of leukemia. However, the vast majority of leukemia cases—especially in children—have no clear etiology.

CLASSIFICATION

Leukemias are classified according to morphological, immunological, biochemical, and cytogenetic characteristics. The French-American-British (FAB) system of morphological classification distinguishes three types of ALL (L1 through L3, Table 26-1), but has not proven to be clinically useful. ALLs are further classified by their expression of normal lymphoid-associated surface markers (Table 26-1). Eight types of AML (M0–M7, Table 26-2) are defined morphologically and show correlations with clinical features, cytogenetics, and outcome. Immunophenotyping is also performed in AML but is used primarily to distinguish undifferentiated cases of AML from ALL.

Leukemias can also be classified according to specific chromosomal abnormalities, which can be identified in over 90% of ALL, AML, and CML cases. Difficulties in obtaining sufficient metaphases have hampered cytogenetic analysis in CLL, but approximately two-thirds of CLL patients have clonal chromosomal abnormalities. Recurring chromosomal abnormalities, including changes in both chromosome structure and number, are associated with specific biological and clinical features. For example, hyperdiploidy with a chromosome number greater than 50 is identified in approximately one-fourth of childhood ALL cases and is associated with favorable prognostic factors, such as lower leukocyte count and a better treatment outcome, even with antimetabolite-based therapy. Several structural chromosomal abnormalities also have prognostic and therapeutic implications; the t(9;22)(q34;q11) or t(4;11)(q21;q23) confers a particularly poor prognosis in ALL, whereas the dic(9;12)(p11-12;p12) is associated with a favorable prognosis. In AML, cases with t(8;21)(q22;q22) or inv(16)(p13q22) respond well to chemotherapy regimens that contain high-dose cytarabine, whereas leukemic cells containing the t(15;17)(q21;q21) differentiate in response to all-*trans*-retinoic acid. In contrast, cases of AML with monosomy 7 have a particularly poor outcome and require allogeneic bone marrow transplantation for cure.

MOLECULAR ANALYSIS OF LEUKEMIA

Cytogenetic analysis has been the standard method of identifying translocations, but it is technically difficult and dependent on an adequate diagnostic specimen. The molecular characterization of translocation breakpoints has led to alternative approaches,

Table 26-1
Classification of Acute Leukemias

		Frequency, %	
		Adult[a]	Childhood[b]
Acute lymphoblastic leukemia			
Morphologic classification			
L1	Small, homogeneous cells with scanty cytoplasm	30	80
L2	Larger, heterogeneous cells with irregular nuclei and at least one large nucleolus	60–70	17
L3	Large, homogeneous cells with deep basophilic cytoplasm and prominent cytoplasmic vacuoles	5	3
Immunophenotype			
Early pre-B	CD19+, CD22+, cIg–, sIg–	50–60	57
Pre-B	cIg+	15–25	25
Transitional pre-B	cIg+, sIg+, sIgκ–, sIgλ	Unknown	1
B cell	sIg+	5	2
T cell	CD3+, CD7+, and CD5+ or CD2+	20–25	15
Ploidy			
Hypodiploid (<45 chromosomes)		5–10	7
Diploid (normal 46 chromosomes)		25–35	8
Pseudodiploid (46 chromosomes with structural abnormalities)		50–60	42
Hyperdiploid (47–50 chromosomes)		5–10	15
Hyperdiploid (>50 chromosomes)		5–10	27
Triploid or tetraploid (>65 chromosomes)		1	1
Acute myeloid leukemia			
M0	Minimal differentiation	2–3	2
M1	Poorly differentiated myeloblasts	10–20	13
M2	Differentiated myeloblasts	30–35	28
M3	Promyelocytic	10–15	6

[a]Based on literature review.
[b]Based on 600 consecutive cases of newly diagnosed ALL and 180 cases of AML in children less than 18 years of age studied at St. Jude Children's Research Hospital from 1984–1992 (N Engl J Med 1995;332:1618).

including fluorescence *in situ* hybridization (FISH), Southern blot analysis, and reverse transcriptase-polymerase chain reaction (RT-PCR). These techniques can be performed on samples inadequate for cytogenetic analysis and are quicker, more sensitive, and more specific than cytogenetics. For example, molecular rearrangements of *MLL* (located at 11q23) are seen in approximately 80% of infants with ALL, whereas only about 60% of these cases have 11q23 alterations by cytogenetics.

Molecular approaches can also detect important submicroscopic genetic abnormalities not visible by cytogenetics. The *TEL-AML1* gene fusion, which results from the t(12;21)(p12-13;q22), occurs in greater than one-fourth of B-lineage childhood ALL cases, few of which have cytogenetic evidence of the t(12;21). Likewise, *TAL1* gene rearrangements (Table 26-1), the most common abnormality in T-cell ALL, are generally detectable only at the molecular level. Finally, the tumor suppressor gene *p16*, located at 9p21, is homozygously deleted in about one-fourth of ALL cases, including many that have cytogenetically normal chromosome 9p.

Moreover, some lesions can appear identical by cytogenetics, yet they differ when analyzed at the molecular level. RT-PCR assays have detected *E2A-PBX1* fusions in patients with normal or unsuccessful cytogenetic studies and have identified patients who have the t(1;19) but lack the fusion gene. The distinction is clinically important, because patients with *E2A-PBX1* fusions fare poorly on nonintensive therapies, whereas patients with t(1;19)

who lack *E2A-PBX1* do quite well on standard antimetabolite-based protocols.

MOLECULAR ABNORMALITIES IN LEUKEMIA

Chromosomal rearrangements can cause leukemogenesis by two mechanisms: the activation of dominant cellular proto-oncogenes, and the inactivation of tumor suppressor genes (Fig. 26-1). Proto-oncogenes are activated by at least four pathways. First, in T- and B-cell leukemias, cellular oncogenes may be activated by transcriptional deregulation, following their juxtaposition with T-cell receptor (TCR) or immunoglobulin (Ig) genes (Fig. 26-1A, Table 26-2). Second, in B-precursor ALL and in AML, translocations frequently create chimeric fusion genes that encode novel oncogenic proteins (Fig. 26-1B, Table 26-2). Third, gene amplification can lead to oncogene overexpression, an event that is less common in leukemias than in certain solid tumors. Fourth, point mutations of the *ras* gene, reported in up to 50% of AML cases, are likely key events in leukemogenesis.

Many of the genes at the breakpoints of leukemia-specific translocations are oncogenic transcription factors involved in cellular proliferation and differentiation. Oncogenic transcription factors are classified by their structural motifs, including basic helix-loop-helix (bHLH), leucine-zipper, and LIM domains (Table 26-2) (*see also* Chapter 3). Other oncogenes identified in this manner include protein kinases, growth factors, and proteins involved in signal transduction (*see* Chapter 7).

[a]Based on literature review.
[b]Based on molecular analysis.

COMMON TRANSLOCATIONS IN ALL
t(9;22)(q34;q11)

The balanced translocation t(9;22)(q34;q11), also referred to as the Philadelphia chromosome (Ph), occurs in about 95% of all CML cases, 25% of adult ALL cases, 3–5% of pediatric ALL cases, and less than 1% of AML cases. In both CML and ALL, the t(9;22) results in the translocation of the *ABL* proto-oncogene from the distal long arm of chromosome 9 into the *BCR* gene on chromosome 22, forming a *BCR-ABL* fusion gene (Fig. 26-2). In the majority of CML cases, and in about one-half of adult Ph+ ALL cases, the *BCR* breakpoints are located in the major breakpoint cluster region (M-bcr), producing chimeric mRNAs that encode a fusion protein of approximately 210 kDa (p210). p210 has enhanced tyrosine kinase activity, compared to ABL, a cytoplasmic intracellular location, and the ability to transform hematopoietic precursors in experimental systems. Most cases of childhood Ph+ ALL and the other half of adult Ph+ ALL cases are characterized by *BCR-ABL* fusions in which the breakpoints in the *BCR* gene are distributed in a second breakpoint cluster region (m-bcr). The resulting fusion gene encodes a 190-kDa protein (p190) in which tyrosine kinase activity and transforming potential are enhanced compared to those of p210.

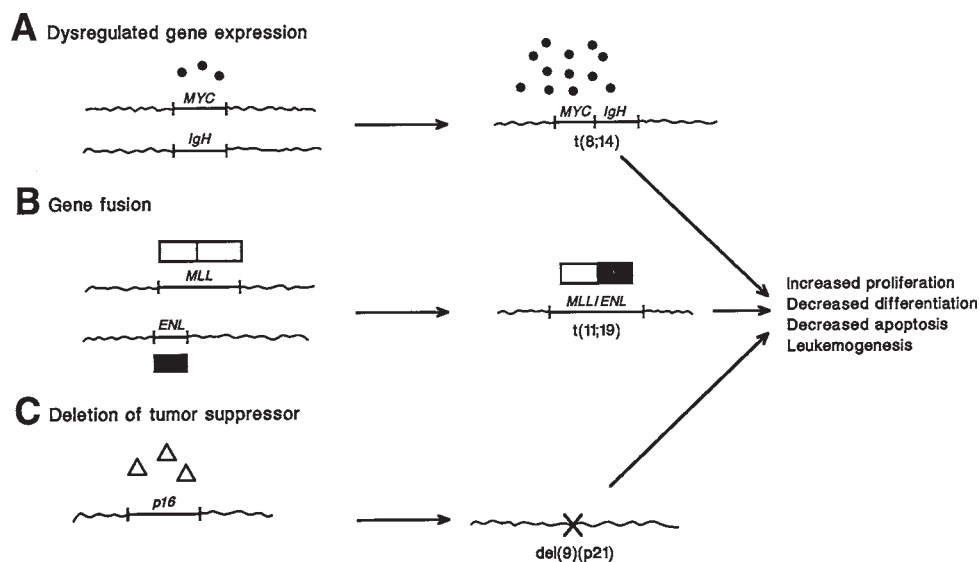
t(1;19)(q23;p13.3)   The t(1;19)(q23;p13.3) is present in 1% of early pre-B ALLs and 25% of cases with a pre-B (cytoplasmic Ig positive) immunophenotype. The t(1;19) breakpoint on chromosome 19 involves the *E2A* gene, which encodes the Ig enhancer binding proteins E12 and E47. E12 and E47 both contain N-terminal transactivation domains and C-terminal helix-loop-helix DNA-binding and dimerization motifs. In pre-B ALL, the t(1;19) disrupts *E2A* and fuses the N-terminal transactivation domain of E12/E47 to the DNA binding domain of PBX1, a homeodomain protein (Fig. 26-3). Transformation by E2A-PBX1 presumably results


Figure 26-1 Mechanisms of leukemogenesis. **(A)** Cellular proto-oncogenes, such as *MYC*, may become deregulated, following their juxta-position with transcriptionally active genes, such as the immunoglobulin heavy-chain gene *(IgH)*. **(B)** Gene fusion activates cellular oncogenes. The t(11;19) fuses the N-terminal portion of the *MLL* gene with the *ENL* gene to create the chimera *MLL/ENL*. **(C)** The tumor suppressor gene *p16* is inactivated by deletion of the 9p21 region.
Figure 26-2 BCR-ABL fusion as a result of the t(9;22). *BCR* is a schematic representation of the *BCR* gene, which lies on chromosome 22 and contains 24 exons (depicted as vertical bars). ALL (m-bcr) and CML (M-bcr) breakpoints are indicated by arrows. *ABL* shows the genomic structure of the *ABL* gene on chromosome 9, with ALL and CML breakpoints indicated between exons 1 and 2. p210 and p190 represent BCR-ABL fusion proteins created as a result of CML (p210) or ALL (p190) breaks. p210 is encoded by exons 1 through 13 or 14 of *BCR* fused to exon 2 of *ABL*, whereas p190 is encoded by exon 1 of *BCR* fused to exon 2 of *ABL*.

Figure 26-3 E2A-PBX1 fusion created by t(1;19). E2A contains two activation domains (AD) and a basic helix-loop-helix domain (bHLH), whereas PBX1 contains a homeodomain (HD). The t(1;19) results in the fusion of the N-terminal portion of E2A to the C-terminal portion of PBX1. Arrows indicate breakpoints.

from the inappropriate expression of PBX1 in lymphoid cells, allowing PBX1 to bind specific DNA sequences and transactivate unknown target genes. As predicted by this model, E2A-PBX1 is a transactivator in vitro, transforms NIH-3T3 fibroblasts, and induces lymphomas in transgenic mice. In contrast to pre-B ALL, cytogenetically indistinguishable early pre-B (cytoplasmic Ig negative) ALL cases containing the t(1;19) do not involve either *E2A* or *PBX1*.

11q23 Rearrangements Structural lesions involving chromosome 11, band q23, occur in approximately 80% of infant ALL cases and in 85% of secondary leukemias (generally AML) that arise in patients treated with topoisomerse II inhibitors. Over 40 reciprocal chromosomal loci participate in 11q23 translocations, the most common being 4q21, 9p22, and 19p13. The gene on chromosome 11 that is disrupted by these translocations is designated *MLL* (mixed lineage leukemia), but is also referred to as *HRX*, *ALL-1*, and *HTRX1*. *MLL* rearrangement in ALL identifies a high-risk subgroup of patients who are unlikely to be cured with conventional chemotherapy. In contrast, cases that have 11q23 abnormalities but lack *MLL* rearrangements have an intermediate prognosis.

MLL is a 431-kDa protein with two central zinc finger domains, a C-terminal region that shows high homology to the *Drosophila* trithorax protein, a region with homology to DNA methyltransferases, and an N-terminus that contains three AT hooks (Fig. 26-4). 11q23 translocations cluster in an 8.5–kb region of *MLL* and fuse
Figure 26-4 The *MLL* gene, located at 11q23, encodes a protein (MLL) with 3 AT-hooks near the N-terminus, a methyltransferase domain (MT), two zinc fingers (Zn-fingers), and a region of homology to the Drosophila trithorax protein (TRX homology). The t(11;19) involves the *ENL* gene at 19p13, which encodes a small serine/proline-rich (SP-rich) protein. The MLL-ENL fusion protein includes the N-terminal portion of MLL fused to nearly all of ENL. Breakpoints are indicated by arrows.

the N-terminal portion of MLL—containing the AT hooks and methyltransferase domains—to a variety of proteins. In ALL with the t(11;19), for example, MLL is fused to a small serine/proline-rich protein (ENL) that has in vitro transactivation activity (Fig. 26-4). Accordingly, MLL fusion proteins are thought to function as chimeric transcription factors in early hematopoietic progenitor cells.

t(12;21)(p13;q22) The *TEL* gene, located at 12p13 and encoding a novel ETS-like transcription factor, is fused to the DNA-binding and transactivation domains of *AML1* as a result of a cryptic t(12;21)(p13;q22) in ALL. *AML1* encodes the DNA-binding component of the AML1/CBFβ transcription factor complex, which is also targeted by the myeloid-associated translocations t(8;21), t(3;21), and inv(16) (Fig. 26-5). Although the t(12;21) is detected by standard cytogenetic techniques in less than 1 in 1000 cases, molecular analyses have demonstrated that *TEL-AML1* is actually the most common genetic lesion in pediatric ALL, occurring in approximately one-fourth of B-lineage cases. In addition, this fusion gene is associated with an excellent prognosis. Because the relationship of *TEL-AML1* expression to a favorable prognosis is independent of recognized prognostic features in B-precursor leukemia, including age and leukocyte count, *TEL-AML1* identifies a large subset of children with favorable-prognosis B-precursor leukemia who cannot be identified by clinical features. These patients may be candidates for less intensive therapy, designed to reduce both early and late adverse effects.

Translocations in B-Cell ALL B-cell ALL is characterized by the presence of surface immunoglobulin, FAB L3 morphology, frequent extramedullary disease, and translocations involving the *MYC* gene on chromosome 8, band q24 (Table 26-2). Approximately 80% of B-cell cases contain the t(8;14)(q24;q32), in which *MYC* is translocated to the immunoglobulin heavy chain gene locus. Nearly all of the remaining cases contain the t(2;8)(p12;q24) or the t(8;22)(q24;q11), in which either the κ (located at 2p12) or λ (located at 22q11) light chain gene is translocated to chromosome 8 adjacent to *MYC*. All three translocations result *MYC* dysregulation and ultimately lead to transformation.

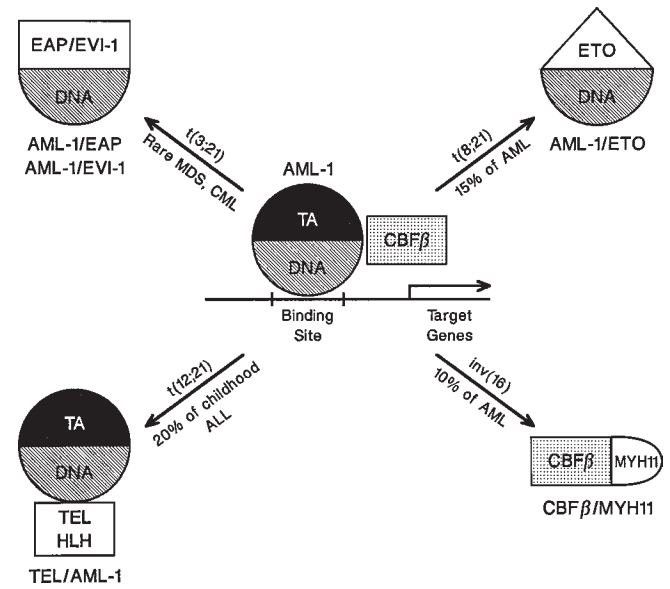
Translocations in T-Cell ALL Recurring translocations in T-cell ALL often involve the TCR β locus (7q34) or the TCR α/δ


Figure 26-5 The transcription factor complex AML-1/CBFβ (center) is the target of a variety of translocations. TA and DNA represent the transactivation and DNA-binding domains of AML-1. The t(3;21) (upper left) fuses the DNA binding domain of AML-1 to either EAP or EVI1 in rare cases of myelodysplastic syndrome (MDS) or CML. In ALL, the t(12;21) (lower left) creates a chimeric protein consisting of AML-1 fused to the helix-loop-helix (HLH) portion of TEL. In AML, CBFβ is fused to MYH11 as a result of inv(16) (lower right), and in the t(8;21) the DNA-binding portion of AML-1 fuses to ETO (upper right).

locus (14q11) (Table 2). For example, the t(1;14)(p32;q11) results in abnormal *TAL1* expression, following translocation of *TAL1* into the TCR α/δ locus. *TAL1* encodes a bHLH transcription factor that is also involved in the t(1;7) (Table 26-2). *TAL2* and *LYL1* encode related members of the bHLH family that are translocated to TCR sites in cases of T-cell ALL. Other proteins involved in T-cell leukemias include MYC, the cysteine-rich proteins TTG1 and TTG2, the homeodomain transcription factor HOX11, the tyrosine kinase LCK, and the transmembrane protein TAN-1 (Table 26-2).

COMMON TRANSLOCATIONS IN AML

t(8;21)(q22;q22)

Approximately 15% of AML cases carry the t(8;21)(q22;q22), which is associated with a tendency to form tumor masses (granulocytic sarcomas) in extramedullary sites and a favorable response to therapy. The t(8;21) disrupts *AML1* (located at 21q22), which encodes a transcription factor that contains a transactivation domain near its C-terminus and a DNA-binding region of homology with the *Drosophila runt* gene near its N-terminus. *AML1* shares homology with the alpha subunit of core-binding factor (CBFα), which binds conserved sites in the enhancers of murine leukemia viruses, the T-cell receptor gene, and several myeloid-specific genes. In the t(8;21), the runt domain of *AML1* is translocated to the derivative 8 chromosome and joined to *ETO* (Fig. 26-5). In vitro, AML1-ETO binds AML1 sites and represses transcription of reporter genes. Thus, the t(8;21) may lead to transformation by creating a protein that competes in vivo with AML1 and inhibits AML1-mediated expression of myeloid-specific genes.

inv(16)(p13q22) and t(16;16)(p13;q22) Approximately 10% of AML cases carry pericentric inversions or translocations of chromosome 16. These cases are associated with myelomono-

cytic differentiation, the presence of abnormal bone marrow eosinophils (commonly FAB subtype M4Eo), a propensity for central nervous system (CNS) involvement, and a favorable prognosis. In the inv(16) and t(16;16), sequences from the β-subunit of core binding factor *(CBFb)* at 16q22 are joined to the smooth muscle myosin heavy chain gene *(MYH11)* at 16p13. CBFβ interacts with and increases the DNA-binding affinity of AML1. Thus, disruption of the AML1/CBFβ transcription complex by inv(16), t(8;21), t(3;21), or t(12;21) may lead to leukemia (Fig. 26-5).

t(15;17)(q21;q21)   Acute promyelocytic leukemia (APL, AML-M3), characterized by coagulopathy and severe bleeding diathesis, is frequently associated with a balanced translocation that involves the retinoic acid receptor-alpha *(RARa)* gene (17q21) and the *PML* gene (15q21). RARα, a transcription factor, binds various retinoids, including all-*trans*-retinoic acid, and interacts directly with DNA. PML contains a putative DNA-binding domain, a potential dimerization domain, a serine/proline-rich region, and a phosphorylation site. The PML-RARα fusion protein formed by the t(15;17) contains the PML dimerization and DNA-binding domains fused to the DNA-binding and retinoid-binding portion of RARα. The PML-RARα fusion retains the ligand binding and dimerization properties of RARα, but displays altered transactivation activities.

SECONDARY AML   Therapy-induced secondary AML, involving 11q23 translocations, is typically seen in patients treated with topoisomerase II inhibitors, particularly the epipodophyllotoxins etoposide and teniposide. Unlike the secondary leukemias that occur after treatment with alkylating agents, secondary AMLs containing 11q23 abnormalities have a short latent period, lack a prior myelodysplastic phase, and generally have features of monocytic differentiation (M4 and M5 subtypes). Molecular analyses have shown that the majority of patients with topoisomerase-induced secondary AML have *MLL* rearrangements analogous to those seen in ALL.

TRANSLOCATIONS IN CML   Greater than 95% of CML patients have cytogenetic evidence of the t(9;22)(q34;q11). As stated earlier, this translocation creates a *BCR-ABL* fusion gene that encodes a 210-kDa protein with altered kinase activity. Detection of *BCR-ABL* has important implications for diagnosis and the detection of minimal residual disease. In general, the persistence or increase in the level of minimal residual disease detectable by RT-PCR after allogeneic bone marrow transplantation is closely correlated with subsequent relapse.

TRANSLOCATIONS IN CLL   Clonal abnormalities occur in approximately two-thirds of CLL patients, of which about one-third has trisomy 12. Although the biological significance of trisomy 12 is unknown, patients with this abnormality have a worse prognosis than patients with other single abnormalities. The most common structural cytogenetic abnormality in CLL is partial deletion of the long arm of chromosome 13, including band q14, the site of the retinoblastoma type 1 gene *(RB1)*. Homozygous deletion of a region telomeric to *RB1* suggests that a new tumor suppressor gene might be involved in CLL.

TUMOR SUPPRESSOR GENES   Tumor suppressor genes, in which loss of function may cause transformation, include *RB1*, the Wilms' tumor gene, and *p53*. Although *p53* is mutated or deleted in a variety of human malignancies, it does not play a significant role in the development of pediatric leukemia. Mutations in *p53* occur in only 1–2% of B-precursor and T-cell ALLs at diagnosis but are present in about 25% of relapsed T-cell leukemia cases. Among the relapsed T-cell cases, patients with *p53* mutations have a shorter second remission than those patients without *p53* mutations. Therefore, *p53* mutations may be important in the development of drug-resistant disease.

Recently, two candidate tumor suppressor genes, designated *p16 (MTS1, INK4a)* and *p15 (MTS2, INK4b)*, were localized to 9p21, a site of nonrandom chromosomal abnormalities in gliomas, melanomas, esophageal carcinomas, lung carcinomas, and leukemias. p16 and p15 are highly homologous and function as specific cell cycle inhibitors by targeting activated cyclin D-cdk4/6 complexes. Deletions of *p16* have been detected in 46% of cell lines and 10–20% of primary tumor samples. In ALL, homozygous deletions of *p16* and *p15* have been detected in 20–30% of B-precursor ALLs and 70–80% of T-cell ALLs. In other leukemias, however, *p16/p15* deletions are quite rare, being reported in less than 10% of AML, CLL, and CML cases.

CLINICAL APPLICATIONS OF MOLECULAR ANALYSIS

Molecular analyses have improved our abilities to diagnose and risk-stratify patients, monitor response to therapy, and detect minimal residual disease. In ALL, the presence of *BCR-ABL* or *MLL-AF4* is associated with poor prognostic indicators, such as hyperleukocytosis, organomegaly, and CNS leukemia. Furthermore, despite overall improvements in outcome for ALL, patients with these genetic abnormalities still have a dismal prognosis and are candidates for innovative therapies or allogeneic bone marrow transplantation in first remission. Because cytogenetic studies fail to detect these abnormalities in some patients, molecular detection methods become even more valuable. Similarly, molecular techniques are essential to identify patients with *E2A-PBX1* fusions, because these patients fare poorly on standard moderately intense therapies, but they do quite well when treated more aggressively. This observation was first made at St. Jude Childrens Research Hospital, where patients with *E2A-PBX1* fusions had a 4-year EFS of about 50% on Total Therapy Study X, but a 4-year EFS of 79% on the more intensified Study XI.

Molecular detection of *PML-RARa*, *AML1-ETO*, and *CBFb-MYH11* also has significant therapeutic implications. Approximately 95% of patients with acute promyelocytic leukemia and *PML-RARa* achieve complete remission when treated with all-*trans*-retinoic acid. Treatment with all-*trans*-retinoic acid is associated with leukemic promyelocyte differentiation, onset of normal hematopoiesis without bone marrow aplasia, and correction of the associated coagulopathy that was formerly a leading cause of death during induction therapy. The combination of all-*trans*-retinoic acid with anthracycline-based chemotherapy has greatly improved the overall outcome of these patients. Detection of *AML1-ETO* or *CBFb-MYH11* is associated with a high rate of long-term remission following treatment with high-dose cytarabine chemotherapy.

Finally, early detection of minimal residual disease by use of molecular techniques can potentially improve cure rates for patients with leukemia. Adoptive immunotherapy with donor leukocytes forestalls clinical relapse in patients who have CML and molecular evidence of minimal residual disease after allogeneic bone marrow transplantation. Therefore, molecular techniques can be used to monitor the minimal residual disease level and potential for relapse in these patients.

FUTURE DIRECTIONS

Molecular characterization of translocation breakpoints has identified new oncogenes and tumor suppressors, and it has led to the development of molecular diagnostic assays that have improved therapeutic management and detection of residual disease. To further elucidate the pathways leading to malignant transformation, research will focus on oncogenic transcription factors and their downstream targets. These proteins may represent molecules to which novel tumor-specific therapies can be directed. In addition, gene replacement therapy of inactivated tumor suppressor genes could play a role in the future treatment of leukemia. Finally, attempts to induce leukemic cells to undergo normal differentiation and apoptosis will be the basis of important future research.

27 Lymphomas

Finbarr E. Cotter

INTRODUCTION

Molecular analysis of chromosomal translocations in human lymphoma cells has led to the identification of new cellular proto-oncogenes that contribute to lymphoma formation. Genes encoding for the B-cell immunoglobulin heavy chain *(IgH)* and T-cell antigen receptors *(TCR)* are frequent targets for such rearrangements. Many of these rearrangements are detectable by Southern blot analysis, hybridizing with the immunoglobulin *(Ig)*, *TCR*, or appropriate DNA probes for other genes involved at the point of translocation.

An increased incidence of lymphoma has followed the era of organ transplantation and more recently, acquired immuno-deficiency syndrome (AIDS). The development of lymphoma in human immunodeficiency, congenital and acquired, is approximately 100 times greater than expected and is predominantly associated with Epstein-Barr virus (EBV) genome within tumor cell DNA. The lymphomas are B cell in origin and may often be associated with specific oncogene deregulation.

The process of lymphoma formation probably represents a multistep process that requires a number of mutations leading to the development of clinically malignant disease, the described translocations being an essential step. However, further progression may occur following additional mutations involving the p53 or tumor suppressor genes such as the retinoblastoma gene (*see* Chapter 7). Ultimately, defining the mechanism of oncogenesis at a molecular level may increase the therapeutic options and include those based on the biological action of the lymphoma. The molecular alterations and their role in the pathogenesis of lymphoma is presented in this chapter.

EPIDEMIOLOGY OF LYMPHOMAS   Lymphomas are a heterogeneous group of disease with varying incidence, geographical distribution, etiology, and response to therapy. The incidence of lymphoma in the Western world has been steadily increasing over the last few decades. The cause for this is unclear, although the increased occurrence of organ transplantation, human T-cell lymphotrophic virus human (HTLV1), and human immunodeficiency virus (HIV) may in part be contributory factors. Interestingly an association between *Helicobacter pylori* and stomach lymphomas of mucosa-associated lymphoid tissue (MALT) is observed and responds to antibacterial treatment, suggesting a role for infective organisms in the etiology of some lymphomas. In America and Europe, 85% of lymphomas are B cell in origin. B-cell lymphomas, however, have a considerably lower incidence in the Far East; T-cell lymphomas account for half the number of lymphomas in Japan, although this is mainly owing to the prevalence of HTLV1 in that country. In general, there is a slightly increased incidence in males and with rising age. Follicular and large cell diffuse lymphomas account for 23 and 20%, respectively, of all lymphomas and make up the largest subgroups by far.

CLASSIFICATION   The classification of lymphoma has been a consistent cause for debate with divided views predominantly between the two sides of the Atlantic. During the 1980s, attempts at a unification were made with the working formulation that basically divided the lymphomas into three groups—low, intermediate, and high grade—according to the morphological appearance (low equating to small mature-looking lymphoid cells and high to large immature cells). However, with the advent of cytogenetic and molecular analysis of lymphoma, it became increasingly clear that these alterations could be of considerable importance indicating prognosis and treatment and that the classifications based solely on morphology were inadequate. Over the last 3 years, significant attempts have been made in reclassification, taking into account specific morphological, clinical, and molecular cytogenetic features. This unifying classification termed, the Revised European American Lymphoma (REAL) Classification, is far from perfect, but it is practical and applicable for the pathologist, clinician, and molecular hematologist (Fig. 27-1).

MOLECULAR PATHOLOGY OF B-CELL LYMPHOMA

The first molecular alteration involved the *C-MYC* proto-oncogene associated with Burkitt's lymphoma (BL). The t(11;14)(q13;q21) translocation involving the *IgH* locus and the B-cell lymphoma/leukemia-1 *(BCL-1)* region was next described almost exclusively in Mantle cell lymphoma and indicating a poor prognosis. Soon after this, the t(14;18)(q32;q21) seen in follicular lymphomas (FL) and some high grade B-cell lymphomas was cloned owing to its involvement of a J$_H$ segment of the *IgH* locus. The translocation partner gene is *BCL-2* proto-oncogene which has subsequently been found to play a vital role in preventing programmed cell death—also termed apoptosis (after the Greek word referring to the falling of leaves from at tree or petals from a flower, being descriptive for the morphological appearances). Subsequently, the t(10;14)(q24;q32) found in 7% of low grade and occasional high grade B-cell lymphomas was cloned and found to involve the *LYT-10* transcriptional factor on chromosome 10, which becomes juxtaposed to the *IgH* gene. Most recently the *BCL-6* and *BCL-7* genes have been cloned on chromosomes 3 and

Neoplasm	Phenotype	Genetic changes	Comments
Entities seen mainly in lymph node biopsies			
Small lymphocytic lymphoma/leukaemia	Usually B, less commonly T	No common abnormalities	Includes chronic, lymphocytic, prolymphocytic, and large granular T lymphocyte leukaemias
Lymphoplasmacytoid lymphoma	B cell	No common abnormalities	Also known as immunocytoma
Mantle cell lymphoma	B cell	t(11;14), *bcl-1* rearrangement and *PRAD1/cyclin D1* overexpression in many cases	'Centrocytic' lymphoma in the Kiel scheme
Follicular lymphoma	B cell	t(14;18). *bcl-2* rearrangement	'Centroblastic/centrocytic' lymphoma in the Kiel scheme; the official title is 'follicle centre lymphoma, follicular'
Burkitt's lymphoma	B cell	t(2;8), t(8;14) or t(8;22); *c-myc* rearrangement	
Diffuse large B-cell lymphoma	B cell	t(14;18) in some cases	Combines 'immunoblastic' and 'centroblastic' lymphomas
Lymphoblastic leukaemia/lymphoma	B cell, less commonly T	t(1;19), in a few B lineage cases; *Tal-1/SCL* rearrangement in some T cell cases	Official title; 'precursor B-(or T-) lymphoblastic leukaemia/lymphoma'
Peripheral T-cell lymphomas, unspecified	T cell	No common abnormalities	'Unspecified' reflects the strong conviction that this is a heterogenous category
Adult T-cell leukaemia/lymphoma	T cell	No common abnormalities; integrated HTLV1 genome	
Angiommunoblastic T-cell lymphoma (AILD)	T cell	No common abnormalities	
Anaplastic large cell lymphoma	T cell, B cell or null	t(2;5) in some cases	Sometimes known as 'Ki-1 lymphoma'
Entities seen mainly at extranodal sites			
Hairy cell leukaemia	B cell	No common abnormalities	Localized to spleen and bone marrow
Plasmacytoma/myeloma	B cell	t(11;14) in a few cases	Seen in bone marrow
MALT lymphoma	B cell	Trisomy 3 in some cases	Arises in gut and other epithelial sites
Intestinal T-cell lymphoma	T cell	No common abnormalities	Seen in gut, with or without associated enteropathy
Angiocentric lymphoma	T cell	No common abnormalities	Arises in nose and other extranodal sites; includes mid-line granuloma; also known as 'nasal T-cell lymphoma'
Mycosis fungoids/Sezary syndrome	T cell	No common abnormalities	Seen in skin

Figure 27-1 REAL Classification for lymphoma.

12, respectively, because of their involvement of the *IgH* locus as the reciprocal partner gene on chromosome 14. Little is known at present about *BCL-7*. All these translocations are thought to occur as a mistake during the process of variable-diversity-joining (V-D-J), joining under the influence of recombinase enzyme responsible for normal V-D-J rearrangement, which is an essential mechanism for B-cell development (Fig. 27-2). Other chromosomal alterations have been observed; however, their significance is not always clear. For example, MALT lymphoma is commonly associated with chromosome 3 alterations. Although this may be helpful diagnostically, the role in the disease process remains unclear. Some of the more common translocations are described in the following section.

B-CELL LYMPHOMAS INVOLVING PROTO-ONCOGENE DEREGULATION

The majority of lymphomas are of B-cell lineage in origin. Translocations involving the q32 region of chromosome 14, the

site of *IgH*, are most often observed (Figs. 27-2, 27-3). Rearrangement of one of the two alleles of this *IgH* gene is essential for development of the pre–B cell into a functional B cell and takes place normally under the influence of a DNA recombinase enzyme system. B-cell lymphomas predominantly involve the deregulation of proto-oncogenes following their juxtaposition to Ig genes. Their occurrence in part must be a result of their obligate DNA breaks and rearrangement within the Ig loci and probably involves a mistake mediated by the recombinase enzyme system responsible for normal Ig rearrangement.

MYC GENE DEREGULATION IN LYMPHOMA   t(8;14)

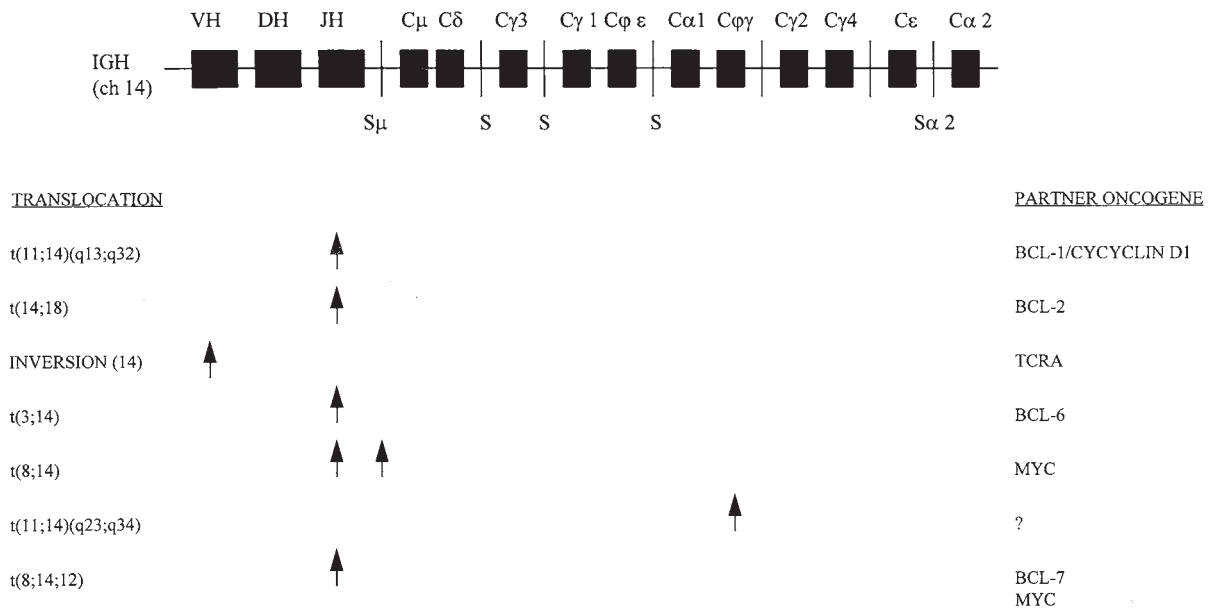
C-MYC plays an important role in the regulation of cell growth and differentiation mediated by a transcriptional role. Characteristically, *C-MYC* rearrangement in malignant lymphoma is associated with a t(8;14) translocation (90%), or more rarely, a t(2;8) or t(8;22) translocations of Burkitt's lymphoma. The breakpoint regions for the t(8;14) translocation, on both chromosomes differ between African (endemic) BL and non-African (sporadic) BL,


Figure 27-2   Schematic representation of the Immunoglobulin heavy chain *(IgH)* gene on chromosome 14. The arrows indicate the sites of common breakage within the *IgH* gene in reciprocal chromosome translocations, indicated on the left. The partner gene involved in the translocation is indicated on the right.

suggesting differing translocation mechanisms (Fig. 27-4). In sporadic BL, there is a loss of promoter sequences in exon 1 of the *C-MYC* gene and can be detected with exon 2 or 3 probes, whereas the break on chromosome 14 occurs within the switch region for the *IgH* μ constant region with loss of the enhancer sequence between the *IgH* joining and switch regions. Endemic BL predominantly has a breakpoint on chromosome 8 upstream of the *C-MYC* gene, too far for detection by exon 2 or 3 probes. The breakpoint on chromosome 14 differs, breaking within the *IgH* joining region. HIV-associated t(8;14) translocation predominantly has a breakpoint pattern similar to the endemic form of BL. Endemic BL t(8;14) associated translocation is thought to involve an error brought about by the recombinase enzyme system at the time of V-D-J rearrangement of the *IgH* locus on chromosome 14 and is supported by the introduction of point mutations into the *C-MYC* promoter region in exon 1 or either of the two coding exons 2 and 3 on chromosome 8, during or following the translocation. This is less common in sporadic BL, for which the translocation mechanism remains unclear; however, the suggestion is that the translocation takes place at an earlier stage in B-cell development.

Translocation involving the *C-MYC* gene in both varieties of BL leads to deregulation of the gene and excessive C-MYC mRNA and C-MYC protein production in the BL cell. This leads to excessive production of *C-MYC* in B-lineage cells with continuous growth and division. However, the quantitative changes may be less important than the inability of the rearranged gene to respond to regulatory factors, owing to loss of promoter or enhancer sequences or point mutations. The *C-MYC* gene may be deregulated as a result both of transcriptional enhancement by the proximity to the IgH locus and of point mutations in the structure of the *C-MYC* gene.

An oncogenic potential for the deregulated *C-MYC* gene is suggested by study of transgenic mice, in which lymphomas frequently develop when *C-MYC* is linked to an Ig enhancer. Excessive production of C-MYC in B-lineage cells appears to leads to

immortalization by preventing the B-cell from leaving the cycling pool leading to oncogenesis. Downregulation of *C-MYC* expression results in a return to normal B-cell development. Additional steps such as *p53* mutations may be important with a 37% frequency in BL.

THE ROLE OF *BCL-2* IN LYMPHOMAS   t(14;18)(q32;q21)
The t(14;18) translocation is the most common alteration seen in lymphomas (Fig. 27-5). It is found in 85% of FL and 25% diffuse lymphomas. It involves the B-cell lymphoma/leukemia-2 *BCL-2* gene on chromosome 18. FL starts usually as a low-grade disease, consisting mainly of small mature-looking lymphoid cells; however, progression to a high-grade aggressive histology, with diffuse large cells frequently occurs and is associated with the accumulation of additional cytogenetic defects. The presence of the t(14;18) translocation persists and confers a poor prognosis. The breakpoint was first cloned in 1984 and led to the discovery of the *BCL-2* gene, consisting of three exons. The human *BCL-2* gene transcripts generate two proteins, p26 α and p22 β. These two proteins have in common the first 196 amino acids at the NH$_2$-terminus and two highly conserved (from *Candida elegans* through to the human) dimerization motifs, BH1 and BH2. These motifs are found in a range of "survival" and "death" molecules, including BAX, BCLX$_l$, and BCLX$_s$. Dimerization to form homo- and heterodimers affects the ability of the cell to avoid or induce programmed cell death (apoptosis). An excess of *BCL-2* protects against apoptosis even in the presence of apoptosis inducing chemotherapeutic agents.

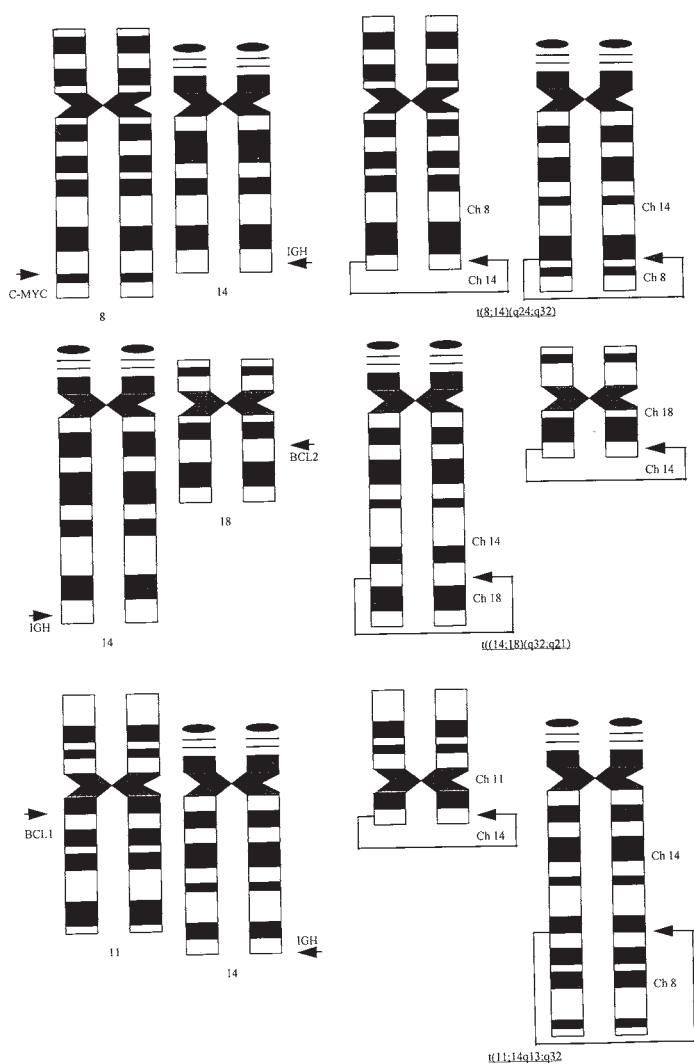
The t(14;18) translocation breakpoint occurs within two very short breakpoint regions on chromosome 18. The first contains 60% of the breakpoints, is approximately 150 bases long at the downstream (3' or telomeric) untranslated region of the BCL-2 on exon III and is known as the major breakpoint region *(mbr)*. The second is known as the minor cluster region *(mcr)*, approximately 20 kb downstream of the gene where an additional 25% of breakpoints are found. The coding regions of the *BCL-2* gene are left intact, so that a *BCL-2/IgH* fusion gene is created and leads to


Figure 27-3 Schematic representation of three common B-cell lymphomas associated translocations involving the IgH gene. The normal chromosomes, with arrows indicating the breakpoint positions, and the genes involved are on the left. The derivative chromosomes formed following the translocations are indicated on the right.

Figure 27-4 Schematic diagram of the *C-MYC* gene orientated 5' ("upstream"/cetromeric) to 3' ("downstream"/telomeric) and two possible derivative 14q+ chromosomes (A) and (B) from translocation t(8;14) in Burkitt lymphoma (BL). P1 and P2 indicate the sites of the two promotors for *C-MYC* gene transcription, and the arrows indicate the direction of transcription. The filled boxes indicate the C-MYC protein coding segments. The major breakpoint regions in BL and their associated translocations are indicated below the *C-MYC* gene by arrows. //, translocation junction between chromosomes 8 and 14; Sµ, µ switch; Cµ, µ constant Region of the immunoglobulin heavy chain constant region (IgHC). In (A), the derivative 14 chromosome has lost exon 1 and the promotor sequences unlike (B). Both (A) and (B) derivative 14 chromosomes have reversed their *C-MYC* orientation with a loss of Cµ enhancer sequence.
Figure 27-5 Schematic diagram of the derivative 14q+ and 18q– chromosomes resulting from the t(14;18) translocation in lymphoma, at the major breakpoint region *(mbr)*. V_H, D_H, J_H, represent the *IgH* gene variable, diversity, and joining regions respectively. N, "N" segment (insertions of random nucleotides found between the two breakpoints, reminiscent of "N insertions" normally observed between recombining segments following *IgH* rearrangement and mediated by the recombinase enzyme system); Sµ, µ switch region; Cµ, µ constant region; *mcr*, minor cluster region. It is of note that the BCL-2 protein encoding region remains intact on the 14q+ derivative chromosome and that a portion of the J_H segment is deleted on the 18q-derivative chromosome.

marked deregulation both in transcription and efficiency of RNA processing with ensuing elevation of BCL-2-IG chimeric RNA as well as normal-sized 25-kDa protein. The excess of BCL-2 protein effectively "immortalizes" the lymphoma cell by preventing apoptosis and protects against chemotherapy induced cell death. This may in part explain the lack of "curability" associated with the t(14;18) translocation in B-cell lymphoma. The breakpoint on chromosome 14 occurs within the joining region of the *IgH* gene predominantly involving the J5 and J6 segments placing the IgH enhancer µ alongside the *BCL-2* gene. An error mediated by the recombinase enzyme system, normally responsible IgH rearrangement, has again been implicated in the mechanism of this translocation supported by the presence of N regions between the breakpoints and somatic point mutations within the translocated joining regions. Although the physiological role of BCL-2 appears to be the generation and maintenance of long-term B-cell memory, its role as an oncogene is suggested by the development of lymphoma in mice with the *BCL-2/IgH* fusion gene placed into the germline. Interestingly, involvement of the *C-MYC* is often seen

in these lymphomas and complements prolonged survival by promoting proliferation. It is also of note that the majority of t(14;18) bearing lymphomas overexpress *C-MYC*. Retroviral introduction of human *BCL-2* complementary DNA into human B-lineage cells

constitutionally expressing C-MYC gene promotes proliferation of B-cell precursors, some of which become tumorigenic. Finally, downregulation of *BCL-2* with antisense oligonucleotides overcomes the malignant phenotype of lymphoma cells showing the essential role *BCL-2* plays in the lymphoma process. These experimental findings suggest *BCL-2* protein contributes to neoplasia and suggest a multistep progression to tumorigenesis.

***BCL-1* IN MANTLE CELL LYMPHOMA t(11;14)(q13;q32)**
The *BCL-1* gene was first described in association with the t(11;14) translocation of mantle cell lymphoma (MCL). It was subsequently realized that the gene involved in this translocation was the *Cyclin D1* gene, also known as *PRAD1* (at chromosome 11 band q13); however, it was not directly disrupted. BCL-1 now describes a breakpoint region of 120 kb upstream of the *Cyclin D1* gene and following the characteristic t(11;14) translocation high expression of the 4.5-kb Cyclin D1 transcript occurs. Although low levels of this gene are seen in many lymphoproliferative disorders, overexpression of the gene is restricted to MCL and some hairy cell leukemias. It maybe a reliable marker for the classification of MCL being detectable by both immunocytochemistry and immunoblotting. *Cyclin D1* is a cell cycle control gene that is localized predominantly to nuclei, with a striking variation of protein levels among the exponentially growing cells, reflecting the maximum levels reached in mid/late G1 and the lowest levels in S-phase. This cell cycle dependent oscillation is owing to the requirement of Cyclin D1 protein for G1 phase progression (*see* Chapter 6). In MCL, the excess of *Cyclin D1* overcomes the G1 phase control essentially driving the cell into continual proliferation. In normal cell cycle, as the cell progresses through G1, the dephosphorylated (active form) of retinoblastoma combines with *Cyclin D1*, which in turn dimerizes with the cdk4 and cdk6 protein kinases in order to deactivate retinoblastoma by phosphorylating the molecule (Fig. 27-6). In the active form, retinoblastoma inhibits cell cycle by preventing DNA synthesis. This is carried out by inhibiting E2F, a transcription factor that normally initiates the DNA synthesis required for the cell to progress from G1 to the S phase of cell cycle. As the retinoblastoma gene is progressively deactivated by phosphorylation in G1 (mediated by Cyclin D1), so E2F loses its inhibition and activates DNA synthesis, thus permitting the cell-cycle to progress into S phase (Fig. 27-7). In mantle cell lymphoma, the excess of Cyclin D1 and loss of normal homeostasis loops controlling cell cycle causes excessive deactivation of retinoblastoma, greatly increased E2F activity, and consequent increased cycling of the lymphoma cells. Interestingly, a protein called p16 is an inhibitor of cdk4 and cdk6, which, in the presence of excess Cyclin D1, may slow down cell cycling by decreasing the necessary protein kinases (e.g., cdk4 and 6). However, as the mantle cell lymphoma progresses, becoming more resistant to treatment, mutations in p16 (inactivating the protein) have been detected. Mutation of p16 removes an antitumor control by removing a mechanism of controlling the rate of cell cycle (Fig. 27-7). From this, it can be seen how stepwise progression can occur as malignancy progresses and how retinoblastoma and p16 genes are essential suppressors of tumor in which loss of function permits malignancy. Comprehension of these pathways makes them attractive targets for therapeutic intervention in mantle cell lymphoma.

***BCL-6* IN DIFFUSE LARGE CELL LYMPHOMA (DLCL) t(3;R)(q27;R)** The *BCL-6* gene (also known as *LAZ3*) was identified by its rearrangement in 3q27 translocations associated with
Figure 27-6 Normal cyclin D1, cell cycle kinases, inhibitors, and their association with different stages of the cell cycle as indicated.
Figure 27-7 The association of protein kinases (K4, K6, and K2), Cyclin D1 (D1), retinoblastoma protein (pRb) and E2F with DNA synthesis, and cell cycle. (pRb-P) represents the phosphorylated form of retinoblastoma. The lower dark arrow and boxes represent the G1 and S phases of cell cycle. pRb inhibits E2F and thus DNA synthesis and cell cycle. Inactivation of pRb by phosphorylation to pRb-P by the Cyclin D1 and K2 protein kinase permits E2F to initiate DNA synthesis and subsequent cell cycle progression.

45% of DLCL, 10% of diffuse mixed cell lymphomas and 6% of follicular lymphomas. In addition, an association with immunodeficiency state lymphomas has been observed: all are of B-cell type. The reciprocal partner chromosomes are considerable, including chromosomes 14q32 (site of IgH gene) (Fig. 27-2) and 22q11, as well as 1p32, 1p34, 3p14, 6q23, 12p13,14q11, and 16p13. The breakpoints on chromosome 3 cluster within the 5' regulatory region of *BCL-6* spanning its first noncoding exon and results in deregulated expression of a normal BCL-6 protein, analogous to BCL-2 following the t(14;18) translocation. *BCL-6* is predicted to be a transcriptional factor and has a punctuated nuclear localization in most germinal center B cells and a small number of marginal zone B cells, suggesting that *BCL-6* is important in the maturation of immune responses and may play some physiological role in germinal center B cells. In vivo homodimerization of the protein is observed. The exact role of *BCL-6* in oncogenesis has yet to be determined; however, deregulated expression may contribute to malignancy by preventing postgerminal center differentiation.

MOLECULAR PATHOLOGY OF T-CELL LYMPHOMA

T-cell lymphomas are rare compared to B-cell tumors. The prognosis is considerably worse, with the majority dying of their disease similar to T-cell leukemias. Much of the identification of

genes involved in T-cell malignancy oncogenesis has been through their consistent involvement of TCR genes. As with B-cell lymphomas, it is postulated that this involves a mistake within the recombinase enzyme mechanism during antigen receptor rearrangement. Consistent translocations involving the TCR genes predominantly affect the 14q11-12 regions where the *TCR* α and δ loci are situated. Less frequently, the *TCR* γ or β loci on the long arm and short arm respectively of chromosome 7 are involved in T-cell lymphoma associated translocations. Frequently, genes encoding transcriptional factors are involved as the reciprocal partner in the translocation. The first two recurrent abnormalities defined were the t(8;14)(q24;q11) and inversion 14 [inv(14)(q11q32)] (the latter also described in ataxia-telangiectasia). The inversion 14 is heterogeneous at a molecular level, involving a variable region of the IgH locus and a TCR J_α segment leading to transcription of a hybrid IgH–TCR mRNA. The function of the hybrid fusion product is unknown, although suspicion is high that it has a role in oncogenesis, particularly as the inversion 14 has additionally been described in B-cell lymphoma. Interestingly, there is another recurring translocation in T-cell lymphomas involving the V_H region of the IgH locus and the region containing the TCR beta chain gene on chromosome 7, the t(7;14)(q35-q36;q32). It is not clear as yet if the same sequences are involved. Other reciprocal translocations in T-cell malignancies include t(11;14)(p15;q11) involving the TCR delta locus with the TTG-1 (or Rhombotin) on chromosome 11 and the t(10;14)(q24;q11), where a putative proto-oncogene called *TCL3* (T-cell leukemia/lymphoma 3) has now been characterized as a new homeobox gene, *HOX11*, on chromosome 10, which is redirected into the δ TCR locus. The t(10;14) is particularly associated with T-ALL and high grade T-cell lymphomas. The significance of translocations involving TCR genes is less clear than for those involving Ig genes; however, their recurrent involvement leads to speculative implication in the development of malignant transformation. Some of the more common translocations are described *below*.

T-CELL TRANSLOCATIONS AND TRANSCRIPTIONAL FACTORS

Much of the understanding of T-cell neoplasia is based on studies of T-cell leukemias and have been shown to involve both T-cell antigen receptors and transcriptional factor genes in reciprocal translocations (*see* Chapter 3). Those implicated in lymphomas relate to one of four specific transcriptional families, namely, helix-loop-helix (e.g., *C-MYC*), Homeobox (e.g., *TCL3/HOX11*), LIM motif (e.g., *TTG-1/rhombotin-1*), and REL (e.g., *LYT-10*). Altered transcription factor expression appears to be the consequence of translocations, involving them in lymphomas. The mechanism of oncogenesis can be divided into three broad categories (deregulation ectopic expression, and formation of a chimeric gene) examples of which are given *below*.

Deregulation   The first involves deregulation, illustrated by the t(8;14)(q24;q11) involving *C-MYC*, as seen in T-cell high grade lymphomas and ALL. The mechanism of oncogenesis is similar to that of Burkitt's Lymphoma.

Ectopic Expression   The second involves ectopic expression in a cell type that normally has none or low levels. For example, *HOX11* is not normally detectable in T-cells. Following the t(10;14)(q24;q11) in T-cell neoplasia, high ectopic expression occurs. Possibly aberrant expression of *HOX11* is initiated by transcriptional factors acting on the *TCR* loci δ and the *HOX11* is

exposed to other transcriptional factors in the T cell with which it interacts. As it would not normally be exposed to the T-cell specific transcriptional factors, this interaction would not normally take place. The alteration within the T cell may lead to a growth advantage, and additional steps are required for a frankly malignant cell to arise. *TTG-1/rhombotin-1* acts in the same manner.

Formation of a Chimeric Gene   The third mechanism is the formation of a chimeric gene, following a reciprocal chromosomal translocation leading to a fusion protein with altered transcriptional properties. This is illustrated by the t(10;14)(q24;q32) translocation of B-cell lymphomas. The *LYT-10* protein normally contains an amino-terminal DNA-binding (REL-like) domain and a carboxy-terminal domain homologous to ankyrin and mediates protein–protein interaction. Following the translocation, the ankyrin domain is deleted in the fusion protein and replaced by IgH C α sequences. This produces a fusion protein with greatly increased DNA-binding properties, deregulated transcription, and the potential for oncogenesis.

t(2;5)(p23;q35) Translocation   This translocation is a consistent finding in many cases of anaplastic large-cell lymphoma (ALCL) that express the Ki-1 (CD30) antigen, a cytokine receptor for a ligand related to a tumor necrosis factor family. The result of the translocation is the chimeric Nucleophosmin-anaplastic lymphoma kinase (*NPM-ALK*) gene. *NPM* is a nucleolar phosphoprotein gene on chromosome 5, whereas ALK is a member of the insulin receptor subfamily. As a result of the t(2;5) translocation, transcription of the portion of the *ALK* gene encoding its kinase domain is driven by the strong *NPM* gene promoter, leading to its inappropriate expression in lymphoid cells, where it is normally not expressed. The fusion genes oncogenic potential is demonstrated by its ability to transform fibroblast cell lines. ALCL is frequently misdiagnosed as other conditions, such as Hodgkin's disease, malignant histiocytosis, and mycosis fungoides. Detection of the translocation is beneficial in making the correct diagnosis that in turn leads to appropriate therapy.

LYMPHOMA IN THE IMMUNOCOMPROMISED PATIENT

Immunodeficiency, both congenital and acquired, predisposes to lymphoma. The majority are high grade and are often associated with EBV genome within the tumor. It is possible that a failure of immune surveillance may play a role. In the setting of organ transplantation, much of the immunosuppression is aimed at reducing T-cell function; this seems to greatly increase the risk of lymphoma, suggesting a pivotal role for T cells in preventing lymphoproliferation and malignancy. Therefore, it is not surprising that patients with HIV infection have a greatly increased risk of developing lymphoma.

HIV AND LYMPHOMA   HIV-associated lymphomas are predicted to account for up to 27% of all cases of lymphoma in the United States. The HIV does not appear to directly induce lymphoma, but it may participate in the process indirectly by inducing cytokine release, such as IL-6 from monocytes/macrophages. IL-6 is a differentiating factor for B-lymphocytes and has been demonstrated as an autocrine growth factor in non-HIV and non-EBV lymphomas. It has also been shown that IL-10, which may have a role in B-cell growth and immortalization, is expressed in large amounts in HIV-related BL. HIV stimulates a cascade of cytokine release that subsequently stimulates B-cell proliferation and development. This, accompanied by DNA rearrangement and the

increased possibility of developing mutations and chromosomal translocations involving the *IgH* and *IgL* genes, will lead to the increased development of lymphoma. This hypothesis is supported by the high incidence of Burkitt's type translocations and subsequent *C-MYC* deregulation and, more recently, the recognition of *BCL-6* rearrangements (including involvement of the IgH gene) in HIV-associated lymphomas.

Present evidence indicates that in HIV lymphomas, EBV integration occurs before clonal B-cell expansion and suggests EBV may play a significant role in the development of lymphoma. However, not all HIV-associated lymphomas contain EBV, and many of these contain *BCL-6* rearrangements. The etiology of lymphoma in these patients must be diverse with HIV, EBV, or both, creating the environment for mutations within oncogenes or tumor suppressor genes and translocations leading to *C-MYC* or *BCL-6* activation, clonal selection, and development of monoclonal B-cell lymphoma.

POST TRANSPLANT LYMPHOPROLIFERATIVE DISORDERS (PTLD)   PTLDs are a well-known complication of iatrogenic immune deficiency and almost certainly result from EBV-infected lymphocytes, as described for HIV above. Many will progress to frank lymphoma, usually of high-grade type, if immunosuppression continues. Similar to HIV lymphomas, an association with BCL-6 translocations has been detected.

HTLV1 AND LYMPHOMA   HTLV-I is the etiological agent in some cases of T-cell lymphoma and leukemia. There appears to be a multistep process following HTLV-I infection of T-cells, with an initial polyclonal proliferation and immortalization progressing to a monoclonal tumor. HTLV-I carries a unique region located at the 3' end called pX, and this confers the immortalizing function, as well as playing an important role in regulating the virus life cycle. The pX region encodes for three proteins, one of which is the 40-kb transcriptional transactivator protein—*Tax*—a transactivator of viral transcription acting through a 21-bp enhancer element in the long terminal repeats in HTLV-I. *Tax* also stimulates the expression of selected cellular genes in the infected T-cell, leading to their immortilization. These genes are predominantly early mitogen response genes and play a role in the initiation and maintenance of cellular proliferation in T-cells. This is in a similar manner to HIV, creating an environment for further DNA alterations and the induction of a malignant clonal T-cell proliferation.

CLINICAL APPLICATION OF MOLECULAR ABNORMALITIES

Detection of the defect within a lymphoma cell owing to the molecular alterations described above may provide pathological information for the diagnosis, prognosis, and management of the disease. Presence of specific molecular alterations such as the t(11;14) of mantle cell lymphoma and t(8;14) of Burkitt's lymphoma can assist with the diagnosis, and it can additionally act as prognostic markers, suggesting a poor outcome with a need for more aggressive therapy, such as autologous or even allogeneic bone marrow transplantation. Such DNA-related analysis is primarily the role of molecular pathology and should be performed alongside conventional histopathology and immunophenotyping. Methods to detect these alterations are being refined and are evolving from the research to the diagnostic laboratory. Southern analysis was one of the earliest molecular techniques, but it is essentially limited to diagnosis or frank relapse

because of its relative insensitivity (maximum sensitivity of 1%, although in real terms, this is nearer 5%). One of the single most powerful techniques in this new branch of pathology has been the polymerase chain reaction (PCR), which has greatly increased the sensitivity of detection. An added bonus of the PCR is that it is highly robust; the technique can enzymatically amplify specific sequences from high-quality template DNA prepared from fresh frozen tissue as well as degraded DNA extracted from paraffin-embedded tissue.

The t(14;18) translocation detected by PCR has been extensively investigated. Detection of this translocation prognostically suggests that lymphoma that will not be cured by conventional chemotherapy. Detection of minimal disease using t(14;18) PCR has a useful role. The disappearance of the marker in the bone marrow setting may suggest effective therapy, whereas persistence or return of the marker may suggest that a clinical return of the disease will occur. However, the time course can be very variable from weeks to years. With quantitative techniques, it may become easier to determine rising or falling levels of disease in a more predictive manner. The t(8;14) translocation of Burkitt's lymphoma and the t(2;5) translocation of Ki 1 positive lymphoma are also amenable to PCR, although their clinical application is less well investigated. Disappearance of the disease marker suggests a good response to therapy.

Other markers, such as the t(11;14) of mantle cell lymphoma are not readily detected by PCR or Southern blot analysis owing to the relatively large area of chromosome breakage on chromosome 11. This has been overcome recently in part by the use of a number of less sensitive but as powerful techniques, including fluorescence *in situ* hybridization (FISH). This uses a large DNA probe that covers the whole breakage region and has the advantage of being applicable on interphase as well as metaphase chromosomes.

Molecular therapy, such as antisense oligonucleotides, are now entering the clinical setting, using the basic understanding of the molecular basis of disease to obtain an antilymphoma effect. For example, high *BCL-2* expression in follicular lymphoma leads to a failure of apoptosis and chemoresistance. Treatment with *BCL-2* antisense has been shown to lower *BCL-2* expression and permit improved lymphoma cell kill. In order to determine the most useful therapy option, it will become essential to determine the molecular alteration. In turn, the molecular marker will allow monitoring of the disease response and predict potential "cure" at an earlier stage

SUMMARY

Chromosomal translocations in both B- and T-cell lymphomas appear to be the prime initiating step in the development of malignancy. They predominantly involve proto-oncogenes and transcriptional factors that are juxtaposed to the *Ig* or *TCR* genes, leading to the deregulation of the oncogenes expression. Selective protection against apoptosis is achieved by the lymphoma cell permitting a clone to persist until other oncogenes are activated in a multistep progression to tumorigenesis. The occurrence of these translocations is assisted by obligatory DNA breaks and rearrangements of *Ig* and *TCR* that have to occur in order for B and T cells to mature and function. The molecular alterations specific to lymphomas provide a potential for detection of disease, indicate prognosis, permit monitoring of therapy, and in the future may suggest specific target for molecular therapy.

28 Regulation of Humoral Immunity

RALPH C. WILLIAMS, JR.

BACKGROUND

Any discussion of mechanisms involved in the regulation of humoral immunity must address what we think we know in terms of factors that influence antibody production and the vast spectrum of human disorders that may be directly or indirectly related to B-cell function and production of a humoral immune antibody response. Many human diseases cannot get a foothold in the susceptible host if the host already has manifest humoral immunity—e.g., specific protective antibodies to the prospective pathogen. Thus, prior vaccination with a mixture of 23 pneumococcal polysaccharides from the current most prevalent pathogenic pneumococcal serotypes will often protect an individual who otherwise might develop a serious bacterial infection with the pneumococcal organisms. Similarly, childhood and subsequent youthful booster immunizations with tetanus toxoid can also protect from otherwise nearly certain fatal tetanus infection. However, humoral antibody alone cannot itself provide fail-safe protection or successful defense against many human diseases. This is readily illustrated by the still unsolved problem of human immunodeficiency virus (HIV) infection (acquired immunodeficiency syndrome, or AIDS) as well as the ongoing long-term difficulty that has faced research scientists in producing a successful, fully protective malaria vaccine. Thus, naturally occurring humoral antibodies alone do not appear to afford sufficient protection to arrest the inevitable progression of HIV. Similarly, although initial reports looked extremely promising, the falciparum malaria vaccine designed around the unique repeat motifs of Asn-Ala-Asn-Pro in the malarial pathogen currently does not appear to be the whole solution.

In a similar fashion a number of other human disorders of unknown primary cause—often called autoimmune diseases—clearly are associated with the presence of important autoantibodies. Perhaps one of the first autoimmune diseases felt to be directly associated with an autoantibody response was idiopathic thrombocytopenia, or ITP, in which production of antiplatelet antibody was invariably linked to initiation of the disease. Several other common human diseases—also felt to be produced by immune mechanisms, including systemic lupus erythematosus (SLE), rheumatoid arthritis (RA), and insulin-dependent diabetes mellitus (IDDM)—have been strongly associated with autoantibodies such as anti-DNA antibody (SLE), rheumatoid factor (RA), or anti–islet cell antibody (IDDM). Although such antibodies are undoubtedly an important aspect of each of these human disease states, there are also other important key features of cell-mediated immune responses that represent critical features of these same diseases. This section will cover several key elements of the humoral immune response including B-cell activation, the molecular mechanisms that have been identified as contributing to autoantibody production, and what is known concerning the specificity of various autoantibodies including anti-DNA and other antinuclear antibodies in SLE, rheumatoid factors in RA, antineutrophil cytoplasmic antibodies (anti-cANCA) in Wegener's granulomatosis and polyarteritis, and islet cell antibodies in IDDM.

Much of the new information concerning humoral antibody responses in many human diseases derives from our recent insight into precise molecular mechanisms that constitute the genomic basis for antibody production and the eventual pathways involved in antibody affinity maturation and binding specificity. Antibody molecules achieve their specificity by forming a combining site that expresses exquisite binding capacity for three-dimensional structures representing the primary antigenic determinants actually involved in reaction with the receptor structures of the antibody. Despite intensive focus on the specifics involved in making up antigenic determinants, surprisingly little solid evidence has yet emerged as to exactly what constitutes antigenic determinants. Much of the recent conceptualization of precise antigenic components or conformations, crucial for antigenic determinants, has come from computer-assisted modeling of three-dimensional simulations of critical interactive molecules. Within the immune system, examples of available crystal structures include the HLA class I or class II structures and the few monoclonal antibodies or myeloma proteins that have now been studied to provide general shape–function relationships. With respect to antibodies, molecular identification of general families of variable region (V-region) genes making up crucial antibody-combining site structures recently has at last begun to make some sense out of basic biologic mechanisms leading to antibody specificity.

In this chapter we will explore several molecular mechanisms that have now been identified to generate both humoral antibody and specificity. Another important aspect of humoral immunity is control of antibody production and the basic mechanisms involved in regulation of the humoral immune response.
Figure 28-1 Diagram of one-half of the IgG molecule showing three hypervariable regions located within the V_H and V_L segments. These regions, designated CDRs for complementarity-determining regions, are most directly involved in forming the actual antibody-combining site.

Figure 28-2 Diagram of an IgG molecule indicting constant and variable regions of both heavy and light chains. Both heavy and light chains have domains consisting of intrachain disulfide-linked loops. The variable regions of heavy (V_H) and light chains (V_L) are involved in forming the actual antibody combining sites.

Figure 28-3 **(A)** Sequential process of splicing out of introns whereby widely separated exons coding for variable and constant region domains, and hinge region of IgG are brought close together and rearranged to make the final mRNA and hence the final IgG heavy-chain sequence. **(B)** Gene groups for κ chains and λ light chains are located on chromosomes 2 and 22, respectively. The gene families making up variable (V), diversity (D), joining (J), and constant (C) regions of heavy chains are located on chromosome 1.

MOLECULAR BASIS FOR ANTIBODY SPECIFICITY

Antibody molecules derive their specific combining activity by way of their variable or V-region segments. These portions of all antibody molecules are made up of the variable regions of immunoglobulin Ig heavy and light chains. The V-regions of both Ig heavy and light chains each contain three loops that participate in forming the antibody-combining site. These loops are referred to as complementarity-determining regions, or CDRs, which contribute to the three dimensional structure of the antibody-combining site itself (Fig. 28-1). The remarkable diversity of the antibody repertoire is derived from the combinatorial rearrangement of a relatively small number of gene segments composed of variable (V_H) diversity (D), and joining (J_H) segments for the heavy chain V region and variable (V_L) and joining (J_L) segments for the light chain V region. During the gene rearrangement process, the J_H and J_L segments are spliced to the constant region genes coding for the (C_H) and (C_L) segments of the heavy and light chains (Fig. 28-2 and 28-3). The V_H segment itself encodes a hydrophobic leader peptide and between 96 and 101 amino acids of the V_H domain, which includes two antigen-binding loops (H1 and H2). The third antigen-binding loop (H3) is a part of the region produced by the joining together of V_H, D, and J_H gene segments. This third H3 antigen-binding loop is considered to represent the most critical region contributing to the antibody-combining site because it is actually situated exactly within the center of the site. Additional diversity for each individual antibody produced by the rearrangement process is generated by the association of the variable regions of the heavy chain with the variable portions of the light chain that encode three additional antigen-binding loops (L1, L2, and L3) and represents itself the product of a similar combining rearrangement of V_L and J_L gene segments.

Human V_H segments have been classified into seven families, which have been designated as V_H1–V_H7, with different members of each family being at least 80% homologous within the nucle-

otide sequence level. Southern blot hybridization using different V_H-family-specific probes has been employed to provide estimates of the approximate number of V_H segments within the human genome, as well as the dimensions of the V_H locus. These estimates have varied from 60 to 200 V_H segments ranging over a region of 1000–3000 kb on chromosome 14. Unfortunately this strategy has the disadvantage of the fact that different V_H gene segments or restriction fragments of the same length will comigrate on a gel, thereby leading to underestimates of total numbers of separate gene segments. Also, hybridization studies actually produce no direct information about the sequences of the gene segments or more importantly whether the gene segments represent functional genes or only pseudogenes. Based on a number of recent improvements in genomic analysis, a much more direct examination of the germline human V_H repertoire has become possible, as follows.

GERMLINE V_H REPERTOIRE ANALYSIS

Because members of a particular V_H family show considerable conservation of germline nucleotide sequence, sets of oligonucleotide primers for analysis have been designed with the polymerase chain reaction (PCR). Such primers anneal to the leader V-intron region and to the recombination signal sequence (RSS), which is situated just downstream of the coding region. Because the RSS is deleted by the rearrangement process and V_H-D joining, these primers only amplify germline V_H segments. Using this approach recently, 74 germline sequences were obtained from a single normal donor, and an additional 14 segments subsequently identified.

PHYSICAL MAPPING OF THE V_H LOCUS ON CHROMOSOME 14q32.3

The V_H locus is 1100 kb in length and includes approximately 95 V_H gene segments. Actually, the exact dimensions and numbers of V_H segments vary with the individual haplotype. Different members of the seven different V_H families are interspersed throughout the locus unlike the organization of the murine V_H locus in which V_H family constituents are clustered together.

In humans, the heavy chain V gene repertoire is assembled from a comparatively small number of basic genomic segments: there are 51 V_H segments, approximately 30 D segments, and six J_H segments (Fig. 28-4). The relatively small size within the germline repertoire underlines the importance of both junctional diversity and the cojoining with different variable regions on light chains to provide a broad final diversity of antibody molecule products. In addition to gene segment rearrangement, additional antibody diversity is also generated by somatic mutations within antibody V-regions. Very little is currently understood about mechanisms stimulating such mutation.

POSSIBLE V-REGION RESTRICTION IN AUTOIMMUNE DISEASE

Considerable present experimental evidence suggests that, in some autoimmune diseases, both the B- and T-cell repertoires may be restricted. Such a view suggests the possibility that V-region restriction might allow a single antigenic epitope derived from a single antigen (possibly an infectious agent or part of a self-antigen) to produce expansion of a small number of immunologically committed cells, which then become critical for disease pathogenesis. It follows that characterization of such a population of restricted lymphoid cells might then lead to identification of the

Figure 28-4 The interposition of D segments provides for additional variability within antibody genes. D segments connected to J segments are capable of combining with any variable region gene sequence.

original target antigen. Such an approach could conceivably provide important insights into etiology of many autoimmune diseases.

V-GENE RESTRICTION

Considering the fact that there are several hundred V, D, and J gene segments in the germline—and adding to that the combinatorial, junction, N segment, and somatic mutation in B-cells thus contribute to antibody diversity—clearly no focused immune response would use the entire genomic repertoire. Restricted V-gene use usually indicates dramatic overuse of a few V-gene segments. Thus, if more than 75% of a given B-cell response is limited to a maximum of three gene segments, it would be labeled restricted for V-gene usage. V-gene restriction, on the other hand, does not imply clonality.

From a theoretical point of view, the notion of V-gene restriction implies possible uniformity or focusing of both the immunizing antigen as well as the genetic profiles of individuals who are responding. However, all of the important genetic elements involved in the immune response are polymorphic. Besides the remarkable polymorphism of HLA class I and class II genes, T-cell receptor genes of the α, β, γ, and σ complex contribute polymorphism, as do the immunoglobulin genes of the heavy, κ, and λ loci. In addition, the degree of polymorphism at each of these loci results in every individual being heterozygous at most of the loci contributing to immune responses, which further complicates the notion of V-gene restriction.

Following on the initial studies of idiotypes in various human diseases, it was demonstrated that many autoantibodies obtained

from different unrelated patients contain crossreactive idiotypes. Moreover, most idiotypes have been localized to specific V-gene segments and often represent the products of single germline genes. Patients with the same disease (SLE, RA, or scleroderma [PSS]) often express these idiotypes in their signal autoantibody populations.

Direct sequencing of heavy and light polypeptide chains of a large number of human autoantibodies from a broad variety of autoimmune disorders has shown almost no restriction of V-gene segments, with the exception of the clear-cut restriction of the V_H 4–21 gene segment in cold agglutinin disease. Thus, sequencing of more than 20 V_H and V_L gene segments from specific rheumatoid factors from patients with RA has not revealed restriction of one particular set of genes for this particular autoantibody. Instead, the data suggest that almost any combination of V_H and V_L gene segments can be selected to make a rheumatoid factor. Similar results have been found when individual V_H and V_L gene segments have been examined in other autoantibodies, such as anti–acetylcholine receptor antibodies, anti–striational antibodies or antibodies to thyroglobulin. These findings, therefore, do not support the concept of a conventional superantigen (SAg) being responsible for these various autoimmune diseases. Rather, the heterogeneous V-gene repertoire recorded in the large variety of autoantibodies from autoimmune diseases thus far examined suggests that they are the products of an antigen-driven process.

B-CELL SUPERANTIGENS—A POSSIBLE ALTERNATIVE PATHWAY FOR B-CELL ANTIBODY PRODUCTION

For a number of decades, B-cell interactions involving membrane-anchored immunoglobulin (mIg) triggered by direct reaction with antigen were felt to represent the only way in which B-cells could be activated to produce antibody and subsequently to induce clonal activation and further antibody secretion. This conventional clonal activation mechanism involved mIg antibody-combining sites produced through the hypervariable regions of mIg molecules. Recently an additional mode of interaction has been recognized in which various molecules termed B-cell superantigens can bind to human B cells bearing immunoglobulin receptors of a given variable V-gene family. Such a mechanism involves interaction from antibody regions outside the conventional hypervariable V-region CDR loops and appears to be able to initiate a B-cell response of considerably increased magnitude. Studies of the expressed repertoires of certain V_H-gene families have shown that these particular subsets interact in a specific way with a newly recognized group of antigens, called B-cell super-antigens (SAgs).

SAgs were initially recognized for T cells and, in contradistinction to conventional antigens, do not appear to require presentation by allelic and isotypic forms of major histocompatibility complex (MHC) molecules. Instead of the conventional or usual way of binding, the T-cell SAgs bind directly with a site on the Vβ segment of the T-cell receptor (TCR) heterodimer that is different from the region for binding of self-MHC and foreign antigenic peptides. It has recently been recognized that this Vβ specificity of T-cell SAgs has a parallel analogy in the humoral B-cell response. Thus, protein A of the *Staphylococcus aureus* (SPA) may actually represent a B-cell SAg because 40% of human polyclonal IgM binds to protein A. Moreover, the binding of human IgM, IgA, and IgG to SPA is highly restricted to the V_H3 gene family. Additional

observations now indicate that 60% of Ig Fab fragments from V_H3, derived from at least 15 different germline V_H-gene segments, also showed SPA-binding activity. In addition, there appears to be a hierarchy within the binding affinities of V_H3 genes that seems to reflect V-gene usage. Additional B-cell SAgs may also be present in viral components, such as the gp120 major envelope protein of HIV-1. Thus, HIV-1 gp120 has been found to bind to V_H3$^+$ B cells and to serum V_H3$^+$ IgG from normal individuals independent of the L-chain isotype. In addition, staphylococcal enterotoxin D (SED) appears to target preferentially a subset of B cells by way of a V_H-specific mechanism without any restricted distribution of J_H and D_H elements.

ATTEMPTS TO DELINEATE IG DOMAINS INTERACTING WITH B-CELL SAgS

Several experimental approaches have attempted to delineate the structural basis for V_H3 SAg binding. Initially it was suggested that the SAg-binding area included the amino acid residues both in the framework 1 (FR1) or FR3 regions or both. These particular immunoglobulin domains are known to be highly conserved among V_H3 gene products. Experiments in which residue 57 within the hypervariable region CDR2 was mutated from glutamic acid to lysine altered a V_H3-family member from a non-SPA binder to one which bound SPA, suggesting that CDR2 may be directly involved in the actual SPA contact binding site. Other studies, however, have shown that an epitope encompassing the amino acid residues of FR1, the 3' end of CDR2, and even FR3 may be involved in direct nonconventional IgG-SPA binding. This work suggests that some motif or Ig-binding region for SPA may be present between residues 75 and 84—entirely outside the conventional paratope or antibody-combining sites of the three hypervariable CDR loops making up conventional antibody molecules. A theoretical model of how staphylococcal SAgs bind to V_H3 or Ig molecules is shown in Fig. 28-5. Despite the experimental evidence cited above, the precise linear or three-dimensional immunoglobulin sites binding to SAgs have still not been definitively identified. Indeed, several other portions of immunoglobulin structure besides the conventional combining site CDRs may be involved.

IN VITRO STIMULATION OF B CELLS BY SAgS

The precise mechanism of how B cells may be activated by SAgs remains unclear. SPA has repeatedly been demonstrated to be a highly effective stimulator for human peripheral blood B cells. Moreover, SPA activation of such B cells selects for V_H3-associated idiotypes. Subsequent experimental data also indicate that SPA can selectively activate V_H3$^+$ IgM-positive B cells and, in addition, such a stimulus can activate their differentiation and immunoglobulin secretion. Furthermore, the HIV gp120 interaction with V_H3-gene segment products appears selectively to induce Ig secretion by V_H3$^+$ B cells. Finally, another SAg encoded by the *Mycoplasma arthritidis* (MAM) can also activate resting human B cells and induce a polyclonal Ig response through MAM-stimulated B cells.

There also seem to be other alternative mechanisms of B-cell SAg activation that must be considered—such as the *Peptostreptococcus magnus* protein L, which specifically binds to VK1, VK3, and VK4 chains without blocking the parallel antibody combining sites of IgG molecules. This same protein L is also capable of activating mast cells and basophiles by binding to IgE.
Figure 28-5 Alpha carbon representations of the V_L and V_H domains of an antibody molecule from approximately equal orientations. The view above shows the hypervariable regions (CDR1, CDR2, and CDR3) merging together to form the combining site. In the other view, in which the boundaries of framework 3 (FR3) are shown, it can be noted that FR3 of V_L is folded toward the CDRs. In contrast, because the folding occurs in FR3 of V_H toward the solvent, it is less favorably situated for antigen contact, but has a protruding region (lighter gray) that can interact with superantigens (SAg).

It has been hypothesized that there may also exist B-cell SAgs of endogenous origin, such as autologous protein Fv, which is synthesized in the human liver and released in the digestive tract and which can bind secretory IgA. A single protein Fv molecule is able to bind six F(ab)'$_2$ fragments by way of the V_H domains of all Ig isotypes. The majority of V_H3 and V_H6 IgM molecules bind protein Fv. An additional self-protein, human CD4, can bind to 78% of human myeloma proteins by way of the Fab region representing the portion of the IgG molecules containing the antibody-combining sites.

WHAT HAPPENS TO B CELLS AFTER ACTIVATION?

After interaction with antigen, B-cell activation is dependent on the stage of B-cell maturation, the actual antigen-binding affinity, and crosslinking of the B-cell antigen receptors. This can lead to a spectrum of results, including clonal expansion, differentiation, anergy, clonal deletion, or a newly recognized homeostatic mechanism that has been called receptor editing. Because B-cell-activating SAgs appear to differ from ordinary antigens in that they trigger much greater numbers of B cells than ordinary antigens, and also differ by their ability to react with different sites on B-cell receptors, the ultimate fate or result of such SAg–B-cell interaction is still unclear.

For HIV, recent data appear to indicate that gp120 can be within the B-cell repertoire. Thus, in patients with progressive disease, HIV-specific B-cell activation decreases while polyclonal B-cell activation increases. Understanding the mechanisms involved in gp120 as a B-cell SAg could lead to the design of new therapeutic strategies for this disease.

B-CELL ACTIVATION AND SIGNALING

Considerable basic investigation into both B-cell and parallel T-cell activation indicates that in each cell type, transmembrane signaling and activation are linked to similar enzymatic and phosphorylation mechanisms. In B cells, membrane IgM (mIgM) is the first isotype expressed with mIgD appearing later on in maturing cells.

The B-cell receptor complex appears to be a substrate for receptor-triggered tyrosine kinases and phosphatases. Currently it has been proposed that Ig-associated proteins interacting with other components within or close to the B-cell membrane actually provide biochemical transducers at early stages of a strictly tyrosine or serine kinase activity and also are linked to phosphatidyl inositol pathways as well. Anti-Ig or B-cell mIg interacting with antigen triggers a complex cascade of events in which kinase and phosphatase activities are sequentially released. Tyrosine kinases (and phosphatases) have repeatedly been demonstrated to act as key elements in signal transduction within B cells. Tyrosine kinase activation is followed by phosphorylative changes generated through Ig crosslinking.

Two highly conserved hydrophobic sequences have been identified within transmembrane regions of mIgM. Mutagenesis experiments indicate that the TAST sequence in humans is critical for transport from endoplasmic reticulum to the cell membrane but itself is not crucial for either signal transduction or antigen presentation. A second amino acid motif YSTTVT, which is closer to the cytoplasmic boundaries appears to be involved in antigen presentation and Ca^{2+} mobilization.

SIGNALING PATHWAYS

A picture has now emerged that suggests that the C_H4 Ig domain and the amino terminus proximal transmembrane sequence TAST represent the key elements for membrane transport. The carboxyl proximal sequence (YSTTVT), the cytoplasmic tail, and also possibly the α and β associated proteins contribute to transduction of signals by providing sites for one or more nonreceptor kinases. Crosslinking of IgM or IgD activates the enzymatic activity of such Ig receptor-bound enzymes. A tyrosine kinase is probably the first active component to be released. Later activation pathways almost certainly lead to G-protein-dependent phospholipase C

(PLC) activation, Ca^{2+} fluxes, and activation of protein kinase C (PKC) and Ca^{2+}–calmodulin-dependent kinase. These interactions are shown schematically in Fig. 28-6. Recently B-cell activation has also been linked to CD22, a membrane immunoglobulin (mIg)-associated B-cell protein that is tyrosine-phosphorylated after mIg is ligated.

DELINEATION OF ANTIGENIC DETERMINANTS OR STRUCTURES IN AUTOIMMUNE DISEASE

For some time there has been a simplistic attempt to define what really constitutes precise antigenic moieties generating an immune response—particularly with respect to autoimmune disorders such as RA, SLE, Wegener's granulomatosis, or scleroderma. Not surprisingly, antigenic structures have been sought within the various molecules or tissue components that our sometimes fumbling laboratory tests have demonstrated actually react with the presumed autoantibodies being studied. The most familiar example of such a broad line of investigation can be illustrated in the case of rheumatoid factors (RFs). RFs were first recognized as probable autoantibodies to γ-globulins based on the primary observations of Waaler more than five decades ago. The finding that these anti-γ-globulin antibodies were often present in very high titer of serum dilutions from patients with a common chronic crippling disorder, rheumatoid arthritis, produced the name rheumatoid factors. These strange autoantibodies have now been exhaustively studied literally by thousands of investigators. Their primary specificity—felt to be structures on the Cγ3 and Cγ2 domains of IgG or the Fc portion—has been presumed principally based on the laboratory test procedures used to measure RFs, e.g., hemagglutination or sensitized particle agglutination, later succeeded by turbidity measurements of the 19S RF interacting with 7S IgG autologous γ-globulin molecules. Levels of serum RFs in patients with RA have repeatedly been correlated with vasculitis, neurovascular disease complications, severe rheumatoid nodulosis or parenchymal organ involvement, and unrelenting progressive disease. The major specificity of RF has always been presumed to be epitopes on the Fc portion of autologous IgG—principally because we can demonstrate that RFs agglutinate particles coated with this same autologous IgG. In this way as in most other presumed autoantibodies associated with various autoimmune or connective tissue diseases, the positive results obtained in the original type of antibody detection assay later strongly influenced how the clinicians would subsequently regard this particular autoantibody.

Recently we have been interested in attempts to precisely map or delineate the real antigenic determinants on autologous proteins or other well-defined self components. This approach has often employed overlapping heptamers of primary amino acid sequence or the presumed antigenic regions of the protein previously established to be the principal antigenic molecule reacting with the autoantibodies in question. Thus, overlapping heptamers of Cγ3 and Cγ2 of IgG can be demonstrated to have strong enzyme-linked immunosorbent assay (ELISA) reactivity with several selected regions of the Ig domain primary sequences. In like manner these same RFs can be shown to react with similar, but not exactly the same, linear heptamer peptides from other immunoglobulin supergene related molecules, such as β_2-microglobulin or HLA class I MHC molecules. Perhaps if β_2-microglobulin or HLA class I MHC molecules had been the first sort of test substrate employed, RFs would go by another name and have entirely different connotations.
Figure 28-6   When IgM membrane Ig is crosslinked by antigen or anti-IgM antibody, a series of events is initiated, including eventual tyrosine kinase activation, phosphorylation of transduction components, and eventual activation of G-protein-dependent phospholipase C (PLC). The highly conserved hydrophobic transmembrane sequence TAST is crucial for export from endoplasmic reticulum to the cell membrane. The second region YSTTVT is involved in antigen presentation and Ca^{2+} mobilization. The short RVK sequence within the cytoplasmic tail is required for signal transduction and antigen presentation.

In a similar fashion we have recently tried to map antigenic epitopes on proteinase-3 or PR-3, the major cytoplasmic neutrophil antigen that reacts with anti-cANCA, the autoantibody closely associated with Wegener's granulomatosis or occasionally polyarteritis nodosa. In the case of anti-cANCA antibodies, again a number of well-defined linear heptamers derived from the primary amino acid sequence of PR-3 were found to represent reactive antigenic epitopes.

DEFINITION OF ACTUAL ANTIGENS

When a complex structure such as the Cγ3 and Cγ2 of IgG or the entire PR-3 is analyzed for regions that apparently represent antigenic determinants, the reactive linear regions cannot be assumed to constitute all of the reactive antigenic moieties involved because the reactive antigenic determinants must be composed of noncontiguous loops or folds of the primary structure that also make up important antigenic determinants. Nevertheless, the use of similar or parallel strategies of molecular modeling and epitope analysis has recently provided an additional potent tool to examine what make up antigenic sites on a number of molecules or autoantigens of interest.

REGULATION OF THE IMMUNE RESPONSE

Despite an immense amount of investigative effort and much focus on the question of immune system regulatory control, there is still very little clear insight into what features in a particular disease actually play the key roles in immune regulation. Some years ago there were strong proponents of a probably much oversimplified yin-yang theory that both humoral and cell-mediated immune responses were largely controlled by an appropriate balance between helper and suppressor cells that either upmodulated or downregulated various immune reactions. This still may be true in a limited way; however, the entire subject of immune regulatory response and balanced control of immune responsiveness has now become considerably more complex—particularly with the virtual explosion of knowledge in the area of active immunocyte-produced cytokines. This area will be discussed in a separate chapter within this section.

IDIOTYPES (Id) AND ANTI-Id REGULATION

Jerne and coworkers first proposed the concept of idiotypic control of the immune system based on the idea that both antibodies and T-cell receptors must have some sort of mechanism that was individually specific and could provide ultimate stable modulation. Currently there is considerable evidence that the Id–anti-Id feedback loops do indeed influence and to some extent control both normal immune reactivity as well as abnormal disease states, such as myasthenia gravis or SLE. The concept of individual antibody responses stimulating a self-modulating counter influence is based on the model originally proposed by Jerne of Ab1, Ab2, and Ab3 and is derived from the idea that the body or immune system sees internal images of antibody-combining sites or T-cell receptors and reacts to them in such a way as to gently downregulate their magnitude and overall effect.

Presently clinical medical problems in which Id–anti-Id mechanisms may actively be involved have not been defined to an extent that exquisite specific turning on or off of an anti-Id response is possible either through drugs given or other strategies under the control of the treating primary physician. It has been postulated, however, that the use of intravenous γ-globulins (IVGG), as in dermatomyositis, juvenile rheumatoid arthritis, or some patients with intractable ITP, may actually involve administration of generic polyclonal anti-idiotypic antibody capable of downregulating pathogenic autoantibodies associated with a patient's primary disease. Hopefully, as our understanding of Id–anti-idiotype regulation increases, our ability to incorporate such an approach into common therapeutic protocols will progressively improve and become a rational method of treatment.

29 Molecular Regulation of Cellular Immunity

Eric Sobel

INTRODUCTION

The task of the immune system is a formidable one. Out of the enormous array of antigens encountered daily, it must respond to eliminate the harmful (i.e., foreign and self altered by malignancy and infection) and ignore the useful (i.e., normal self). The response must be rapid, sensitive, and specific. Moreover, the immune system must be extremely adaptable, because it must provide a defense for all possible invaders, including novel ones. All of these demands are finely balanced. If the immune response is deficient, the individual risks recurrent and life-threatening infections or malignancy. If the response is too vigorous or not restricted to unique aspects of the pathogen, autoimmunity ensues.

Impressive strides in the understanding of how the immune system accomplishes these tasks have been made in the past 10–15 years. Although the normal immune response has classically been divided into humoral and cell-mediated arms, in reality, the generation of a response is governed by a complex interplay of cellular interactions and the elaboration of a number of soluble factors (cytokines). Antibody- and cytokine-mediated regulation will be discussed in more detail in separate chapters (28 and 30, respectively). Advances in our understanding of the molecular basis of autoimmunity (Chapter 34) and immunodeficiency (Chapter 33) will also be presented elsewhere, as will the role of the major histocompatibility complex (Chapter 31). This chapter will focus on a general understanding of the molecular basis for the regulation of the immune response, with an emphasis on a few key advances in antigen presentation, coactivation, and programmed cell death (apoptosis).

MOLECULAR BASIS FOR ANTIGEN RECOGNITION

It has long been recognized that antibodies, produced by cells of B-lymphocyte lineage, are the effector molecules of the humoral arm of the immune system and that these molecules bind directly to antigen. The nature of the antigenic determinant recognized is unrestricted, and numerous examples of antibodies specific for determinants on protein, polysaccharide, lipids, nucleoprotein complexes, nucleic acid, and simple chemicals have been described. In some cases, antibodies recognize linear epitopes on protein, but in many other cases, the determinants are conformational and require that the macromolecule be in its native state. In contrast, the molecular basis for antigen recognition by T cells is a rela-

From: *Principles of Molecular Medicine* (J. L. Jameson, ed.), ©1998 Humana Press Inc., Totowa, NJ.

tively recent discovery, dating back to the identification and cloning of the T-cell receptor in 1983 and X-ray crystallographic resolution of the structure of major histocompatibility complex (MHC) molecules in 1989. Since then, progress has been rapid. T cells recognize peptide fragments of protein antigens only when bound to and "presented" by MHC molecules (Chapter 31). Thus, MHC molecules act as restriction factors, and the interaction between T cells and target is said to be "MHC-restricted."

There are two major types of MHC molecules. Class I molecules are ubiquitously expressed on virtually every nucleated cell. The class I antigen is a heterodimer consisting of β2 microglobulin (not encoded in the MHC) noncovalently linked to a 300-amino acid protein. This heterodimer forms a β-sheeted floor with two opposing α helical "walls" (Fig. 29-1). Within the groove separating the helixes lies the peptide antigen. Residues from both the peptide and the MHC molecule act as contact points for the T-cell receptor. Class II molecules are very similar in structure to class I (Fig. 29-2), but differ in three fundamental ways. First, class II molecules are expressed by a more limited population of hematopoietically derived "professional antigen-presenting cells." The major cell types expressing class II are B cells, monocytes or macrophages, and dendritic cells. In humans, but not mice, activated T cells also express class II, the role of which is unclear. Second, class II molecules are composed of αβ heterodimers. Third, bound peptides have less stringent size requirements and can be significantly larger than the 9 to 11-amino acid-length peptides found in class I molecules. This is because the groove in which the peptide sits has closed ends in class I molecules. Class I and class II molecules differ in one other crucial respect: class I molecules preferentially interact with T cells having the CD8 coreceptor whereas class II molecules interact with the CD4 coreceptor.

Numerous studies have been conducted on identification of motifs of peptides that bind to specific MHC molecules. In general, residues near the amino and carboxy terminal ends determine binding to the MHC class I molecule and are called anchor residues. The interior peptides are more variable and are more likely to determine whether a given T-cell receptor will bind. Frequently, the interior residues can kink and protrude from the groove. Binding to class II has fewer restrictions, not only in size but in sequence, so that anchor residues are not as readily recognized. This is presumably because the open ends of the class II molecule allow more flexibility in the alignment of the peptide within the groove. Peptides up to 30 amino acid residues in length have been described. Compared with class I, peptides in class II molecules tend to be in an extended conformation.

259
Figure 29-1 Peptide-binding constraints differ between class I and class II molecules. Size of peptide constrained to 8–10 amino acids in length by "closed ends" of class I molecule.

THE T-CELL RECEPTOR

STRUCTURE OF THE T-CELL RECEPTOR   One of the major puzzles of immunology was how the immune system could encode for the staggering number of immunoglobulin and T-cell receptors found. It is now known that diversity in both classes of molecules is generated during maturation of the cell by a unique process of somatic genomic rearrangements. This is done in a clonal fashion such that an individual B or T cell expresses a single immunoglobulin or T-cell receptor. Although a detailed description of the structure and development of the T-cell receptor is beyond the scope of this chapter, it is important to appreciate in a general sense how receptor diversity is generated.

T-cell receptors are covalently linked heterodimers. The majority are composed of α and β polypeptide chains, each containing a variable and constant region. A significant minority of T cells express instead a γδ heterodimer, the function of which is still incompletely understood but may recognize nonpeptide antigens. The variable region itself is encoded by the combination of different gene segments. In the case of the α and γ chain, the variable region is produced by combining a variable (V) and a joining (J) gene segment by gene rearrangement (Fig. 29-3). There are approximately 50–75 different V and 70 different J gene segments available for the α chain. The β (and γ) chain has an additional diversity (D) gene segment inserted between the V and J segments. The constant region, as the name implies, is much less diverse. There are two gene segments available for recombination in the case of the β chain and one for the α.

GENERATION OF THE T-CELL REPERTOIRE   Recombination proceeds in an orderly fashion, mediated by the products of the RAG-1 and RAG-2 genes. As of this writing, it is still unclear whether these genes are physically part of the recombinase machinery or are regulatory proteins. The β-chain locus on one allele is the first to attempt to rearrange, with first a DJ joining, followed by joining of the V segment. Functional rearrangement of the β chain triggers the rearrangement of the α gene in a similar fashion, except that, lacking the D region, it is a direct VJ joining. Additional junctional diversity is introduced through the random addition of nucleotides at the VD, DJ, and VJ regions, mediated by the enzyme terminal deoxyribonucleotidyl transferase (TdT). If

an attempted rearrangement is nonproductive (through frameshift mutations or other problems), the rearrangement of the alternate allele is activated. With successful rearrangement, further rearrangement activity ceases. Thus, a given T cell expresses only one α chain and one β chain, a phenomenon known as allelic exclusion. If all attempts at productive rearrangement fail, the developing T cell will die, a very common event. It is the huge number of combinatorial possibilities arising from random rearrangements that generates the diversity of the T-cell repertoire.

ANTIGEN PROCESSING

In the past 5–6 years, there have been major advances in our understanding of the pathway by which protein antigens are degraded and displayed bound to MHC. It has been appreciated for some time that antigenic peptides bound to class II are predominantly extracellular, whereas peptides of endogenous origin are presented by class I. It has also been known that fixed cells could present protein as antigen only if the protein had been cleaved into peptide fragments. This clearly demonstrated the need for an active process.

THE CLASS II PATHWAY   The difference in source of antigens between class I and class II is reflected in the difference in antigen processing pathways (Figs. 29-4 and 29-5). Exogenous antigens destined for class II presentation are taken up by different antigen-processing cells (APC) by different mechanisms. The nature of the antigen may dictate which type of APC is dominant and affect the outcome. Macrophages internalize antigen primarily by phagocytosis, whereas dendritic cells use endocytosis or pinocytosis. Unlike the nonspecific binding of most APCs, B cells can bind antigens with high selectivity through immunoglobulin receptors. Once bound, the antigens become localized to intracellular membrane-bound vesicles called endosomes. It is in these acidic vesicles that protein is degraded by proteases and the resulting peptides associate with the class II molecules. The class II molecules themselves have been synthesized and assembled with the invariant chain (Ii) in the endoplasmic reticulum and transported to the endosomes in vesicles derived from the Golgi apparatus. The invariant chain serves to assist in assembly of class II molecules and to prevent endogenous antigen from binding prematurely. Furthermore, evidence suggests that the invariant chain contains endosomic targeting signals for the class II molecule. In the acidic environment of the vesicles and in the presence of peptides, the invariant chain dissociates and allows binding of processed peptide. From here, the class II molecule with peptide is transported to the cell surface. Interestingly, a number of peptides from class II molecules have been sequenced, and many of them have been found to be cell surface molecules derived from self.

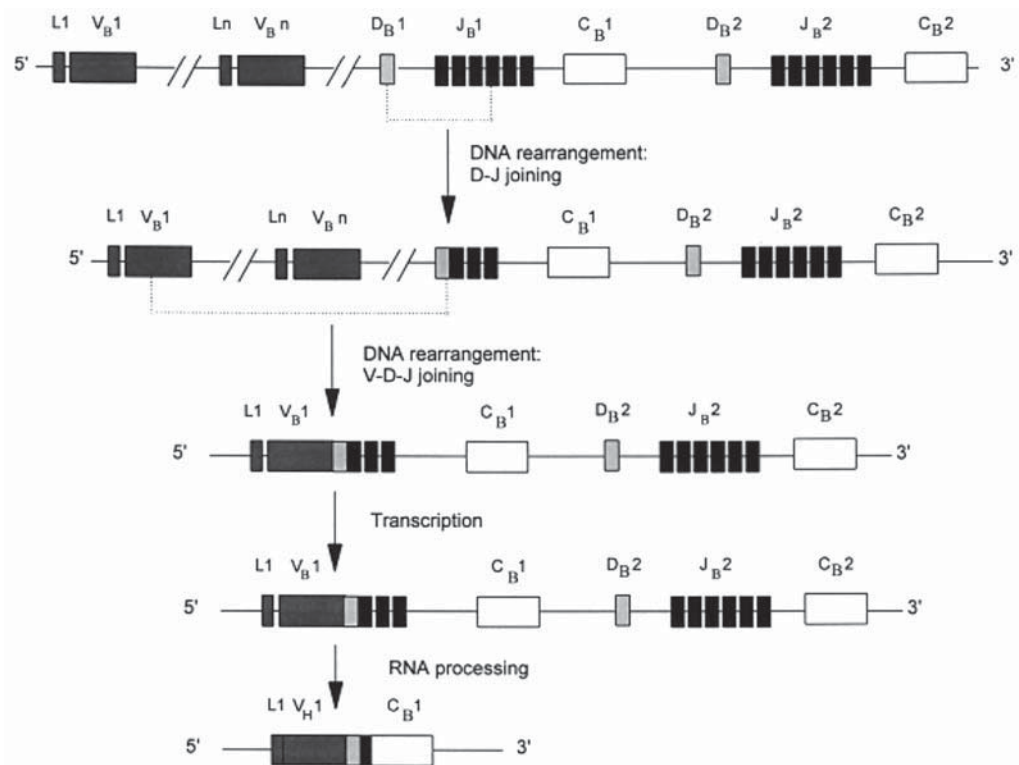
THE CLASS I PATHWAY   Endogenously synthesized cytosolic antigens follow a different pathway. Proteins targeted for proteolysis are bound covalently by a small molecule (ubiquinin). Such bound proteins are degraded by a large cytoplasmic organelle called a proteasome, which is composed of as many as 24 protein subunits. Interestingly, two of these subunits map to the class II region of the MHC and, although not absolutely required, seem to enhance processing. In addition to the proteasome subunits, two "transporter in antigen processing" (TAP) genes have also been mapped to the class II region. The products of these two genes form an endoplasmic reticulum membrane-bound heterodimer that serves to transport proteasome-produced peptides into the endoplasmic reticulum. Here the peptides bind to and stabilize the
Figure 29-2 The "open ends" of class II molecule permit larger peptides and overhanging residues. (*See* color insert following p. 684.)


Figure 29-3 DNA gene rearrangement, also seen in immunoglobulins, is responsible for the enormous diversity of T-cell receptors. Individual T cells undergo somatic and random rearrangement of germline DNA. There are approximately 75 V_β segments available. The α chain follows a similar process except that no D regions exist and subsequently, the first step is V-J rearrangement. With the addition of N-region diversity at the D-J and V-D junctions, total available diversity has been estimated to be greater than 10^{15}.
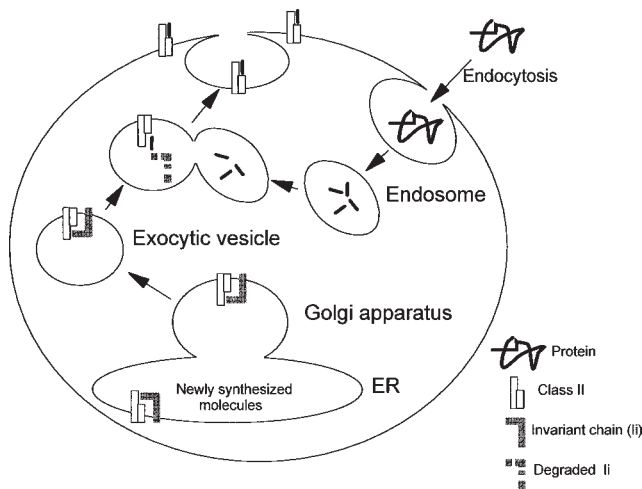

Figure 29-4 Antigen-processing pathways differ for class I and class II molecules. Presentation by class II is limited to "professional" antigen-presenting cells and is tailored to present preferentially peptide derived from exogenous sources. This is accomplished by the invariant chain (Ii), which prevents binding of peptide within the class II cleft until the Golgi-derived exocytic vesicle has fused with the endosome.
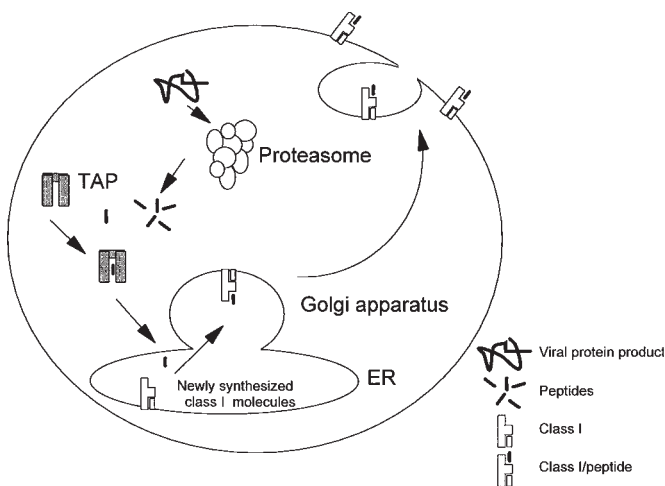

Figure 29-5 Presentation by class I molecules is performed by virtually all nucleated cells. Peptides, derived from cytosolic proteins, are targeted for degradation by proteasomes and transported to the endoplasmic reticulum (ER) by specific transporter (TAP) proteins.

formation of nascent class I molecules. Thus, the class I pathway is well-suited to present neoantigens derived from malignant or viral transformation. Compared with the restricted expression of class II, the wide expression of class I allows the immune system to survey most nucleated cells.

T- AND B-CELL MATURATION AND THE DEVELOPMENT OF TOLERANCE

CENTRAL T-CELL TOLERANCE Tolerance mechanisms have been classified as either central (thymic) or peripheral. Intrathymic tolerance involves clonal deletion whereas peripheral tolerance can occur either through deletion or anergy. Cells committed to the T-cell lineage migrate to the cortex of the thymus

from the bone marrow, probably homing there through as yet uncharacterized receptors. As immature thymocytes, their T-cell receptors (TCR) are in the germline configuration, and none of the mature T-cell markers, such as CD4 or CD8, is expressed. Within the cortex, the thymocytes begin the process of random somatic rearrangement of their TCR genes. Once a thymocyte has successfully rearranged and expressed its TCR (at low levels), it can coexpress CD4 and CD8 and migrate from the cortex to the medulla. It is at this point that positive and negative selection occur. For positive selection, some threshold affinity of TCR for MHC molecule is required. However, those maturing T cells having a TCR that engages a self-MHC molecule too avidly are deleted from the repertoire through negative selection. An understanding of the selection process has been greatly enhanced by the discovery of endogenous superantigens and the development of transgenic and targeted deletion technology. Negative selection by clonal deletion was first conclusively demonstrated for superantigens, which are molecules that activate a much larger subset of T cells than conventional antigen. It has now been shown that this occurs because superantigens can bind to certain V_β genes regardless of which D_β, J_β, or even α chains are used. Moreover, these superantigens have binding sites that can engage certain class II molecules by binding to nonpolymorphic regions outside the peptide-binding cleft. In mice, some superantigens are encoded by endogenous retroviruses and are thus considered self. For example, one well-studied superantigen present in certain strains of mice engages $V\beta17a$ in the presence of the class II molecule I-E. In these mice, $V\beta17a^+$ $CD4^+CD8^+$ thymocytes were found. However, mature $V\beta17a^+$ cells were not found in the periphery. Further analysis showed that these cells were deleted at the $CD4^+CD8^+$ stage within the thymus, because no $CD4^+$ or $CD8^+$ thymocytes expressing high levels of TCR could be detected.

Positive selection was demonstrated in a similar way by the use of TCR transgenic mice. One of the best-studied introduced a TCR that, in the context of the class I molecule H-2D^b, was specific for a peptide derived from the male-associated antigen H-Y. Transgenic female mice expressing H-2D^b had T cells expressing the transgene, whereas male mice of the same haplotype did not. To demonstrate that the female mice expressed this transgene through positive selection and not through the absence of negative selection, the transgene was bred onto another MHC background. In the presence of only irrelevant class I molecules, T cells from female mice did not express the transgene.

Those cells that survive this selection process emerge as $CD4^+$ or $CD8^+$ cells bearing high levels of TCR. For TCRs that engage class II, CD8 expression is downregulated and the converse is true for TCRs engaging class I. The exact mechanism for this downregulation is still unclear, but an individual T cell probably commits to the CD4 or CD8 lineage before selection. Cells that are negatively selected or have TCR that do not engage MHC die from apoptosis, a series of regulated steps characteristically resulting in endonuclease activation, DNA fragmentation, cell fragmentation, and blebbing. In contrast to necrosis, death by apoptosis causes little inflammation.

The cells within the thymus responsible for positive and negative selection arise from different populations. Positive selection is mediated by non–bone marrow-derived thymic epithelial cells, whereas negative selection can apparently be mediated by more than one cell type. This has been shown most convincingly in some recent bone marrow cell transfer experiments using a mouse strain

with a mutation induced in its class II molecule. Such mice, lacking expression of class II, failed to express CD4$^+$ T cells in the periphery, owing to a lack of positive selection on class II. When these mice were lethally irradiated and reconstituted with bone marrow from normal mice, few CD4$^+$ T cells were found in the periphery, indicating that bone marrow-derived cells expressing class II could not mediate positive selection. Conversely, infusion of class II-negative bone marrow into normal mice resulted in normal expression of CD4$^+$ T cells. In both cases, the mice were tolerant to donor and host cells.

B-CELL TOLERANCE A similar process of tolerance occurs in the bone marrow for developing B cells. As for T cells, through random rearrangements, a vast repertoire of immunoglobulin receptors develops. Again, transgenic technology has been vital in demonstrating negative selection. In a particularly elegant set of experiments, mice transgenic for an antibody to hen egg lysozyme (HEL) were generated. The construct was such that expression of both IgM and IgD through alternative splicing was possible, and easily detectable anti-HEL antibody was found in the serum. Two other transgenic strains, one expressing HEL on the cell membrane and the other expressing HEL in secreted form, were also created. When the anti-HEL transgenic was crossed with the strain expressing membrane-bound HEL, essentially no B cells expressing anti-HEL were found in the periphery and no anti-HEL was found in the serum of the F$_1$ offspring. In contrast, when the anti-HEL mice were crossed with the strain expressing only secreted HEL, the B cells in the offspring were not deleted but had downregulated their IgM (but not IgD) expression on the cell surface. Again, no anti-HEL was found in the serum. Moreover, these mice could not be induced to produce anti-HEL with immunization. Thus, in the case of the cross with membrane-bound HEL, B-cell tolerance through clonal deletion was induced, whereas in the case of soluble HEL, B-cell tolerance by clonal anergy was induced.

PERIPHERAL T-CELL TOLERANCE This pathway of intrathymic (central) negative selection goes a long way in explaining T-cell tolerance to self-antigens that are secreted or common to all cells. However, it does little to explain organ-specific tolerance, as it is hard to see how all such antigens could be efficiently transported to the thymus. Other hypotheses, such as the presence of thymus-specific peptides inducing tolerance, have been proposed but have found little experimental support. Clonal anergy in B cells could be understood as a result of stimulation in the absence of T-cell help. However, T-cell tolerance by clonal anergy was more difficult to explain. In the last few years, the discovery of coactivation molecules and the two-signal hypothesis for T-cell activation has provided a molecular framework for the concept of clonal anergy (*see below*).

REGULATION OF CELLULAR INTERACTIONS IN THE DEVELOPMENT OF AN ANTIBODY RESPONSE

It is now possible to outline, in some detail, the specific steps leading to a T-cell-dependent antibody response. Classic experiments in the 1970s, using the hapten-carrier system, demonstrated that, for effective T-B collaboration, both T and B cells must recognize the same antigen. The actual epitope need not be the same, but they must be physically linked. Early experiments also showed that soluble factors were important. However, for optimal help, physical contact (i.e., cognate interactions) between T and B cells must be established.

It is now apparent that effective activation of T and B cells requires at least two signals, one acting through the TCR or immunoglobulin receptor, respectively, and the other a costimulatory signal generated by recently described molecules. The following section will outline the current understanding of these interactions.

THE ROLE OF COSTIMULATORY MOLECULES The first costimulatory pair to be identified was CD28-B7, important in the activation of T cells. B7 has now been shown to be a family composed of at least three members: B7-1 (CD80), B7-2 (CD86), and B7-3. B7-1 is a 55- to 60-kDa glycoprotein not normally expressed on resting B cells, but which can be induced by a variety of stimuli, including polysaccharides and crosslinking of cell surface IgM or class II. B7-1 expression can also be induced on monocytes by interferon-γ (IFN-γ). Expression after induction is slow in onset, with peak expression occurring 2–3 days after exposure. In contrast, expression of B7-2, a 70-kDa glycoprotein can be induced on B cells much more rapidly with the same stimuli. B7-2 is also constitutively expressed on monocytes at a low level and on dendritic cells at a higher level. Less is known about B7-3. Its expression is slow in onset, similar to B7-1. The first receptor to be discovered for B7 was CD28. This is an 88-kDa, disulfide-linked homodimer constitutively expressed on T cells but subject to further upregulation in vitro with phorbol ester or anti-CD3 stimulation. It is expressed by CD4$^+$CD8$^+$ thymocytes, but its role in intrathymic selection is unclear inasmuch as thymocyte development appears normal in CD28-deficient mice. CTLA-4, a second receptor for B7, is found only on activated T cells. Both B7 and CD28 are members of the immunoglobulin supergene family.

In contrast to the CD28–B7 receptor–ligand interactions, the CD40L–CD40 system is important in B-cell activation. CD40L, a 39-kDa glycoprotein also called gp39, is expressed on activated T cells. CD40, a member of the tumor necrosis receptor family, is a 45 to 50-kDa glycoprotein expressed constitutively on B cells and dendritic cells. Crosslinking of CD40 on B cells induces class switching and stimulates proliferation. The importance of this system has been dramatically illustrated by the discovery that the hyper-IgM syndrome, characterized by poor germinal center formation in response to foreign antigen and deficient class switching, is caused by a defect in CD40L. The reciprocal interactions between B7–CD28 and CD40L–CD40 are crucial to the development of the immune response. Engaging CD28 on activated T cells causes an increased expression of CD40L. Conversely, engagement of CD40 on B cells causes an increased expression of B7-1 and B7-2.

TRACING A T-CELL-DEPENDENT B-CELL RESPONSE IN VIVO With this as background, the sequence of events leading to a T-cell-dependent antibody response can be outlined. When foreign antigen enters the organism, it is taken up into the cortex of draining lymph nodes. Into these same areas, naive T cells migrate by passing through venules specialized for diapedesis, called high endothelial venules. Here, they encounter the processed antigen presented, in the context of class II, on "professional" antigen-presenting cells, primarily thought to be the bone marrow-derived dendritic cells. These cells express high levels of class II and B7-2. If the APC can interact with the naive T cell through engagement of the TCR while simultaneously crosslinking CD28 through B7, the T cell becomes an activated effector cell. One of the end results of activation is expression of CD40L on the T cell.

The activated T cell is now capable of interacting with naive B cells, which also circulate through this area of the lymph node.

B cells that express surface immunoglobulin that can bind the foreign antigen will preferentially display peptides derived from this antigen and will be efficient APCs for the activated T cells. When such an encounter occurs, the B cells are stimulated to upregulate B7 expression through engagement of constitutively expressed CD40 by the activated CD40L⁺ T cells, and the B cells are themselves activated. These activated B cells begin secreting antibody and migrate to nearby primary lymphoid follicles, where they interact with follicular dendritic cells. The follicular dendritic cells are epithelial-derived cells that bear no relationship to the dendritic cells of bone marrow origin mentioned earlier. Furthermore, they have the unique and critical property of binding and trapping antibody–antigen complexes for interaction with the germinal center B cells. B cells under this stimulation are driven to somatically hypermutate and, through additional T-cell signals delivered by cytokines (Chapter 30), to begin undergoing class switching. As the immune response develops, competition for binding to the follicular dendritic cells ensues such that those B cells expressing the highest affinity immunoglobulin receptors are preferentially selected, while those that have mutated to a lower affinity antibody die through apoptosis. This results in the phenomenon of affinity maturation that marks an adaptive immune response. With an ongoing immune response, the selected cells undergo rapid clonal expansion, and some of these cells begin migrating into the circulation. With additional help from activated T cells, some of these cells will be triggered to develop into long-lived memory B cells. The remainder will become short-lived plasma cells designed to secrete enormous amounts of antibody.

Although the CD28–B7 and CD40–CD40L costimulation signals are crucial to development of the immune response, other molecules are also clearly important. The best-studied of these are lymphocyte function-associated antigen-1 (LFA-1) and CD2 present on T lymphocytes. The counterreceptors for LFA-1, present on antigen-presenting cells, are the intercellular adhesion molecules ICAM-1, ICAM-2, and ICAM-3, whereas the counterreceptor for CD2 is LFA-3. Although antibodies to CD2 or LFA-1 can block activation of T cells, activation can occur normally in induced mutants deficient in either of these molecules, suggesting a redundancy of function. The exact function of these and other activation molecules, such as CD43, CD73, and CD7, for which counterreceptors have not yet been identified, is still uncertain. However, it is thought that these nonspecific interactions provide for a multivalent low-affinity system between T cell and APC, thus allowing prolonged contact and the opportunity for the T cell to sample numerous MHC molecules with peptide. When signaling occurs through the TCR, a conformational change is induced in LFA-1 causing an increased affinity for the ICAMs. ICAM-2 is also constitutively expressed on vascular endothelial cells, and ICAM-1 is inducibly expressed in the presence of inflammatory mediators. Thus, these molecules also subserve the important function of lymphocyte migration into the areas of active inflammation and may have an important role in the pathogenesis of vasculitis. The potential clinical importance of these interactions has also been illustrated by recent studies in primates, which showed that attachment and subsequent infection by rhinoviruses could be blocked by soluble analogs of ICAM.

REGULATION OF CELL-MEDIATED IMMUNITY

The pathway outlined above for a specific antibody response to antigen results in the development of Th2 CD4 effector cells. These cells produce interleukin-4 (IL-4), IL-5, IL-6, IL-9, and IL-10, all important in the regulation of antibody production (Chapter 32). CD4⁺ cells are also capable of becoming Th1 effector cells, characterized by the elaboration of IL-2 and IFN-γ, crucial to the activation of macrophages for elimination of intracellular pathogens such as *Listeria* species. The specific mechanisms in vivo leading to activation of a polarized Th1 or Th2 response is unclear but probably reflects the microenvironment in which the T cells were activated. For example, in vitro studies have shown that addition of IL-4 during T-cell stimulation with antigen resulted in a Th2 response. Conversely, addition of IFN-γ stimulated a Th1 pattern. The costimulatory molecules may also play a role. In experimental allergic encephalomyelitis, an animal model of multiple sclerosis, specific blockage of B7-2 by antibody treatment caused an increased Th1 response, whereas blockage of B7-1 led to a Th2-predominant response and less disease. Finally, there is evidence to suggest that undetermined genetic factors are involved.

REGULATION OF CELL-MEDIATED CYTOTOXICITY

The molecular basis for the interactions leading to a specific immune response by CD8⁺ T cells is less well-understood than for CD4⁺ responses but basically follows the same paradigm. The importance of B7 as a costimulator has been illustrated by a number of studies in which B7 has been transfected into tumor cells and transferred to a naive host. Under these conditions, the tumor is cleared much more readily. Conversely, blockage of the B7–CD28 pathway can lead to reduced rejection. In infections or malignancies involving cells that cannot express B7, CD4⁺ Th1 cells stimulating CD8⁺ cells are important, and the role of B7 as the direct costimulator of CD8⁺ T cells is less clear. The CD4⁺ cells themselves are presumably activated through professional APCs as outlined above and are therefore stimulated to secrete IL-2. It has been shown that engagement of the TCR on CD8⁺ cells in the presence of sufficient IL-2 can circumvent the need for costimulation. Inasmuch as CD8⁺ cells are responding to peptide plus class I, whereas CD4⁺ cells are responding to peptide with class II, it is not yet clear whether CD4⁺ T cells are stimulating CD8⁺ T cells through a common APC or by bystander effects.

Only two different effector mechanisms appear to account for cell-mediated cytotoxicity. In the first mechanism, death is caused by a secretory pathway mediated by perforin and granzymes. Perforin, structurally related to the terminal component of complement C9, performs a similar function by creating large pores in the membrane of the target cell. Serine proteases (granzymes) are cosecreted, resulting in target lysis. The perforin and granzymes are stored in specialized vesicles and are released by a Ca²⁺-dependent mechanism that spares the effector cell from self-lysis. In the second mechanism, target cells are induced to undergo programmed cell death (apoptosis) by crosslinking of a specific receptor called Fas (CD95). The regulation of apoptosis is an area of intense investigation. Although the exact pathway leading to apoptosis remains to be elucidated, recent evidence points to ceramide, a product of sphingomyelin hydrolysis, as a second messenger.

Although the intramolecular signals leading to apoptosis are still being delineated, more is understood about the cell surface molecules involved. Fas, the receptor signaling apoptosis, is a 48-kDa glycoprotein and member of the tumor necrosis factor (TNF) receptor family. It is expressed on activated T and B lymphocytes. Mutations of Fas have arisen spontaneously, the

best known of which is called *lpr*. Mice homozygous for the *lpr* mutation develop a systemic autoimmune disease characterized by the accumulation of a massive number of peripheral T cells that bear neither CD4 nor CD8 and express decreased levels of TCR. Furthermore, these mice develop high titers of autoantibodies. The *gld* mutation, which causes disease phenotypically identical to *lpr*, has been shown to be a point mutation of the ligand binding Fas, rendering it nonfunctional. Fas ligand (FasL), a 40-kDa glycoprotein expressed on cytotoxic T cells, is without an intracellular signal sequence, suggesting it functions purely as a ligand. The physiologic roles of Fas and FasL are still under investigation. Despite the expression of Fas on CD4$^+$CD8$^+$ thymocytes, central tolerance appears to be intact, pointing to a role in peripheral tolerance by clonal deletion.

T-CELL SIGNALING PATHWAYS

Complementing the great progress in understanding the cell surface interactions leading to immune responses has been the elucidation of the intracellular signaling pathways involved. This is a complicated field, and, although a great number of detailed steps are known, full integration of all of the events leading to activation is still incomplete. Therefore, a broad overview will be provided, mentioning some of the steps that have been shown to be potentially clinically relevant.

The T-cell receptor itself has little in the way of a cytoplasmic component and therefore does not itself transduce the intracytoplasmic signals. Instead, the TCR has associated with it a number of additional invariant proteins, collectively called CD3. CD3 consists of three proteins (CD3γ, CD3δ, and CD3ε), which have homology to immunoglobulins, and two additional proteins, η and ζ, which do not. The ζ chain is an alternatively spliced variant of the η chain and, in the TCR complex, exists as either ζ-ζ or ζ-η disulfide-linked dimers. The CD3ε chain is present in two copies per TCR complex; ε, γ, and δ all have large extracellular domains, whereas ζ and η do not. All five proteins associate with the TCR through noncovalent bonds and can associate with cytosolic tyrosine kinases.

PHOSPHORYLATION With crosslinking of the TCR complex, a set of four interdependent events occurs: (1) tyrosine phosphorylation of membrane and cytosolic proteins; (2) hydrolysis of membrane inositol phospholipids; (3) intracellular calcium fluxes; and (4) increased protein kinase C activity. All members of the CD3 complex have intracytoplasmic tyrosine residues that become phosphorylated with activation. In addition, three major phosphotyrosine kinases have been described: lck, fyn, and ZAP (ζ-associated protein) kinase. Lck is physically associated with the intracytoplasmic domains of CD4 and CD8. It is a crucial protein, as shown by the lack of T-cell development in lck-deficient mice created by homologous recombination. Fyn is weakly associated with the ζ chain of the TCR. In contrast to lck, however, deletion of fyn has shown no effect on development and relatively little effect on T-cell activation. ZAP 70, the third protein, becomes tightly associated with the ζ chain after activation. Interestingly, a form of immunodeficiency characterized by deficient T-cell signaling and an absence of CD8 cells has been described in patients lacking ZAP 70 (*see* Chapter 32). The specific substrates for each of these phosphotyrosine kinases are still being defined. Also regulating phosphorylation is the cell surface molecule CD45, also called leukocyte common antigen, which has intrinsic intracytoplasmic phosphatase activity. One of the functions of CD45 is to remove phosphate from carboxy terminal tyrosine residues on lck and fyn, thereby increasing their activity. Mice deficient in CD45 have deficient B-cell responses and undergo defective intrathymic positive selection.

TRANSCRIPTION After these early events, a number of transcription factors are expressed, now thought to number greater than 70. These factors are divided into three broad groups: immediate, which require no *de novo* protein synthesis; early factors, which require synthesis but appear before mitosis; and late factors, which occur only after mitosis. Some of the most important immediate factors are in the Jun/Fos family of proto-oncogenes. They are activated by phosphorylation by JNK kinase and bind to the transcription factor called nuclear factor of activated T cells (NF-AT). This complex binds to the DNA regulatory sites of many cytokine genes. Other important regulatory proteins include the NF-κB complex, which, when activated, translocates to the nucleus and is a regulatory factor for IL-2. Other factors, such as calcineurin, a calcium-dependent phosphatase, are important in regulation of the activity of these transcription factors. Dephosphorylation causes activation and translocation to the nucleus. The potent immunosuppressant cyclosporin A, which binds to calcineurin, prevents the association of calcineurin with NF-AT, thus blocking transcription of IL-2 (*see* Chapter 30).

THE TWO-SIGNAL HYPOTHESIS AND REGULATION OF ACTIVATION The requirement for costimulatory molecules would predict that, on a molecular level, engagement of TCR alone vs TCR plus CD28 would lead to differences in phosphorylation and gene transcription. Originally, in fact, the two-signal hypothesis arose out of observations that engagement of TCR alone in some CD4$^+$ clones resulted in lack of IL-2 production and a poor proliferative response. The defect appears selective; IL-4 gene expression can be induced in an anergic cell having little IL-2 production. In previously anergized cells, the anergy can again be overcome in vitro by stimulation in the presence of IL-2 but not by B7. Conversely, use of altered peptides designed to bind within the MHC cleft but not engage TCR effectively results in secretion of IL-4 but little proliferation. A current hypothesis for the molecular role of costimulators is that engagement of CD28 causes its phosphorylation and a cascade of events that ultimately converges with the TCR pathway to increase levels of Jun. Without maximal activation of Jun provided by both pathways, there is no transcription of IL-2, a cytokine critical for the development of an armed effector cell. Costimulation provides the means for autocrine production, a requirement that can be overcome in vitro by an exogenous source. However, the hyporesponsiveness of anergic T cells has been shown to be an active response, as it is blocked by protein synthesis inhibitors in vitro. Thus, suboptimal production of a kinase alone seems unlikely to explain all aspects of tolerance. The complete elucidation of stimulatory and costimulatory pathways affords the possibility of developing novel therapies to enhance specific anergy, particularly in transplantation.

DOWNREGULATION OF THE IMMUNE RESPONSE

In the past, it had been assumed that the downregulation of the immune response was a passive process, the natural result of decreased stimulation resulting as antigen was cleared. It has become increasingly clear in recent years that there is also an active component to this regulation, and that apoptosis is an important mechanism by which this operates. Again, it appears

that the Fas-FasL system is important. In vitro experiments have shown that activated T cells express Fas but become susceptible to anti-Fas antibodies after only a few days of stimulation. Cells derived from *lpr* mice, deficient in Fas, failed to undergo activation-induced apoptosis. Fas-mediated apoptosis, then, may be a means by which chronic inflammatory reactions are limited. In vivo and in vitro studies have suggested that, at least for T cells, Fas can be crosslinked by FasL present either on its own cell surface or on a neighboring cell. The relative importance of these two pathways in normal circumstances remains to be determined. In addition, there is evidence that the second receptor for B7, CTLA-4, may act to downregulate activation. As an area of research for the treatment of autoimmunity, the activation-induced apoptosis pathway holds promise, because its manipulation may allow downregulation of an ongoing immune response.

30 Cytokines

William L. Lowe, Jr., and Barbara A. da Silva

BACKGROUND

Cytokines encompass diverse groups of multifunctional proteins that play key roles in a variety of biological processes, including cell growth and activation, inflammation, immunity, hematopoiesis, tumorigenesis, tissue repair, fibrosis, and morphogenesis. Chemotaxis is stimulated by a recently defined group of cytokines, the chemokines. Consistent with their relatively diverse functions, cytokines are synthesized in a variety of cell types, including cells of the mononuclear phagocyte system, lymphocytes, epithelial cells, fibroblasts, endothelial cells, and chondrocytes. These peptides interact with receptors on a wide variety of cell types to initiate intracellular signaling cascades that are responsible for mediating their effects. Interactions of the cytokines with these receptors can occur locally in an autocrine fashion on the cells that produced the cytokine or in a paracrine fashion on cells adjacent to the site of production. Finally, cytokines can function at distant sites in an endocrine fashion. This chapter will provide an overview of the major cytokines and their actions, their receptors and intracellular signaling cascades, and the role of cytokines and their receptors in specific disease processes.

CLASSES AND ACTIONS OF CYTOKINES AND CHEMOKINES

Given the diverse nature of cytokines, their pleiotropic effects, and, in some cases, their functional redundancy, it has proven difficult to categorize them into families based on structure or function. Families of cytokines that are important for immune function and inflammation include the interferons, interleukins, tumor necrosis factors, and colony-stimulating factors. Details about their sites of production and action are reviewed in Table 30-1. In addition to those cytokines, a variety of others also have been characterized, including: (1) hormones such as growth hormone, prolactin, and leptin; (2) hematopoietic factors such as erythropoietin and thrombopoietin, which are required for erythrocyte and megakaryocyte maturation and differentiation, respectively; (3) the neurotrophins, including brain-derived neurotrophin factor, nerve growth factor, neurotrophin-3, neurotrophin-6, and glial-derived neurotrophic factor, which are important for growth and differentiation of neurons; (4) neuropoietic factors such as ciliary neurotrophic factor (CNTF), oncostatin M, and leukemia inhibitory factor (LIF), which modulate neuronal differentiation; and (5) the transforming growth factor-β (TGF-β) family, which includes

the TGF-βs, bone morphogenic proteins, activins, and inhibins, whose members have diverse effects on cell growth and differentiation in various organ systems.

Chemokines are chemotactic cytokines that attract leukocytes to sites of inflammation and are generally 8- to 10-kDa proteins that can be divided into four different subfamilies based on structural characteristics. The CXC or α-chemokines contain four cysteines, the first two of which are separated by a single amino acid. Some members of this family contain the sequence glutamic acid-leucine-arginine near the N-terminus and are chemotactic for neutrophils, whereas those members of the subfamily that do not contain that sequence are chemotactic for lymphocytes. A second subfamily is the CC or β-chemokines, which, like the α-chemokines, contain four cysteines, but the first two cysteines are adjacent to each other. These chemokines are chemotactic for eosinophils, basophils, and lymphocytes but not, in general, for neutrophils. The sole member of the third subfamily is fractalkine. In fractalkine, the first two cysteines are separated by 3 amino acids, and it is chemotactic for natural killer cells, monocytes, and activated T cells. The last subfamily of chemokines also contains a single member, lymphotactin. Lymphotactin contains only two cysteines and is chemotactic for T cells. Over 40 different chemokines have been identified, and almost all cell types are able to produce them. The different inflammatory infiltrates that are characteristic of different disease processes are controlled, in part, by the chemokines that are expressed locally at the site of disease. Stimuli for chemokine production include several pro-inflammatory cytokines (e.g., IL-1 and TNF-α), T cell products like IL-4 and IFN-γ, bacterial products (e.g., lipopolysaccharide), and viral infection.

MECHANISM OF CYTOKINE-MEDIATED SIGNAL TRANSDUCTION

CYTOKINE RECEPTORS The effects of cytokines are mediated by specific receptors that initiate signal transduction pathways with subsequent activation of gene transcription (*see* Chapter 46). Cytokine receptors contain extracellular, transmembrane, and cytoplasmic domains and are grouped into five classes based on unique amino acid motifs (Table 30-2).

1. Class 1 receptors: These receptors contain conserved amino-terminal cysteine pairs and an extracellular tryptophan-serine-X-tryptophan-serine (WSXWS) motif proximal to the transmembrane domain. The class 1 cytokine receptors can be further subdivided into the IL-2R, IL-3R, and IL-6R subgroups based on use of one of

Table 30-1
Features of the Major Cytokines

Cytokine	Major sites of production	Principal targets	Major effects
IFN-α/β	leukocytes, epithelial cells, fibroblasts, produced by most cell types in culture	lymphocytes, receptors present on most cell types	stimulates natural killer cells; MHC class I induction; antiviral effect
IFN-γ	T lymphocytes, natural killer cells	lymphocytes, monocytes, multiple other cell types	activates monocytes; MHC class I and II induction; enhances lymphocyte adherence to endothelial cells via increased expression of adhesion molecules
IL-1α,β	major source is macrophages but made in other cell types (e.g., B cells, fibroblasts, endothelial cells)	essentially all cell types have receptors for and can respond to IL-1	stimulates T and B cells; proinflammatory mediator; pyrogen; increases ACTH release from pituitary gland; induces production of acute phase proteins
IL-2	T cells	T cells, B cells, monocytes	T cell proliferation and differentiation; activation of cytotoxic lymphocytes and macrophages
IL-3	T cells, mast cells	stem cells, basophils	multi-lineage colony stimulating factor; chemotactic for basophils
IL-4	T cells	B cells, T cells	growth and differentiation factor for B cells leading in particular to IgG1 and IgE production; T cell growth and activation factor
IL-5	TH2 lymphocytes, macrophages	eosinophils, lymphocytes	Growth and differentiation factor for eosinophils; activates lymphocytes
IL-6	most cell types with greatest production by T cells, macrophages, B cells, fibroblasts, and endothelial cells	acts on most cells types	B cell differentiation; activates B cells; induces production of acute phase proteins; proinflammatory mediator; growth factor for multiple myeloma
IL-7	Bone marrow and thymic stroma	pre-B and T cells	Growth factor for pre-B and -T cells; activates T cells
IL-9	Activated T cells	hematopoietic stem cells, mast cells	Mast cell growth and differentiation; growth factor for hematopoietic stem cells
IL-10	TH2 and TH1 lymphocytes, other cell types	B lymphocytes, TH1 lymphocytes, macrophages	inhibits IFN-γ and IL-3 production by TH1 lymphocytes; inhibits macrophage production of multiple cytokines, including IL-1, IL-6, and TNF-α; activates B cells
IL-11	mesenchymal cells	hematopoietic stem cells, receptor present in wide variety of tissues	stimulates production and maturation of megakaryocytes
IL-12	monocytes, B cells	TH1 lymphocytes, natural killer cells	stimulates natural killer cells; stimulates activation and proliferation of TH1 lymphocytes; induces IFN-γ secretion by resting and activated T and natural killer cells
IL-13	activated T lymphocytes	B lymphocytes, monocytes	IL-4-like effects; anti-inflammatory via effects on monocytes; stimulates immunoglobulin synthesis
IL-14	T lymphocytes	B lymphocytes	growth factor for B lymphocytes
IL-15	monocytes, multiple tissues including skeletal muscle and placenta	T and B lymphocytes, NK cells	T and NK cell growth factor; chemoattractant for T cells; B cell proliferation and differentiation
IL-16	T lymphocytes	T lymphocytes, eosinophils, monocytes	competence factor for growth of T cells; induces cytokine synthesis by T cells; chemoattractant for T cells; chemotactic factor for eosinophils and monocytes
IL-17	T lymphocytes	receptor is ubiquitously expressed	limited information suggests that it functions as a pro-inflammatory cytokine
TNF-α	neutrophils, lymphocytes, macrophages, NK cells, neutrophils and many nonlymphoid cells including endothelial cells, adipocytes, and smooth muscle cells	macrophages, neutrophils, lymphocytes, fibroblasts, endothelial cells and multiple other non-lymphoid cell types	activation of macrophages, leukocytes, and cytotoxic cells; pro-inflammatory cytokine; increases leukocyte adhesion to endothelial cells; induces acute phase response; induces cachexia; pyrogen; stimulates angiogenesis; enhances MHC class I production
TNF-β	T lymphocytes	same as above	same as above
M-CSF	monocytes, fibroblasts, endothelial cells, epithelial cells	macrophage precursors	proliferation of macrophage precursors; chemotactic factor for monocytes
GM-CSF	T and B lymphocytes, monocytes, fibroblasts, and endothelial cells	stem cells; monocytes	induces proliferation and differentiation of bone marrow precursors (macrophages, neutrophils, and eosinophils); enhances monocyte migration into inflamed tissue
G-CSF	monocytes, macrophages, endothelial cells, fibroblasts	stem cells	stimulates division and differentiation to promote differentiation of neutrophils

IFN, interferon; IL, interleukin; TNF, tumor necrosis factor; CSF, colony stimulating factor.

Table 30-2
Cytokine Receptors

Cytokine receptor class	Subgroup	Cytokine receptors
Class 1	IL-2R - share γc	IL-2R, IL-4R, IL-7R, IL-9R, IL-13R (does not use γc but may dimerize with ligand binding subunit of IL-4R), IL-15R
	IL-3R - share βc	IL-3R, IL-5R, GM-CSF receptor
	IL-6R - share gp130	IL-6R, IL-11R, cardiotrophin-I receptor, CNTF receptor, LIF receptor, oncostatin M receptor, leptin receptor (no evidence demonstrating association with gp130), IL-12R (uses a subunit related to but distinct from gp130)
	Others	growth hormone receptor, erythropoietin receptor, prolactin receptor
Class 2		IFN-α/β-R, IFN-γ-R, IL-10R
Immunoglobulin		type I and II IL-1R
TNF receptors		p55 TNF-α-R, p75 TNF-α-R, Fas receptor, lymphotoxin-β receptor, CD-40 ligand receptor
Chemokine receptors		four receptors for CXC chemokines (CXCR1-4), eight receptors for CC chemokines (CCR1-8), and one receptor for fractalkine (CX₃CR1)

three common subunits, which are required for ligand-mediated signal transduction: γc for the IL-2R subgroup, βc for the IL-3R subgroup, and γp-130 for the IL-6R subgroup (Table 30-2). The ligand-binding and signal transduction subunits each contain a single transmembrane domain and heterodimerize upon ligand binding.

2. Class 2 receptors: These receptors contain conserved amino- and carboxy-terminal cysteines without a WSXWS motif. The receptors in this class include the IFN-α/β, IFN-γ, and IL-10 receptors. Interferon-α and -β bind to the type I interferon receptor, whereas interferon-γ binds to the type II interferon receptor.

3. Ig class receptors: This class of receptors contains three immunoglobulin motifs in the extracellular domain. These immunoglobulin motifs have a specific tertiary structure that may be involved in ligand binding. The type 1 and type 2 IL-1 receptors, both of which bind to IL-1α and IL-1β, are members of this class of receptors. It is thought that the type 2 receptor does not have a role in signaling, but may be more important in modulating signal transduction by preventing ligand binding to the type 1 receptor.

4. TNF receptor class: These receptors contain conserved cysteine rich repeats in the extracellular domain. There are several members of this receptor class, including the two receptors for TNF-α, p55 and p75.

5. Chemokine receptors: These receptors are members of the family of seven transmembrane domain receptors that are coupled to G proteins. To date, four receptors for the CXC chemokines, eight receptors for the CC chemokines, and one receptor for fractalkine have been identified. Activation of these receptors results in stimulation of signaling pathways characteristic of G-protein-coupled receptors (*see* Chapter 46), including activation of phospholipases and protein kinase C and release of intracellular calcium. In addition to expression on hematopoietic cells, chemokine receptors also have been found on nonhematopoietic cells, including neurons, astrocytes, epithelial cells, and endothelial cells, suggesting that they have other, as yet, unknown functions.

With the exception of the chemokine receptors, many of the cytokine receptors also exist as soluble forms, generated by either alternative splicing or proteolytic cleavage of the extracellular domain. The function of these soluble receptors is incompletely understood, but they may block cytokine action, stabilize the cytokine by acting as a carrier protein in the circulation, and/or contribute to receptor activation (which has been observed for IL-6). In some cases, circulating levels of the soluble receptors may be a marker for activation of a cytokine network and disease activity. For example, increased levels of the soluble receptors for TNF-α are present in patients with sepsis and rheumatoid arthritis.

INTRACELLULAR SIGNALING PATHWAYS ACTIVATED BY CYTOKINE RECEPTORS Cytokine binding to the class 1 and 2 receptors activates one or more members of a family of cytoplasmic tyrosine kinases, the Janus kinases (Jaks). Cytokine receptors do not possess intrinsic kinase activity, so they depend on the Jaks for this function. The Jaks are a family of four tyrosine kinases (Jak1, Jak2, Jak3, and Tyk1) that associate with specific cytokine receptors and catalyze phosphorylation of tyrosine residues in the cytoplasmic domain of the cytokine receptor. These phosphorylated residues then serve as docking sites for proteins with phosphotyrosine binding (PTB) or Src homology 2 (SH2)-binding domains. Binding of these proteins is important for ligand-mediated signal transduction and helps to confer specificity to the intracellular effects of the different cytokines.

Among the proteins with an SH2 domain that bind to these phosphorylated tyrosine residues are the signal transducers and activators of transcription (STATs). The STATs are a family of transcription factors with at least seven members: STAT1, STAT2, STAT3, STAT4, STAT5a, STAT5b, and STAT6. The SH2 domain of the STATs is important for binding to the phosphorylated receptor, and, like the Jaks, specific STATs interact with specific cytokine receptors. Once the STAT protein binds to the receptor, it is phosphorylated on tyrosine residues by Jak, which allows it to form either homo- or heterodimers with other phosphorylated STAT proteins. These activated STAT complexes translocate to the nucleus, where they can interact with specific DNA sequences to induce gene transcription. In addition to the STATs, other signal transduction pathways, e.g., the Ras/Raf/ERK and phosphatidylinositol 3-kinase pathways, can be activated in response to cytokine binding (*see* Chapter 46). The mechanisms for the termination of signal transduction via activated cytokine receptors are currently less clear, but may involve phosphotyrosine phosphatases and/or degradation of the STAT proteins.

ROLE OF CYTOKINES IN PATHOLOGIC AND PHYSIOLOGIC PROCESSES

The cytokines are intimately involved in a wide variety of physiologic and pathologic processes, a complete description of which is beyond the scope of this chapter. Rather, a description of the role of cytokines in the pathophysiology of rheumatoid arthritis and sepsis and the physiology of weight regulation will be provided as examples of the pleiotropic effects of cytokines, their potentially synergistic interactions, as well as their potentially opposing and antagonizing effects.

RHEUMATOID ARTHRITIS Rheumatoid arthritis is a chronic polyarthritis characterized by an inflammatory synovitis that involves the peripheral joints, typically in a symmetrical fashion. The disease is characterized by additional systemic symptoms, including fatigue, anorexia, weight loss, and a low-grade fever. The etiology of rheumatoid arthritis is not fully understood and is likely secondary to both genetic and environmental factors.

Table 30-3
Effects of the Cytokines that Contribute to the Pathogenesis of Rheumatoid Arthritis

Cytokine	Manifestations of rheumatoid arthritis
IL-1	Contributes to fever and constitutional symptoms; stimulates the acute phase response; contributes to tissue destruction by increasing matrix metalloprotease and PGE$_2$ production; increases fibroblast proliferation via increased PDGF production; T cell activation and proliferation; activates endothelial cells; stimulates production of itself, IL-6, IL-8, LIF, and GM-CSF
TNFα	Synergizes with IL-1 to increase PGE2 and matrix metalloprotease production; stimulates fibroblast proliferation; activates endothelial cells; increases production of IL-1, IL-6, IL-8, LIF, TGF-β, and MCP-1; contributes to constitutional symptoms; stimulates acute phase response
IL-6	Stimulates antibody production; participates in T cell activation; stimulates the acute phase response; stimulates production of TNF-α and Fc receptors
GM-CSF	Increases expression of HLA class II antigens; increases macrophage number by helping to maintain macrophage viability; participates in the induction of IL-1 and TNF-α production
LIF	Induces expression of IL-1, IL-6, IL-8, and itself; activates monocytes, proinflammatory effects similar to IL-6
M-CSF	Stimulates TNF-α production; promotes macrophage survival
IL-2	T cell proliferation
IFN-γ	Endothelial cell activation; stimulates antibody production

PG, prostaglandin; PDGF, platelet-derived growth factor; LIF, leukemia inhibitory factor; MCP, monocyte chemoattractant protein

The synovitis is characterized by hyperplasia and hypertrophy of synovial lining cells, perivascular infiltration by mononuclear cells, microvascular injury, and neovascularization. The synovial fluid also demonstrates acute inflammatory changes, with large numbers of polymorphonuclear leukocytes and limited numbers of mononuclear cells being present.

Cytokines play a critical role in the maintenance of active synovitis, tissue destruction, and systemic symptoms characteristic of rheumatoid arthritis (Table 30-3), although the role of cytokines in the initiation of the synovitis is unclear. IL-1 and TNF-α are the two proinflammatory cytokines that make major contributions to the pathogenesis of rheumatoid arthritis. In addition to mediating many of the inflammatory and constitutional symptoms, cytokines also establish positive feedback loops to help sustain the inflammatory process. For example, IL-1 regulates not only its own production but that of TNF-α, whereas TNF-α is capable of increasing IL-1 production. Moreover, both IL-1 and TNF-α stimulate the production of a variety of other cytokines, including IL-6, IL-8, and LIF, that are important for the inflammatory process. Finally, IL-1 and TNF-α act synergistically to stimulate a variety of other inflammatory effects, e.g., matrix metalloprotease and prostaglandin production, fibroblast proliferation, and endothelial cell activation.

Interestingly, not only inflammatory cytokines, but a variety of anti-inflammatory cytokines are present in synovial fluid and/or tissue. For example, increased levels of a naturally occurring antagonist of IL-1, IL-1ra, are present in synovial tissue from patients with rheumatoid arthritis. IL-1ra is a member of the IL-1 gene family that is a competitive inhibitor of IL-1 and, as such, binds to, but does not activate, the IL-1 receptor. It is produced by monocytes, neutrophils, and other cell types in response to a variety of cytokines, including IL-1, IL-4, and IL-10. High levels of TGF-β1 and -β2 are also present in synovial fluid. Both of these cytokines have anti-inflammatory effects that include inhibition of T cell, B cell, and fibroblast proliferation and antibody production. Moreover, they are able to deactivate macrophages, decrease production of TNF-α and IL-1 by macrophages, and stimulate production of extracellular matrix. A third inhibitory cytokine present in inflammatory synovial fluid is IL-10. IL-10 inhibits expression of IL-1, IL-6, IL-8, GM-CSF, and TNF-α by monocytes, which may help to inhibit synovitis. It is unclear whether exacerbations and remissions of the disease may be related to shifts

in the balance between production of the proinflammatory and inhibitory cytokines.

Chemokines also contribute to the pathogenesis of rheumatoid arthritis. The C-C chemokines monocyte chemoattractant protein-1 (MCP-1), macrophage inflammatory protein-1α (MIP-1α), and RANTES (regulated upon activation normal T-cell expressed and secreted) are produced by fibroblasts and macrophages in response to IL-1 and TNF-α. These peptides are chemotactic for monocytes and T cells. In addition to the above, the C-X-C chemokines IL-8, gro, and epithelial cell-derived neutrophil-activating peptide 78 (ENA-78) are produced by macrophages and chondrocytes in response to TNF-α and IL-1. These peptides are chemotactic for neutrophils and, in the case of IL-8, also for lymphocytes. Thus, chemokines contribute to the inflammatory process by attracting inflammatory cells into the synovium and synovial fluid.

Given the critical role of cytokines in the pathogenesis of rheumatoid arthritis, they have served as targets for novel therapies for the disease. Since IL-1ra is a competitive antagonist for binding to the IL-1 receptor, it has been tried as a therapeutic agent. In humans, early phase I and now phase II trials of IL-1ra administered subcutaneously have resulted in improvement of several clinical measures of disease, including the number of painful and swollen joints. Other clinical trials have examined the efficacy of monoclonal antibodies directed against specific cytokines in patients with rheumatoid arthritis. Antibodies to both IL-6 and TNF-α have demonstrated potential efficacy in early trials. Cytokines may represent, therefore, an important target for novel therapeutic strategies for rheumatoid arthritis.

SEPSIS   Cytokines are also important in septic shock, which occurs secondary to the systemic inflammatory response to an overwhelming infection. It is characterized by fever, hypotension, and tissue hypoperfusion with resulting organ dysfunction and lactic acidosis. Sepsis, in addition to trauma, burn injuries, and meningitis, is one of the conditions in which large amounts of TNF-α are released into the circulation. Cytokine production, and specifically release of TNF-α, is induced by bacteria themselves or soluble bacterial products, including lipopolysaccharide (LPS), exotoxins, and cell-wall glycopeptides. A primary role for TNF-α in the host response to sepsis is suggested by several findings. For one, infusion of TNF-α into humans results in fever, myalgias, headaches, hypotension, a vascular leakage syndrome, and increased protein degradation, all of which are characteristic of the response to sepsis. TNF-α–induced hypotension is secondary to decreased cardiac contractility and decreased vascular resistance mediated by increased nitric oxide release. A second piece of evidence supporting a primary role for TNF-α in septic shock is the observation that mice with a null mutation of the TNF-α gene are protected from the lethal effects of LPS.

Although TNF-α is a primary mediator of the manifestations of septic shock, a cascade of cytokines is released during sepsis, many in response to TNF-α. One of the other primary cytokines that contributes to septic shock and acts synergistically with TNF-α is IL-1. Similar to TNF-α, IL-1 infusion in humans induces fever, sleepiness, anorexia, generalized myalgias, arthralgias, headache, and, in high doses, hypotension. Hypotension occurs secondary to the release of nitric oxide, prostaglandins, and platelet-activating factor. Two other effects of IL-1 contribute to the body's response to stress. For one, IL-1 increases production of adrenocorticotropic hormone (ACTH) by the pituitary gland, which stimulates glucocorticoid production by the adrenal gland. Interestingly,

glucocorticoids decrease IL-1 and TNF-α production and may serve to modulate the inflammatory response. Second, IL-1 stimulates IL-6 production and, together, these cytokines mediate the hepatic acute phase response, which helps to maintain systemic homeostasis. The hepatic acute phase response is characterized by fever, leukocytosis, and increased hepatic production of C-reactive protein, α₁-acid glycoprotein, serum amyloid A, fibrinogen, factor B, haptoglobin, complement C3, α₁-proteinase inhibitor, α₁-chymotrypsin, ceruloplasmin, and C1 esterase inhibitor and decreased production of albumin, transferrin, and lipoprotein lipase. Finally, additional cytokines are released either directly or indirectly in response to TNF-α, including IL-2, IL-4, IL-6, IL-10, IL-12, IFN-γ, and TGF-β.

Like rheumatoid arthritis, cytokines have been the target of therapeutic interventions in sepsis. Both IL-1ra and monoclonal antibodies directed against TNF-α have been used. Results with both agents have been similar in that early mortality was reduced and a trend toward reduced 28-day mortality was apparent, although statistically significant reductions in 28-day mortality have not, as yet, been demonstrated. These cytokines likely represent important therapeutic targets, and additional studies to address this issue are underway.

BODY-WEIGHT REGULATION   Apart from their known immunologic, proinflammatory, and growth and differentiation functions, cytokines are involved in body-weight regulation and metabolic perturbations such as insulin resistance. At least three cytokines are important for these metabolic effects. Leptin, an adipose-derived factor, is secreted in proportion to body fat mass and is transported across the blood–CSF and blood–brain barriers via a saturable transporter, which is likely an isoform of the leptin receptor. It then exerts at least some of its effects, including regulation of food intake and energy expenditure, by binding to leptin receptors in hypothalamic nuclei. Second, TNF-α is secreted by adipose cells and increases leptin output from adipose cells. TNF-α also interferes with the insulin signaling pathway and, thus, contributes to obesity-related insulin resistance. Finally, neural-derived ciliary neurotropic factor (CNTF) has been implicated in body-weight regulation because of its effects on hypothalamic neuropeptide Y (NPY). NPY production by the hypothalamus increases food intake and decreases thermogenesis. CNTF interferes with NPY production and/or secretion, which results in anorexia and weight loss. The ability of leptin to inhibit food intake also is mediated, in part, by decreasing NPY production in the hypothalamus.

ROLE OF CYTOKINE RECEPTORS IN DISEASE

Alterations in cytokine receptors and associated signal transduction molecules are now being recognized as important in the etiology of specific disease processes. A dramatic example of this is the severe combined immunodeficiencies (SCIDs). SCID occurs in ~1 in 100,000 live births, with 50% of cases having X-linked SCID (XSCID). Males with XSCID exhibit a profoundly decreased number of T cells with normal to increased B cells. The B cells, however, are nonfunctional, and the patients exhibit hypogammaglobulinemia. These children present with failure to thrive, severe and recurrent infections, and premature death in the absence of a curative bone marrow transplant. Insight into the etiology of XSCID came with the recognition that the gene encoding the γ-subunit of the IL-2R was localized to a region of the X-chromosome, Xq13, known to contain the XSCID locus. A variety of mutations, including premature stop codons, truncations, insertions, deletions, frame shifts, and single amino acid changes, in the

Table 30-4
Disorders Associated with Cytokine Receptor Mutations

Cytokine Receptor	Type of Mutation/Inheritance	Effect of mutation/disorder associated with mutation
Growth hormone receptor	Inactivating mutation; autosomal recessive	Laron Dwarfism (growth hormone resistant dwarfism)
IL-2 receptor α chain	Inactivating mutation; autosomal recessive	Immunodeficiency characterized by decreased peripheral T cells which proliferate abnormally, normal B cell development, and lymphocytic infiltration of multiple tissues accompanied by tissue atrophy and inflammation
γc subunit	Inactivating mutation; X-linked recessive	X-linked severe combined immunodeficiency
Interferon-γ receptor 1	Inactivating mutation; autosomal recessive	Immunodeficiency characterized by altered IFN-γ-induced TNF-α production, defective antigen processing and presentation, and susceptibility to mycobacteria infections
Erythropoietin receptor	Activating mutation; autosomal dominant	Familial erythrocytosis
IL-4 receptor α chain	Activating mutation; autosomal dominant with incomplete penetrance	Hyper-IgE syndrome, severe atopic dermatitis, atopy
Receptor common β chain (βc)	Decreased expression of βc (mechanism unclear - missense mutation present in one subject)	Probable molecular defect in some cases of childhood-onset pulmonary alveolar proteinosis

γ-subunit now have been demonstrated in these patients. All of these mutations abrogate ligand-activated function of the γ-subunit. Initially, the γ-subunit was known to be associated with only the IL-2 receptor, but with the recognition that the phenotype of patients with XSCID was more severe than that of patients with IL-2 deficiency, it was subsequently demonstrated that the γ-subunit, which was renamed γc (for common), was associated with the receptors for several cytokines, including IL-4, IL-7, IL-9, and IL-15. Comparison of the phenotype of patients with γc mutations to that of patients with IL-2 deficiency or mutations of the IL-2 receptor α chain *(see below)*, demonstrates that all or some subset of these cytokines are required for normal development of the immune system. A subset of patients with an autosomal recessive form of SCID have now been shown to have mutations in Jak3. This was predicted, since Jak3 associates with γc. Recognition of the molecular defects responsible for XSCID and some cases of autosomal recessive SCID likely will facilitate development of new and more targeted therapies for treatment of these patients, especially those for whom a bone marrow transplant is not available.

As the number of cytokine receptors continues to grow, an increasing number of disease processes have been ascribed to mutations in cytokine receptors (Table 30-4). Although many of these mutations are associated with rare syndromes, the activating mutation in the IL-4R α chain appears to be a relatively common mutation that underlies, in part, the genetic predisposition to allergic diseases. This mutation was initially identified by screening a small group of patients with the hyper-IgE syndrome and severe atopic dermatitis for IL-4R mutations. Six of the ten patients were found to be heterozygous for a missense mutation (substitution of arginine for glutamine at position 576) in the IL-4R α chain gene. Subsequent screening of the general population demonstrated that the frequency of the mutant allele was 35% in those with a history of atopy and only 10% in those without a history of atopy, thus demonstrating a strong association of the

mutation with atopy. Additional studies demonstrated a probable molecular basis for this increased susceptibility. IL-4 is important for production of IgE by B cells, and enhanced signaling of the mutant compared to the wild-type receptor was demonstrated. This recent elucidation of the contribution of an IL-4 receptor mutation to a common problem like atopy will be important for future attempts to identify susceptible individuals and, possibly, for developing and/or targeting the use of new therapeutic modalities.

31   The HLA Complex

ROBERT W. KARR

INTRODUCTION

The human major histocompatibility complex (MHC) , or HLA (for human leukocyte antigen), is located on chromosome 6 and contains multiple genes that encode proteins which play central roles in the generation of immune responses. The HLA complex can be divided into three regions, each of which contains genes that encode molecules of similar structures: the class I and II genes encode the HLA class I and II molecules, respectively, and the class III genes encode the C4, C2, and Bf components of the complement system. The HLA class I and II molecules are intimately involved in the process of discriminating self from nonself, and these molecules share the characteristic of being highly polymorphic in the population.

STRUCTURE OF CLASS I AND II MOLECULES

The HLA class I molecules, HLA-A, -B, and -C, are heterodimers composed of a polymorphic, HLA-encoded, 44-kDa transmembrane glycoprotein, referred to as the heavy or α chain, and β-2-microglobulin (β2m), a nonpolymorphic, 12-kDa protein encoded outside the MHC that noncovalently associates with the extracellular portion of the heavy chain (Table 31-1). HLA class I molecules are expressed on virtually all cells, and these molecules restrict recognition of antigenic peptides by $CD8^+$ T cells. Based on analysis of the linear sequences of the genes and proteins, it was shown that HLA class I molecules belong to the immunoglobulin supergene family, that the extracellular region of the α chain can be divided into three domains (α1, α2, and α3), each containing approximately 90 amino acids, and that the polymorphism in the α chain is localized to hypervariable regions in the α1 and α2 domains.

A seminal contribution to our understanding of the structure and function of class I molecules was the solution of the three-dimensional structure of the HLA-A2 molecule by X-ray crystallography by Bjorkman et al. in 1987. These data demonstrated that the membrane-proximal α3 and β2m domains are associated with each other and are folded into structures resembling immunoglobulin constant regions (Fig. 31-1). The membrane-distal α1 and α2 domains form a platform composed of a single eight-stranded β-pleated sheet topped by two α-helices with a long groove between the helices. Importantly, this groove was shown to be the binding site for antigenic peptides. The α1 and α2 domains each

contribute half of the platform or floor and one of the α-helices. The previously identified polymorphic residues in the α1 and α2 domains are located in the floor of the peptide-binding site or on the α-helices where they are likely to influence function through effects on peptide binding or T-cell receptor (TCR) recognition. Additional key concepts about class I molecules emerged from subsequent determination of the three-dimensional structures of HLA-A68 and -B27 molecules. Polymorphic differences between class I molecules create unique subsites or pockets within the peptide-binding groove that determine the physical characteristics of peptides that may be bound by each molecule. In general, the grooves of class I molecules contain about three peptide-binding pockets.

Considerable progress has been made in understanding the nature of the peptides bound by HLA class I molecules. Although there is some variation in length, most peptides bound by class I molecules are 9 amino acids and bind in an N-to-C orientation with the C-terminus to the right end of the groove and the N-terminus to the left end of the groove (Fig. 31-1B). Peptides bound to class I molecules usually have an arched conformation with a kink in the middle. The termini of the peptides are anchored by hydrogen bonds with conserved class I residues located in relatively deep pockets at the ends of the peptide-binding site, and a polymorphic peptide-binding pocket in the central portion of the groove determines allele-specific peptide binding. The physical characteristics of peptides that bind to a specific class I molecule are referred to as the peptide motif for that molecule. For example, HLA-B27 molecules bind nonamers, almost all of which have an arginine at the P2 position of the peptide that fits into the B pocket of the B27 groove.

The HLA class II molecules, HLA-DR, -DQ, and -DP, are heterodimers in which both chains, an α chain of ~32 kDa and a β chain of ~28 kDa, are MHC-encoded, transmembrane glycoproteins (Table 31-1). DRβ, DQα and β, and DPα and β chains are polymorphic, whereas the DRα chain is nonpolymorphic. HLA class II α and β chains are also members of the immunoglobulin supergene family, and α and β chains each contain two extracellular protein domains, referred to as α1 and α2, and β1 and β2, respectively. Whereas β2 domains have minimal sequence variability, β1 domains are highly polymorphic, and like class I heavy chains, the polymorphisms are localized to specific regions of the linear sequences, called hypervariable regions. For example, in DRβ chains, three such regions have been identified: the first hypervariable region encompasses amino acids 9–13, the second, amino acids 26–37, and the third, amino acids 67–74.

Table 31-1
Comparison of HLA Class I and Class II Molecules

	Class I	*Class II*
Name	HLA-A, -B, and -C	HLA-DR, -DQ, and -DP
Structure	Heterodimer ~44 kDa heavy chain ~12 kDa β2m	Heterodimer ~32 kDa α chain ~28 kDa β chain
Distribution	Virtually all cells	B cells, macrophages, and activated T cells
Function	Bind and present antigenic peptides to CD8$^+$ T cells	Bind and present antigenic peptides to CD4$^+$ T cells
Peptide length	8–10 residues	10–25 residues

The three-dimensional structures of the HLA-DR1 molecule with a mixture of peptides or a single peptide bound were reported in 1993 and 1994. As predicted in an earlier hypothetical model of a class II molecule based on the class I HLA-A2 structure, the general organization of the DR1 molecule is similar to class I molecules. In the DR1 structures (Fig. 31-2), the α1 and β1 domains form a membrane-distal peptide-binding groove composed of two α-helices that rise above a floor of β strands. The α1 and β1 domains each contribute half of the floor and one of the α-helices. As with class I molecules, the polymorphisms previously noted in the linear sequences are located in regions where they seem very likely to determine function. The DRβ chain first and second hypervariable regions are located in the floor of the peptide-binding groove, where the polymorphic residues may influence peptide binding or conformation, and the third hypervariable region is located on the α-helix. The side-chain orientations of these third hypervariable region residues suggest that some may influence peptide conformation, whereas others may directly contact the TCR. DR1 molecules also contain peptide-binding pockets, although the number of pockets is larger than that found in class I molecules. For example, pocket 1, formed by residues β85, β86, β89, β90, α24, α31, α32, and α43, is deep and plays a key role in anchoring the bound peptide. The side chains of DRβ residues 13, 70, 71, 74, and 78, as well as α9, form a shallow pocket, referred to as pocket 4, that exerts a major and disproportionate influence on the outcome of T-cell recognition. The recently reported structure of the HLA-DR3 molecule with a bound peptide is similar to the DR1 structures.

Although class I and class II molecules have very similar structures overall, class II molecules bind peptides differently than class I molecules. Class II molecules bind peptides of variable lengths, ranging from 12 to 25 amino acids. In contrast to class I molecules, which use conserved residues at each end of the groove to make hydrogen bonds near the ends of the peptide, class II molecules use multiple, mostly conserved, residues throughout the groove to make hydrogen bonds with the main chain of the peptide. For example, in the DR1 structure with a single peptide bound, there are hydrogen bonds between 12
Figure 31-1   The three-dimensional structure of a class I molecule, HLA-A2. (**A**) Schematic representation of the A2 molecule shown in the side view, with the α1, α2, and α3 domains of the HLA heavy chain and β2m labeled. The peptide binding groove is formed by two α-helices rising above the floor of β-pleated sheets. (**B**) Top view of the molecule showing the peptide-binding groove. nonpolymorphic and 3 polymorphic DR1 residues and main-chain atoms of the peptide. Peptides bind to class II molecules in an N-to-C orientation and in a fully extended or straight conformation. The combination of polymorphic residues in the class II peptide-binding pockets determine the characteristics or motif of the peptides that may be bound by each class II molecule. The motif of peptides that bind to DR1 is best characterized based on the three-dimensional structure, peptide-binding studies, and sequencing of naturally occurring peptides eluted from the DR1 molecules. These motifs usually include four anchor residues, for example P1, P4, P6, and P9, that are known or thought to interact with pockets 1, 4, 6, and 9, respectively, in the class II binding groove. It is important to note that these motifs are usu-
Figure 31-2 Schematic representation of the structure of HLA-DR1 and DR1–peptide contacts. DR1 was cocrystallized with the influenza hemagglutinin peptide, PKYVKQNTLKLAT. The top view of DR1 is shown in the Cα trace with the peptide binding groove formed by the α chain α-helix at top, the β chain α-helix at bottom, and the floor of the groove. Lines enclose all DR1 residues in contact with each peptide side chain (large letters). The DR residues in contact with the same peptide residue define the peptide-binding pockets. For example, the residues in pocket 1 (residues β85, β86, β89, β90, α24, α31, α32, and α43) contact the P1 residue (Y), and pocket 4 (DRβ residues 13, 70, 71, 74, and 78, as well as α9) contacts Q, the P4 residue. (Reprinted with permission from Nature 1994;368:215–221. Copyright 1994 Macmillan Magazines Limited.)

ally located in the central portions of the 12–25 residue peptides, suggesting that the N- and C-termini of bound peptides extend out the ends of the peptide-binding groove. The first residue in the DR1 peptide motif, P1, which fits into pocket 1, is hydrophobic, with a strong preference for aromatic residues, whereas the P4 residue is often aliphatic, but is polar in some DR1-binding peptides. DR1 molecules have a strong preference for peptides with alanine or glycine at P6. In contrast, P9 is said to be degenerate, because there is no preference for the residue at this position. The sum of the restricted or degenerate requirements at each peptide position results in an allele-specific peptide-binding motif that is determined by the unique combination of polymorphic residues in the peptide-binding groove of that class II molecule.

The tissue distribution of class II molecules is more restricted than class I molecules; class II molecules are expressed primarily on immunocompetent cells, including macrophages, monocytes, dendritic cells, B cells, and activated T cells (Table 31-1). Class II expression may also be induced on other cell types, such as endothelial cells, by cytokines, such as interferon-γ. HLA class II molecules restrict the recognition of antigenic peptides by CD4[+] T cells, in contradistinction to class I molecules that restrict the recognition by CD8[+] T cells. Although the details of the interactions are not yet known, the TCR is thought to simultaneously contact portions of the α-helices of the class II molecule and the bound peptide. In addition, the CD4 molecule on the same T cell interacts with specific conserved residues in the membrane-proximal β2 domain of the class II molecule.

GENETIC ORGANIZATION, POLYMORPHISM, AND NOMENCLATURE OF THE HLA SYSTEM

More than 100 genes have been mapped in the 4000 kb of DNA that comprise the HLA complex on the short arm of chromosome 6 (Fig. 31-3). The class II region, which contains the genes encoding HLA class II molecules, as well as other genes, is located most centromeric in the HLA complex. The class III region, which contains complement and other genes, is located between the class II region and the most telomeric region, the class I region, which contains the genes encoding HLA class I heavy chains. The class I region contains the genes that encode the classic HLA-A, -B, and -C heavy chains of class I molecules, as well as other genes that encode the more recently described nonclassic HLA-E, -F, and -G heavy chains. The class II region is organized into three subregions, DR, DQ, and DP, each of which contains the corresponding α and β chain genes. In addition, the class II region contains the LMP and TAP genes, which encode molecules involved in class I antigen processing and transport, as well as the gene that encodes HLA-DM, a molecule recently shown to be involved in class II peptide loading. The class III region contains genes encoding a variety of proteins, including the complement components C4, C2, and properdin factor B, tumor necrosis factor-α and -β, 21-hydroxylase, and heat shock protein 70.

A notable hallmark of HLA-A, -B, -C, -DR, -DQ, and -DP genes and molecules is their extensive polymorphism or sequence variability in the population. As of 1995, these numbers of alleles had been identified at the various loci based on DNA sequencing: HLA-A, 59; HLA-B, 118; HLA-C, 36; HLA-DRB1, 128; HLA-DQA1, 16; HLA-DQB1, 25; HLA-DPA1, 8; and HLA-DPB1, 62. During the evolution of the current understanding of the HLA system, a variety of nomenclature schemes, often resulting in a seemingly self-defeating alphabet soup of names, have been used. In recent years, a standard nomenclature has evolved for HLA class I and II genes and molecules. Alleles at each locus are named by this convention: the locus name is followed by an asterisk and four or five digits to denote the specific allele. When possible, the first two digits of the allele designation correspond to the historical serologic specificity associated with a family of alleles. For example, 2 of the 10 HLA-B locus alleles related to the B27 serologic specificity are named B*2701 and B*2704. Likewise, DRB1 alleles related to the DR4 serologic specificity are named DRB1*0401 through DRB1*0422. Class II A and B genes, such as DRA1*0101 and DRB1*0401, encode α and β chains, respectively. Although each chromosome 6 contains an HLA-A, -B, -C, -DRA, -DRB1, -DQA1, -DQB1, -DPA1, and -DPB1 gene that encodes an expressed protein, haplotypes containing different DRB1 alleles may also contain and express one of three other DRB genes, DRB3, DRB4, or DRB5. Haplotypes with DRB1*15 or 16 alleles also express β chains encoded by a DRB5 allele; haplotypes with DRB1*03, 11, 12, 13, or 14 alleles also express a DRB3 allele, and haplotypes with DRB1*04, 07, or 09 alleles also express DRB4. DRB1*01 and 08 haplotypes do not express a second DRβ chain. Because the two copies of chromosome 6 usually contain different alleles at each of the HLA loci, most individuals express six class I molecules (two each of HLA-A, -B, and -C) and eight class II molecules (two each of HLA-DRβ1, -DQ, and -DP and two of DRβ3, 4, or 5).

HLA-typing methods have evolved over time with changes in the understanding of the HLA genes and molecules and improved technology. Historically, HLA typing was done by complement-

The human major histocompatibility complex
Figure 31-3 Map of the HLA complex. The three regions of the HLA complex, class II, class III, and class I, were named for the class of genes first mapped to each region. The numbers below the line denote kilobases of DNA within the 4000-kb HLA complex. This material was originally published in Immunology Today 1993;14:349–352. Clinical Immunology: Principles and Practice. St. Louis: Mosby, 1995.)

mediated cytotoxicity using alloantisera from multiparous women. Panels of sera were accumulated that detected many of the HLA-A, -B, -C, -DR, and -DQ polymorphisms subsequently characterized at the nucleotide and amino acid sequence levels. Other class II polymorphisms, including HLA-DP and those on DR molecules referred to as HLA-D, are detected by T cells in primary or secondary mixed lymphocyte reactions and are termed T cell-defined specificities. With the wide availability of molecular genetic methods, DNA typing for HLA alleles has been applied recently, especially for class II. Analysis of DNA using restriction fragment length polymorphism (RFLP) or, more recently, sequence-specific oligonucleotides permits identification of the specific alleles that an individual possesses at the locus of interest.

HLA-DISEASE ASSOCIATIONS

With the availability of serologic testing for HLA class I specificities in the early 1970s, investigators began to search for associations between specific HLA antigens and diseases. HLA-disease associations have been described for more than 100 diseases. The experimental approach in HLA-disease association studies is to compare the frequencies of HLA antigens (serologic or cellular typing) or alleles (DNA typing) in persons with the disease of interest and a control population without the disease. Because the frequencies of HLA antigens and alleles normally vary in different ethnic and racial groups, it is important that the disease and control groups be composed of individuals of the same ethnic and racial background. The relative risk or incidence is used

to quantify the strength of the HLA-disease association or how many times more frequent the disease is in individuals positive for the HLA antigen than in individuals negative for the antigen. After determining the percentages of patients and controls with (P^+ and C^+, respectively) and without (P^- and C^-) the antigen or allele, the relative risk is calculated by the formula $(P^+ \times C^-) / (P^- \times C^+)$. The greater the relative risk above 1, the stronger the association between the HLA antigen or allele and the disease.

The first HLA-disease association described, that of B27 and ankylosing spondylitis (AS), remains the prototypical example because of the high relative risk (Table 31-2). B27 was present in 88% of American white patients with AS and in 8% of controls, resulting in a relative risk of 81. Among African-Americans, B27 occurred in 50% of AS patients and 2% of controls, with a relative risk of 49. B27 is also associated with Reiter's syndrome and reactive arthritis, other spondyloarthropathies.

Multiple diseases are associated with HLA class II antigens. The HLA class II associations with insulin-dependent diabetes mellitus (IDDM), multiple sclerosis, and pemphigus vulgaris will be briefly summarized (Table 31-2), and the association with rheumatoid arthritis will be reviewed in detail, as an example of how these data might begin to influence clinical practice. HLA-DR3 and 4 are individually associated with IDDM, and DR3, 4 heterozygotes have a relative risk (RR), 20, that is much higher than the sum of the relative risks for DR3 and 4 alone. The HLA allele most highly associated with IDDM is DQB1*0302 (also referred to as DQ3.2 in earlier literature), which is found in linkage with

Table 31-2
HLA-Disease Associations

Disease	Associated HLA antigen	Patients, %	Controls, %	Relative risk
Ankylosing spondylitis				
Whites	B27	88	8	81
African-Americans	B27	50	2	49
Insulin-dependent diabetes mellitus	DR3	69	27	6.1
	DR4	66	20	7.8
	DQB1*0302	59	12	11
Pemphigus vulgaris				
Ashkenazi Jews	DR4	97	30	25
Multiple sclerosis	DRB1*1501	63	30	3.9

HLA-DR4–positive haplotypes and appears to account for the DR4 association. Examination of the amino acid sequences of DQβ chains positively or negatively associated with IDDM led to the observation that negatively associated chains often have aspartic acid at position 57, whereas chains associated with IDDM, such as DQβ1*0302, have an amino acid other than aspartic acid (usually serine or alanine) at this position. Based on these data, it was proposed that DQβ aspartic acid 57 was protective for IDDM. However, others have argued that this hypothesis is not correct, because the DQB genes most highly associated with IDDM in some ethnic groups encode aspartic acid 57. Pemphigus vulgaris is strongly associated with DR4 in Ashkenazi Jews; DRB1*0402 was subsequently shown to account for the DR4 association. Multiple sclerosis is associated with the DRB1*1501-DQA1*0102-DQB1*0602 haplotype.

HLA ASSOCIATIONS WITH RHEUMATOID ARTHRITIS

In retrospect, the first evidence for an HLA association with rheumatoid arthritis (RA) was presented in 1969 by Astorga and Williams, who found that lymphocytes from 64% of RA patients did not activate each other in a mixed lymphocyte culture. However, it was not until 1976 that a definite HLA association with RA was established; 68% of white RA patients, but only 12% of controls (RR, 15.6), typed for the class II antigen, HLA-Dw4. As serologic reagents became available to detect HLA class II antigens, Stastny reported in 1978 that HLA-DRw4 (later referred to as DR4) was present in 70% of white RA patients, compared with 28% of controls (RR, 6.0).

By 1987, the list of HLA-D antigens associated with RA had expanded to include the DR4-associated T-cell-defined specificities Dw14 and Dw15, and DR1, in addition to DR4, Dw4. Notably, no association between RA and two other DR4-associated specificities, Dw10 or Dw13, was reported. In the mid-1980s, important progress was made in the understanding of the molecules that bear the DR4-associated class II antigens and in the isolation of cDNAs and genes encoding these molecules. The latter studies established that the β chains of the five DR4-associated HLA-D specificities defined at that time (Dw4, 10, 13, 14, and 15) were largely identical except for differences of 2–4 amino acids at positions 57, 67, 70, 71, 74, and 86 (Table 31-3). In the current nomenclature, these chains are referred to as DRβ1*0401, 0402, 0403, 0404, and 0405, respectively. Based on the amino acid sequences of the DRβ1 chains that are or are not associated with RA, Gregersen et al. proposed the shared epitope hypothesis in 1987 to

Table 31-3
RA-Associated and -Non-Associated DRβ1 Chains

DRβ1 chain	Serologic specificity	T-cell-defined specificity	70	71	72	73	74	RA association
			\multicolumn Amino acids					
0401	DR4	Dw4	Q	K	R	A	A	+
0404	DR4	Dw14	Q	R	R	A	A	+
0405	DR4	Dw15	Q	R	R	A	A	+
0101	DR1	Dw1	Q	R	R	A	A	+
1402	DR14	Dw16	Q	R	R	A	A	+
1001	DR10	—	R	R	R	A	A	+
0402	DR4	Dw10	D	E	R	A	A	–
0403	DR4	Dw13	Q	R	R	A	E	–

explain how different class II molecules might predispose to the same disease. They proposed that amino acids at DRβ1 positions 67–74 in the different RA-associated chains form a group of related epitopes that confer the risk to RA. The DRβ1*1402 and 1001 chains, which were subsequently found to be associated with RA in some populations, also have similar sequences in this region. Although the shared epitope was originally discussed in terms of residues 67–74, in more recent times, most authors have focused their discussions on residues 70–74. This segment of sequence has subsequently been referred to by multiple names, including rheumatoid or RA epitope. The sequences of amino acids 70–74 of the RA epitope differ slightly at positions 70 or 71 in different molecules: QKRAA in DRβ1*0401; QRRAA in DRβ1*0404, 0405, 0101, and 1402; and RRRAA in DRB1*1001.

In general, the association of DRβ1 molecules bearing the rheumatoid epitope with RA has been found in most ethnic and racial groups analyzed (Table 31-4). HLA-DR4 is associated with RA in most white populations studied as a result of increased frequencies of DRB1*0401 and 0404 in patients. Notably, two other DR4-associated alleles, DRB1*0402 and 0403, are not associated with RA in any population studied. Four other alleles that encode the rheumatoid epitope, DRB1*0101, 1402, 1001, and 0405, another DR4-associated allele, are associated with RA in other ethnic and racial groups. The DRB1*0101 association was found in Basque, Israeli Jew, and Indian RA patients, whereas DRB1*1001 is associated with RA in Greeks, Spanish, Israeli Jews, and Basques. The DR4 association in Japanese, Chinese, New Zealand Polynesians, and Spanish is caused by increased frequencies of DRB1*0405, in contrast to the increased frequencies of DRB1*0401 and 0404 noted above. Among Yakima Indians in the United States, DRB1*1402 is the RA-associated allele. Arabs in Kuwait are

notable for the absence of an association with the shared epitope; DR3 is associated with RA in this population.

Based on a provocative series of studies of white RA patients examined at the Mayo Clinic in Rochester, Minnesota, Weyand, et al. have called attention to the role of DRB1 alleles in determining disease severity, in addition to disease susceptibility. In their initial study, 81 patients with seropositive, erosive rheumatoid arthritis were stratified into three groups based on disease manifestations: those without or with rheumatoid nodules and those with extraarticular manifestations in addition to nodules. DR4 and the RA epitope were found at high frequencies in the three groups: nonnodular (78 and 93%), nodular (100 and 100%), and extraarticular (95 and 100%). They also noted a strong correlation of the HLA-DRB1 alleles possessed by the patients with their clinical manifestations. Half of the patients with extraarticular manifestations in addition to nodules (vasculitis, Felty's syndrome, rheumatoid lung disease, and neuropathy) were homozygous for DRB1*0401, suggesting that a double dose of this disease-associated allele may predispose to more severe disease. In contrast, in the patients with nodules but no major organ involvement, homozygosity for DRB1*0401 occurred in only 1 of the 36 patients. However, 56% of the latter group had two DRB1 alleles with the RA epitope, but only 11% of the nonnodular patients were homozygous for the RA epitope. These data suggested a hierarchy among RA-associated DRB1 alleles, with 0401 and 0404 being associated with more severe disease.

In another study from the Mayo Clinic of 102 patients with seropositive, erosive RA, 89% were positive for the RA-associated alleles DRB1*0401, 0404, or 0408, 96% possessed alleles with the RA epitope, and 46% were homozygous for the disease-associated epitope. One hundred percent of patients with two disease-associated DRB1*04 alleles had nodular disease, and 61% had additional extra-articular disease. In contrast, patients heterozygous for DRB1*04 and the RA epitope-containing DRB1*0101 or 1402 alleles and those heterozygous for a DRB1*04 allele and a non-RA-associated B1 allele had comparable frequencies of nodular disease (58 vs 59%) and little or no extraarticular disease (in addition to nodules). Based on these data, the authors suggested that genotyping for both DRB1 alleles may provide prognostic information that could be used to select patients for early aggressive therapy.

This approach has recently been extended to compare DRB1 alleles in white seropositive and seronegative RA patients. Seropositive patients were more likely to have DRB1*04 alleles and seronegative patients were more likely to have DRB1*0101. DRB1*04 alleles were present in 22% of controls, 91% of seropositive patients, and 42% of seronegative patients, whereas DRB1*01 alleles occurred in 27, 23, and 42%, and the RA epitope occurred in 41, 97, and 68%, respectively. Among the seronegative patients, DRB1*04 alleles were enriched in patients with early erosive disease and those requiring aggressive therapy, whereas patients without an RA-associated DRB1 allele had milder dis-
Figure 31-4 Proposed hierarchy of HLA-DRB1 alleles in determining disease severity in seronegative and seropositive RA. DRB1*0404 in this sheme represents the group of alleles including DRB1*0404, 0405, and 0408. (Reproduced by permission from The Journal of Clinical Investigation 1995;95:2120–2126 by copyright permission of The American Society for Clinical Investigation.)

ease, as judged by the frequent use of nonaggressive therapy and the presence of nonerosive or late erosive disease. The frequencies of the DRβ1 amino acid 70–74 sequence QKRAA encoded by DRB1*0401 and 0409 and the QRRAA sequence encoded by DRB1*0404, 0405, 0408, 0410, 0101, and 0102 were also compared. QKRAA occurred much more frequently in seropositive (65%) than seronegative (35%) patients, and 35% of the seropositives, but none of the seronegatives, expressed both QK and QR alleles. QRRAA alleles occurred at similar frequencies (57 vs 58%) in the two groups. Based on this series of studies, a hierarchy of DRB1 alleles and allelic combinations for determining disease severity in RA has been proposed (Fig. 31-4). In this scheme, DRB1*0401, which encodes lysine at position 71, has the strongest effect and is associated with the most severe disease, especially when present in the homozygous combination. DR4-associated alleles that encode arginine 71 (DRB1*0404 and 0405) have less potent effects, and DRB1*0101, which encodes the rheumatoid epitope in the context of a different sequence in the floor of the peptide-binding groove, is less potent than DRB1*0404 and 0405. Finally, the presence of two non-RA-associated alleles correlates with the mildest disease.

The possibility, based on studies in whites, that determining DRB1 alleles in patients with early RA may permit prediction of eventual disease severity and selection of patients for early aggressive therapy has stimulated a reassessment of the role of DRB1 alleles and the shared epitope in African-Americans with RA. Analysis of 86 African-American patients with RA from Alabama and southeast Texas found that most patients do not have the rheumatoid epitope; only 32% of the seropositive patients and 40% of the seronegative patients have the rheumatoid epitope. In addition, disease severity did not correlate with the presence of the RA epitope in these patients. The frequencies of DRB1 alleles were similar in the patients and controls, except for a modest increase of DRB1*04 alleles in seropositive (27%; RR, 2.5) and seronegative patients (25%; RR, 2.2), compared with 13% of controls. These investigators concluded that determination of DRB1 alleles in African-American RA patients cannot be used to predict

disease severity, and they suggested that the products of other undefined non-HLA genes that may interact with RA-associated DRβ1 chains in whites may not be present in African-Americans. However, the absence of a significant DRB1 association in this study differs somewhat from other studies of black RA patients in the United States and Africa (Table 31-4). In earlier studies from St. Louis and Washington, DC, DR4 was present by serologic typing in 46 and 58%, respectively, of patients and 14 and 18% of controls. In studies of other black populations, DRB1*04 (29 vs 4%) and DRB1*1001 (19 vs 2%) were significantly increased in Shona patients with RA from Zimbabwe compared with controls. DRB1*04 was also associated with RA in black South Africans of Sotho and Zulu origin and patients in Durban and the Western Cape region.

Although the influence of DRB1 alleles on RA disease severity is clearly demonstrated in the studies of white Americans examined at the Mayo Clinic, the results have been variable in other studies. The presence of DR4 was associated with seropositivity and more severe radiographic changes, in a study of whites from Nashville. Among British patients with erosive, seropositive RA being treated with disease-modifying drugs, the frequency of DRB1*04 homozygotes was increased significantly. The relative risks for the DRB1*0401/0401, 0404/0404, and 0401/0404 allelic combinations were 15, 20, and 49, respectively. On the other hand, disease severity did not correlate with the presence of the RA epitope in other studies. In agreement with the study of African-Americans from Alabama and Texas, there was not an association between the presence of the RA epitope and disease severity among African-American RA patients in Atlanta.

POSSIBLE MECHANISMS UNDERLYING HLA-DISEASE ASSOCIATIONS

Although many HLA-disease associations have been described, the molecular basis for these associations remains undefined. Several hypotheses have been proposed to explain HLA-disease associations. The first hypothesis proposes that the disease-associated HLA molecule is a receptor for the etiologic agent, such as a virus or bacteria. In the second hypothesis, the peptide-binding groove of the disease-associated HLA molecule uniquely binds a peptide that is the cause of the disease. The third hypothesis suggests that a specific T-cell receptor, which corecognizes the complex of HLA molecule and peptide, is ultimately responsible for the disease. The fourth hypothesis proposes that the disease-associated HLA molecule is structurally similar to a microbial antigen and that the HLA antigen becomes a target for T cells in the course of the normal immune response to the microbe. This possible scenario has been termed the molecular mimicry hypothesis. The fifth hypothesis postulates that a gene in the HLA complex that encodes a protein involved in antigen processing, such as a TAP gene, is defective, resulting in lower expression levels of class I molecules or more molecules on the cell surface without peptides bound in their grooves (empty molecules). An alternative version of this hypothesis is that a normal TAP allele preferentially transports a disease causing peptide.

Recent studies strongly support the hypothesis that selective binding of peptides is the major mechanism underlying some HLA-disease associations. Hammer et al. have established that peptides with different characteristics bind to DR molecules containing the RA-associated DRβ1*0401 and 0404 chains and the nonassociated DRβ1*0402 chains. As noted in Table 31-3, within the shared

Table 31-5
Disease-Associated DRβ and DQβ Polymorphisms
Determine Selective Binding of Self Peptides

Disease	Disease-associated polymorphism	Self-peptide characteristics
Rheumatoid arthritis	DRβ1*0401 71 Lys	P4 Asp or Glu
	DRβ1*0404 71 Arg	P4 Asp or Glu
Pemphigus vulgaris	DRβ1*0402 71 Glu	P4 Lys or Arg
	DQβ1*05032 57 Asp	P9 Lys or Arg
IDDM	DQβ1*0302 57 Ala	P9 Asp or Glu

epitope, DRβ1*0401 and 0404 chains both have glutamine at position 70 and a highly conservative lysine to arginine difference at position 71, whereas non-RA-associated DRβ1*0402 chains have aspartic acid at 70 and glutamic acid at 71. Using designer peptides in which positions P3 to P7 of the peptide were individually substituted with all natural amino acids (except cysteine), significant differences between DRβ1*0402 molecules and the two RA-associated molecules were observed in the effect of charged peptide residues on peptide binding. The most striking difference is that peptides with positively charged residues, lysine or arginine, at P4 or P6 bind 100 to 1000-fold better to DRβ1*0402 molecules than to DRβ1*0401 or 0404 molecules. Conversely, peptides with negative charges, aspartic acid or glutamic acid, at P4 or P5 bind 100 to 500-fold less well to DRβ1*0402 molecules than to DRβ1*0401, and ~50-fold less well to DRβ1*0404 molecules. A site-directed mutant molecule in which DRβ1*0401 lysine 71 was changed to glutamic acid exhibited a binding specificity similar to that of DRβ1*0402 molecules. Thus, the position 71 lysine to glutamic acid difference in DRβ1*0401 and DRβ1*0402 chains seems to account for most of the difference in peptide binding specificity between these RA-associated and nonassociated molecules. In other experiments, the position 71 lysine to arginine acid difference in DRβ1*0401 and DRβ1*0404 chains was also shown to account for minor differences in peptide binding between these molecules. In summary, residue 71 of the RA-associated DRβ1*0401 or 0404 chains determines that these molecules bind peptides in which P4 has a negative, but not a positive, charge (Table 31-5).

Based on these data on selective binding of peptides to RA-associated DR molecules and other related studies, a model has been proposed in which charge–charge interactions between specific disease-associated HLA polymorphic residues and specific residues of self peptides result in selective binding of self peptides by disease-associated molecules, the HLA-self peptide complexes become the targets of autoreactive T cells, and autoimmune disease develops. In addition to the data with RA-associated polymorphisms cited above, these authors have cited other examples in which DR or DQβ polymorphisms linked to pemphigus vulgaris (PV) or IDDM may determine selective binding of disease-associated self peptides (Table 31-5). In some ethnic groups, PV is associated with DRβ1*0402. The prediction is that the disease-associated DRβ1*0402 molecules, with a negatively charged glutamic acid at DRβ71, bind peptides with a positive charge at P4. Within the target antigen of PV, desmoglein 3 (an epithelial adhesion molecule), seven peptides were identified with the common anchor residues at P1 and P6 and lysine or arginine at P4. According to the model, one or more of these peptides may be involved in the autoimmune process in PV. In other ethnic groups,

PV is associated with DQβ1*05032, which has aspartic acid at position 57 and is modeled to be located in pocket 9 of DQ molecules. In IDDM, many disease-associated DQβ chains, such as DQβ1*0302, do not have aspartic acid at position 57. Therefore, the model predicts that P9 of a pemphigus-associated peptide that binds to DQβ1*05032 molecules will have a positive charge. According to the model, the non-IDDM-associated DQ molecules with Asp 57 should bind peptides with a positively charged residue at P9. However, because many IDDM-associated DQβ chains have serine or alanine, residues that are not strongly charged, at position 57, it is more difficult to predict the characteristics of the P9 residue, but it may be negatively charged.

32   Inherited Immune Deficiency

RICHARD HONG

INTRODUCTION

The immune system provides protection from infectious agents, using two major lymphocyte subsets, known as T cells and B cells. The immune system can respond specifically to millions of different stimuli (epitopes) by virtue of the vast clonal repertoire created by the processes described in other chapters of this volume (Chapters 28 and 29). Because the numerous complicated and varied steps that lead to a competent immune system provide many sites that can be affected by genetic disease, the potential causes of primary immunodeficiency are legion. Granulocytes, although an important member of the host defense system, are not components of the immune system. Therefore, granulocyte disorders are considered elsewhere, in the section on Molecular Hematology.

To place the many events into a framework that highlights the unique developmental aspects of the host defense system, I will divide the processes of an immune response into three phases. First, multipotential stem cells, which give rise to hematopoietic cells as well as lymphocytes, generate cells destined to become mature T and B lymphocytes. Second, an immense repertoire is created through a complex set of differentiation steps. Finally, antigen engagement initiates effector functions (e.g., recruitment of other cells and secretion of molecules) that result in containment or death of infectious agents. Tables 32-1 and 32-2 summarize, respectively, events in T- or B-cell biology necessary to yield a competent immune response. Because of space considerations, only diseases for which the biochemical basis is known are described in this chapter and are tabulated in Tables 32-3 (T cell) and 32-4 (B cell). For further discussion of immune deficiency in general, the reader should refer to other standard texts. Secondary immunodeficiency states, i.e., those secondary to another disorder such as cancer, will not be included, except for acquired immunodeficiency syndrome (AIDS), secondary to infection with human immunodeficiency syndrome (HIV), which is considered in Chapter 33.

SYMPTOMS OF IMMUNE DEFICIENCY

Regardless of the specific cause of the defect, the clinical presentations are similar for the various diseases. The manifestations depend upon the degree of incompetence of the T cells or B cells, or whether combined T- and B-cell disorders coexist. Unique

symptoms, associated with specific diseases, will be described in the relevant sections.

The major symptoms of immune deficiency are increased susceptibility to infection. Because the T and B cells are effective against different groups of agents, defects in either system produce different patterns of susceptibility. Antibodies protect against infections from extracellular pyogenic bacteria, whereas T cells prevent viral, fungal, tuberculous, and opportunistic infections, such as *Pneumocystis carinii* pneumonia.

Patients with immune deficiency are susceptible to agents that are nonpathogenic for those with intact host defense systems, and also will experience unusually severe and sometimes fatal manifestations of infections caused by ordinarily benign bacteria or viruses. Thus, in immunodeficiency states, cytomegalovirus causes retinitis and severe pneumonia, atypical mycobacteria or parasites can cause severe protracted diarrhea, and measles is a fatal disease. Overwhelming pneumonia is a particularly virulent and often fatal complication of varicella, rubeola, or parainfluenza.

LABORATORY ASSESSMENT

QUANTITATIVE TESTS   Tests of the immune status can be either quantitative or qualitative. If an element of the immune system, e.g., lymphocyte subset or immunoglobulin (Ig) level, is completely absent, obviously no immune function is possible, but this degree of deficiency is usually not seen. An absolute lymphocyte count of less than 1200/mm^3 is abnormal. T and B cells are enumerated most conveniently by the technique of flow cytometry, using a panel of antibodies that identify surface markers characteristic of each of the lymphocyte subsets (Table 32-5). In addition, the absence of certain markers are diagnostic of some diseases, e.g., CD43 in Wiskott-Aldrich syndrome. Serum immunoglobulin levels provide a quantitative measure of B-cell secretion. However, immunoglobulin levels should be compared with age-adjusted normal ranges because serum values increase with age. The Ig levels in patients with clinically significant B-cell disease hardly ever overlap with normal ranges. Therefore, 95% confidence limits are not useful in differentiating between deficient and normal immunoglobulin values. In the presence of low levels of lymphocytes or Igs, a functional or qualitative test is the only reliable assessment to decide whether the patient is at risk.

QUALITATIVE (FUNCTIONAL) TESTS   T-cell function can be assessed by measuring in vitro proliferative responses to various stimuli. Three types of stimuli are used: mitogens, allogeneic cells, and antigens. Mitogen-induced proliferation implies the

Table 32-5
Surface Markers

Marker	Comment
T-cell series	
CD 1a, b, c	Cortical thymocytes
CD2	T cells, natural killer (NK) cells, LFA–3 receptor
CD3	Part of the T-cell receptor complex; a pan-T-cell marker
CD4	T cells reactive with class II HLA-presented antigen (helper T cell)
CD5	Pan-T-cell marker; present on a B-cell subset
CD8	T cell reactive with class I HLA-presented antigen (killer T cell)
CD28	T-cell subset, activated B cell, thymocytes, site of second signal stimulus
CD43	Leukocytes except B cells (leukosialin); deficient in Wiskott-Aldrich syndrome
CD45RA	Naive T cell (has not reacted with antigen); recent emigrant from thymus
CD45RO	Memory T cell
CD56	Natural killer cell
B-cell series	
CD10	Common acute lymphatic leukemia antigen (CALLA)
CD19	Pan-B-cell marker
CD20	Pan-B-cell marker
CD21	Epstein-Barr virus receptor
CD23	Activated B cells, macrophages, eosinophils, platelets; the low affinity $Fc_{\epsilon}RII$
Myeloid series	
CD14	Monocytes, granulocytes, Langerhans' cells, macrophages
CD16	NK cells, granulocytes, macrophages; the $Fc_{\gamma}RIIIA$, $Fc_{\gamma}RIIIB$ receptor
CD34	Hematopoietic precursor cells, endothelial cells
CD35	Granulocytes, monocytes, NK, B cells; the CR1/C3b receptor
Other	
CD 11a, b, c	LFA–1 integrin chains; adhesion molecule on leukocytes
CD62E, L, P	Selectin adhesion molecules on endothelial cells, leukocytes, platelets
CD69	Early activation marker of T cells

presence of T cells with surface receptors characteristic of T cells; allogeneic cells stimulate on the basis of transplantation-antigen differences. Of the three stimuli, antigens are the most informative, and a positive response provides the best correlate of the ability of the patient to resist infection. However, antigen response occurs only after sufficient exposure to the agent and, therefore, may not be elicited in young children during the first year of life. A delayed hypersensitivity skin test in which the antigen is injected intradermally and localized swelling of the puncture site measured 48 h later is a classic test of T-cell responses; it can be considered an in vivo correlate of the in vitro antigen-induced proliferation response. Other tests of T-cell capability involve the release of cytokines and the lysis of target cells (T-killer-cell assay). The functional capability of B cells is tested by measuring the specific antibody response to ubiquitous or vaccine antigens.

CARRIER STATE AND PRENATAL DIAGNOSIS Once the gene has been cloned, the availability of specific molecular DNA probes allows definition of the specific cause of the deficiency and also can be used for prenatal diagnoses. When the molecular basis has not been defined at the gene level, a diagnosis of the carrier or disease state can be made if an informative probe (i.e., near the chromosome lesion) is available and used in conjunction with restriction fragment length polymorphism (RFLP) analysis (*see* Chapter 4). When the restriction fragments are electrophoresed, then probed, two bands will be seen, one corresponding to each parentally inherited chromosome. In an X-linked disease, an identical size fragment will be found in the heterozygote mother and her affected male child, because both carry the disease-associated chromosome. Family analysis may reveal that the carrier mother inherited the disease-associated chromosome from her mother. Healthy boys will show the chromosome band of the healthy maternal allele. RFLP analysis has been most informative for X-linked diseases because of the larger numbers of probes available and the greater knowledge of the approximate gene location as compared with autosomal chromosomes.

A carrier status can be defined in females, based upon nonrandom inactivation of the X chromosome by carriers in cell lines affected by the disease. If one prepares DNA from carrier lymphocytes and granulocytes (or fibroblasts), it will be seen that T or B lymphocytes will show only one restriction digest band, whereas nonlymphocyte populations will show two bands. If the disease affects both T and B cells, all lymphocytes will show only the pattern of the healthy allele; if the disease is restricted to B cells, e.g., hypogammaglobulinemia, T lymphocytes will show two bands and B lymphocytes will show the single pattern of the healthy allele. Apparently, cell lines using the disease-carrying X chromosome in healthy heterozygotes suffer a growth disadvan-

tage and, with time, the population is converted entirely or nearly so, to lymphocytes that use the healthy X chromosome. Thus, RFLP analysis of cell lines of a putative obligate heterozygote will confirm the carrier state and the X-linked inheritance pattern, and define the cell lines affected by the disorder. Carrier detection studies have shown that in lethal X-linked diseases, a third to a half of the patients are affected by a new mutation, thus giving a negative family history. At the present time, informative probes are available for investigation of Wiskott-Aldrich syndrome, X-linked severe combined immunodeficiency disease, X-linked proliferative syndrome, and X-linked agammaglobulinemia.

As will be described later, the genes for Wiskott-Aldrich syndrome, ataxia telangiectasia, X-linked hyperimmunoglobulin M, X-linked agammaglobulinemia, and autosomal and X-linked severe combined immunodeficiency have been cloned. Thus, these disorders may be analyzed precisely at the DNA level.

Prenatal diagnosis is accomplished by biochemical testing of cultured amniotic fibroblasts (enzyme deficiency) or molecular analysis of chorionic villus biopsies.

THERAPY

INTRAVENOUS GAMMA-GLOBULIN   For isolated B-cell deficiency, γ-globulin, prepared from Cohn Fraction II, provides excellent replacement therapy. Intramuscular preparations, used extensively in the past, have now been replaced by intravenous products, which provide much higher body stores and serum levels. Intravenous γ-globulin (IVIG) will not provide significant amounts of IgA or IgM. Paradoxically, it may contain a sufficient amount of IgA to sensitize patients with isolated IgA deficiency, endangering them for anaphylaxis as a result of anti-IgA antibodies in the future. Therefore, IVIG therapy for selective IgA deficiency is not recommended.

Some preparations of IVIG have been associated with transmission of hepatitis C. Patients on IVIG therapy should be monitored for occult liver disease by periodic transaminase studies. Transmission of HIV has not been reported and seems unlikely because the virus is being eliminated by the methods of preparation of the product.

BONE MARROW TRANSPLANTATION   Because the defects of immune deficiency disorders are caused by faulty cell lines, replacement by means of bone marrow transplants will cure the disease. Transplantation in patients with sufficiently profound T-cell disease will not require ablation, so the morbidity associated with radiation or chemotherapy can be avoided. Also, for reasons not entirely clear, patients with immune deficiency (with the notable exception of Wiskott-Aldrich syndrome) tend to have little or no graft-vs-host disease. In general, if the recipient is in reasonable health and does not have a serious infection at the time of transplant, his clinical course is much less complicated than that seen in the usual bone marrow transplant recipient suffering from hematologic malignancy.

The donor may be a matched sibling, a haploidentical family member (usually a parent), or a matched unrelated individual. Results are in general better with a matched sibling donor, but nearly equal results are seen with alternative donors.

It is not necessary to know the defect precisely because the transplanted cells will replace all of the cell lines in patients receiving ablation therapy or, when ablation is not used, the transplanted healthy cell lines will manifest a growth advantage over the diseased lines of the recipient. Overall, success rates with permanent cure of the disease range from 25 to 75% when the recipient is in good health at the time of transplant for both matched and mismatched transplants.

GENE THERAPY   Because bone marrow transplantation is essentially stem cell replacement therapy, immunodeficiency patients are ideal candidates for gene therapy. The outcome depends on successful transfection of the stem cells with the appropriate gene, resulting in normalized stem cells that then mature into competent T and B lymphocytes. At present, a major stumbling block is the technology for transfection, which is quite inefficient. This, combined with the low frequency of stem cells in the bone marrow, makes the total number of successfully transduced cells quite small. Other problems depend on the level of gene expression obtained and the complexity of the gene product, i.e., single versus multiple polypeptide chain structures.

Adenosine deaminase deficiency, a major cause of autosomally transmitted combined immunodeficiency, is ideally suited for gene therapy. The enzyme is a single polypeptide chain that is constitutively produced, and close regulation of cell levels is not required. An injectable form of adensosine deaminase can be used to support the patient while undergoing gene correction. An encouraging response has been obtained recently. The details are described more fully later.

COMBINED T- AND B-CELL DISEASES

X-LINKED SEVERE COMBINED IMMUNODEFICIENCY

The term combined immunodeficiency refers to involvement of both T and B lymphocytes; severe was used in the original descriptions because most children had a severe clinical disease with death occurring within the first 2 years of life. However, with more sensitive diagnostic tests and with improved treatment, the arbitrary 2-year limit on lifespan in untreated patients is no longer valid. The term "severe" is of little descriptive value today.

The genetic fault in X-linked severe combined immunodeficiency (SCID) involves the γ_c chain of the interleukin-2 (IL-2) receptor. IL-2 is a cytokine that is necessary for the antigen-induced proliferative response. Impairment of the IL-2 response would cripple the immune system, but does not readily explain the magnitude of the immune system deficit seen in this disease. Indeed, mice lacking the IL-2 gene show only mild disease and no infectious susceptibility at all. The explanation for the global effects of IL-2R γ_c chain deficiency was shown by Kondo et al., Noguchi et al., Russell et al. The receptors for IL-4, IL-7, IL-9, and IL-2 all share the same γ_c chain, and thus, deficiency involving multiple cytokines is present. These cytokines affect T- and B-cell development and differentiation as well as mast cell enhancement (IL-9), thus accounting for the multicellular nature of the defect. The transduction of these receptor signals involves the tyrosine phosphorylation of multiple cellular substrates, including the Janus family kinases Jak1 and Jak3; the γ_c chain associates with Jak3. Hence, it is not surprising that mutations in Jak3 have now been shown to result in an autosomally transmitted SCID phenotype.

Most patients present during the first year of life with a history of excessive numbers of severe, often life-threatening infections, cutaneous or oral candidiasis not responding to local therapy, or opportunistic infections. Bone marrow transplantation is curative.

BARE LYMPHOCYTE SYNDROME   Transplantation antigens, which determine the acceptance or rejection of tissue transplants between individuals, are controlled by genes on chromosome 6 that form the major histocompatibility complex (MHC). In actuality, this highly polymorphic system is related to transplantation only because humans transplant tissues or organs.

The actual biologic role of the MHC products is to present antigen to T cells. The class I MHC antigens, expressed on virtually all nucleated cells and denoted human leukocyte antigens (HLA) -A, -B, and -C, present antigens digested in the cytosol to CD[8+] cytolytic T cells, forming an important mechanism of viral control. The Class II MHC antigens (HLA-DP, -DQ, and -DR), are expressed constitutively by phagocytes and B cells; cytokines such as interferon-γ (IFN-γ) may induce class II MHC expression on other cells. Antigens that are phagocytosed or organisms that multiply in intracellular vesicles are protected from cytosolic degradation, but digested by the acidic lysosomal enzymes and incorporated into class II molecules for antigen presentation to CD[4+] helper T cells. Patients may manifest deficiency of class I MHC products only, class II MHC products only, or both classes.

Of the two types, the MHC class II deficiencies have been the most extensively studied and are caused by a heterogeneous array of abnormalities in autosomal recessive genes that regulate MHC expression. Complementation studies suggested four complementation groups; however, most defects described to date are of two varieties. *Trans*-acting genes, not linked to the MHC, control the transcription of MHC class II structural genes. A class II transactivator splicing mutant has been found. Other genes initiate gene transcription by means of proteins that bind to *cis*-active promoter elements (X and Y boxes). Reith et al. found a defect in one such DNA-binding protein, RF-X; defects in accessory proteins that stabilize or enhance DNA binding have been described. Class I MHC deficiency can be caused by a defect of a transporter protein (TAP) necessary for peptide incorporation into the MHC cleft. Without an associated peptide, the MHC molecules are not expressed on the cell surface. The lack of MHC antigen expression is usually complete, but a few patients may express low levels, which in some cases can be upregulated by cytokines, such as interferon, or Epstein-Barr virus infection.

The lack of MHC antigens results in the inability to present peptide to T cells, thus subverting an immune response. In addition, thymic selection, which is controlled in large part by MHC expression, is affected, so that the bare lymphocyte syndrome is also manifested by inappropriate thymopoiesis with mature T-cell subset deficiencies. For example, in class II MHC deficiency, there is often a lack of CD[4+] T cells.

Symptoms of excessive and overwhelming infections usually begin in the first year of life, and without therapy, death is the usual outcome by 4 years of age. Bone marrow transplantation is curative. Because the patients cannot be typed for transplantation by the usual methods, newer techniques of MHC typing by DNA are required for matching.

WISKOTT-ALDRICH SYNDROME   Wiskott-Aldrich syndrome (WAS) is characterized by thrombocytopenia with small platelets, frequent infections, eczema, and a high incidence of malignancy. It is inherited as an X-linked defect. Characteristic immunologic abnormalities include inability to respond to polysaccharides and a characteristic immunoglobulin pattern of low IgM and high IgA. Lymphocyte counts and functional analysis may be fairly normal at first, but diminish with time.

The first abnormality noted in WAS lymphocytes was a defective expression of CD43 (sialophorin). However, the X-linked inheritance pattern could not be reconciled with the location of the CD43 gene on chromosome 16. Recently, the WAS gene was cloned, and the product, the Wiskott-Aldrich syndrome protein (WASP) was shown to be a 501-amino acid proline-rich structure. How it is related to CD43 is as yet unknown, but WASP may play a central role in formation of cell surface microvilli, which play an important role in antigen responses evoked by large inflexible molecules such as polysaccharides. Characteristically, patients with WAS do not make polysaccharide antibodies.

The bleeding manifestations caused by the thrombocytopenia are usually the first clinical symptoms. The onset of infections may be delayed for some years. The patients are unusually susceptible to herpetic infections. Malignancy may occur in as many as 15% of the untreated patients.

Bone marrow transplantation is curative. Use of T-cell depleted marrows when a matched sibling donor is unavailable has met with variable results, often with less success than other immunodeficiency diseases treated by other than HLA matched donors. The less than salutary results are because of the high incidence of B-cell lymphomas and severe graft versus host disease. B-cell lymphomas may respond to monoclonal antibodies or cellular infusions, however.

PURINE ENZYME (ADENOSINE DEAMINASE, PURINE NUCLEOSIDE PHOSPHORYLASE) DEFICIENCY   Two enzymes of purine metabolism, adenosine deaminase (ADA, located on chromosome 2) and purine nucleoside phosphorylase (PNP, located on chromosome 14), are associated with immune deficiency. ADA deficiency accounts for 40% of autosomal recessively inherited combined immunodeficiency. PNP deficiency is much rarer (4%) and usually involves only the T-cell system, with relative sparing of the B cells.

Adenosine deaminase and purine nucleoside phosphorylase are enzymes of the purine salvage pathway, which recycle purines resulting from cell breakdown for re-use in synthesis of new DNA required for cell proliferation. ADA deaminates adenosine to yield inosine, which is then converted to hypoxanthine by PNP. In the absence of either enzyme, toxic metabolites accumulate. ADA absence leads to high levels of deoxyadenosine, which, in the presence of the high levels of deoxycytidine kinase in lymphocytes, becomes phosphorylated to deoxyadenosine triphosphate. The excessive amounts of deoxyATP interfere with ribonucleotide reductase, an enzyme essential for synthesis of DNA precursors. In PNP deficiency, deoxyguanosine triphosphate accumulates with similar consequences. The reason for sparing of the B cells in PNP deficiency is at present unknown. In addition to the accumulation of deoxyATP and deoxyGTP, inactivation of *S*-adenosyl homocysteine hydrolase occurs, leading to inhibition of methylation, which has further toxic effects. Although ADA and PNP are present in all cells, clinically evident pathology involves only a few tissues, probably because of differing susceptibility of various tissues to the toxic metabolites. In addition to the lymphocytes, lesions involving the growing ends of bones and neurologic disturbances are apparent clinically. However, at autopsy, renal and adrenal lesions have also been found.

In symptomatic patients, the defect in ADA must be nearly complete because only 1–5% of normal amounts is necessary for competent immunity. Patients with ADA deficiency have been divided into four groups, in order of increasing serum levels of ADA. Group 1 (ADA-SCID) shows the usual symptomatology of early life-threatening infections and severe lymphopenia. Groups 2 and 3 show delayed onset, and autoimmune diseases are a prominent feature. Group 4, designated partial ADA deficiency, has normal immunity and the defect is discovered only incidentally. Asymptomatic PNP-deficient patients have not been described as yet. A high incidence of neurologic disorders are found, including mental retardation and developmental delay. Autoimmune disease is common.

Most mutations of ADA are missense; only two PNP mutants have been studied. One was a missense and the other a frameshift mutant.

A number of treatments are available for ADA deficiency. Bone marrow transplantation is curative. In milder deficiency states, benefit from a polyethylene glycol-modified preparation of bovine ADA, PEG-ADA, has been observed.

Patients with ADA deficiency are ideal candidates for gene therapy. ADA has a single polypeptide chain and overexpression should not present a problem. At first, two children were treated with their own T cells that had been transfected with the ADA gene. After seven monthly infusions, totaling 7×10^{10} cells, the first patient showed persistent ADA activity in her peripheral T cells to levels 25% of normal. Improvement in many immune function tests and clinical well-being have persisted for at least 6 months after the last infusion. Results in the second patient are less dramatic, but both children participate fully in school and social activities and tolerated the infusions without incident.

These encouraging results led to the treatment, by insertion of the ADA gene in the cord blood stem cells, of three neonates in whom the diagnosis of ADA deficiency had been made prenatally. Transfected umbilical cord stem cells were reinfused into the infants without cytoablation and have persisted for 18 months. PEG-ADA, given at first to support the patients while the transfected cells were engrafting, has been dropped to 50% of normal treatment doses. With the decrease in PEG-ADA, although the total numbers of lymphocytes has decreased, the numbers of vector-containing lymphocytes has increased, demonstrating that transduced ADA-producing cells can expand in response to the demand for more immunocompetent cells.

ATAXIA-TELANGIECTASIA   Ataxia-telangiectasia (AT) is an autosomal recessively inherited immunodeficiency disorder with an extremely diverse clinical phenotype characterized by ataxia, conjunctival telangiectasia, combined immunodeficiency, predisposition to lymphoreticular malignancies, and sensitivity to ionizing radiation. Studies at the cellular level suggest checkpoint defects at the G1 and G2 phases of the cell cycle, reduced life-span, and higher growth factor requirements.

The cloning of the AT gene provides insight into a number of biochemical mysteries and helps to explain the multitude of clinical manifestations of AT. The gene, located on the long arm of chromosome 11 (region q22–23) has been named ATM (AT, mutated) and bears strong homology to phosphatidylinositol-3' (PI-3) kinases, enzymes important in signal transduction, meiotic recombination, and cell cycle control. The demonstration of a PI-3 kinase role in maintaining brain growth factors may explain the Purkinge cell loss in the cerebellum, a hallmark of AT. Similar pivotal roles of PI-3 kinases probably account for defective cellular responses to insulin and immunologic deficiency.

A role for ATM in DNA damage repair has particularly profound implications. Not only does it explain the sensitivity of AT patients' cells to radiation, but it may define a group of women who possess a single copy of the mutant and are at increased risk for breast cancer, as suggested by previous epidemiologic studies. In such patients routine diagnostic X-rays and mammograms may be contraindicated.

T-CELL DISEASES

DIGEORGE ANOMALY   The DiGeorge anomaly (DGA) is characterized by facial abnormalities (hypognathia, hypertelorism, downward slope of the lateral aspects of the eyes, defective ear pinnae), hypoparathyroidism, conotruncal heart abnormalities, and T-cell deficiency. Other organ involvement, namely brain, gastrointestinal, thyroid, eye, and renal have been described.

The pathogenesis of DGA is understood in developmental terms, but the mechanistic correlation with the observed chromosome 22 defect has not been elucidated. A failure of incorporation of the facial neural crest tissue into branchial arch derivatives is at the heart of the symptom complex, and explains the symmetrical character of the lesions. Facial neural crest tissue is injured by the multitude of causations that have been incriminated in DGA. These include first-trimester infections, alcohol exposure, retinoic acid, and maternal diabetes.

Usually, the DiGeorge anomaly occurs sporadically. However, familial cases have been described with various modes of transmission. Parents may have asymptomatic mild versions of the anomaly and only on careful questioning or examination will the subtle manifestations be revealed. A deletion of chromosome 22q11 was found in 33 of 35 DGA patients when sufficiently sensitive methodology was employed and, thus, most likely represents the genetic basis for the disorder.

Diagnosis should be considered in all cases of neonatal hypocalcemia or conotruncal heart defects. The facies, particularly hypognathia and defective ear pinnae formation are other highly suggestive signs. T-cell lymphopenia is common, but immunodeficiency requiring therapy is necessary only in about 25% of the cases; in the remainder, spontaneous correction is seen. Phytohemagglutinin responses less than 10% of the lowest acceptable normal value or CD^{4+} lymphocytes less than 300/mm^3 define patients in whom spontaneous remission of immune deficiency is extremely unlikely; they should be considered for transplantation. Hypoparathyroidism is associated with parathormone deficiency. This problem may spontaneously improve with time or disappear completely. The chromosome 22 deletion is readily demonstrated by fluorescence *in situ* hybridization.

Symptoms of T-cell deficiency occur, but the clinical course is mostly punctuated by the serious heart disease and hypocalcemia.

Thymus transplantation is curative. Bone marrow transplantation from a matched sibling donor has been successfully accomplished twice. T-cell-depleted haploidentical transplants from the parents will not succeed because the T-cell defect is caused by absence of the thymus and bone marrow stem cells cannot be differentiated. The hypoparathyroidism is controlled by vitamin D and calcium. The heart defects usually require corrective surgery that are well-tolerated despite the defects in the immune system.

ZAP-70 DEFICIENCY   Most instances of T-cell deficiency are associated with lymphopenia involving both major subsets, CD^{4+} and CD^{8+} T cells. In an unusual variety marked by a normal to slightly elevated lymphocyte count, CD^{8+} T cells are virtually absent. The CD^{4+} T cells will respond to stimuli that bypass the T-cell receptor (TCR), e.g., phorbol ester plus calcium ionophore, but not to crosslinking of CD3, phytohemagglutinin, or allogeneic cell stimuli. A protein tyrosine kinase (PTK), ZAP-70, is lacking in such patients.

Other PTKs involved in TCR signal transduction, Lck, Fyn, and Syk, are normal in these patients, but cannot compensate for the defect. Further, ZAP-70 appears to be unnecessary for CD^{4+} T-cell thymic maturation, selection, and export to the periphery, whereas CD8+ thymopoiesis is ZAP-70-dependent. This defect is inherited as an autosomal recessive trait.

T-CELL RECEPTOR (TCR) DEFECT   The T-cell receptor is a heterodimer of α and β or γ and δ chains. The $\alpha\beta$ TCR is the most common variety and accounts for essentially all of the routine protection from infectious agents. The $\gamma\delta$ TCR may represent a more primitive structure capable of reacting without the restraints

required for usual T-cell activation (e.g., MHC antigen presentation) and may respond to nonpeptidic epitopes, such as those found in lipids, mycobacteria, and heat shock proteins. Immunodeficiency involving γδ TCRs has not been described. Surface expression of the αβ TCR requires complexing with proteins of the CD3 complex, a mixture of γ, δ, ε, ζ, and η subunits. The TCR α and β chains lack cytoplasmic tails and, therefore, would not transduce activation signals effectively. The CD3 complex provides the necessary cytoplasmic extensions that allow TCR stimulation to initiate the intracellular events necessary for a competent T-cell antigen response. Mutations of chains of the CD3 complex, most commonly the γ or ε chains, have been described and are associated with abnormal or diminished expression of the TCR. The γ chain defect results in a more clinically severe disease.

TRANSDUCTION DEFECTS A number of primary signal transduction defects have been described, characterized by failure to proliferate after ligation of TCR-CD3, CD2, or CD3 surface molecules. If membrane activation is bypassed, using phorbol ester plus calcium ionophore or G-protein activators, the T cells will respond, thus placing the lesions early in the activation pathway.

In another variety, a structural defect in the nuclear factor of activated T cells (NF-AT) was found. Thus, lesions from the beginning to the end of the signal transduction pathway have been described.

B-CELL DISEASES

X-LINKED AGAMMAGLOBULINEMIA (XLA) The first immunodeficiency disease was described by Ogden Bruton in 1952. The patient was a 4-year-old boy with a history of repeated septic episodes. Using the new technique of serum protein electrophoresis, Bruton showed that gamma globulin was lacking. Following treatment with intramuscular gamma globulin injections, the patient remained infection free. Subsequently, autosomal recessive forms of agammaglobulinemia and late onset ("acquired") varieties were described. To date, the molecular bases for those variants have not been delineated.

The development of mature immunoglobulin-secreting B cells involves, first, the differentiation from pre-B cells into progressively more mature stages, next, switching to isotype commitment, and ultimately, antigen-driven terminal differentiation with synthesis and secretion of Ig. The first step, from pre-B to B cell, is blocked in X-linked agammaglobulinemia as a result of a fault in the Bruton tyrosine kinase (*Btk*) gene, located in the midportion of the long arm of the X chromosome, at Xq22. Several varieties of mutations have been described, resulting in inactivity or deficient expression of *Btk*. *Btk* is related to the *src* family of cytoplasmic protein tyrosine kinases and is vital to supporting the clonal expansion of pre-B cells.

Recently, a point mutation in the SH2 domain, which was associated with a milder form of disease, was found in a family with three affected males. In two of the brothers, the levels of IgG were higher than usually seen (470 and 590 mg/dL). In all three, the peripheral blood B cells numbered from 0.3 to 2% in contrast to the mean value of 0.1% for XLA patients. The clinical disease was much milder in all three; in fact, one patient had no serious infections even though he complied poorly with therapy.

Recurrent infections with extracellular pyogenic pathogens resulting in meningitis, pneumonia and septicemia characterize hypogammaglobulinemia.

The disease is usually well-controlled by replacement gamma globulin. Intramuscular injections can be used in small infants in whom access is difficult, but intravenous preparations have largely supplanted this route and are necessary to achieve appropriate therapeutic levels in older children and adults. A critical factor in the ultimate prognosis in these patients is the degree of pulmonary involvement by chronic infection leading to bronchiectasis and pulmonary fibrosis. Therefore, close monitoring of the pulmonary status by regular function studies is important.

HYPER-IgM (HIM) The initial response of the cell system to antigen stimulates IgM clones. With continued stimulation or with a booster injection, the antibody response is shifted to IgG, IgA, or IgE clones that have developed by T-cell-dependent isotype switching of the IgM precursors. Isotype switching is dependent on the interaction of CD40, a B-cell surface growth factor receptor, with CD40 ligand (CD40L or gp39) expressed primarily on CD4+T cells shortly after activation. HIM shows X-linked, autosomal recessive, and autosomal dominant forms of inheritance. Most patients with X-linked hyper-IgM (X-HIM) lack CD40L and, as a result, show increased levels of IgM, with virtually no IgG, IgA, or IgE. Four of 17 male patients with suspected X-linked HIM, however, were shown to have normal CD40L but defective CD40-mediated signal transduction. It is not certain that the CD40L+ variety is also X-linked; one of the patients had affected male relatives, whereas the others did not.

HIM patients have two problems not seen in agammaglobulinemia because of B cell defects, infections with opportunistic infections and neutropenia. These complications are more common in the CD40L− type of HIM. The clinical course is otherwise similar to panhypogammaglobulinemia.

In contrast to carriers of most immunodeficiency disorders studied to date, phenotypically normal mothers of X-HIM patients may show a significant number of cells of the affected (T-cell) line that express the diseased maternally derived chromosome; in some cases as many as 68% are CD40L negative. Thus, normal levels of immunoglobulins and freedom from infectious susceptibility can be attained with levels of only 30% CD40L+ cells. These observations also suggest that CD40-CD40L interactions are not critical for intrathymic T-cell selection and export to the periphery.

Most patients with HIM respond to intravenous immunoglobulin therapy. When the clinical history warrants, bone marrow transplant can be performed.

SUBCLASS DEFICIENCY The immunoglobulins are divided into subclasses, based on minor amino acid sequence differences in the constant region. IgG has four subclasses, denoted IgG1 through IgG4. The subclasses have slightly different biologic activity. Most importantly, the major carbohydrate antibody response shifts from IgG1 in children to IgG2 in adults. It can be argued that a deficiency of the IgG2 subclass could impair the antibody response to many bacteria. Furthermore, if a subclass is missing or low, total IgG determinations will usually not reflect this deficiency. Other subclasses are normal or elevated to mask this defect. However, whether IgG subclass deficiency is a clinically significant defect is a debatable issue. The major disclaimer is the fact that individuals completely lacking in IgG2, IgA1, IgG4, and IgE because of a structural gene defect have been described who have no increased susceptibility to infectious disease whatever. It is postulated that subclass deficiency as a result of gene deletion is an asymptomatic condition with compensatory antibody formation by other subclasses, whereas subclass deficiency because of immune dysregulation is symptomatic because antibody formation is impaired. The distinction can be made by measuring specific antibody responses.

33 Human Immunodeficiency Virus and Acquired Immune Deficiency Syndrome (AIDS)

John W. Sleasman and Maureen M. Goodenow

AIDS AND HUMAN RETROVIRUSES

Acquired immunodeficiency syndrome (AIDS) is a result of infection with human immunodeficiency virus type 1 (HIV-1), a human retrovirus. Retroviruses cause a variety of diseases ranging from immunodeficiency to malignancy. Human retroviruses are divided into two major families. Oncornaviruses, including human T-cell lymphotropic viruses (HTLV-1 and HTLV-2), have the capacity to cause tumors. Lentiviruses, which include HIV, are a second family of retroviruses that have the capacity to be cytopathic and cause cell death, usually after a long period of incubation. There are two recognized subtypes of HIV: HIV-1, which causes AIDS and related complexes worldwide; and HIV-2, which may be less pathogenic and is more geographically restricted than HIV-1. HIV-2 is genetically more closely related to simian immunodeficiency virus than to HIV-1.

AIDS was initially described in 1981 as an immunodeficiency syndrome restricted epidemiologically to gay males living in the United States. The disease was quickly recognized to affect men, women, and children living throughout the world. By 1983 the causal relationship between HIV-1 infection and the development of AIDS was realized. Today AIDS has become a major worldwide cause of death in both adults and children. The World Health Organization estimates that there are more than 20 million infected individuals worldwide. In the United States, AIDS is the leading cause of death of men between the ages of 25 and 45 and the fifth leading cause of death of women of reproductive age. HIV-1 is transmitted primarily through sexual contact, intravenous (iv) exposure to contaminated blood or blood products, and vertical transmission from mother to child. The clinical manifestations of AIDS result from a profound deficiency in cell-mediated immunity, and to a lesser extent, humoral immunity. The clinical manifestations of HIV-1 infection, as categorized by the Centers for Disease Control and Prevention, are summarized in Table 33-1.

NATURAL HISTORY OF HIV-1 INFECTION

The pathogenesis from initial HIV-1 infection to the development of AIDS results from a dynamic interaction between the

virus and the host immune system. The principal mechanism leading to immunodeficiency is the progressive loss of CD4$^+$ lymphocyte number and function. Immunologic abnormalities can be demonstrated soon after initial infection before the loss of CD4$^+$ T lymphocytes, indicating that attrition of CD4$^+$ T lymphocytes alone does not explain completely all of the clinical and immunologic manifestations seen in HIV-infected individuals.

The clinical history of HIV-1 infection generally follows three stages: an acute "flulike" illness, a relatively asymptomatic "latent" period, and the reappearance of symptoms and immunodeficiency ultimately resulting in AIDS (Fig. 33-1). Primary symptomatic HIV-1 infection is generally characterized by an acute febrile illness, lymphadenopathy, and malaise, which occur 3–4 weeks after exposure. However, not all HIV-1-infected individuals exhibit symptoms during this acute stage of viral infection. This acute phase is associated with high levels of HIV-1 replication and plasma viremia. Laboratory evaluation reveals evidence of T-cell activation, transient inverted CD4 to CD8 T-lymphocyte ratio, and mild hypergammaglobulinemia. During this stage of acute infection, individuals are HIV-1-antibody negative yet potentially infectious. Seroconversion and the production of antibody to core and envelope proteins occurs 4–6 weeks after viral exposure. The emergence of immunologic suppression of HIV, as measured by the production of antibodies to viral proteins, results in a decline in plasma viremia and clinical symptoms. At this point the patient enters a period of clinical latency. However, viral replication continues in the lymphoid system often at subclinical levels.

In adults, the diagnosis of HIV-1 infection is based on the detection of serum antibodies to HIV proteins using enzyme-linked immunosorbent assay (ELISA) and is confirmed by Western blot analysis. In newborn infants, antibody-based assays of detection of HIV infection are not helpful because of the presence of passively acquired maternal antibody. Because only about a third of infants born to HIV-infected mothers are infected, a direct means of detecting the virus is required to differentiate infected from uninfected infants. The most sensitive means for identifying infected infants is the use of the polymerase chain reaction to amplify HIV proviral DNA within infected CD4$^+$ T lymphocytes.

Although a small percentage of infected infants will develop a rapid progression to the AIDS, the majority of infected adults and

Table 33-1
1993 CDC Clinical Categories for Adolescents and Adults[a]

Category A
  Asymptomatic HIV infection
  Persistent generalized lymphadenopathy
  Acute (primary) HIV infection with accompanying illness or
    history of acute HIV infection
Category B
  Bacillary angiomatosis
  Candidiasis, oropharyngeal (thrush)
  Candidiasis, vulvovaginal; persistent, frequent, or poorly
    responsive to therapy
  Cervical dysplasia (moderate or severe) and cervical carcinoma
    in situ
  Constitutional symptoms, such as fever (38.5°C) or diarrhea
    lasting >1 month
  Hairy leukoplakia, oral
  Herpes zoster (shingles), involving at least two distinct
    episodes or more than one dermatome
  Idiopathic thrombocytopenic purpura
  Listeriosis
  Pelvic inflammatory disease, particularly if complicated by
    tubo-ovarian abscess
  Peripheral neuropathy
Category C
  CD4$^+$ T-lymphocyte count <200 cells/μL or CD4$^+$
    percentage <14%
  Candidiasis of bronchi, trachea, or lungs
  Candidiasis, esophageal
  Cervical cancer, invasive
  Coccidioidomycosis, disseminated or extrapulmonary
  Cryptococcosis, extrapulmonary
  Cryptosporidiosis, chronic intestinal (>1 month's duration)
  Cytomegalovirus disease (other than liver, spleen, or nodes)
  Cytomegalovirus retinitis (with loss of vision)
  Encephalopathy, HIV-related
  Herpes simplex: chronic ulcer(s) (>1 month's duration); or
    bronchitis, pneumonitis, or esophagitis Histoplasmosis,
    disseminated or extrapulmonary
  Isosporiasis, chronic intestinal (>1 month's duration)
  Kaposi's sarcoma
  Lymphoma, Burkitt's (or equivalent term)
  Lymphoma, immunoblastic (or equivalent term)
  Lymphoma, primary, of brain
  Mycobacterium avium complex or *Mycobacterium kansasii*,
    disseminated or extrapulmonary
  Mycobacterium tuberculosis, any site (pulmonary or
    extrapulmonary)
  Mycobacterium, other species or unidentified species,
    disseminated or extrapulmonary
  Pneumocystis carinii pneumonia
  Pneumonia, recurrent
  Progressive multifocal leukoencephalopathy
  Salmonella septicemia, recurrent
  Toxoplasmosis of brain
  Wasting syndrome due to HIV

---

[a]The revised CDC classification system for HIV-infected adolescents and adults categories persons on the basis of clinical conditions associated with HIV infection and CD4$^+$ T-lymphocyte counts.
Figure 33-1 Natural history of HIV infection. After initial infection there is an acute phase of plasma viremia, as represented by the solid line. Acute viremia peaks 2–6 weeks after exposure but falls soon after the appearance of antibodies to HIV viral proteins, as represented by the dotted/dashed line. HIV antibodies develop within 4–8 weeks after exposure and remain detectable throughout infection. During the acute phase of infection there is evidence of T-cell activation, inverted CD4 to CD8 T-cell ratios, and a suppression of CD4$^+$ T-lymphocyte number, as indicated by the dashed line. During latency CD4$^+$ lymphocyte number is mildly depressed and viremia is low. Latency may last months to years. As CD4$^+$ T-lymphocyte counts fall plasma viremia reappears. Continued attrition of CD4$^+$ T-cell number finally results in depletion of cell-mediated immunity and the development of AIDS.

gens, age of the patient, and the use of antiretroviral drugs. The events that trigger the onset of clinical symptoms and mark the end of latency are poorly understood. During the end of latency, blood CD4$^+$ T-lymphocyte numbers decline and plasma viremia levels increase. Although CD4$^+$ T lymphocytes are the principal reservoir of HIV-1 in peripheral blood, less than 10% of blood CD4$^+$ T cells harbor HIV-1. HIV-1 infection of other cell types plays an important role in the progression to AIDS. Expression of the CD4 peptide is not limited to helper T lymphocytes. Cells of macrophage lineage, including dendritic cells, Langerhans cells, and microglia, also express CD4, which renders them susceptible to HIV-1 infection. HIV-1 has been detected in macrophages from blood, lung, and brain of infected individuals. Viral particles are localized primarily in the cytoplasm of infected macrophages and are not particularly cytopathic. HIV-1 isolates obtained from individuals soon after infection display a greater ability to replicate in monocytes and macrophages and are not as cytopathic as viral isolates obtained at late-stage disease. HIV-infected macrophages may play a critical role in many of the organ-specific manifestations of AIDS, particularly in the brain where infection leads to a chronic inflammatory process that ultimately results in HIV-1 encephalopathy.

HIV-1 MOLECULAR ORGANIZATION AND VIRAL LIFE CYCLE

The basic structure of HIV-1 is similar to that of other retroviruses. The virus particle is surrounded by a lipid envelope containing the envelope glycoproteins protruding from the surface. Within the virus particle, core proteins surround the HIV-1 genome, which is composed of ribonucleic acid (RNA). The inner core also contains enzymes required for HIV-1 replication.

children will enter an asymptomatic latent period after acute infection that may last from months to 10 years or more. Factors that may play a role in the length of latency include viral virulence, the magnitude of the immune response, infection with other patho-
Figure 33-2 HIV-1 genetic organization, proteins, and viral structure. The principal HIV-1 structural genes, *gag*, *pol*, and *env*, a flanked by the long terminal repeats (LTRs). The regulatory genes, *vif*, *vpr*, *vpu*, *tat*, *rev*, and *nef*, overlap *pol*, *env*, or the 3' LTR. *Gag* encodes the core proteins including p24. *Pol* encodes the HIV proteinase, reverse transcriptase, and intergrase. *Env* encodes gp160, which is cleaved by a cellular proteinase into gp120 and gp4l. Viral enzymes and genomic RNA are wrapped within the core proteins and packaged into a complete virion. The lipid envelope contains gp120, which is anchored to gp4l.

Proteins and enzymes involved in the structure and replication of HIV-1 are encoded by the linear viral genome, which is organized into three major genes; *gag*, *pol*, and *env* (Fig. 33-2). These genes are transcribed into RNA and ultimately translated into the viral proteins that are generally identified by their molecular size. For example, p24 refers to a 24-kDa core protein, whereas gpl20 is a 120-kDa glycoprotein located in the envelope. *Gag* is a major gene encoding the HIV-1 core proteins. *Pol* encodes at least three enzymatic activities: proteinase, an enzyme involved in cleavage of *gag*- and *pol*- encoded protein precursors; reverse transcriptase, essential for transcribing the RNA genome into DNA; and integrase, required for the covalent linkage between the viral DNA and the host cell chromosomal DNA. *Env* encodes gpl60, a glycoprotein that is processed into gp4l and gpl20. The smaller gp4l spans the lipid envelope membrane and serves as an anchor for gpl20, which interacts with receptors on the surface of target cells. In addition to *gag*, *pol*, and *env*, the HIV-1 genome contains a set of regulatory genes that are involved in positive and negative modulation of virus replication. The regulatory genes include *Tat*, a potent transactivator of HIV gene expression that facilitates the initiation of RNA transcription; *Rev*, which facilitates the transport of unspliced mRNA from the nucleus to the cytoplasm; and less well-understood regulatory and accessory genes, which include *Nef*, *Vpr*, *Vpu*, and *Vif*. The regulatory genes, which overlap *pol* and *env*, and are expressed by complex splicing mechanisms, are unique to the lentiviruses and do not appear in the genomes of the oncogenic retroviruses. Flanking the coding regions of the HIV-1 genome are long terminal repeats (LTRs) composed of sequences that regulate virtually every aspect of the virus life cycle, including replication, integration, and viral gene expression. Some of the proteins encoded by the regulatory genes of HIV-1 act directly or indirectly on target elements in the LTRs.

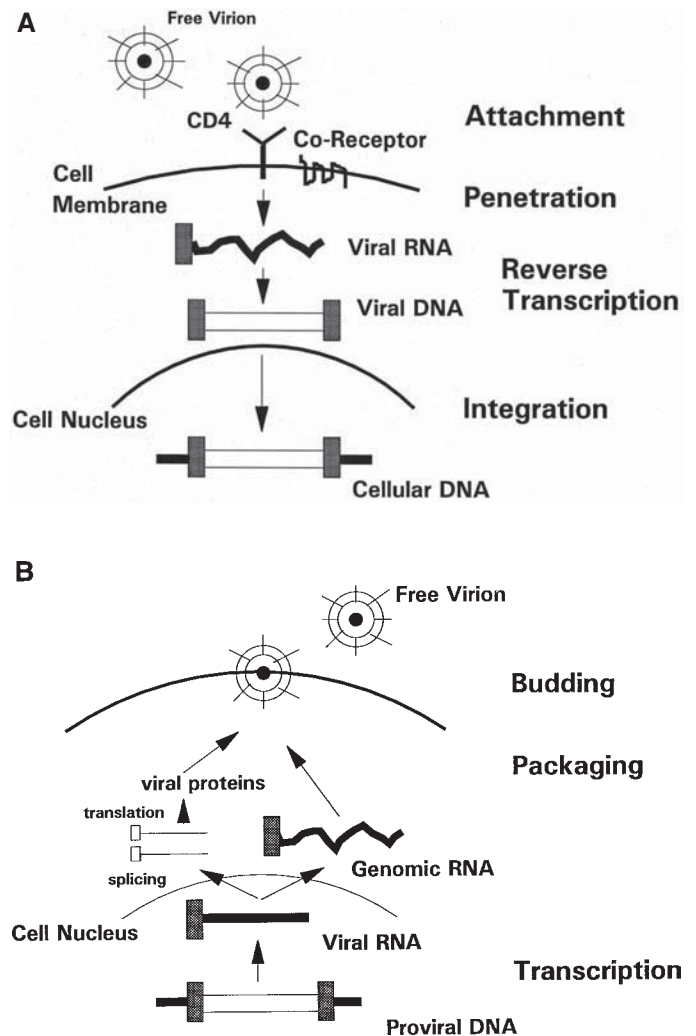
HIV-1 LIFE CYCLE Knowledge of the viral life cycle is essential to understanding the natural history of HIV-1 infection


Figure 33-3 HIV life cycle (**A**) Phase of viral replication. Free virus attaches to CD4+ T cells by the binding of gpl20 to the CD4 molecule. The virus penetrates the cell, and viral RNA is reverse transcribed into double-stranded DNA. This process is initiated at the 5' LTR, indicated by the shaded box. Proviral DNA is transported to the nucleus where it integrates into host cellular DNA. (**B**) Phase of viral expression. Viral transcription is initiated at the LTR and depends on cellular proteins and host cell activation. Viral RNA is spliced into genomic RNA or mRNA, which are ultimately translated into viral proteins. Viral proteins are further cleaved by the HIV proteinase for packaging and budding into new virions.

and is vital to the development of medical strategies to attenuate the disease (Fig. 33-3A). The first step in HIV-1 infection is attachment of the virus to its receptor. The HIV-1 envelope glycoprotein gpl20 binds directly to a molecule called CD4, a protein found on the surface of T helper cells and macrophages. This second step is viral penetration. CD4 is necessary, but not sufficient, for HIV-1 entry into target cells. Interactions between gp120 and CD4 increases the affinity of gp120 for a second class of cell surface molecules, the chemokine receptors, which contribute to virus entry. Chemokine receptors are seven-transmembrane, G-protein-coupled proteins that normally function in cell trafficking and response to inflammation. CCR5 and CXCR4 are two

chemokine receptors that function as major coreceptors for HIV-1. CCR5 and CXCR4 are differentially expressed on distinct subsets of CD4-positive cells and are critical in determining viral tropism for primary T lymphocytes, macrophages, or transformed T-cell lines. Viruses that use CCR5, which is expressed by macrophages and lymphocytes, are macrophage-tropic and most commonly found during acute and early infection. Viruses that use CXCR4, which is expressed by lymphocytes and transformed T-cell lines, can evolve during disease progression. The lipid envelope membrane of the virus containing gpl20 and gp4l fuses with the cell membrane of the target cell, allowing viral entry and uncoating of the core proteins, enzymes, and genomic RNA in the cytoplasm of the target cell. Within the cytoplasm viral RNA is transcribed into double-stranded DNA by the unique retrovirus enzyme, reverse transcriptase. The viral DNA is transported into the nucleus of the cell and is poised for the next step in the viral life cycle, integration.

The viral-encoded integrase enzyme enables integration of viral DNA by a covalent linkage to the chromosomal DNA of the host cell, resulting in the HIV-1 DNA becoming an actual component of the host cell genome. Viral DNA is replicated along with host DNA as the infected cell divides. The integrated DNA form of HIV-1 is termed the provirus. HIV-1 provirus DNA can remain hidden in the host cell DNA and evade immunologic recognition. Viral latency describes the state of the provirus in which it is integrated within the host DNA but the virus proteins are not expressed and viral replication is dormant.

Proviral expression results in transcription of viral DNA into viral RNA (Fig. 33-3B), which is dependent on host cell activation and host cell enzymes. Lymphokines that activate T cells also activate provirus expression through target sequences in the LTR. The full-length RNA transcripts are spliced and transported to the cytoplasm, where HIV-1 RNA is then translated into viral proteins by normal cellular mechanisms. The regulatory gene products for *Tat* and *Rev* are thought to play a key role during this phase of the viral life cycle. Viral proteins are processed, assembled into new viral particles, and bud from the surface of the HIV-1-infected cell. Because replication of HIV-1 does not always result in cell death, persistence of HIV-1 can result from the chronic production of low levels of virus in infected individuals.

It is now obvious that the factors leading to CD4+ T-cell depletion involve more than the cytopathic effects of HIV-1 replication. One hypothesis is that the slow attrition of CD4+ T cells that leads to AIDS is an HIV-induced apoptosis of CD4+ T lymphocytes. CD4+ T cells are destroyed by a two-step process. First, HIV-1 gpl20 crosslinks CD4 on the target T cells. Second, antigen stimulation through the T-cell receptor results in an aberrant signal transduction pathway to the nucleus leading to cell death. HIV-1 infection results in the loss of CD4+ T-cell capacity for regeneration and self-renewal. Over time the total CD4+ T-cell number falls and a profound defect in cell-mediated immunity occurs. This ultimately leads to the clinical manifestations of opportunistic infections and malignancy that characterize AIDS, the final stage of HIV-1 infection.

IMPLICATIONS OF HIV-1 GENETIC VARIABILITY IN THE TREATMENT AND PREVENTION OF AIDS

Lentiviruses in general, and HIV-1 in particular, demonstrate extensive variability among virus genomes. Errors introduced by HIV-1 reverse transcriptase occur as frequently as 1 in 10,000 nucleotides, the approximate size of the HIV-1 genome. This error rate can produce one genetic change during each replication cycle of the virus. In addition to nucleotide substitutions, nucleic acid deletions, insertions, and duplications can occur in the process of reverse transcription of HIV-1. Genetic variability is modulated by selective pressures for virus viability and host interactions. The result of genetic variability is that every HIV-1 genome is unique. The HIV-1 genome evolves into a collection of genetically different viruses, or a quasi-species. Genetic variability in HIV-1 manifests itself not only among different infected individuals, but within each infected individual as well. The virus population within an individual changes over time. The extent of genetic variability among strains of HIV-1 has important implications for tracking the epidemiology of HIV-1 as it is transmitted from one person to another.

Although nucleotide changes can occur anywhere within the viral genome, the extent of genetic variability is not uniform within the various gene segments. Regions in *gag* and *pol* display less variability than *env* presumably because the function of proteins encoded by *gag* and *pol* are easily disrupted by amino acid changes. In contrast, the most variable regions of the virus genome are centered in five hypervariable regions, Vl through V5, in *env* gpl20. Within these regions there is a high ratio of nonsynonymous to synonymous substitutions, an indication that changes in the nucteotide sequences are likely to result in amino acid changes of the gpl20 protein. This finding suggests that this region of HIV-1 is driven by positive selection, perhaps as a result of the influence of the host immune response, thereby providing the virus with an escape mechanism from immune surveillance. There is a highly conserved region of gpl20, localized between V4 and V5, which is part of the CD4-binding site.

HIV VACCINES HIV-1 genetic diversity has profound implications in the management and treatment of disease progression. Although a vigorous antibody and cellular immune response is generated by infected individuals against HIV-1, the life cycle pattern of infection, latency, and replication, in combination with genetic changes, particularly within gp120, results in evasion of the immune response and ultimately disease progression. Furthermore, the intimate relationship between HIV-1 infection and the immune response creates several potential pitfalls to the development of an effective vaccine. There is evidence that vaccination with gpl20-subunit vaccines results in the production of neutralizing antibody against the vaccine strain of HIV-1 but not for infecting viral strains. Alternatively, cytotoxic CD8+ T cells directed against HIV-1 epitopes expressed on infected CD4+ T cells may contribute to CD4+ T-cell attrition and accelerate the development of AIDS. These and other factors may render traditional vaccine development difficult as a strategy in preventing infection.

ANTIRETROVIRAL THERAPY The current therapeutic strategies to slow disease progression in infected individuals uses antiretroviral agents that act at distinct stages of the viral life cycle. Dideoxynucleoside reverse transcriptase inhibitors, such as zidovudine (also known as AZT), act only on the infection phase of the viral life cycle by competing with endogenous deoxynucleotides for incorporation into proviral DNA during reverse transcription from viral RNA. Once the drug is incorporated into proviral DNA further elongation of the DNA chain is terminated. In addition to zidovudine and related analogs, there are several other nondeoxynucleoside analogs that inhibit the infective phase of the viral life cycle but have no activity against the phase of viral replication.

A new class of antiretroviral agents targeted against the HIV aspartyl protease have been approved for clinical use. The HIV protease is a unique enzyme that is responsible for the cleavage of the large *gag* and *pol* polyprotein gene products, an essential requirement for the production of infectious virus. Protease inhibitors compete with the substrate for binding to the enzymatic active site. This results in incomplete processing of the polyprotein precursors into viral structural proteins and enzymes, and ultimately in the production of immature noninfectious virions.

Compared with genes that display a high degree of genetic variability, such as *env*, the sequences of *gag* and *pol* that encode the HIV reverse transcriptase of protease and its cleavage sites, exhibit only a small degree of genetic drift because of the essential role of these enzymes in infection and replication. However, emergence of drug-resistant variants occurs in a short period of time because the genes are placed under selective pressure by potent inhibitors of reverse transcriptase or protease. The future direction of HIV-1 therapy will be the use of combinations of antiviral agents that act at different stages of the viral life cycle. The goal of therapy will be to reduce viral load, thereby prolonging latency and perhaps reducing the risk of transmission from an infected individual. This therapeutic strategy has been greatly enhanced by the development of sensitive diagnostic techniques, such as quantitative competitive PCR amplification of viral RNA and branched chain DNA, which can quantify the precise number of viral particles in a patient's blood. These methods are currently being used to monitor response to therapy. The recent advances in drug therapy and monitoring of disease progression have been demonstrated to prolong survival and improve the quality of life of HIV-infected individuals.

34 Autoimmune Diseases

N. LAWRENCE EDWARDS

BACKGROUND

Our current understanding of the immune system and the diseases associated with its aberration has evolved from the work of countless investigators over the past century. Initially conceived of as a mechanism to simply discriminate "infectious nonself" from "noninfectious self," the immune system is now recognized as a tightly regulated process by which the antibody response to both foreign and endogenous antigens requires the interaction of B cells, T cells, and specialized antigen-presenting cells (usually macrophages). In the early 1900s, the concept that the immune system might not be able to distinguish self from nonself lead to Erhlich's projection of a "horror autotoxicus," in which the individual's immune system would attempt to destroy itself. Burnett and other investigators in the mid-1900s postulated that diseases in which antibodies or immune competent cells reacted against normal body tissue were caused by the release of "forbidden clones" of immunologic cells and such rare occurrences were the result of faulty immune mechanisms.

Autoimmunity as we now understand it bears little resemblance to Erhlich's "horror autotoxicus," but rather is a common phenomenon that is often under normal immune regulation. In some circumstances this "self-attack" is beneficial, as in the natural clearing of exhausted red blood cells or in the response to cancer cells. These housekeeping and surveillance functions of the immune system are mediated by natural autoantibodies. The failure to distinguish these from pathogenic autoantibodies has lead to great confusion and slowed the progress in our understanding of autoimmune diseases.

Autoimmune diseases are conventionally grouped under the headings of organ-specific diseases and non-organ-specific (systemic) diseases (Table 34-1). In organ-specific autoimmunity, antigens peculiar to one cell type or tissue are the targets of an aggressive immune reaction. Examples of this type of targeting include the insulin-producing cells of the pancreas in type I diabetes mellitus, the acetylcholine receptors of muscle endplates in myasthenia gravis, and thyroid tissue in Hashimoto's disease. The non–organ-specific disorders include the rheumatic or connective tissue diseases. Because of their systemic manifestations, this group was the first to be associated with autoimmune mechanisms and they will be the subject of this chapter. The connective tissue diseases are frequently lumped together because of shared clinical and pathologic features (Table 34-2). However, the molecular mechanisms that initiate and maintain each of these conditions vary greatly.

From: *Principles of Molecular Medicine* (J. L. Jameson, ed.), ©1998 Humana Press Inc., Totowa, NJ.

In this chapter I will discuss the common clinical features of the connective tissue diseases and discuss the criteria used to diagnose and distinguish these conditions. These diseases of systemic autoimmunity are generally considered to be antigen-driven processes that occur in genetically predisposed individuals (Fig. 34-1). In the final sections of this chapter, I will discuss the genetic basis for susceptibility and the molecular mechanisms that foster and perpetuate antigenic stimulation. Finally, I will attempt to describe how new molecular understanding of immunity and autoimmunity may improve our ability to treat these conditions.

CLINICAL FEATURES

RHEUMATOID ARTHRITIS (RA) Rheumatoid arthritis is a systemic autoimmune disease in which initial and primary manifestations involve the joints and soft tissue structures of the musculoskeletal system. The hallmark of the disease is the chronic, symmetric polyarthritis with proliferative and destructive changes that progress over years to decades. The most universal feature of active RA is morning stiffness in the joints that lasts in excess of 1 h and may be present for most of the day. There are marked undulations in the clinical symptoms over time with periods of severe and debilitating inflammation followed by spontaneous partial abatement of symptoms. Virtually any joint in the body can be involved with RA although the distal interphalangeal joints of the hand and the thoracic and lumbar spine are usually spared. Associated extra-articular manifestations of RA include subcutaneous nodules and inflammatory changes in the lungs, pericardium, and eye. These manifestations may be severe and life-threatening and are correlated with the presence of rheumatoid factor in the serum and the MHC class II DR B1 allele, 0401. Other nonarticular manifestations, such as fatigue and malaise, are common to all individuals with RA.

Rheumatoid arthritis is the most common of the inflammatory arthritides, affecting between 1 and 2% of the world's adult population. Although it can be found worldwide, the prevalence of RA does vary among races with whites living in temperate climates being primarily affected. This may be related to MHC class II differences between blacks, Asians, and whites. Like most of the systemic autoimmune diseases, RA is predominantly a disease of women, with an overall female to male ratio of 2.5:1. There has been an apparently subtle shift in the epidemiology of RA during the past few decades with a tendency for later onset of disease activity. However, women of the child-bearing ages of 20–45 years remain the group at greatest risk for this disease.

Table 34-1
Disorders of Autoimmunity

Organ-specific disorders	Non–organ-specific disorders
Hashimoto's thyroiditis	Rheumatoid arthritis
Grave's disease	Systemic lupus erythematosus
Type I diabetes mellitus	Systemic sclerosis
Pemphigus vulgaris	Polymyositis and dermatomyositis
Thrombocytopenic purpura	Sjögren's syndrome
Myasthenia gravis	Various vasculitic syndromes
Multiple sclerosis	
Primary biliary sclerosis	
Pernicious anemia

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) Because of the high level of antibody expression in SLE, this disease is considered by many to be the prototypic autoimmune disorder. It is truly a multiorgan disease with marked variability in clinical manifestations as well as in morbidity and mortality. The organ systems most frequently involved include the skin, joints, kidneys, lungs, and brain. The gastrointestinal and cardiac systems may also be affected by the immune complex-mediated tissue injury associated with SLE.

The clinical spectrum of SLE ranges from patients having only mild "nuisance" symptoms of rash and arthritis to acute, life-threatening involvement of the central nervous system or kidneys. Although most patients with SLE require close clinical supervision, only a small fraction will develop potentially catastrophic illnesses. SLE is considered a rare disorder with a prevalence in the general population of 0.05%. This is primarily a disease of young women with a peak age of onset between 15 and 40 years. The overall female-to-male ratio is 5:1. The prevalence in young and middle-age women is 0.14%. For black and Hispanic women in this same age group, the prevalence is even higher at 0.4%. Although the exact genetics of SLE are not understood, it has been shown clinically to cluster in first-degree relatives of patients. SLE is concordant in 25–50% of monozygotic twins and 5% of dizygotic twins. Despite these high percentages, most cases of SLE are considered to be sporadic.

SYSTEMIC SCLEROSIS (PSS) Systemic sclerosis is a rare connective tissue disease that also goes by the names progressive systemic sclerosis and scleroderma ("hard skin"). Although the edematosis and indurative and atrophic changes in the skin are the most common and recognizable manifestations of PSS, most of the morbidity associated with the disease is because of vascular involvement of the gastrointestinal tract, lungs, kidneys, and heart. Underlying the pathogenesis of PSS is an increased fibrosis in skin and internal organs associated with marked increased production and deposition of collagens in the extracellular matrix leading to small vessel occlusive disease.

Cold and stress-induced vasospasm causing blanching or cyanosis of the digits (Raynaud's phenomenon) is the most common presenting manifestation of PSS and will eventually be present in 75–100% of these patients. The skin manifestations occur in stages, with the early diffuse edematous changes leading to the characteristic "hidebound skin." This leathery tightening of the skin can cause contractures in the extremities and limited facial mobility. In time, this "hard skin" gives way to some atrophy and softening. Disuse atrophy of muscles is a common feature, as is pulmonary fibrosis. Renal involvement is rare but may be life-threatening and is frequently associated with poorly controlled hypertension. Esophageal and other gastrointestinal hypomotility are common clinical problems that may affect the nutritional and health status of these patients.

PSS is probably best viewed as a spectrum of fibrosing disorders. On the milder end of the spectrum is a condition called the CREST syndrome. CREST is an acronym for the clinical manifestations of calcinosis of the skin, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly (thickened skin over the digits) and telangiectasias appearing on the fingers, face, or mucosal surface.

The exact prevalence of PSS is difficult to assess because of the lack of a specific diagnostic test. However, recent estimates of the prevalence in this country range from 20 to 70 cases per 100,000 population (0.0004–0.001%). Women are more commonly affected than men with a female-to-male ratio similar to that of SLE. Peak incidence of onset is in the third and fourth decades of life. Most PSS appears to be idiopathic, but some scle-

rodermalike syndromes have been associated with environmental exposures (silica and vinyl chloride), certain drugs (bleomycin and methysergide), or adulterated food products (rapeseed oil in Spain and *L*-tryptophan in the United States).

POLYMYOSITIS AND DERMATOMYOSITIS (PM AND DM)   PM and DM are inflammatory diseases of skeletal muscle that may present as distinct connective tissue diseases or as "overlap syndromes" with SLE, PSS, or RA. The dominant feature of these conditions is symmetric muscle weakness involving the proximal muscles of the upper or lower extremities. The muscle weakness may begin acutely, but more characteristically has an insidious onset. Patients will describe difficulty climbing stairs, getting out of chairs, or combing their own hair. If the disease goes unrecognized or untreated the patient can become bedridden and occasionally even require assisted ventilation.

DM and PM differ only in the appearance of skin lesions with DM. The skin manifestations may precede, follow, or appear concomitantly with the muscle symptoms. The only pathognomonic skin changes in DM are Gottron's papules. These are flat-topped, red-to-purple papules that occur over the interphalangeal joints of the hand. Another characteristic rash of DM is the heliotrope (lavender-colored) rash of the eyelids. The eyelids are usually edematous.

Malignant neoplasms are found in a higher than expected percentage of patients with PM and DM. The highest incidence of coincidental muscle disease and malignancy is with DM and is approximately 15%. This association is found only in adult populations and the most frequently associated cancers are adenocarcinomas of the lungs, ovaries, breasts, and stomach.

Inflammatory muscle diseases can occur at any age but have their peak onset in the fifth decade. Women are twice as likely as men to get either PM or DM. These conditions are rare with an annual incidence of 5–10 cases per million population.

SJÖGREN'S SYNDROME (SS)   Sjögren's syndrome is a chronic autoimmune exocrinopathy primarily involving the lacrimal and salivary glands. Chronic inflammation of these glands results in dry eyes (xerophthalmia), dry mouth (xerostomia), and recurrent salivary gland pain and swelling. The persistent lack of good tear production results in destruction of corneal and bulbar conjunctival epithelium (keratoconjunctivitis sicca). This accounts for the ocular burning and itching and light sensitivity experienced by patients with SS. Sjögren's syndrome may occur as a primary connective tissue disease or as a secondary condition when associated with any of the organ-specific or non–organ-specific autoimmune diseases listed in Table 34-1. In the first 5–10 years of their disease, 50% of patients with primary Sjögren's syndrome will develop organ involvement in extraglandular sites, such as lungs, kidney, or the blood vessels of the central or peripheral nervous systems.

SS is the second most common systemic autoimmune disease, behind RA. Ninety percent of SS patients are women with a peak age of onset in the fourth and fifth decades of life. SS can affect all age groups and patients as young as 3 years old have been identified.

DIAGNOSIS

RHEUMATOID ARTHRITIS (RA)   In 1987, the American Rheumatism Association introduced revised criteria for the diagnosis of RA. A person is said to have RA if they fulfill at least four of the seven criteria listed in Table 34-3. A requirement for the first four criteria is that these symptoms be present for at least 6 weeks.

Table 34-3
Classification Criteria for Rheumatoid Arthritis

Morning stiffness
Arthritis of three or more joint areas
Arthritis of hand joints
Symmetric arthritis
Rheumatoid nodules
Serum rheumatoid factor
Typical radiographic changes

Table 34-4
Classification Criteria for Systemic Lupus Erythematosus

Malar rash
Discoid rash
Photosensitivity
Oral ulcers
Arthritis
Serositis
Renal disorder
Neurologic disorder
Hematologic disorder
Antinuclear antibody
Other immunologic disorder

This provision helps to differentiate RA from various acute viral arthritides that may mimic RA in its earliest stage. As mentioned above, morning stiffness of at least 1 hour is present in most all patients with active RA. Prolonged stiffness after periods of rest is also common in other systemic autoimmune disorders. The 14 possible "joint areas" referred to in criterion 2 (Table 34-3) are the right and left proximal interphalangeal (PIP), metacarpal phalangeal (MCP), wrist, elbow, knee, ankle, and metatarsal phalangeal (MTP) joints. Further criteria are fulfilled if the same joints are involved on both the right and left side of the body and if the PIP, MCP, or wrist joints are affected.

Rheumatoid nodules are hard, rubbery subcutaneous masses measuring several millimeters to several centimeters in size and are present in 25–50% of individuals with RA. These nodules occur around joints or over bony prominences or extensor surfaces. Rheumatoid nodules occur almost exclusively in patients with a positive serum rheumatoid factor. Rheumatoid factors are the prototypic autoantibodies, although their role in the etiopathogenesis of RA remains unclear. They are present in 85% of patients with RA, as well as in approximately 3% of healthy persons. The prevalence of rheumatoid factor positively increases with age in the general population. The rheumatoid factors measured in clinical laboratories are IgM molecules that react with the Fc portion of IgG molecules. Rheumatoid factors may play an important "housekeeping" role in normal immune defense by promoting clearance of small antigen–antibody complexes (immune complexes) from the circulation or by enhancing removal of micro-organisms.

The final criterion in the diagnosis of RA is the presence of "typical" bony changes on radiographs of the hands and wrists. These bony changes include marked decalcification localized to areas around involved joints or actual erosions of the bony cortex adjacent to the joint.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)   A person is said to have SLE if they fulfill 4 of the 11 criteria listed in Table 34-4. These criteria may be present serially or simulta-

Table 34-5
Criteria for Classification of Systemic Sclerosis

Major criterion
  Proximal scleroderma
Minor criteria
  Sclerodactyly
  Pitting scars at tips of fingers or loss of digital pad tissue
  Bibasilar pulmonary fibrosis

neously over the course of observation. The first six criteria represent the distinguishing clinical manifestations of the disease whereas the remaining five are the laboratory parameters used to define SLE. The three cutaneous criteria of (1) a fixed erythematous rash over the bridge of the nose and cheeks; (2) the raised discoid lesions with atrophic scarring; and (3) the unusual sensitivity to sunlight are but a few of the dermal eruptions associated with SLE, but these three are the most specific for lupus. The oral and nasal mucosal ulcers are usually painless. The arthritis generally involves the same joints as RA but, unlike RA, the arthropathy of SLE tends to be nonerosive and nondestructive. Inflammation of the serosal surfaces of the pleura or pericardium are common manifestations of SLE.

Renal involvement with SLE is evidenced by either persistent proteinuria of greater than 0.5/d or the presence of cellular casts in the urine. Neurologic abnormalities are extremely common in SLE and vary from persistent headaches to coma and stroke. For the purpose of classifying SLE, however, only the symptoms of seizure and nonmetabolic psychosis are considered. The reduction of red blood cells, granulocytes, lymphocytes, or platelets by immune mechanisms is considered a criterion for diagnosing lupus.

The immunologic features of SLE include a positive antinuclear antibody test (ANA), a false-positive serologic test for syphilis, and the more specific serologies of antibodies against native (double-stranded) DNA or the Smith (Sm) nuclear antigen. The detection of ANAs by indirect immunofluorescence is highly sensitive for SLE (>98%) but not very specific because most other forms of systemic autoimmune diseases have circulating antinuclear antibodies. A negative ANA test is strong evidence against a diagnosis of lupus although a few patients with photosensitivity, arthritis, and Raynaud's phenomenon will occasionally fall into a diagnosis of seronegative SLE. Most of these individuals will demonstrate laboratory autoimmunity to other cellular (nonnuclear) components.

SYSTEMIC SCLEROSIS (PSS)   The diagnosis of advanced PSS is quite obvious with the typical features outlined above. The clinical criteria used to classify this disease are listed in Table 34-5 and a person is said to have systemic sclerosis if the one major or at least two of the minor criteria are present. For these criteria to be meaningful, the localized form of cutaneous sclerosis, such as linear scleroderma, morphea, and eosinophilia fasciitis, need to be excluded. Proximal scleroderma refers to thickened, hidebound skin proximal to the metacarpophalangeal (MCP) joints, whereas sclerodactyly is similar skin tightening over the fingers.

Virtually all individuals with PSS have serum antinuclear antibodies. The specificity of several of the autoantibodies found in PSS is quite remarkable. Antibodies to the nuclear centromere are found almost exclusively in PSS and the CREST syndrome. Anti-topoisomerase I autoantibodies (also called SCL-70) are selective for PSS and tend to occur in subjects with diffuse cuta-

neous involvement. In addition to these two specific autoantibodies, PSS may be associated with numerous other nonspecific antibodies such as anti-ribonucleoprotein (anti-RNP), and SS-A (anti-Ro) and SS-B (anti-La).

POLYMYOSITIS AND DERMATOMYOSITIS (PM AND DM)   The diagnosis of PM and DM is made in patients with proximal muscle weakness who also have at least two of the three laboratory abnormalities associated with these autoimmune muscle diseases. These laboratory findings are, (1) elevated serum levels of various muscle-associated enzymes; (2) myopathic changes on electromyography (EMG) and nerve conduction velocity (NCV); and (3) typical pathologic changes of inflammatory myositis on muscle biopsy.

Serum creatine kinase or aldolase is elevated in virtually all patients with PM and DM. In rare cases in which these serum muscle enzymes are not elevated, the other two diagnostic parameters should be abnormal. Even without treatment, muscle enzyme levels will fall in patients after they have lost substantial muscle mass.

The characteristic findings of autoimmune muscle disease on EMG or NCV are (1) small-amplitude, short-duration, polyphasic motor-unit potentials; (2) spontaneous fibrillations, positive spike waves at rest, and increased irritability; (3) bizarre, high-frequency complex discharges; and (4) absence of neuropathic changes. The muscle biopsy is the single most accurate parameter for establishing the diagnosis of PM and DM. However, the site of biopsy must be carefully chosen to select a muscle that is actively inflamed and weak although not having undergone clinical evidence of atrophy. Also sites of needle probes for EMG or NCV should be avoided. The characteristic pathologic changes are those of focal or diffuse inflammatory infiltrates of lymphocytes and macrophages surrounding muscle fibers and small blood vessels. The myocytes themselves show features of both degeneration and regeneration, such as size variation, fiber necrosis, and centralization of nuclei.

Antinuclear antibodies are detected in one-third to one-half of individuals with PM and DM. A speckled ANA pattern is usually associated with antibodies to ribonucleoprotein or antihistidyl-transfer RNA (t-RNA) synthetase (Jo-1). Anti-Jo-1 occurs primarily in patients with PM and significant pulmonary involvement. A nucleolar ANA pattern is usually associated with anti-PM and Scl and occurs in patients with the overlap disease of polymyositis and systemic sclerosis.

SJÖGREN'S SYNDROME (SS)   The combination of dry eyes and dry mouth are quite common in elderly patients and persons taking various medications. The diagnosis of SS requires not only documenting significant dryness in the eyes and mouth but also evidence of autoimmunity on laboratory evaluation. Decreased lacrimal gland function is documented by an abnormal Schirmer's test. This test uses a strip of filter paper placed in the lower palpebral fissure. After 5 min, if 5 mm or less of wetting occurs, the test is abnormal. Oral dryness is usually documented by the patient's history of difficulty swallowing or chronic thirst and the absence of saliva pools in the mouth on physical examination.

Biopsy of the minor (lip) or major (parotid) salivary glands should reveal clusters of lymphocytic infiltrates with acinar atrophy. Other evidence of autoimmunity in SS is the frequent occurrence of autoantibodies. Rheumatoid factors are present in 70% patients with primary and secondary Sjögren's syndrome. Antinuclear antibodies are present in about 90% of patients. Antibodies to SS-A (anti-Ro) are detected in 55% of SS patients and may be associated with vasculitis. Antibodies to SS-B (anti-La) are

more likely to be found in patients with secondary Sjögren's syndrome.

GENETIC BASIS OF AUTOIMMUNITY

The current theories of autoimmune susceptibility generally support a multifactorial paradigm with contributions from both genetic and environmental influences (Fig. 34-1). The relative importance of each of these factors may vary greatly among the different autoimmune diseases and may, in fact, differ substantially between individuals presenting with the same autoimmune disease. Familial clustering of single autoimmune diseases has been reported, but it is even more common to find kindreds in which multiple family members are affected with different autoimmune diseases. In monozygotic twin studies, the concordance rates for any autoimmune disease is less than 50% and in general the genetic contribution to autoimmune susceptibility is thought to be about 30%. This low level of penetrance for genetic risk factors in autoimmunity may be explained by the fact that otherwise genetically identical individuals have dissimilar immune systems as a result of unpredictable rearrangement of gene segments in the immunoglobulin and T-cell receptor genes. In addition, immunoglobulin genes undergo somatic mutation throughout life.

The major and minor genetic factors that regulate normal immune function also play key roles in permitting and perpetuating autoimmunity. These genes include those encoding the histocompatibility antigens, T-cell receptors, immunoglobulins, the complement molecules, and the genes affecting antigen processing and presentation. In addition to these genetically controlled systems, the sex-linked genes are also important in the pathogenesis of autoimmunity. The marked female predominance of most systemic autoimmune disorders offers circumstantiated evidence of an important endocrine-immune regulatory mechanism that is corroborated by in vitro and animal studies.

The major histocompatibility complex (MHC) genes are some of the most polymorphic in the immune system and impart a great deal of the individuality of responses to endogenous and foreign antigens. The MHC molecules have been divided into two classes: class I and class II. Class I molecules are present on the surface of most nucleated cells and bind short peptides arising from the cytoplasm of the cell. The MHC class I molecule "charged" with its peptide antigen alerts CD8 (cytotoxic) T cells to the presence of virus infection or an alteration of normal cells and thus provides important immune surveillance. Class II molecules are sometimes designated "DR" and are normally found on monocytes, B cells, and other antigen-presenting cells. MHC class II molecules bind larger peptides derived from extracellular proteins and interact with T-cell receptors on CD4$^+$ lymphocytes that regulate delayed hypersensitivity and immunoglobulin production. Most autoimmune diseases have been associated with genes in the class II region of the MHC. Hypotheses of how a particular MHC class II molecule could predispose to autoimmunity include altered binding of a "self" peptide increasing its autoantigenicity; altering the T-cell repertoire by generating peptides within the thymus; or the intrathymic deletion of T-cell populations that help control infection.

The T-cell receptor (TCR) complex is another extremely polymorphic immune system. The TCR complex is a heterodimer composed of polypeptide chains with variable and constant domains. There are two types of receptors: the abundant α-β heterodimers and the minor component of γ-δ heterodimers. The TCRs encoded

by the γ and δ genes may play a role in the inflammatory response that characterizes autoimmunity. Some γ-δ T cells react with autologous antigens on stressed cells. Certain γ-δ T cells also recognize bacterial heat shock proteins without the usual requirement of an MHC molecule to present this antigen.

Immunoglobulins are the products of differentiated, activated B cells and may be secreted from the cell as antibodies or may adhere to the surface of the B cell and function as receptors. The importance of immunoglobulins in helping to define autoimmunity is obvious because circulating autoantibodies are hallmarks of this group of diseases. However, the mere presence of autoantibodies does not necessarily imply a causative role in the etiopathogenesis of disease. Rheumatoid factors are unique autoantibodies whereas immunoglobulins serve both as antibody and antigen. Despite a high frequency of occurrence in autoimmune disease (especially rheumatoid arthritis), no pathogenic role for these autoantibodies has been proved.

In human fetal B cells certain light- and heavy-chain variable region genes are expressed in cell surface immunoglobulins much more frequently than would be anticipated from their representation in the genome. In fact, a single human κ light-chain variable region gene (Humkv 325) accounts for 10–20% of all κ rearrangements even though there are over 50 variable region genes in the κ locus. This particular κ variable gene is used to encode several important autoantibodies including rheumatoid factors and anti-DNA autoantibodies.

Genetic deficiencies of the early complement components may also predispose to autoimmunity. These complement proteins are important for rapid removal of immune complexes from the circulation and their deficiencies greatly enhance the damaging effects of immune complexes on vascular endothelium. The complement genes are inherited in an autosomal codominant fashion with null alleles encoding for nonsynthesis of the particular protein. The inheritance of a single null allele results in half normal levels whereas the inheritance of two null alleles for the same complement factor will result in a complete deficiency. Complete deficiencies of the complement proteins, C1, C2, and C4 are associated

with autoimmune syndromes, including SLE, vasculitis, inflammatory myositis, and glomerulonephritis.

RHEUMATOID ARTHRITIS A clear association between an MHC haplotype and the development of clinical disease is difficult to establish. In 1978, Peter Stastny demonstrated a genetic risk for developing rheumatoid arthritis in individuals expressing the HLA-DR4 and -Dw4 class II proteins. Since the initial observations, multiple subtypes of DR4 have been recognized with some conferring susceptibility (Dw4, Dw14, and Dw15), while others (Dw10 and Dw13) do not (Table 34-6). The distinguishing region of the class II molecule that appears to impart susceptibility resides in the α-helical rims of the peptide-binding cleft. Specifically the RA-associated alleles of DR4 share an amino acid sequence of QK/RRAA at position 70–74 of the DR β chain. It should be stated that most people who carry this DR4 "RA epitope" will not develop any autoimmune disease and at least 10% of whites with RA do not express the QK/RRAA sequence. It remains unclear whether these DR4 subtypes actually enhance susceptibility to the initiation of synovitis or are responsible for imparting a more severe clinical expression in people who have the disease. The latter hypothesis appears to be gaining acceptance and other MHC and non-MHC genetic factors are probably responsible for actual disease initiation.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE) The first recognized genetic marker for SLE was the MHC class I allele B8. However, subsequent correlations have been stronger with the MHC class II DR2 and DR3 alleles. The DR3 allele was later proved to be in linkage disequilibrium with HLA-B8. These class II associations are strongest for whites of western European ancestry, but in other racial and ethnic groups no MHC associations have been detected. The class II DQ alleles, DQ1 and DQ2, exist in linkage disequilibriums with DR2 and DR3, respectively. Correlation with these markers are primarily for the SS-A (anti-Ro) and SS-B (anti-La) autoantibodies, which may be present in either SLE or Sjögren's syndrome. Patients with homozygous deficiencies of the complement proteins, C1q, C1r-C1s, C4, C3, or C2 have a high frequency of SLE or a lupuslike illness. In general, homozygous complement deficiencies are rare although the homozygous deficiency of C4 is more common. The C4A and C4B genes are located in the MHC region of human chromosome 6. The null allele of C4A exists in linkage disequilibrium with DR3. Interestingly, the homozygous and heterozygous deficiencies of the C4A complement protein are strongly associated with SLE even in ethnic populations in which no association between DR3 and SLE exists.

SYSTEMIC SCLEROSIS Although no clear MHC association has been observed for disease susceptibility in systemic sclerosis (PSS), there are several scleroderma-specific autoantibodies that do have class II associations. The anti-topoisomerase I (Scl-70) autoantibody is associated with DR5 and the polymyositis and scleroderma overlap marker, anti-PMScl, is associated with DR3.

NON-MHC GENETIC ASSOCIATIONS WITH AUTO-IMMUNITY Dr. Betty Diamond and her colleagues have had a special interest in the origin and pathogenicity of anti-DNA antibodies in patients with SLE. These investigators generated monoclonal antibodies to the specific antigen-binding areas, or idiotypes, of anti-DNA antibodies from a patient with SLE. One of these anti-idiotypes, designated 3I, recognizes a specific determinant on the κ light chain of anti-DNA antibodies. The anti-DNA antibodies from 85% of 200 unrelated patients with SLE exhibited strong reactivity with 3I. These patients with SLE also had antibodies that reacted with 3I but were not directed against DNA. Healthy individuals use the 3I κ chain segments only rarely, and none are directed against DNA. In one study, a cluster of patients with familial SLE were examined for 3I reactivity in their immunoglobulins. High percentages of patients with SLE (6 of 8) and family members (15 of 19) had strong 3I reactivity. The 3I reactivity in family members without SLE was with antibodies that did not bind DNA. These data suggested that the preferential use of the immunoglobulin variable region gene, 3I, in the normal immune response may contribute to the genetic predisposition to SLE.

These same investigators have also examined the role of somatic mutation in autoimmunity. A mouse myeloma cell line, S107, produces an antibody against the pneumococcal cell wall antigen, phosphorylcholine (PC). A point mutation in the gene controlling the hypervariable region of the heavy chain of this antibody results in a single amino acid substitution. This mutation greatly alters the antigenic specificity of the antibody to that of low affinity for PC but with a newly acquired high affinity for DNA. This study demonstrates that a somatic mutation of immunoglobulin genes can convert antibacterial antibodies (protective immune response) to anti-DNA antibodies (pathologic response). Thus, part of the genetic predisposition to SLE may result from the preferential use in the normal immune response of specific variable region genes that require only a few mutations to acquire pathogenic autoreactivity.

MOLECULAR PATHOPHYSIOLOGY

If the entire genetic basis for each of the autoimmune diseases was known—including the preferential expressions or deletions of specific MHC and non-MHC genes—we would still be a long way from unraveling the critical events leading to the induction of autoimmunity. Most investigators now believe that autoimmunity results from a failure of immune tolerance for specific self-antigens and that this failure of tolerance is driven by repeated exposures to autoantigens. This premise leads to two important questions: What is the initiating antigen? And why does immune tolerance fail? While the answers to these questions remain unknown, many theories have been promoted.

Several lines of investigation now support the notion that tolerance at the T-cell level is critical to the prevention of autoimmunity. Three models have been promoted to explain how T-cell tolerance for self-antigens develops. Any one or all of these proposed schemes may be important in the normal regulation of the immune system. And any one or all of these schemes may be defective in autoimmune diseases.

The first model of tolerance for self-antigens states that T cells with self-reactivities undergo clonal deletion in the thymus. Direct evidence for this model has been presented by Kappler and colleagues in mouse thymus. Immature T cells from the bone marrow migrate to the thymus and develop an unselected repertoire of T-cell receptors on their surface because of unrestricted T-cell receptor gene rearrangements. This unselected T-cell repertoire comes in contact with thymic epithelial cells, which express histocompatibility complexes on their surface and function as antigen-presenting cells. The antigens being presented are ubiquitous self-antigens contained in the thymus. Any immature T cell with high affinity for the self-peptide/self-MHC on the thymic epithelium is passed on to thymic macrophages or dendritic cells for elimination. In this way, the T-cell repertoire that is allowed to

mature and leave the thymus has been selected for low T-cell reactiveness to self peptides. One problem with this scheme is that certain organ-sequestered self-antigens (e.g., from the brain, uveal tract, or testes) may never be in the thymus, and, therefore, T cells with high-affinity receptors for these peptides may exist in the peripheral lymphocyte population.

The second model of T-cell tolerance for self peptides theorizes that certain suppressor T cells are capable of controlling the reactiveness of T cells with self-recognizing receptors. This suppressor activity may be directed against specific antigen-combining sites in the T-cell receptor or may be directed against entire families of receptors that share similar variable regions (idiotypes). This model has been criticized because it is not clear which immune cell might exert this postthymic suppression.

The final model of self tolerance may be important for preventing certain organ-specific forms of autoimmunity. In immunologically privileged sites (such as the islet cells of the pancreas, central nervous system, and uveal tract) a natural deficiency of MHC class II antigen-presenting cells may be the primary defense against self-reactivities. If infection or other nonspecific inflammation was to attract class II-bearing cells to these sites, then autoimmunity may occur.

Immunologic tolerance is strongly influenced by both antigen availability and antigen presentation. An increased availability of self-antigens or an altered mode of self-antigen presentation may lead to autoimmunity. The availability of autoantigens may be increased by specific deficiencies in complement components or natural autoantibodies that would normally be involved in removal of cellular debris and immune complexes. Repeated exposure to certain environmental antigens may cause tissue destruction with increased release of self-antigens, or the environmental antigen may mimic certain host antigens leading to autoimmunity. Molecular mimicry is a much more common phenomenon in nature than previously thought. A microbe that mimics part of its host structure at the molecular level is at an advantage because it may avoid immunologic detection by the host. Alternatively, if an antibody response is generated against the microbe then these same antibodies may interact with host peptides, making them more

antigenic and promoting autoimmunity. The most convincing example of molecular mimicry resulting in a disease is the role of β-hemolytic group A streptococci in causing acute rheumatic fever (ARF). All the relevant organs that are involved in clinical manifestations of ARF share crossreacting determinants with various components of the streptococcus cell wall. For instance, antibodies against the cell wall M protein will crossreact with synovial structures leading to arthritis. Similarly, antibodies to the specific streptococcus group A carbohydrate will crossreact with heart valves leading to tissue damage.

An experimental model of autoimmunity that involves molecular mimicry is the adjuvant arthritis induced in rats when they are injected with heat-killed mycobacteria suspended in mineral oil. The rats develop an arthritis 2–3 weeks after the injection that is histologically similar to human rheumatoid arthritis. The microbial antigen participating in this mimicry is a 9-amino acid epitope on a mycobacterium heat-shock protein (hsp65). The crossreactive host epitope appears to be in the proteoglycan component of the joint cartilage. The overall importance of molecular mimicry in the etiopathogenesis of human autoimmune diseases remains to be established.

MANAGEMENT AND TREATMENT

RHEUMATOID ARTHRITIS (RA) The ideal management of RA involves not only a complex selection of pharmacotherapeutics but additional input from physical and occupational therapists and orthopedic surgeons. Until recent years the early stages of mild to moderate RA were treated with rest, nonsteroidal anti-inflammatory drugs (NSAIDs), and occasionally intra-articular steroids. The "second-line" drugs were reserved for patients with severe disease or deformities (Table 34-7). A new therapeutic trend is to use these second-line or disease-modifying drugs sooner in the course of disease with the hope that suppressing the inflammatory process earlier will improve the long-term outcome for people with this disease. Antimalarials (hydroxychloroquine, 200–400 mg/d) and sulfasalazine (1500–4000 mg/d) are good adjunctive therapies but by themselves are usually not adequate to suppress active disease. Intramuscular gold salt injection has been a mainstay of treatment for RA for many decades. Despite the potential toxicity to the lungs, kidneys, and bone marrow, gold salt injections continue to be used because of their effectiveness. Over the past 10 years, low-dose weekly methotrexate has become the most widely used second-line agent in the treatment of RA. Oral dosing with 7.5–20 mg/wk yields excellent benefits in the majority of patients. Methotrexate toxicity in the liver and lungs needs to be monitored carefully.

Several products of recent molecular advances have already been used in trials as immunotherapies for RA. Various antilymphocytic monoclonal antibodies (MAb) are undergoing clinical trials to determine their efficacy in RA. CAMPATH-1H is a lymphocyte-depleting IgG humanized MAb directed against the surface antigen CD52, which is present on all lymphocytes and some monocytes. Patients with refractory RA developed immediate, profound, and sustained reduction in peripheral lymphocyte count after the intravenous infusion of CAMPATH-1H. Although side effects were frequent, 65% of the study patients did develop a clinical response. Surprisingly, there was no correlation between the level of lymphocyte depletion and the clinical response. Immunotherapy with a chimeric anti-CD4 MAb (cM-T412) significantly decreased the number of circulating CD4 cells, which are believed

to be important in the initiation and perpetuation of autoimmunity. The reduction of CD4$^+$ T cells was associated with decreased synovial inflammation histologically and reduced expression of adhesion molecules in the synovium. However, clinical effectiveness has not been demonstrated with this form of therapy. The experiences with both CAMPATH-1H and anti-CD4 MAb suggest that a treatment strategy directed at depleting circulating lymphocytes may have insufficient effects in the target tissue to result in clinical improvement of the disease process.

SYSTEMIC LUPUS ERYTHEMATOSUS (SLE)   The improvements in medical management of SLE during the past 30 years has greatly reduced morbidity and mortality, so that now the 15-year survival rate is at least 90%. Part of this improvement can certainly be attributed to the more effective and judicious use of corticosteroids and cytotoxic agents. Advances in general medical support of patients with severe renal, pulmonary, and hematologic problems have also been key factors in our improved management of SLE.

For patients with photosensitivity, avoidance of sun exposure is essential. Other more chronic rashes may respond to topical corticosteroids or hydroxychloroquine. Non-life-threatening manifestations of SLE, such as low-grade fever, myalgia, arthritis, or pleuritis, are most commonly treated with nonsteroidal anti-inflammatory drugs or low-dose prednisone (less than 10 mg/d or less than 20 mg on an alternate day dosage). High dose corticosteroids (1–2 mg·kg^{-1}·d oral prednisone or 1 g/d of iv methylprednisolone daily for 3 days) are usually reserved for acute fulminant nephritis, CNS disease, hemolytic anemia or thrombocytopenia. Occasionally, intravenous cyclophosphamide (0.75–1.0 g/m^2 body surface) is given monthly for severe and unresponsive cases. Other cytotoxic agents, such as azathioprine and chlorambucil, are sometimes used instead of cyclophosphamide, although their effectiveness remains controversial.

SYSTEMIC SCLEROSIS (PSS)   Scleroderma or PSS is certainly one of the most difficult management problems in all of the connective tissue diseases. Unlike most other forms of autoimmunity, PSS does not generally respond well to corticosteroid therapy and in fact prednisone may be deleterious because of its enhancing effects on blood pressure. Raynaud's phenomenon can be effectively treated with hand warming, stress reduction, and calcium channel blockade (nifedipine). Esophageal dysmotility can be improved with metoclopramide and octreotide acetate. The sclerodermatous skin changes can be debilitating, but little therapeutically can be done other than preventing dryness. The only treatment measure that has ever been shown to improve survival rates in PSS is an aggressive approach to blood pressure control. Using calcium channel blockers or angiotensin converting enzyme (ACE) inhibitors, even borderline or mildly elevated blood pressures should be treated. Target diastolic pressures of 70 mmHg or less and systolic pressures of 125 mmHg or less may prevent the hypertensive renal crisis that is almost universally fatal in this disease.

POLYMYOSITIS AND DERMATOMYOSITIS (PM AND DM)   Corticosteroids are the mainstay of therapy for PM and DM. When the disease is newly diagnosed and active, prednisone is begun in doses of 60–100 mg/d in divided doses. When a therapeutic response has been obtained and creatine phosphokinase (CK) levels have returned to normal, the prednisone is consolidated into a single morning-time dose and the steroid is gradually tapered. If the disease proves to be recalcitrant (requiring high-dose prednisone for greater than 3 months) or if the patient is showing evidence of early steroid toxicity, another immunosuppressive or cytotoxic agent may be used for the steroid-sparing effect. Methotrexate in initial doses of 7.5–10.0 mg/wk orally or azathioprine (2–3 mg/kg body weight) can be given to allow a more rapid steroid taper. It is important to remember that corticosteroids may actually cause muscle weakness and atrophy. In the setting of high-dose prednisone and worsening muscle symptoms, a steroid myopathy should be considered. Even with optimal medical care the patient's strength will lag far behind other evidence of disease improvement such as normalization of serum muscle enzyme levels. A muscle-strengthening program should be started after muscle inflammation has been controlled with medication.

SJÖGREN'S SYNDROME (SS)   In most patients with primary SS, therapy is directed at relief of "sicca symptoms," i.e., dry eyes and dry mouth. Artificial tears should be used every 2–3 hours throughout the day to prevent keratoconjunctivitis sicca. The treatment of dry mouth is more problematic and patients are seldom seen without a glass of water in their hands. Sugar-free lemon drops can help stimulate whatever salivary gland function remains. Systemic corticosteroids and cytotoxic drugs are generally reserved for patients with life-threatening extraglandular involvement of the brain, lungs, or kidneys. Through the course of therapy, patients should be evaluated for the development of lymphoma or Waldenstrom's macroglobulinemia. These malignant complications of SS may occur years to decades after the initial diagnosis of Sjögren's syndrome.

FUTURE DIRECTIONS

Molecular technologies and genetic-based therapies will soon have an impact on the treatment of the autoimmune diseases. I described in the preceding section how monoclonal antibodies are currently being used to selectively delete lymphocyte subsets. Other forms of immune manipulation that are currently being developed include cytokines, cytokine antagonists, and recombinant proteins that block adhesion or migration of immune cells. Several drugs that interfere with genetically mediated T-cell activation are already undergoing clinical trials for various autoimmune diseases. These include cyclosporine and FK506, which inhibit T-cell differentiation and replication. The efficacy of these drugs in early trials is encouraging but their toxicities and lack of specificity of immune suppression make it clear that we are still a long way from the breakthrough remedies we are seeking for autoimmune disease.

The therapeutic dilemma in autoimmunity is that as long as the autoantigens and autoreactive lymphocytes persist, the autoimmune disease will be self-perpetuating. All of the new therapies mentioned so far in this section may effectively interfere with the inflammatory process created by the interaction of autoantigens, class II MHC molecules, and T-cell receptors. However, these therapies would have to be given for the patient's lifetime or the autoimmunity would rekindle. The truly futuristic approaches to therapy will include ways of eliminating the source of autoantigens and selectively eliminating the pathogenic population of autoreactive lymphocytes.

Another therapeutic approach for the future would require a much more complete identification of the susceptibility genes responsible for each of the autoimmune diseases. Monitoring genetically susceptible individuals for preclinical serologic evi-

dence of autoimmunity may permit treatment options that would not be possible or appropriate once target tissue damage has occurred. Advances in gene therapy may allow for selective DNA-based therapeutics, such as antisense drugs, that could combine with the susceptibility genes and downregulate their expression.

35 Allergic Diseases
Asthma as a Model

*S*USAN *M. M*AC*D*ONALD

BACKGROUND

Allergic disease and asthma affect approximately 12 million people in the United States and account for 1% of total health care costs. Between 1965 and 1983, hospitalizations of adults with asthma increased 50%, whereas hospitalizations of children increased 200% (*see* Chapter 36). Additionally, both the lay press and scientific publications report that, from 1985 to 1991, mortality from asthma has increased. The prevalence, the tremendous cost, the increased mortality, as well as the time lost from work or school, mandate investigations to curtail or prevent these diseases.

Previously, asthma was viewed as a respiratory disease of acute airway obstruction related to bronchospasm. The mast cell and its products, histamine, sulfidopeptide leukotrienes, and prostaglandins, became the primary focus for pharmacologic interventions. More recently, asthma has been defined (by the Expert Panel Report 2, *Guidelines for Diagnosis and Management of Asthma*, NIH publication) as a disease of the airways characterized by "airway inflammation, airway hyperresponsiveness, and reversible airway obstruction." Antigen exposure in an allergic asthmatic individual results in an acute reaction resulting in a decrease in forced expiratory volume in 1 second (FEV_1). This acute reaction subsides, but if the initial antigenic stimulus is sufficiently high, there is a recrudescence of symptoms termed the late-phase reaction (LPR) some 6–24 hours later. With its bronchial inflammation and enhanced bronchial responsiveness, the LPR is a useful tool to explore the pathogenesis of asthma.

The LPR is characterized by edema and erythema in the skin, and increased resistance to air flow in the nose and lungs. There are several reasons why the LPR may be a more appropriate model of allergic inflammation than is the acute response to antigen. The duration, susceptibility to oral steroids, and characteristic infiltration by eosinophils, neutrophils, and basophils resembles that of chronic allergic inflammation. The role of specific cell types in the LPR has not been proven, but several lines of evidence suggest that the basophil, and not the mast cell, plays a significant role in the LPR. First, the mast cell mediators that are found associated with the symptoms of the acute reaction, i.e., histamine, prostaglandin D_2 (PGD_2), tryptase, and leukotriene C_4 (LTC_4) are clearly different than those found in the late reaction, i.e., histamine and LTC4 but no PGD_2 or tryptase. Basophils do not contain tryptase or PGD_2. Second, by morphologic and flow-cytometric evidence,

basophils clearly appear during antigen-induced LPR in skin chambers and in the nose. Furthermore, the IgE-bearing cells in late-phase nasal lavages express CD18, an adhesion molecule found primarily on basophils and other leukocytes, but not on the mast cell. Additionally, basophils have been identified as the histamine-containing cells in bronchoalveolar lavage fluids obtained during the late response. Of the alcian blue-positive cells that increased 15-fold in the antigen versus the saline site in late-phase bronchoalveolar lavage fluids, 96% were morphologically and functionally defined as basophils. Finally, basophils have been shown to increase dramatically in the airways of those subjects experiencing asthmatic episodes and in biopsies of patients dying of asthma. These data would suggest that the infiltration of proinflammatory cells, including basophils, is of critical importance in the LPR of allergic asthmatic diseases.

The pathogenesis of the late reaction is complex and not well-understood. An initial event in the human response to antigen might well be mast cell degranulation and release of mediators that, in turn, attract inflammatory cells and upregulate adhesion molecules on endothelium and leukocytes. The basophils and eosinophils that infiltrate are known to be activated or primed to be hyperresponsive to stimuli. Elevated levels of histamine and neutrophil chemotactic factor have been found in the blood hours after antigen bronchoprovocation. Using an in vivo model of intranasal antigen challenge, mediators such as histamine have been shown to be elevated in nasal washes coincident with symptoms in those individuals experiencing an LPR. In both the skin and nasal models, this late mediator release is not caused by continued antigenic stimulation. Furthermore, cytokines known to potentiate mediator release, such as interleukin-1 (IL-1), IL-3, and granulocyte-macrophage colony-stimulating factor (GM-CSF), have been found to be released locally during the cutaneous allergic LPR. Thus, mediator release clearly occurs in vivo during the late response to antigen, and there can be selective recruitment of cells that seem to be important in this late response. However, the actual stimulus for activation remains unknown.

Although mediators and cells have been identified in the LPR, two key questions remain: (1) what is the stimulus for basophil activation during the late response? and (2) why do only some people have this response? These questions prompted our initial investigation of a histamine-releasing factor (HRF). HRF was first reported as a factor that was present in late-phase skin blister fluid that caused basophil histamine release. This factor was not present in early blister fluids when antigen was present. Subsequently,

such a factor was found to exist in nasal lavages obtained during the LPR and that these HRFs have functional and physicochemical characteristics similar to those of HRF from macrophages and from the macrophagelike cell line, U937. One working hypothesis is that these factors are related and that this family of molecules is responsible for stimulation of basophils during the IgE-mediated LPR in an allergic asthmatic individual.

Much of what is known concerning the pathogenesis, epidemiology, diagnosis, and management of asthma has been reviewed previously. The purpose of this chapter is to update the reader with regard to new molecular discoveries that might impact on the thinking and eventual treatment of this disease. The emphasis of these new discoveries will relate to the LPR as mentioned above. As previously stated, this LPR clearly mimics the inflammation of chronic allergic asthma. Additional topics will address the genetics of asthma (although no current gene therapy is available), the relatively new concept of heterogeneity of the IgE molecule, and clinical trials of new therapies for asthma. All of this will be discussed in the context of the traditional management of asthma.

CLINICAL FEATURES

For comprehensive reviews of the clinical features and diagnosis of asthma, the reader is referred to references listed at the end of this chapter. It is now well-established that there are several epidemiologic parameters that demonstrate asthma is an increasing problem. The prevalence is high, approximately 5% in adults and 10% in children. The incidence, morbidity, and mortality of asthma have been increasing. The actual reasons for these increases are not defined. Several factors, such as decreased access to medical care for those of lower socioeconomic status, increased indoor allergens, in modern central air-conditioned homes, such as house dust mite, the increased incidence of smoking mothers, and the exposure to viral infections at day care centers and in the preschool environment are several potential factors that contribute to the apparent rise in morbidity and mortality of this disease.

Asthma is classically divided into two types: extrinsic, synonymous with allergic asthma, intrinsic, not associated with atopy. There is an interesting correlation among bronchial reactivity, the diagnosis of asthma, and the total serum level of immunoglobulin E (IgE). In fact, the presence of allergic disease associated with asthma ranges from 50 to 90%, with the highest association existing in children. The existence of a history of allergies and the exposure to an environmental allergen that is associated with exacerbation of the symptoms of asthma point to allergies as having an important role in the pathogenesis of asthma.

The symptoms of asthma—wheezing, dyspnea, cough, and chest tightness—can be explained by airway obstruction. This airway obstruction is caused by edema, mucous production, epithelial cell sloughing, smooth muscle constriction, and mucosal inflammation. The inflammatory changes that are seen in asthma include cellular infiltrates, including basophils, eosinophils, mast cells, and mononuclear cells; epithelial cell damage and cellular mediators, including histamine, sulfidopeptide leukotrienes, tryptase, prostaglandins, kinins, eosinophil-derived proteins, and several cytokines, such as IL-4, IL-5, and GM-CSF. This inflammatory process can lead to enhanced vascular permeability, mucous production, smooth muscle contraction, and reflex bronchospasm.

DIAGNOSIS

Asthma is episodic in nature, with asymptomatic periods intermingled with symptomatic exacerbations. Table 35-1 has a list of causes of asthma and conditions that exacerbate it. A careful history should be taken to detect any of these factors. In the majority of patients, a thorough history by the physician will lead to the diagnosis of asthma. Table 35-2 illustrates other considerations that are important for the differential diagnosis of asthma. Because asthma is characterized by reversible bronchial obstruction and airway hyperresponsiveness, it is very useful to document the presence of these hallmarks. Formal pulmonary function tests showing a decrease in the forced expiratory volume in 1 s (FEV_1) and a decrease in the forced vital capacity (FVC) can be used to document obstruction. This decrease in FVC can be attributed to air trapping in the asthmatic lung. As a general rule, the ratio of FEV_1 to FVC is less than 0.80. Normally, the decrease in these two parameters is readily reversible with the inhalation of a β_2-adrenergic bronchodilator. The major drawback of formal pulmonary function testing is the cost. This can be overcome to some degree with the use of an inexpensive hand-held peak flow meter that measures the peak expiratory flow rate, which correlates with FEV_1. The other advantage of this device is the ability of the patient to use it at home to monitor exacerbations of asthma and effectiveness of therapy. In some patients it may be necessary to demonstrate airway hyperresponsivesness with the use of a standardized methacholine or histamine inhalation challenge. A detailed list of all the laboratory tests useful in diagnosing asthma is beyond the scope of this chapter but is summarized in Table 35-3.

GENETIC BASIS OF DISEASE

The ability to identify the genes responsible for human diseases has markedly expanded during the last several years. Indeed, as illustrated in other chapters, genes associated with cystic fibrosis, myotonic dystrophy, neurofibromatosis, Duchenne's muscular dystrophy, and Huntington's disease have been identified. Atopic allergies and asthma are complex diseases and it is unlikely that a single gene will be responsible for allergic diseases or asthma. Instead, the interaction of different classes of genes combined with environmental factors are more likely to be responsible. For a comprehensive review of the potential genes that are likely to be associated with allergic asthma, the reader is referred to the references.

There are three major categories of genes that appear to be associated with asthma. The first are genes that are disease-specific, and that may be responsible for increasing the inflammatory response leading to hyperreactive airways. The second type of genes determine the ability of an individual to synthesize total IgE antibody. As previously mentioned, several epidemiologic studies have shown that the risk of asthma is related to the total serum IgE level. Furthermore, in patients with very low IgE levels, no asthma was found. Finally, a third group of genes, the immune response (*Ir*) genes, determines the ability of patients to make specific immune responses, such as IgE antibody to specific inhaled allergens. Classical *Ir* genes map to the major histocompatibility complex. It is this group of genes that is influenced by environmental factors, such as the level of exposure to indoor allergens and seasonal allergens.

APPROACH TO GENE MAPPING Molecular genetic analysis of human diseases involves two approaches, forward and reverse genetics. The forward approach examines candidate genes.

Table 35-1
Causes of Asthma and Exacerbating Conditions

Causes	*Exacerbating conditions*
Allergy	Infections
Allergic asthma	Bronchiolitis
Allergic bronchopulmonary aspergillosis	Upper respiratory tract infections
Industrial-occupational or environmental exposure	caused by viruses (influenza, rhinovirus, respiratory syncytial virus)
Chemicals (e.g., toluene diisocyanate, TDI)	Bronchitis
Allergens (e.g., plicate acid)	Sinusitis
Vasculitis (Churg-Strauss allergic angiitis and	Gastroesophageal reflux
granulomatosis)	Pregnancy
Idiopathic (intrinsic)	Hyperthyroidism
Aspirin or other nonsteroidal anti-inflammatory	Psychological stress
agents (associated with nasal polyps, Samter's triad)	
Sulfiting agents	
β-adrenergic antagonists	
Exercise

Table 35-2
Differential Diagnosis of Asthma

More common	*Less common*	*Rare*
Aspiration (gastroesophageal reflux)	Cystic fibrosis	α1-Antitrypsin deficiency
Bronchiectasis	Laryngeal edema	Allergic bronchopulmonary aspergillosis
Cardiac failure ("cardiac asthma")	Laryngeal or tracheal obstruction	Carcinoid syndrome
Chronic bronchitis and emphysema	Pulmonary embolism	Foreign bodies
Factitious wheezing		Hyperventilation syndrome
Sarcoidosis		Löffler's syndrome
Tumors in the central airways		Tropical eosinophilia

Modified from Kaliner M, Lemanske R, Rhinitis and asthma. JAMA 1992;268:2807–2829. Copyright 1992, American Medical Association.

Before discussing the forward approach it is necessary to describe the likely candidate genes associated with asthma. The reverse genetic approach, also called positional cloning, tries to establish linkage between a disease and anonymous DNA markers. Both of these approaches use the polymerase chain reaction (PCR) to amplify DNA markers.

An example of the latter approach is the Cookson and Hopkin hypothesis. Their initial family studies suggested an autosomal dominant mode of inheritance of atopy. In genetic linkage studies the putative atopy gene was linked to the DNA marker, D11S97, which is located on chromosome band 11q13. Their data showed that the β-subunit of the high-affinity IgE receptor on chromosome 11 is maternally linked to atopy. Furthermore, a common polymorphism of this receptor subunit, Leu 181–Leu 183, was identified in 4.5% of the population in a rural town of Australia. The children who inherited this variant from their mothers were atopic and had an increased risk of positive skin-prick test to house dust mite and grass pollen, antigen-specific IgE antibody levels, and bronchial hyperresponsiveness. Thus, this is one particular chromosomal localization of a gene associated with atopy.

To discuss the forward approach to gene mapping, the candidate genes associated with allergies and in particular allergic asthma must be discussed. To accomplish this, it is necessary to summarize the T helper cell, Th1 versus Th2 dichotomy. Th1 cells are associated with cell-mediated immunity, including delayed-type hypersensitivity, whereas Th2 cells facilitate the humoral immune response, including IgE antibody production. The cytokine production profiles of these T helper cell subsets are very different. Th1 cells produce IL-2 and interferon-γ (IFN-γ), whereas Th2 cells secrete IL-4, IL-5, and IL-13.

In humans, IL-4 or IL-13 is absolutely required for the immunoglobulin heavy-chain isotype switching that produces ε germ-line transcripts. Interestingly, basophils, which are an important cell type in the allergic LPR, also produce IL-4 and IL-13. IFN-γ downregulates IgE production. IL-5 is important for eosinophil activation and recruitment, and the eosinophil is another cell found in large numbers in allergic LPR. It is noteworthy that the genes encoding IL-13, IL-4, IL-5, and interferon regulatory factor 1 map to a cluster of a few million basepairs on chromosome 5. Because of the pivotal role that IL-4 and IL-13 play in IgE production,

Table 35-3
Utility of Various Tests in the Evaluation of Patients Suspected of Having Asthma

Test	Diagnostic utility
Pulmonary function testing	
Peak flow monitoring ± bronchodilators	Document pulmonary function, its variability, and response to therapy
FEV_1/FVC ± bronchodilators	Distinguish reversible vs fixed obstruction or restriction
Residual volume, total lung capacity	Distinguish obstruction vs restriction
Diffusion capacity (DL_{co})	Document impaired gas exchange in COPD and interstitial lung disease
Flow volume loops	Distinguish extra- vs intrathoracic obstruction
Histamine/methacholine challenge	Document airway hyperreactivity
Exercise testing	Document oxygen desaturation, exercise-induced asthma
X-rays	
Chest X-ray	Document hyperinflation, infiltrates, hilar lymphadenopathy, tumors, heart failure
Esophagram	Document reflux
Sinus X-rays	Document acute sinusitis
Sinus CT	Document chronic sinusitis, polyposis
Blood testing	
Total IgE	Allergic bronchopulmonary aspergillosis
Total eosinophil count	Often elevated in asthma
Aspergillus precipitants	Allergic bronchopulmonary aspergillosis
α1-Antitrypsin levels	Emphysema
Angiotensin converting enzyme	Sarcoidosis
Arterial blood gases (oximetry)	Document degree of hemoglobin desaturation, oxygenation
Other tests	
Skin testing (RAST)	Evaluate allergic status
Esophageal pH monitoring	Document gastroesophageal reflux
ECG	Document arrhythmia, ischemia, cor pulmonale, left ventricular hypertrophy
Sputum culture/Gram stain/cytology	Document infection, eosinophilia
Sweat chloride test	Assess for cystic fibrosis
Serum immunoglobulin levels	Assess for humoral immunodeficiency

COPD, chronic obstructive pulmonary disease; CT, computed tomography; ECG, electrocardiogram; FEV_1, forced expiratory volume in 1; FVC, forced vital capacity.

likely candidate genes for atopy would be in this IL-4 gene cluster on chromosome 5, in particular 5q31.1.

As previously mentioned, there is a striking correlation between the total serum IgE level and the prevalence of asthma. Using the candidate gene approach, Marsh and coworkers measured concentrations of total serum IgE and analyzed 349 sib pairs. These data demonstrated linkage between total serum IgE concentrations and a marker in the IL-4 gene cluster located in chromosome 5q31.1. Markers mapping outside 5q31.1 showed no evidence of linkage. These findings are supported by other groups who showed evidence for linkage of various markers in the 5q31 and q33 region with total IgE level and an association between the total serum IgE level and a polymorphism in the IL-4 gene.

In conclusion, although the genetics of asthma are complex, there is evidence to suggest a link between asthma and genes in the IL-4 gene cluster. Work is ongoing to investigate other candidate genes for atopy.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

As mentioned in the Background section of this chapter, the LPR mimics the chronic inflammation that is the hallmark of asthma. Many laboratories have been working to decipher the etiology of this LPR. As previously noted, basophils and eosinophils are increased in the LPR, and the stimuli that cause mediator release from these cells have been under intense investigation.

During the last decade, there has been an explosion of interest in cytokines that either augment basophil histamine release or are direct agonists (Table 35-4). One type of HRF was shown to interact with the IgE molecule, and that only a subpopulation of atopic donors basophils are responsive to this HRF. Work by MacDonald et al. designated the

IgE that interacts with this HRF, IgE$^+$, and therefore, by definition, the remaining IgE molecules that do not interact with HRF are IgE$^-$.

In the context of purifying this IgE-dependent HRF, and with the availability of recombinant cytokines, it became imperative to investigate whether our HRF was a known, stimulatory cytokine. Of the interleukins that caused direct histamine release from basophils, namely IL-3 and IL-8, it was evident that the kinetics of release and the lack of crossdesensitization of basophils differentiated these interleukins from our HRF, and, indeed, their mechanism of release is IgE-independent. The possibility also developed that the chemokines, a family of low molecular weight (8–11 kDa) molecules, might be involved in the LPR. The chemokines are divided into two groups, C-X-C or α chemokines, found on chromosome 4, including PF-4, IL-8, NAP-2, and CTAP-III, and the C-C chemokines or β chemokines, found on chromosome 17, including MCP-1, MCP-3, RANTES, and MIP-1α. It is clear from recent reports that MCP-3 is a potent histamine secretagog, as is MCP-1. RANTES is an eosinophil chemokine attractant, and to a lesser degree, a histamine-releasing agent. However, again, the kinetics of histamine release caused by these stimuli are very rapid and do not mimic that induced by the IgE-dependent HRF.

PURIFICATION OF THE IgE-DEPENDENT HRF   The IgE-dependent HRF was purified from 50 L of supernatant from the human U937 monocyte-macrophage cell line and subcloned. It was found to have a 94% homology to p21, a protein from mouse tumor cells, as well as identity to p23, the human homolog. Both molecules were cloned on the basis of their abundant expression in tumor cells, and no function could be ascribed to either molecule. The cDNA for rp21 was kindly supplied by Drs. Margaret Koots and George Brawerman of Tufts University, Boston, MA. Primers were designed and the PCR product was expressed in *Escherichia coli* as protein fused to glutathione-*S*-transferase (GST). The fusion protein was purified by affinity chromatography using immobilized glutathione. The same primers were used to generate the human rp23 from the U937 cell line, which was also expressed as a GST fusion protein and affinity purified.
Figure 35-1   Representation of the histamine release produced by various stimuli: human recombinant histamine-releasing factor (HrHRF), native, nasal pool HRF (NP HRF) and polyclonal anti-IgE antibody (AIgE) on lactic acid-treated basophils passively sensitized with IgE$^+$ (hatched bars) or IgE$^-$ (closed bars).

Both recombinant fusion proteins, and their cleaved products, caused IgE-dependent histamine release from IgE$^+$ donors' basophils. Figure 35-1 shows a comparison of IgE-dependent histamine release using three stimuli: human recombinant HRF (HrHRF), native, nasal lavage-derived HRF (NP HRF), and anti-IgE antibody (AIgE). Cell surface IgE was removed using lactic acid, and the cells were then passively sensitized using sera containing either 200 ng of known IgE$^+$, or IgE$^-$. On washing and stimulation, the IgE-sensitized basophils did not support release to HrHRF or to NP HRF, whereas histamine release occurred to both stimuli only when IgE$^+$ was placed on the basophils. As expected, release induced by anti-IgE did not discriminate between IgE$^+$ and IgE$^-$.

In a separate series of Western blot experiments, a polyclonal rabbit antibody generated against cleaved human recombinant p23 recognized mouse recombinant p21, human recombinant p23, native HRF from the U937 cell line, and native HRF from supernatants of peripheral blood mononuclear cell cultures. Thus the recombinant HRF produced in *E. coli* was identical to the native material found in vivo.

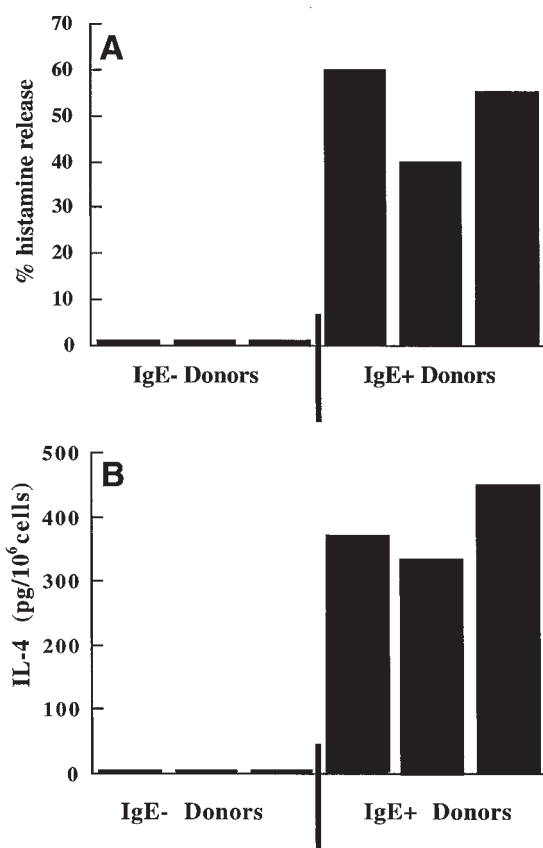
As previously mentioned, basophils infiltrate tissues and are thought to play an important role in the pathogenesis of chronic allergic diseases. This concept is supported by recent studies showing that basophils generate and secrete high levels of IL-4, a proinflammatory cytokine having immunoregulatory properties that affect many different cell types that interact during allergic inflammation. The secretion of IL-4 protein from basophils, however, unlike that described for histamine release, seems more dependent on IgE-dependent stimulation, with little evidence thus far that other, non-IgE-dependent physiologic stimuli can induce secretion of this cytokine. Because the recombinant protein caused IgE-dependent basophil histamine release, MacDonald et al. asked whether this HRF could also cause IL-4 protein production. In basophil cell cultures challenged for 4 h with recombinant HRF, the secretion of IL-4 correlated with histamine release in 14 donors ($r = 0.9$, $p = 0.001$). Figure 35-2 shows histamine release and IL-4 production in three IgE$^-$ donors and three IgE$^+$ donors. As is evident, none of IgE$^-$ donors' cells released histamine or IL-4 protein when stimulated with recombinant HRF. In contrast, his-


Figure 35-2 The % histamine release (**A**) and the IL-4 protein production (**B**) in basophils stimulated with $4 \times 10^{-7}\ M$ HrHRF from 3 IgE$^-$ and 3 IgE$^+$ donors is shown.

tamine release and IL-4 production occurred with the IgE$^+$ donors' basophils stimulated with HRF. These data strongly support the concept that the IgE-dependent HRF has the potential to play a key role in the pathogenesis of human allergic disease.

CLINICAL RELEVANCE Chemokines with IgE-independent histamine-releasing activity have been found in vivo; MCP-1 levels were increased, and IL-8 levels decreased, in resting nasal lavages of symptomatic patients during the appropriate pollen season, and bronchoalveolar lavage fluids of asthmatic subjects have higher levels of RANTES and MIP-1α than do those of normals. Furthermore, MCP-1 expression has been shown by immunohistochemical techniques to be increased in bronchial tissue from asthmatic patients. The IgE-dependent HRF also has been detected in human respiratory secretions, late-phase skin blister fluids, and nasal lavages. Knowing that the IgE-dependent HRF caused basophil histamine release in approximately 50% of allergic donors and that it is found in vivo in late-phase blister fluids and nasal lavages, it was questioned whether responsiveness to HRF was associated with disease severity. In a previous study of 55 ragweed-sensitive hay fever patients, a significant correlation ($p < 0.02$) was found between the intensity of symptoms in the LPR and basophil histamine release to the IgE-dependent HRF. Also, when an IgE-dependent, platelet-derived HRF was investigated, basophils from allergic asthmatics, and not from nonallergic asthmatics, responded to this stimulus. Of those allergic subjects who responded in vitro, methacholine sensitivity and symptoms of asthma were highly correlated ($r = 0.87$, $p < 0.005$).

Sampson et al. showed that production of HRF also is associated with the clinical status of food allergy and atopic dermatitis. Using blood from food-allergic children with atopic dermatitis, they found that the children's basophils have a high spontaneous release of histamine and their mononuclear cells spontaneously produce an IgE-dependent HRF in culture. When these children are placed on an avoidance diet that eliminates the offending food allergen, they improve clinically, their basophils no longer spontaneously secrete histamine, and their mononuclear cells no longer spontaneously produce HRF.

With the availability of recombinant material, MacDonald et al. examined the lymphocytes of allergic and nonallergic patients for the generation of HRF mRNA and protein. Twelve patients (four allergic IgE$^+$, four allergic IgE$^-$, and four nonallergic) were recruited. Peripheral bood mononuclear cells (PBMCs) were cultured for HRF protein production and processed for mRNA extraction and subsequent reverse transcription PCR (RT-PCR) for HRF message. The quantity of mRNA for HRF, when compared with β-actin, did not appear different among the groups. However, the bioactivity of the IgE-dependent HRF protein produced by mononuclear cells from IgE$^+$ donors, when tested on lactic acid-treated cells passively sensitized with IgE$^+$ serum was greater than in the allergic IgE$^-$ patients and the nonallergic subjects. Thus it appears that all individuals make mRNA for HRF but atopics are more effective at translating it to protein.

CONCLUSION The gene for the IgE-dependent HRF has been subcloned. The recombinant protein has biologic activity and shows a band of identity with the native material from nasal lavage and peripheral blood mononuclear cell supernatants by Western blots. The availability of recombinant material will enable us to determine its exact relationship to the severity of allergic disease and to determine the nature of IgE heterogeneity. Currently, several hypotheses that could explain the heterogeneity of the IgE molecule (i.e., IgE$^+$ vs IgE$^-$) include a genetic polymorphism, differential glycosylation, or alternatively spliced forms of IgE found in atopic sera. Investigations are in progress to determine whether HRF binds IgE$^+$ directly or alternatively interacts with its own receptor.

MANAGEMENT AND TREATMENT

For more details, the reader is referred to the Selected References. Additionally, specific strategies for treatment are outlined in Guidelines for the diagnosis and Management of Asthma. The first line of treatment is patient education. The patient must understand that asthma is episodic in nature and that certain situations, such as exposure to an allergen or an upper respiratory infection, can exacerbate the disease. Patient recognition of a change in symptoms can lead to early therapy that can control the inflammation of asthma. Because asthma has triggers specific to the individual, avoidance of the particular allergen is recommended. Pets should be removed from the home if the family is in agreement. In the case of dust mite sensitivity, mattresses and pillows should be encased in plastic and, if possible, carpets removed. The following nonspecific irritants should be avoided: cigaret smoke, cold air, air pollution, and, in some patients, perfumes. Because viral infections are a frequent cause of asthma exacerbations, influenza vaccination is recommended.

Pharmacologic treatment of asthma has changed in the last 10 years. It is now appreciated that bronchodilators that provide immediate symptomatic relief do not alleviate the inflammatory process involved in asthma. For this reason, the treatment of the

Asthma Severity

Mild	Moderate	Severe

Inhaled Bronchodilators As Needed

Low Dose Inhaled Steroids	High Dose Inhaled Steroids

Cromolyn Sodium or Nedocromil

Theophylline

Immunotherapy

Oral Steroids

Exp. Rx*

asthmatic patient needs to be individualized according to the severity of disease. Figure 35-3 outlines the current approach. The use of inhaled bronchodilators alone is for patients with mild disease with symptoms occurring less than once or twice a week. This therapy is made more effective by use of a metered dose inhaler with a spacer that increases the amount of inhaled medication reaching the lower airways by reducing particle size and can reduce side effects such as candidiasis. The available selective β_2 agonists in the United States are albuterol, metaproterenol, terbutaline, bitolterol, pirbuterol, and isoetharine. Their duration of action is 6 h. Salmeterol, a longer acting $\beta2$ agonist, has recently become available. For mild disease, these agents are used "as needed." If the patient uses the inhaler more than three times per day, then addition of an anti-inflammatory medication is necessary to control the disease. Corticosteroids are the most potent anti-inflammatory treatment. The newer inhaled corticosteroids, such as fluticasone have much less systemic side effects than oral corticosteroids. As a general rule, oral short-acting steroids, such as prednisone, are used only in patients whose disease is not controlled. Cromolyn sodium is another locally acting treatment with apparent anti-inflammatory activity. If it is used, one must wait 6–10 weeks before a full effect is seen. Often cromolyn sodium is tried in children before to initiating corticosteroids. It has been proven to be efficacious for exercise-induced asthma. Nedocromil sodium, another anti-inflammatory medication, has the same indications for use as does cromolyn. Theophylline, a methylxanthine with bronchodilating effects, and a previous mainstay in the treatment of asthma for a century and a half, is now used as a third-line agent for patients who have not responded to inhaled bronchodilator or anti-inflammatory agents. An obvious inconvenience with

the use of this medicine is the necessity to monitor blood levels, which should be in the range of 5–15 µg/mL. Also the side effect profile necessitates setting levels for individual patients.

FUTURE DIRECTIONS

The management and therapy of asthma is likely to change in the future. Several investigational treatments are in place. Cytokines such as IL-4 and IL-13 are important in immunoglobulin switching to IgE, and trials in severe combined immunodeficient mice (SCID) transplanted with human fetal thymus and bone have demonstrated suppression of ongoing IgE synthesis when treated with IL-4 and IL-13 receptor antagonists. It is logical to assume that these successful trials in an animal model will progress to clinical trials in man.

Several pharmaceutical companies have ongoing clinical trials with pharmacologic agents that block leukotrienes. These compounds are aimed at directly antagonizing the actions of these mediators or inhibiting the enzyme, 5-lipoxygenase, that is responsible for the production of leukotrienes. These treatments appear promising and might lead to additional medications that could be used in conjunction with known drug therapy.

Classic immunotherapy has been used with varied efficacy in some patients with allergic asthma. This treatment, which was first reported almost a century ago, is hampered by the availability of purified allergen extracts. A new approach in this field is the use of purified peptide epitopes of the known allergen. In mice, administration of these peptides results in T-cell tolerance such that T cells no longer proliferate to the allergen, and no longer secrete the cytokines responsible for the maintenance of allergic inflammation. These peptides do not react with specific IgE antibody and therefore do not produce allergic symptoms. The advantage of this treatment is the ability to administer much larger quantities of the peptides vs the intact allergen. These studies are already in phase 2 clinical trials and may provide an exciting new form of therapy.

Finally, the use of an anti-IgE antibody is in clinical trials. At first glance, the concept of using an anti-IgE antibody to treat allergic asthma might seem contradictory. Two groups have produced monoclonal antibodies that recognize epitopes on the IgE antibody molecule when it is bound to B cells but not when it is bound to the high-affinity IgE receptor, F$\chi\epsilon$R1. Thus these monoclonal antibodies would recognize IgE bound to B cells and IgE in the circulation, but not IgE bound to mast cells or basophils. The hypothesis is that treatment with this type of antibody will clear IgE from the circulation and downregulate IgE synthesis from B cells. In clinical trials these anti-IgE antibodies have been shown to reduce IgE without producing symptoms of allergic disease. Currently ongoing clinical trials are designed to test the efficacy of this treatment in the early stages and LPR of allergic disease. The future of treatment of allergic asthma might be drastically altered by any of the above-mentioned therapies.

INTRODUCTION

Asthma is often defined as a lung disease with three character-
istics: reversible airway obstruction, increased airway responsive-
ness (hyperreactivity) to inhaled stimuli, and airway inflammation.
The disease is generally a chronic condition, and it affects between
7 and 20 million Americans, 2 to 5 million of whom are children.
The impact of asthma on any individual is highly dependent on the
control of the disease that can be achieved by elimination of pre-
cipitating factors and the effective use of medical therapy. Despite
improved understanding of these factors and the availability of
more effective drugs for treatment of the condition, the prevalence
of asthma, the numbers of hospitalizations for asthma, and deaths
attributed to the disease have all been increasing, especially among
minority and inner-city populations. At least some of the increases
in mortality and morbidity are based on poor use of medication
and, in particular, inadequate long-term treatment with anti-
inflammatory drugs. Nonetheless, the marked increases in fre-
quency and severity of asthma during the past decade serve to
underscore the need for a better understanding of the molecular
basis for the disease.

Perhaps the single most important conceptual "advance" in
defining molecular mechanisms of asthma has been the recogni-
tion that it is an inflammatory disease. Evidence that inflammation
is an important component of asthma was evident even in early
descriptions of the cytopathology and histopathology of the dis-
ease. For example, analysis of sputum samples and airway tissue
indicated that epithelial desquamation and airway eosinophilia
were invariably present during acute attacks. However, the critical
role of inflammation as a cause of the abnormal physiology was
only firmly established in two important ways: first, in experimen-
tal models of the disease induced by nonallergic and allergic
stimuli, asthmatic pathophysiology was closely linked to the
development of an inflammatory response; second, in studies
of asthmatic subjects under baseline conditions and during spon-
taneous or provoked flares of the disease, evidence of abnormal
airway function was again closely correlated with the presence of
inflammatory cells and mediators. Both types of studies were
strongly influenced by the development of bronchoscopic tech-
niques for obtaining airway tissue and histochemical techniques
for analyzing the types of inflammatory cells and mediators in the

tissue. In the context of the three characteristics of asthma (airway
obstruction, hyperreactivity, and inflammation), morphologic
studies of asthma now appear to indicate that an overexuberant
inflammatory response is what causes the hyperreactivity of air-
way end-organs (e.g., increases in airway smooth muscle contrac-
tion and mucous gland secretion), and this hyperreactivity may in
turn be responsible for the characteristic asthmatic attacks of air-
way obstruction.

Accordingly, the challenge that now confronts researchers and
clinicians is twofold: first, defining the biochemical mechanisms
responsible for asthmatic airway inflammation, and then deter-
mining the pharmacologic means to more effectively inhibit
inflammatory pathways or potentiate anti-inflammatory ones.
Thus, this chapter is aimed mainly at reviewing prominent bio-
chemical pathways responsible for airway immunity and inflam-
mation. Defining these pathways has provided initial clues to the
identity of genes activated in the course of asthmatic disease. Con-
sequently, we also review initial studies aimed at linking the loci
for these immune-response genes to the asthmatic phenotype.

MECHANISMS OF AIRWAY INFLAMMATION

The concept that inflammation leads to airway hyperreactivity
and narrowing has led to a widening search for the types of inflam-
matory cells and mediators responsible for the cascade of events
linking the initial stimulus to the final abnormality in airway func-
tion. Cell types implicated in the development of airway inflam-
mation include immune cells (including basophils, eosinophils,
mast cells, lymphocytes, neutrophils, and macrophages) as well as
sentinel parenchymal cells (including airway epithelial cells, vas-
cular endothelial cells, and airway smooth muscle cells). Cell–cell
interactions are attributed to classes of mediators that include lip-
ids, proteases, peptides, cytokines, and chemokines. It is not yet
possible to integrate all of this information into a single model for
the development of airway inflammation; however, a useful frame-
work for this system may be based on the classification of T-cell
responses to allergic and nonallergic stimuli that are inhaled into
the airway.

Using a scheme that was developed in murine models of the
immune response, T-cell-dependent responses may be classified
into T-helper-1 (Th1) or Th2 types. Th1 cells characteristically
mediate delayed-type hypersensitivity reactions and selectively
produce interleukin (IL)-2 and interferon (IFN)-γ, whereas Th2
cells promote B-cell–dependent humoral immunity and selectively
Figure 36-1 Cell–cell interaction cascade for a Th2-type response in the airway. Proposed steps include: (1) inhaled allergen stimulates mast cells (by crosslinking surface IgE) and Th2 cells (via antigen-presenting dendritic cells, DC) to cause release of IL-4 and TNF-α; (2) IL-4 and TNF-α synergistically induce VCAM-1 expression on the endothelium causing VLA-4-dependent eosinophil adhesion; (3) TNF-α also induces ICAM-1 expression on the endothelium for Mac-1- or LFA-1-dependent transendothelial migration; (4) activated T cells also release chemokines (CK) and IL-5 that in combination with IL-4 and TNF-α promote recruitment, survival, and activation of eosinophils; and (5) activated eosinophils release additional IL-4, IL-5, and TNF-α that autoamplifies eosinophil influx and local production of eosinophil-derived arachidonate products, matrix metalloproteinases, toxic peptides, and other mediators contributing to epithelial damage.

produce IL-4 and IL-5. In the simplest case, a Th2-type reaction may underlie the bronchial hyperreactivity and inflammation characteristic of the delayed response to allergen inhalation and (by extension) the allergen-dependent inflammatory response in patients with extrinsic asthma. Alternatively, a Th1-type reaction may be responsible for the hyperreactivity and inflammation that results from exposure to nonallergic stimuli (such as respiratory viruses). However, this dichotomous concept may not be completely accurate for several reasons. First, the separation between these two types of immune responses is less distinct in humans than in mice, and some evidence suggests that both responses may be triggered by allergic and nonallergic stimuli. In addition, there is cross regulation of the two types of responses, so that a Th2-derived mediator (e.g., IL-10) may serve to downregulate Th1-type responses, and a Th1-derived mediator (e.g., IFN-γ) may downregulate Th2-type responses. Nonetheless, the classification still forms a useful basis for beginning to organize a molecular scheme of airway inflammation.

TH2-TYPE T-CELL RESPONSE The percentage of asthma that is caused by an abnormal sensitivity to inhaled allergen is uncertain, but there is little question that allergen is a primary stimulus of airway inflammation and asthma in at least some subjects. Thus, it is natural to propose that a Th2-type allergic response, already incriminated in other types of antibody-dependent allergic responses, may also be invoked in the IgE-driven response to inhaled antigens that is characteristic of atopic individuals with asthma. This possibility is supported by evidence of increased numbers of activated T cells exhibiting a Th2 phenotype in airway tissue from atopic asthmatic subjects.

A scheme for the cascade of cell–cell interactions during a Th2-type response in the airway is depicted in Fig. 36-1. In this scheme, inhaled allergen provides the trigger for the first step in the cascade, and allergen triggering may occur in two ways: (1) allergen is bound to the surface of IgE-bearing mast cells for antibody (Ab) crosslinking and subsequent production or release of mast cell mediators; or (2) allergen is taken up by an antigen-presenting cell (e.g., a dendritic cell recruited to the

mucosal epithelium) followed by antigen presentation to the T-cell receptor (TCR) and TCR-dependent cytokine production. In the context of a scheme for airway inflammation calling for recruitment of immune cells, it would appear that some of the most critical mediators are derived from the cytokine class (e.g., IL-4, IL-5, and tumor necrosis factor-α [TNF-α]). In this regard, studies of asthmatic airway tissue indicate that: (1) mast cells and Th2 cells generate IL-4, IL-5, and TNF-α; (2) the level of cellular production is increased relative to nonasthmatic subjects; and (3) the levels can be further increased by inhalation challenge with antigen.

IL-4 Generation By comparison with other cytokines (especially IL-2), little is known concerning the regulation of IL-4 production. In other cases, the control of cytokine levels may depend on the status of cytokine gene activation and the consequent rate of transcription, and in turn, the level of transcription depends on specific DNA–protein interactions within the gene promoter region. In the case of IL-4, only preliminary information has been obtained incriminating the involvement of specific transcription factors that bind to the promoter region and trigger IL-4 gene activation. Initial work indicated that a nuclear factor of activated T cells (NFAT) may exert some control over the T-cell specificity of IL-4 production, but this factor does not yet explain the capacity of T cells to regulate IL-4 production during inflammation. As described in more detail below, a member of a new family of transcription factors designated the STAT family (for *s*ignal *t*ransduction and *a*ctivation of *t*ranscription) may serve to regulate IL-4 production. The newest member of this family (designated Stat6) binds to the IL-4 gene promoter region (suggesting it may regulate transcription of IL-4) and appears to mediate the capacity of IL-4 to activate its target genes (e.g., those controlling IgE production). Thus, Stat6 may serve to create an autoamplifying loop whereby its activation leads to further IL-4 production and consequently further Stat6 activation. Such a positive feedback loop is consistent with observations that IL-4 is a product of Th2 cells and, once produced, IL-4 also promotes further Th2-type T-cell differentiation.
Figure 36-2   IL-4 and TNF-α synergistically induce expression of VCAM-1 on vascular endothelial cells. Human umbilical vein endothelial cell (HUVEC) monolayers were stimulated with 10 ng/mL TNF-α **(A)**, 0.2 ng/mL TNF-α **(B)**, 100 U/mL IL-4 **(C)**, or both 0.2 ng/mL TNF-α and 100 U/mL IL-4, and then fixed in methanol, pretreated with 2% fish gelatin to block nonspecific Ig binding, and incubated with Abs against VCAM-1. Primary antibody binding was detected with FITC-conjugated goat antimouse IgG. Bar = 40 μm.

IL-4–Dependent Recruitment of Immune Cells   IL-4 has a number of actions that influence the development of airway inflammation. As noted above, it is critical for the gene activation underlying differentiation of B cells into Ab-forming cells and consequent production of IgE and IgG isotypes. In the context of the scheme for Th2-type immune cell recruitment to the airway, IL-4 may also exert a separate but critical influence. In particular, IL-4-driven expression of a cell adhesion molecule (VCAM-1) on the endothelial cell surface may serve in the recruitment of inflammatory cells (especially T cells and eosinophils bearing the $\alpha_4\beta_1$- and $\alpha_4\beta_7$-integrins) from the circulation. This possibility is supported by evidence of increased levels of immune cell IL-4 and endothelial cell VCAM-1 in tissue from asthmatic subjects as well as inhibition of allergen-induced airway inflammation in animals lacking the IL-4 gene or treated with anti–VCAM-1 antibodies. The precise mechanism for how IL-4 exerts its effect on VCAM-1 expression is uncertain, but it appears that it is not dependent on Stat6-driven gene activation. Instead, IL-4 acts in concert with other cytokines (TNF-α and IL-1). These cytokines are responsible for transcriptional activation of the VCAM-1 gene through two adjacent NF-κB sites in the promoter region, whereas IL-4 stabilizes the resulting mRNA. This cytokine synergy results in exaggeration and prolongation of VCAM-1 levels on the endothelial cell surface (Fig. 36-2). As depicted in Fig. 36-1, this cytokine synergy may also reflect an important cell–cell interaction in which TNF-α (and in some cases IL-1) derived from mast cells and eosinophils acts in concert with IL-4 (and in some cases IL-13) derived

from mast cells, eosinophils, Th2 cells, and possibly basophils to promote immune cell recruitment to the airway.

Other Mechanisms for Recruitment of Immune Cells   In addition to IL-4 and TNF-α effects on VCAM-1, other events in endothelial cells and immune cells are also critical for full development of the Th2-type inflammatory response. For example, at least two other cell adhesion systems appear to be activated during allergen-triggered airway inflammation: (1) selectin binding to mucin-like molecules; (2) other cell adhesion molecules of the Ig supergene family that bind to integrin receptors. In the case of endothelial cells, allergen may trigger endothelial-leukocyte adhesion molecule-1 (E-selectin) expression, which enables binding to a corresponding leukocyte sialyl-Lewis X carbohydrate ligand; and intercellular adhesion molecule-1 (ICAM-1) expression, which allows for binding to the leukocyte β_2-integrins LFA-1 ($\alpha_L\beta_2$) and Mac-1 ($\alpha_M\beta_2$). In addition to these cell adhesion systems for direct cell–cell contact, endothelial cells and immune cells also appear capable of generating a series of *chemo*attractant cyto*kines* (or chemokines) that may act over a greater distance to direct immune cell movement and activation in airway tissue. These three systems—selectin binding to mucinlike molecules, cell adhesion molecules binding to integrins, and chemokine binding to G-protein–coupled receptors—may act in a specific combination to dictate the type of immune cells that enter or get retained in the airway tissue (Fig. 36-3). These same systems also serve to control the activation status of immune cells acting at least in some cases through distinct signal transduction pathways.
Figure 36-3 Endothelial cell-dependent recruitment of immune cells from the circulation during inflammation. Proposed steps include: (1) selectin interaction with its carbohydrate ligand (e.g., E-selectin interaction with sialyl Lewis X); (2) Ig family member interaction with the corresponding integrin receptor (e.g., VCAM-1 and ICAM-1 interaction with VLA-4 and Mac-1 or LFA-1, respectively); and (3) α- or β-chemokine interaction with a corresponding chemokine receptor (e.g., RANTES interaction with the serpentine superfamily of G protein-coupled receptors). These three steps may occur sequentially in some but not all cases. For example, VCAM-1–VLA-4-integrin interaction may by itself initiate immune cell rolling as well as subsequent adhesion to endothelium.

Once inflammatory cells are recruited from the circulation, they are often directed toward the epithelial surface. It appears that epithelial cells (along with other parenchymal cells and resident immune cells) also possess at least two important mechanisms for influencing the movement of inflammatory cells after they arrive in the airway tissue: (1) concomitant activation of cell adhesion molecules on the epithelial cell surface that may interact with corresponding integrin receptors on the immune cell surface; (2) release of chemotactic factors that bind to specific receptors on the immune cell. In the case of airway epithelial cells (as noted *below*), these systems appear to be more responsive to Th1-type cytokines, but there is evidence that they are also influenced by the level of TNF-α. Thus, even in the absence of a Th1-type response, epithelial levels of cell adhesion molecules (especially ICAM-1) and certain chemokines (from the α- and β-chemokine families) are capable of supporting transepithelial migration and activation of immune cells.

Interestingly, there is no evidence of selectin or VCAM-1 expression on airway epithelial cells (or fibroblasts and smooth muscle cells); thus, it is likely that these cell types present fewer ligands than do endothelial cells for directing leukocyte movement. The biologic basis for this difference is not certain, but it makes sense: endothelial cells must be armed with ligands that slow down passing leukocytes (to allow tethering and triggering) and then select a specific leukocyte subset (to allow adhesion and transmigration) from the diverse circulating pool. This requires multiple specific molecular interactions. By contrast, parenchymal cells (epithelial cells, fibroblasts, and smooth muscle cells) come into contact with immune cells after selection and some

degree of activation, so that they are required only to facilitate further leukocyte migration and retention. ICAM-1 is well-suited to mediate this process because nearly all immune cells constitutively express the β2-integrins LFA-1 or Mac-1. In the case of T-cell traffic, the endothelial cells (and likely epithelial cells) also express a series of receptors (designated homing receptors or addressins) that serve to direct distinct subsets of lymphocytes to appropriate locations of lymphoid tissue. This type of cell adhesion (exemplified by some of the β7-integrin interactions) is probably most important in maintaining a resident population of immune cells, but whether this system is also regulated during airway inflammation remains uncertain.

Eosinophil-Derived Mediators Causing Inflammation Several lines of evidence indicate that eosinophils, once recruited to the airway, are a source of substances that mediate epithelial damage and endorgan dysfunction in asthma. As noted above, eosinophils may contribute to the local concentrations of IL-4, IL-5, and TNF-α that augment immune cell recruitment and activation. In addition, they contain a series of inflammatory mediators capable of causing dysfunction of airway smooth muscle, nerves, and glands, as well as damage to epithelial tissue. For example, eosinophils represent an active source of mediators derived from phospholipid arachidonic acid metabolism. This metabolic pathway leads to the production of bioactive compounds (including prostaglandins, leukotrienes, and platelet-activating factor) at higher than normal levels in asthmatic airways. Enzymes (including prostaglandin synthases, lipoxygenases, and phospholipases) and cell surface receptors for this pathway have been structurally characterized, and, in some cases, this information has led to the development of specific pharmacologic antagonists. For example, recombinant 5-lipoxygenase and its accompanying docking protein—the 5-lipoxygenase activating protein (designated FLAP)—have been expressed and used as targets for drug development. The functional significance of 5-lipoxygenase and its capacity to generate biologically active leukotrienes is underscored by the efficacy of 5-lipoxygenase and leukotriene antagonists to diminish airway responsiveness and improve airway function in asthmatic subjects.

Eosinophils also store and release a variety of substances (including major basic protein, eosinophilic cationic protein, and eosinophil-derived neurotoxin) that are toxic to cells. Because these substances are potent cytotoxins, some have suggested that epithelial detachment is a consequence of cell death. However, denudation of the epithelium may require proteolysis of the extracellular and membrane-associated proteins involved in cell adhesion to the basal lamina. This proteolytic activity may be provided by matrix metalloproteinases. For example, eosinophils are selectively capable of synthesizing and releasing an abundance of a specific matrix metalloproteinase (the 92-kDa gelatinase) with a substrate specificity capable of mediating epithelial detachment. This enzyme, as well as other proteases, may also aid in immune cell movement through tissue. Other matrix metalloproteinases (as well as members of the cysteine and serine protease families) derived from diverse cell types (including mast cells and T cells) may also influence immune cell movement and contribute to epithelial damage and end-organ dysfunction.

Other Mechanisms of Epithelial Damage and End-Organ Dysfunction In addition to lipid mediators and proteases, it is also possible that local production of nitric oxide is a component of airway inflammation in asthma. As noted below, this concept
Figure 36-4 Cell–cell interaction cascade for a Th1-type response in the airway. Proposed steps include: (1) respiratory virus (or other nonallergic stimulus) triggers NK cells (as well as Th1 cells and CD8+ T cells) to release IFN-γ; (2) IFN-γ triggers monocyte and macrophage release of IL-1 and TNF-α that in turn induce E-selectin (E-sel) and ICAM-1 expression on the endothelium and Mac-1 or LFA-1-dependent transendothelial migration of neutrophils; (3) IFN-γ also drives Stat1-dependent expression of ICAM-1 on epithelial cells that enables epithelial–T cell interaction and antigen presentation of virus to CD8+ T cells; (4) activated T cells (and epithelial cells) also release α- and β-chemokines (CK) that serve to direct neutrophils and mononuclear cells, respectively, to the airway; and (5) activated neutrophils and later mononuclear cells release additional cytokine and chemokine that autoamplifies immune cell influx and activation and local production of mediators contributing to epithelial damage.

may be more relevant to Th1-type models of host defense against respiratory pathogens, but in either case, it appears that local production of IL-1 can drive expression of an inducible nitric oxide synthase (i-NOS) in airway epithelial cells. Thus, the damaging effects of IL-1 on the epithelium may depend on overproduction of nitric oxide by the respiratory epithelium itself or by adjacent leukocytes. The precise cellular sources of IL-1 and nitric oxide in asthmatic airways, the pathway and specificity of nitric oxide-mediated damage, the effects of IL-1 and nitric oxide on epithelial repair, and the possibilities for therapeutic intervention by inhibiting nitric oxide production are still under study. For example, an i-NOS inhibitor given to asthmatic subjects is capable of reducing nitric oxide levels in the airway, but possible effects on airway inflammation are still uncertain.

TH1-TYPE T-CELL RESPONSE An abnormal sensitivity to inhaled allergen is responsible for asthma in some cases, but in other cases, it appears that patients develop asthma in response to nonallergic stimuli. Thus, just as IL-4-driven, Th2-dependent hypersensitivity to allergen may underlie allergic asthma, it is also natural to propose that an overexuberant or aberrant IFN-γ–driven, Th1-type reaction, incriminated in delayed-type hypersensitivity reactions, may underlie nonallergic airway inflammation and asthma. This possibility is consistent with evidence of increased IL-4– and decreased IFN-γ–producing T cells in airways of allergic asthmatics, as well as selective overexpression of IFN-γ in intrinsic asthmatics. As noted *above*, however, this concept may not be completely correct. Thus, the capacity for IFN-γ production may be increased even in atopic asthma. In addition, there may be concomitant release of IFN-γ (and IL-4) in response to allergen challenge. Thus, a Th1-type response may contribute to allergic as well as nonallergic asthma, but perhaps the clearest circumstance for a predominantly IFN-γ–driven Th1-type response in the airway may occur in response to infection with respiratory viruses. In some individuals, this response may mediate virus-induced airway inflammation and hyperreactivity. A scheme depicting the

cell–cell interactions that might occur in this type of Th1-dependent cascade is depicted in Fig. 36-4.

IFN-γ Generation The precise cellular and molecular events leading to generation of IFN-γ are uncertain, but it would seem likely that, in the case of respiratory viruses, an initiating event may be attachment of virus to the (epithelial) cell surface. Some viruses have learned to subvert the immune response by using epithelial cell adhesion molecules (such as ICAM-1) to gain attachment and possibly entry into the host cell. The next step, in which proliferation of intracellular virus may stimulate cytokine (especially IFN-γ) production is incompletely defined. This effect may occur directly, for example by virus-dependent major histocompatibility complex (MHC) class I repression and consequent stimulation of natural killer (NK) cells, or indirectly, by class I-dependent presentation of viral antigens to Th1 cells or antiviral CD8+ cytotoxic T cells. It is also possible that epithelial cells, once infected with virus, are induced to generate cytokines or chemokines that in turn activate immune cells, including IFN-γ–producing T cells. In either case, it appears that IFN-γ production may be controlled at a transcriptional level, but most information on the regulation of the IFN-γ gene promoter rests on cell model systems that use transformed T cells. In some systems, Th1-cell development and consequent IFN-γ production depends on the activity of IL-12. Interestingly, IL-12 may exert its actions through two additional members of the STAT family of transcription factors (Stat3 and Stat4).

IFN-γ–Dependent Recruitment of Immune Cells Once released, IFN-γ exerts a number of actions aimed to enhance antiviral defense. Perhaps most relevant to inflammation, IFN-γ may act to recruit and activate immune cells (especially T cells and macrophages) in the airway by enhanced expression of cell adhesion molecules and chemokines. As depicted in Fig. 36-4, activation of each of these systems at the level of the airway endothelium and epithelium may influence the development of airway inflammation and hyperreactivity. In the case of endothelial-dependent recruitment of inflammatory cells, IFN-γ–dependent activation of
Figure 36-5 Epithelial cell-dependent modulation of immunity and inflammation. Based on studies of airway epithelial cells in vivo and ex vivo, at least five families of mediators have been proposed to act as mediators of inflammation within the epithelium itself and in the underlying tissue: (1) lipid mediators include arachidonic acid metabolites prostaglandin E$_2$ (PGE$_2$) and 15-hydroperoxyeicosatetraenoic acid (15-HPETE); (2) cell adhesion molecules include ICAM-1; (3) cytokines include IL-1, IL-6, IL-10, IL-11, and IL-12; (4) chemokines include RANTES, IL-8, and MCP-1; and (5) redox species include nitric oxide (NO). Some of these substances act in autocrine regulation of epithelial cell functions (including ion transport and mucous secretion) whereas others act to regulate immune cell behavior.

tissue macrophages may result in the generation and release of IL-1 and TNF-α. As was the case for allergic inflammation, this mechanism serves to activate endothelial–immune cell adhesion. In particular, IL-1β and TNF-α are potent inducers of endothelial E-selectin and ICAM-1 expression.

As noted above, after inflammatory cells are recruited from the circulation, they are often directed toward the epithelial surface. This observation has led to the specific proposal that epithelial cells are a source of mediators that direct immune cell movement and the general concept that epithelial–immune cell interaction may influence inflammation (Fig. 36-5). In this regard, it appears that airway epithelial–T cell adhesion, transmigration, and activation depend on the cytokine-dependent expression of ICAM-1 on the epithelial cell surface, as well as the concomitant levels of expression and activation of LFA-1 on the T-cell surface. This system appears activated in asthma because there are increased numbers of activated T cells as well as increased ICAM-1 expression in the epithelium of asthmatic subjects. Interestingly, it is often epithelial (and not endothelial) expression of ICAM-1 that is consistently increased in biopsies of asthmatic versus normal airway tissue, and this appears to be the case in both allergic and nonallergic subjects.

Based on studies of isolated airway epithelial cells, it appears that the level of ICAM-1 is regulated by a specific IFN-γ–driven signal transduction pathway that consists of the IFN-γ–receptor, receptor-associated Jak1 and Jak2 tyrosine kinases, additional serine kinase(s), the Stat1 transcription factor, and a specific Stat1–DNA interaction in the ICAM-1 gene promoter region (Fig. 36-6). In this pathway, Stat1 serves to relay the signal from the cytoplasm to the nucleus (Fig. 36-7). Interestingly, Stat1–DNA interaction (as well as Stat1–Sp1 synergy) in the ICAM-1 gene promoter region may also be critical for IFN-γ responsiveness of other epithelial immune-response genes, especially interferon regulatory factor-1 (IRF-1). The IRF-1 gene product is itself a member of a transcription factor family and is responsible for activating the genes for i-NOS and possibly MHC class I molecules. Thus, a cascade of common molecular building blocks enables IFN-γ to efficiently and selectively activate an immune-response subset in the airway epithelial barrier to mediate mucosal immunity and inflammation. Stat1 appears to sit at a critical site in the development of this cascade, but the characteristics of Stat1-dependent gene regulation in airway inflammation in vivo are still poorly defined. Similarly, only a little has been established for the regulation or expression of chemokines in airway epithelial (or other parenchymal) cells in airway tissue. Initial evidence indicates that members of each chemokine family—α-chemokines (e.g., IL-8) and β-chemokines (e.g., monocyte chemoattractant protein-1 [MCP-1] and regulated upon activation, normal T expressed, and presumably secreted [RANTES])—are expressed in airway epithelial cells ex vivo and *in situ*, and, in some cases, the profile of chemokine activity fits with the pattern of immune cell infiltration (e.g., RANTES acts on T cells and eosinophils).

ASTHMA AS A GENETIC DISEASE

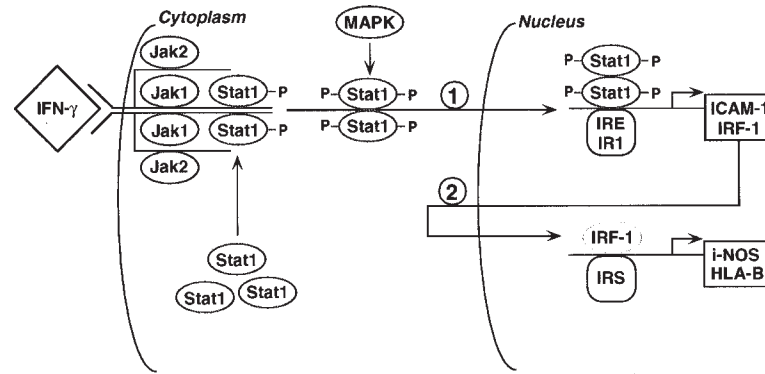
POPULATION AND FAMILY STUDIES Evidence that genetic factors are important in common diseases often comes initially from studies comparing the frequency of disease among genetically related individuals with that in the general population. Accordingly, the evidence for a genetic component to the development of asthma includes: (1) family studies indicating more frequent occurrence of asthma in first-degree relatives of asthmatic subjects; (2) familial aggregation patterns in which the rates of asthma were found to be significantly higher in those families with one or more asthmatic parent; and (3) studies showing that monozygotic twins are significantly more concordant for asthma than dizygotic twins. Reports during the past 50 years have proposed both simple mendelian and multifactorial models to explain the familial clustering of asthma (or allergy). These studies provided the general (not surprising) conclusion that the expression of asthma is likely to be heterogeneic and polygenic and to be the result of an interaction between genetic and environmental factors. Statistical analysis of data was often hampered by the absence


Figure 36-6 IFN-γ–driven signal transduction and gene activation. IFN-γ signal transduction begins when IFN-γ binds to its receptor and triggers activation of α-chain–associated Jak1 and β-chain–associated Jak2 tyrosine kinases and consequent α-chain phosphorylation. This step enables α-chain recruitment of Stat1 via its SH2 domain and subsequent Stat1 phosphorylation and release of the phosphorylated Stat1-homodimer. Additional evidence indicates an additional action of a serine-threonine kinase is needed to convey full activity. Two consequences (labeled 1 and 2) then occur: (1) activated Stat1 homodimer translocates to the nucleus where it binds to an inverted-repeated type motif in the IFN-γ–response element (IRE) or IFN-response 1 (IR1) site and activates (in concert with Sp1) transcription of the corresponding genes (ICAM-1 and IRF-1, respectively); and (2) newly generated IRF-1 mRNA is translated into protein that returns to the nucleus (based on its nuclear localization signal), binds to an IFN-response stimulation (IRS) site, and activates a second wave of transcription (for the i-NOS and HLA-B genes).
Figure 36-7 IFN-γ activates Stat1 and induces ICAM-1 in airway epithelial cells. Human tracheobronchial epithelial cell (hTBEC) monolayers were unstimulated (top row, A–C) or stimulated (bottom row, D–F) with IFN-γ (100 U/mL), fixed in methanol, pretreated with 2% gelatin to block nonspecific Ig binding, and then incubated with Abs against ICAM-1 (left column; A and D), Sp1 (middle column; B and E), or Stat1 (right column; C and F) in 2% fish gelatin. Primary antibody binding was detected with CY3-conjugated goat anti-mouse IgG. Control nonimmune IgG gave no signal above background. Bar = 40 μm.

of physiologic criteria for a specific asthmatic phenotype, the difficulty in separating inheritance of the atopic predisposition from the inheritance of asthma, or the lack of controls for environmental factors. The development of phenotypic markers for asthma (or subtypes of asthma) has served to facilitate studies of its inheritance.

PHENOTYPIC MARKERS AND INHERITANCE Bronchial hyperreactivity is a common phenotypic marker of asthma, and family studies (and animal models) suggest that hyperreactivity is under genetic influence. In fact, concordance among identical twins is significantly greater for bronchial reactivity than for asthma symptoms. In addition, bronchial hyperreactivity may be found in asymptomatic parents of asthmatic children without evidence of positive allergen skin tests or increased serum IgE, and the hyperreactivity is inherited in an autosomal dominant pattern. Other studies have provided similar results, but some indicate that the trait may not be caused by segregation at a single autosomal locus.

The discovery of IgE and the observation that its levels may increase in association with atopic disease quickly placed IgE (and in particular its level of biosynthesis) as a candidate marker for atopy. Several recent observations indicate that the level of total serum IgE may correlate even better with the development of asthma than for atopy. These results suggested that asthma resulted from IgE-dependent mechanisms even in the absence of identifiable allergen sensitivity. A separate follow-up study confirmed the relationship between asthma and IgE levels and established a similar link between bronchial hyperreactivity and total serum IgE levels. Other investigators have confirmed these results and have added that an increase in circulating eosinophils may also be linked to the asthma phenotype. Genetic models for the inheritance of IgE levels were proposed in a series of population and family studies to support the existence of a relatively common recessive regulatory locus, with recessive homozygotes maintaining persistently high levels of IgE. In addition, a significant multifactorial background was detected.

DNA MARKERS AND MOLECULAR GENETICS By using markers for DNA polymorphisms, at least two genetic loci have been linked to atopy and possibly to asthma. Initial work defined a single dominantly inherited locus located on chromosome 11q13 controlling IgE hyperresponsiveness. The apparent discrepancy in mode of inheritance between results derived from segregation versus linkage analysis may be related to the definition of phenotypes employed by the two types of studies. In the linkage studies, the definition of atopy was expanded to include asymptomatic subjects (identified by abnormal IgE responsiveness). Subsequent work on the 11q13-linked atopy "gene" suggested that it may be genetically linked to the site of the β-subunit of the high-affinity receptor for IgE and that a putative variation within this gene (Ile181Leu) may be associated with atopy. These findings suggest that the IgE receptor (FcεRI-β) is a candidate gene predisposing to atopy. However, at least three other studies failed to reproduce the association of the 11q13 locus with atopy or asthma, perhaps reflecting the variability in clinical expression, a role for environmental effects, or effects of genes at other loci. In further support of the view that there are other genes specific to asthma, additional work has linked markers for chromosome 5q31–33 with atopy (defined by total serum IgE) and bronchial hyperreactivity. The 5q site is near the genes for IL-4, IL-9, and IL-13 (implicated in the control of IgE biosynthesis) as well as additional candidate genes encoding for other cytokines, growth factors, and receptors (including the β$_2$-adrenergic receptor). Finer mapping of this region is aimed at better definition of candidate genes linked to asthma.

Because antigen-dependent immune and inflammatory mechanisms participate prominently in the expression of the asthmatic phenotype, a number of investigators have also attempted to establish linkage of asthma to loci within the major histocompatibility complex (MHC). The class I (HLA-A, -B, and -C) and class II (HLA-DP, -DQ, and -DR) genes are among the most polymorphic human genes described, with more than 10 alleles defined for each locus. The nature of this polymorphism has been extensively investigated using serologic reagents and more recently using nucleic acid typing probes. In some studies, significant HLA associations with asthma have been found, but in others there is no association between asthma and specific HLA alleles. It is likely that weak or conflicting associations are again realted to the heterogeneity of the phenotype and the possibility that a discrete abnormality may be restricted to a subset of asthmatic subjects. It also appears likely that a particular sequence is a necessary but not sufficient requirement of responsiveness to a particular antigenic epitope and that further genetic and environmental factors are required for the expression of specific immune responsiveness.

SUMMARY

Understanding and treating asthma depends on understanding how inflammatory cells infiltrate the pulmonary airway and how the resulting infiltrate leads to characteristic pathologic changes in airway tissue. In this context, investigators have pursued the regulatory controls over genes encoding for critical components of the immune response to inhaled allergic and nonallergic stimuli. Initial evidence indicates that allergic and nonallergic asthma exhibit separate but overlapping cell–cell interactions orchestrated by immune cells and airway parenchymal cells. In that context, several lines of evidence also point to genetic factors in the development of asthma. Population and family studies indicate that specific biologic abnormalities (increased serum IgE, bronchial hyperreactivity, and blood eosinophilia) may be useful markers of the asthmatic phenotype, and segregation analysis and linkage analysis for the asthmatic phenotype have suggested mendelian and polygenic patterns of inheritance as well as an influence of environmental factors. Taken together, the biochemical and genetic studies offer compatible approaches for further pursuit: (1) biochemical studies will aim to define individual candidate genes and mechanisms for gene regulation under conditions in which confounding environmental and genetic factors are largely eliminated; and (2) genetic studies will aim to link these candidates (forward genetics) and other unknown genes (reverse genetics) to the asthmatic phenotype. Evidence of linkage will in turn lead to finer mapping and perhaps further definition of genes that are abnormally expressed in the airway of asthmatic subjects.

37 Cystic Fibrosis

Daniel B. Rosenbluth and Steven L. Brody

INTRODUCTION

Cystic fibrosis (CF) is one of the most common lethal hereditary diseases of monogenic origin. The frequency of the disease is approximately 1 in 2500 births in the white population. CF is characterized by a classic triad that includes an increase in sweat chloride concentration, pancreatic insufficiency, and recurrent pulmonary infections. The onset of symptoms is typically within the first decade of life, often at birth. Lung disease is the most common cause of morbidity and mortality in individuals with CF. More than 90% of all CF deaths are directly related to respiratory disease. Remarkably, survival has increased dramatically during the past 20 years largely because of improved antibiotic therapies, pancreatic enzyme replacement, and nutritional support, so that median survival now exceeds 30 years. The cloning of the "CF gene" in 1989, called the cystic fibrosis transmembrane conductance regulator (CFTR) gene, has led to the identification of one specific mutation in approximately 70% of alleles in individuals with CF and more than 600 other disease-causing mutations. The characterization of CFTR has made possible the development of novel molecular strategies for the treatment of CF-related lung disease and potential cure of CF through gene therapy.

Identification of the CFTR gene has also driven the search for understanding how the genetic defect leads to the disease-causing cellular defect. The CFTR protein has been identified as a cyclic adenosine monophosphate (cAMP)-regulated chloride channel that functions in the apical aspect of epithelial cells. The current concept of pathogenesis of CF-related lung disease is that mutations in the CFTR gene result in inadequate function of the CFTR protein leading to abnormal airway secretions, inflammation, bacterial infection, abnormalities in lung architecture, and decline in lung function. The first major challenge for CF research is to define precisely how the absent or abnormal CFTR protein triggers the cascade of inflammation and infection in the lung, as well as how intestinal and pancreatic dysfunction occur. A second challenge is to use the current information regarding CFTR to further develop therapies that will improve the life of the individual with CF. This chapter will review the current understanding of the CFTR gene and protein function, the pathogenesis of CF, and emerging data from molecular-based therapies, including gene therapy. The major focus of this chapter is CF-related lung disease, the most common cause of morbidity and mortality in CF.

THE CFTR GENE

The CF gene was isolated in 1989 using the technique of positional cloning, based on the relationship of genetic linkage analysis of CF families to known chromosomal markers. Genetic analysis of affected families revealed that the CF gene was inherited in an autosomal recessive pattern and linkage analysis localized the gene to the region of a polymorphic DNA marker on the long arm of chromosome 7 at q31–32. Using other known gene markers, the CF gene was localized to a specific region of the chromosome that could be cloned and sequenced. Final identification of the gene was based on three findings related, in part, to previous observations of CF cell biology. First, on the basis of the predicted chloride or sodium channel functions of the protein, a specific deduced amino acid sequence with conserved features of an ion-transport channel was found. Second, transfection of the putative CFTR cDNA into epithelial cell lines derived from individuals with CF demonstrated an ability to reverse the defect of chloride conductance and to confer cAMP-regulated chloride channel activity. And third, a common 3-bp mutation that resulted in a deletion of a codon for the amino acid phenylalanine at position 508 (ΔF508) was found only in DNA from affected families.

The CFTR gene is located within a 250-kb region of genomic DNA and contains 27 exons. The gene codes for a 6.5-kb mRNA and a deduced protein composed of 1480 amino acid residues. Several alternatively spliced forms of mRNA have been identified. The promoter of the CFTR gene contains a G + C rich region with multiple transcription start sites and does not contain a characteristic TATA transcription complex initiation element. Promoter activity is relatively weak; however, transcription is tightly regulated and transcript abundance varies greatly with cell type. Transcription can be modulated in vitro using cAMP, phorbol esters, and protein kinase C activators. Putative *cis*-acting elements include sites for binding transcriptional activators AP1 and Sp1, factors that may be induced by cAMP and phorbol esters. Analysis of chromatin structure and methylation status of the CFTR promoter region suggests that several other mechanisms may be important for transcriptional regulation.

THE CFTR PROTEIN

Based on the CFTR cDNA sequence, the predicted amino acid sequence was found to contain regions similar to the ABC (ATP-binding cassette) family of transporters. These proteins have highly conserved transmembrane and nucleotide-binding domains and include well-characterized family members, such as the yeast ster-

CFTR cDNA
CFTR protein
Figure 37-1　Structure of cystic fibrosis transmembrane conductance regulator (CFTR) cDNA and protein. Shown above is a schematic diagram of the structure of the CFTR cDNA with 27 exons indicated by boxes and labeled with the predicted protein domain coded for by the cDNA. A model of the CFTR protein positioned in the apical membrane of the epithelial cell is shown below. The transmembrane domains are flanked by nucleotide-binding domains (NBD) that bind ATP. The regulatory domain (R domain) contains sites for protein kinase A (PKA) and C (PKC) phosphorylation. The location of the ΔF508 mutation is indicated. N is the amino-terminus and C is the carboxy-terminus of the protein. Sites of posttranslational glycosylation by amino (N)-lined carbohydrates are indicated. (Adapted from Zielenski and Tsui with permission from the Ann Rev Gen, 1995; 29; 777–807. © 1995 by Annual Reviews Inc.)

ile 6 protein and the eukaryotic P glycoprotein (the multiple drug-resistance protein). The structure of the CFTR protein consists of two membrane-spanning domains, each containing six transmembrane segments, two nucleotide-binding domains (NBD), and an intracellular hydrophobic regulatory (R) domain (Fig. 37-1). The R domain contains several putative sites for protein kinase A and protein kinase C phosphorylation that play a central role in CFTR regulation. The two NBDs are located intracellularly and flank the membrane-spanning domains. The NBDs represent putative sites for binding and hydrolysis of ATP. The CFTR structure is therefore consistent with a regulated channel molecule. However, unlike other members of the ABC family, CFTR exhibits chloride channel activity.

The function and regulation of the CFTR protein as a chloride channel is based on structural features and is consistent with classic observations in cells obtained from individuals with CF. Before the identification of CFTR, studies in CF cells in the 1980s revealed a defect in cAMP-activated chloride conductance in the epithelial cells of the sweat gland and airway. In the sweat duct, CF cells are unable to normally reabsorb chloride ions, resulting in a high concentration of chloride in the sweat. In the CF airway, epithelial cells are unable to secrete chloride in response to cAMP agonists and sodium reabsorption is markedly increased. Based on alteration in sweat chloride, abnormal chloride conductance across cells, and abnormal sodium reabsorption, it was predicted that the CF gene may be involved with ion transport. Thus, the observation

that expression of the normal CFTR cDNA in CF epithelial cell lines corrected the defect in cAMP-regulated chloride permeability was consistent with clinical observations. The specific function of CFTR was more directly verified by demonstrating that purified, reconstituted CFTR fused into lipid bilayers resulted in chloride channel activity with characteristics identical to the CFTR expression in epithelial cell membranes.

The CFTR protein is regulated by phosphorylation of the R domain by cAMP-regulated protein kinase A; however, this alone is not sufficient to activate CFTR chloride channel activity. After phosphorylation, binding and hydrolysis of ATP at the NBD is essential for normal channel gating (opening and closing). Chloride movement through the gate is determined by the electrochemical gradient and does not require further energy. CFTR is proposed to have other functions such as regulating sodium and water channels, transporting other ions, acidification of intracellular vesicles, regulation of endosome fusion, and plasma membrane recycling.

CFTR functions at the apical cell membrane of the epithelial cell to move chloride out of the cell and into the lumen, and also regulates chloride and sodium transport through other channels. In the apical membrane, the alternate chloride channel (Cl_a), the outwardly rectifying chloride channel (ORCC), or other channels also move chloride out of the cell. Recent studies suggest that CFTR directly influences ORCC activity by regulating release of or directly transporting ATP out of cells. The extracellular ATP activates the ORCC in an autocrine fashion, presumably by bind-

ing to an apical membrane purinergic receptor, to move additional chloride out of the cell. Intracellular electrical neutrality and sodium and water movement are also regulated at the apical membrane by the epithelial sodium channel (ENaC) and at the basal lateral membrane by sodium–potassium ATPase. In vitro, CFTR has been shown to regulate ENaC by inhibiting sodium reabsorption through ENaC. The absence of CFTR expression results in increased ENaC activity and enhanced sodium reabsorption, likely accounting for the enhanced sodium reabsorption noted in measurements in vitro and in vivo.

LOCALIZATION OF CFTR EXPRESSION Normal CFTR expression exhibits cell specificity and is developmentally regulated. CFTR expression can be detected using RNA blot analysis, *in situ* hybridization, or immunohistochemistry in epithelial cells of the sweat gland, nose, lung, salivary gland, bile ducts, gall bladder, pancreas, small intestine, colon, kidney, epididymis, uterus, and fallopian tube. Unexpectedly, CFTR expression in the airway is at a low level and is difficult to detect, despite a detectable cAMP-regulated chloride transport function. Onset of CFTR expression in the yolk sac, intestine, and lungs of the normal fetus occurs as early as the seventh week of gestation. During lung development, the CFTR gene is expressed in a temporal and spatial pattern within airway epithelial cells. CFTR expression is initially detectable in primitive epithelial cells of the lung bud during the glandular stage (at 5–10 weeks) but at birth is limited to the epithelial cells of the bronchi and small airways, with none detectable in the alveolar sacs. In the normal adult lung, CFTR expression is most marked in epithelial cells of the submucosal glands and is present at lower levels in bronchial and bronchiolar epithelial cells. In general, the expected localization of CFTR appears to be directly related to the sites of pathologic change in CF. However, CFTR can also be detected in some organs not typically affected in individuals with CF, including the salivary glands and kidney, suggesting that CFTR function is not important in these tissues or that nongenetic factors may also play a role in phenotype.

PATHOGENESIS OF CF-RELATED LUNG DISEASE

The relationship between the loss of CFTR function, abnormal chloride and sodium transport, and disease pathology remains a fundamental question. The current paradigm that relates a loss of CFTR function with dysfunction in multiple organ systems is that defective chloride secretion (and sodium reabsorption) results in abnormal, dehydrated secretions within the epithelial cell-lined ducts of the involved organ. The abnormal secretions lead to impaired fluid flow, plugs and obstructions within these ducts, and eventually, end-organ injury and dysfunction. The size and complexity of a duct, the nature of duct secretions, and the flow rate within the duct are all postulated to be important factors that lead to variation in CF phenotype. Many of these pathogenic factors can be appreciated when considering the example of CF-related pathologic changes in the pancreas. The pancreatic ducts become obstructed with inspissated secretions and concretions, and dilated, leading to fatty replacement and fibrosis of the pancreas and pancreatic exocrine insufficiency occurring in greater than 85% of individuals with CF. By similar mechanisms, bile duct obstruction leads to focal biliary cirrhosis. Obstruction of the vas deferens, a long tortuous tube carrying a high glycoprotein load, may account for the obliteration of the vas deferens found in greater than 95% of men with CF. CF-related lung disease may develop by similar mechanisms; however, direct contact with the environment

through the airway makes the pathogenesis of lung injury more complex.

As with the pathogenesis of all CF organ injury, the development of the chronic obstructive pulmonary disease typical of CF-related lung injury is incompletely understood. The CF lung at birth appears histologically normal. It is believed that airway epithelial cell defective chloride secretion and excessive sodium absorption contribute to the formation of dehydrated, excessively viscid airway secretions. These secretions are postulated to be ineffectively cleared by the airway mucociliary apparatus because of high viscosity and an inability of the airway epithelial cells to alter the height of the periciliary sol layer for optimal ciliary function. The retained secretions are thought to lead to an increase in airway inflammation and, when infected by bacteria, lead to an ongoing cycle of lung injury. The current concepts of the pathogenesis of lung inflammation, infection, and injury are discussed *below* and are diagrammed in Fig. 37-2.

INITIATION OF AIRWAY INFLAMMATION The initiation of inflammation or infection in the CF lung occurs in the small airways or bronchioles less than 1 mm in diameter. Abnormal mucus results in retained mucous plugs or foreign particles that serve as a nidus for bacterial colonization and infection, and initiate an inflammatory response. Airway inflammation has been demonstrated to begin early in life without evidence of coexisting infection. Analysis of bronchoalveolar lavage fluid obtained from infants with CF, when compared with normal infants, reveals increases in numbers of neutrophils, concentration of neutrophil chemotaxis cytokine interleukin-8 (IL-8), free neutrophil elastase, and elastase–α_1-antitrypsin (α_1-AT) complexes. In these studies, bacterial pathogens could not be isolated in nearly half the infants with CF, indicating that airways inflammation may precede infection. These findings support the hypothesis that airway inflammation may be elicited solely by the accumulation of abnormal secretions. Alternatively, infection may have been present previously but cleared by the inflammatory response, or may have been present below the level of detection. Another interpretation of this data is that there is an obligatory role for CFTR in the regulation of the inflammatory cascade such that the lack of CFTR function results in increased inflammation. Regardless, the lack of proper CFTR expression is clearly associated with the initiation of airway inflammation and infection.

BACTERIAL PATHOGENS SPECIFIC TO THE CF AIRWAY The unique pattern of bacterial infection in the CF lung is a hallmark of the disease. However, the mechanism of bacterial species-specific infection has yet to be elucidated. In infants and children, *Staphylococcus aureus* and *Haemophilus influenzae* are the predominant pathogens. With advancing age, *Pseudomonas aeruginosa* becomes the most common pathogen. Once the CF lung has established colonization with *P. aeruginosa*, the bacteria is rarely eradicated. Several factors may be responsible for *P. aeruginosa* persistence, including virulence factors produced by *P. aeruginosa*, factors related to CFTR function, and host response.

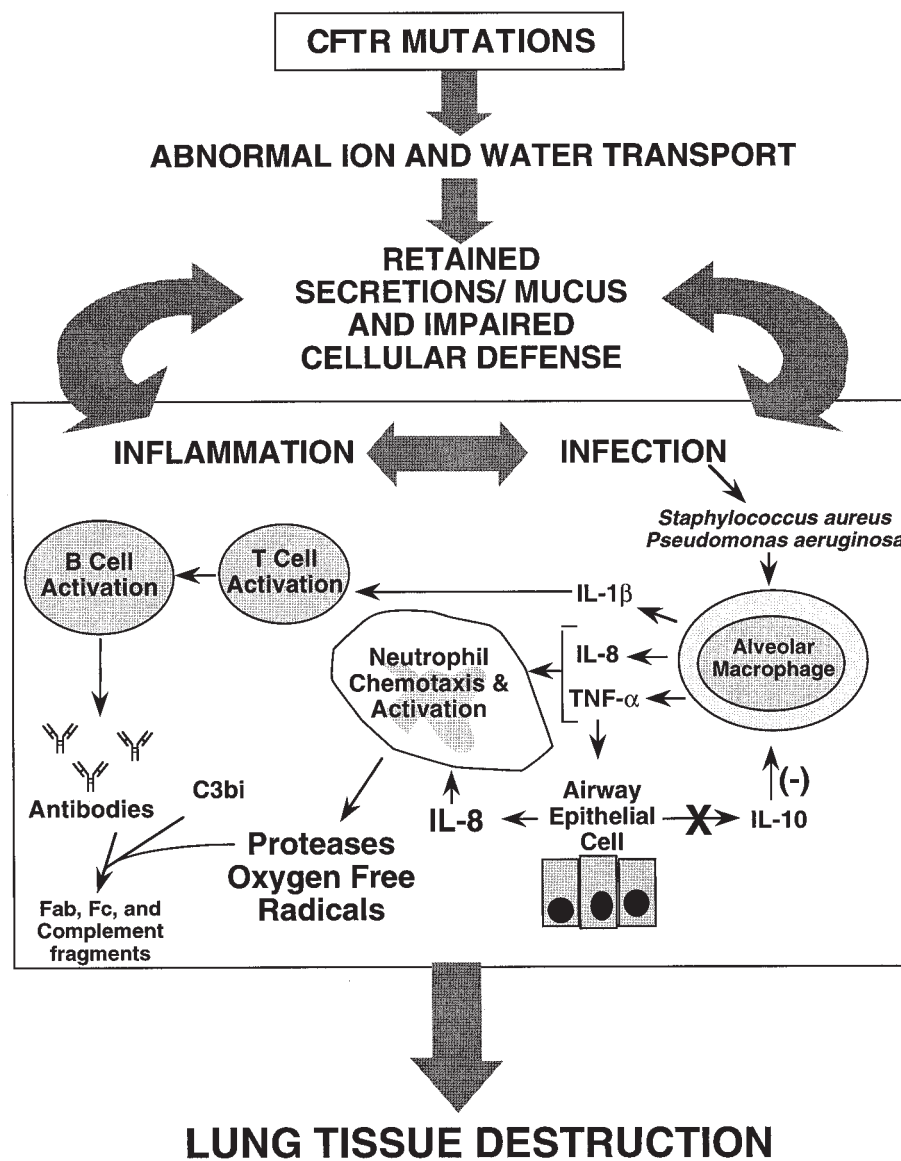
Bacterial factors leading to persistent infection include those elaborated by *Pseudomonas* to enhance bacterial survival. *Pseudomonas aeruginosa* can produce unique ciliotoxins capable of impairing ciliary function and *Pseudomonas*-specific proteases that can cause local lung tissue damage and injure cilia. Persistent colonization is also facilitated by the expression of *Pseudomonas*-specific bacterial genes coding for the production of alginate. Alginate is an exopolysaccharide that causes the mucoid appearance of


Figure 37-2 Pathogenesis of cystic fibrosis-related lung disease. Proposed mechanism for the development of CF-related lung disease. CFTR mutations lead to abnormal salt and water transport, which in turn result in retained desiccated airway secretions and possibly impaired defensin function. This results in chronic airways infection and inflammation that culminates in lung tissue destruction. The neutrophil is the central component of the inflammatory response being attracted to and activated in the CF airway by IL-8, TNF-α, and components of complement. Proteases and cytokines released by neutrophils attract additional inflammatory cells to CF airways, directly damage the airway, and may even perpetuate infection by cleaving antibodies and complement. (*See text* for further details.)

P. aeruginosa when cultured, and protects the bacterium from host defenses, antibiotics, and phagocytosis by neutrophils.

Loss of CFTR function may specifically allow enhanced epithelial cell infection and impair bacterial clearance. A predisposition for chronic infection of CF airways specifically with *S. aureus* and *P. aeruginosa* is suggested by studies proposing that impaired CFTR function raises the pH within the *trans*-Golgi complex. Alkalinization of the intraorganelle environment decreases sialyltransferase activity and results in the production of undersialylated proteins. Increased numbers of undersialylated proteins and gangliosides have been found in the apical membranes of CF epithelial cells, and in contrast to normally sialylated molecules (in non-CF cells), these asialogangliosides have been shown to specifically bind *S. aureus* and *P. aeruginosa*, but not

other bacterial pathogens. Additional studies have shown that a ΔF508 airway epithelial cell line failed to internalize applied *P. aeruginosa*. This effect was specific for *P. aeruginosa*, and growing the cells at 26°C (a process that partially corrects ΔF508 CFTR expression on the cell surface) resulted in epithelial cell *P. aeruginosa* ingestion similar to that of control cells. Last, defensins, antibacterial peptides that possess an ability to specifically kill *S. aureus* and *P. aeruginosa* has been found to be secreted by both normal and CF cells. This bactericidal activity is inhibited by high sodium chloride concentrations, similar to the conditions predicted to be present in the sol layer of CF airway epithelial cells. Transfer of the normal CFTR cDNA to the CF cells results in eradication of the infection. If these conditions can be shown to exist in vivo it may provide a more specific explanation for the

relationship between CFTR dysfunction, the chloride imper-meability of CF airway epithelial cells, and the development of chronic infection in CF airways.

The antibody-mediated immune response resulting in the clearance of *P. aeruginosa* from the CF lung also appears to be impaired. Anti-*Pseudomonas* IgG titers increase with chronic infection and rising titers correlate with worsening lung disease. The increase in total IgG is primarily caused by an increase in the IgG_2 subclass antibody. The increased IgG_2 impairs *P. aeruginosa* clearance for two reasons. First, IgG_2 has a relatively low affinity for macrophage and lymphocyte Fc and complement receptors, decreasing the efficacy of the normal antibody-mediated antibacterial immune response. Second, IgG_2 is the predominant IgG subclass found in circulating immune complexes that compete with opsonized bacteria for Fc receptors located on phagocytic cells. Thus, the shift in IgG subclass production and consequent inhibition of phagocytosis may contribute to the persistence of *P. aeruginosa* airway colonization and the inflammatory response in the CF lung.

THE CHRONIC INFLAMMATORY RESPONSE The immune response to chronic airways infection is robust, and recruitment and activation of neutrophils is a central feature. Major cytokine mediators of neutrophil chemotaxis that are increased in the CF airway include tumor necrosis factor-α (TNF-α) and IL-8. These cytokines are released from macrophages that are activated by lipopolysaccharide (LPS), TNF-α, and other mediators of inflammation. TNF-α also may induce airway epithelial cells to express IL-8. Additionally, *P. aeruginosa* directly stimulates respiratory epithelial cells to produce IL-8 via two mechanisms. First, *P. aeruginosa pili* and flagella that mediate *P. aeruginosa* adhesion to epithelial cells can induce IL-8 production by epithelial cells. However, *P. aeruginosa* mutants that do not express either of these adhesins (and which may be present in CF lungs with chronic disease) can stimulate IL-8 production by epithelial cells through a second mechanism. *Pseudomonas aeruginosa* secrete an exoproduct called the *Pseudomonas* autoinducer (PAI). PAI is a homoserine lactone derivative that can stimulate epithelial cell IL-8 production in a dose-dependent manner and this may perpetuate airway inflammation. Neutrophils recruited into the airway also express IL-8 and amplify the inflammatory process.

Inflammation and immune activation is also mediated by interleukin-1β (IL-1β), a cytokine with elevated levels in the bronchoalveolar lavage fluid from individuals with CF. IL-1β is produced by macrophages and activates neutrophils and T cells that, in turn, produce various other cytokines resulting in B-cell differentiation and antibody production. Counterregulatory cytokines capable of decreasing TNF-α and IL-1β levels are inhibited in CF. Interleukin-10 (IL-10) can attenuate inflammation by decreasing LPS-induced macrophage production of TNF-α and IL-1. IL-10 is constitutively produced by normal bronchial epithelial cells but is downregulated in the bronchial epithelial cells of individuals with CF, resulting in unopposed inflammatory cytokine release.

Bacterial products, abnormal mucus, complement activation products (e.g., C5a), and proinflammatory cytokines all contribute to the persistence of a high neutrophil burden in the CF airway. Neutrophils release oxygen free radicals and proteases that result in lung tissue damage, and ultimately can contribute to the development of bronchiectasis that is characteristic of CF. Proteases are released from activated neutrophils during phagocytosis or cell death. Proteases include cathepsin G, proteinase-3, collagenase, and others, but the serine protease neutrophil elastase appears to be most important for several reasons. First, neutrophil elastase can directly damage lung epithelial cells and degrade elastin and other components of lung extracellular matrix. Second, neutrophil elastase is capable of cleaving the Fc portion of intact IgG, and thereby inhibits macrophage-mediated phagocytosis of *P. aeruginosa*. Third, neutrophil elastase also cleaves CR1, which is the neutrophil receptor for C3b (one of the major opsonic components of complement that binds *P. aeruginosa*), and C3bi, which is the other major opsonic component of complement. By inhibiting neutrophil complement-mediated phagocytosis and antibody-mediated phagocytosis, neutrophil elastase likely contributes to the persistence of *P. aeruginosa* infection in the CF airway and ongoing lung destruction. Fourth, neutrophil elastase also stimulates epithelial cells to produce additional amounts of neutrophil chemotactic factor IL-8. Finally, neutrophil elastase induces hyperplasia of goblet cells and mucous-secreting cells of the airway. Mucous hypersecretion and extracellular DNA and actin released from dead neutrophils are added factors that adversely alter the physical properties of the abnormal CF airway secretions and promote the "vicious cycle" of lung inflammation, infection, and injury (Fig. 37-2).

The lung is normally protected from the deleterious effects of neutrophil elastase by the antiprotease α_1-AT and secretory leukoprotease inhibitor (SLPI). Although measured concentrations of α_1-AT and SLPI appear normal in airway epithelial lining fluid obtained from individuals with CF, most of the α_1-AT is complexed with neutrophil elastase or degraded. The persistent increased neutrophil elastase activity found in the airway epithelial fluid of the adult CF lung suggests that the relative level of α_1-AT is inadequate to protect the lung from injury.

CFTR GENOTYPE-PHENOTYPE RELATIONSHIPS

More than 600 disease-causing CFTR mutations have been identified. However, the ΔF508 mutation accounts for 66% of all mutant CFTR alleles identified. The ΔF508 mutation is a three-nucleotide deletion that results in the in-frame deletion of phenylalanine in position 508 of the CFTR protein. The next most common CFTR mutation, G542X, has a frequency of only 2.4%. Although most CFTR mutations are relatively infrequent, mutation frequencies vary considerably between nationalities, ethnic groups, and geographic locations. Some of the most common CFTR mutations are listed in Table 37-1.

TYPES OF MUTATIONS CFTR mutations may be classified by genetic mechanism into categories of missense, nonsense, frameshift, RNA splicing, and amino acid deletions. Mutations can also be separated into five classes based on the biochemical and physiologic consequences of the mutation on CFTR function. Class I mutations are those that result in absent or truncated CFTR protein synthesis because of premature termination of CFTR mRNA translation or the production of unstable mRNA. These mutations are usually caused by nonsense mutations resulting in a premature stop codon, frameshift mutations, or mutations that result in abnormal splicing of the mRNA. Class II mutations result in defective CFTR protein processing. In these mutations, CFTR protein is improperly folded and is degraded in the endoplasmic reticulum. Consequently, CFTR activity at the apical membrane is absent. An important example of this class is the ΔF508 mutation, which results in a partially glycosylated protein that is eventually degraded in the endoplasmic reticulum. It has been observed that,

Table 37-1
Common Cystic Fibrosis Mutations[a]

Mutation	Frequency (%)[b]	Mutation class[c]	Phenotypic association	Population with increased prevalence[b]
ΔF508	66	II	Severe disease	
G542X	2.4	I	Severe disease	Spanish
G551D	1.6	III	Severe disease	English
N1303K	1.3	II	Severe disease	Italian
W1282X	1.2	I	Severe disease	Ashkenazi-Jewish
R553X	0.7	I	Severe disease	German
621 + 1G→T	0.7	I	Severe disease	French Canadian
1717-1G→A	0.6	I	Severe disease	Italian
R117H	0.3	IV	Pancreatic sufficiency

[b]Mutations are designated by the code letter for the normal amino acid, followed by the amino acid position, and the letter of the substituted amino acid or an X, which denotes a nonsense mutation. A Δ indicates deletion of the amino acid whose letter follows it at the noted position. A + or – indicates mutations at various positions within introns relative to the cited position.

[c]Mutation class designated by biochemical or physiologic effect on CFTR protein.

if cells with the ΔF508 mutation are maintained at 26°C, some of the mutant protein becomes fully glycosylated and is transported normally to the apical membrane, where it is functional. Class III mutations result in proper localization of CFTR but in defective CFTR regulation. The degree of dysregulation can be determined by the response to ATP stimulation and may be mild if there is some residual chloride channel function, or severe (e.g., G551D) if the protein is fully dysfunctional. Class IV mutants result in defective chloride channel conductance and are often caused by mutations within regions coding for the transmembrane domains of the CFTR protein. The reduction in chloride channel activity caused by these mutations is variable. Class V mutations are those that result in the reduced synthesis of normal, functional CFTR protein and may be caused by mutations that result in alternative mRNA splicing, altered protein processing, or mutations in promoter sequences.

GENOTYPE-PHENOTYPE CORRELATION Following identification of multiple CFTR mutations, another aim of CF research has been to determine whether specific CFTR mutations and resultant CFTR dysfunction could be correlated with the variability in clinical manifestations of CF. It has been hypothesized that persons with two of the more severe CF mutations (usually from classes I, II, or III), might have different or more severe manifestations of their disease than those with more moderate CF mutations (i.e., class IV or V), in which some residual CFTR function may be expected. Studies have shown that patients who are compound heterozygous for a severe mutation (e.g., ΔF508) and one of a few more moderate mutations (e.g., R117H, A455E, 3849+10kbC→T) are more likely to maintain pancreatic sufficiency than patients with two "severe" mutations. One small study suggests an association between the A455E mutation and mild lung disease. However, in general, good correlation between CF mutations and lung disease has not been demonstrated. Furthermore, no genetically based explanation has been provided to account for differences in clinical manifestations of individuals with identical mutations. These studies may be hindered by the cross-sectional design, mortality bias, and the small number of individuals with various mutations. They also are confounded by environmental, infectious, and other

genetic factors that may be important for the development of CF-related problems.

The recognition that chromosomal background affects CF phenotype has been important for understanding some genotype-phenotype correlation. These observations are based on differences in the nucleic acid sequence of the CFTR gene intron 8 splice site acceptor. The normal variant intron 8 splice site acceptor contains a sequence of seven thymidines (7T). Variants containing five thymidines (5T) and nine thymidines (9T) are also found, and these variants affect exon 9 splicing of the CFTR mRNA. In the presence of the 5T allele, the CFTR mRNA lacks exon 9 and codes for a nonfunctional protein. The effect of chromosomal background on phenotype can be observed in the example of the moderate R117H mutation. The R117H mutation can be found on the same allele as a 5T or 7T intron 8 variant. When R117H is found on the 7T background in the compound heterozygous individual, CF is a phenotypically less severe disease than if the mutation is found on the 5T background.

Congenital bilateral absence of the vas deferens (CBAVD) occurs in 95% of individuals with CF (leading to sterility), but may occur in isolation. When individuals with CBAVD who were otherwise asymptomatic were screened for CF mutations and the presence of the 5T variant, it was found that greater than half had either a non-5T variant + CF mutation on each allele, or a non-5T variant + CF mutation on one allele and a 5T variant with a wild-type CFTR on the other allele. These genotypes are correlated with decreases in the level of CFTR function and not necessarily with CF disease. These data, together with other studies, have led to the concept that CFTR-related end-organ dysfunction is based on the amount of active CFTR properly expressed in cells (Fig. 37-3). In this paradigm, the vas deferens is most sensitive to CFTR dysfunction, possibly related to the complex structural and flow aspects of the tubule. Individuals expressing more than 8–12% of normal CFTR mRNA are phenotypically normal, whereas those with only 1–3% of normal CFTR activity have typical pancreatic-insufficient CF with chronic lung disease. Individuals with levels of CFTR activity between these ranges have varying degrees of end-organ involvement, including CBAVD and CBAVD with pancreatic sufficiency and CF-related lung disease.
Figure 37-3 The relationship of CFTR activity to CFTR phenotype and genotype. Individuals with greater than approximately 10% normal CFTR activity are unaffected. Levels of normal CFTR activity below 10% are associated with increasingly severe disease ranging from congenital bilateral absence of the vas deferens (CBAVD), to pancreatic-sufficient cystic fibrosis lung disease (PS-CF Lung Disease), to typical pancreatic-insufficient CF lung disease (PI-CF Lung Disease), in a CFTR activity-dependent fashion. Genotype examples are shown on the right, indicating a normal CFTR (WT), an intron 8 polythymidine normal variant (7T) or altered splicing variant (5T), a moderate CFTR mutation [CF(M)], or a mutation associated with typical CF disease (CF). Phenotypes are not strictly correlated with exact thresholds of CFTR activity, therefore the same genotype may express different phenotypes in different individuals. The combination of a CF mutation with a 5T variant on the other allele may be associated with unaffected, CBAVD, or the PS-CF Lung Disease phenotypes. Genotype combinations with one CF(M) may preserve some residual CFTR activity. CF(M) plus one severe CF mutation (CF), or two CF(M) together are associated with CBAVD or PS-CF Lung Disease. The presence of two severe CF mutations is usually associated with typical PI-CF lung disease. (Adapted from Chillón et al. with permission of the publisher.)

Figure 37-4 Molecular strategies for cystic fibrosis (CF) therapies. Novel molecular-based therapies for CF-related lung disease target several sites within the CF airway epithelial cell. To catalyze the breakdown of viscous secretions present in the CF-lung, recombinant human deoxyribonuclease (rhDNase) is delivered by aerosol. To inhibit neutrophil-mediated proteolytic injury, exogenous protease inhibitors α-1 antitrypsin (α_1-AT) and secretory leukoprotease inhibitor (SLPI) have been administered. To modulate apical membrane ion transport, the alternative chloride channel (Cl-a) can be activated by extracellular nucleotides and their analogs to secrete chloride in compensation for the defective cystic fibrosis transmembrane conductance regulator (CFTR) channel. Also, the hyperabsorption of sodium, mediated by the epithelial sodium channel (ENaC) when CFTR channel function is absent, can be blocked by amiloride and its analogs. Molecular chaperones can correct the abnormal intracellular trafficking of mutant CFTR (e.g., ΔF508) and help deliver mutant CFTR (degraded in the Golgi) to the apical membrane. To complement the mutant CFTR gene, strategies using gene therapy vectors to deliver a normal CFTR cDNA can be used. The gel and sol layers of airway mucus are labeled.

MOLECULAR-BASED THERAPEUTIC STRATEGIES

The increased knowledge of the molecular mechanisms of CFTR structure and function provides opportunities to design innovative therapies aimed at correcting the CF defect at the molecular level. These therapies might include those that attenuate inflammation, normalize CFTR trafficking within the cell, correct the ion transport abnormalities found in CF, deliver normal CFTR to cells within the lung, or deliver the normal CFTR gene to cells (Fig. 37-4). Many of these experimental strategies have been logically directed toward CF-related lung disease. In this regard, the lung is uniquely in communication with the outside environment, allowing novel approaches for aerosolized delivery of therapeutic agents, specifically directing therapy to the affected organ.

DEOXYRIBONUCLEASE I Extracellular DNA released from degraded neutrophils in the CF lung contributes to increased airway mucous viscosity. Deoxyribonuclease I (DNase) is an enzyme that cleaves extracellular DNA in CF airway secretions and is capable of decreasing CF sputum elasticity. When recombinant human DNase is administered via aerosol to the airways of individuals with mild to moderate CF-related lung disease, there

is an improvement in lung function and decreased need for administration of intravenous antibiotics. Actin is an additional neutrophil product that increases CF sputum viscosity. Two agents that cleave actin, gelsolin and thymosin β4, are currently under investigation for use in CF-related lung disease.

ANTI-INFLAMMATORY THERAPY Chronic inflammation is present throughout life in the lungs and other organs of individuals with CF and is a major contributor to the structural damage characteristic of CF. It has been hypothesized that modulation of the inflammatory response might favorably alter the progression of CF-related lung disease and improve survival. Systemic nonspecific agents and lung-directed anti-inflammatory therapies have been investigated.

Systemic anti-inflammatory therapy with corticosteroids or nonsteroidal anti-inflammatory agents have been evaluated in clinical trials. Corticosteroids (prednisone, 1 mg/kg) administered orally on alternate days slowed the decline in lung function in individuals with mild to moderate CF-related lung disease compared with the placebo-treated group. This result was attributed to the anti-inflammatory effects of corticosteroids, but after 2 years of therapy, the therapeutic benefit was offset by growth retarda-

tion, cataract formation, and a higher incidence of abnormal glucose metabolism in the steroid treated group. The incidence of these adverse effects is decreased by the use of inhaled corticosteroids, although a definite benefit has not been demonstrated. Another anti-inflammatory agent, ibuprofen, in high doses, inhibits migration and aggregation of neutrophils and release of neutrophil lysosomal products. Administration of high-dose ibuprofen to individuals with mild CF-related lung disease was well-tolerated and slowed the decline of lung function in some groups; however, the study size was small.

The benefit of pentoxifylline, a phosphodiesterase inhibitor that blocks TNF-α- and IL-1β-mediated neutrophil chemotaxis and degranulation in vitro, was also evaluated for CF-related lung disease. A small, placebo-controlled trial demonstrated that individuals with CF treated with systemic pentoxifylline for 6 months had no increase in sputum elastase concentrations, whereas elastase concentrations increased significantly in the placebo group. A trend toward improved pulmonary function in the pentoxifylline-treated group was noted and a larger study is underway.

PROTEASE INHIBITORS Endogenous protease inhibitors capable of binding and neutralizing neutrophil elastase have been evaluated in an attempt to blunt neutrophil-mediated lung injury in the CF lung. α_1-Antitrypsin is an endogenous inhibitor of neutrophil elastase produced by the liver that circulates in plasma to all tissues. Secretory leukoprotease inhibitor (SLPI) is an inhibitor of neutrophil elastase produced by the lung airway epithelial cells. Aerosolized inhaled α_1-AT has been shown to increase concentrations of α_1-AT in the respiratory epithelial lining fluid of individuals with CF, inhibit neutrophil elastase activity in the epithelial lining fluid, and restore the ability of neutrophils exposed to CF epithelial lining fluid to kill *P. aeruginosa*. Similarly, aerosolized SLPI decreased neutrophil elastase activity, total neutrophil numbers, and IL-8 levels in CF epithelial lining fluid. These results suggest that the deleterious effects of neutrophil elastase on the CF lung could be mitigated by the exogenous administration of protease inhibitors.

CORRECTION OF CFTR TRAFFICKING Increasingly, strategies to alter abnormalities in CFTR posttranslational processing and protein trafficking are being considered. Most attention has been directed toward ΔF508 CFTR with the prospect of altering the maturation and trafficking of the improperly folded and subsequently degraded protein. Correction of ΔF508 CFTR trafficking will permit some chloride channel function if ΔF508 is expressed in the apical cell membrane. CFTR ΔF508 degradation has been demonstrated to be mediated by the binding of molecular chaperones, including calnexin, to abnormal CFTR protein. These chaperones act as a cellular quality control mechanism, detecting and degrading abnormal or improperly synthesized proteins. It has been proposed that selective inhibition of chaperone function may result in an increase in ΔF508 CFTR at the apical membrane. An alternative strategy is to use a reagent that can function as a chemical chaperone to stabilize immature ΔF508 CFTR and prevent protein degradation. In vitro, glycerol treatment of ΔF508 CFTR stabilizes the abnormal protein and leads to an increase in cellular cAMP-activated chloride conductance, suggesting a gain of CFTR function in the apical membrane.

MODULATION OF ION AND WATER TRANSPORT Correction of electrolyte and water transport abnormalities that result from CFTR deficiency is a promising approach to therapy, especially if used before to the development of structural lung damage. This may potentially be achieved by activating dysfunctional mutant CFTR, inducing higher levels of activity in a smaller number of CFTR channels that are correctly localized in the cell membrane, or by activating or inhibiting alternative cellular electrolyte transport channels.

In vitro, varied classes of compounds have shown an ability to activate CFTR-mediated chloride secretion through different mechanisms. The activity of some of these compounds may be specific for the ΔF508 CFTR mutation. Examples include type III phosphodiesterase inhibitors, amrinone and milrinone, that have been shown to stimulate CFTR-mediated chloride conductance, putatively by affecting cAMP-mediated CFTR regulation. The adenosine$_1$ receptor antagonist CPX activates ΔF508 CFTR in CF cell lines by an unknown mechanism. Another agent, NS004, a substituted benzimidazolone, can activate both wild-type and ΔF508 CFTR. The efficacy of these agents has not been evaluated in vivo.

Activity of alternative ion channels may compensate for deficient CFTR-mediated chloride secretion under certain situations. It is believed that expression of an alternative chloride channel in the lungs and pancreas of CFTR(–/–) mice protect them from the usual lung and pancreatic disease seen in human CF. Nucleotide triphosphates such as ATP and UTP activate chloride secretion in both normal and CF epithelial cells. Their mechanism of action is believed to be activation of the alternative chloride channel by raising intracellular Ca^{2+}. Amiloride, by inhibiting the epithelial sodium channel, may block the hyperabsorption of sodium and water seen in the CF airway. A preliminary clinical study of aerosolized amiloride in CF-related lung disease yielded promising results, but subsequent studies have not conclusively demonstrated a benefit. Further clinical evaluations of amiloride and UTP and some of their longer acting analogs, alone and in combination, are underway.

GENE THERAPY The discovery of the CFTR gene and simultaneous improvements in gene transfer have made possible the consideration of gene therapy for CF. The primary effort for human gene therapy for CF has been directed toward the delivery and expression of a normal CFTR cDNA in bronchial airway epithelial cells, thereby complementing the defective gene. The CF airway epithelial cells represent a difficult challenge for gene transfer for several reasons. First, lung cells cannot be removed, then reimplanted, making in vivo gene transfer necessary. Second, the airway epithelial cells do not rapidly divide, so that vectors such as retroviruses (which only integrate DNA into dividing cells) cannot provide the necessary transfection efficiency. Third, the airway is capable of mounting a marked immunologic response to foreign agents, potentially limiting some viral gene transfer systems. Finally, the presence of abnormal airways, marked inflammation, and increased mucus in the individual with even moderate pulmonary disease may impair efficient gene delivery, particularly to the submucosal glands where normal CFTR expression is more marked. Given these limitations, a variety of vector systems have been evaluated. Currently, adenovirus vectors have been shown experimentally to be advantageous compared with other vectors. However, no single vector is problem-free and liposomes, molecular conjugates of cell receptors, adeno-associated viral vectors, and other viral vectors may also be useful.

Before clinical trials, in vitro and animal gene transfer studies demonstrated that it would be reasonable to attempt gene therapy for CF-related lung disease, even if the gene could be transferred

to only 5–10% of the airway epithelial cells. This was based on the observation that in vitro transfer of the CFTR cDNA to 5–7% of CF airway epithelial cells in a monolayer corrected the defect in cAMP-mediated chloride conductance, and that individuals with up to 90% defectively spliced mRNA as a result of the exon 8 splice site acceptor 5T-variant (i.e., producing 90% dysfunctional CFTR) had no lung disease. The CFTR cDNA could be transferred to approximately 5% of airway epithelial cells of experimental animals using adenovirus vectors, and transfer in experimental animals appeared to be safe. Furthermore, the adenovirus vectors carrying the CFTR cDNA can be made to be replication defective and are not known to be oncogenic.

Adenovirus has been investigated as a CFTR cDNA transfer vehicle in several clinical trials for CF therapy. The goal of these trials is to assess the safety of gene transfer vectors and to obtain biologic evidence of gene transfer. Trial design is typically to deliver a replication-defective adenovirus containing the CFTR cDNA in vivo to the nasal or lung epithelium of adults (and some children) with CF. Early evidence suggests that there is minimal expression of the transferred CFTR and that there is no change in chloride channel activity to the normal range. Although no evidence of clinical improvement has been expected in these early trials, there is evidence of immune reaction to the adenovirus. The inflammatory response to the adenovirus vector has been a critical limiting factor for some trials but has been important for driving the development of less immunogenic adenovirus vectors that are also being clinically evaluated. To date, at least 14 CF gene transfer trials (in the United States and Europe) are in progress or have been completed, employing various adenovirus vectors. Also, DNA with liposomes (two trials) and an adeno-associated virus vector (one trial) are being tested. The early studies of gene therapy for CF have been a major stimulus for rapidly developing improvements in gene delivery vectors for many other diseases.

SUMMARY

Information obtained in less than a decade has lead to the burgeoning of the field of basic CF research with important implications for many other diseases found to share common features. A relatively obscure area for investigation until the CF gene was isolated in 1989, it is now known that CF is a genetic disorder that results from mutations in the CFTR gene coding for a cAMP-regulated chloride channel. A rigorous scientific understanding of the pathophysiology of abnormal salt and water movement that leads to the clinical characteristics of CF continues to be a major endeavor in the CF field. Currently, most evidence suggests that a defect in the CFTR protein leads to abnormal salt and water movement in the epithelial cells of the sweat duct, pancreas, lung, and other organs, and the subsequent clinical manifestations of CF. Current observations in CF-related lung disease support the notion that abnormal secretions are linked to an exuberant inflammatory response exacerbated by infection with specific species of bacteria, leading to chronic inflammation and lung injury. Genetic and biochemical studies indicate that if the amount of CFTR functioning in the apical aspect of the epithelial cell is above a specific threshold of about 10% of the normal amount, then salt and water movement is adequate and clinical disease is absent. Based on these and other rapidly acquired data, it is now possible to consider a variety of novel molecular-based therapies for CF.

38 Pulmonary Emphysema

Steven D. Shapiro and Robert M. Senior

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

EPIDEMIOLOGY   Chronic obstructive pulmonary disease (COPD) is defined by the American Thoracic Society as "a disease state characterized by the presence of airflow obstruction due to chronic bronchitis or emphysema; the airflow obstruction is generally progressive, may be accompanied by airflow hyperreactivity, and may be viewed as partially reversible."

COPD occurs worldwide, but it is principally a major health problem in societies in which cigaret smoking is common and the average life-span extends into the sixth decade or beyond. The number of people in the United States afflicted with COPD has been rising sharply in recent decades. Estimates are that about 14 million persons in the United States have COPD, a number that has increased approximately 40% since 1982. The death rate as a result of COPD in the United States has also been increasing in recent decades in contrast to falling death rates from heart and cerebrovascular diseases for the same interval. COPD is now the fourth most common cause of death in the United States, accounting for nearly 4.5% of all deaths, and is a contributory factor in additional 4.3%.

Cigaret smoking is by far the most important risk factor for the development of COPD. Accelerated deterioration of ventilatory function is common among smokers; however, its magnitude is relatively small in most smokers. The relationship between amount of smoking and risk of COPD is quite unpredictable on an individual basis. Many persons with a high number of pack-years of smoking still have a normal or near-normal forced expiratory volume in 1 s (FEV_1), whereas some individuals have a reduced FEV_1 with relatively modest smoking histories. Among smokers who have already sustained reductions in FEV_1, the consequences of continued smoking on ventilatory function are much more impressive than when all smokers are lumped together. The Lung Health Study found that among middle-aged smokers with an FEV_1 between 55 and 90% of predicted, differences of several hundred milliliters of FEV_1 developed within 5 years between those who quit smoking and those who did not quit.

The percentage of smokers in the adult population in the United States has dropped during the past 30 years, particularly among males, from greater than 50% to approximately 25%. However, COPD will continue to be common into the foreseeable future because the United States still has 48 million smokers, and 3000 people, mostly teenagers, take up the habit daily. In fact, smoking is increasing among teenagers. With the large-scale marketing of tobacco products to developing countries that is happening now, an increased prevalence of COPD can be expected throughout the world in the future.

STRUCTURE-FUNCTION   In stating that COPD may be caused by either chronic bronchitis or emphysema, it is implied that COPD can result from diseases of either the airways or the lung parenchyma. Although this may be true, COPD is usually a result of pathology and dysfunction of both airways and lung parenchyma.

Cigaret smoking leads to changes in the large airways, small airways, and lung parenchyma (Fig. 38-1). The changes in the large airways, which include mucous gland enlargement and goblet cell hyperplasia, are responsible for chronic bronchitis, defined as cough and sputum on most days for at least 3 months for at least 2 successive years without another explanation. It should be noted that criteria for the diagnosis of chronic bronchitis do not include airflow obstruction and that, in fact, the large airway changes associated with chronic bronchitis do not cause airflow obstruction. Some evidence, however, does implicate chronic bronchitis as a risk factor for chronic airflow obstruction.

Approximately 30 years ago, Hogg and associates found that airways 2 mm or less in diameter were the principal sites of increased airway resistance in COPD. These studies gave rise to the concept that COPD is a "small airway disease," a concept that has stood the test of time. Although from a physiological standpoint the obstruction to airflow in COPD is in the small airways, in most individuals with COPD the relative importance of emphysema vs intrinsic abnormalities of the small airways as the structural basis for the obstruction is complex. It is evident that there is not a single pathologic feature that explains airflow obstruction in every individual with COPD. Emphysema and small airway pathology are both present in most persons with COPD; their relative contributions to obstruction probably vary from one person to another. Emphysema appears to lead to airflow obstruction because the alveolar wall attachments that help maintain the patency of small airways by producing outward traction on their walls are decreased in number and the capacity of the attachments that do remain to develop traction is decreased.

THE PATHOGENESIS OF EMPHYSEMA

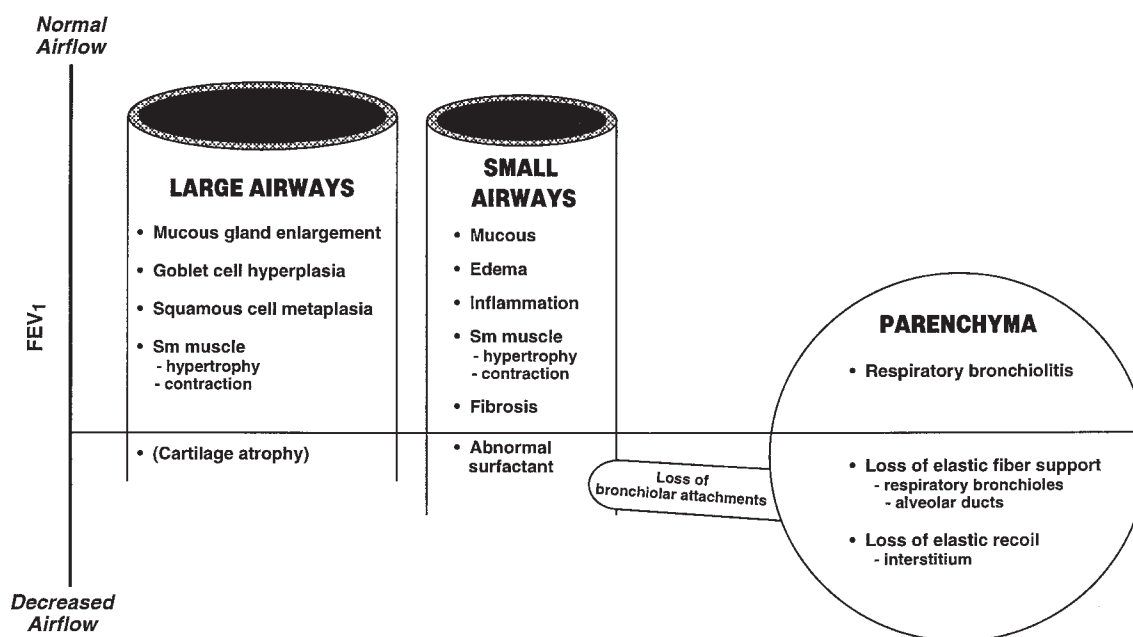
Emphysema is defined "as a condition of the lung characterized by abnormal, permanent enlargement of airspaces distal to the terminal bronchiole, accompanied by destruction of their walls, and without obvious fibrosis." Thus, emphysema is a structural


Figure 38-1   Pathologic changes in relation to airflow in chronic obstructive pulmonary disease (COPD). Changes observed in large airways (>2 mm), small airways (<2 mm), and lung parenchyma are depicted. Those abnormalities above the line are associated with normal airflow (normal forced expiratory volume in 1 s [FEV$_1$]), whereas those below the line are likely to cause decreased airflow (low FEV$_1$). Note, while controversial, our belief is that most airway changes associated with excess material in the airway do not cause airflow obstruction. A unifying hypothesis for airflow obstruction involves loss of lung elastin resulting in both decreased small airway attachments and decreased parenchymal elastic recoil.

abnormality of the gas-exchanging airspaces, that is, the respiratory bronchioles, alveolar ducts, and alveoli, characterized by obliteration and perforation of airspace walls with coalescence of airspaces into much larger ones than normal.

PROTEINASE–ANTIPROTEINASE HYPOTHESIS   In 1963 Laurell and Eriksson reported an association of chronic airflow obstruction and emphysema with deficiency of serum α_1-antitrypsin (α_1-AT); and in 1964 Gross and associates described the first reproducible model of emphysema in experimental animals by injecting papain, a plant-derived proteinase, into the lungs via the trachea. Together these observations indicated that emphysema could be induced by proteolytic injury to the lung extracellular matrix, and eventually they led to the proteinase–antiproteinase hypothesis of emphysema that has been the prevailing concept of the pathogenesis of emphysema ever since. Subsequently, when it was established that α_1-AT is primarily aimed at inhibition of neutrophil elastase and that only proteinases with activity against elastin produce emphysema when given experimentally, emphysema came to be seen as a disease resulting primarily from destruction of lung elastin.

According to the proteinase–antiproteinase hypothesis of emphysema, there is a steady or episodic release of proteolytic enzymes with elastolytic activity into the lung parenchyma (Fig. 38-2). Normally, plasma proteinase inhibitors, especially α_1-AT, permeate lung tissue and prevent proteolytic enzymes from digesting structural proteins of the lungs. Proteinase inhibitors synthesized locally in the lungs also contribute to the antiproteinase shield. Emphysema results from an augmentation of proteinase release in the lungs, a reduction in the antiproteinase defense within the lungs, or a combination of both increased proteinase burden and decreased proteinase inhibitory capacity. Accordingly, emphysema occurs when there is an imbalance between proteinases and antiproteinases in favor of proteinases.

During study of proteinases in emphysema it has become appreciated that events controlling proteolytic injury to the extracellular matrix of the lung do not necessarily operate over the lungs as whole. In fact, important events are tightly controlled and occur at or near the cell membrane of inflammatory cells. Thus, the proteinase–antiproteinase hypothesis has been modified to consider "imbalance" between proteinases and their inhibitors in compartments as small as the microenvironments immediately surrounding inflammatory cells.

Despite the plausibility of the proteinase–antiproteinase hypothesis as the basis for the development of emphysema, many fundamental questions are still unanswered. Inflammatory cells are the presumed source of injurious proteinases, but specifically which inflammatory cells are the culprits? Is it possible that resident cells of the lungs, such as fibroblasts, also contribute to alveolar septal destruction? What are the signals that initiate and perpetuate inflammation in the lungs during the development of emphysema associated with smoking? Which proteolytic enzymes are involved in lung destruction, and how do they make contact with the lung extracellular matrix and maintain their catalytic activity in the presence of an abundance of proteinase inhibitors? Advances in molecular biology will allow investigators to begin to tackle these critical issues.

INFLAMMATION–DESTRUCTION–REPAIR HYPOTHESIS
A broader conception of the pathogenesis of emphysema associated with cigaret smoking has been termed the "inflammation–destruction–repair" hypothesis. In this hypothesis, proteolytic enzymes from inflammatory cells and possibly resident lung cells are still central to production of lung injury but, in addition, it is proposed that aberrant repair of the damaged lung also occurs. Abnormal-appearing elastic fibers have been found in human emphysema. Aberrant collagen repair may also contribute to the emphysematous process. Recent studies indicate increased col-
Figure 38-2 Proteinase–antiproteinase balance in the lung parenchyma determines the risk of proteolytic degradation of lung extracellular matrix. Proteinases released by neutrophils, macrophages, and perhaps resident cells have the capacity to degrade lung extracellular matrix components including elastin, thus predisposing to emphysema. Matrix proteolysis is limited by the presence of inhibitors to each class of proteinases. Some inhibitors are locally derived (TIMP, cystatin C), whereas others arrive via the bloodstream (α_1-AT, α_2-macroglobulin). The predominant sources are depicted by solid arrows; lesser sources are indicated by dashed arrows. (Adapted from Evans MD, and Pryor WA. Cigaret smoking, emphysema, and damage to α_1-proteinase inhibitor. Am J Physiol 1994;266:L593–L611.)

lagen per unit volume of airspace wall in emphysematous lungs from smokers and in experimental animals subjected to chronic cigaret smoke inhalation. These findings suggest that the concept of emphysema formation as a purely destructive process may be in error.

INFLAMMATORY CELLS AND THEIR PROTEINASES IN THE LUNGS

Cigaret smoking leads to neutrophil retention in the pulmonary microcirculation circulation and deposition in the lung parenchyma. Cigaret smoking also causes activation and marked accumulation of alveolar (and perhaps interstitial) macrophages. These cells are capable of producing a variety of metallo- and cysteine proteinases that can degrade all components of the extracellular matrix. Other immune and inflammatory cells, such as eosinophils, T lymphocytes, and mast cells, might also contribute to lung destruction; and resident cells within the lung, such as fibroblasts and alveolar type II cells, may be induced to synthesize proteolytic enzymes in response to cigaret smoking.

Defining the cells and proteinases responsible for destruction of lung extracellular matrix associated with cigaret smoking will be critical for development of appropriate proteinase inhibitors for future application in COPD. For example, neutrophils produce predominantly serine proteinases, whereas macrophages synthesize a variety of metallo- and cysteine proteinases as well as some serine proteinases. Neutrophil elastase, a serine proteinase, is almost certainly a critical enzyme in the pathogenesis of the panacinar emphysema associated with marked α_1-AT deficiency, but other elastolytic enzymes that are not serine proteinases, and not necessarily from neutrophils, might be involved in

the pathogenesis of emphysema in smokers with normal levels of serum α_1-AT.

Not only do the profiles of proteinases differ between these inflammatory cell types, but regulation of the proteinase expression is quite distinct. Neutrophils are short-lived and package active proteinases into granules ready for quick release, optimal for rapid egress from the vasculature and delivering a lethal blow to microorganisms. Macrophage metalloproteinase expression, on the other hand, is highly regulated by inflammatory cytokines, matrix fragments, and other agents, resulting in much slower release but sustained synthesis. Thus, macrophages appear to monitor and respond to their environment, properties that could allow for tissue remodeling and possibly control of other inflammatory events.

NEUTROPHILS   As noted, smoking causes retention of neutrophils in the lungs, apparently by increasing adhesiveness of neutrophils and pulmonary microvascular endothelium, and possibly by increasing neutrophil stiffness so that the cells cannot deform enough to get through pulmonary capillaries normally. Bronchoalveolar lavage (BAL) fluids from smokers contain more neutrophils than lavage fluids from nonsmokers, indicating that smoking leads to recruitment of neutrophils into lung tissue.

Neutrophil Serine Proteinases   Serine proteinases are characterized by conserved His, Asp, and Ser residues that form a charge relay system that functions by transfer of electrons from the carboxyl group of Asp to the oxygen of Ser, which then becomes a powerful nucleophile able to attack the carbonyl carbon atom of the peptide bond of the substrate. Serine proteinases are synthesized as preproenzymes in the endoplasmic reticulum that are processed by cleavage of the signal peptide (pre-) and removal of a

Table 38-1
Elastases Present in the Lung Parenchyma

Enzyme class	Enzyme	Molecular mass[a], kDa	Cell of origin	Matrix substrates other than elastin	Relative elastolytic activity, pH 7.5
Serine	Neutrophil elastase	27–31	Neutrophil (monocyte)[d]	BM components[b]	100%
	Proteinase 3	28–34	Neutrophil (monocyte)	BM components[b]	40%
	Cathepsin G	27–32	Neutrophil (monocyte, mast cell)	BM components[b]	20%
Matrix metalloproteinase	92-kDa gelatinase	92–95	Macrophage, neutrophil, eosinophil	Denatured collagens, types IV, V, and VII collagen	30%
	Metalloelastase	54	Macrophage	BM components[b]	35%
Cysteine	Cathepsin L	29	Macrophage	(Inactive at pH 7.5)	0%[c]
	Cathepsin S	28	Macrophage	(Unknown)	80%[c]

[a]Denotes pre-proenzyme forms.
[b]Basement membrane (BM) components include fibronectin, laminin, entactin, vitronectin, and type IV collagen (nonhelical domains).
[c]These enzymes are significantly more potent than neutrophil elastase at pH 5.5.
[d]Parentheses denote minor cellular sources.

dipeptide (pro-) by cathepsin C, and stored in granules as active packaged proteins. Distinct subsets of serine proteinases are expressed in a lineage-restricted manner in immune and inflammatory cells. Serine proteinases are also expressed in a developmentally specific manner. For example, neutrophil elastase, proteinase 3, and cathepsin G are major components of primary or azurophil granules that are formed at a specific stage during the development of myeloid cells. The fact that neutrophil serine proteinases have a pH optimum of about 7.4 suggests that these enzymes could damage lung tissue if liberated from the neutrophil. Also, the finding that active neutrophil elastase and cathepsin G are concentrated on the outer face of the plasma membrane of activated neutrophils may help explain how these enzymes can function in the extracellular environment despite large excesses of α_1-AT and other inhibitors.

Neutrophil Elastase (HNE) HNE has activity against a broad range of extracellular matrix proteins including elastin (Table 38-1). After the discovery of α_1-AT deficiency and the capacity of HNE to cause emphysema in experimental animals, HNE has been considered to be of primary importance in the pathogenesis of pulmonary emphysema. Further evidence supporting involvement of HNE in this disease process includes (1) the presence of HNE and neutrophils in the lung tissue and BAL of patients with emphysema in some (but not all) studies, (2) the observation that smoking leads to an acute increase in a specific peptide released by HNE action on fibrinogen, and (3) the demonstration that cigaret smoke can oxidize a methionine residue in the reactive center of α_1-AT, inactivating α_1-AT, and thus altering the HNE–α_1-AT balance *(see below)*. Whether oxidative inactivation occurs in vivo is uncertain. Despite these tantalizing pieces of information, however, there are no studies directly linking HNE to the pathogenesis of the common form of emphysema related to cigaret smoking.

Proteinase 3 (PR3) PR3 is roughly 40% as potent as HNE against elastin. PR3 has been shown to cause emphysema in experimental animals. This molecule has been identified as the autoantigen target of cytoplasmic-staining anti–polymorphonuclear neutrophil (PMN) autoantibody in Wegeners granulomatosis.

Cathepsin G (CG) CG is stored in neutrophil primary granules and to a lesser degree in mast cells and a subset of peripheral blood monocytes. CG is chymotryptic, but also has matrix-degrading activity with nearly 20% the elastolytic capacity of

HNE. Moreover, CG has been reported to increase elastolytic activity of HNE and may facilitate neutrophil penetration of epithelial and endothelial barriers by increasing their permeability.

Neutrophil Metalloproteinases Neutrophils contain two matrix metalloproteinases (MMPs), the 92-kDa gelatinase (gelatinase B) and neutrophil collagenase. In the neutrophil these MMPs are stored within the specific granules. Neutrophil collagenase can degrade interstitial collagens, but is less active against other extracellular matrix components. Gelatinase B is active against a number of substrates, including denatured collagens (gelatins), basement membrane components, and elastin.

MONOCYTES Monocytes resemble neutrophils in that they contain HNE and CG in peroxidase-positive granules, which are similar to the azurophil granules of neutrophils. These proteinases are synthesized by monocyte precursors in the bone marrow, and can be rapidly released by the circulating cell, perhaps for transvascular migration. Interestingly, expression of both of these serine proteinases is limited to a subset of "proinflammatory" monocytes (~15% of total) that appear to be those capable of tissue penetration. As monocytes differentiate into macrophages in tissues they lose their HNE and CG, but acquire the capacity to synthesize and secrete metalloproteinases.

MACROPHAGES Alveolar macrophages are the most abundant defense cells in the lung under normal conditions and during states of chronic inflammation. Alveolar macrophages are prominent in the respiratory bronchioles of cigaret smokers, where emphysematous changes are first manifest. Because they are capable of producing factors that both promote destruction of extracellular matrix and protect against matrix destruction, macrophages may have a complex role in the pathogenesis of emphysema. Clearly, alveolar macrophages do have the capacity to degrade elastin by means of several different proteolytic enzymes (Table 38-1).

Cysteine (Thiol) Proteinases Cysteine proteinases represent a large, diverse group of plant and animal enzymes with amino acid homology at the active site only. They are inhibited by cystatins, which are produced ubiquitously in local tissue environments (Table 38-2). Human alveolar macrophages produce the lysosomal thiol proteinases, cathepsins B, H, L, and S. These enzymes share similar sizes of 24–32 kDa and high mannose side chains (typical of proteins targeted for lysosomal accumulation).

Table 38-2
Proteinase Inhibitors Present in the Lung Parenchyma

Inhibitor	Molecular mass, kDa	Cell of origin	Class of proteinases inhibited
α_2-Macroglobulin	725	Hepatocyte	Serine
		Lung fibroblast	Metallo
		(Macrophage)[a]	Cysteine
α_1-AT	52	Hepatocyte:	Serine[b]
		(Macrophage)	
SLPI	12	Large airway epithelial cell	Serine[c]
		Type II pneumocyte	
			Serine[c]
Elafin	12	Large airway epithelial cell	Serine
TIMP-1	27.5	Macrophages	Metallo
		Resident lung parenchymal cell	
Cystatin C	13	Bronchial epithelial cell	Cysteine
		(Macrophage)	

[a]Parentheses denote minor cellular sources.
[b]α_1-AT has greater affinity for neutrophil elastase than for proteinase 3 and cathepsin G.
[c]SLPI does not inhibit neutrophil elastase.
α_1-AT, α_1-antitrypsin; TIMP-1, tissue inhibitor of matrix metalloproteinase-1.

Cathepsins B and H have little endopeptidase activity and may function to activate other proteins similar to a distant relative, interleukin converting enzyme. Cathepsins L and S have large active pockets with relatively indiscriminate substrate specificities that include elastin and other matrix components. These enzyme have an acidic pH optimum, but cathepsin S retains ~25% of its elastolytic capacity at neutral pH (making it approximately equal to NE). Thus, these enzymes clearly have the capacity to cause lung destruction if they are targeted to the cell surface or extracellular space (especially if macrophages can acidify their microenvironment). These properties are plausible but remain to be proven. Cathepsin L production is increased in smokers' alveolar macrophages.

Matrix Metalloproteinases (MMPs) MMPs comprise a family of matrix-degrading enzymes believed to be essential for normal development and physiologic tissue remodeling and repair. Abnormal expression of metalloproteinases has been implicated in many destructive processes, including tumor cell invasion and angiogenesis, arthritis, atherosclerosis, arterial aneurysms, and pulmonary emphysema. MMP family members share about 40% identity at the amino acid level, and they possess common structural domains. MMPs are secreted as inactive proenzymes that are activated at the cell membrane surface or within the extracellular space by proteolytic cleavage of the N-terminal domain. Catalytic activity is dependent on coordination of a zinc ion at the active site and is specifically inhibited by members of another gene family, called TIMPs for tissue inhibitors of matrix metalloproteinases (Table 38-2). Optimal activity of MMPs is around pH 7.4. All MMPs except matrilysin have a carboxyl terminal hemopexin-like domain that is important for conferring substrate specificity and for TIMP binding. The 92- and 72-kDa gelatinases have an additional fibronectin-like domain that mediates their high binding affinity to gelatins and elastin.

Individual members of the MMP family can be loosely divided into groups based on their matrix-degrading capacity. As a whole, they are able to cleave all extracellular matrix components. The collagenases have the unique capacity to cleave native triple-helical interstitial collagens but have a restricted substrate speci-

ficity, being unable to degrade elastin or basement membrane molecules. There are two gelatinases of 72 kDa (gelatinase A) and 92 kDa (gelatinase B), which differ in their cellular origin and regulation, but share the capacity to degrade gelatins (denatured collagens), type IV collagen, elastin, and other matrix proteins. Stromelysins have a broad spectrum of susceptible substrates, including most basement membrane components. Matrilysin, the smallest MMP (28 kDa as a proenzyme) has the broad substrate specificity of stromelysin plus it has some elastase activity. Macrophage metalloelastase also has a potent broad substrate specificity that includes elastin. The MMP family keeps growing. The newest members are membrane-type metalloproteinases (MT-MMPs). MT-MMP-1 activates the 72-kDa gelatinase; however, the full spectrum of cellular expression of and substrates susceptible to MT-MMPs are currently unknown. MMPs are active against a variety of proteins besides extracellular matrix. They cleave and activate latent tumor necrosis factor-α (TNF-α), thereby regulating inflammation. MMPs degrade and inactivate α_1-AT, thus indirectly enhancing the activity of HNE.

Alveolar macrophages produce several MMPs, including significant amounts of metalloelastase, interstitial collagenase, and 92-kDa gelatinase, and smaller amounts of stromelysin-1 and matrilysin. Expression of these MMPs is highly regulated, and under quiescent conditions, such as in normal mature lung tissue, expression is limited. MMPs are induced and their production and activity are carefully controlled during normal repair and remodeling processes. With chronic inflammation, regulation of MMPs can go awry, and MMPs can be overexpressed and produced at inappropriate sites. There is evidence that expression of metalloelastase and to a lesser degree matrilysin is upregulated in alveolar macrophages of cigaret smokers.

EXPRESSION OF MATRIX METALLOPROTEINASES BY OTHER LUNG CELLS Many cells in the lung have the capacity to produce MMPs. Eosinophils produce significant amounts of the 92-kDa gelatinase. T lymphocytes interacting with endothelial cell vascular cell adhesion molecule-1 (VCAM-1) are induced to express the 72-kDa gelatinase. Various resident lung cells can produce MMPs. Fibroblasts, for example, are a potential promi-
Figure 38-3 Mechanism of metalloelastase-mediated monocyte recruitment in response to cigaret smoke. Inhaled cigaret smoke induces constitutive lung macrophages to produce macrophage metalloelastase (MME). MME proteolytically generates a chemotactic gradient, presumably by cleaving a protein into a chemotactic fragment (chemokine[s] X) that attracts blood monocytes into the lung parenchyma.

nent source of interstitial collagenase, stromelysin, 72-kDa gelatinase, and MT-MMPs. Type II alveolar epithelial cells produce matrilysin and perhaps other MMPs. Considering the variety of lung cells capable of producing MMPs, it seems plausible that MMPs participate in the lung destruction resulting in emphysema.

WHICH ELASTASES ARE INVOLVED IN EMPHYSEMA ASSOCIATED WITH SMOKING?

Efforts to implicate specific elastases in the pathogenesis of emphysema have taken on the form of a criminal trial; attempting to place proteinase X at the scene of the crime (emphysema) with a loaded weapon (elastolytic capacity). Many studies have attempted, with variable success, as noted above, to link neutrophil elastase with emphysema. MMP expression has also been associated recently with emphysema. The chronicity, general absence of smoking late in the disease, and the static nature of these types of studies contribute to the complexity of correlating the presence of elastases with changes in lung architecture.

Based on available literature and our experience with these enzymes, one can rank the relative elastolytic activities of these candidate enzymes (Table 38-1). However, the in vivo situation may defy such simple comparisons. Indeed, even the weakest elastases may contribute to emphysematous changes over many years of cigaret smoking. Other matrix components decorating the elastic fibers must also be degraded. Moreover, the capacity to degrade matrix may be limited to microenvironments of cell matrix interaction that concentrate enzymes and exclude inhibitors.

With the rapidly expanding group of potential candidates capable of causing lung destruction characteristic of pulmonary emphysema, it is imperative to directly determine the relative contribution of these proteinases in smoking-associated emphysema. The most direct methods available to establish protein functions are to perform gain of function and loss of function experiments in complex biologic organisms (mammals). Recently, investigators have taken advantage of transgenic technology to overexpress and delete specific proteinases in mice.

GAIN OF FUNCTION (OVEREXPRESSION) Overexpression of a human collagenase-1 (MMP-1) transgene driven by the haptoglobin reporter unexpectedly resulted in lung-specific expression in several independent founder lines of mice. These mice developed enlarged airspaces characteristic of emphysema. This was the first demonstration that an MMP could directly cause

emphysema. Also, because MMP-1 is inactive against mature elastin, this result suggested that collagen degradation was sufficient to cause emphysema. However, it is not certain whether the alveolar pathology in these animals was caused by destruction of collagen in mature lung tissue or whether expression of the transgene during growth and development interfered with normal elastic fiber assembly, perhaps through destruction of the elastic fiber microfibrillar scaffold. Use of cell-specific inducible promoters could circumvent this problem, but none exist at present. Another approach is in vivo transfection of a proteinase to adult animals; however, at present only low levels of non–cell-specific expression are possible.

LOSS OF FUNCTION (UNDEREXPRESSION) Underexpression represents the most direct experimental approach at present. Targeted mutations in genes of embryonic stem cells allow one to generate strains of mice deficient in specific proteins. These mice can be used to directly establish the function(s) of the protein in controlled experiments. Strains of mice deficient in individual candidate elastases can be compared with each other and normal littermates with respect to their capacity to develop emphysema in response to cigaret smoke.

Like humans, wild-type mice chronically exposed to cigaret smoke develop a macrophage predominant inflammatory infiltrate in the lungs, followed by airspace enlargement. In contrast to wild-type littermates, mice deficient in macrophage elastase (MMP-12) failed to recruit macrophages and did not develop pulmonary emphysema in response to cigaret smoke exposure. Whether human emphysema is also dependent on this single MMP is of course uncertain. At the very least, this study demonstrates a critical role of macrophages in the development of emphysema and unmasks a proteinase-dependent mechanism of inflammatory cell recruitment that may have broader biologic implications (Fig. 38-3).

α_1-ANTITRYPSIN (α_1-AT) DEFICIENCY

α_1-AT is a glycoprotein of 52 kDa synthesized primarily by the liver, consisting of a single polypeptide chain of 394 amino acids. Fully processed α_1-AT has three carbohydrate side chains that account for 12% of the molecular mass. The gene for α_1-AT is 12.2 kb located on chromosome 14 near the gene for α_1-antichymotrypsin, the inhibitor for cathepsin G, which like neutrophil elastase is contained in neutrophil azurophil granules. The α_1-AT gene has seven exons and six introns. Exons four through seven code for the mature protein. The first two exons and a 5' segment of exon three

are encoded in the transcript expressed in macrophages, but not in hepatocytes. α_1-AT is an acute-phase reactant. Plasma levels of α_1-AT rise with trauma, estrogen therapy, birth control pills, and pregnancy.

Proteolytic inhibition of neutrophil elastase and other serine proteinases by α_1-AT involves cleavage of the "strained" reactive open center of α_1-AT between methionine[358] and serine[359], resulting in an altered, "relaxed" α_1-AT conformation in complex with the proteinase. Formation of the complex renders the proteinase inactive and, because the complex is quite stable, inactivation is essentially permanent. α_1-AT inhibits many serine proteinases and does so on a 1:1 molar basis; however, α_1-AT associates with neutrophil elastase much faster than with trypsin or other serine proteinases suggesting that inhibition of neutrophil elastase is the primary function of α_1-AT. Because α_1-AT inhibits neutrophil elastase and other serine proteinases besides trypsin, some authors prefer the designations α_1-proteinase inhibitor or α_1-antiproteinase, but the name α_1-AT is still commonly used for historic reasons. When α_1-AT is complexed with a proteinase the complex binds to receptors (called serpin-enzyme complex (SEC) receptors) on hepatocytes and monocytes.

α_1-AT is transmitted codominantly. Thus, the gene product from each parent is expressed in the offspring. A large number of α_1-AT alleles are known, but most involve a single amino acid changes that does not alter expression of the protein or its function. The states produced by these different alleles are referred to as follows: normal, in which there is a normal serum concentration of functional α_1-AT; deficient, in which the serum α_1-AT is lower than normal; null, in which there is no measurable serum α_1-AT; and dysfunctional, in which there is a normal serum concentration of α_1-AT, but it does not have the normal antiproteinase activity.

The nomenclature for the α_1-AT polymorphism uses letters to specify the allelic variants. The original letters were chosen to reflect electrophoretic mobility: F for fast; M, medium; S, slow; and Z, ultraslow. The normal phenotype, Pi M, exists in >90% of the population, with the MS and MZ phenotypes the next most common. The MS, MZ, and SS phenotypes, which are associated with modest deficiencies of α_1-AT (about half of the normal serum concentration), do not present an increased risk of emphysema, although there has been an increased frequency of Pi MZ individuals in some COPD populations. Pi MS individuals may have an increased frequency of airway hyperreactivity. Because individuals with Pi SZ, who have an average of 37% of normal α_1-AT serum concentration, rarely develop emphysema, serum levels >35% of normal are thought to be enough to provide protection.

As mentioned above, cigaret smoke can oxidize a methionine residue in the reactive center of α_1-AT, inactivating its capacity as a proteinase inhibitor. The potential consequences of this reaction were demonstrated in a dog model in which animals treated with chloramine-T, an agent that profoundly depresses α_1-AT functional activity, developed pulmonary emphysema. However, the initial studies in smokers that demonstrated oxidatively inactivated α_1-AT in the bronchoalveolar lavage fluid have not been corroborated.

Several α_1-AT phenotypes are associated with very low serum concentrations of α_1-AT. Of these, the Pi Z phenotype is by far the most common, accounting for >95% of such individuals. Pi Z individuals have about 15% of the normal serum concentration of α_1-AT. The prevalence of the Pi Z phenotype in the United States is about one in 3000 people. The Z allele is rare in Asians and African-Americans.

The small number of other individuals with marked deficiency of α_1-AT have Pi SZ, Pi null-null, or Pi null-Z phenotypes.

Most Pi Z individuals eventually become symptomatic with COPD as a result of emphysema, but there is considerable variation and some individuals reach advanced age with minimal symptoms. Silverman and colleagues confirmed the wide variability in pulmonary function among Pi Z subjects and found evidence for familial factors that segregated with deterioration in pulmonary function. Smoking has a marked effect on the age at which shortness of breath appears. On the average, Pi Z smokers have symptoms by age 40, about 15 years earlier than Pi Z nonsmokers.

The Pi Z phenotype is caused by a point mutation involving a single nucleotide at codon 342 that results in coding for lysine instead of glutamic acid. This amino acid substitution alters the charge attraction between the amino acids at positions 342 and 290 present in the normal form of α_1-AT and prevents the formation of a fold in the molecule. This change in tertiary structure promotes dimerization of α_1-AT molecules. It is the dimerization that leads to the aggregation of α_1-AT in the endoplasmic reticulum, which impedes secretion of the protein from the cell and results in the low levels of α_1-AT in plasma and other body fluids. The Z form of α_1-AT also has a rate of association with neutrophil elastase that is significantly slower than the association rate of normal α_1-AT with neutrophil elastase. Thus, the Pi Z phenotype leads to both a deficiency of α_1-AT protein and a form of α_1-AT that is less effective than normal α_1-AT as an inhibitor of neutrophil elastase.

The S variant of α_1-AT, which involves a single nucleotide alteration leading to substitution of glutamic acid[264] with a valine, does not accumulate in the liver. This protein is less stable, presumably because of loss of a salt bridge between the glutamic acid in position 264 and the lysine in position 387. The Pi null phenotype arises because either the α_1-AT gene is missing or there is a mutation in the α_1-AT gene that results in premature termination of the gene's transcription.

REPAIR OF LUNG ELASTIN

The seminal observations about α_1-AT deficiency and production of emphysema in animals with elastolytic enzymes (and only with elastolytic enzymes) led to the concept that destruction of elastin in the lung parenchyma is key to the development of emphysema.

Elastin is the principal component of elastic fibers. Elastic fibers, which possess rubber-like reversible extensibility, come under tension and provide elastic recoil throughout the respiratory cycle. In the lung parenchyma, elastic fibers loop around alveolar ducts, form rings at the mouths of the alveoli, and penetrate as wisps into the alveolar septae, where they are concentrated at bends and junctions.

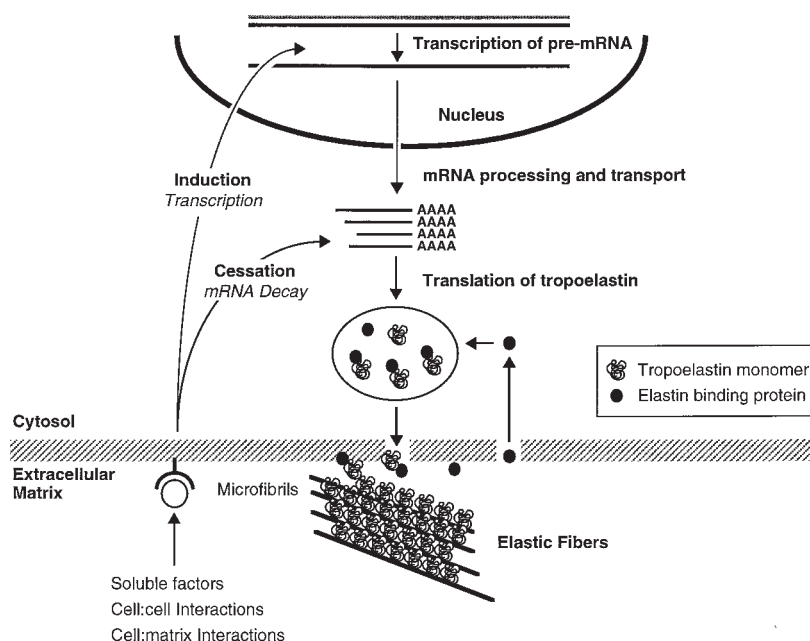
Elastin is secreted as a soluble protein of 60–70 kDa called tropoelastin (Fig. 38-4). Tropoelastin molecules, encoded by a gene on chromosome 7 in the human, are deposited into the extracellular space and aligned on a "scaffold" of microfibrils that consist of a number of proteins, including fibrillins, microfibril-associated proteins, and latent transforming growth factor-β (TGF-β) binding proteins. In the extracellular space, lysyl oxidase modifies most of the lysine residues in tropoelastin monomers, causing them to crosslink and form elastin, a highly insoluble, rubber-like polymer. The lysine-derived crosslinks in elastin are known as desmosines. Desmosines are unique to elastin, and therefore can be used to quantify elastin in tissues and as markers of elastin degradation in body fluids.


Figure 38-4 The synthesis of tropoelastin and assembly of the elastic fiber. Under the influence of extracellular and intracellular factors, tropoelastin pre-mRNA is transcribed within the nucleus of the elastogenic cell. Differential splicing of tropoelastin pre-mRNA leads to different tropoelastin mRNAs and tropoelastin isoforms. After tropoelastin is secreted from the cell it associates with microfibrils adjacent to the cell surface. Uncertainty exists as to whether there is a carrier protein that facilitates the secretion of tropoelasin. Microfibrils are thought to be a scaffold on which tropoelastin monomers align. On the microfibril, most of the lysines in tropoelastin monomers are modified by lysyl oxidase to form covalent crosslinks (desmosines) between the monomers. The resultant polymer is elastin. (Provided by William C. Parks, PhD).

Elastin is resistant to many proteinases, most notably the collagenases that cleave interstitial collagens, but there are a number of enzymes that may come in contact with the lung that can degrade elastin (Table 38-1). Under normal conditions, elastin synthesis in the lung begins in the late neonatal period, peaks during early postnatal development, continues to a much lesser degree through adolescence paralleling lung growth, and stops in adult life. There is some evidence that the tropoelastin gene always remains transcriptionally active but rapid mRNA degradation prevents expression of the protein. Multiple cell types are responsible for elastin synthesis in the lungs and associated structures. Lung elastin normally lasts a human lifespan, and there is virtually no elastin synthesis in the normal adult lung.

Although destruction of lung elastin appears to be necessary for the development of emphysema caused by smoking, it remains unknown precisely how the breakdown of elastin translates into the deformity recognized as emphysema. Elastin depletion appears to be restricted to the sites of emphysema, rather than being a global deficiency of the lung that contains regions of emphysema. It has also been difficult to determine the capacity of the lung parenchyma to undergo repair after proteolytic injury. It is not known if normal elastic fibers can be properly formed in the lung after the period of growth and development. After an intratracheal injection of human neutrophil elastase into an experimental animal, there is acute depletion of elastin followed by a burst of extracellular matrix synthesis, so that, during the course of a few weeks, the elastin content of the lungs returns to normal, although the lungs develop emphysema. However, the newly synthesized elastic fibers appear disorganized, similar to the elastic fibers in human emphysema. Recent studies of lung growth after pneumonectomy in adult rats indicate that elastin synthesis can be reinitiated in the adult lung and deposited at the sites at which elastin is normally produced during lung development. Nothing is known about the turnover of other extracellular matrix components in human lungs affected by COPD.

CONCLUDING COMMENTS

Intrapulmonary proteolytic activity that degrades lung elastin is generally accepted as the predominant mechanism for emphysema in smokers. Although elastin degradation may be central to emphysema, the biology of emphysema is clearly complex and still poorly understood. Moreover, degradation of extracellular matrix components besides elastin, particularly collagens, may also be essential. To probe the roles of the many factors involved in the development of emphysema and the lung's response to the remodeling called emphysema, researchers are now taking advantage of transgenic mice technology. From these studies, it should be possible to assess more precisely than ever before what is happening in the lung injury that culminates in the development of emphysema.

39 Surfactant Deficiency

JEFFREY A. WHITSETT AND TIMOTHY E. WEAVER

BACKGROUND

Pulmonary surfactant is a complex mixture of phospholipids and associated proteins that reduces surface tension at the air–liquid interface at the alveolar surfaces. In the absence of surfactant, collapsing forces of ~70 dyne/cm^2, generated by unequal intramolecular forces among water molecules at the alveolar surfaces, cause atelectasis, cyanosis, and associated respiratory distress. Pulmonary surfactant is a phospholipid–protein complex produced by type II epithelial cells lining the alveolus of the lung. Surfactant is secreted into the alveolar space, forming an array of macromolecular forms that produce a monolayer or multilayer of phospholipids at the air–liquid interface, reducing collapsing forces and maintaining lung volumes at end-expiration. The critical role of pulmonary surfactant in lung function was first discerned from the studies of respiratory distress syndrome (RDS) in premature infants. Subsequent biochemical, biophysical, and molecular studies have elucidated important features of the pulmonary surfactant system that have led to the widespread application of surfactant replacement therapy for RDS and other clinical abnormalities of surfactant. The present review will discuss the structure, function, and regulation of pulmonary surfactant, focusing attention to the role of surfactant proteins in surfactant function and respiratory distress associated with mutations in the surfactant protein-B gene. Readers are referred to several texts and reviews that are listed in the references.

SURFACTANT DEFICIENCY AND RESPIRATORY DISTRESS

Surfactant deficiency is a life-threatening disorder, the pathophysiology of which is most clearly represented by the respiratory failure associated with infantile respiratory distress (IRDS) that accompanies premature birth. Pulmonary surfactant is composed primarily of phospholipids (PL) that are particularly enriched in dipalmitoylphosphatidylcholine (DPPC). Surfactant phospholipids are packaged in lamellar bodies of type II epithelial cells and secreted into the airspace by exocytotic processes stimulated by stretch, catecholamines, and purinoceptor agonists. After secretion, lamellar bodies form tubular myelin, a highly organized phospholipid–protein mixture that is the most abundant form of extracellular pulmonary surfactant (Fig. 39-1). Surfactant phospholipids move rapidly from tubular myelin to the gas–liquid interface, forming a monolayer in multilayers of phospholipids,

thereby creating an interface between alveolar gas and the fluid subphase overlying alveolar cells. The dense packing of phospholipids at this interface is maintained by the parallel packing of the acyl chains of the phospholipids, and further strengthened by interactions of the choline and glycerol head groups of the phospholipid molecules. This dense packing of phospholipids excludes interactions between gas and liquid molecules, reducing surface tension in the alveolus. The reduction of surface tension in the alveolus maintains lung volumes at end-expiration, stabilizing the alveolar spaces from collapse.

Although surfactant proteins represent less than 10% of the mass of pulmonary surfactant, they appear to play a critical role in the routing, storage, secretion, and activity of pulmonary surfactant. Three abundant proteins, surfactant proteins A, B, and C, mediate the packaging of surfactant lipids within the type II cell, contribute to tubular myelin formation, and enhance the spreading and stability of surfactant phospholipids in the alveolar space. Deficiencies in these various components of surfactant contribute to lung dysfunction in a variety of human disorders. Surfactant proteins and lipids are subject to a variety of regulatory stimuli and their expression is precisely controlled during perinatal development, the concentrations of surfactant lipid and protein synthesis increasing markedly with advancing gestational age. In infants, the paucity of surfactant lipids and proteins related to prematurity is associated with a lack of biochemical and morphologic differentiation of the distal respiratory epithelium. Surfactant deficiency is also associated with respiratory failure in adult respiratory distress syndrome (ARDS), a disorder often associated with aspiration, infection, trauma, or shock in older patients. Advances in our understanding of the structure and function of surfactant have recently led to the widespread clinical use of exogenous surfactant replacement for prevention and therapy of IRDS in premature infants. Surfactant replacement is also being studied in the care of infants with other pulmonary disorders, including meconium aspiration, and is under investigation for therapy of ARDS and other lung disorders in older patients.

STRUCTURE AND FUNCTION OF SURFACTANT PROTEINS

The recognition that mixtures of surfactant phospholipids alone do not form a fully active surfactant led to the identification of surfactant proteins A, B, and C and the recognition that each plays a unique role in the organization, function, and catabolism of pulmonary surfactant.

SURFACTANT PROTEIN A (SP-A)   Gene: SPA-Structure and Regulation of Expression   SP-A belongs to a family of proteins, referred to as calcium-dependent lectins (collectins), encoded by a cluster of genes on the long arm of human chromosome 10. There are two SP-A genes in the human that differ by approximately 1% in the coding region. Although both genes are transcribed, the functional significance of two genes remain unclear, particularly in view of the fact that other species (mouse, rat, and rabbit) contain only a single gene. Transcription from the SP-A locus is regulated both temporally and spatially. SP-A expression is restricted to alveolar type II epithelial cells and nonciliated bronchiolar cells (Clara cells) of the respiratory tree. Synthesis of SP-A mRNA is detectable as early as the second trimester of pregnancy, but secretion of SP-A into the amniotic fluid is not generally detectable until approximately 30 weeks' gestation. Accumulation of SP-A in amniotic fluid during late gestation correlates strongly with surfactant function and lung maturity. The developmental, cell-specific, and basal regulation of SP-A expression is complex. Binding of the nuclear transcription protein TTF-1, thyroid transcription factor-1, to the SP-A promoter is required but is not sufficient to direct appropriate temporospatial SP-A gene transcription. The identification of transcription factors that modulate expression of SP-A independent of or by interacting with TTF-1 is an active area of research that will provide new insight into the regulation of SP-A expression during normal growth and development and in response to lung injury.

Structure and Biosynthesis   Translation of the human SP-A mRNA gives rise to a preprotein of 248 amino acids. Cotranslational cleavage of the 20-amino acid signal peptide results in an SP-A monomer comprising four discrete functional domains, including (1) a 7-residue amino-terminal domain involved in association of multiple SP-A subunits, (2) a 72-residue collagenlike domain, (3) a 130-residue C-terminal carbohydrate-recognition domain (lectin-binding domain), and (4) a short neck region that links the lectin-binding and collagenlike domains (Fig. 39-2). The cotranslational addition of asparagine-linked carbohydrate and subsequent processing of the oligosaccharide tree(s), including sialation and sulfation, results in multiple forms of monomeric SP-A ranging in size from 28,000 to 36,000 Dalton. Assembly of mature, oligomeric SP-A is initiated in the endoplasmic reticulum and involves the interaction of the collagenlike domains of three SP-A monomers to form a triple helix; subsequent formation of sulfhydryl bonds between the amino-terminal domains of adjacent trimeric subunits leads to the formation of the mature SP-A molecule comprising 18 monomers. Secretion studies in isolated Type II epithelial cells, fetal lung explants, and rabbit lung in vivo suggest that most of the newly synthesized SP-A is secreted independently of surfactant phospholipids.

Functional Domains   SP-A avidly binds to surfactant phospholipids, particularly DPPC, a property thought to be mediated by the C-terminal domain of the protein. The role of SP-A in organizing newly secreted surfactant phospholipids in the airway was deduced from in vitro studies demonstrating that SP-A promotes the calcium-dependent aggregation of lipid vesicles and is also required for the formation of tubular myelin. Binding of SP-A to a receptor on the surface of the type II epithelial cell results in an inhibition of secretagog-stimulated secretion of phospholipid consistent with a role for SP-A in modulation of surfactant secretion. SP-A has also been shown to facilitate the uptake of phospholipid by isolated type II cells. The effect of SP-A on structure,
Figure 39-1   Life cycle of surfactant. Newly synthesized surfactant lipids and proteins are stored in the form of lamellar bodies within the type II epithelial cell. Lamellar bodies are secreted into the alveolus and unravel into tubular myelin, a process facilitated by SP-A, SP-B, and calcium. Adsorption of phospholipids to the air–liquid interface and formation of the surface-active monolayer is facilitated by surfactant proteins B and C. Repeated compression and expansion of the monolayer results in the formation of small lipid vesicles, which are taken up by the type II cell and incorporated into lamellar bodies for reuse; a minor proportion of surfactant is degraded in lysosomes of type II cells or macrophages.

secretion, and uptake of surfactant phospholipid by the type II cell is consistent with the key role for this protein in regulation of surfactant homeostasis. This hypothesis, however, requires careful reassessment in view of the apparently normal lung function in mice lacking SP-A protein (SP-A knockout mice): genetic ablation of the mouse SP-A gene in transgenic mice markedly disrupted the formation of tubular myelin in homozygous SP-A(–/–) mice, but did not alter lung structure, phospholipid content, or function in vivo.

Apart from surfactant-related functions, there is growing evidence that SP-A may play an important role in host defense of the airways. SP-A has been shown to stimulate migration of macrophages and to increase production of oxygen radicals involved in the destruction of pathogens internalized by macrophages. SP-A is an opsonin, enhancing phagocytosis of viruses and bacteria, and stimulates phagocytosis of bacteria opsonized by complement or immunoglobulins. Consistent with the broad binding specificity of SP-A, the carbohydrate moieties, the neck region, and the lectin-binding domain have all been implicated in the binding of SP-A to various pathogens. Further insight into the role of SP-A in nonimmune lung defense is certain to come from the study of SP-A knockout mice. Indeed, preliminary evidence with these SP-A(–/–) mice suggests their susceptibility to lung infection.

SURFACTANT PROTEIN B (SP-B)   SP-B Gene: Structure and Regulation of Expression   SP-B is encoded by a single gene on human chromosome 2. Transcription from the SP-B locus
Figure 39-2 Structure of SP-A. SP-A is a 32- to 36-kDa polypeptide that forms trimers, which further assemble into hexamers and larger multimers. The molecules contains a globular lectin domain (C-terminal) and a rigid collagenous domain (N-terminal).

is regulated both developmentally and in a cell-specific manner. As for SP-A, expression of SP-B is restricted to Clara cells and type II cells of the respiratory epithelium. *Cis*-acting elements regulating cell-specific expression have been mapped to the proximal region of the SP-B promoter (–80 to –110) and shown to bind TTF-1 and HNF-3 (hepatocyte nuclear factor-3); in addition, TTF-1 binds at distal sites (–459 to –331) in the promoter resulting in significant enhancement of transcriptional activity. Phosphorylation of TTF-1 by cAMP-dependent protein kinase significantly increases transcription of SP-B consistent with a broad role for cAMP in the regulation of surfactant protein expression. Regulation of developmental expression by binding of specific nuclear proteins to sites within the SP-B promoter has not been systematically evaluated although it is likely that both TTF-1 and HNF-3 are involved in the temporal and spatial determination of SP-B gene expression. SP-B mRNA is detected as early as 12 weeks of gestation but significant amounts of protein are not detected in amniotic fluid before 31 weeks; secretion of SP-B increases significantly to term and is strongly correlated with surfactant function and lung maturity in infants. Overall, the developmental, cell-specific, and basal transcription of the SP-B gene is strongly influenced by TTF-1 and HNF-3; however, the widespread expression of these transcription factors in tissue derived from the embryonic foregut axis indicates that other nuclear proteins may also contribute to the unique pattern of SP-B expression.

Structure and Biosynthesis   Human SP-B is synthesized as a preprotein of 381 amino acids; however, the active peptide associated with surfactant phospholipids is only 79 residues, indicating that extensive proteolytic processing occurs in type II epithelial cells (Fig. 39-3). In the alveolus, SP-B is closely associated with surfactant phospholipids, contributing to tubular myelin formation. Translocation of newly synthesized preproprotein into the endoplasmic reticulum is accompanied by cleavage of a 23-amino acid

signal peptide and the addition of asparagine-linked oligosaccharide to the COOH-terminal propeptide. Although glycosylation of the proprotein occurs in all species examined, the functional significance of this modification is not apparent; the mature peptide is not modified by oligosaccharide addition and glycosylation of the proprotein is not required for intracellular trafficking of SP-B. In contrast, the 177-residue NH_2-terminal propeptide is absolutely required for trafficking of SP-B. The propeptide acts as an intramolecular chaperone to prevent nonspecific interactions of the extremely hydrophobic mature peptide with cellular membranes during transport through the secretory pathway; further, the NH_2-terminal propeptide is essential for directing the mature peptide to the lamellar body. Both the NH_2- and COOH-terminal propeptides are proteolytically cleaved before incorporation of the mature peptide into the lamellar body. The function of the COOH-terminal propeptide, the metabolic fate of the cleaved propeptides, and the identity of the endoprotease(s) involved in their cleavage are currently not known.

Functional Domains   Mutations in the SP-B gene leading to a complete absence of mature peptide are neonatal lethal in human infants and in SP-B-deficient mice created by gene targeting. Fetal lung development proceeds normally in the absence of SP-B but inflation of the newborn lung is compromised resulting in the rapid onset of respiratory distress. It is likely that many of the histopathologic changes described in SP-B-deficient infants are related to intensive postnatal therapy. Several attempts to rescue SP-B-deficient infants with surfactant preparations containing SP-B have not been successful, suggesting that replacement by the mature peptide alone is insufficient. Consistent with this conclusion, SP-B deficiency is accompanied by aberrant processing of the SP-C proprotein to a diagnostic fragment (M_r = 12,000) detectable in amniotic fluid or alveolar lavage; in addition, mature SP-C peptide is significantly reduced, likely exacerbating RDS in these infants. These findings, coupled with the observation that lamellar body
Figure 39-3 Structure of SP-B. Active SP-B, a 79-amino acid polypeptide, is produced by proteolytic processing of a 381-amino acid precursor. SP-B associates with the surfaces of phospholipid membranes, contributing to the adsorption and stability of the phospholipids.

formation is abnormal in SP-B knockout mice, suggest that the SP-B proprotein plays a critical role in assembly of the bioactive pulmonary surfactant complex.

The mature SP-B peptide is very hydrophobic and avidly associates with surfactant phospholipids. There are four regions within the peptide that have the potential to form amphipathic helices, and one or more of these domains may facilitate its interaction with phospholipids. The presence of a large number of cationic residues in SP-B likely accounts for the affinity of this peptide for phosphatidylglycerol, an abundant surfactant phospholipid containing a negatively charged head group. SP-B has been shown to accelerate the transition of newly secreted surfactant to the surface-active film and facilitate respreading of the surface film after dynamic compression and expansion. SP-B has also been shown to stimulate the uptake of phospholipids by type II cells in vitro, suggesting that the peptide may play a role in clearance of surfactant.

SURFACTANT PROTEIN C (SP-C)   SP-C Gene: Structure and Regulation of Expression   SP-C is encoded by a single gene on human chromosome 8. As for surfactant proteins A and B, transcription of the SP-C locus is regulated both developmentally and in a cell-specific manner; however, unlike the other surfactant proteins, expression of SP-C is restricted to type II epithelial cells. Although TTF-1 plays an important role in the regulation of basal and lung-specific transcription of the SP-C gene, other as yet unidentified transcription factor(s) are clearly required to maintain type II cell-specific expression. Elements of the SP-C promoter contained within 3.7 kb of the 5' flanking sequence of the gene have been shown to confer appropriate lung-specific and developmental expression on a reporter gene in transgenic mice. SP-C mRNA is detected at low levels early in the second trimester and increases significantly during the third trimester coincident with mRNAs for SP-A and SP-B. Assessment of SP-C protein levels is complicated by the lack of a monospecific antiserum directed against the active airway peptide; however, immunocytochemical studies with antisera directed against the SP-C proprotein indicate that the time course of SP-C precursor synthesis during lung development approximates that for SP-A and SP-B and therefore parallels overall lung development and functional status.

Structure and Biosynthesis   The SP-C gene encodes a proprotein of 197 amino acids (Fig. 39-4); however, differential splicing of the primary mRNA transcript leads to several different SP-C mRNAs, at least one of which results in a reduction in the size of the proprotein to 191 amino acids. It is not known if the multiple SP-C mRNAs are all translated and whether this apparent redundancy is functionally significant. Unlike SP-A and SP-B, the SP-C proprotein is not glycosylated and does not contain an NH_2-terminal signal peptide. The hydrophobic mature peptide (amino acids 24–58) mediates translocation of the NH_2-terminal propeptide into the lumen of the endoplasmic reticulum resulting in a transmembrane protein. As for the SP-B proprotein, the mature 35-amino acid SP-C peptide is generated by proteolytic cleavage of the NH_2- and COOH-terminal propeptides, an event that likely occurs in the multivesicular body of type II cells. The identity of the protease(s) involved in propeptide cleavage and the fate and function of the liberated propeptides are not known. It is also not clear how the mature SP-C peptide, which is presumably oriented within the interior of the vesicle membrane, is assembled with surfactant phospholipids for secretion into the airspace.

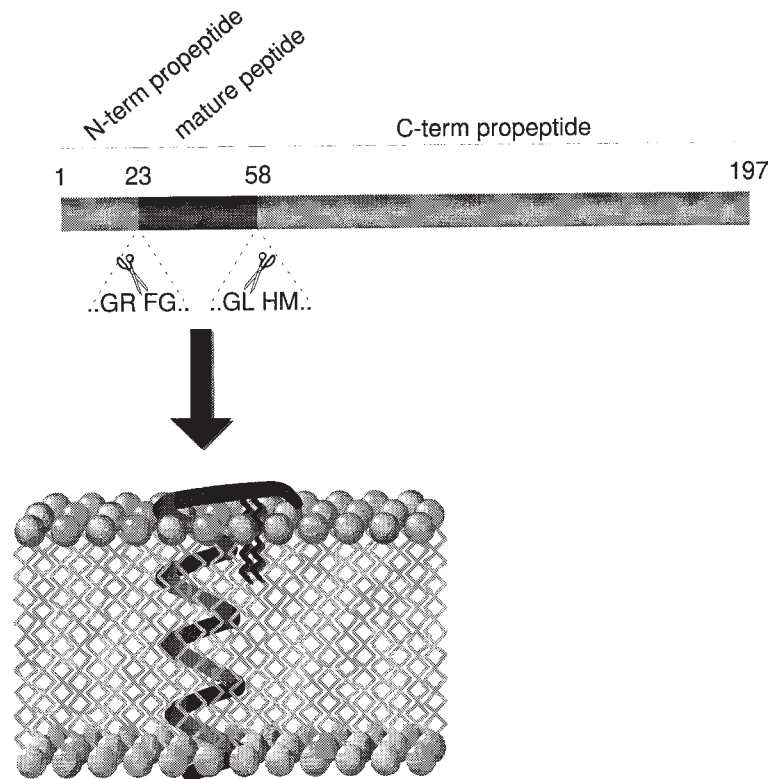
Functional Domains   Mature SP-C is an extraordinarily hydrophobic peptide consisting of 77% nonpolar amino acids. The most hydrophobic portion of the peptide is the 23-residue, valine-rich C-terminal region that forms a rigid α-helix capable of spanning the membrane bilayer. The relatively hydrophilic NH_2-terminal portion of the peptide contains several positively charged residues that likely anchor SP-C to one side of the membrane by interacting with the negatively charged phospholipid head groups; in addition, the covalent attachment of palmitic acid to cysteines at positions 5 and 6 ensures that the NH_2-terminus of SP-C is firmly anchored to the membrane. Although the function of SP-C is not entirely clear, the membrane-spanning helical region of the peptide is required for rapid adsorption of surfactant phospholipids to the air–liquid interface. The role of SP-C in the surface-active monolayer remains much less clear. Recent studies in vitro suggest that SP-C may play in important role in the clearance of alveolar surfactant lipids by the type II epithelial cell.


Figure 39-4 Structure of SP-C. SP-C is produced by proteolytic processing of a 197-amino acid precursor. The active SP-C peptide of 33–35 amino acids inserts deeply into lipid monolayers and bilayers, enhancing the surface activity of the phospholipids.

LIFE CYCLE OF PULMONARY SURFACTANT

Pulmonary surfactant phospholipids and proteins are synthesized by type II epithelial cells lining the alveolar surface of the lung. Phospholipids are synthesized *de novo* and are re-used at high rates by the type II epithelial cell in a highly regulated, conservative manner. Phospholipids and proteins are synthesized and trafficked to membranous structures of the endoplasmic reticulum, Golgi, and multivesicular bodies, and ultimately packaged in lamellar bodies, the storage form of phospholipids and proteins in the type II cell. Surfactant, in the form of lamellar bodies, is secreted into the airway by exocytosis. The presence of calcium, SP-A, SP-B, and phospholipids produces tubular myelin, the most abundant form of alveolar surfactant. Monolayers or sheets of monolayers are likely formed by the actions of surfactant proteins B and C and phospholipids. The membranes spread over the alveolar surface, reducing surface tension at the air–liquid interface. The dynamic compression of surfactant during the respiratory cycle generates a variety of structural forms containing surfactant lipids and proteins, and it is likely that some of these forms determine whether the particles are catabolized or taken back up by type II cells for reutilization. Inactive particles, in the form of small, less dense vesicles, that are relatively depleted in surfactant proteins are likely catabolic forms that are taken up by the respiratory epithelium. Surfactant proteins B and A serve to maintain the large aggregates (tubular myelin) that are highly surface active. Differences in the abundance or type of surfactant proteins associated with the various lipid particles may influence the rates of uptake and recycling. Although surfactant proteins and lipids are taken up by the type II epithelial cell and recycled at high rates, a subfraction of surfactant lipids and proteins are taken up and degraded by alveolar macrophages. Although only approximately 15% of phospholipids are catabolized by alveolar macrophages in vivo, this process may be a critical determinant of the steady state concentrations of surfactant, which are maintained at precise levels in the alveolar spaces of the adult animal. Thus, the life cycle of pulmonary surfactant represents a balance between synthesis, secretion, formation of distinct structural forms, reuptake, and catabolism. Each of these processes is influenced at various regulatory levels.

HEREDITARY SURFACTANT PROTEIN B DEFICIENCY

The critical role of surfactant protein B (SP-B) in lung function was emphasized by the finding that full-term infants lacking SP-B develop lethal respiratory distress immediately after birth. Hereditary SP-B deficiency was first recognized in 1993 in a kinship of three full-term infants dying of respiratory failure at birth. Affected infants develop respiratory distress with grunting, retraction, cyanosis, pulmonary hypertension, and radiographic findings consistent with diffuse atelectasis after birth, similar to the findings in premature infants with IRDS. Initial chest radiograms show reticular-granular infiltrates that progress to severe atelectasis. Infants require intubation and intensive care immediately after birth. Therapy with oxygen and positive-pressure ventilation fails in spite of vigorous and continued respiratory management. Although the number of treated infants is not extensive to date, the infants do not have a consistent or prolonged response to exogenous surfactant replacement. Where available, SP-B-deficient infants are often treated with extracorporeal membrane oxygenation (ECMO) before the diagnosis is entertained. Hereditary SP-B deficiency has been consistently fatal and infants usually succumb in the first months of life in spite of continued intensive respiratory

support. Several infants with hereditary SP-B deficiency have undergone lung transplantation.

DIAGNOSIS OF HEREDITARY SP-B DEFICIENCY The diagnosis of SP-B deficiency is made on the basis of family history. All infants diagnosed to date have two defective SP-B genes inherited as autosomal recessive genes. The infants develop respiratory distress in the first 24 h and are generally critically ill with increasing respiratory distress in the absence of prematurity, infection, or other underlying causes of respiratory failure. Tracheal aspirates from infants lack the active SP-B peptide and contain a diagnostic fragment of proSP-C (of approximately 12 kDa), which accumulates in the air spaces. Amniotic fluid from these infants contains the 12-kDa proSP-C fragment, a paucity of phospholipids, a decreased lecithin:sphinyomyelin (L:S) ratio, and the absence of the SP-B active peptide and phosphatidylglycerol (PG). Lung biopsy samples generally reveal diffuse lung disease with accumulation of proteinaceous material in the air spaces of affected infants. This material is distinct from that detected in adults with alveolar proteinosis, the former being devoid of the SP-B and enriched in the proSP-C fragment. Electron microscopic examination of lung tissue from SP-B-deficient infants demonstrated the lack of lamellar bodies and tubular myelin, as well as abnormal and injured epithelial cells likely related to prolonged intensive care and oxygen therapy. The definitive diagnosis is made by genetic analysis of the SP-B alleles from the infants and family members.

MOLECULAR DIAGNOSIS OF CONGENITAL SP-B DEFICIENCY The most common genetic defect associated with SP-B deficiency results from a frameshift mutation in exon 4 (121 ins 2), which has been detected in approximately 75% of the affected infants analyzed to date. At present, 38 infants with this disease have been diagnosed since the recognition of the disorder in 1993. Missense and nonsense mutations have also been identified, with the infants generally presenting as compound heterozygotes in concert with the common exon 4 mutation. Definitive diagnosis is made by sequence analysis of the SP-B alleles.

PATHOPHYSIOLOGY OF HEREDITARY SP-B DEFICIENCY IN SP-B GENE-TARGETED MICE The murine SP-B gene was disrupted by homologous recombination in embryonic stem cells used to make SP-B gene-targeted (knockout) mice. Like affected infants, SP-B-deficient mice succumb from respiratory distress postnatally, but are otherwise unaffected. Abnormalities in these mice are confined to the lungs, which are atelectatic but have developed normally. Type II cells of the SP-B(–/–) mice lack lamellar bodies and contain large atypical multivesicular bodies. Tubular myelin is lacking in the air spaces, and there is decreased content of the active SP-C peptide and a complete lack of both proSP-B and SP-B in the gene-targeted mice. Insertional mutagenesis in exon 4 of the mouse gene and the missense mutation in exon 4 of the human gene both result in an unstable messenger RNA and the lack of synthesis of proSP-B. Mutations in other regions of the human gene are associated with expression of abnormal forms of SP-B and proSP-B, which are detected intracellularly and extracellularly. ProSP-C, normally routed through the secretory pathway of the type II epithelial cell in concert with proSP-B, is aberrantly processed, resulting in the secretion and accumulation of proSP-C of $M_r = 12$ kDa in the air spaces of SP-B(–/–) in humans and mice. Thus, in addition to the lack of SP-B, SP-B(–/–) mice and patients are deficient in SP-C active peptide and accumulate high concentrations of proSP-C fragments in the air spaces that likely further impair surfactant function. The aberrant packaging,

storage, and organization of surfactant lipids in the SP-B deficiency also are likely to contribute to surfactant dysfunction, leading to respiratory failure in hereditary SP-B deficiency.

HETEROZYGOUS SP-B DEFICIENCY SP-B deficiency is generally inherited as an autosomal recessive gene. Although clinical lung disease has not been associated with heterozygous family members of SP-B-deficient infants, these families have not been intensively studied to date. Heterozygous SP-B gene-targeted mice develop normally for more than a year in the laboratory without apparent abnormalities. However, SP-B mRNA, proSP-B, and the mature SP-B peptide are reduced by approximately 50% in SP-B(+/–) offspring. Careful analysis of lung function in the SP-B-deficient heterozygous mice revealed air trapping and decreased lung compliance, consistent with abnormalities of small airway function. Whether SP-B(+/–) humans have abnormalities of lung function or are susceptible to lung dysfunction is unknown at present. The small airway dysfunction and air trapping seen in the SP-B(+/–) mice suggests that phenotypic alterations in SP-B deficiency might include asthma and other forms of small airway disease.

DISTINCTION OF HEREDITARY SP-B DEFICIENCY FROM PULMONARY ALVEOLAR PROTEINOSIS (PAP) Although associated with the accumulation of surfactant lipids in the air space, the hereditary form of SP-B deficiency is distinct from infants or adults with pulmonary alveolar proteinosis in which both surfactant lipids and proteins accumulate in the alveolar space. Adult forms of alveolar proteinosis are generally idiopathic and are associated with malignancy, immune disorders, and exposure to inhaled particles and are not associated with the acute respiratory failure seen in SP-B-deficient infants. Alveolar proteinosis appears to be caused by disruption in surfactant homeostasis that leads to decreased clearance of surfactant by alveolar macrophages or by the respiratory epithelium. Genetic ablation of granulocyte-macrophage colony-stimulating factor (GM-CSF) or its receptor causes severe alveolar proteinosis in transgenic knockout mice. Unlike hereditary SP-B deficiency, surfactant from these animals or patients with PAP is highly surface-active, contains normally processed surfactant proteins, and lacks the proSP-C fragment, the latter being diagnostic for hereditary SP-B deficiency. The analysis of the GM-CSF of knockout mice has provided novel insight into the role of GM-CSF in lung homeostasis consistent with a critical role for GM-CSF in autocrine-paracrine signaling within the lung. These findings support a role for GM-CSF in the modulation of surfactant homeostasis in the postnatal lung and suggest the potential role of GM-CSF and its receptor subunits in the pathogenesis of alveolar proteinosis in humans.

SECONDARY CAUSES OF SP-B DEFICIENCY Hereditary SP-B deficiency must be distinguished from other causes of surfactant or surfactant protein B deficiency in newborn infants. Secondary causes of SP-B deficiency may be related to infection, prematurity, or to other as yet unknown factors. SP-B content was below the level of detectability in lung lavage fluid from some infants with severe respiratory failure and with no discernible abnormalities in the SP-B genes. SP-B deficiency has also been observed in the lungs of infants dying of congenital lung disease associated with abnormal lung morphogenesis, such as congenital acinar hypoplasia. Lungs from these infants are also deficient in SP-A and SP-C, and the pathogenesis of this disorder may be related to the lack of synthesis of regulatory factors that influence the expression of surfactant proteins in lung epithelial cell differentiation or on pulmonary organogenesis *per se*.

FUTURE DIRECTIONS FOR DIAGNOSIS AND THERAPY OF HEREDITARY SP-B DEFICIENCY   Because of the severe disruption of surfactant homeostasis of hereditary SP-B deficiency and the severity of respiratory distress, these infants generally succumb within the first months of life despite extensive ventilatory support and intensive care. SP-B(–/–) infants have not responded to exogenous surfactant replacement even when initiated relatively early in the course of the disease. Genetic testing of the fetus can be used to identify infants with hereditary SP-B deficiency before birth. Both protein and DNA analyses have been used to identify siblings of previously affected kindred with SP-B deficiency. Such information can be useful in genetic counseling of these families. Several infants with SP-B deficiency have received lung transplants for correction of SP-B deficiency and two of these infants have now survived more than a year. Long-term outcome of neonatal lung transplantation is unknown, however, and this procedure should be considered experimental. SP-B mRNA can be transferred to respiratory epithelial cells for the correction of SP-B deficiency in the laboratory, and adenoviral vectors capable of efficiently transferring SP-B mRNA to type II epithelial cells have been used in animal models. However, correction of hereditary SP-B deficiency in infants will require relatively high levels of SP-B gene expression within type II epithelial cells. At present, the inefficiency of gene transfer vectors and immune responses for the use of such vectors provide formidable barriers to successful gene therapy of SP-B deficiency in the lung.

Nevertheless, hereditary lung diseases, such as SP-B deficiency, cystic fibrosis, and α_1-antitrypsin deficiency, may someday be amenable to somatic cell gene transfer.

40 Lung Cancer

The Role of Tumor Suppressor Genes

STEVEN JAY WEINTRAUB

BACKGROUND

The leading cause of cancer deaths in the United States is carcinoma of the lung. Despite the innumerable advances in the treatment of other types of cancer, lung carcinomas remain nearly uniformly fatal. In the past few years, however, there have been many new findings regarding the series of events that occur on a molecular level during lung carcinogenesis. These findings should prove to be of value not only in understanding the evolution of lung cancer, but also in its diagnosis and treatment.

The different types of lung cancer have been divided into two categories. Small cell lung cancer (SCLC) is thought to be of neuroendocrine origin. Chemotherapy extends survival of patients with this type of lung cancer by several months. Squamous cell carcinoma, adenocarcinoma, and large cell carcinoma are all thought to arise from a bronchoalveolar progenitor cell. This group of carcinomas has been designated non–small cell lung cancer (NSCLC). Current chemotherapeutic regimens have no effect on survival of patients that are afflicted with NSCLC.

Early cytogenetic studies of both SCLC and NSCLC demonstrated that several chromosomal abnormalities occurred consistently in lung cancer tissue and cell lines derived from these tumors, suggesting that a specific set of mutations occurs in each type of lung cancer. Indeed, it is now known that several genes are frequently expressed aberrantly in lung cancer. Of these, the retinoblastoma gene and the p53 gene, both of which are tumor suppressors, are the best studied. Therefore, the function of the retinoblastoma protein (Rb) and p53 protein (p53) in normal cell growth and differentiation and the mechanism by which alteration of their activity promotes lung carcinogenesis will be the focus of this chapter.

THE RETINOBLASTOMA PROTEIN–E2F PATHWAY

Studies of the neoplastic process initially led to the description of oncogenes, which are genes whose expression induces cellular transformation. However, a consistent finding among human retinoblastomas was the deletion of chromosomal band 13q14, suggesting the existence of a gene whose inactivation is necessary for progression to retinoblastoma (*see* Chapters 7 and 105). Thus the existence of antioncogenes or tumor suppressor genes was postulated. Accordingly, a gene, now known as the retinoblastoma gene

and found at this locus, is expressed in all normal retinal cells, as well as all normal adult tissue, but is either absent or mutated in all retinoblastomas. Confirmation that Rb is a tumor suppressor was provided by experiments in which wild-type Rb was artificially introduced into retinoblastoma cells. Restoration of Rb in these cells resulted in growth inhibition and loss of tumorigenicity, indicating that inactivation of Rb is necessary for tumorigenesis.

In addition to retinoblastomas, loss of Rb function has been associated with osteosarcomas and bladder, breast, prostate, cervical, and lung cancers. Among patients with bladder cancer, those with Rb(–) carcinomas have more invasive tumors and their prognosis is significantly worse than those with Rb(+) bladder cancers. In cancer of the cervix, disruption of Rb function must be necessary for tumor progression because almost all cervical cancers fall into one of two categories: either they express the human papilloma virus protein E7, a protein that is known to bind to and inactivate Rb, or they produce only a mutant, inactive form of Rb. Similarly, loss of functional Rb appears to be important in lung cancer since it is mutated in over 90% of SCLCs and 20–30% of NSCLCs. Underscoring the role of disruption of Rb function in the pathogenesis of lung cancer is the finding that relatives of retinoblastoma patients who have germline mutations in the Rb gene are at markedly increased risk of developing SCLC.

Rb has two domains that are strongly conserved across species and among two other cellular proteins, p107 and p130, and the region that encompasses these domains has become known as the pocket (Fig. 40-1). Accordingly Rb, p107, and p130 are collectively known as the pocket proteins. The integrity of the pocket is critical for the interaction of these proteins with several other cellular proteins, including the transcription factor E2F *(see below)*. An intriguing early finding was that most mutations of Rb in tumors that express a stable protein involve the pocket, suggesting that a function of the pocket has an essential role in the tumor suppressing activity of Rb (i.e., disruption of an Rb pocket function is important in tumor pathogenesis). Additionally, several DNA tumor virus oncoproteins bind to the Rb pocket and displace cellular pocket-binding proteins. Any mutation in these oncoproteins that interferes with their capacity to bind Rb and displace these proteins disrupts their oncogenicity, suggesting that they are oncogenic because they block the interaction of the Rb pocket with other cellular proteins.

It is now known that Rb plays a role in regulation of progression through the normal cell cycle (*see* Chapter 6). Rb does so at least
Figure 40-1   Schematic of the pocket proteins. The pockets of Rb, p107, and p130 each consist of two regions, domain A and domain B, that contain amino acid sequences that are conserved both among these three proteins and across species and a nonconserved spacer between these two conserved regions. Most of the cellular functions of the pocket proteins that have been identified to date are dependent on the integrity of the pocket domain. The white areas represent the regions that are conserved between Rb, p107, and p130 and among each of these proteins across different species.

Figure 40-2   Rb is phosphorylated in a cell cycle-dependent fashion and its interaction with E2F is controlled by its phosphorylation state. Rb becomes hyperphosphorylated in late G_1 and remains so until late in mitosis; during anaphase Rb becomes hypophosphorylated. Only the hypophosphorylated form binds E2F. E2F is a family of transcription factors that activate genes whose expression is necessary for progression through the cell cycle. When E2F is complexed with Rb (or one of the other pocket proteins), however, the complex is a transcriptional repressor that inhibits expression of these same genes. Rb is thought to regulate cellular proliferation through its interaction with E2F and the resultant transcriptional repression of these genes.

in part through the interaction of the pocket with a family of transcription factors known collectively as E2F. Binding sites for E2F are found in the promoters of several genes whose expression is necessary for progression through the cell cycle, including thymidylate synthase, dihydrofolate reductase, and DNA polymerase-α. Rb is phosphorylated in a cell cycle-dependent fashion. It is in its "hypophosphorylated" state at the end of mitosis and remains so during most of G_0/G_1, but as the cell enters late G_1 it becomes "hyperphosphorylated." The phosphorylation cycle controls the interaction of Rb with E2F: when it is in its hypophosphorylated form, it binds to E2F; however, when it is hyperphosphorylated in late G_1, it dissociates from E2F leaving free E2F behind on the promoter (Fig. 40-2). Only the hypophosphorylated form of Rb, the form that binds E2F, inhibits growth. The complex of hypophosphorylated Rb and E2F is a transcriptional repressor that inhibits the activity of *trans*-activating factors on the promoter, and the "free" E2F that is left on the promoter upon hyperphosphorylation and dissociation of Rb from E2F is a transcriptional activator. The complex of the Rb-related proteins p107 and E2F are also transcriptional repressors. p107 and p130 also bind to E2F in a cell cycle-dependent fashion, but their pattern of binding differs from that of Rb. So it is envisioned that cell cycle progression is regulated by the Rb–E2F pathway as follows: several genes whose expression is necessary for cell cycle progression contain E2F sites and, at specific stages of the cell cycle, free E2F activates these genes; however, when Rb or one of the other pocket proteins bind to E2F, the complex of the pocket protein and E2F inhibits the activity of these same genes. In this fashion Rb and related proteins control the expression of these genes in a cell cycle-specific fashion. If Rb is inactivated through mutation, some of these genes will be constitutively expressed, removing an important constraint on cellular proliferation. It is likely that this is a critical step in the pathogenesis of lung cancer as well as other tumors.

The mechanism by which the Rb–E2F complex represses transcription has recently been elucidated. It was found that the Rb pocket has intrinsic transcriptional repressor activity. This was demonstrated through the use of a chimeric protein in which the pocket was fused to a heterologous DNA binding domain, that of the yeast transcription factor Gal4. The activity of the resultant protein was assessed using an artificial transcriptional reporter construct that contains the Gal4 DNA binding sequence (Fig. 40-3).

This facilitated the targeting of Rb to a promoter in an E2F-independent fashion. When the activity of a Gal4-Rb-pocket fusion protein was assessed in this fashion, it was found to be as effective a transcriptional repressor as wild-type Rb when it is tethered to a promoter by E2F. When control proteins or other regions of Rb were fused to Gal4, the resulting chimeric proteins were inactive in this assay. Thus, it is likely that the repressor activity of the Rb–E2F complex is a function of the Rb pocket, and the role of E2F in this complex is to target the repressor activity of Rb to the appropriate promoters. Further, it was shown that this repressor activity is a function of the ability of Rb to disrupt critical interactions of several proteins that activate transcription.

Even though Rb has been shown to interact with several cellular proteins, there is evidence, at least in one cell line, that E2F is the most important mediator of Rb activity. In these cells, overexpression of a form of E2F that lacks Rb, p107, and p130 binding activity, but still encodes a *trans*-activation function will disrupt the growth-inhibitory effect of Rb. When it is overexpressed, this protein will bind to E2F sites and displace cellular proteins that are bound to these sites, such as the Rb–E2F complex, and, like free E2F, it will *trans*-activate promoters that contain E2F sites. Unlike E2F, because it does not bind pocket proteins, it will not mediate transcriptional repression by Rb (or any other effect of the pocket proteins) and it will not affect the interaction of the pocket proteins with other proteins in the cell. The net result of overexpression of this protein then is disruption of the effect of Rb and Rb-related proteins on promoters that contain E2F sites with-
Figure 40-3 The transcriptional repressor activity of Rb is a function of its pocket domain. Chimeric proteins in which the different regions of Rb are fused to the DNA-binding domain of the yeast transcription factor Gal4 are targeted to promoters that contain a Gal4-binding site. This permits an assessment of the activity of the different domains of Rb. When the Rb pocket domain is targeted to a promoter in this fashion it represses the activity of enhancers on the promoter, thereby blocking expression of the gene. The only region of Rb that has repressor activity in this assay is the pocket, suggesting that the repressor activity of Rb is a function of its pocket domain.

out a direct effect on any other function of the Rb family of proteins. The finding that this protein disrupts the growth inhibitory effect of Rb indicates that the interaction of Rb with Rb binding proteins other than E2F is not sufficient for growth suppression. Indeed, it has been suggested that E2F may be the only critical effector of Rb activity.

Although Rb is not inactivated by mutation or deletion in all tumors, it may be functionally inactive in several tumor types that express wild-type Rb. As outlined above, the activity of Rb is controlled by its phosphorylation state, hypophosphorylated Rb being the active growth-inhibitory form and hyperphosphorylated Rb the inactive form. It is becoming apparent that the most important regulators of Rb phosphorylation are the D cyclins and their associated cyclin-dependent kinases (CDKs). The D cyclins activate certain CDKs, which in turn phosphorylate Rb. It has been found that in some NSCLCs that express wild-type Rb, cyclin D_1 is overexpressed. This could lead to constitutive hyperphosphorylation and, therefore, inactivation of the Rb. So even though these cells express wild-type Rb, they are likely to be functionally Rb negative. Additionally, a newly discovered class of proteins has been found that inhibit the activity of cyclin-CDKs. The most relevant one to this discussion appears to be p16. This protein binds to cyclin D–CDK complexes and inhibits phosphorylation of Rb, maintaining Rb in its active growth-suppressive state. Disruption of p16 function would result in inappropriate hyperphosphorylation and, therefore, inactivation of Rb. Accordingly, p16 has been found to be mutated in several different types of cancer and it has been shown that replacement of wild-type p16 into p16(−) cancer cell lines results in inhibition of their growth and suppression of tumorigenicity. It is therefore of note that in a study of 55 SCLC cell lines it was found that whereas the 48 that lacked wild-type Rb expressed p16, 6 of the cell lines expressed wild-type Rb but lacked p16. In the second set of cells, lack of the p16 inhibitor will lead to increased kinase activity of cyclin D–CDK complexes, which in turn should result in increased phosphorylation and functional inactivation of Rb. So although these

SCLC cells express wild-type Rb, it is likely to be functionally inactive because of the lack of p16. These findings suggest that inactivation of Rb, whether by mutation or constitutive hyperphosphorylation, is a necessary step in the pathogenesis of lung cancer; in fact, it has recently been postulated that the Rb–E2F pathway may be dysregulated in all human malignancies.

THE p53 CHECKPOINT FOR DNA DAMAGE

p53 plays a critical role in controlling cellular proliferation by either arresting cells in G_1 or by inducing apoptosis under the appropriate conditions (*see* Chapter 7). p53 functions in a pathway that serves as a checkpoint for DNA damage in that various agents that are known to cause mutagenesis of DNA, such as ionizing radiation, will induce either p53-dependent cell cycle arrest or apoptosis. Both of these effects are known to be dependent on p53 activity because mutation of p53 disrupts them and reintroduction of p53 into p53(−) cells restores them. Whether a cell undergoes p53-dependent arrest or apoptosis appears to be cell type-specific.

It is likely that the cell cycle arrest that occurs with DNA damage allows the cell to pause and repair its DNA whereas apoptosis serves to limit proliferation of cells with genomic damage. Evidence for these hypotheses is provided by the finding that cells that lack p53 are one million times more likely to contain abnormally amplified DNA than cells that express p53. Additionally, mice that have homozygous p53 mutations develop normally through birth but invariably develop tumors by 6–9 months. This is probably because of the fact that cells that lack the p53-dependent checkpoint for DNA damage continue to proliferate while accumulating mutations—if the appropriate set of mutations occurs in these cells they will undergo malignant transformation.

The p53 gene is the most frequently mutated gene among cancers of all types. In regard to lung cancer, p53 is mutated in about 90% of SCLCs and 60% of NSCLCs. Additionally, although wild-type p53 is expressed in some lung cancers, it may be inactivated by mechanisms other than mutation. In a recent study, it was found that several NSCLCs that express wild-type p53 overexpress a second protein, mdm2, that binds to and inactivates p53. Overexpression of mdm2 was found to occur only in cells that expressed wild-type p53. These findings suggest that in certain lung tumors the p53 pathway is inactivated by overexpression of mdm2 instead of mutation of p53. This is analogous to the situation with Rb outlined above. Even though Rb is not inactivated by mutation in all SCLCs, it may be functionally inactivated by inappropriate phosphorylation if cyclin D_1 is overexpressed or if CDK inhibitor p16 activity is absent.

After exposure of cells to ionizing radiation there is an increase in cellular p53 levels that is coincident with p53-dependent cell cycle arrest. Like Rb, p53 is a transcription factor, except that p53 is a *trans*-activating protein. Underscoring the role of its *trans*-activating function in cell cycle arrest and, therefore tumor suppression, is the finding that most of the mutant forms of p53 found in tumors have lost this activity. This suggested that wild-type p53 inhibits cellular proliferation by activating the expression of genes that block progression through the cell cycle (Fig. 40-4). It is now known that in nontransformed cells the increase in the cellular level of p53 that occurs with ionizing radiation increases expression of at least two proteins that arrest cellular proliferation, p21 and GADD45. p21, like p16, inhibits the kinase activity of cyclin–CDK complexes. Increased cellular levels of p21 will block phosphorylation of Rb by inhibiting the activity of the Rb-specific cyclin–CDK complexes, thereby maintaining Rb (and possibly
Figure 40-4　The ability of p53 to stimulate transcription is essential for tumor suppression. The critical role that the transcriptional activation function of p53 has in tumor suppression was first suggested by the finding that transforming mutants of p53 do not activate gene expression.
Figure 40-5　Schematic of the mechanism by which p53 mediates ionizing radiation-induced cell cycle arrest. The promoters of the genes for p21 and GADD45 contain binding sites for p53. Ionizing radiation increases p53 in the cell resulting in activation of transcription of the p21 and GADD45 genes. These proteins arrest cell growth.

Rb-related proteins) in its hypophosphorylated growth-suppressive form—resulting in a G_1 cell cycle arrest. GADD45, the other protein whose expression is induced by p53, is thought to arrest cellular proliferation by inhibiting DNA synthesis, probably through an interaction with proliferating cell nuclear antigen (PCNA) (Fig. 40-5).

CONCLUSIONS

A series of mutations resulting in aberrant production of a specific set of proteins culminates in cellular transformation. It is estimated that 10–20 mutations occur during the pathogenesis of lung cancer. Several genes have been identified that are consistently mutated in lung cancers, but the best studied of these are the Rb and p53 genes. Both of these genes encode tumor suppressors. An understanding of the role of these and other tumor suppressors in maintenance of normal cellular physiology and the significance of their inactivation in cancer pathogenesis has advanced significantly during the past decade. The retinoblastoma protein is important for maintaining a controlled progression through the cell cycle by regulating the activity of several growth-promoting genes. p53 limits the transmission of potentially harmful genetic alterations that occur with DNA damage to future generations of cells either by arresting the cell cycle to allow for DNA repair or by inducing apoptosis. Therefore, the inactivation of Rb or p53 disrupts constraints that inhibit the transformation of normal lung tissue to lung carcinoma. The understanding of these processes should allow for more efficient treatment of lung cancer in the future, possibly by the restoration of their function in malignant cells.

41 Hepatology

PIET C. DE GROEN AND NICHOLAS F. LARUSSO

INTRODUCTION

During the past century, hepatology has gradually progressed from a discipline focused on simply describing the signs and symptoms associated with a specific liver disease, via clinical observations, biochemical abnormalities, and organ pathology, to a science that involves describing and understanding abnormal cell function. Rapid progress in the techniques of molecular biology in the last three decades has added an entirely new dimension to the concept of disease; it has led to the development of molecular hepatology as an emerging area of interest that attempts to generate new knowledge of the molecular mechanisms responsible for normal and abnormal liver function.

Recently, several genes responsible for inherited liver diseases have been either localized to a specific part of a chromosome or cloned and characterized. Some of these genes have been found by applying traditional molecular techniques (e.g., the gene was cloned using antibodies to a normal or abnormal protein or cDNA probes were used to screen CDNA libraries [α-1 antitrypsin deficiency]). Other genes have been found using linkage analysis and chromosome jumping or walking (e.g., cystic fibrosis, Wilson's disease, hemochromatosis) or cytogenetic deletions and rearrangements (e.g., Alagille syndrome). Relevant bacterial and viral DNA/RNA compositions have also been identified using a variety of techniques, such as virus purification (Hepatitis B) or cDNA cloning (Hepatitis C and G).

At present, we are beginning to understand why certain genes are expressed only in liver. Hepatocyte-specific promoters have been described and the search for specific transcription factors is ongoing. In vitro as well as in vivo transfection techniques are being developed, and the first human trials of gene therapy in both inherited as well as acquired (e.g., cancer) liver diseases have been started. At least five viruses are now known to preferentially infect the liver, and new therapeutic modalities aimed at selectively interfering with viral metabolism are being developed.

Because of limited space and the fact that substantial components of what might be covered in a chapter on molecular hepatology will be covered in other chapters, our approach will be a very focused one. In this chapter, we briefly describe liver development, bile formation (including the enterohepatic cycle of bile acids), and the molecular mechanisms leading to cirrhosis. Next,

we discuss five inherited (i.e., Crigler-Najjar, Gilbert's, Dubin-Johnson, Alagille, and the progressive familial intrahepatic cholestasis [PFIC] syndromes) and two important immune-mediated (i.e., primary biliary cirrhosis [PBC] and primary sclerosing cholangitis [PSC]) cholestatic diseases; finally, we review selected developments in autoimmune hepatitis, polycystic liver disease, amyloidosis, and alcohol- and drug-induced (i.e., acetaminophen, aspirin, and NSAIDS) liver disease.

The classic inherited disorders of the liver are reviewed in Chapter 42 by Ruiz and Wu, who address the molecular basis of Wilson's disease hemochromatosis, α-1-antitrypsin deficiency, cystic fibrosis, the porphyrias, galactosemias, and fructose deficiency. In Chapter 43, Gupta and Shafritz explain in detail the molecular aspects of hepatitis caused by viruses, with particular attention to hepatitis B, C, and D.

MOLECULAR ASPECTS OF LIVER FUNCTION AND BILE FORMATION

During embryogenesis, the liver develops as an extension of cells from the hepatic diverticulum, the caudal portion developing into the gallbladder and cystic duct, and the cranial portion forming the common bile duct and liver bud. The endogenous liver cell population is composed of hepatocytes and intrahepatic bile duct epithelial cells, or cholangiocytes, which are of epithelial cell origin, and a variety of mesenchymal cells, including Kupffer cells, vascular and sinusoidal endothelial cells, fat-storing cells, and pit cells. Within the liver, these cells are organized into histologic and functional units forming the classic hepatic lobules.

The hepatocyte has three important, unique features: first, it is the sole producer of a large number of serum proteins, carbohydrates, and lipids; second, it metabolizes endogenous and foreign substances and excretes the modified products into the biliary system. Third, it synthesizes primary bile acids. All features require hepatocyte-specific promoters and transcription factors for hepatocyte-specific expression of secretary proteins, receptors, or enzymes. Several hepatocyte-specific promoters are now known and include, among others, the albumin, transthyretin, and phosphoenol pyruvate carboxykinase promoters. These specific promoters have been identified by a standard molecular strategy. First, the coding region of the genes was cloned (cDNA) and, subsequently, their genomic structure identified. Next, the upstream untranslated genomic sequence was analyzed for DNA sequences (i.e., *cis*-acting elements) able to drive expression of reporter genes only in hepatocyte-derived cell lines, such as HepG2
Figure 41-1 Albumin promoter. Transcription factors binding to regulatory elements in the albumin gene are depicted in this schematic, simplified diagram. Parts of the gene (double-stranded DNA) representing the enhancer and promoter regions are shown as a double horizontal line; the distance between the enhancer and the promoter is approximately 10-kb pairs. The arrow to the right of the TATAA box indicates the position and orientation of the transcription start of the albumin mRNA. Transcription factor binding sites are shown as ovals or circles, with the names of several transcription factors that bind to these sites shown above and with the names of representative tissues where these factors have been found shown below. The high degree of tissue specificity of this gene is conferred by the combination of the enhancer as well as promoter regulatory elements. NF-1, nuclear factor 1 or CCAAT transcription factor (CTP); LAP, liver-enriched transcriptional activator protein [also named nuclear factor interleukin-6 (NF-IL6), C/EBPβ, and cysteine-rich protein 2 (CRP2)]; NF-Y, nuclear factor Y. (Adapted from: Zaret KS. Control of hepatocyte differentiation by liver-enriched transcription factors. In: Tavoloni N, Berk PD, eds. Hepatic Transport and Bile Secretion: Physiology and Pathophysiology. New York: Raven, 1993; pp. 135–143.

cells. Finally, the unique DNA sequences able to drive expression were analyzed for binding sites for proteins or transcription factors able to drive hepatocyte-specific transcription. Examples of these factors include CCAAT/enhancer-binding protein (C/EBP) and hepatocyte nuclear factors 1, 3, and 4 (HNF-1,3,4) (Fig. 41-1). Other well-known, unique hepatocyte proteins include the asialoglycoprotein receptor, bile acid formation regulating enzymes, and several transport proteins in the hepatocyte canalicular membrane.

Bile acids are organic acids derived from cholesterol. As natural ionic detergents, they are of vital importance in absorption, transport, and secretion of lipids. The primary bile acids in humans are cholic and chenodeoxycholic acid. Both are excreted predominantly in conjugated form, linked either to glycine or taurine. Dehydroxylation of these bile acids by intestinal bacteria produces the more hydrophobic, secondary bile acids, deoxycholic acid and lithocholic acid. In other mammalian species, alternative hydroxylations can occur. For instance, bears generate ursodeoxycholic acid, the 7β-epimer of chenodeoxycholic acid. After release into the intestine, the majority of bile acids is absorbed and returned to the liver via the portal venous system. This cycling of bile acids between liver and intestine is called the enterohepatic circulation. A small fraction of secondary bile acids is further metabolized in the liver to tertiary, conjugated forms, which are not reabsorbed after excretion. Most enzymes required for cholesterol and bile acid synthesis have been extensively studied, and metabolic defects for several enzymes have been described. For example, deficiency in 26-hydroxylase results in a syndrome of premature arteriosclerosis, cataracts, and dementia, known as cerebrotendinous xanthomatosis. A defect in the final step of the bile acid synthesis pathway, that is, side-chain cleavage in peroxisomes, causes the cerebrohepatorenal syndrome of Zellweger, characterized by severe hypotonia, profound psychomotor retardation, and a characteristic facial appearance. Recently, proteins required for bile acid conjugation and transport have been cloned, either by searching for proteins able to bind to labeled bile acids or by expression cloning for proteins able to transport bile acids. For

example, an hepatic sodium/bile acid cotransporter, an ileal bile acid binding protein, an enzyme capable of conjugating bile acids with both glycine and taurine, and the protein responsible for most, if not all, of the sulfation of bile acids in human liver have been cloned.

Secretion of bile acids is coupled to secretion of phosphatidylcholine and cholesterol and thereby provides a major pathway for cholesterol excretion in bile. Deficiency of bile acids results in reduced cholesterol solubility in bile and is thought to contribute to formation of gallstones. On the other hand, expansion of the bile acid pool with ursodeoxycholic acid causes a reduction of biliary cholesterol excretion and has been found to be of therapeutic value in patients with cholesterol gallstones. The exact molecular mechanisms leading to cholesterol gallstone formation are unknown; however, bile with a high cholesterol saturation index strongly predisposes to cholesterol stone formation. Epidemiological studies have shown a familial risk of gallstones and suggest that probably the main cause of this risk is genetic. This concept is supported by the recent description of the lith1 gene associated with development of gallstones in mice.

Until recently, the bile duct epithelial cell, or cholangiocyte, was considered a rather passive cell, that formed a three-dimensional network of interconnecting ducts that served as simple conduits for delivering bile to the intestine. New data show that cholangiocytes actively participate in secretory and absorptive processes. For instance, these cells express the cystic fibrosis transmembrane conductance regulator (CFTR), a regulatory chloride channel, and the chloride/bicarbonate exchanger at their apical domain; the water channel aquaporin 1, or CHIP28, likely at both apical and basolateral domains, and a variety of ion exchangers and ATP-driven pumps at the basolateral domain. Together with cytosolic carbonic anhydrase, these proteins form the basis of a secretory system that is activated, or inhibited by, changes in cytosolic cAMP concentrations. This whole system is finely regulated by peptide hormones. For example, secretin binds to the secretin receptor at the basolateral domain, activates adenyl cyclase, and increases cAMP concentrations, thereby inducing secretion of bicarbonate

Uridine Diphosphate (UDP) Glucuronosyltransferase 1 Gene
Figure 41-2 The uridine diphosphate (UDP) glucuronosyltransferase 1 gene (UGT1) and bilirubin UDP-glucuronosyltransferase 1 mRNA. The more than 100-kb UGT1 gene is located on chromosome 2. Ten mRNAs are derived from the UGT1 gene, each encoding a different UDP-glucuronosyltransferase. The mRNAs differ only in their most 5' sequence. Each of the 5' exons (exon 1A to 1J) encodes the amino-terminus of one UGT1 isoform. Bilirubin UDP-glucuronosyltransferase 1 mRNA uses exon 1A as is shown. Exon 1A encodes for the substrate binding site, exons 3 and 4 for the uridine diphosphate glucuronic acid binding site and exon 5 for the membrane spanning region and endoplasmatic reticulum retention signal. A (TA) insertion in the TATAA box of the promoter preceding exon 1A has been associated with Gilbert's syndrome; point and splice site mutations, deletions, insertions, and formation of stop codons with Crigler Najjar type I syndrome; and only point mutations with Crigler Najjar type II syndrome. Distances are not to scale. (Adapted from: Janssen PLM, Bosma P. Inherited unconjugated hyperbilirubinemias. AASLD postgraduate course 1995 syllabus, pp. 87–100.)

and water; in contrast, binding of somatostatin to its receptor has the opposite effect.

Kupffer cells are macrophages lining the sinusoidal spaces between rows of hepatocytes. They have a variety of functions, including:

1. Endocytosis of viruses, bacteria, and endotoxins.
2. Antigen processing.
3. Secretion of prostaglandins, interferons, and cytokines.
4. A direct cytotoxicity for parasites and tumor cells.

Pit cells, a population of large granular lymphocytes with natural killer cell activity, are thought to protect the liver from colonization by metastatic tumor cells and viruses. In addition, they may function in the regulation of hepatocyte proliferation. Endothelial cells lining the hepatic sinusoids act as sieves, allowing only free diffusion of particles smaller than 0.2 μm, such as chylomicron remnants, through their fenestrations into the space of Disse. They also are actively engaged in endocytosis and excrete prostaglandins and cytokines in response to various stimuli.

Fat-storing cells, lipocytes, Ito cells, or stellate cells are mesenchymal cells situated in the space of Disse, between endothelial cells and hepatocytes. Under normal conditions, they store large quantities of vitamin A in the form of membrane bound droplets. Recent evidence suggests that fat-storing cells are able to transform into myofibroblast-like cells in response to hepatic injury. The factors involved in activation and transformation of these cells include TNF, TGF-β, PDGF, and, possibly, acetaldehyde. Of these, TGF-β probably is the most important. Secreted by fat-storing cells as well as other nonparenchymal cells in response to injury, it activates fat-storing cells and induces production of collagen and other extracellular matrix proteins. At the same time, synthesis of matrix-degrading proteolytic proteins is inhibited, thereby further disrupting the balance between collagen formation and degradation.

In addition to induction of collagen synthesis, a change in the relative amounts of collagen types occurs. Quiescent cells produce mainly collagen types III and IV, laminin and to a lesser extent collagen type I and fibronectin. Activated myofibroblast-like cells secrete collagens type I, III and IV, fibronectin, laminin and a variety of proteoglycans at a much higher level. In particular, collagen type I, fibronectin and proteoglycans containing chondroitin and dermatan sulfate are expressed at very high levels. Together, these changes result in marked hepatic fibrosis. With continued exposure to agents inducing the abnormal extracellular matrix formation, irreversible fibrosis develops. When this fibrotic process is associated with destruction of the classic hepatic lobule, a histology characteristic of cirrhosis develops: regenerating nodules of hepatocytes separated by dense strands of fibrous tissue.

CHOLESTATIC LIVER DISEASES: INHERITED AND IMMUNE-MEDIATED

A single enzyme, UDP-glucuronosyltransferase 1, is responsible for most of the bilirubin glucuronidating activity in humans. Absence of UDP-glucuronosyltransferase 1 results in a syndrome known as Crigler-Najjar type I, whereas mutations causing severe deficiency of the enzyme result in Crigler-Najjar type II (Fig. 41-2). Both syndromes are inherited in a recessive pattern. Crigler-Najjar type I patients have severe unconjugated hyperbilirubinemia with plasma bilirubin levels fluctuating between 26 and 45 mg/dL. As a result, they develop severe neurologic deficits (kernicterus) and frequently die in their first year of life. Crigler-Najjar type II patients have less severe unconjugated hyperbilirubinemia (usually less than 20 mg/dL) and usually do not develop neurologic symptoms. In contrast to type I, the bile of these patients does contain bilirubin conjugates, and treatment with phenobarbital or glutethimide increases bilirubin metabolism resulting in markedly reduced plasma bilirubin concentrations.

Gilbert's syndrome is characterized by a mild, chronic unconjugated hyperbilirubinemia in the absence of liver disease or overt hemolysis. The mode of inheritance is not clear, as both autosomal dominant as well as recessive patterns of inheritance have been described. The defect is a decreased hepatic glucuronidating activity to approximately 30% of normal, resulting in an increased relative concentration of bilirubin monoglucuronide in bile. The enzyme UDP-glucuronosyltransferase 1 itself is normal (i.e., normal sequence of coding region) in many patients thus far examined, but the 5' promoter region of the gene contains two extra bases (TA) in the TATAA element [$A(TA_7)TAA$ rather than normal $A(TA_6)TAA$] (Fig. 41-2). The presence of the longer TATAA element results in the reduced expression of a reporter gene, encoding firefly luciferase, in a human hepatoma cell line and therefore appears to be a cause for reduced expression of bilirubin UDP-glucuronosyltransferase 1 in vivo. However, this explanation is not sufficient to explain the complete manifestation of the syndrome.

Dubin-Johnson syndrome is a rare autosomal recessive disorder characterized by chronic conjugated hyperbilirubinemia. Patients have impaired hepatobiliary transport of nonbile salt organic anions. Recently the disease was shown to be caused by a mutation in the canalicular multispecific organic anion transporter, or multidrug-resistance-associated protein 2 (MRP2), on chromosome 10q24. This protein mediates adenosine triphosphate-dependent transport of a broad range of endogenous and xenobiotic compounds across the apical canalicular membrane of the hepatocyte.

Alagille syndrome (also referred to as Alagille-Watson syndrome, syndromic bile duct paucity, or arteriohepatic dysplasia) is an autosomal dominant disorder characterized by abnormal development of liver, heart, skeleton, eye, face, and, less frequently, kidney. Major manifestations of this syndrome are neonatal jaundice and cholestasis in older children; histopathology shows paucity of intrahepatic bile ducts and cholestasis. Analyses of patients with cytogenetic deletions or rearrangements led to the identification of the JAG1 gene on chromosome 20 as the gene mutated or absent in this syndrome. JAG1 encodes a ligand for the Notch transmembrane receptor. This receptor, called Notch for the shape of the malformed wings of fruit flies with only one functional copy, plays a critical role during morphogenesis. The features of Alagille syndrome seem to develop due to the absence of adequate amounts of JAG1 protein during morphogenesis (so-called haploinsufficiency) rather then due to pertubations caused by a mutant protein.

Progressive familial intrahepatic cholestasis (PFIC) is a heterogeneous group of autosomal recessive liver disorders, characterized by early onset of cholestasis that usually progresses to cirrhosis and liver failure before adulthood. Currently, PFIC is divided in three subcategories: PFIC type 1, or Byler disease, is thought to be caused by defective bile salt secretion. Two loci for Byler disease have been found and mapped to chromosome 18q21-q22 and 2q24. The locus on chromosome 18 also maps the gene for benign recurrent intrahepatic cholestasis (BRIC), and it is possible that different mutations in a single gene lead to this variant of Byler disease and BRIC. A second type of PFIC is thought to be caused by defects in bile salt synthesis; multiple genetic loci may be responsible for this phenotype. Patients with this second type and patients with Byler disease have normal serum γ-glutamyltransferase levels. A third type of PFIC can be distinguished from
Figure 41-3 Histopathology of primary biliary cirrhosis. This liver specimen, obtained at the time of liver transplantation, shows end stage PBC. A regenerative nodule surrounded by inflammatory tissue and blood vessels can be detected; however, bile ducts and ductules are completely absent. (original magnification ×31.)

the other two types by high serum γ-glutamyltransferase activity and liver histology showing portal inflammation and ductular proliferation at an early stage. The genetic defect is due to mutations in the multidrug resistance P-glycoprotein MDR3. This protein is responsible for biliary phospholipid excretion at he canalicular membrane of the hepatocyte as was shown by knockout of the mouse homolog MDR2. As patients with MDR3 mutations, the MDR2 knockout mice develop severe liver disease, characterized by inflammation of the portal tracts, proliferation of the bile ducts, and fibrosis.

Primary Biliary Cirrhosis (PBC) is a liver disease occurring primarily in women and characterized by cholestasis as a result of destruction of septal and interlobular bile ducts (Fig. 41-3) resulting in jaundice and pruritus, hyperlipidemia, fat and fat-soluble vitamin malabsorption, and metabolic bone disease. The liver histology progresses over years to decades from lymphocytic portal infiltrates with bile duct destruction and ductular hyperplasia, to end-stage biliary cirrhosis with complete absence of septal and interlobular bile ducts. At this stage, the usual complications of cirrhosis develop: portal hypertension, variceal hemorrhages, ascites, spontaneous bacterial peritonitis, hepatic encephalopathy, and hepatorenal syndrome.

The molecular defect or abnormality responsible for development of PBC is not known, but an autoimmune basis seems most likely. This presumption is based on the presence of autoantibodies, a possible association with HLA-antigens, known association with other autoimmune diseases, a lymphocytic infiltrate in the early histopathology, and a partial response to a variety of immune-function modifying drugs. The major autoantibodies seen in PBC are directed against the E2 subunit of the mitochondrial pyruvate dehydrogenase enzyme complex and the E2 subunit of the branched chain 2-oxo-acid dehydrogenase complex. It is unclear whether these antibodies are simply a result of the disease process or whether they are actually involved in bile duct destruction. There is an increased frequency of HLA class II antigen DR8 in patients with PBC; how this antigen increases susceptibility to PBC remains unexplained. Exogenous factors also have been implicated; for instance, antibodies as well as T-cell clones derived from patients with PBC crossreact with exogenous antigens such as an *E. coli* pyruvate decarboxylate enzyme complex-E2 peptide.

This suggests that molecular mimicry (i.e., the recognition by the immune system of endogenous proteins with structural similarity to microbial-derived proteins) at the T cell clonal level may be a possible cause of PBC.

Totally effective medical treatment for PBC does not exist. A large number of immune-function modifying and anti-inflammatory drugs have been tried in randomized, controlled, and prospective studies. These drugs included prednisone, azathioprine, chlorambucil, D-penicillamine, cyclosporine, methotrexate, colchicine, and malotilate; none have substantially improved survival, symptoms, or biochemical parameters. However, use of ursodeoxycholic acid has been shown to improve liver tests as well as symptoms, and a recent meta-analysis suggests increased survival or time to liver transplantation; the mechanisms of this apparently beneficial effect are unknown. Finally, liver transplantation clearly has been shown to improve survival, with 1- and 5-year survivals reported as greater than 90 and 80%, respectively.

Unlike PBC, primary sclerosing cholangitis (PSC) is seen predominantly in men. Destruction of bile ducts also forms the basis of this disease, but the inflammatory process is much less pronounced when compared to PBC. Extensive fibrosis of the portal tracts, especially involving the bile ducts (periductal fibrosis), is a histologic hallmark. Unlike PBC, all bile ducts can be affected; that is, the disease can extend from the common bile duct (extrahepatic) to the smallest septal bile ducts (intrahepatic). Involvement of the larger ducts results in a very characteristic radiologic appearance: When the bile ducts are filled with contrast, multiple strictures and localized areas of ectasia are seen (Fig. 41-4). Over years to decades, PSC progresses and end-stage disease is associated with similar complications as discussed for PBC. However, three additional complications are frequently seen. First, stasis of bile in the biliary tree as a result of strictures can lead to intraductal stone formation as well as to development of recurrent infection of the biliary tree (i.e., bacterial cholangitis). Second, in approximately 10% of patients, transformation of bile duct epithelial cells into bile duct cancer occurs. Third, chronic ulcerative colitis, a disease associated with PSC in approximately 70% of cases (*see below*), predisposes to the development of colon cancer.

PSC, like PBC, probably is an autoimmune disease. PSC is also associated with other autoimmune diseases, particularly with chronic ulcerative colitis. As mentioned above, this association is seen in approximately 70% of patients and supports the presumed autoimmune basis of the disease. However, antibodies specific for PSC have not been identified, and an obvious, strong association with a particular HLA class I or II phenotype is not seen. Weak associations have been reported for HLA class II DR3, DR8, and DR52 antigens.

All medical regimens tried thus far have been unsuccessful. At present, only liver transplantation offers patients with PSC significant improvement in survival as well as symptoms.

AUTOIMMUNE HEPATITIS

Autoimmune hepatitis can be defined as an idiopathic autoimmune disease in which the hepatocyte is the predominant target of immune-mediated destruction. It can occur at any age but tends to follow a bimodal age distribution (10–30 and above 50 years), most frequently in women. Symptoms and signs are nonspecific and include general malaise, lethargy, and fatigue. The disease is characterized by negative viral serologies, hypergammaglobulinemia, and a number of circulating autoantibodies. Liver histol-

Figure 41-4 Cholangiogram of a patient with primary sclerosing cholangitis. This cholangiogram shows the typical features of primary sclerosing cholangitis: multiple strictures and dilatations throughout the intra- and extrahepatic bile ducts. Three metal clips were placed during cholecystectomy. (Source: LaRusso NF, Wiesner RH, Ludwig J, MacCarty RL. Primary sclerosing cholangitis. N Engl J Med 1984;310:899–903.)

ogy shows active hepatitis with mononuclear infiltration of portal tracts and surrounding liver lobule (i.e., piecemeal necrosis). Frequently, plasma cells and eosinophils are seen within the infiltrate, in addition to a mixture of helper and suppressor lymphocytes. In general, the disease progresses to cirrhosis. However, treatment with corticosteroids, alone or in combination with azathioprine, markedly delays disease progression and ameliorates symptoms.

As for PBC and PSC, the pathobiology of autoimmune hepatitis is poorly understood. There is a strong linkage with the MHC class II antigens DR3 and DR4 on chromosome 6. In addition, autoimmune hepatitis is also associated with other autoimmune diseases, such as thyroiditis and Sjogren's syndrome. Based on the type of autoantibodies present, several subgroups can be identified. In type I autoimmune hepatitis, autoantibodies are directed against non–organ- and non–species-specific antigens (e.g., antinuclear and antismooth muscle antibodies). These antibodies are unlikely to be involved in the pathogenesis. Type II autoimmune hepatitis is characterized by antibodies against specific cytochrome P450 isoenzymes (anti–liver-kidney microsomal antibodies; putative target cytochrome P450 2D6), which may be expressed on the cell membrane of hepatocytes. Immunogenic cytochrome P450 also can be induced by drug metabolism and haptenation, which indicates that environmental or medicinal xenobiotics may initiate autoimmune liver disease. Finally, a type

III autoimmune hepatitis has been proposed based on the presence of antisoluble liver antigen antibodies.

Treatment goals are to decrease inflammation and prevent progression to cirrhosis. In general, immunosuppressant therapy is only used in symptomatic patients. As mentioned, the therapeutic efficacy of corticosteroids, with or without the addition of azathioprine, is well established. Survival with therapy is excellent. Once cirrhosis and its complications are present, only liver transplantation results in restoration of an acceptable quality of life.

POLYCYSTIC LIVER DISEASE

Simple hepatic cysts are detected in 2–5% of patients undergoing ultrasound examinations of the abdomen. Cysts are seen more frequently in older patients and women. In 60–75%, cysts are solitary and, in general, a maximum of three cysts are detected in patients with multiple lesions. Polycystic liver disease, therefore, should be considered in patients who are found to have four or more hepatic cysts. The most common cause of polycystic liver disease is autosomal dominant polycystic kidney disease (ADPKD). At least three genetic loci are known to predispose to the disease and are located, respectively, on chromosome 16 (ADPKD1), chromosome 4 (ADPKD2), and a still unmapped location (ADPKD3) (*see* Chapter 70). In 1994, the gene from ADPKD1 was cloned and, based on DNA sequence analysis, it codes for a large transmembrane protein called polycystin-1. The function of this protein remains to be determined; a role in cell–cell or cell–matrix interactions is hypothesized. Preliminary evidence suggests that this protein is expressed during fetal development. In normal adults, it is present at very low levels in kidney and biliary epithelial cells; however, its expression is significantly increased in the epithelia lining both kidney and liver cysts of patients with ADPKD1, suggesting that failure to downregulate polycystin expression may be the molecular defect leading to polycystic disease. Recently, the ADPKD2 gene also was cloned; it too seems to encode an integral membrane protein, named polycystin-2, which is ~50% homologous to polycystin-1 at the amino acid level. Polycystin-2 also shows homology to the family of voltage-activated calcium channels. In addition to ADPKD, development of renal as well as hepatic cysts can be a result of other genetic defects, such as autosomal recessive polycystic kidney disease, obstruction of ureter or common bile duct, or a variety of drugs. Finally, multiple families have been described with polycystic liver disease in the absence of significant renal cystic disease; whether these families have a genotype different from all the above-mentioned is unknown.

Liver cysts can range in size from microscopic to several inches in diameter and, therefore, the liver can be normal to massively enlarged (Fig. 41-5). Cysts usually are thin-walled, composed of a single layer of cuboidal epithelial cells, filled with fluid resembling the bile salt independent fraction of bile (i.e., approximate values for sodium, potassium, chloride, and bicarbonate of, respectively, 145, 4, 115, and 25 mEq/L). The cells lining cysts stain positively for biliary epithelial cell markers (i.e., cytokeratin 7 and 19) and secrete ions and water into the cyst in response to secretin, strongly supporting a biliary epithelial origin. Liver cysts are rare in children with ADPKD, but the frequency increases with age to approximately 70% in the seventh decade. Women are likely to have more and larger cysts at an earlier age than men, perhaps related to the use of estrogens and pregnancies. Most patients with polycystic liver disease do not have symptoms. If symptoms occur,

Figure 41-5 CT Scan of a patient with polycystic liver disease. Multiple, large hepatic cysts are present within the liver of this patient with ADPKD.

these reflect abdominal distension due to liver size, venous or biliary obstruction, hemorrhage into cysts, and torsion, rupture, or infection of cysts. Because the volume of the hepatic parenchyma remains normal, overall hepatic function is preserved.

The primary goal of treatment is to reduce the volume of the cysts; this can be established by avoidance of factors associated with cyst development or expansion, such as estrogens and possibly alcohol. Cyst aspiration followed by installation of a sclerosing agent (e.g., 95% alcohol or tetracycline) is used for patients with symptoms a result of one or a few dominant cysts. Finally, surgical fenestration or fenestration combined with cyst resection is performed in patients with advanced disease, whereas liver transplantation is used in the rare patient without liver segments free of cysts.

AMYLOIDOSIS

Amyloidosis is caused by deposition of amyloid substance in the extracellular matrix of various tissues. Frequently the liver is involved, although symptoms and signs because of liver involvement, predominantly hepatomegaly, are nonspecific and relatively infrequent. The amyloid substance is composed of fibrils, which are polymers of low molecular weight proteins in β-pleated sheet conformation. Systemic amyloidoses can be classified into four types as listed in Table 41-1. It is beyond the scope of this chapter to discuss all types in detail; instead, we will discuss the molecular basis of one of the best studied types of hereditary amyloidoses: familial amyloid polyneuropathy caused by point mutations in the transthyretin gene.

Transthyretin is the product of a single copy gene on chromosome 18. This gene has four exons that code for a 127 amino acid mature protein and an 18 amino acid signal peptide. The mature protein functions as a plasma transport protein for both thyroxine and retinol-binding protein. Most of the protein is synthesized in the liver; the remainder is synthesized in the choroid plexuses of the brain and eye. The structure of transthyretin is dominated by eight β strands, which contain approximately 50% of the amino acids and form two four-stranded β sheets. This extensive β-sheet

Table 41-1
Systemic Amyloidoses[a]

Type	Protein
Immunoglobulin (AL)/primary	Kappa or lambda light chains
Reactive (AA)/secondary	Serum amyloid A
Hereditary/familial	Transthyretin (prealbumin)
amyloid polyneuropathies	Apolipoprotein A-1
	Gelsolin
β2-microglobulin/dialysis	β2-microglobulin

[a]Source: Reilly MM, King RH. Familial amyloid polyneuropathy. Brain Pathol 1993;3:165–176.

structure makes the transthyretin protein "amyloidogenic." All 30 (approximately) point mutations predisposing to development of neuropathy are located in exons 2, 3, and 4; the most frequent one is a valine to methionine point mutation at amino acid 30. At the genome level, the frequent occurrence of this mutation can be explained by a "CpG hot spot" (i.e., the dinucleotide sequence CpG is more frequently the target sequence of mutations than would be expected on a random basis). Two additional point mutations in exon 2, one mutation in exon 3, and at least three mutations in exon 4 can lead to either hyperthyroxinemia or cardiomyopathy.

Nearly all patients with a transthyretin mutation are heterozygotes; thus, both the normal as well as the mutated protein can be detected in blood. Because the liver is responsible for over 90% of transthyretin production, liver transplantation theoretically should correct the disease. Preliminary results after liver transplantation, performed in patients with familial amyloidosis polyneuropathy as a result of a point mutation converting the valine codon of amino acid 30 into a methionine codon, indeed show dramatic reductions in the abnormal transthyretin serum concentration and, in some cases, associated improvement in autonomic nervous system function.

ALCOHOL-INDUCED LIVER DISEASE

Alcoholic liver disease occurs only in a subset of individuals who consume large amounts of alcohol (10–20%); the precise reason for this is not understood, but a difference in alcohol-metabolizing enzymes caused by genetic differences is suspected to be responsible for the individual variation in the severity of liver disease among heavy drinkers. Alcohol is predominantly metabolized in the liver. Two enzyme systems are of key importance; the first one consists of alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH) (Fig. 41-6). ADH converts alcohol into acetaidehyde, which in turn is converted to acetate by ALDH. The second enzyme system is the cytochrome P450 2El or microsomal ethanol oxidizing system (MEOS).

Acetaldehyde and increased production of reducing equivalents, such as NADH, are thought to be responsible for most of the hepatotoxicity of alcohol. At least seven different genomic loci are known to encode for over 20 different isoenzymes of ADH. All are expressed in liver and are thought to be derived from a common ancestral gene. They are grouped into five main classes based on the genetic and protein structure. Most are also expressed in other tissues such as the stomach, kidney, and lung. In women, the expression of ADH in the stomach is significantly lower than in men, and this, in part, may explain why women develop alcoholic hepatitis and subsequently progress to cirrhosis sooner, faster, and
Figure 41-6 Metabolic pathway of alcohol. Two enzymes, alcohol dehydrogenase (ADH) and Aldehyde dehydrogenase (ALDH), are responsible for most of the alcohol metabolizing capacity within the liver. Both enzymes require the presence of NAD$^+$ to convert alcohol via the toxic intermediate product acetaldehyde into the nontoxic product acetate. The cytochrome P450 2El or microsomal ethanol oxidizing system (MEOS) pathway, in general, is not important with infrequent, low-dose alcohol use; however, it is markedly induced during chronic alcohol abuse.

after lower amounts of ethanol consumed than men. Two ALDHs are responsible for more than 90% of acetaldehyde metabolism: ALDH1 and ALDH2. Both are NAD$^+$-dependent; ALDH1 is cytosolic whereas ALDH2 is mitochondrial.

Many people with an Oriental background develop flushing after moderate alcohol use. This phenomenon is related to a decreased ALDH2 activity that results in relatively high acetaldehyde levels that, in turn, cause the flushing. This side effect of alcohol use may in part explain why alcohol abuse is less common in eastern Asia. Disulfiram is an inhibitor of ALDH; it produces rapid accumulation of acetaldehyde at levels 5–10 times higher than those found during metabolism of the same amount of alcohol alone. The unpleasant effects (flushing, headache, nausea, and vomiting) of high acetaldehyde concentrations caused by disulfiram, even after small amounts of alcohol, are used therapeutically in the treatment of alcoholism; it reminds motivated patients to abstain from alcohol.

Acetaldehyde is known to condense with plasma proteins, forming stable adducts that can be recognized as foreign by the immune system. A prevalence of severe hypersensitivity reactions of 0.54% was found among a large population of non-Oriental individuals. The reactions were severe enough to deter these individuals from consuming all types of alcoholic beverages. Individuals presenting such reactions had significantly elevated levels of circulating anti-acetaldehyde-protein IgE antibodies.

The exact mechanism whereby alcohol induces hepatitis and subsequently cirrhosis is not known. Cytokines and growth factors likely play a major role; interleukin-1, TNF-α, PDGF, EGF, and basic FGF all are known to stimulate Ito cell proliferation or enhance fibrogenesis. Other interleukins, in particular IL-6 and IL-8, also have been implicated in the pathogenesis of alcoholic liver disease. However, more research is needed to explain how alcohol induces production of these growth factors and cytokines.

DRUG-INDUCED LIVER DISEASES

Nearly every drug can cause liver injury, because the liver is the central organ in most drug metabolic pathways. Some drugs cause a predictable, dose-dependent injury, whereas use of others only results in hepatotoxicity in patients with a genetic predisposition.

Figure 41-7 Metabolic pathway of acetaminophen. Under physiologic conditions acetaminophen is predominantly metabolized via phase 2 reactions (glucuronidation and sulfation). If the capacity of phase 2 reactions is exceeded, or if the cytochrome P450 complex is induced, increasingly phase 1 biotransformation occurs. In the presence of adequate amounts of reduced glutathione (GSH) the intermediate metabolite *N*-acetyl-*p*-benzoquinoneimine is converted into mercapturic acid; in the absence, covalent binding to cell proteins occurs. UDP, uridine diphosphate. (Adapted from: Lee WM. Drug-induced hepatotoxicity. N Engl J Med 1995;333:1118–1127.)

Two general mechanisms of injury are seen: first, direct disruption of the intracellular function or membrane integrity by the drug or its metabolites; and second, indirect damage from immune-mediated mechanisms.

Most drugs are hydrophobic compounds that require biochemical transformations for excretion, processes that transform the hydrophobic native drug into hydrophilic metabolites that are filtered by the glomerulus or excreted into bile. Biotransformation can be divided into two categories: phase 1 and phase 2 reactions. Phase 1 reactions include oxidation or demethylation and are mediated by the cytochrome P450 enzyme system. For instance, the result of a phase 1 reaction is generation of hydroxyl groups. In phase 2 reactions a large, water-soluble group is attached by glucuronidation or sulfation via ether or ester linkage to the phase 1 intermediate, such as an hydroxylated metabolite, or to the native drug. Enzymes involved in these reactions include the already discussed UDP-glucuronosyltransferases and several species of sulfotransferases. A third metabolic pathway for detoxifying many drugs involves a reduction reaction where an electrophilic compound is inactivated by glutathione-*S*-transferase–mediated glutathione coupling. Some drugs undergo all the processes (e.g., acetaminophen [Fig. 41-7]), others only one or two.

The most common reaction leading to hepatotoxicity is the formation of covalent bonds between a metabolite of the native drug and cell proteins or DNA. Another mechanism likely to lead to cell death is lipid peroxidation. As already mentioned, the toxic effect of a specific drug can directly be related to the dose used (e.g., acetaminophen) or to a genetic variant in the enzymes required for its metabolism (e.g., autosomal recessive deficiency for cytochrome P450 2D6, which is required for metabolism of drugs such as debrisoquin, propranolol, and quinidine). How covalent binding of substrate or lipid peroxidation causes cell death remains unknown.

A commonly used classification of drug reactions is based on three end points: the histologic appearance, the cell type involved, and the clinical picture. Table 41-2 lists examples of toxic reactions and the causative agents. Detailed information regarding individual drugs is readily available and will not be discussed. A few widely used drugs and recently reported drug reactions deserve attention, however.

Acetaminophen has already been mentioned. Its toxicity is enhanced by drugs, inducing the P450 system, such as barbiturates and alcohol, and by depletion of glutathione as seen in starvation and alcohol abuse (Fig. 41-8A). On the other hand, both cimetidine and *N*-acetylcysteine protect against acetaminophen toxicity, the former by inhibition of the P450 2E1 isoenzyme responsible for the conversion of acetaminophen into *N*-acetyl-*p*-benzoquinoneimine, and the latter by replenishing glutathione stores.

Reye's syndrome is defined as acute, noninflammatory encephalopathy in association with liver disease, without a clear explanation for both (Fig. 41-8B). Frequently, it follows a viral illness. Epidemiologic studies have shown a markedly increased risk for development of Reye's syndrome after exposure to aspirin. The molecular mechanisms of aspirin-induced liver injury are poorly understood, but seem to involve inhibition of normal mitochondrial enzyme functions. In patients with hepatitis B, treatment with the nucleoside analog, fialuridine, induced a severe toxic reaction, characterized by hepatic failure, lactic acidosis, pancreatitis, neuropathy, and myopathy. The clinical picture of hepatic failure and the hepatic histology resembled the fulminant hepatic steatosis that occurs with Reye's syndrome. Indeed, this toxic reaction also was a result of widespread mitochondrial damage. Similar toxic reactions may infrequently occur during treatment with other nucleoside analogs.

Finally, recent evidence suggests that bacterial toxins, such as the emetic toxin of Bacillus cereus, also can inhibit hepatic mitochondrial fatty acid oxidation and cause fulminant hepatic failure.

Table 41-2
Types of Toxic Reactions and Examples of Provoking Agents[a]

Type of reaction	Examples of agents
Direct reaction	Acetaminophen, carbontetrachloride, mushrooms, phosphorus
Idiosyncratic reaction	Isoniazid, disulfiram, propylthiouracil
Toxic-allergic reaction	Halothane, isoflurane, ticrynafen
Allergic hepatitis	Phenytoin, amoxicillin-clavulonic acid, sulfonamides
Cholestatic reaction	Chlorpromazine, erythromycin estolate, estradiol, captopril, sulfonamides
Granulomatous reaction	Diltiazem, quinidine, phenytoin, procainamide
Chronic hepatitis	Nitrofurantoin, methyldopa, isoniazid, trazodone
Alcoholic hepatitis-like syndrome	Amiodarone, perhexiline maleate, valproic acid
Microvesicular steatosis	Tetracyclines, aspirin, zidovudine, didanosine, fialuridine
Fibrosis or cirrhosis alone	Methotrexate, vitamin A, methyldopa
Veno-occlusive disease	Cyclophosphamide, other chemotherapeutic agents, herbal teas
Ischemic damage	Cocaine, sustained-release nicotinic acid, methylenedioxyamphetamine

Nonsteroidal anti-inflammatory drugs (NSAIDS), frequently used anti-inflammatory, and analgesic agents are commonly implicated as causes of liver injury. One of the better studied drugs is diclofenac (Fig. 41-8C). In rare cases, it is associated with the development of fulminant hepatic necrosis. Both direct toxic effects of a diclofenac metabolite and hypersensitivity reactions have been suggested as possible molecular mechanisms of liver injury. In vitro experiments have shown that direct hepatocyte toxicity is increased with inhibition of the glucuronidation pathway and decreased by inhibition of cytochrome P450-dependent oxidative biotransformation. On the other hand, the covalent binding to hepatocellular proteins is greatly reduced when glucuronide formation was selectively blocked. Therefore, diclofenac acyl glucuronide formation is likely associated with covalent binding of a reactive metabolite to hepatocellular proteins, which may be toxicologically relevant for the expression of diclofenac hepatitis.

SUMMARY

We now understand a growing number of the molecular mechanisms responsible for the signs and symptoms, the biochemical abnormalities, and the histopathology of many inherited as well as acquired liver diseases. At present, we are beginning to understand the regulation of gene transcription and translation within the various individual cell types of the liver. Among possible advances, this has resulted in the development of new classes of pharmacological agents and in the possibility of hepatocyte gene transfer. Although much has been learned, even more remains unknown: What are the molecular signals that determine overall liver size and induce the unique phenomenon of liver regeneration to its original size after drug- or virus-induced necrosis or surgical partial hepatectomy? How do different cell types within the liver communicate with each other? Why are genes transfected into
Figure 41-8 Histopathology of drug-induced liver disease. Liver histopathology of acetaminophen-, aspirin-, and diclofenac-hepatotoxicity. **(A)** Shows liver specimen with severe necrosis around the central veins (CV, zone 3 of the hepatic lobule) as the result of an acetaminophen overdose. The hepatic parenchyma around a large portal tract (PT, zone 1 of the hepatic lobule), showing a portal vein branch, an hepatic artery, and a bile duct, is well-preserved. **(B)** Shows the liver parenchyma of a patient with Reye's syndrome after aspirin use. Within the hepatocytes there are abundant fat droplets; the fat has been dissolved and therefore the cells appear white in this illustration. **(C)** The liver specimen is from a patient who had received diclofenac for arthritis. While on the drug, she developed jaundice and therefore diclofenac was discontinued with resolution of symptoms. However, several months later, diclofenac was restarted with recurrence of jaundice. Only a few hepatocytes are seen in the part of the specimen shown in this picture (arrows). The close proximity of several bile ducts and the extensive inflammatory reaction suggest massive destruction of hepatocytes with collapse of the fibrous septa: submassive necrosis. The marked ductular proliferation is evidence of hepatic regeneration. (original magnifications: [A] ×31, [B] ×125, [C] ×62.

hepatocytes only transiently expressed in vivo? Clearly, the answers to many of these important questions will, in part, depend on further molecular studies of the diverse cell types forming the liver.

42 Inherited Liver Disease

JUAN RUIZ AND GEORGE Y. WU

INTRODUCTION

The liver is a major site of metabolism in humans, playing a central role in the metabolism of carbohydrate, protein, lipid, trace elements, and vitamins. In addition, detoxification and biliary excretion of various endogenous and exogenous compounds, especially lipophilic molecules, including most common drugs, and the degradation and elimination of a variety of hormones and hormonal metabolites, are distinct hepatic characteristics. Because of its involvement in so many metabolic pathways, it is not surprising that many inherited diseases of the liver are manifested as inborn errors of metabolism. Disease occurs as a result of lack of the required gene product or accumulation of a toxic metabolite.

Molecular defects responsible for these disorders can be classified as single basepair substitutions, insertions, or deletions, and are exemplified in Fig. 42-1.

ABNORMAL METAL METABOLISM

WILSON DISEASE   Wilson disease (hepatolenticular degeneration) was described in 1912 by Kinnear-Wilson. The disease results from a disturbance in hepatic copper metabolism characterized by an inability to secrete copper into bile resulting in hepatic accumulation, progressive liver damage and, after hepatic overflow, accumulation in the brain and other organs. In addition, there is a defect in the incorporation of copper into ceruloplasmin.

Copper is an important metal cofactor present in several enzymes (superoxide dismutase, tyrosinase, lysyl oxidase, dopamine-β-hydroxylase, peptide α-amidating enzyme, cytochrome oxidase, and ceruloplasmin). Although essential, only trace quantities are required and larger amounts are toxic. The normal body content is 70–100 mg and depends on the balance between intestinal absorption and biliary excretion (1–5 mg daily). The liver plays a major role in copper metabolism by the uptake of the recently absorbed metal that is excreted into bile and also incorporated into ceruloplasmin.

Clinical Manifestations   (Table 42-1) The disease has a worldwide prevalence of about 1–30,000 (1:200 for the gene) without ethnic preferences. There is a broad organ involvement. Approximately 40% of patients present with hepatic features, followed by neurological (34%) and endocrine, hematological (10%), or neuropsychiatric (12%). Hepatic manifestations tend to appear earlier than those of neurological origin (6–12 years for the hepatic

presentation vs 12 years or more for the neurological forms) and will be present always, irrespective of the initial presentation, if adequate treatment is not implemented. There may be a chronic insidious presentation, sometimes punctuated by transient icteric episodes or an acute onset with hemolysis and hepatic or renal failure as a result of an acute release of free nonceruloplasmin bound copper from the liver. Neuropsychiatric symptoms appear later than the hepatic manifestations and are associated with the presence of Kayser-Fleischer rings, which are a manifestation of copper deposition in the Descemet's membrane. There is a strong correlation between the presence of Kayser-Fleischer rings in Wilson disease and copper deposition in the brain. Although the intellect is preserved, there may be a slow deterioration of the personality. Renal changes are related to copper deposition in tubular cells resulting in amino aciduria, glucosuria, uricosuria, hyperphosphaturia, hypercalciuria, renal tubular acidosis, and stone formation.

Diagnosis   It is most important to consider Wilson disease in the differential diagnosis of chronic liver disease in children and young adults and whenever liver disease is associated with neurological symptoms.

Important parameters are:

1. Serum ceruloplasmin <20 mg/dL.
2. Hepatic copper concentration >250 μg/g dry weight.
3. Urinary copper excretion >100 μg/d.

Diagnosis can be made by showing either parameter 1 and the presence of Kayser-Fleischer rings or both parameters 1 and 2. However, 50% of patients without neurological symptoms do not have Kayser-Fleischer rings at presentation, and 5–10% of patients have ceruloplasmin levels in the lower normal range. In those patients, the most important determination is liver copper content. If further discrimination is required, orally administered radiocopper ([67]Cu) incorporation into ceruloplasmin can be used. An absence of an increase in [67]Cu serum levels after 24–48 h is diagnostically helpful.

Linkage analysis using specific DNA markers can be applied to siblings. However, because of genetic heterogeneity, it is not useful for screening of potential heterozygotes in the general population. Confirmation in siblings should be sought by measuring serum copper, ceruloplasmin, and urinary copper.

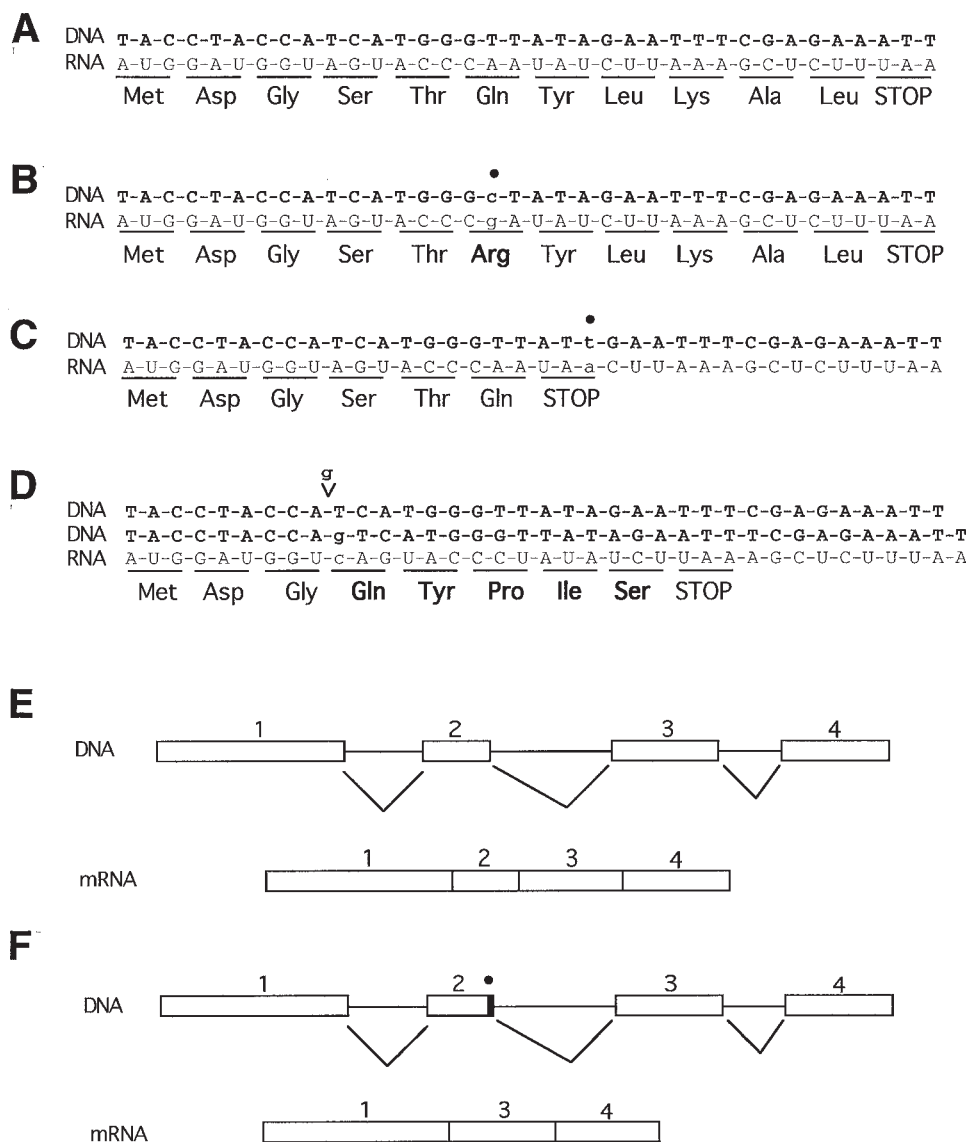
Genetic Basis of the Disease   Wilson disease has an autosomal recessive inheritance. The gene (ATP7B), recently identified by positional cloning and the use of the closely related Menke's


Figure 42-1 Different gene defects and its consequences. **(A)** Normal gene, messenger RNA, and encoded polypeptide. **(B)** Missense mutation leading to a single amino acid substitution: The results can be either a different isoform of the molecule (when the affected amino acid is not functionally essential) or a significant functional alteration of the product. **(C)** Missense mutation resulting in a premature stop codon and termination of the polypeptide: the final product is a truncated protein that has abnormal function or no function at all. **(D)** Insertion of a nucleotide producing a frameshift (modification of the amino acid sequence downstream from the mutation) and a premature stop codon (truncation of the polypeptide): The result is complete abolition of the protein activity (null phenotype). The same effect is produced by nucleotide deletions. **(E)** Scheme of the structure of a gene with the exons (boxes) and introns (lines). After transcription and splicing of the introns, the mRNA is produced. **(F)** Effects of mutations on the splice acceptor or donor sequences: Substitutions in exon/intron splice sites can result in improperly spliced message and abnormal gene product containing intronic sequences or missing exonic elements. In this case, exon 2 is removed from the mature mRNA. The black dot indicates the nucleotide mutation.

disease gene as a probe, is located on chromosome 13. It contains 23 exons and a 4.3-kb region that codes for a membrane-bound cation-transporting P-type adenosine triphosphatase. The family of P-type ATPases also includes the Menke's Disease gene and several related bacterial and yeast genes. There is a 56% identity with the gene for Menke's disease (ATP7A), an X-linked disorder characterized by a defective intestinal absorption of dietary copper. The identity is even higher (75–100%) at the amino acid level of functionally important domains. ATP7B is expressed mainly in the liver, kidney, and placenta. There is alternative splicing for some exons in the liver and the brain. The alternative isoforms may

have some functional significance, and the differential splicing may help regulate the amount of functional protein produced.

The genetic defects in Wilson disease are heterogeneous. Using single-strand conformation polymorphism (SSCP) to identify the mutations, followed by sequencing, more than 30 different mutations have been described to date. Genotype analysis has revealed insertions and deletions causing frameshifts, stop codons (nonsense), altered splicing, and missense mutations. In particular, nucleotide substitutions have been described in the phosphorylation consensus sequence and in the hinge region of the ATP-binding site. Unlike Menke's disease, where 20% of patients have

Table 42-1
Clinical Features of Wilson Disease

Hepatic	Acute hepatitis, fulminant hepatitis, chronic hepatitis, liver cirrhosis
Neurological	Akinesia, rigidity, muscle spasms, dystonia, dysarthria, dysphagia, resting and intention tremor, epilepsy, encephalopathy, peripheral neuropathy
Psychiatric	Cognitive impairment, behavioral changes, psychosis, affective disorders
Gastrointestinal	Cholelithiasis, pancreatitis
Ophthalmological	Kayser-Fleischer rings, sunflower cataracts
Hematological	Hemolysis (acute, chronic), coagulopathy, intravascular coagulation, hypersplenism
Renal	Renal tubular dysfunction, nephrolithiasis
Musculoskeletal	Osteoporosis, osteomalacia, osteoarthropathy
Cardiovascular	Cardiomyopathy, arrhythmias
Endocrine	Amenorrhea, miscarriages

large gene deletions, no large deletions have been found. Most patients studied are compound heterozygotes, having two different allelic mutations, a result of the large number of mutations.

Molecular Pathophysiology of Disease   It has been shown that copper transport across membranes is an ATP-dependent process. The P-type adenosine triphosphatase involved in Wilson disease contains several domains: six copper binding, nine transmembrane, transduction, channel, phosphorylation, phosphatase, and adenosine triphosphate-binding regions. A decrease in the number of active molecules or a decrease in its activity causes a defect in the secretion of copper into the bile because of a deficiency in the activity of the transporter system. The precise intracellular localization of the transport defect has not yet been elucidated. In addition, a reduction in the incorporation of copper into apo-ceruloplasmin to generate holo-ceruloplasmin, possibly a result of the same genetic defect, causes the accumulation of the metal in the hepatocytes. Damage in tissues where copper has accumulated is probably secondary to membrane lipid peroxidation, glutathione depletion, and polymerization of copper-thionein, resulting in abnormal function of the mitochondria, lysosomes, microtubules, and nuclear DNA.

Wilson disease is an excellent example of a metabolic disease caused by a single gene defect, with a correlation between genotype and phenotype based on the different defects in the mutated protein, e.g., domain modifications or complete absence of gene product. Specific types of mutations may predict the severity of the disease. For example, those mutations that destroy the function of the gene, stop codons truncating the protein or insertions, or deletions causing frameshifts, appear to correlate with an earlier onset of the disease, in one study approximately 7.2 years of age. Interestingly, the same study shows that in those mutations causing modifications in specific domains without affecting the whole molecule (missense mutations), the average age of onset of symptoms is higher, 16.8 years. In fact, some authors suggest than if the genetic defect is so substantial, e.g., large deletions leading to a null phenotype, the result would be a very early onset of the disease that could be misdiagnosed as some cases of Indian Childhood

Cirrhosis. Another important phenomenon is that of mutations affecting regions of the gene where a possible alternative splicing can occur. The removal of the mutation in some tissues would mitigate its deleterious effects and lead to a later onset of the disease. As an example, a severely detrimental mutation, 2010del7, located in exon 6, causing a frameshift, results in a later onset, neurological form of Wilson disease by an alternative splicing that removes the deletion.

Ceruloplasmin carries 80% of the copper present in plasma and its function, although not well-understood, can be related to its ferroxidase, amine oxide, and antioxidant properties. The importance of the ferroxidase activity of ceruloplasmin is underlined by the deposition of iron and subsequent damage in the liver, pancreas, retina, and brain in patients with severe ceruloplasmin deficiency. Most patients with Wilson disease show a decrease in serum ceruloplasmin levels that correlate with the clinical manifestations of the disease. However, this decrease is not universal and no pathophysiological correlation has been established. Ceruloplasmin is synthesized in the liver in an inactive form, apo-ceruloplasmin, and is transformed to the active form, holo-ceruloplasmin, by the incorporation of up to six to seven atoms of copper per molecule. Both forms are different antigenically and holo-ceruloplasmin is the form usually detected in plasma in normal subjects. Normal amounts of ceruloplasmin in liver tissue from patients with Wilson Disease, normal ceruloplasmin RNA levels in Long Evans Cinnamon (LEC) rats, an animal model of Wilson Disease, together with the exclusive presence of apo-ceruloplasmin in serum, suggest a posttranslational defect in the incorporation of copper into ceruloplasmin rather than a defect in the ceruloplasmin gene itself.

Management and Treatment   Treatment is aimed at reducing the amount of copper in the body and to prevent the toxic effects of free copper in the tissues. *D*-penicillamine (1–2 g/d divided in two doses) is the most common treatment and must be given lifelong. *D*-penicillamine chelates copper, permitting urinary excretion. Additionally, it has detoxifying activity on intracellular copper. In some cases, neurological symptoms may worsen at the beginning of the treatment as copper is released from the liver. In cases of adverse effects to *D*-penicillamine, an alternative agent is trientine, another copper chelator. Other possible agents include tetrathiomolybdate, a chelator that is possibly more effective for neurologic disturbances, and zinc, which decreases intestinal copper absorption and stimulates metallothionein production, which in turn binds copper. Urinary copper determinations are used to monitor the treatment.

Liver transplantation is the treatment of choice for patients with irreversible liver disease or fulminant hepatitis. Its role in cases of neurologic disease without hepatic insufficiency is not clear.

Future Directions   LEC rats possess a genetic defect characterized by a deletion of at least 900 bp at the 3' end of the rat-homologous Wilson gene. No mRNA is detected in the liver or other tissues by Northern blots. The same clinical and biochemical features characteristic of Wilson disease have been demonstrated: excessive hepatic copper accumulation, defective holo-ceruloplasmin biosynthesis, and impaired biliary copper excretion. Gene therapy could be a potential option as a curative treatment of Wilson disease in the future and its feasibility can be tested in LEC rats.

HEMOCHROMATOSIS   The term hemochromatosis was first used by von Recklinghausen in 1889. The disease is caused by an inappropriately high intestinal absorption of iron that first ac-

cumulates in the parenchymal cells of the liver and later in other organs. Unlike most inborn errors of metabolism, the basic defect in hereditary hemochromatosis is not located primarily in the liver. However, its clinical manifestations are largely the result of liver disease and dysfunction.

Iron is absorbed both as heme and nonheme forms (ferrous salt) by the intestinal mucosa. Once inside the enterocyte, it is coupled to transferrin and transported to tissues. Cells having transferrin receptors internalize the protein, and iron is released into the cytoplasm to be incorporated to heme and apoproteins. Because of its high toxicity, excess iron is stored in the body as ferritin or hemosiderin. Iron absorption is a poorly understood but extremely important process, because there is no physiological mechanism for excretion of excess iron. Absorption is responsible for regulation of normal iron balance. Losses because of shedding of mucosal cells along the gastrointestinal and genitourinary tracts and skin desquamation are relatively constant around 1 mg/d, and are compensated by a 10% absorption of the 10–20 mg of iron present in an average diet. Deregulation of the absorption in the presence of fixed losses lead to a constant increase in body iron stores (up to 40 g) with subsequent cell damage.

Clinical Manifestations (Table 42-2) Although all races are affected, hemochromatosis is most common among Caucasoids of Celtic origin, with a prevalence of 1:300–400 and a carrier rate of 1:20. The disease is characterized by a latent period for many years while the iron stores increase in liver. This latent period depends greatly on the dietary iron intake as well as physiologic and pathologic blood loss. This explains the 9-to-1 ratio between affected men and women.

The clinical picture is that of a multisystemic disease. Liver disease has mostly a benign and prolonged course with cirrhosis and liver failure present as late features. However, hepatocellular carcinoma can be the first manifestation of the disease. Hyperpigmentation of the skin is the result of an increase in melanin in the cells of the basal layer. Deposition of iron in the pancreas, heart, pituitary, and joints result in diabetes mellitus, cardiomegaly, arrythmias, heart failure, hypogonadism, hypoparathyroidism, hypothyroidism, chondrocalcinosis, demineralization, and chronic arthropathy.

Diagnosis The introduction of routine serum iron studies for asymptomatic individuals as well as the use of HLA markers in families of affected individuals have improved the rate of early diagnosis and the time of diagnosis before the development of significant disease. This is important because treatment can restore life expectancy to normal if irreversible organ damage, e.g., cirrhosis, has not occurred. Diagnosis is made by serum iron studies, the most important being the transferrin saturation index. An index below 50% excludes the diagnosis, while one above 70% is suggestive of hemochromatosis. Serum ferritin concentration >200 µg/L in asymptomatic homozygotes and >900 µg/L in symptomatic patients is helpful. A high serum iron concentration >30 µmol/L alone is less specific. Confirmation of the diagnosis is made by liver biopsy, the definitive laboratory test, that shows increased iron deposition in hepatocytes (at the periportal areas in early stages) with paucity of iron elsewhere. This is in contrast to secondary iron accumulation in reticuloendothelial cells. Measurement of hepatic iron content allows the quantification of iron in the liver and the calculation of the hepatic iron index (tissue iron in mmol/g liver dry weight/age [years]). The index helps discriminate homozygotes, having indices >1.9, from heterozygotes and

individuals with other iron-loading diseases with indices <1.5. Heterozygotes do not develop the disease, even though some may have elevated serum iron and saturations.

All blood relatives of an identified homozygote patient should be investigated. In addition to biochemical studies, HLA haplotyping and other DNA markers, such as microsatellites, have been used until now in order to determine whether any relatives share all four haplotypes of the index patient (homozygotes), half (heterozygotes), or none.

The recent discovery of a candidate gene and the identification of a single mutation present in 83–100% of patients will help in the development of more accurate genetic tests both for diagnosis and population screening.

Genetic Basis of the Disease Hereditary hemochromatosis is an autosomal recessive disease. Numerous studies had previously mapped the hemochromatosis gene to chromosome 6p, closely linked to the HLA-A locus. Recently, a candidate gene responsible for the disease, originally designated HLA-H, has been identified and named HFE. Eighty-three percent of 178 hemochromatotic patients were homozygous for the same missense mutation. Eight out of nine who were heterozygous for this mutation were observed to have a different missense mutation on the other allele. The mutations identified are: (1) a G-to-A transition at nucleotide 845 results in a cysteine-to-tyrosine substitution at amino acid 282 (C282Y). This mutation is homozygous in 83, 91, or 100% of hemochromatosis patients according to different studies. The same mutations are only present in heterozygosity in 5–6% of controls. (2) A second mutation, a C-to G-change that results in a histidine-to-aspartic acid substitution at amino acid 63 (H63D), has also been observed, although at a frequency similar to that of the control population (17–21%).

Before the HFE gene identification, several candidate genes, such as transferrin, transferrin receptor, ferritin or iron-regulating factor, had already been excluded because of their location in chromosomes other than 6p. Tumor necrosis factor-α (TNF-α) gene is located at chromosome 6p, close to the HLA cluster, and had also been implicated because it downregulates iron absorption and its production is decreased in stimulated monocytes of patients with hemochromatosis. However, the TNF-α gene locus does not

coincide with possible sites proposed for the HLA, linked iron-loading gene.

Molecular Pathophysiology of Disease The HFE gene encodes a protein with a strong similarity to MHC class I molecules (HLA-A2) and nonclassical class-I–like molecules (HLA-G and the Fc receptor). The gene comprises seven exons encompassing 12 kb and encodes a 343-amino acid protein. Based on the significant similarity to MHC class I proteins, which are membrane proteins, it was predicted to have three characteristic extracellular domains or loops, a transmembrane domain, and a short cytoplasmic region. The C283Y mutation eliminates a cysteine residue, thus disrupting a disulfide bridge. As a result, the conformation of the α3 domain of the molecule is altered, preventing noncovalent binding to β2-microglobulin. Because the transferrin receptors have also been demonstrated to interact with the β2-microglobulin-HFE protein complex, failure of HFE to bind the complex to the cell surface may prevent normal downregulation of iron transport. Data derived from β2-microglobulin knockout mice support a role for nonclassical class I genes in the control of iron metabolism. β2-Microglobulin-deficient animals develop hepatic iron overload resembling that of hereditary hemochromatosis, and the defect has been related to a failure to limit the transfer of iron from the mucosal cells into the plasma.

Iron can be a very toxic element. Damage in the affected organ is related to:

1. Membrane lipid peroxidation associated with impairment of membrane-dependent functions of mitochondria (oxidative metabolism and calcium sequestration), lysosomes (fluidity, membrane integrity, and pH), microsomes (enzyme activities and calcium sequestration), and cell surface (cellular integrity).
2. Fibrosis resulting from iron-mediated stimulation of collagen synthesis through its action as a cofactor for proline and lysine hydroxylase in collagen synthesis. It appears that Kupffer cells are induced to release cytokines by lipid peroxidation products released from hepatocytes. These cytokines activate stellate cells, resulting in alteration of the extracellular matrix in liver.

Management and Treatment Standard treatment for hereditary hemochromatosis consists of periodic phlebotomies of 500-mL once or twice weekly. One 500-mL unit of blood contains 200–250 mg iron, allowing removal of up to 25 g in a period of 2 years. Gradual decrease in body iron stores is monitored by serum ferritin levels. Plasma transferrin saturation does not change until available iron stores are depleted. Once transferrin saturation is less than 50% and ferritin levels are less than 50 µg/L, phlebotomies can be spaced, usually every 2–4 months. Chelating agents such as desferoxamine are used only when anemia or hypoproteinemia prevents phlebotomy.

Liver transplantation carries a higher mortality in patients with hereditary hemochromatosis, probably because of complications of late pretransplant diagnosis and treatment.

Future Directions Studies on the HLA-H gene and its defects will clarify the complex mechanisms of iron absorption and distribution. Molecular screening tests will be available to identify affected patients and carriers bearing the C282Y mutation. In addition, earlier diagnosis will help prevent the development of the disease.

OTHER RELATIVELY COMMON GENETIC LIVER DISEASES

ALPHA-1-ANTITRYPSIN DEFICIENCY AND LIVER DISEASE (For a general description of the disease, *see* Chapter 38.) Alpha-1-antitrypsin was isolated in 1955 by Schultze et al. and first associated with liver disease in 1968 by Freier et al. in two brothers with cirrhosis. It is the most important circulating protease inhibitor, and its deficit results in pulmonary emphysema. Liver damage occurs in 10–15% of patients.

Alpha-1-antitrypsin is produced mostly in hepatocytes, but also in other cell types, particularly monocytes and macrophages of the alveoli. Its main function is to neutralize neutrophile elastase. In addition, it represents 90% of the total trypsin inhibitor capacity and inhibits chymotrypsin, plasmin, thrombin, tissue kallikrein, factor Xa, collagenase, renin, and urokinase.

Clinical Manifestations (Table 42-3) Alpha-1-antitrypsin deficiency (PiZZ) affects 1:1600–1800 births in North American and Northern European populations. Development of pulmonary emphysema is the most important clinical manifestation. Neonatal cholestasis is the most frequent hepatic disturbance, present in 10% of PiZZ subjects, and although it usually resolves, it may progress to juvenile cirrhosis, especially in cases of prolonged cholestatic jaundice. Liver disease may also be first diagnosed in late childhood or early adolescence because of the appearance of cirrhosis and its complications. There is an increased risk of cirrhosis and hepatoma in adult life in PiZZ males over the age of 50.

Diagnosis Alpha-1-antitrypsin deficiency should be suspected in patients with emphysema, jaundice in infancy, and chronic liver disease in childhood or adult life. Concentration of alpha-1-antitrypsin in plasma is determined either by functional assays, such as evaluation of trypsin or elastase inhibition, or by immunochemical methods. Although serum concentrations of alpha-1-antitrypsin are decreased to 10–15% of normal values in PiZZ and to a 50% in *PiSS* or *PiMZ*, results can be misleading whenever there is an inflammatory process, because alpha-1-antitrypsin is an acute phase reactant.

Definitive diagnosis is based on alpha-1-antitrypsin phenotype determination of the abnormal protein by isoelectric focusing or agarose electrophoresis at acid pH or by genomic DNA analysis by polymerase chain reaction followed by oligonucleotide probe hybridization.

Liver histology shows periodic acid-Schiff-positive, diastase-resistant globules into hepatocytes, caused by the aggregation of deficient alpha-1-antitrypsin in the rough endoplasmic reticulum. These inclusion bodies may not be present in patients younger than 3 months.

Genetic Basis of the Disease Alpha-1-antitrypsin deficiency has a codominant inheritance pattern. The gene, located in chromosome 14, was identified by linkage studies using markers of the gamma immunoglobulins. It is 12.2 kb in length and con-

tains seven exons. Messenger RNA transcripts from the liver lack the first two exons (1A and 1B) and differ from those of monocytes and macrophages that contain the whole coding sequence (although the first two exons and the 5' region of the third exon remain untranslated in these cell types).

To date, more than 75 different variants of the gene have been identified. They are classified into normal allelic variants, resulting from single mutations that do not modify serum levels or antiprotease activity; deficient variants, representing mutations in important nucleotide-amino acids that lead to decreased serum levels or altered function; and null alleles resulting from insertions or deletions that result in no detectable alpha-1-antitrypsin in serum. Variants were named according to their mobility in acid starch gel electrophoresis: F (fast), M (medium), S (slow), and Z (the most cathodal) and, when more variants with similar mobility were identified, birthplace names were used. PiM is the most common normal allele, present in 89% of the population, and PiZ (Glu 342-Lys) the most frequent deficient variant. Other deficient variants are PiS, PiMMALTON, PiSIIYAMA, or PiMDUARTE. Some variants involve more than one mutation.

Molecular Pathophysiology of Disease   Alpha-1-antitrypsin is the most abundant circulating proteinase inhibitor and is the prototypic member of the serine proteinase inhibitor (serpin) superfamily. These proteins have a globular shape and are composed of α-helices and β-pleated A sheets. The reactive centers are situated on a mobile α-helix peptide loop. On interaction with the protease, there is cleavage at the reactive site and a structural rearrangement of the molecule with insertion of the reactive loop into a gap in the β-pleated A sheet molecule. That insertion can also occur with sites on other alpha-1-antitrypsin molecules, leading to polymerization (loop-sheet polymerization). The Z mutation leads to a single amino acid substitution: the negatively charged glutamic acid at position 342 is substituted by a positively charged lysine residue. As a result, the mobility and conformation of the loop changes, leading to a misfolding of the molecule. It also allows the reactive loop to interact spontaneously with the β-sheet of an adjacent molecule. This interaction involves several molecules, leading to the polymerization and aggregation of the molecules within the endoplasmic reticulum of hepatocytes. These aggregates appear as the periodic acid-Schiff-positive, diastase-resistant globules dilating the rough endoplasmic reticulum of hepatocytes in liver biopsies. The polymerization phenomenon is an equilibrium process, and there are some monomeric proteins that are released from the cell, accounting for the 12–15% of Z antitrypsin present in the plasma of patients. Although these monomers retain 85% of the wild-type protein antielastase activity, the number of molecules is not sufficient to protect the lungs against the proteolytic attack by neutrophile elastase that leads to emphysema. However, liver damage is not caused by a deficiency in antiprotease activity, but by accumulation of alpha-1-antitrypsin aggregates in the hepatocytes, resulting in enhanced lysosomal activity within the cell. Supporting this concept are observations in transgenic mice carrying human Z alpha-1-antitrypsin and normal endogenous mouse antiprotease activity. In spite of the presence of normal mouse antiprotease, the mice developed liver injury with PAS-positive globules. Another observation that supports the hypothesis is the fact that patients with a null genotype, who lack the protein altogether, have a more severe pulmonary disease, but do not develop liver disease.

Polymerization and aggregation of alpha-1-antitrypsin have also been observed with other variants like the PiSIIYAMA

(Ser 53 to Phe) and the PiMMALTON (Phe 52 deleted). PAS-positive globules and liver disease have been reported in some of these patients.

The aggregation hypothesis for the mechanism of liver injury does not explain why only 10–15% of PIZZ patients develop liver disease. Therefore, it appears that both inherited traits and environmental factors seem to be involved. It has been shown that PiZ homozygous patients that develop liver disease have a delay in the degradation of the accumulated mutant alpha-1-antitrypsin protein in the rough endoplasmic reticulum compared with carriers of the mutation that do not develop liver damage. Other possible explanations include an excessive production of the protein in response to different stimuli or an special sensitivity to the accumulation of the protein. Environmental factors may predispose some individuals to liver disease by upregulating the synthesis of alpha-1-antitrypsin as an acute phase reactant.

An increased prevalence of PiMZ heterozygotes in adult patients with cirrhosis or chronic hepatitis, and the liver disease associated with phenotypes other than PiZZ, has been reported. However, these may represent coincidental findings as other etiologies for the liver disease have been identified.

Management and Treatment   There is no specific treatment for liver disease associated with alpha-1-antitrypsin deficiency other than that of the complications of cirrhosis and liver transplantation for the decompensated disease. Plasma-derived or synthetic alpha-1-antitrypsin used for the treatment of lung disease are not effective in preventing liver damage. In fact, they can worsen the evolution of the disease because of the upregulation of alpha-1-antitrypsin synthesis by the interaction of alpha-1-antitrypsin–protease complex and the serpin-enzyme complex (SEC) receptor. Other situations likely to upregulate the synthesis of alpha-1-antitrypsin as an acute phase reactant (infections, inflammatory processes) have to be avoided or promptly corrected. Liver transplantation for end-stage liver disease is the only option.

Future Directions   Therapeutics directed toward reducing the retention of the mutant protein in the rough endoplasmic reticulum through the use of synthetic peptides is one of several future therapeutic strategies. These decoy molecules mimic the binding domain of alpha-1-antitrypsin responsible for intracellular retention in the rough endoplasmic reticulum. This strategy could not only prevent the intracellular accumulation of alpha-1-antitrypsin, but also provide the delivery of functionally active protein to extracellular fluid and tissues.

Finally, null phenotypes pose a different challenge because even if alpha-1-antitrypsin could be provided, an immune response against the protein is likely to occur. Transgenic mice carrying the PiZ variant of the alpha-1-antitrypsin deficiency provide a convenient model for testing novel therapeutic agents.

CYSTIC FIBROSIS AND LIVER DISEASE   (For a general description of the disease, *see* Chapter 37.) Cystic fibrosis is a common lethal genetic disorder affecting 1 in 2000 live births among Caucasians, with liver and biliary tract disease as frequent complications. The gene for the cystic fibrosis transmembrane conductance regulator (CFTR) encodes a protein that acts as a chloride channel. In addition, it probably has other functions, including the regulation of other channel proteins. There is an intracellular CFTR fraction, on endosomal membranes, that probably participates in the control of the level of intravesicular acidification, an important step in the protein secretory pathway and receptor-mediated endocytosis. The chloride channel is located in

Table 42-4
Hepatobiliary Manifestations of Cystic Fibrosis

Liver	Biliary tract
Neonatal cholestasis	Cholelithiasis
Fatty liver	Gallbladder hypoplasia
Hepatosplenomegaly	Common bile duct stenosis
Portal hypertension	Intrahepatic bile duct stenosis
Decompensated cirrhosis	

the liver at the apical membrane of epithelial cells lining the intrahepatic bile ducts. This makes cystic fibrosis the only inherited metabolic disease of the liver in which the primary abnormality is in biliary cells rather than hepatocytes.

Clinical Manifestations (Table 42-4) Liver disease in cystic fibrosis affects 25–30% of patients. It may appear as neonatal cholestasis, fatty change, or progress to biliary cirrhosis when the pulmonary and pancreatic diseases have been present for a long time. Hepatomegaly is the most significant liver feature. Although some authors suggest that liver disease increases with age expectancy, it seems that there is a peak at adolescence and it does not increase after 18 years.

Diagnosis Criteria for diagnosis include any one of the major clinical features (typical pulmonary and/or gastrointestinal manifestations) or history of cystic fibrosis in the immediate family plus a sweat chloride concentration >60 meq/L. Demonstration of pathologic CFTR mutations on both chromosomes is also sufficient to make the diagnosis.

Genetic Basis of the Disease The CFTR gene is assigned to the long arm of chromosome 7, spans 230 kb, and contains at least 27 exons. The mRNA is approximately 6.5 kb long and encodes a protein that contains 12 membrane-spanning domains, two nucleotide (ATP)-binding domains (NBDs), and a regulatory (R) domain that contains consensus sites for phosphorylation by protein kinases. Mutations are well-characterized and a total of more than 300 have been described. The most common (68% of patients) consists of a 3-bp deletion of codon 508 (phenylalanine) in the first NBD (ΔF508). All the other mutations account for less than 5% each, and only 13 different mutations affect more than 1% of the patients. The effect of different mutations includes:

1. Failure to synthesize a full-length protein (splice-site abnormalities, frameshifts, and nonsense mutation-stop codons) leading to a null phenotype.
2. Defective protein processing that leads to improper folding of the molecule and incomplete intracellular transport and glycosylation (fails to traffic to the Golgi). The isolated protein seems to be capable of functioning as a Cl⁻ channel, but the problem is that it is not present at the apical membrane. This is the mechanism involved in the prevalent ΔF508 mutation and probably most mutations.
3. The protein gets to the membrane, but its function is not regulated (missense mutations).
4. The protein gets to the membrane but its function is slightly altered in the pore size or the opening time. Null mutations and those impairing the intracellular traffic of the protein to the membrane are associated with the more severe phenotypes.

Molecular Pathophysiology of Disease The alteration in the CFTR protein in the liver produces an increase in the bile acid concentration as a result of a decrease in the sodium and water secretion that parallels that of chloride. There is also an impaired mucin secretion that disrupts the protective mucous layer coating the ducts. Finally, the increased fecal loss of taurine-conjugated bile acids increases the proportion of glycoconjugates that, being more hydrophobic than tauroconjugates, are potentially hepatotoxic. The combination of an abnormally concentrated bile containing an excess of hydrophobic bile acids, a lack of mucus protection produces a fibrosing cholangiopathy characterized by multiple constrictions and/or dilatations of the extrahepatic biliary tree. The intrahepatic bile duct lesion causes portal fibrosis and portal hypertension with secondary hepatocyte dysfunction.

It is important to note that liver involvement is not predicted by genotype or severity of lung disease, and only 25% of patients develop liver disease. Possible explanations include individual genetic factors involving other susceptibility genes, HLA A2-B7-DR2-DRw6, the evidence for the latter being the strongest.

Management and Treatment Ursodeoxycholic acid has recently been introduced as a possible therapeutic and preventive agent. The beneficial effects are derived from its choleretic and cytoprotective properties, and it has been shown to improve liver function tests and the hydrophobic/hydrophilic balance of the bile acid pool. Further studies are needed to establish any improvements in histology or prognosis. Liver transplantation has successfully been used for advanced disease without significant respiratory complications.

Future Prospects Introduction of DNases, and novel mucin-clearing agents are undergoing trials. Early gene therapy trials have been disappointing in general. However, much progress in eliminating the immune-mediated disappearance of virally introduced genes is being made.

THE PORPHYRIAS The porphyrias are inherited and acquired disorders caused by enzyme abnormalities in the heme biosynthetic pathway (Fig. 42-2). The liver accounts for 15% of the heme synthesized in the body, utilized for the formation of cytochromes and catalases. The remaining 85% is synthesized in the bone marrow. Partial enzymatic activity of any of the eight enzymes involved in heme synthesis results in excessive accumulation and excretion of porphyrins and their precursors, the porphyrinogens. However, only a small percentage of carriers of the gene defect develop clinical symptoms of the diseases. Thus, additional factors are required to express the phenotype. As a result, the porphyrias represent a complex paradigm for the interaction between genetic and environmental factors that can lead to the clinical manifestation of a disease.

The clinical picture is characterized by a combination of neurological symptoms resulting from toxicity from accumulation of δ-aminolevulinic acid (ALA) and porphobilinogen (PBG), and decreased heme availability; photocutaneous lesions caused by accumulation of porphyrins in the skin that, under UV light stimulation, produce cell damage followed by autolysis and inflammation; or liver damage. Significant liver disease is only present in porphyria cutanea tarda and a subgroup of erythropoietic porphyrias patients. Although classified as erythropoietic, this subgroup can be considered erythrohepatic.

Most porphyrias are inherited in an autosomal dominant pattern, except for δ-aminolevulinic acid dehydratase porphyria, congenital erythropoietic porphyria and some forms of erythropoietic protoporphyria. Patients are heterozygotes for the defect and show a 50% decrease in the activity of the deficient enzymes. The excep-

Figure 42-2 Enzyme deficiencies of porphyrias ALA, δ-aminolevulinic acid; PBG, porphobilinogen; ADP, ALA dehydratase porphyria; PCT, porphyria cutanea tarda; HEP, hepatoerythropoietic porphyria; EPP, erythropoietic protoporphyria.

tion is hepatoerythropoietic porphyria that is the homozygous form of the defect present in porphyria cutanea tarda (deficit of uroporphyrinogen decarboxylase) and shows a 90–95% reduction in the enzyme activity.

Several environmental factors leading to the clinical manifestation of the disease act through stimulation of the first enzyme in the pathway, the δ-aminolevulinic acid synthase (ALA synthase). This enzyme condenses succinyl CoA and glycine in the mitochondria to form ALA. There are two tissue-specific isozymes encoded by two different genes: the housekeeping ALA synthase gene (ALAS-N or ALAS1, expressed in all tissues, including the liver, assigned to chromosome 3) and the erythroid-specific ALA synthase enzyme (ALAS-E or ALAS2, expressed exclusively in erythroid cells, have been localized to chromosome X). Regulation of the synthesis and activity of the ALAS1 in the liver constitutes the rate-limiting step for the heme synthesis in that organ. The reduction in heme production because of the decrease in activity of any enzyme of the pathway upregulates ALA synthase in an attempt to increase heme synthesis. A new equilibrium is achieved with normal synthesis of heme at the cost of accumulation of more toxic porphyrins and porphyrinogens. In addition, ALAS1 is induced by a large amount of drugs, chemicals, and endogenous compounds, including various steroid metabolites. This step is not rate-limiting in erythroid cells, and ALAS2 is not

inducible by compounds that induce the hepatic enzyme. ALAS2 mRNA translation is regulated by iron levels through the interaction of iron-regulatory factor with an iron-responsive element at the 5' untranslated region of the RNA, a characteristic similar to ferritin and transferrin regulation. Patterns of expression of the genes can vary between the liver and the bone marrow, with some of the genes having specific transcripts only present in the erythroid cells. This has led to the classification of porphyrias as hepatic or erythropoietic, according to the principal site of the expression of the enzymatic abnormality.

Acute Intermittent Porphyria (AIP) Hepatic porphyria is caused by a defect of porphobilinogen deaminase that results in increased levels of ALA and PBG in plasma and urine.

Clinical Manifestations Typically, the disease is more frequent in women after puberty and is characterized by acute attacks of abdominal pain, vomiting, constipation, and sometimes psychiatric manifestations, such as anxiety, depression, confusion, or delirium. Motor neuropathy, including muscle weakness or respiratory impairment, is common. There is no cutaneous photosensitivity.

Diagnosis Acute attacks are associated with increased urinary excretion of PBG and, to a lesser extent, ALA. However, levels can be normal in the quiescent phase of the disease. Definite diagnosis includes determination of PBG deaminase activity in

erythrocytes and DNA analysis. Gene studies are complicated because of the heterogeneous nature of the genetic defects. Several systems can be used, including denaturing gel electrophoresis when the defect is not known. Relatives to the index case have to be investigated for the defect in order to avoid precipitating factors.

Genetic Basis of the Disease   The disease is transmitted as an autosomal dominant trait. The gene responsible for AIP has been mapped to chromosome 11 and contains 15 exons. The use of two separate tissue-specific promoters and alternative splicing produce two different transcripts: nonerythropoietic transcripts contain 52 bp more than the erythropoietic forms, leading to the incorporation of 17 extra amino acids at the amino-terminus of the protein.

Gene defects in AIP are characterized by great heterogeneity, but three groups can be distinguished: the "crossreactive immunological material" negative form (type I) that represents 85% of all patients and is produced by mutations leading to stop codons, frameshifts, or altered splicing whose consequence is a 50% reduction in immunoreactive protein with a parallel 50% decrease in enzyme activity. The type II (<5% patients) is characterized by normal porphobilinogen deaminase activity in the erythroid cells and a 50% reduction in hepatic activity, caused by mutations in exon 1 in the nonerythroid portion of the gene. The "crossreactive immunological material" positive type III (15% patients) is a result of mutations that severely impair the enzyme activity. Only a few mutations related with this phenotype have been described.

Molecular Pathophysiology of Disease   The genetic defect itself is not sufficient for the development of the disease, and 90% of the carriers remain asymptomatic throughout life. Factors that increase the synthesis of porphyrins can induce the appearance of clinical symptoms, including hormones, drugs, alcohol, nutritional factors, and so on, that stimulate ALA synthase.

Management and Treatment   Treatment is aimed at avoiding precipitating factors. Glucose and hematin infusion are the standard treatments.

Hereditary Coproporphyria (HCP) and Variegate Porphyria (VP)   These are also hepatic acute porphyrias, caused by defects in coproporphyrinogen oxidase in hereditary coproporphyria, and protoporphyrinogen oxidase in variegate porphyria. Clinically, they are indistinguishable from acute intermittent porphyria except for the presence of cutaneous photosensitivity in 30% of hereditary coproporphyria and 45–80% of variegate porphyria patients. The gene for coprophyrinogen oxidase has been mapped to chromosome 9 and is now under investigation. The gene responsible for protoporphyrinogen oxidase has not yet been identified. Interestingly, there is a small group of patients in both diseases who are homozygous for the defect. Clinically they are characterized by an early onset of the disease and lifelong photosensitivity.

The diagnosis is similar to AIP but, in addition to PBG and ALA detection in urine, there is increased fecal excretion of coproporphyrin in HCP and protoporphyrin in VP. The most important test is the demonstration of normal PBG erythrocyte activity.

Porphyria Cutanea Tarda (PCT)   The most common porphyria, PCT, represents an heterogeneous group of diseases caused by defects in the activity of uroporphyrinogen decarboxylase. These defects can be acquired (sporadic PCT or type I and toxic form) or inherited (familial PCT, types II and III). Inheritance adopts an autosomal dominant pattern.

Clinical Manifestations   Clinically, the disease is characterized by bullous cutaneous lesions on the light-exposed areas of the skin. Patients with the familial type of the disease have an early onset compared with sporadic cases. Liver disease is a common feature with the development of cirrhosis and, in some patients, hepatocellular carcinoma. The sporadic PCT (type I) affects more often adults (40–50 years) and is precipitated by alcohol consumption, estrogens, and iron. It has been reported associated with many types of liver disease and, recently, a strong association with hepatitis C infection has been described in Spain and Italy.

Diagnosis   The diagnosis is based on the clinical symptoms and confirmed by determination of uroporphyrin and coproporphyrin in plasma, urine, and feces. Uroporphyrin > coproporphyrin in urine is highly indicative of PCT. Gene studies are only useful in type II PCT.

Genetic Basis of the Disease   Inheritance occurs in an autosomal dominant pattern. The gene has been assigned to chromosome 1 and contains 10 exons.

No mutations have been found in patients with the sporadic form despite intensive investigation. Several different mutations have been found in patients with familiar PCT. They include missense and splice-site mutations.

Molecular Pathophysiology of Disease   Type II familial porphyria cutanea tarda is characterized by a 50% decrease in enzymatic activity and protein immunoreactivity in all tissues, while type III familial porphyria cutanea tarda shows normal enzymatic activity and protein present in all tissues except the liver. The consequence of the mutations, as shown in vitro expression studies, is a significantly shorter half-life of the mutated protein compared with the wild type. In the case of sporadic PCT, the pathogenesis of the disease seems to be a process that specifically inhibits the enzyme without decreasing its concentration. The process could be iron-related.

Management and Treatment   Treatment is based on alcohol abstinence and phlebotomies. If phlebotomy is not tolerated, low doses of chloroquine or hydroxychloroquine are used. Treatment of other accompanying diseases may be helpful and, in fact, interferon treatment of HCV infection has been shown to correct the clinical manifestations of PCT in one patient.

Hepatoerythropoietic Porphyria (HEP)   This is an extremely rare defect (only 20 patients described) resulting from a homozygous defect in uroporphyrin decarboxylase activity. The mutations described are different from those seen in porphyria cutanea tarda. The activity of the enzyme can be as low as 5% and, as in porphyria cutanea tarda mutations, the cause is a shortened half-life of the molecule.

Erythropoietic Protoporphyria (EPP Protoporphyria)   This porphyria belongs to the group of erythroid porphyrias, together with congenital erythropoietic porphyria (CEP), and is caused by a partial deficiency of ferrochelatase, the last enzyme of the heme biosynthetic pathway. The defect results in massive accumulations of protoporphyrin in erythrocytes, plasma, and feces. The inheritance pattern is autosomal-dominant.

Clinical Manifestations   Clinically, the most important findings are redness, swelling, burning, and itching of the skin following light exposure. Vesicular lesions (typical of other porphyrias) are uncommon. Development of gallstones (composed in part by protoporphyrin) occur in some patients as well as liver disease that can progress to cirrhosis (5–10%). The most serious complication is acute liver failure preceded by jaundice. There are no neurovisceral manifestations nor precipitating factors.

Diagnosis Elevated concentrations of free protoporphyrin in erythrocytes, plasma, and feces, with normal urinary porphyrins, are diagnostic.

Genetic Basis of the Disease The gene for ferrochelatase is assigned to chromosome 18 and contains 11 exons. Genetic defects are heterogeneous with missense and splicing mutations that frequently remove exon 2. Losses of exon 7 and 10 have also been described leading to unstable mRNA transcripts.

Management and Treatment Treatment is based on the avoidance of exposure to the sun, and the use of β-carotenes. Liver transplantation has not been successful because protoporphyrin production in the bone marrow leads to reaccumulation in the graft.

Porphyrias: Future Directions Three-dimensional and crystallographic studies of the proteins will help understand the mechanism of activity and the effect of different mutations. It will also be useful in establishing better genotype-phenotype correlations and identifying those patients at a higher risk of important complications.

Gene therapy for symptomatic patients is a possibility. Metabolic correction of the defect in cell lines derived from a patient with CEP using retroviral vectors carrying the URO III synthase gene has been shown. However, treatment strategies will be complicated because of the double synthesis and regulation of some of the enzymes of the pathway in the liver and in the bone marrow.

GALACTOSEMIA Inherited disorders of galactose metabolism are comprised of three diseases: classic galactosemia, galactokinase deficiency, and UDP-galactose-4-epimerase deficiency. They are characterized by the inability to catabolize galactose to carbon dioxide. Galactose metabolism fulfills two purposes: an energy source by the generation of glucose-1-phosphate and synthesis of galactosides (glycoproteins and glycolipids) using UDP-galactose as the galactosyl donor. Defects in the galactose metabolic pathway lead to accumulation of toxic metabolites, galactose-1-phosphate, and galactitol, and depletion of UDP-gal, both of which are potentially lethal.

Three enzymes are involved in galactose metabolism: galactokinase, galactose-1-P uridyl transferase (GALT), and UDP-galactose-4-epimerase (Fig. 42-3). Classic galactosemia derives from GALT deficiency and less frequently from severe epimerase deficit. Galactokinase deficit only produces galactitol, and the only pathological manifestation are cataracts.

Clinical Manifestations (Table 42-5) Severely affected patients with the classic form of galactosemia, that are not quickly diagnosed and continue taking galactose with the diet, develop hepatic and kidney failure and die in few weeks resulting from septicemia. Milder forms are characterized by failure to thrive, vomiting, and diarrhea. Jaundice develops during the first few weeks of life and, if untreated, the liver disease may progress to cirrhosis. However, because of *in utero* exposure to toxic galactose metabolites, long-term outcome may include cataracts, speech defects, ovarian dysfunction, growth decline, and poor intellectual function, despite adequate treatment.

Diagnosis Diagnosis is made by demonstration of severe deficiency or lack of GALT activity in red cells, fibroblasts, or liver. Widespread screening of newborns for elevated blood galactose are effective, provided the newborns have been fed prior to the test. The test has allowed early identification of patients. The demonstration of a reducing sugar in urine that is not glucose has similar value. Prenatal diagnosis can be made by determination of
Figure 42-3 Galactose metabolism. Enzymes: (1) galactokinase, (2) galactose-1-phosphate uridyl transferase, (3) uridine diphosphate galactose-4-epimerase, (4) aldose reductase (nonspecific).

Table 42-5
Clinical Features of Galactosemia

Neonatal/early infancy period		*Chronic*	
Failure to thrive	(M)	CNS dysfunction	(TI)
Vomiting	(M)	Speech abnormality	
Diarrhea	(M)	Intellectual deficit	
Jaundice	(M)	Growth retardation	(TD)
Hemolysis	(M)	Ovarian dysfunction	(TI)
Hepatomegaly	(M)	Liver disease	(TD)
Cataracts	(M)		
Mental retardation	(M)		
Ascites	(S)		
Septicemia (*E. coli*)	(S)		
Renal failure	(S)		

CNS, central nervous system; M, mild disease; S, severe disease; TI, treatment independent (no improvement despite galactose withdrawal from the diet); TD, treatment dependent (not developed, if treatment is correct).

GALT activity in cultured amniotic cells, biopsied chorionic villi, or determination of galactitol in amniotic fluid.

Genetic Basis of the Disease The galactose-1-P uridyl transferase gene is located at chromosome 9. Gene polymorphisms abound because of point mutations and changes in noncritical amino acid residues. The consequences are partial enzyme deficiencies that are usually asymptomatic. The most frequent gene defect is a Asn 314 to Asp mutation resulting in the Duarte variant of the enzyme. It is present in 4–14% of the population and produces a 50% decrease in enzymatic activity. Duarte/Normal allele heterozygotes show 75% activity, Duarte homozygotes 50%, and Duarte/Galactosemic heterozygotes 25%. The most frequent lethal mutation is Gln 188 to Arg in exon 6 (60% in overall patient population and 68% in Caucasians; only 16% in African Americans). This mutation is close to the catalytic active site and results in undetectable enzyme activity, as determined in yeast expression studies. In addition, several other point mutations including splice site mutations have been described, leading to instability of the protein or decrease in activity. Crossreacting immune protein may or may not be present indicating the heterogeneity of the genetic

defects. Finally, the protein acts as a dimer, raising the possibility of the presence of mixed heterodimers in the case of heterozygotes. The prevalent Gln 188 to Arg mutation can be determined by PCR amplification, followed by restriction enzyme digestion with Hpa II that can cleave a newly created site resulting from the mutation.

Molecular Pathophysiology of Disease Galactose-1-P accumulation is probably responsible for the liver damage although the mechanism of toxicity is not clear. It could be related to energy depletion, as ATP used to phosphorylate galactose to galactose-1-P cannot be metabolized. Galactitol accumulation in the lens causes osmotic swelling and the formation of cataracts. UDP-galactose depletion has been correlated with ovarian dysfunction and probably mental impairment, but the mechanism is not completely understood.

Management and Treatment The only available treatment consists of a complete exclusion of galactose from the diet.

EPIMERASE DEFICIENCY This condition is inherited in an autosomal recessive pattern, and two forms have been described: one without clinical significance and one resembling classic galactosemia (described in only two patients). The gene is located on chromosome 1, but the defects have not been yet published. Clinical findings are indistinguishable from those derived from galactose-1-P uridyl transferase deficiency. Diagnosis is similar to classic galactosemia, but galactose-1-P uridyl transferase activity is present.

HEREDITARY FRUCTOSE INTOLERANCE This is an autosomal recessive disease caused by a defect in aldolase B, an enzyme responsible for the metabolism of the fructose present in sugar, juices, and fruit. Sucrose and sorbitol are also metabolized to fructose. Fructose-bisphosphate aldolase is the enzyme responsible for the conversion of fructose-1-phosphate into D-glyceraldehyde and dihydroxyacetone phosphate. It has three distinct isoforms: aldolase B is the isoform expressed in the liver, kidney, and intestinal mucosa; aldolase A is expressed ubiquitously and is the only one in the muscle, while aldolase C is characteristic of the brain.

Clinical Manifestations (Table 42-6) Symptoms typically start after cessation of breast feeding. Exposure to fructose leads to vomiting, diarrhea, and abdominal pain. Symptomatic hypoglycemia causes pallor and trembling in infants. Loss of consciousness can occur. Ingestion of large quantities can cause convulsions and coma. Continuous exposure leads to failure to thrive, jaundice, liver disease progressing to cirrhosis, metabolic acidosis, renal tubular disease, and growth retardation. Heavy administration causes hemorrhagic diathesis and death. Patients develop a protective aversion to fructose-containing foods.

Diagnosis Clinical suspicion together with demonstration fructosemia and fructosuria are the basis of the diagnosis. Enzyme activity can be determined in liver or intestinal biopsy, which demonstrates that leukocytes or fibroblasts in affected individuals do not contain aldolase B.

Genetic Basis of the Disease Aldolase B is a tetramer of 364 amino acids. The gene is located in chromosome 9 and contains nine exons, the first of which is not translated. The genetic defects are heterogeneous. The most frequent involves a point mutation causing Ala-149 to Pro (exon 5, 67% alleles), close to residues responsible for the binding to the substrate, followed by Ala-174 to Asp (exon 5, 16%). Several other missense mutations have been described, leading to amino acid change or frameshift

Table 42-6
Clinical Features of Hereditary Fructose Intolerance

Acute exposure	Chronic exposure	Sequelae
Sweating	Poor feeding	Cirrhosis
Pallor	Failure to thrive	Liver steatosis
Trembling	Vomiting	Aversion to sweets
Dizziness	Irritability	Peculiar feeding habits
Nausea	Apathy	
Vomiting	Jaundice	
Abdominal pain	Hepatomegaly	
Apathy, lethargy	Abdominal distention	
Coma	Edema, ascites	
Convulsions	Hemorrhage	
Growth retardation	Tremor, jerking	

and truncated protein, as well as deletions from a single base to 1.65 kb, stop codon mutations, and a translation codon mutation. An Ala-149 to Pro mutation was demonstrated by PCR followed by digestion with *Aha*II, as this novel restriction site was generated by the mutation. Most gene defects can be studied with a limited number of allele-specific oligonucleotides.

Molecular Pathophysiology of Disease Fructose ingestion or intravenous administration in these patients leads to fructose-1-P accumulation. This induces hypoglycemia by inhibition of glycogenolysis and gluconeogenesis, and ATP depletion, used in the formation of high amounts of fructose-1-P. A small infusion of fructose lead to phosphorylation of fructose that can sequester up to 80% of the liver inorganic phosphate.

Management and Treatment Treatment consists of absolute removal of fructose, sorbitol, and sucrose from the diet. Contrary to galactosemia, in which some problems can remain despite strict adherence to the diet, recovery is complete, except when liver cirrhosis has already been established.

43 Viral Hepatitis and Liver Disease

*S*ANJEEV *G*UPTA AND *M*ICHAEL *O*TT

DEFINITION

Viral hepatitis is characterized by necroinflammatory liver disease with asymptomatic, acute and chronic presentations. The "hepatitic" presentation refers to a significant rise in serum aminotransferases in the presence of normal or minimally increased serum alkaline phosphatase levels. Hepatitis viruses may be cleared with no lasting sequalae, persist indefinitely without causing apparent disease, or cause chronic hepatitis and multiple complications, including cirrhosis and hepatocellular carcinoma (HCC). Acute hepatitis usually refers to recent onset of virus infection with viral persistence for not longer than 6 months. The susceptibility to and consequences of viral hepatitis are determined by incompletely defined host factors, the size of the initial viral inoculum, and the presence or absence of infection with other hepatitis viruses. The diagnosis of specific viral etiologies requires laboratory testing because clinical presentations may be indistinguishable from one another.

INTRODUCTION

Even though hepatitis epidemics have been recorded from the ancient times, the nature of viral hepatitis remained obscure until after the Second World War. In the 1950s, based on epidemiological evidence, such as observations of the route of transmission, incubation period, case clustering, and so on, the existence of more than one hepatitis virus was surmised, and early investigators distinguished between the short-incubation or "infectious" (type A) and the long-incubation or "serum" (type B) hepatitis. The progress during the past three decades in isolating and characterizing commonly encountered hepatitis viruses has been truly remarkable. These advances could not have been made without the advent of molecular biology methods. In 1965, an important advance was made when serologic testing revealed the hepatitis B virus surface antigen (HBsAg) in Australian aborigines, so the antigen was initially called Australia antigen. This discovery provided means for diagnosing hepatitis B infection and paved the way for defining the biology of the hepatitis B virus (HBV). In 1973, the hepatitis A virus (HAV) was visualized. However, despite the ability to recognize HAV and HBV infection, a number of patients showed evidence for neither of these viruses, and such cases were classified as suffering from NonA, NonB viral hepatitis. Each succeeding decade brought forth implausible new discoveries and more

hepatitis viruses have been identified. The hepatitis delta virus (HDV) was recognized in the mid 1970s, the hepatitis C virus (HCV), which is responsible for a large proportion of nonA, nonB hepatitis, was cloned in 1989, and in the 1990s, further additions have been made to this viral alphabet, with the cloning of the hepatitis E virus (HEV), the provisionally designated hepatitis G virus (HGV), and the hepatitis GB viruses (HGBVs). A tentatively designated hepatitis F virus turned out not to be a true viral isolate. Hepatitis may be a result of additional nonhepatotropic viruses, e.g., cytomegalovirus, herpes simplex virus-1, Epstein-Barr virus, and so on. Also, a "hepatitic" presentation may be encountered in disorders, such as autoimmune hepatitis, heavy metal accumulation, or drug-toxicity, which need to be carefully considered in differential diagnosis.

The applications of modern molecular genetics tools have unraveled some mysteries of the hepatitis viruses and provided novel insights into the biology of viral persistence and hepatic oncogenesis, although much further work is necessary to translate these insights into molecular therapies. Similarly, molecular immunology needs to generate insights into how circulating antibodies confer lifelong immunity against some viruses, e.g., HAV or HBV, but do not protect against others, e.g., HCV or HDV. Our goal here is to provide an overview of the molecular biology of hepatitis viruses and how this information helps to understand hepatic pathophysiology. The limited scope of this chapter precludes a full discussion of this rapidly advancing and broad area, which, fortunately, excites enormous interest among investigators worldwide.

GENOME STRUCTURES AND ORGANIZATION

The shared bond among hepatitis viruses is their proclivity for causing liver disease. However, the individual viruses themselves differ significantly in phylogenetic relationships, genome organization, replication strategy, and so on. For instance, HAV belongs to the picornavirus family, HBV to the hepadnavirus family (with other members infecting the woodchuck, Peking duck, ground squirrel, heron, and a tree shrew), HCV to a new genus in the flavivirus family, and so on (Table 43-1). Also, it is at times forgotten that virus replication is not necessarily restricted to the liver and individual viruses, e.g., HBV or HCV, may infect additional organs, including hematopoietic cells, pancreas, kidney, and spermatozoa, depending on which cell type offers permissive conditions for viral gene expression. The presence of extrahepatic virus reservoirs imposes limitations on therapies, e.g., orthotopic liver transplantation (OLT) is difficult in the presence of ongoing HBV

Table 43-1

Virus	Family	Genome structure	Genome size
HAV	Picornaviridae	Positive strand RNA	7.5 kb
HBV	Hepadnaviridae	Double stranded DNA with incomplete circle	3.2 kb
HCV	Flaviviridae	Positive strand RNA	9.5 kb
HDV	Viroid Deltaviridae	Negative strand RNA	1.7 kb derives envelope from HBV
HEV	Calciviridae	Positive strand RNA	7.5 kb
HGV and related HGBVs	Flaviviridae	Positive strand RNA	9 kb

Figure 43-1   Schematic depiction of the structure of various hepatitis viruses and their general genomic organization. *See* the text for more detailed descriptions.

replication because the transplanted liver is virtually always reinfected with the virus leading to a peculiarly aggressive disease and rapid liver failure.

HEPATITIS A VIRUS   In 1973, immunoelectron microscopy showed the virus in the stool of infected patients. Subsequently, development of immunoassays provided seroepidemiological insights, including ones for the existence of additional water-borne hepatitis viruses, such as HEV, and the ability to culture HAV in the 1980s led to the development of effective vaccines. The HAV is an important cause of acute water-borne hepatitis and afflicts enormous number of populations worldwide who have limited access to safe drinking water, specially in underdeveloped regions. However, the virus does not cause chronic disease. The infection most commonly affects children and may manifest with no or easily overlooked symptoms. Serological evidence indicates a rising level of immunity with age in hyperendemic areas, such that by the age of 40 years, approximately 50–60% of the population may be immune. On the other hand, acute HAV hepatitis in patients older than 40 years, e.g., in nonimmune travelers, could be severe and fatal.

The virion particles exhibit a smooth and round exterior with a protein shell (capsid) enclosing a single-stranded RNA of approximately 7.5 kb in size (Fig. 43-1). The genomic organization of HAV follows that of other picornaviruses. There are untranslated regions (UTR) at both the 5' and 3' ends of the genomic RNA extending to ~0.7 and ~0.06 kb in length, respectively. The open reading frames are designated P1, P2, and P3 regions. The P1 region encodes the capsid polypeptides termed VP1, VP2, VP3, and VP4. The P2 region encodes the non-structural proteins designated P2A, P2B, and P2C, the functions of which are poorly defined, although viral protease and other enzymatic activities have been identified. The P3 region encodes for P3A, P3B, P3C, and P3D proteins, which are necessary for viral replication and serve as the genome-linked protein Vpg (P3B), a viral protease (P3C), and the viral RNA polymerase (P3D). The function of the P3A protein remains unknown. The virus uses a mucin-like glycoprotein of 451-amino acids on the cell surface as its receptor. In similarity with other RNA viruses, HAV exhibits differences in nucleotide sequences, which lead to
altered genotypes (*see below*). However, the mutations do not alter the immunogenic epitopes encoded by the P1 region and immunity against the virus is not abrogated. During natural infection, the initial host response is manifested with IgM class antibody against capsid polypeptides followed by the protective IgG class antibody, which confers lifelong immunity against reinfection. An important recent advance has been the development of highly effective vaccines arising from the ability to propagate HAV in cell culture.

HEPATITIS B VIRUS   One of the most important hepatitis viruses, HBV infection represents a major public health burden with an estimated 350 million cases worldwide. The virus is commonly acquired by exposure to contaminated blood or via sexual activity. The HBsAg carrier rates in low endemic areas (e.g., 0.1–0.2% in the United States, United Kingdom, and parts of Western Europe) contrast with areas of moderate endemicity (2.5% in Spain, Italy, Japan, and Greece) or high endemicity (11–15% in South Africa, Taiwan, and Hong Kong). In some geographically isolated communities, prevalence of HBV infection, as indicated by any serological marker, is very high, e.g., in Alaskan Eskimos. Very young age is a most important factor predisposing to persistent HBV infection and unless altered by immunization, infection is the rule in infants born to HBV carrier mothers (90–100% transmission). Persistent infection is increased in the immunocompromised and with small viral inoculum.

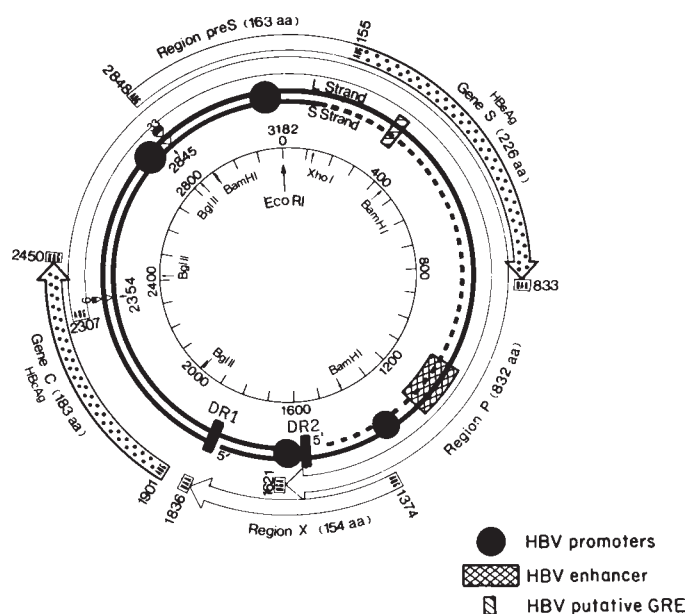
Much more is known about the molecular biology of HBV than the other hepatitis viruses, although even here critical aspects of


Figure 43-2 The genome of HBV is constituted by two circular DNA strands, of which the shorter one (S strand) is incomplete and constitutes the "sense" orientation. The positions of various regulatory sequences are as shown.

Table 43-2
HBV Gene Products

Gene	Protein product	Function
pre S1	p39/p42[a] (large HBsAg)	Envelope
pre S2	P33[a]/p36[a] (middle HBsAg)	Envelope
S	p24/p27[a] (small HBsAg)	Envelope
C	15 kDa (HBcAg)	Nucleocapsid
pre C/C	16–25 kDa (HBeAg)	Unknown
P	70–90 kDa	DNA polymerase
X	15 kDa (HBxAg)	Unknown/cellular transactivator

[a]Glycosylated species.

virus replication and other events have not been fully determined. The virus was physically demonstrated by electron microscopy more than 20 years ago and identified as the agent responsible for "serum hepatitis." The HBV primarily exists in the liver and serum. The infectious virion is represented by the "Dane particle," which has a diameter of 42 nm and contains an outer envelope of protein and membrane lipids with an inner nucleocapsid of 27-nm size (Fig. 43-1). However, the most abundant particles (10^3- to 10^6-fold excess) are 16- to 25-nm spherical particles and 22-nm diameter filamentous particles (up to 1000 nm long), which are devoid of viral nucleic acids and are noninfectious.

The HBV genome is a small circular DNA of 3.2–3.3 kb arranged in two strands (Fig. 43-2). The long DNA strand, also designated the minus (–) strand, is of full length and is complementary to viral mRNAs. This full-length strand is complete other than missing only one or a few nucleotides at 1800 nucleotides from the *Eco*RI restriction enzyme recognition site (which is arbitrarily used as 0 to map nucleotide positions). The other DNA strand is shorter, lacks from 15 to 50% of the sequence and is designated as the plus (+) strand. The 5' end of the short strand is located at nucleotide 1560, but its length and the 3' end differ considerably. The circular configuration of the genome is maintained by base pairing of the 5' termini of the two DNA strands with a "cohesive end" region constituted by 250–300 overlapping nucleotides. A viral DNA polymerase activity associated with the nucleocapsid repairs this single-stranded region of the (+) or short-strand DNA by adding nucleotides to its 3' end, although, despite formation of a complete circle, it is not covalently closed. The HBV genome shows additional asymmetries at the 5' ends with a covalently linked protein at the (–) or long strand and an oligoribonucleotide attached to the (+) short strand DNA. In addition, the cohesive end region contains 11 bp direct repeats, termed DR1 and DR2 regions, which serve important functions during virus replication.

The HBV contains four translational open reading frames (ORFs) on the (–) or long DNA strand (Table 43-2). The overlapping nature of these ORFs and transregulation by enhancer elements are one of the unique features of the complex genomic organization. The hepatitis B surface antigen (HBsAg) ORF spans map positions 833–2848 and constitutes the 3' portion of another larger coding region. An upstream reading frame (ORF pre-S) with two conserved initiating ATG codons directs transcription of the larger HBsAg-related envelope proteins, termed pre-Sl and pre-S2. The HBcAg (ORF C) is encoded by nucleotides spanning 1836–2450 bases and is preceded by another upstream ORF termed pre-C region, which could encode a larger HBcAg-related polypeptide. The viral polymerase is encoded by ORF P, map position 1621–2357. Finally, the HBxAg, which has transactivating properties, is encoded by a region overlapping the HBsAg and HBcAg ORFs that constitute the ORF X (map positions 1374–1818). The ORF X is the only one that is not well-conserved in all hepadnaviruses and is absent in duck HBV. The (+) or short DNA strand is not known to transcribe any viral gene product.

The HBV expresses 3.5 kb (genomic) and 2.4 or 2.1 kb (subgenomic) polyadenylated mRNA species. The 5' end of the 3.5 kb genomic mRNA arises from the pre-C region and the 3' end from the C gene, where a specific polyadenylation signal is located. The genomic mRNA contains an additional approximately 100 nucleotides beyond the genome, implying that the 3.5-kb genomic RNA is transcribed from the covalently closed double-stranded DNA and that the polyadenylation signal is skipped over during the first cycle around the genome. The 2.4-kb subgenomic mRNA encodes the pre-S1 protein, although it also transcribes pre-S2, S, and X proteins. The 5' end of the 2.1-kb RNA has been mapped to approximately 20 nucleotide pairs upstream of the pre-S2 region and this mRNA generates the pre-S2 and S proteins. The mRNAs encoding X or P have not yet been identified, although the pregenomic mRNA possibly is responsible for the DNA polymerase. In patients with chronic HBV infection, novel HBV mRNA species can be found and represent fusion transcripts of integrated viral DNA and flanking cellular sequences. The viral gene expression is regulated by several elements: Promoters have been found for pre-S1, pre-S2, HBcAg, and HBxAg; two enhancer elements designated HBEn I (map position 1080–1234) and HBEn II (in pre-C region) have been identified; a glucocorticoid responsive element is also present. Viral mRNA transcription is terminated by a conserved element in ORF C responsible for RNA cleavage and polyadenylation. The HBV enhancer and promoter sequences bind specific cellular transcrip-

tion factors, among which the C/EBPs and HNFs-1 and -3 are most significant. The cell type-specificity of HBV expression is regulated by interactions among cellular transcription factors with both upregulatory and downregulatory effects, although more knowledge is necessary for understanding their interactions.

The viral gene products subserve somewhat expected functions but also have poorly understood effects upon the host cell. All virion particles are enclosed in HBsAg. The envelope HBsAg proteins produced by the ORF S are three: small HBsAg (226 amino acids), pre-S2 plus S or middle HBsAg (281 amino acids), and pre-S1 plus pre-S2 plus S or large HBsAg (389–400 amino acids). The small HBsAg is rapidly secreted from cells, whereas excess production of the large HBsAg leads to intracytoplasmic retention of HBsAg and development of so-called "ground-glass" hepatocytes seen in chronic HBV carriers. The HBsAgs are principally present in 22-nm particles that contain approximately 25% lipid derived from the host cytoplasm. The HBsAg proteins are generally resistant to proteases, heat, and chaotropic substances but not to detergents. The viral envelope is mostly composed of small HBsAg (~ 90%). The presence of pre-S2 in the envelope facilitates binding to serum albumin, whereas the preS1 domain is thought to be involved in receptor-mediated entry of virion particles into hepatocytes. The HBsAg contains a major serologic group-specific determinant termed "a" and subtype determinants d, y, w, and r, producing four main serotypes adw, ayw, adr and ayr. Each viral subtype shows differences in geographic distribution.

The nucleocapsid core contains a 21-kDa basic phosphoprotein termed the hepatitis B core antigen (HBcAg). The HBcAg may exist in multiple sizes because of posttranslational processing. Nucleocapsid cores are found in the nuclei of infected hepatocytes and are a marker of HBV replication. The nucleocapsids enclose the pregenomic mRNA and viral DNA polymerase during replication. The viral DNA polymerase is a putative 70–90-kDa protein with reverse transcriptase activity. An endogenous protein kinase activity is also present in hepadnaviral core particles, but the functional significance of core phosphorylation is unknown. The pre-C region of the virus contains an inphase sequence with an ATG codon approx 80 nucleotides upstream to the core ATG to serve as the HBeAg mRNA initiation site. Expression of the pre-C gene generates a 25-kDa HBe protein and this undergoes removal of several NH2-terminal amino acids to generate a 23-kDa protein (p23). The transmembranously located p23 is further modified for secretion as p16 to p20 unglycosylated and mature HBeAg. The HBeAg is found in serum during viral replication, although its function is unknown. The HBxAg is the smallest HBV protein at approximately 15 kDa. Although this protein is expressed during HBV infection and can be found in the infected liver, as well as serum, its precise function has been elusive. In vitro DNA transfection studies show that HBxAg can transactivate a variety of viral enhancer and promoter elements.

Viral replication occurs through a complex series of events with key steps requiring more information (Fig. 43-3). After entry into cells, the virion DNA undergoes conversion in the nucleus to covalently closed circular DNA (ccc DNA), although how this occurs is unknown. This is followed by transcription of the 3.5-kb pregenome mRNA from the (-) strand of the ccc DNA. The host RNA polymerase is used for generating the "pregenome" by reverse transcription within a nuclear core particle, which is then transported to the cytoplasm. The "genomic" RNAs are hetero-
Figure 43-3 HBV replication steps include translocation of the double-stranded viral DNA into cell nucleus and conversion to covalently closed circular (ccc) DNA, transcription of the 3.4-kb pregenome mRNA and nucleocapsid formation. The genome is replicated by reverse transcription in nucleocapsids and packaged in the viral envelope constituted by the HBsAg proteins before secretion of virion particles.

geneous with several choices for 5' ends over a 31-bp region that includes the first ATG in the ORF C. Synthesis of the (-) strand DNA is initiated in the short DR1 sequence near either the 3' or 5' end with the participation of an unidentified protein primer. An RNAse H function of the polymerase degrades mRNAs as the (–) strand elongates. Why the (+) strand remains incomplete is unknown. Although the viral replication mechanism with the use of a reverse transcriptase step is similar to the replication strategies of retroviruses and cauliflower mosaic viruses, the viruses are fundamentally different. Nonetheless, use of reverse transcriptase comes with a greater likelihood of mutations in the viral genome at a frequency greater than DNA viruses, although the frequency of such errors may be less than that of RNA viruses (*see below*). The viral genomes isolated from a single patient are homogeneous, as determined by restriction enzyme mapping, and within a single HBV subtype only occasional differences are noted. However, different serological subtypes show considerable variation in nucleotide sequences, which may differ by up to 10%, with small additions or deletions scattered throughout the genome.

After infection, serum HBsAg is the first marker to be detected followed by serum HBeAg and then virion particles containing HBV DNA and DNA polymerase. The serum HBV DNA best correlates with replicating and infectious HBV. Serum HBV DNA positivity beyond 4 weeks of acute hepatitis indicates delayed viral clearance and predisposition to chronic hepatitis. Anti-HBc directed against HBcAg appears before anti-HBs in patients with viral clearance and both persist for several years. Much of the anti-HBc is of the IgG class, although early on serum anti-HBc is of an IgM class and is helpful in diagnosing acute HBV infection. After clearance of HBV with anti-HBs, lifelong immunity may be developed. This protective capacity of anti-HBs is the basis for successful vaccination against HBV. Anti-HBs is primarily of "a" group specificity and protects against all HBV subtypes. However, vaccine-escape mutants have been recognized (*see below*).

HEPATITIS C VIRUS Despite recognition of posttransfusion nonA, nonB hepatitis in the early 1970s, cloning of HCV required ingenious use of molecular biology methods and was finally accomplished in 1989. Worldwide, HCV infection may be as prevalent, if not more, than HBV. Within the United States, HCV is responsible for more than one million cases with liver disease and for probably a far greater number of people with asymptomatic or silent infection. The risk factors include intravenous drug use (38%), sexual/household contact (10%), blood transfusion-related (4%), occupational exposure (2%), and renal dialysis (1%), although in most cases no obvious source is apparent. A minority may acquire the infection at birth (0–13% risk). The disease is particularly prevalent in Asia (25%) and subsaharan Africa and less so in Europe, United States, and Australia. The development of disease is poorly defined, though it may be related to the size of the viral inoculum, the titer of the virus, and possibly the viral genotype. Unlike HBV, which infrequently causes chronic infection (<1% after acute hepatitis), HCV far more frequently causes chronic hepatitis (approximately 50%).

The virion particles are 30–50 nm large and are sensitive to chloroform, formalin, heat, and ultraviolet light. Although HCV was deduced to be an RNA virus, its cloning proved difficult and required novel strategies. The ultimately successful strategy by a group in the United States used enriched HCV particles from a chimpanzee infected with NonA, NonB virus. Viral nucleic acids were extracted and cDNA expression libraries made in a bacteriophage system. This system allowed expression of recombinant viral proteins, which were screened with a panel of serum samples from chronic NonA, NonB virus carriers containing antibodies. Extensive screenings (>1×10^6 clones) yielded five serum-reactive cDNA clones, of which one (clone 5-1-1) proved to be specific for viral sequences and hybridized only with viral RNAs. Using this 5-1-1 clone, three additional overlapping clones were then obtained, and to generate immunoassays, one clone (c100-3) was expressed as a superoxide dismutase fusion protein in yeast. Japanese workers also cloned HCV in 1989 from 100 L of pooled human serum. Of the 29 Japanese clones isolated, 12 were identical to the clone identified by the United States group. Despite enormous subsequent work in learning about HCV, knowledge of its molecular biology and replication mechanisms is limited.

The viral genome is encoded by an approximately 9.4 kb size single-stranded RNA of (+) sense orientation. The genome is organized with only one ORF in the center flanked at both the 5' and the 3' end with UTR regions of variable length (Fig. 43-1). The viral genome is subdivided into a domain transcribing structural genes (Core [C] and Envelope [E1 and E2]) toward the 5' end and

Table 43-3
HCV Gene Products

Gene	Protein product	Function
C	p22	Nucleocapsid
E1	gp33	Envelope
E2/NS1	gp70	Envelope
NS2	p23	Metalloproteinase
NS3	p72	Serine protease/helicase
NS4 (a/b)	p10/p27	Unknown
NS5 (a/b)	p58/p70	RNA-dependent DNA-polymerase

a large domain transcribing nonstructural genes (NS1-5) toward the 3' end. The 5' UTR region spans 324–341 nucleotides and contains up to five ORFs with the potential to transcribe small polypeptides, but no such proteins have been identified. The 5' region is also the most highly conserved area of the virus and contains a secondary stem-loop structure, which initiates 5' cap-independent polyprotein translation from the first AUG codon and thus serves as the viral internal ribosomal entry site (IRES). This mechanism of protein translation is also found in other viruses, such as picornavirus members (poliomyelitis virus, hepatitis A virus, and so on). The single ORF spanning virtually the entire genome encodes a large HCV polypeptide of approximately 3010 amino acid residues and gives rise to additional proteins (*see below*). The 3' UTR region is downstream from the central ORF and spans 27–55 nucleotides. A single stem-loop structure precedes the stop codon in the NS5 region. A polyadenylated tail distal to the 3' UTR was present in the original viral isolate but has been absent in some other isolates. The overall genomic organization has led to classification of HCV as a distant member of flaviviridae (typical members: yellow fever virus, dengue fever virus, and so on), although a separate genus has been proposed for HCV.

The HCV polyprotein gives rise to multiple proteins by cotranslational or posttranslational processing using both viral and host proteases (Table 43-3). The structural proteins are thought to be processed by host-encoded signal peptidases. The core protein is highly basic, lacks N-glycosylation sites, shows RNA-binding capacity, and serves in nucleocapsid formation with roles possibly extending to a signal sequence function. Antibodies against the recombinant core protein are useful for demonstrating viral replication in cells or tissues. The E1 protein, as well as the E2/NS1 proteins, contribute to the viral envelope and contain N-glycosylation sites. These domains are hypervariable and provide one explanation for the lack of protective antibodies against the virus, as well as the difficulties in generating effective future vaccines. The E2/NS1 region corresponds to the first nonstructural protein of flaviviruses, but, unlike other viruses, the HCV protein is not secreted outside the cell. The NS2 protein is highly hydrophobic, and its function is unknown at present. The NS3 protein contains a nucleoside triphosphate-binding activity and serves as a helicase for unwinding the RNA genome during replication. In addition, the NS3 protein is involved in processing of nonstructural viral proteins via its protease activity. The NS4 protein is hydrophobic and binds to the membrane but its function is unknown. Finally, the NS5 protein serves as the viral RNA-dependent RNA polymerase and is necessary for viral replication.

No DNA intermediate is necessary for HCV replication, and it proceeds through an intermediate (–) RNA strand, which is
Figure 43-4   Replication of HCV does not require any DNA intermediate. The (+) strand polarity genomic RNA is transcribed by the NS5 region RNA-dependent RNA polymerase and the (–) strand RNA is transcribed again to generate new viral genomes.

reverse-transcribed to generate new viral genomes (Fig. 43-4). The presence of this (–) strand HCV RNA has been demonstrated during active viral replication. In addition, subgenomic RNA species have also been found in chronic HCV carriers, although the significance of this finding is unclear because subgenomic RNAs could simply represent defective RNAs or viral particles. During prolonged viral replication, proofreading errors may be common. In addition, selection pressures may lead to the emergence of mutated viruses. Among the hepatitis viruses, HCV shows the most extensive capability for mutating, as indicated by viral heterogeneity. As noted above, the 5' UTR region and the core region are most conserved. The least conserved portion of the virus appears to be the NS5 region between nucleotides 7400–7550. The HCV E1 and E2/NS regions are also poorly conserved.

During acute hepatitis, HCV RNA is detected in the blood within days after infection, although why the RNA should circulate without secretion of core particles is unclear. The overall level of HCV RNA may be low, although heavy viremia may be associated with 1×10^7 or more genome equivalents/mL. The diagnosis of active viral replication is usually based on demonstrating HCV RNA in serum with quantitative polymerase chain amplification reactions (PCR). The PCR systems most commonly utilize reverse transcription of the viral RNA with primers based on highly conserved 5'-end structural sequences. The reverse-transcribed cDNA is further amplified with a second set of primers representing sequences "internal" to the first set of primers and this is referred to as a "nested PCR." Modifications have been made to the PCR method by incorporation of enzymatically labeled oligonucleotides so that amplification of the oligonucleotides can be quantitated by chemical reactions. Such a branched DNA (bDNA) PCR offers greater convenience in quantitating the virus but may be 50- to 100-fold less sensitive than the nested PCR. Along with viral replication, antibodies against HCV (initially IgM class) also appear in the blood, although this may lag for several weeks. The anti-HCV is nonprotective, however, and its presence correlates with ongoing viral replication. Viral clearance is characterized by disappearance of both HCV RNA and anti-HCV.

HEPATITIS D VIRUS   The presence of HDV in the liver of chronic HBV carriers was detected serendipitously during immunostaining analysis. Initially, it was thought that a new HBV antigen had been stained. However, further studies, including transmission in animals, soon showed that this was a novel, albeit

defective, virus requiring HBV for some of its components. The HDV is a unique RNA virus related to plant viroids and satellite viruses, although with sufficient differences for proposed classification in a separate floating genus termed deltaviridae. Viroids contain nonencapsidated infectious RNA particles and are incapable of producing virions, whereas plant satellite viruses require a helper virus for replication and encapsidation. In similarity with these agents, HDV is unable to establish autonomous infection, requires a genetically unrelated virus (HBV), is smaller than all known animal viruses with a unique single-stranded circular structure, possesses ribozyme activity for self cleavage and ligation, and *in situ* analysis shows the presence of HDV RNA in the nucleus instead of the cytoplasm, which is a characteristic of RNA viruses. However, HDV is distinct from viroids in the ability to encode its own protein (HDAg).

The virus is prevalent worldwide, with significant endemicity in the Mediterranean basin, Middle East, South America, West Africa, and some South Pacific islands. Its significance derives from extensive worsening of disease in chronic HBV carriers, as well as its unique genetic mechanisms. Because HDV requires HBsAg for its assembly and virulence, its host range is the same, and it can infect primates, rodents, and ducks in the presence of appropriate hepadnaviruses. The virion particles are 36 nm in size with an outer envelope consisting of HBsAg, which surrounds an 1nm size nucleocapsid containing the hepatitis D antigen (HDAg), and an RNA genome of 1.7 kb (Fig. 43-1). The HDV RNA is a single-stranded circular molecule with a high G+C content (60%) and tendency for much intramolecular base pairing. In nondenaturing conditions, the RNA genome is folded into unbranched structures with terminal loops. The genomic RNA, as well as the replicative antigenomic RNA intermediate, contain multiple ORFs, but only a single HDV RNA domain is translated. The "viroid-like domain" encompasses 600–980 nucleotides toward the 5' end of the virus and includes a ribozyme sequence, whereas the remaining 75% of the ORF encodes for HDAg and constitutes the so-called "cellular domain."

Two HDV mRNA species have been identified and these contain the viroid and virusoid consensus sequences GAAAC and GAUUUU. The GAAAC sequence is essential for the ribozymal self-cleavage of virusoid RNA with similar implications for HDV. The HDV ribozyme occupies 150 nucleotides in the genome and cleaves between U and G at arbitrarily mapped 688/689 genomic positions. The HDV ribozyme shows unique properties, including remarkable efficiency and heat stability with retention of activity at up to 75°C.

The HDAg is a phosphoprotein with the capacity to bind RNA and exists as two polypeptides of 24- and 29-kDa sizes. The HDAg contains a leucine zipper-type domain, nuclear localization signal, HDV RNA-binding domain conferred by the middle one-third of the molecule, as well as a prenylation domain, which facilitates interactions with HBsAg. The HDAg is expressed in the nucleus, however, whereas HBsAg is localized in the cytoplasm. Despite this difference in their subcellular location, viral packaging is unimpeded, although it is a mystery as to how HDAg and HBsAg come together during virion assembly. During HDV replication in the nucleus of infected hepatocytes, a 0.8-kb antigenomic polyadenylated RNA appears in the cytoplasm. This RNA is 500 times less abundant than genomic RNA and is thought to encode HDAg. In vitro studies show that HDV replication does not require HBV and can occur in liver-, as well as non–liver-derived cells. Studies
Figure 43-5 Replication of HDV proceeds through "rolling circle" mechanisms. The genomic (G) viral genome is transcribed by cellular polymerase activity and follows the circle with elongation of a linear sequence containing ribozyme domains. The endogenous ribozyme self cleaves the replicated antigenomic (AG) sequence, which circularizes. Repetition of a second rolling circle mechanism then gives rise to the genomic sequence with completion of the replication process.

in transgenic mice expressing HDV cDNA show that HDV is very well-expressed in the skeletal muscle, brain, testes, and kidney, and expressed relatively poorly in the liver. These findings are in contrast with HBV expression, which is most abundant in hepatocytes and not supported by cells of nonepithelial lineage, such as the skeletal muscle, brain, and testes, including in transgenic animals. The differences are most likely mediated by interactions between cellular transactivators and viral regulatory domains. It is interesting that HDV has not been found to replicate in extrahepatic locations in infected individuals, which must indicate its restricted distribution in the body dependent on the susceptibility of individual organs to HBV infection.

The replication of HDV utilizes a unique "double rolling circle" mechanism (Fig. 43-5). The circular HDV RNA genome serves as the initial template to generate an antigenomic RNA intermediate. The antigenome RNA is initially transcribed in a linear form and the completed transcript undergoes self-cleavage and ligation by the ribozyme activity. The circularized antigenome template is in turn transcribed to similarly originate a linear genomic RNA with cleavage by ribozyme and recircularization. In tissues supporting HDV replication, HDV RNA is present as monomers, dimers, and trimers of both strand polarities, consistent with this rolling circle model of replication. The RNA-dependent RNA replication most likely utilizes the cellular RNA polymerase II itself, because the virus does not contain any polymerase activity and can replicate independently of HBV. There is evidence to suggest that HDV usurps the cellular transcriptional machinery, such as by recruiting specific transcription factors with the aid of small HDAg, which allows the use of RNA polymerase II. In this way, the small HDAg occurs in great abundance during viral replication compared with the large HDAg. In contrast, the large HDAg serves as a dominant repressor of HDV replication by as yet poorly understood mechanisms and also helps package virions.

In acute infection, serum HDAg is often the first detectable marker, although its concentrations decline rapidly, and HDAg is rarely detected for more than 1–2 weeks. Molecular hybridization shows serum HDV RNA in approx 60% within the first week of illness. Persistence of serum HDV RNA beyond 3 weeks of the onset of acute hepatitis may predict chronicity. Antibodies to HDAg (anti-HD) appear in serum and may be either IgM or IgG class. In chronic HDV infection, IgM and IgG anti-HD are often detected for years, along with serum HDV RNA, which correlates with intrahepatic HDAg expression and viral replication. The anti-HDs are not neutralizing and similar to HCV, but unlike HAV, HBV, or HEV, development of anti-HD antibodies does not protect against reinfection.

HEPATITIS E VIRUS This is an important virus involved in epidemics of water-borne hepatitis. The first extensive epidemic ascribed to HEV was recognized in Delhi, India, in 1955, with >29,000 cases. Subsequent large epidemics have occurred elsewhere in Asia, Africa, and Central America, with the epidemic in Xinjiang region of China in 1986–1988 affecting >100,000 people. The HEV is transmitted via the feco-oral route with a high attack rate. Pregnant women suffer from severe or fulminant hepatitis E with high mortality rates, approaching 20%. The virus is encountered sporadically among travelers to endemic areas in the West, including the United States. Infection with HEV has not been identified in animals other than man, although cynomolgus macaques and tamarins are susceptible and provide valuable animal models of HEV infection. The virus does not cause chronic disease.

The HEV virions are spherical, nonenveloped particles with spikes and indentations on the surface (Fig. 43-1), which are characteristic of the calciviridae family, although HEV is thought to constitute a unique genus. The virus was first visualized by immunoelectron microscopy in stool from a patient and an experimentally infected cynomolgus macaque. The virus was subsequently cloned from RNA in infected bile and this utilized molecular hybridization screening of cDNA libraries. The HEV was found to have a 7.6-kb, single-stranded polyadenylated RNA genome. The viral genome contains three open reading frames with the ORF1 spanning 5079 bases in the 5' region and ORF2 spanning 1980 bases toward the 3' region with an additional 65 bases separating the ORF2 from the polyadenylated tail. The ORF3 spans 369 bases and overlaps the ORF1 by one nucleotide on its 5' end and ORF2 by 328 bases toward its 3' end. The ORF1 expresses nonstructural genes and contains a motif encoding an RNA-dependent RNA polymerase, as well as two well-conserved motifs associated with helicases. The structural genes are in the 3' end of the genome and expressed via subgenomic transcripts. The virus expresses two polyadenylated mRNAs of 2- and 3.7-kb sizes. These mRNAs can be detected by PCR in the liver, serum, and fecal extracts of patients with HEV.

The virus expresses type-specific epitopes, which are broadly reactive on immunotransblot analysis, in structural domains conferred by ORFs 2 and 3. There is evidence for significant regional variations in the ORF2 and 3 sequences in viral isolates obtained from different geographic parts of the world, although whether these differences are sufficient for molecular epidemiology studies needs further analysis. The hepatitis E antigen (HEAg) is recognized by immunostaining in the cytoplasm of infected hepatocytes and appears before the onset of clinically overt hepatitis. Serological tests have been developed by recombinant DNA technologies to assay for IgM and IgG class anti-HEV antibodies, although

diagnosis can also be made by detecting HEV nucleic acid sequences by PCR.

HEPATITIS G VIRUS AND HEPATITIS GB VIRUSES   The existence of patients with hepatitis and absence of markers for known hepatitis viruses generated ongoing interest in isolating additional viruses. In the early 1990s, three viruses were isolated from stored blood from a patient encountered in the 1950s with the initials GB. These viruses were designated GBV-A, GBV-B, and GBV-C, and assigned to the flaviviridae family. In 1995, a new RNA virus designated HGV was sequenced from the serum of a chronic HCV carrier by using an immunoscreening approach. The HGV was found to have an RNA genome of approximately 9.1 kb in size with an organization similar to flaviviridae, including HCV. The 5' end of the genome contains the structural genes and the 3' end the nonstructural genes. There are highly conserved sequence motifs for a helicase, two proteases, and an RNA-dependent RNA polymerase, although the polypeptides have not been extensively studied.

Interestingly, sequence analysis showed that HGV was essentially identical to GBV-C (95 and 86% homology at amino acid and nucleotide levels, respectively). The global homologies between HGV and GBV-A (45%), GBV-B (25%), and HCV (26%) were somewhat less striking, although similarities in their genome organization and specific regions of the genome indicated close phylogenetic relationships. The 5' UTR region was found to be highly conserved in HGV, although sequences of viral isolates in different geographic regions show differences in the capsid protein. The HGV polyprotein expressed in a recombinant vaccinia virus system was found to produce multiple peptides using protease activities, similar to that observed with HCV.

The HGV has been transmitted to chimpanzees, tamarins, and cynomolgus macaques with HGV RNA detected in serum by using reverse transcriptase-PCR. The HGV is prevalent in approximately 1–2% of volunteer blood donors in the United States, with increased prevalences in selected populations, such as polytransfused hemophiliacs (20%) and intravenous drug users (50%). However, although serum HGV RNA has been found for prolonged periods in patients with acute, fulminant, or chronic hepatitis, the significance of these findings is unclear because liver disease in HGV carriers can be blamed on other causes. By itself, HGV has not been found to cause liver disease. One view suggests that HGV is not actually pathogenic, and the issue of whether HGV and related HGBVs are even hepatitis viruses is presently under debate. The notion is that HGV is simply a harmless commensal virus.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

Interactions between virus and host factors are most important in determining whether viral persistence and chronic liver disease will occur. The significant differences in the outcomes of infection with various hepatitis viruses are summarized in Table 43-4. Anicteric hepatitis is extremely common in all cases, specially hepatitis A and E. The HAV and HEV cause only acute hepatitis and are cleared by neutralizing antibodies with lifelong immunity. Similarly, HBV may also be cleared by anti-HBs, although the situation may rarely be complicated by the emergence of "vaccine-escape" mutants *(see below)*. On the other hand, HCV and HDV induce nonprotective antibody responses. When the host immune response is impaired, e.g., organ transplant recipients, chronic renal failure, chemotherapy, and so on, viral persistence is more

likely. Small viral inocula may be insufficient to elicit a vigorous immune response and also in this setting viruses may persist. The association of HBV and HCV with diseases involving circulating immune complexes (e.g., polyarteritis nodosa, membranoproliferative glomerulonephritis, aplastic anemia, cryoglobulinemias, and so on) is another example of how viral-host interactions may contribute to disease. Induction of chronic liver disease and disease exacerbations seen frequently in HBV and HCV infections are interlinked first and above all to the replicative states of the virus and the vigor of the host immune response. Both HBV and HCV are thought to cause chronic liver injury arising from activation of the cellular immune response. The injury is mediated by complex mechanisms involving both cytotoxic T lymphocytes (CTL) as well as secondary cytokine-mediated events. Additional mechanisms of cell injury involve expression of injurious viral proteins, although these need further characterization.

Replicating and Nonreplicating States of Viruses   These states of HBV are defined by the presence of replicative virus (serum HBV DNA+, HBeAg+/anti-HBe–, HBV DNA polymerase+, IgM anti-HBc+) or its absence (serum HBV DNA–, IgM anti-HBc–, HBeAg–/anti-HBe+). During HBV replication, hepatocytes display HBsAg and HBcAg and are surrounded by a mononuclear infiltrate containing activated lymphocytes. The HBV replication may be intermittent or persistent, at high levels or at low levels, and liver disease rapidly progresses with patients being infectious. During the nonreplicative phase, HBV DNA is negative and HBcAg is not produced. Active liver inflammation is absent and histologic evidence of HBV may be limited to "ground glass" hepatocytes or inactive cirrhosis. However, the states of replicative quiescence and activity are interchangeable. Such a change may occur in response to pharmacological interventions, such as use of glucocorticoids or chemotherapeutic agents, which increase viral replication, or spontaneously in response to unidentified stimuli. Spontaneous reactivation of HBV replication approaches an annual incidence of up to 10–35% and may lead to fulminant hepatitis, a rapid downhill course, or worsening of chronic liver disease. Nucleotide sequence analysis of HBV DNA in patients with reactivations has suggested that some episodes of reactivation represent reinfection with mutated HBV. During viral replicative states, serum HBV DNA may be found as partially double-stranded DNA, although full-length genomes and DNA:RNA hybrids may also be found. Maternal transmission is most significant for HBV, and the risk correlates with the viral replication status for both HBV and HCV. A characteristic feature of HBV is related to its integration in the host genome. In the replicative phase, HBV DNA in hepatocytes is mainly in free virion or replicating forms, and integration into host genome is not evident. In the nonreplicating phase, random integrations occur, replicative forms of free virion DNA are not found, and HBV is not secreted. In other nonpermissive infections, clusters of HBsAg-producing cells with the appearance of a focal clonal growth have been noted. In these cases, HBV has been identified in liver DNA integrated into the host genome. A mixed type of persistent infection may also occur with features of both replicating and nonreplicating infection in the same liver. In cases with impaired or blocked secretion of HBV, replicative intermediates and extrachromosomal forms may accumulate, facilitating HBV DNA integrations. It has been suggested that the region between DR1 and DR2 may facilitate HBV DNA integrations, but no consistently satisfactory mechanism has yet been identified. No specific cellular sites have

Table 43-4
Comparison of the Clinical Features of Viral Hepatitis

Features	A	B	C	D	E	G
Incubation (days)	15–50	28–160	14–160	20–120	15–60	14–30
Fecal excretion	+	–	–	–	+	–
Viremia	Transient	Prolonged	Prolonged	Prolonged	Probably transient	Prolonged
Routes of transmission						
Oral	+	–	–	–	+	–
Percutaneous	Rare	+	+	+	–	Possible
Blood Transfusion	Rare	+	+	+	–	+
Sexual	+	+	–	–	Unknown	Unknown
Perinatal	–	+	±	–	Unknown	Unknown
Age at onset	Children and adolescents	All ages, neonatal in endemic areas	All ages	All ages	Mostly children and adolescents	Adult
Rash or arthralgia	Uncommon	May occur	Uncommon	Uncommon	May occur	–
Fever	Frequent	Uncommon	Uncommon	Uncommon	Frequent	–
Waxing and waning hepatitis	–	–	+	–	–	?+
Biphasic hepatitis	Rare	–	–	+	–	–
Cholestatic hepatitis	+	–	–	–	+	–
Diagnosis of acute infection	Serum IgM anti-HAV	Serum IgM anti-HBc	Serum HCV RNA; IgM anti-HCV	Serum IgM anti-HDV; HDV RNA	Serum anti-HEV; Serum or stool HEV RNA	Serum HGV RNA
Diagnosis of chronic infection	–	Serum HBsAg; serum HBV DNA	Serum HCV RNA; anti-HCV	Serum IgM and IcG anti-HDV: HDV RNA	–	Serum HGV RNA
Frequency of fulminant hepatitis	Rare	Moderate	Rare	Moderate to high	Very high in the pregnant	–
Chronic carrier state	–	+	+	+	–	+
Hepatocellular carcinoma	–	+	+	±	–	–
Mortality during acute hepatitis	Low, worse in >40 years of age	Low	Low	May be high in superinfected chronic HBV carriers	Low; very high during pregnancy	?None
Vaccine	Yes	Yes	No	No	No	No

been found to support preferential HBV DNA integrations, although topoisomerase I, which is a nuclear enzyme, was shown to cleave open ciruclar HBV DNA at preferred integration positions and to potentially mediate DNA integrations. Nonetheless, more information is necessary to define how HBV DNA integrations occur and what their precise significance might be.

During HBV replication, all viral proteins are expressed. The cellular immune response is thought to be induced most prominently by HBcAg expression. The preS1 and preS2 proteins are preferentially coexpressed with HBcAg during viral replication. Specific cellular immune responses against HBV antigens are well-recognized. Circulating lymphocytes from chronic HBV carriers show cytotoxicity against autologous hepatocytes in vitro, which can be blocked by anti-HBs. The HBV proteins are not usually cytopathic, and liver injury is mediated by activated cytolytic T lymphocytes sensitized by HLA-restricted HBcAg expression. In contrast, HBeAg can occupy lymphocyte receptors used for binding HBcAg and provide immunological escape to the virus by

preventing clearance of infected hepatocytes despite HBcAg expression. The tolerance to HBV can indeed be broken in transgenic animals by administration of activated HLA-restricted CTL, which results in clearance of hepatocytes expressing HBV antigens, as well as decrease in viral gene expression because of cytokine release. In animals, extensive cell clearance has been associated with fulminant hepatitis, recreating the situation in patients with natural infection.

The outcomes of liver disease in patients with HBV and HDV show variability, although it is unclear whether it is a result of viral factors, altered host immune response, or both. In susceptible hosts, HDV is highly infectious, and compared with HBV, its infectivity may be greater by multiple orders of magnitude. When HDV and HBV infections occur simultaneously (coinfection), HDV suppresses HBV replication and may cause a biphasic hepatitis, with the initial hepatic injury caused by HDV replication. Similarly, HDV suppresses HCV replication as well. On the other hand, when HDV infection occurs in chronic HBV carriers (superinfection),

the abundance of replicative HBV intermediates, as well as HBcAg, is reduced, and peripheral markers of HBV, including HBsAg, may disappear without actual virus clearance. In the setting of superinfection, even small HDV inocula that might not cause hepatitis in the setting of HBV and HDV coinfection, may be "rescued" and become pathogenic. Chronic HBV carriers are, therefore, at specially grave risk for acquiring HDV infection, when blood products negative for HBsAg could yet contain infectious HDV. Enhanced virulence of HDV during serial passages or because of unknown factors may cause severe or fulminant hepatitis. Although in vitro replication of HDV, as well as expression of HDAg in transgenic mice, does not necessarily lead to a cytopathic effect, when HDV is efficiently replicated, each cell may contain thousands of virion particles, and toxicity may potentially arise from hijacking of cellular resources. The exclusive use of RNA polymerase II by HDV may attenuate cellular gene expression. Also, evidence has been provided for sequence similarities between HDV RNA and the 7S signal recognition particle in cells for protein translocation, which may interfere with cellular protein synthesis. Finally, immune responses involving cytotoxic lymphocytes against HDV, similar to the host immune response against HBV, may be involved in cell clearance or cytokine-mediated cytotoxicity. In patients with HIV infection or immunosuppression, HDV replication is unchanged, suggesting that immunodeficiency does not influence HDV directly, which is in contrast with increased HBV replication in such settings.

Studies of HCV in experimentally infected chimpanzees showed that HCV could be cleared rapidly, persist indefinitely with continuous replication, or replicate intermittently with variable periods of quiescence. During infection with HCV, the liver is markedly infiltrated with mononuclear cell aggregates containing B lymphocytes in the center surrounded by a network of reticular cells and another zone of various subpopulation of lymphocytes. The lymphocytes from chronic HCV carriers are cytotoxic in vitro to autologous hepatocytes, although this is not HLA-restricted. The activated lymphocytes recognize multiple viral antigens, including core, E1, and E2/NS proteins. In some, manifestations of autoimmune liver disease (liver-kidney-microsomal hepatitis) have been ascribed to molecular mimicry with HCV antigens. Similar to HBV, when HCV replication is attenuated, liver disease may be minimal. Of greater significance perhaps is the host immune response. "Healthy carriers" have been identified in whom chronic HCV infection and replication are established but have no liver disease. Disease progression may be arrested in the fortunate few responsive to interferon-α (IFN-α) with subduing or clearance of HCV replication (Fig. 43-6).

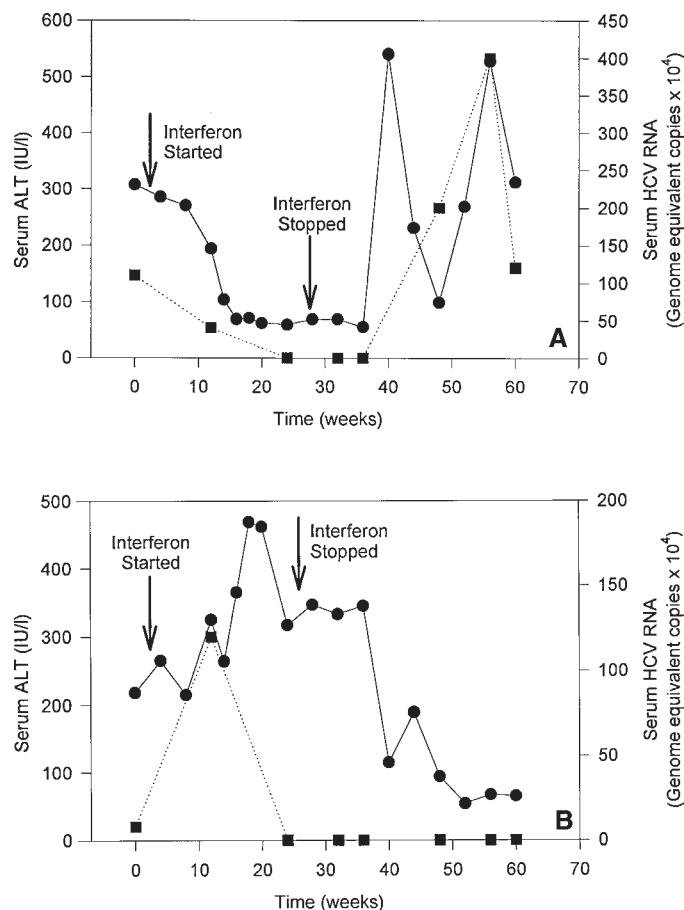
Relationship with Hepatic Oncogenesis A number of epidemiologic studies clearly established relationships between chronic viral hepatitis and HCC. The relative risk for HCC in chronic HBV carriers may be increased by up to >200-fold. Similarly, hepadnavirus infection in woodchucks, and Peking ducks is associated with increased incidence of HCC. Observations in patients, as well as experimentally infected woodchucks indicate that simultaneous infection with HDV and HBV can accelerate the onset of HCC. The association between HCC and chronic HCV infection has also been confirmed by extensive epidemiological studies. For instance, in a large Japanese study, the relative risk for HCC in patients with chronic hepatitis was increased sevenfold in HBsAg+ patients and fourfold in patients with anti-HCV.


Figure 43-6 Representative responses in chronic HCV carriers treated with IFN-α. ●, serum ALT; ■, serum HCV RNA. **(A)** A patient who was found to respond to the drug during treatment but promptly relapsed with resumption of viral replication, as well as hepatic inflammation upon discontinuation of the drug. This is one of the most common responses to IFN-α treatment. **(B)** This patient showed less dramatic decrease in serum HCV RNA while on IFN-α, but the virus was cleared in a delayed manner. Most such patients clear virus temporarily, although in some sustained viral clearance may be associated with significant improvement in liver disease and decreased requirement for OLT.

The potential role of specific viral and cellular gene products in HCC has been subjected to extensive investigation. Whereas candidate genes have been identified for HBV, which integrates into the host genome, similar mechanisms have not been found for HCV, which does not integrate in the genome. The HBV DNA integrations were originally observed in HCC-derived cell lines and similar observations were subsequently made in patients. Most HBV DNA integrations occur during persistent infection in precancerous tissues. Although the majority of HBV integrations produce unique bands on DNA blot analysis, which indicates clonal expansion of cells containing integrated sequences, whether viral integrations contribute to cell transformation or clonal expansion has not been established. The integrated HBV DNA sequences vary from relatively simple to multiple rearrangements, deletions, inversions or duplications, and chromosomal translocations. Most integrations disrupt the viral genome organization, although some may contain greater than unit-length HBV DNA with apparently intact genomes. The HBV integrations have not

been shown to induce insertional mutagenesis, although random HBV integrations have been found in or adjacent to specific genes, including the erb A protooncogene and cyclin A gene. Other HBV integrations have been responsible for translocations between chromosomes 17q22 and 18q11, chromosomes 17 and 7, and chromosomes 9 and 5. However, HBV does not contain an oncogene, and transfection with HBV DNA in general lacks mutagenic potential. Evidence concerning whether HBV could augment or activate specific proto-oncogenes by itself has been inconclusive, although increased c-*myc* expression has been shown in HCC in woodchucks. Alternative mechanisms concerning the loss of tumor suppressor genes, such as p53, have not provided incriminating evidence related to HBV.

Another way to examine the role of viral proteins in causing disease is by using transgenic mouse lines. In transgenic mice expressing only the small HBsAg molecule, no liver disease is observed. However, when large HBsAg is expressed in transgenic mice, the filamentous form of HBsAg is overproduced and entrapped in the cytoplasm. In the HBV transgenic mouse line designated 50-4, expression of large HBsAg leads to hepatic injury, ground glass hepatocytes, cellular degeneration, and Kupffer cell or hepatocyte hyperplasia, followed by aneuploidy, focal nodular hyperplasia or liver cancer. As ground glass hepatocytes are frequently observed in chronic HBV carriers, it is possible that similar pathophysiological mechanisms may be involved. The HBxAg has also been subjected to much study because this protein can transactivate cellular genes, which may be important in cell growth. However, evidence from three lines of transgenic mice expressing HBxAg showed that most animals did not develop HCC, although mild hepatitis, nuclear pleomorphism, focal necrosis, nodular hyperplasia, or increased mitotic activity were noted in some animals. In another transgenic line with more prolonged expression of HBxAg, there were progressive changes in the liver with eventual development of hepatic adenomas or carcinomas. Therefore, under certain circumstances, HBV gene products could interact with other cellular genes to induce oncogenesis.

Whether HDV has an impact at the cellular and molecular level in hepatic oncogenesis requires more study. One possibility is that the HDV ribozyme may alter transcriptional regulation despite a >10-fold lower affinity for heterologous DNA sequences. In addition, HDAg is a basic phosphoprotein with histone-like DNA-binding capacity, and this could also potentially modulate the activity of regulatory genes in infected hepatocytes. Additional possibilities by which HBV, as well as HCV, could induce HCC must include activation of specific cell populations under selection pressure induced by ongoing cell necrosis and regeneration and the responsiveness of emerging cell clones to specific growth factors. The evidence for the involvement of growth factors in HCC has begun to emerge. The transforming growth factor-alpha (TGF-α) may help transform liver cells by increasing cell proliferation and turnover rates, and TGF-α transgenic mice show increased incidence of HCC. In addition, coexpression of TGF-α along with c-*myc* or SV40 TAg accelerates both the onset and growth rate of HCC. Therefore, the current evidence is inconclusive with regard to any single viral gene being oncogenic for the liver. It may be that HCC arises mainly from increased cell turnover and attempt of newly emerged cells to evade virus infection. Repeated cycles of liver injury and cell proliferation could amplify selection events with the help of hepatic growth factors.

VIRAL MUTATIONS AND MUTANT PROTEINS

In general, RNA viruses are more prone to mutations because transcription with the RNA polymerase carries with it less fidelity. However, because HBV utilizes a reverse transcription step, it also shows significant mutations in its nucleotide sequence. Are there additional reasons for mutations to arise? Particularly, could mutations in viruses reflect evolutionary pressures or escape mechanisms? These tantalizing questions are unresolved, but viral mutations have been observed with greater frequency in patients with advanced liver disease, presumably related to active viral replication and robust immune responses, as well as in response to antiviral therapies, such as lamivudine treatment of chronic HBV carriers and IFN-α treatment of chronic HCV carriers.

HAV MUTATIONS Based on differences in the nucleic acid sequence, seven genotypes of HAV have been recognized and designated genotypes I–VII. The genotypes show nucleic acid diversity of 15% or more. Only four HAV genotypes are associated with human disease, with the rest being pathogenic for monkeys. The genotypes I and III have been subtyped with additional nucleic acid sequence differences (IA and B; III A and B) approaching approximately 7.5%. The value of genotyping at present concerns molecular epidemiology studies with certain genotypes being more prevalent in some geographic areas. For instance, the genotype IA is most commonly isolated in the United States. However, despite the genotype variability, HAV constitutes a single serotype and development of neutralizing antibodies after natural infection confers lifelong immunity. The neutralizing IgG class antibodies bind to a common region on the surface of the virus. Although the amino acid sequences of VP1, VP2, and VP3 regions may also exhibit differences in various substrains, these changes do not provide an immunological "escape" for reinfection in an immune host. Analysis of immunogenic domains of the virus, including the use of recombinant DNA technology, has been subject to major efforts because of its significance in the development of effective vaccines.

The HBV mutations identified involve the HBsAg, HBeAg, HBcAg, and possibly HBxAg, coding regions. The most commonly involved HBsAg region is responsible for conferring the "a" group-specific epitope, which is shared by all three small, middle, and large HBsAg molecules. The consequences of point mutations in HBsAg are substitutions in specific amino acids, such as at amino acid positions 122, 145, and others, which result in the loss of epitope conformation. As a result, the virus no longer can bind anti-HBs. The practical consequence is that in patients with anti-HBs, including after vaccination, reinfection with the mutated HBV could occur, along with chronic liver disease. A number of such cases termed "vaccine-escapes" have recently been identified with liver disease in previously immune patients. In addition, patients with mutations in the HBsAg region have been found to be younger and to present with more advanced disease, including cirrhosis, ascites, and HCC, albeit cirrhosis may be less active at such a presentation.

Mutations in the precore HBV region were found in patients that were replicating HBV without producing HBeAg. Analysis of HBV DNA purified and amplified by PCR from sera of such HBV DNA+, HBeAg–/anti-HBe+ patients showed mutations in two codons of the precore region of the ORF C, one of which leads to generation of a TAG translational stop signal. The result is a mutant HBeAg, which is no longer secreted and may be indirectly associated with liver disease of greater severity because HBeAg would

no longer mask HBcAg from being recognized by activated CTL. In additional patients, precore mutant HBV has been identified in the setting of acute or fulminant hepatitis, although the evidence suggests that such mutant HBVs are not necessarily more likely to induce fulminant hepatitis in naive individuals. Nonetheless, patients with precore mutations may present more often with greater symptoms, jaundice, and hepatic inflammation. Mutations in the precore HBV regions have also been known to generate replication-incompetent viruses, which may function in a dominant negative fashion to suppress replication of the wild-type virus, and their potential use for gene therapy has recently been explored *(see below)*.

HCV MUTATIONS Genotyping by type-specific PCR; direct sequencing; restriction-fragment-length polymorphisms; DNA hybridization with type-specific probes or reverse hybridization with sub-type-specific probes; and serologic analysis with group-specific antibodies has identified multiple HCV variants. The substitution rate of HCV has been estimated at 0.9×10^{-3} per nucleotide per year. Proposals for genotype classifications are based on variations in the core region (four subtypes), NS3 region (two subtypes) and NS5 region (two subtypes). Six major genotypes are recognized with a series of subtypes. The original United States HCV isolate is designated HCV type I and is the commonest isolate (72%), followed by type II (14%), type III (6%), and type IV (1%). The type Ia HCV is most widespread in the United States, whereas type Ib is most prevalent worldwide. Mixed genotypes may also coexist (4%). The type I HCV is found in approximately 50% cases with posttransfusion HCV. Although patients with HCV types III and IV tend to be younger, viremia levels are in general similar in all genotypes, and no firm correlations have been established between genotype and disease activity. However, in Japan and Europe, type I HCV may be associated with greater viremia, compared with types 2 and 3. In addition, HCV types II and III may respond better to treatment with IFN-α as compared with type I HCV. Within individual patients, HCV may exist as a spectrum of closely related viral genomes, which is referred to as viral *quasispecies*. The development of HCV quasi-species appears to be related to increasing duration of carrier states, greater viremia, HCV type Ib, and a poor response to IFN-α treatment. The significance of viral quasi-species is unclear and this requires more analysis.
