The diagnosis of AD is based on the constellation of clinical features in Table 87-1. Approximately 50% of patients develop AD by the first year of life, and an additional 30% between age 1 and 5 years. Nearly 80% of patients with AD eventually develop allergic rhinitis or asthma later in childhood. Many of these patients outgrow their skin disease as they are developing respiratory allergy. This observation is consistent with the concept that the clinical expression of allergic disease is determined in part from local tissue allergen sensitization and compartmentalization of the immune response in the skin vs the respiratory mucosa.

SKIN REACTION PATTERNS IN AD Intense pruritus and cutaneous reactivity are the hallmarks of AD. Scratching may be intermittent throughout the day but is usually worse in the early evening and night. Patients with AD also have a reduced threshold for pruritus. Clinically, this is supported by the observation that allergens, reduced humidity, excessive sweating, and irritants— e.g., wool, acrylic, soaps, and detergents—can exacerbate pruritus and scratching.

Several types of inflammatory skin lesions are commonly seen in AD. Acute lesions are intensely pruritic, and characterized by erythematous papules over erythematous skin. These are associated with extensive excoriations, erosions, and serous exudate. Subacute dermatitis is characterized by erythematous, excoriated, scaling papules. Chronic dermatitis is characterized by thickened skin, accentuated skin markings (lichenification), and fibrotic papules. In chronic AD, all three stages of skin reactions usually coexist in the same individual. At all stages of AD, patients usually have dry skin. Skin distribution and reaction patterns vary according to the patient's age and disease chronicity. During infancy, the AD is generally more acute and primarily involves the face, scalp, and the extensor surfaces of the extremities. In older patients who have had long-standing skin disease, the rash is characterized by the chronic form of dermatitis with lichenification and localization to the flexural areas of the extremities.

ROLE OF ALLERGENS IN AD Serum IgE levels are elevated in 80–85% of patients with AD. Approximately 85% of patients have positive immediate skin tests or RAST for specific IgE to a variety of food and inhalant allergens. However, positive immediate skin tests to specific allergens do not always indicate clinical sensitivity and patients who outgrow AD frequently continue to have positive skin tests. Indeed, May first made a distinction between symptomatic and asymptomatic hypersensitivity based on the observation that AD patients with positive food skin tests did not always have positive challenges to the foods implicated by IgE responses. These clinical observations suggest that the relationship between IgE and clinical disease is not exclusively dependent on IgE-mediated mast-cell degranulation.

Well-controlled, double-blind, placebo-controlled food challenge studies (DBPCFC) have, however, demonstrated that food allergens can exacerbate skin rashes in at least a subset of patients particular young children with AD. Importantly, elimination of putative food allergens in such patients results in significant improvement of their skin disease. As patients grow older, they outgrow their food allergy, but a majority of them become sensitized to inhalant allergens. Whereas sensitization to inhalant allergens in most cases reflects the development of coexisting respiratory allergy—e.g., asthma or allergic rhinitis—a number of clinical studies suggest that inhalation or contact with aeroallergen may play a role in the exacerbation of AD.

CUTANEOUS INFECTIONS Patients with AD have an increased tendency to develop viral, fungal, and bacterial skin infections. These infections are generally localized to the skin. Deep-seated infections suggest the possibility of hyperimmunoglobulinemia E

Table 87-1
Diagnostic Features of Atopic Dermatitis[a]

Major features
  Pruritus
  Typical appearance and distribution of skin lesions
    Facial and extensor involvement in infancy and early childhood
    Flexural involvement and lichenification by adolescence
  Chronic or frequently relapsing course (duration >6 weeks)
  Personal or family history of either AD or respiratory allergy
Minor features
  Increased susceptibility to skin infections, particularly *S. aureus*
  Xerosis (dryness of the skin)
  Early age of onset
  Multiple positive immediate prick skin tests
  Elevated serum IgE levels
  Ichthyosis; keratosis pilaris; hyperlinearity of palms
  Nonspecific hand/foot dermatitis
  Scalp dermatitis, e.g., cradle cap

  [a]Modified from Hanifin and Rajka.

Table 87-2
Immunologic Features of Atopic Dermatitis

Increased IgE production
Immediate skin-test reactivity to multiple allergens
Increased basophil spontaneous histamine release
Decreased CD8 suppressor/cytotoxic number and function
Increased expression of CD23 on mononuclear cells
Chronic macrophage activation with increased secretion of GM-CSF, PGE_2, and IL-10
Expansion of IL-4–, IL-5–, and IL-13–secreting Th2-like cells
Decreased numbers of IFN-γ–secreting Th1-like cells

syndrome or another immunodeficiency syndrome. Viral infections include herpes simplex, vaccinia, warts, molluscum contagiosum, and papilloma virus. The most common viral infection is herpes simplex, which tends to spread locally or can become generalized. Superficial fungal infections also appear to occur more frequently in atopic individuals. The potential importance of these dermatophyte infections is suggested by the reduction of AD skin severity following treatment with antifungal agents such as ketoconazole.

Considerable attention has focused on the contribution of *Staphylococcus aureus* colonization and infection to the severity of AD. *S. aureus* is found in over 90% of AD skin lesions. Honey-colored crusting, extensive serous weeping, folliculitis, and pyoderma indicate bacterial infection usually secondary to *S. aureus* in patients with AD. The importance of *S. aureus* in AD is supported by the observation that not only patients with impetiginized AD, but also AD patients without superinfection show clinical response to combined treatment with antistaphylococcal antibiotics and topical corticosteroids.

Recent studies suggest that *S. aureus* exacerbates or maintains skin inflammation in AD by secreting a group of toxins known to act as superantigens that stimulate marked activation of T cells and macrophages. Since staphylococcal enterotoxins (SEs) are globular proteins of 24–30 kDa, the possibility that they could act as allergens has also been studied. In this regard, it has been found that nearly half of AD patients produce IgE directed to staphylococcal toxins, particularly SEA, SEB, and toxic shock syndrome toxin-1 (TSST-1). This is of interest because staphylococci isolated from AD skin lesions predominantly secrete one of these three exotoxins. These findings suggest the possibility that local production of SEs at the skin surface could cause IgE-mediated histamine release and thereby trigger the itch–scratch cycle that can exacerbate AD.

IMMUNOLOGIC FINDINGS IN ATOPIC DERMATITIS

A number of observations suggest an underlying immunoregulatory abnormality in AD (Table 87-2). Studies of T-cell clones support the concept that activation of a subpopulation of helper cells leads to the release of cytokines important in the pathogenesis of AD. In mice, two types of CD4+ T-cell clones have been

described, based on their pattern of cytokine secretion. T-helper type 1 (Th1) cells secrete IL-2 and interferon (IFN)-γ, but not IL-4 or IL-5. In contrast, Th2 cells produce IL-4, IL-5, and IL-13, but not IFN-γ. IL-4 and IL-13 act as IgE isotype-specific switch factors, and induce the expression of VCAM-1, an adhesion molecule involved in the migration of mononuclear cells and eosinophils into sites of tissue inflammation. IL-5 promotes the differentiation, vascular endothelial adhesion, and survival of eosinophils and also enhances histamine release from basophils. In contrast, IFN-γ inhibits IgE synthesis as well as the proliferation of Th2 cells.

The lack of IFN-γ production, as well as the concomitant activation of IL-4, IL-5, and IL-13 is thought to play a critical role in the pathogenesis of AD (Fig. 87-1). In support of the concept that this profile of cytokines arises from the selective activation of Th2, as compared to Th1, cells are a number of studies demonstrating increased frequency of allergen-specific T-cells producing increased IL-4 and IL-5, but little IFN-γ in the peripheral blood and skin lesions of patients with AD. IL-4 inhibits IFN-γ production and downregulates the differentiation of Th1 cells. In addition, atopic monocytes have been found to have elevated cAMP phosphodiesterase and secrete increased levels of IL-10 and prostaglandin E_2. Both IL-10 and PGE_2 inhibit IFN-γ production and may therefore contribute to the decreased IFN-γ production by AD PBMC.

IMMUNOHISTOLOGY OF ATOPIC DERMATITIS

IMMUNOHISTOLOGIC FINDINGS   The histologic features of AD depend on the acuity and therefore the duration of the skin lesion. Uninvolved or clinically normal skin of AD patients is histologically abnormal and demonstrates mild hyperkeratosis, epidermal hyperplasia, and a sparse dermal cellular infiltrate consisting primarily of T lymphocytes. Acute lesions are characterized by marked intercellular edema (spongiosis) of the epidermis, and intracellular edema noted as ballooning of the keratinocytes. A sparse epidermal infiltrate consisting primarily of T lymphocytes is frequently observed. In the dermis, there is a marked perivenular inflammatory-cell infiltrate consisting predominantly of lymphocytes, and occasional monocyte-macrophages. Eosinophils, basophils, and neutrophils are rarely present in the acute lesion. In chronic lichenified lesions, the epidermis is hyperplastic with elongation of the rete ridges, prominent hyperkeratosis, and minimal spongiosis. Increased numbers of Langerhans cells are present in the epidermis, and macrophages dominate the dermal mononuclear cell infiltrate. The number of mast cells are increased in number but are generally fully granulated. Endothelial cells of the superficial venular plexus and deep venules are hypertrophied with enlarged nuclei and prominent nucleoli.

PATTERNS OF CYTOKINE EXPRESSION IN AD SKIN LESIONS The pattern of cytokines expressed locally play a critical role in modulating the nature of tissue inflammation. Therefore, an analysis of cytokine expression in AD is critically dependent on the acuity or duration of the skin lesion. The *in situ* hybridization (ISH) technique has been used to investigate the expression of IL-4, IL-5, and IFN-γ messenger RNA (mRNA) in skin biopsies from clinically normal (uninvolved), acute (erythematous AD lesions of <3 days' duration), and chronic (>2 weeks' duration) skin lesions of patients with AD. As compared with normal control skin, uninvolved skin of patients with AD had a significant increase in number of cells expressing IL-4, but not IL-5 or IFN-γ, mRNA. Acute and chronic skin lesions, when compared to normal skin or uninvolved skin of AD patients, had significantly greater numbers of cells that were positive for mRNA for IL-4 and IL-5. However, neither acute AD or uninvolved AD skin contained significant numbers of IFN-γ mRNA-expressing cells.

As compared with acute AD, chronic AD skin lesions had significantly fewer IL-4 mRNA-expressing cells, but significantly greater IL-5 mRNA-expressing cells. T-cells constituted the majority of IL-5–expressing cells in acute and chronic AD lesions. Chronic lesions also expressed significantly greater numbers of

activated IL-5 mRNA-expressing eosinophils than acute lesions. These data indicate that although cells in acute and chronic AD lesions are associated with increased activation of IL-4 and IL-5 genes, acute skin inflammation in AD is associated with a predominance of IL-4 expression, whereas maintenance of chronic inflammation is predominantly associated with increased IL-5 expression and eosinophil infiltration. In addition, chronic AD lesions are associated with overexpression of GM-CSF and IL-10 expression.

MULTIFUNCTIONAL ROLE OF IgE IN AD SKIN INFLAMMATION

Although the histologic features of AD closely resembles a type IV delayed-type hypersensitivity (DTH) reaction, several lines of evidence indicate that AD is not a conventional DTH reaction, and furthermore that IgE-mediated mechanisms play a role in the pathogenesis of AD. T cells that infiltrate into conventional DTH skin reactions (e.g., tuberculin skin reactions) secrete IFN-γ and therefore induce the expression of HLA-DR on skin keratinocytes. In contrast, keratinocytes in the AD skin lesion do not express HLA-DR. More direct evidence that the T cells in skin lesions of AD differ from the Th1 cells in conventional DTH has

come from studies demonstrating increased IL-4 and IL-5, but not IFN-γ, mRNA expression in acute AD skin lesions. Furthermore, Th2 cells have been found to be just as effective in inducing skin inflammation as Th1 cells. However, the mediation of skin inflammation by Th2 cells is IL-4, but not IFN-γ, dependent. Taken together, these data suggest that two histologically indistinguishable cutaneous DTH reactions exist: The first is mediated by IFN-γ–secreting Th1 cells found in conventional DTH reactions. The second is mediated by IL-4– and IL-5–secreting Th2 cells and involves allergen-induced, cell-mediated reactions.

There are several mechanisms by which IgE molecules can contribute to the induction of a mononuclear cell infiltrate. In this regard, clinically significant allergen-induced reactions are associated with an IgE-dependent biphasic response. In such reactions, following exposure to allergen, mast cells bearing IgE directed to the relevant allergen release various mediators and cytokines into local tissue within 15–60 min of allergen challenge. This immediate reaction likely contributes to the acute pruritus and erythema observed after exposure of AD patients to relevant food and inhalant allergens.

Several hours after this immediate reaction begins to subside, there is onset of an IgE-dependent late-phase reaction (LPR) characterized initially by expression of leukocyte adhesion molecules on postcapillary venular endothelium, followed by the infiltration of eosinophils, neutrophils and mononuclear cells into the inflamed area. Granulocytes reach their maximum cell accumulation at 6–8 h, and by 24–48 h after onset of the reaction, the cellular infiltrate consists predominantly of mononuclear cells. Using ISH, Kay and coworkers have reported that the cellular infiltrate in allergen-induced late-phase skin reactions express increased mRNA for IL-3, IL-4, IL-5, and granulocyte-macrophage colony-stimulating factor but no mRNA for IFN-γ. These results suggest that the T cells infiltrating into the allergen-induced LPR, similar to allergen-specific T cells grown from AD skin lesions, are Th2-like cells.

Langerhans cells and macrophages infiltrating into the AD skin lesion bear IgE antibody. Binding of IgE to Langerhans cells occurs via both high-affinity and low-affinity IgE (CD23) receptors. Macrophages can express CD23 in response to IL-4. Allergens have been demonstrated to activate IgE-bearing macrophages in an IgE-dependent manner with the formation of leukotrienes, PAF, IL-1, and TNF. The activation of IgE-bearing Langerhans cells and macrophages by allergens could thus contribute to the skin inflammation associated with AD.

There is also mounting evidence that IgE-bearing Langerhans cells in AD skin play an important role in cutaneous allergen presentation to Th2 cells. Of note, IgE-bearing Langerhans cells from AD skin lesions, but not Langerhans cells that lack surface IgE, are capable of presenting house-dust-mite allergen to T cells. These results suggest that cell-bound IgE on Langerhans cells facilitate binding of allergens to Langerhans cells prior to their processing and antigen presentation.

Although allergen challenges and experimental models suggest the participation of specific mechanisms of inflammation, it should be emphasized that an analysis of the AD skin lesion does not allow simple classification discretely into an IgE-mediated LPR or a T-cell–mediated immune reaction. Thus, in all likelihood, the mononuclear cell infiltrate in the AD skin lesion reflects a combination of both IgE-dependent mast cell/basophil degranulation and Th2-cell–mediated responses elicited during acute exposures to allergen and other antigens or superantigens.

Finally, although the release of a variety of mediators, e.g., histamine and proteases into the skin following challenge by allergens trigger acute pruritus in AD, clinical studies suggest that the actual development of eczematoid skin rashes is dependent on the skin trauma inflicted by scratching. Once the itch–scratch cycle is triggered, the mechanisms by which scratching promotes inflammation of the skin is suggested by a number of recent observations demonstrating the keratinocyte is an important epidermal source of cytokines including IL-1, IL-6, IL-8, GM-CSF, and TNF-α. In this regard, any injury including mechanical trauma to the keratinocyte will result in the release of cytokines that can induce inflammation through a number of actions. This includes the release of IL-1, TNF-α, and IL-4, which are critical cytokines in the induction of adhesion molecules, such as ELAM-1, ICAM-1, and VCAM-1 that attract lymphocytes, macrophages, and eosinophils into cutaneous sites of inflammation. At this stage, a wide variety of resident and infiltrating cells are then capable of secreting cytokines and mediators that sustain the inflammation. AD therefore results from a combination of specific and nonspecific cellular mechanisms that serve to trigger and maintain skin inflammation.

TARGETING OF Th2-LIKE CELL RESPONSE IN ATOPIC SKIN

Taken together, AD and asthma are both associated with the local infiltration of Th2-like cells, allergen sensitization, the development of chronic local tissue inflammation and the presence of organ-specific (cutaneous vs bronchial) hyperreactivity that may be caused by underlying tissue inflammation. The potential mechanisms that determine tissue specificity of Th2 cell responses in different allergic diseases are therefore of interest. In this regard, studies in experimental animal models have demonstrated heterogeneity in the ability of memory T cells to migrate to mucosal vs nonmucosal tissues. This tissue-selective homing is regulated in large part at the level of T-lymphocyte recognition of vascular endothelial cells (EC) via the interaction of differentially expressed T-lymphocyte homing receptors (HR) and their EC ligands. In humans, lymphocyte/EC adhesion molecule pairs thought to participate in tissue-selective lymphocyte homing include the skin-selective HR, cutaneous lymphoid antigen (CLA), and peripheral lymph node HR, L-selectin.

It has been found that T cells migrating into the skin are highly enriched for the CLA-expressing memory T-cell subset, whereas memory T cells isolated from the airways of asthmatics are predominantly CLA negative. Thus, the propensity of a given individual to develop AD as opposed to asthma may depend on differences in the skin- vs lung-seeking behavior of their memory/effector T cells. Children with food-induced AD provide an opportunity for determining whether there is a relationship between the tissue specificity of a clinical reaction to an allergen and the expression of HR on T cells activated in vitro by the relevant allergen. In this regard, a recent study assessed the expression of CLA and L-selectin on peripheral blood T cells from patients with AD and milk-induced eczema, and compared their HR expression, following stimulation with casein to T cells collected from patients with allergic eosinophilic gastroenteritis, milk-induced enterocolitis, or nonatopic healthy controls. The casein-reactive T cells from patients with milk-induced eczema displayed significantly higher levels of CLA than *Candida albicans*-reactive T cells from the same patients, and either casein- or *C. albicans*-reactive T cells from nonatopic controls or noneczematous atopic patients.

Further evidence for the relationship between CLA and cutaneous T-cell responses in AD has been provided by Babi et al. These investigators analyzed the CLA phenotype of circulating memory T cells in AD vs asthmatic patients who were sensitized with house dust mite. When peripheral blood CLA$^+$CD3$^+$CD45RO$^+$ T cells were separated from CLA$^-$CD3$^+$CD45RO$^+$ T cells, the mite-specific T-cell proliferation response in patients with AD sensitized to dust mite was localized to CLA$^+$ T cells. In contrast, mite-sensitive asthmatics had strong mite-dependent proliferation responses in their CLA$^-$ T-cell subset. The link between CLA expression and skin disease-associated T-cell effector function in AD was demonstrated by the observation that freshly isolated circulating CLA$^+$ T cells in AD patients, but not normal controls, selectively demonstrated spontaneous production of IL-4, but not IFN-γ. These observations strongly support the concept that, in human allergic diseases, immunologic mechanisms exist to target memory Th2 cells to specific organs.

GENETICS OF ATOPIC DERMATITIS AND ATOPY

When the classic studies of Cooke and Van der Veer in 1916 first introduced the concept of allergic sensitization, familial predisposition was considered an important component of these conditions. However, atopy and allergic disorders such as AD are complex genetic diseases that do not follow simple Mendelian inheritance patterns. For atopy and AD, the challenges involved in understanding their genetics include the difficulty of dissecting out the roles of many genes, each with variable degrees of involvement in any given individual. Genetic studies have been difficult because identification of atopic individuals is also confounded by the role of environmental influences. In this regard, atopic, genetically at-risk individuals do not necessarily develop an allergic disease nor are people with allergic disease always carriers of any given disease gene. Nevertheless, there has been considerable progress made in identifying potential genes involved in the inheritance of atopy.

GENETIC STUDIES OF ATOPIC DERMATITIS   A familial predisposition to AD as a manifestation of atopy is well-established. Among subjects with AD, 50–67% have a history of either one or both parents having an atopic disorder and the risk of a child developing AD is 25–30% with a history of a single parent with atopy and 50–75% with a dual history. In addition to an inherited predisposition to AD mediated through atopy, additional genetic factors may specifically predispose to the development of dermatitis. An extensive study of allergy in families in Switzerland confirmed that bronchial asthma, allergic rhinitis, and AD were genetically linked. However, the history of respiratory atopic diseases in relatives of probands with AD was significantly lower than that observed for probands with asthma or allergic rhinitis.

Twin studies are a useful means to assess the presence of a genetic contribution in complex genetic diseases in which there are contributions from both genetic and environmental influences. Twins, whether monozygotic (MZ) or dizygotic (DZ), if raised in the same household, share much of the same environmental influences. However, whereas MZ twins have identical genomes, DZ twins on average have only half their chromosomes in common. Thus a higher concordance rate of a given condition in MZ twins provides evidence for the presence of genetic influences. These data provide the information to produce a heritability estimate, an estimate of the relative contributions to a given condition provided by genetic as opposed to environmental factors. The most extensive investigation of twins for AD was the Swedish Twin Study, which identified a concordance rate of AD of 15% in MZ and 5% for DZ twin pairs. Studies of AD in Danish twins found much higher concordance rates for AD but also confirmed a higher rate in MZ (77%) than DZ twins (15%). These authors concluded that genetic factors play a decisive role in the development of AD.

GENETICS OF IgE   Genetic studies of AD have been problematic because of variable diagnostic criteria among different studies. The identification of IgE and establishment of its role as the basis for allergic sensitization has provided an improved basis for performing genetic studies of atopy. Both the ability to accurately quantify total IgE and to identify the presence of specific IgE toward a given allergen by either skin testing or serum immunoassays have become objective means for phenotyping atopic subjects.

Twin studies of elevated serum IgE performed by Hopp and Townley in 61 monozygotic twin pairs and 46 dizygotic pairs revealed a heritability estimate of 0.61. Several additional studies have placed the heritability index of serum IgE in at 0.60–0.70. These twin studies unambiguously establish a genetic component to the inheritance of elevated serum IgE. Several additional studies have used segregational analysis to attempt to identify the mechanism for this inheritance. Cookson and Hopkin studied the familial occurrence of elevated IgE in 239 members of 43 families recruited by the presence of an asthmatic proband. Ninety percent of the atopic children had one or more atopic parents. These authors concluded that the high IgE phenotype appeared to be inherited as an autosomal-dominant trait with a variable clinical expression. In contrast, Meyers and Marsh studied the inheritance pattern of total serum IgE and concluded that there was evidence for a major IgE-regulating gene that is inherited via an autosomal-recessive model, but confounded with other familial and polygenetic factors. Their studies demonstrated evidence of this major IgE-regulating gene effect only in some families. Parks et al. studied serum IgE levels from 42 families based on an asthmatic proband and determined that a polygenic heritability model best explained the data. These conflicting results are consistent with either an autosomal recessive gene acting in combination with a polygenic component or, alternatively, the presence of a single major gene that is only operative in some families or ethnic groups, but not in others. Thus, even though it provides a more objective basis for phenotyping subjects, the use of total IgE data in segregational analyses has failed to produce unambiguous conclusions regarding its mechanism of inheritance. This confusion results primarily from the impossibility of controlling for environmental factors that influence serum IgE levels.

LESSONS FROM THE GENETICS OF ASTHMA AND BRONCHIAL HYPERREACTIVITY   Similar to the results observed with AD and IgE, genetic studies of asthma have produced conflicting results. As with AD, this also reflects variable diagnostic criteria and the lack of a definitive biochemical or laboratory marker. Edfors-Lubs reviewed nearly 7000 twins in the Swedish Twin Study and reported a diagnosis of asthma in 3.8% of the study population. The concordance rate for asthma was 19% in monozygotic twins and only 4% in dizygotic twins. Most investigators have found higher concordance rates for asthma in twins. Falliers et al. reviewed the literature and reported 30–80% concordance rates for asthma in monozygotic twins and 4–45% in dizygotic twins. As with the IgE studies, these data support a hereditary component in the development of asthma.

More importantly, several studies have now addressed the question of whether asthma is inherited in part separately from atopy. Sibbald recruited asthmatic individuals and investigated the presence of asthma and positive skin tests in the nuclear family. They reported that asthma was more frequent in parents (13%), offspring (9%), and siblings (8%) of the asthmatic probands and there were no significant differences whether or not the subjects were allergic (extrinsic) asthmatics or nonallergic (intrinsic) asthmatics. As would be expected, the prevalence of atopic disorders in general (asthma, allergic rhinitis, or atopic eczema) were higher in the relatives of extrinsic than intrinsic asthmatics. They concluded that asthma and atopy are inherited independently and that the presence of atopy enhances the likelihood of asthma being expressed.

Other studies have investigated the genetics of bronchial hyperreactivity (BHR). Longo et al. performed familial analyses of BHR and documented increased occurrence of BHR in the parents of asthmatic probands. Konig and Godfrey studied exercise challenge and skin-test responses in the nuclear families of 12 children with asthma. A positive exercise challenge developed in 43% of family members and 45% of subjects with at least one positive skin test responded positively. Townley and coworkers found increased BHR in 47 nuclear families of patients with asthma when compared with 26 families with no asthma or family history. Subjects without a personal history of asthma, but from families with a history of asthma, showed bimodal distributions in their BHR, whereas control subjects from families without a history of asthma or allergy had a single uniform distribution. A bimodal distribution was also found in the nonasthmatic parents of asthmatic children. All of these observations supported an inherited component to BHR unrelated to atopy. The segregational analyses of Townley's group supported a genetic component of BHR, but not by a single gene. The consensus of these investigations, however, suggests that in addition to a general susceptibility to the atopic diseases, there may also be a separate inherited tendency to develop asthma. Unfortunately, easily reproductive objective measures of cutaneous hyperreactivity do not exist, but given the parallels between asthma and AD the possibility that cutaneous hyperreactivity may be genetically transmitted in AD must be considered as well.

POSITIONAL CLONING STUDIES OF ATOPIC DISORDERS With diseases such as the atopic disorders for which the responsible gene is unknown, the approach to identifying disease-causing genes frequently utilizes positional cloning. This technique is based on the presence of highly polymorphic markers whose location on the human genome have been mapped. Markers located close to the disease-causing gene will link to the disease when multiple kindreds are analyzed. The frequency of crossover events permits estimation of the distance between the genome marker and the disease gene. Identification of a closely linked marker is followed by "chromosomal walking" until the mutant gene is identified. In the atopic disorders with their variable expression, polygenic inheritance, and the challenges of unambiguously phenotyping subjects, such an approach will be particularly challenging. In addition to all of these previously discussed difficulties that will confound attempts at positional-based cloning, a final challenge is derived from the high frequency of these disorders. This results in the incumbent danger that even though one parent may not be atopic or have an atopic disorder they could still be the carrier of the relevant disease gene.

Despite these difficulties, investigators have utilized positional cloning technology to define the genetic basis for atopy. Cookson and colleagues defined atopic individuals through the presence of either having allergen-specific IgE or a high total serum IgE. Their initial studies of 40 nuclear and 3 extended families was consistent with an autosomal dominant inheritance. Segregational analysis of 7 extended families showed a linkage to the chromosome 11q marker D11S97 and produced a maximal lod score of 5.58. Subsequently, additional studies of 64 families and sib-pair analysis on 743 subjects confirmed this linkage. Analysis of 11q demonstrated that this marker mapped close to the gene for the β chain of the high-affinity IgE receptor. These investigators were able to link atopy to 3 specific amino acid substitutions within the fourth transmembrane hydrophic domain of the β chain. The function of the β chain remains unclear insofar as the α and γ chains are sufficient for transducing activating signals and it is not obvious how the three conservative amino acid substitutions they describe may alter signal transduction. However, it is possible that hydrophobic interactions between transmembrane domains may be critical for proper assembly of the IgE receptor and that, although not necessary for triggering histamine release, the β chain may modulate different signaling pathways. Modulation of cytokine production by a base substitution would be consisting with the biological activity of an asthma gene. Unfortunately, several reports have been unable to confirm these data, although two other groups have confirmed a linkage to this locus The basis for these conflicting results is unclear, except to argue that the development of atopy is a complex genetic process with possibly many genes and pathways leading to the development of the clinical phenotype.

CANDIDATE ATOPIC GENES Because of the difficulties inherent in positional-based cloning strategies, many investigators have opted for an approach based on performing linkage analysis with several specific candidate genes. The basis for this approach is to argue that the genes that cause the atopic disorders are, in fact, known. Specifically, certain proteins may be either abnormally regulated or otherwise function inappropriately to produce atopy and the allergic diseases. These candidate genes include cytokine genes such as *IFN-γ* and *IL-12*, cytokine-receptor genes, the ε heavy-chain gene, the low-affinity receptor for *IgE (FceRII)*, *CD40* and its ligand, and numerous other genes. Additional genes, such as those responsible for increased PGE_2 production and *cyclic AMP-phosphodiesterase* activities are candidate genes more specific for AD. Similarly both the *IL-10* gene and gene(s) controlling its expression may contribute to the diminished cellular immune responses characteristic of this disorder. However, this review will focus on studies of the major histocompatibility complex (MHC) and the cytokine gene complex on chromosome 5.

Linkages have been proposed between MHC class I and class II antigens and both the presence of atopic disease and the specificity of allergen responses. MHC class II alleles are responsible for mediating the genetic component of immune responsiveness to specific antigenic epitopes. Whereas specific MHC alleles have been proposed to link to atopic phenotype, such a linkage has not been well-established. With what is known about the function of the MHC molecules, there is no obvious biochemical basis for the MHC to regulate development of either atopy or an atopic disease. Linkages to MHC are at best likely only to explain a heritable basis for the specific immune response to a given allergenic epitope. Linkages of immune responsiveness to Amb a V and the ryegrass

antigens Lol p I and II have been linked to specific *MHC* loci. However, a clinically important role for *MHC* loci in regulating even specific immune responses to allergens is unlikely given the degeneracy of the binding of allergenic epitopes to class II antigens. Thus, both clinical observations and twin studies on the presence of IgE to specific allergens are more consistent with environmental influences (i.e., presence and concentration of antigen) than by genetic factors.

Several other genes have proved to be better candidates for inducing atopy and allergic diseases. These include numerous genes that regulate IgE production, eosinophilia, and mast-cell proliferation. A surprising number of these genes are clustered on the long arm of chromosome 5, between 5q22 and 5q31. This cluster includes the genes for *ILs-3, -4, -5, -9, -13,* and *GM-CSF*. *IL-4* and *IL-13* are responsible for initiation of ε germline transcription, which in combination with signals generated by CD40 acting through the CD40 ligand leads to the IgE isotype switch. IL-5 is an eosinophilopoietin and is an activating factor for mature eosinophils. Additional factors contributing to eosinophil activation and survival are GM-CSF and IL-3. Proliferation and increased releasability of mast cells is a characteristic feature of atopic diseases and represents a T-cell–dependent process. Within this cluster, both IL-3 and IL-9 function as mast cell growth and differentiating factors, whereas IL-3 also enhances histamine release. Of these genes *IL-4, IL-13,* and *IL-5*, as well as *IL-3* and *GM-CSF* are particularly tightly linked, separated by only approximately 300 kbp.

To some extent, these genes are under shared regulatory control. Thus, GM-CSF, IL-3, IL-4, and IL-5 have all been identified at the sites of allergic reactions. The transcriptional dysregulation of these cytokines may be the basis for the atopic state. Thus, when T-lymphocyte clones are generated towards the dust mite allergen, the clones from atopic donors are characterized by the transcriptional activation of IL-4, whereas those obtained from nonatopic donors are characterized by IFN-γ and IL-2, but not IL4. That genes in close proximity may be coregulated has been observed for several other gene clusters such as has been described for the IL-1 gene cluster (*IL-1a, IL-1b,* and *IL-1ra*) and the *MHC complex*. Such coregulation does not preclude the possibility that under appropriate conditions one or more genes may be transcribed nonsynchronously.

It has therefore been proposed that regulatory elements associated with these genes may be responsible for inducing the atopic state, that these elements may be linked to specific chromosomal markers, and, therefore, that the genetic predisposition to atopy can be identified by the presence of these markers. Two groups have now reported their results utilizing linkage analyses of polymorphisms present on chromosome 5q to asthma or elevated serum IgE. Marsh et al. analyzed 170 individuals from 11 extended Amish families by sib-pair analysis. Utilizing a series of markers within the region 5q31.1 these authors found evidence for genetic linkages to high IgE phenotype for five markers within a narrow region (1.4 cM) of 5q31.1. No linkage was found to specific IgE. Similar results were obtained by Bleeckers' group in a study of 92 nuclear families from northern Holland. Via sib-pair analyses these investigators demonstrated highly significant linkages to both total IgE and to bronchial hyperreactivity with three markers within the chromosome 5q31.1 cytokine gene cluster. In summary, although much work remains to elucidate the genetics of atopic diseases such as AD and asthma, several potential genes have been identified and this is likely to be an exciting area of investigation in the future.

MANAGEMENT OF AD

Current treatment of AD is directed at symptom relief and reduction of cutaneous inflammation and the reduction of exacerbating factors are critical for effective management. Factors that must be considered and eliminated include irritants, allergens, and emotional stresses. Systemic antimicrobial therapy, particular antistaphylococcal antibiotics, is often necessary because AD skin has enhanced binding properties for *S. aureus* and, because of the frequent scratching, becomes secondarily infected. Maintenance of daily skin care with hydration of the skin and appropriate use of topical steroids to reduce skin inflammation is critical. Therapy must be individualized and is dependent on whether the patient is experiencing an acute flare or dealing with the management of chronic AD.

For patients who are poorly controlled on conventional therapy, alternative therapies should be considered. Ultraviolet light therapy may be a useful adjunctive therapeutic modality. Under professional supervision, UVB can be effective and has been found to have antiinflammatory effects in part because of its ability to inhibit lymphocyte trafficking and antigen-processing. Photochemotherapy with oral psoralen therapy followed by UVA (PUVA) may also be helpful in patients with severe disease. However, PUVA is reserved for patients with more recalcitrant disease because of the expense, and the potential increased risk of skin cancer.

Since patients with AD manifest abnormalities in immune regulation, therapy directed toward correction of their immune dysfunction represents an alternative approach. In this regard, therapeutic trials using several experimental immunomodulators or immunosuppressive agents have been reported. IFN-γ, a cytokine that downregulates Th2-cell function, has been found in placebo-controlled trials to reduce clinical severity associated with AD and decrease total circulating eosinophil counts. Cyclosporine, a drug that downregulates cytokine production, has also been reported in double-blind, placebo-controlled trials to cause a significant improvement in AD. Cyclosporine therapy did, however, lead to mild renal and liver toxicity. Thus, the side effects associated with prolonged systemic cyclosporine therapy make it an unlikely candidate for chronic treatment of AD. Of note, FK506, an analog of cyclosporine, has recently been used topically in clinical trials and found to be efficacious with no significant side effects. In addition, the new high-potency phosphodiesterase inhibitors may be useful in targeting the increased PDE activity in atopic monocytes and have demonstrated promising preliminary clinical results.

FUTURE DIRECTIONS

The current review has attempted to highlight several important advances in our understanding of the immunopathogenesis of AD. These include the observation that IgE has a multifunctional role in the pathogenesis of allergic inflammation. Aside from its involvement in IgE-mediated degranulation of mast cells/basophils, it is also involved in the activation of macrophage/monocytes and the stimulation of Th2 cells. Many of the critical cytokines involved in the pathogenesis of AD and the potentially important mechanisms by which inflammation occurs at the sites of allergic responses have now been identified. These important

new advances will allow scientists in the future to target certain candidate genes to determine whether their abnormal regulation or altered function contributes to the molecular basis of atopy. Elucidation of the key genes involved in atopy is likely to provide new methods for classifying atopic diseases, particularly with respect to diagnosis, disease severity, and possibly response to therapy. Considering the complexity of multiple genes involved in atopy it is difficult to envision the use of gene therapy in the foreseeable future.

Novel immunologic therapies for chronic allergic diseases are likely to include the modulation of Th2 cells and their cytokines targeting specific organs. Recent studies with experimental immunomodulatory and immunosuppressive agents are promising and serve as proof of the concept that therapies that downregulate T-cell function and cytokine secretion are effective in reducing the clinical severity of AD. As our understanding of the immunopathogenesis of allergic responses continues to grow, manipulation of the immune response in AD and other allergic diseases is likely to become an exciting new direction in the treatment of this fascinating group of illnesses.

88 Pemphigus Foliaceus and Pemphigus Vulgaris

JANET A. FAIRLEY, XIANG DING, GEORGE J. GIUDICE, AND LUIS A. DIAZ

BACKGROUND

Pemphigus is a group of autoimmune disorders characterized by spontaneous intraepidermal blisters and epidermal-specific autoantibodies. Blister formation occurs by the histologically distinctive loss of epidermal cell–cell adhesion, termed acantholysis. The two major forms of the disease are pemphigus vulgaris (PV) and pemphigus foliaceus (PF). In PV, the epidermal-cell separation occurs just above the basal layer of the epidermis, whereas, in PF, the cell separation occurs at the more superficial level of the granular-cell layer of the epidermis. Although PV and PF are diseases described all over the world, there is an endemic form of PF that has been observed in Brazil since the turn of the century and recently in Colombia. This endemic form of PF is also known as "fogo selvagem" (FS; wild fire). Prior to the advent of immunosuppressive therapy, the mortality caused by these disorders was extremely high.

The histological hallmark of PV and PF, epidermal-cell detachment, has been known since the early 1940s. However it was not until the mid-1960s that a new insight into the pathogenesis of these disorders was gained with the discovery of PV and PF antiepidermal autoantibodies. The following years confirmed the diagnostic value of these autoantibodies and also brought convincing experimental data linking the epidermal-cell detachment seen in these patients with binding of antiepidermal autoantibodies to their target antigens. The true autoimmune nature of PV and PF was tested experimentally, addressing both the autoantibody side as well as the autoantigen side of the reaction. The autoantibody titers in patients were found to correlate well with disease activity and currently are used to follow the therapeutic response of these patients. It was also documented that neonates born to PV mothers presented a blistering disease probably caused by transplacental passage of maternal autoantibodies. These clinical observations suggested a pathogenic role for PV autoantibodies. Experimentally, it was found that the IgG fractions from PV and PF sera promoted cell detachment in primary epidermal-cell cultures and in organ cultures of human skin. In the early 1980s, other studies convincingly demonstrated that PV and PF autoantibodies were indeed pathogenic. In these experiments intraperitoneal injections of the IgG fraction of PV and PF sera were shown to induce intraepidermal blisters in neonatal mice. The injected animals duplicated the key clinical and histological features of the human diseases.

The search for epidermal antigens recognized by PV and PF autoantibodies lead to the characterization of those molecules as components of the desmosome. It had previously been established that desmosomes contain transmembrane glycoproteins and plaque proteins. The desmosomal glycoproteins were characterized as desmoglein 1 (Dsg1, 165 kDa), desmoglein 2 (identified in colonic epithelium), desmoglein 3 (Dsg3, 130 kDa mol wt), and the desmocollins. Furthermore, it is currently accepted that these glycoproteins are members of the cadherin family of cell adhesion molecules. PV and PF autoantibodies recognized calcium-dependent conformational epitopes on the extracellular domain of Dsg3 and Dsg1, respectively (Fig. 88-1).

Finally, PF, and less commonly PV, may also be triggered by medications, most commonly penicillamine. However, captopril, penicillin, ampicillin, and rifampin have also been associated with pemphigus-like eruptions. A paraneoplastic form of pemphigus has been recently reported associated in a great number of cases with underlying lymphoproliferative disorders. The autoantibody response in these patients is complex and directed against desmosomal and hemidesmosomal antigens.

CLINICAL FEATURES

PV is the most common form of pemphigus in the United States and is characterized by the spontaneous development of blisters arising on normal appearing skin (Fig. 88-2A). The lesions are typically flaccid bullae that rupture easily, producing denuded areas of skin and erosions that are slow to heal. The disease usually begins in the oral mucosa, where, because of the fragility of the blisters, the predominant lesions are erosions. Though the oral mucosa is the most common site of involvement, the disease may affect other squamous epithelium including the esophagus, conjunctiva, larynx, vagina, urethra, cervix, and rectum. The disease may remain localized to the mucosae, but generally progresses over a period of months to involve the glabrous skin. The onset of disease is most commonly between the fourth and sixth decade of life, however any age group may be affected.

PF has a different clinical appearance than PV, exhibiting superficial vesicles that rupture easily, producing erosions and crusting (Fig. 88-3A). The skin lesions in PF appear most commonly on the head and neck regions. In chronic cases, these excori-
Figure 88-1   Schematic of Dsg1 and Dsg3. Dsg1 and Dsg3 are both transmembrane proteins with an intracellular, extracellular domain, and a single transmembrane domain. The extracellular domains of both Dsg1 and Dsg3 contain four cadherins repeats (EC1-4). Within the cadherin repeats, the black bars represent calcium-binding sites, and the RAL is the putative cell–cell recognition site.
Figure 88-2   Clinical, histologic, and immunologic features of PV. PV patients typically have flaccid blisters and erosions that can become widespread **(A)**. Histologically, biopsies of PV show suprabasilar acantholysis, with the retention of the basal cells on the dermis **(B)**. Patients have both tissues-bound and circulating autoantibodies directed against the cell surface of the keratinocyte. **(C)** The results of indirect IF performed with PV serum using monkey esophagus as a substrate.

ated lesions may become more hyperkeratotic, verrucous, or vegetating plaques. In other cases, the disease may progress to an exfoliative erythroderm. In contrast to PV, the mucous membranes are spared. The clinical, immunological and histologic features of endemic PF are identical to sporadic nonendemic PF.

DIAGNOSIS

The diagnosis of pemphigus is based on clinical, histologic, and immunologic criteria. Biopsies from the lesional skin of patients with PV reveals intraepidermal vesicles occurring just above the basal-cell layer. Basal keratinocytes remain attached to
Figure 88-3 Clinical, histologic, and immunologic features of PF. This patient with endemic PF has widespread erosions and crusting on the head and neck **(A)**. A skin biopsy specimen shows an intraepidermal vesicle occurring in the granular-cell layer **(B)**. Indirect IF of this patient's serum shows ICS staining, using human skin as a substrate **(C)**.

the dermis, producing the histological "tombstone" sign (Fig. 88-2B). The dermis may show edema and inflammation with the presence of eosinophils in early lesions, and plasma cells in older lesions. The histology of PF also shows intraepidermal vesicles, but occurring high in the epidermis, within or just below the granular-cell layer (Fig. 88-3B). Older lesions of PF may also show hyperkeratosis and thickening of the epidermis.

Immunofluorescence (IF) studies are extremely helpful in confirming the diagnosis of pemphigus. Direct IF, performed on perilesional biopsies shows typical deposition of IgG and/or C3 in the epidermal intercellular spaces (ICS) in 100% of patients with active disease. Indirect IF studies of patients' sera demonstrate circulating autoantibodies that produce an ICS staining pattern on stratified squamous epithelial substrates. Indirect IF tests yield positive results in 80–90% of patients with active disease. Though occasionally PF autoantibodies may bind preferentially to the upper layers of the epidermis, and PV autoantibodies more suprabasilarly, in general the two disorders cannot be differentiated on the basis of indirect or direct IF (Figs. 88-2C and 88-3C). In the majority of patients, the serum autoantibody titers correlate well with extent and disease activity.

Recent advances in the characterization of the antigens recognized by PV and PF autoantibodies have led to the application of other techniques to precisely diagnose these disorders. Immunoblotting and immunoprecipitation have defined the PV antigen as Dsg3, a glycoprotein of 130 kDa and the PF antigen as a 160-kDa glycoprotein, Dsg1. Specialized laboratories can perform immunoblotting and immunoprecipitation (or ELISA) techniques to test patients' sera. A positive result by immunoprecipitation is seen only in PF and PV sera if assayed with recombinant antigens (Dsg3 or Dsg1).

GENETIC BASIS OF DISEASE

Like many other human autoimmune diseases, PV and PF have been associated with certain HLA specificities. Since there is a high frequency of PV cases in the Ashkenazi Jewish background population, the HLA associations have been examined in two groups: Jewish and non-Jewish PV patients. The Jewish group shares the (HLA-B38, SC21, DR4, DQw8) and (HLA-B35, SC31, DR4, Dqw8) extended haplotype, whereas the non-Jewish group share the (HLA Bw55, Drw6, SB45, Dqw5) extended haplotype. These susceptibility alleles are thought to be inherited as a dominant trait in the Jewish group of PV patients. HLA studies have demonstrated that FS is associated with a high frequency of HLA DR1 and/or HLA D4 genes. Moreover, FS patients appear to possess the DRB1*0102 gene as a susceptibility factor (relative risk

[RR] = 7.3, *p* = 0.002) and DQB1*0201 as a gene that confers resistance to FS (RR = 0.04, *p* = 0.006). Recently it has been shown that these alleles are not present in Brazilian Indians affected by FS. Instead, 6 out of 10 Indians of the Xavante tribe with FS shared the HLA DRB1*0404 gene that was present in only 5 out of 74 of the Xavante controls, conferring a RR of 9.6 (*p* = 0.002). These findings have been confirmed recently in other Brazilian Indian tribes. It is interesting to note that the amino acid sequence of residues 67–74 of the third hypervariable region of the DRB1 gene, i.e., LLEQRRAA, is shared by DRB1*0102 (susceptibility gene of non-Indian FS patients) and DRB1*0404, DRB1*1402, and/or DRB1*1406 found with increased frequency in FS patients occurring in Brazilian Indians.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

Following the experimental demonstration that PV and PF autoantibodies are pathogenic in the mouse model system (Figs. 88-4 and 88-5), efforts were concentrated in dissecting the molecular mechanisms leading to acantholysis. It has been well-established that PV and PF autoantibodies induce epidermal-cell detachment in the mouse model independent of complement activation, i.e., C5-deficient strains of mice and neonatal mice depleted of complement by cobra-venom treatment continue to develop extensive blistering disease when passively transfused with PF or PV IgG fractions. Furthermore, in a series of studies we have demonstrated that F(ab')2 and Fab fragments from PF and PV IgG are also pathogenic, suggesting that these autoantibodies may trigger cell detachment by simple binding to their target epitopes on the ectodomain of Dsg1 and Dsg3, respectively. This binding may impair the adhesive function of these molecules. Other potential mechanisms involved in pemphigus acantholysis have been suggested. For example, it has been reported that activation of keratinocyte plasminogen activator (PA) by PV and PF autoantibodies may trigger epidermal-cell detachment. This hypothesis was reinforced by detecting elevated values of PA in epidermal-cell cultures treated with PV or PF IgG. This elevation was abolished by previous treatment of the cultures with dexamethasone, which also abolishes the pathogenic effect of these antibodies. However, this finding could not be reproduced in vivo using the mouse model system. Recently other hypotheses have been put forward, i.e., that PV and PF autoantibodies may bind the keratinocyte surface domain of Dsg1 or Dsg3 and trigger intracellular responses leading to collapse of the cytoskeleton and impairment of cell adhesiveness. These theories need further experimental testing.

Mapping the epitopes recognized by pathogenic PV and PF autoantibodies on Dsg3 and Dsg1 has been hampered by the conformational nature of these regions of the molecules. Furthermore, it appears that the calcium-binding domains of the extracellular regions of Dsg1 and Dsg3 also modulate the optimal recognition and binding of autoantibodies. However the availability of the cDNAs of both desmogleins have opened new approaches to further analyze these conformational epitopes. For example, in recent studies the cDNAs of Dsg1 and Dsg3 have been expressed in the baculovirus system as soluble glycoproteins that are highly immunoreactive with patients' sera. Autoantibodies to Dsg3 have been purified by affinity chromatography from patients' sera utilizing full-length recombinant Dsg3 and shown to be pathogenic in the mouse system. Moreover, preadsorption of patients' sera with recombinant Dsg3 will abrogate the pathogenic effect in the passive-transfer experiments. These studies prove convincingly that
Figure 88-4 Passive-transfer mouse model of PV. Neonatal BALB/c mice injected with purified IgG from PV patient's sera reproduced the clinical (**A**), histologic (**B**), and immunologic features of the disease.

anti-Dsg3 autoantibodies in PV sera are indeed pathogenic and responsible for inducing the lesions in PV patients. Similarly, Dsg1 recombinant protein produced in the baculovirus system has been used to immunoadsorb PF autoantibodies. Like in the PV cases, it has been demonstrated that anti-Dsg1 autoantibodies are pathogenic and responsible for inducing the disease in patients.

Both Dsg1 and Dsg3 share common features with the cadherin family of cell adhesion molecules. Dsg1 and Dsg3 are both transmembrane proteins that have an N-terminal extracellular domain and an intracellular C-terminal domain. The extracellular region contains a series of five repeat domains, termed EC1 to EC5 (Fig. 88-1). The first four of these domains are homologous cadherin repeats. A series of three pairs of calcium-binding sites are also located within these first four extracellular domains. These calcium-binding sites have been hypothesized to be crucial in cell–cell adhesion, and also appear to be important in autoantibody
Figure 88-5 Passive-transfer mouse model of PF. Injection of purified IgG from the serum of a PF patient produces superficial erosions in neonatal BALB/c mice **(A)**. A biopsy shows acantholysis in the granular-cell layer of the epidermis **(B)**.

recognition. A three-amino acid sequence near the amino terminus (RAL) is the putative cell–cell recognition site. The region just outside the transmembrane domain (EC5) shows the greatest divergence between Dsg1 and Dsg3, as a portion of this region is deleted in Dsg1. The importance of the intracellular domain is its function in integrating the desmosomal proteins with the cytoskeleton. Within desmosomes, the 93-kDa desmosomal plaque protein, plakoglobin, is believed to be crucial in linking desmosomes with the cytoskeleton. Plakoglobin is part of both the PV and PF complex, and is believed to directly bind to both Dsg1 and Dsg3.

The genes for both Dsg1 and Dsg3 are located on chromosome 18. *In situ* hybridization and immunofluorescence have been used to localize Dsg1 and Dsg3 in the epidermis. Dsg3 is expressed more strongly in the basal and lower spinous layers of the epidermis, whereas Dsg1 was expressed throughout the epidermis, but appeared to gradually increase during differentiation. This difference in the site of expression of Dsg1 and Dsg3 in the epidermis may help to explain the level at which blistering occurs in PF in comparison to PV.

MANAGEMENT/TREATMENT

Despite the tremendous advances in understanding the molecular pathogenesis of PV and PF, the mainstay of treatment remains corticosteroids and immunosuppressive agents. Prior to immuno-

suppressive therapy, the 5-year mortality of PV approached 100%. The prognosis in PF was slightly better, with a 40–60% mortality rate. In recent years, despite the effective steroid and immunosuppressive therapy, the 5-year mortality remains between 5 and 15%. In mild cases, ultrapotent topical or intralesional steroids may be of value; however, the vast majority of cases will require systemic glucocorticoids. Prednisone is the most commonly used steroid, with an initial dose of approximately 1 mg/kg/d. If no response is seen, this may be increased to 1.5–2 mg/kg/d, not to exceed 100–120 mg/d in our experience. A slow tapering is required to prevent relapse of the disease. Cytotoxic agents, including azathioprine, cyclophosphamide, and methotrexate may be used as the sole therapeutic agents in patients in whom steroids are contraindicated, but more commonly are used in conjunction with prednisone as steroid-sparing agents. The dose of azathioprine and cyclophosphamide is 1–2 mg/kg/d, and 5–15 mg/wk for methotrexate.

Plasmapheresis may be used as a adjunct therapy in patients with refractory disease to cause an acute drop in circulating antibody titers. However, a rebound rise in autoantibody titers will occur if the patient in not concurrently on adequate immunosuppressive therapy. Parenteral gold has been successfully used in the therapy of PV, but because of the incidence of side effects over long-term therapy (dermatitis, nephrotoxicity, blood dyscrasias), its use has been limited. Other drugs occasionally reported to be

effective in pemphigus include cyclosporine, etretinate, and dapsone. Extracorporeal photopheresis has also been recently reported as an alternative therapy for pemphigus, although the results are too preliminary to currently recommend it as a treatment.

Patients undergoing steroid and immunosuppressive therapy must be monitored with a variety of laboratory tests including CBC, liver enzymes, creatinine, urinalysis, and X-rays looking for toxicity, underlying infections, or evidence of osteoporosis. In addition, indirect IF studies of the patient's serum every 6–8 weeks may provide valuable information in monitoring the effectiveness of the patient's therapy.

FUTURE DIRECTIONS

The past 10 years have shown remarkable progress in understanding the pathogenicity of the autoantibodies in PF and PV. Furthermore, the advances in desmosomal biology have furthered our understanding in how antidesmosomal autoantibodies may induce cell detachment in these patients. Furthermore, the availability of full-length recombinant protein for Dsg1 and Dsg3 will allow the dissection of epitopes recognized on these molecules not only by pathogenic autoantibodies by also by T cells from patients. It is expected that within the next few years the cellular mechanisms of autoantibody production in PV and PF will be disclosed. These relevant pathogenic epitopes on Dsg3 and Dsg1 should pave the way for more specific therapies, including induction of immunological tolerance to these molecules. Newer drugs may also be available to modulate the immunopathological events happening at the level of the target cells. Finally the endemic form of PF seen in Brazil might offer the unique opportunity of identifying the etiological agent of PF. This finding could have a major impact in understanding human autoimmunity.

89 Bullous Pemphigoid, Cicatricial Pemphigoid, and Pemphigoid Gestationis

GRANT J. ANHALT AND DIYA F. MUTASIM

BACKGROUND

The term "pemphigoid" applies to several different clinical disorders that share the clinical appearance of blisters, the histologic finding of subepidermal blister, and circulating and skin-bound IgG antibodies against a component of the basement membrane zone (BMZ) (Table 89-1). Extensive skin involvement in the elderly population occasionally leads to significant morbidity. In addition, therapy with systemic corticosteroids and immunosuppressive agents may be associated with significant adverse effects.

CLINICAL FEATURES

The exact incidence of pemphigoid is not known, but it is estimated to be twice that of pemphigus vulgaris (PV). Its incidence in Great Britain is estimated at 1 per 100,000 per year in 1985 and 7.63 per million in France in 1995. There are three closely related pemphigoid diseases, namely bullous pemphigoid (BP), cicatricial (mucosal) pemphigoid (CP), and pemphigoid (herpes) gestationis (HG).

BULLOUS PEMPHIGOID This disease appears to be a phenomenon of the aging immune system, with peak incidence very late in life (Figs. 89-1 and 89-2). There is no known HLA Class II gene that confers susceptibility for the disease. However, in herpes gestationis, there appears to be an HLA Class II-linked susceptibility. Approximately 60–85% of HG patients are HLA-DR3 positive. More strikingly, approximately 45% of women affected with the disease are heterozygote HLA-DR3/DR4.

The disease tends to be generalized with predilection for the lower abdomen, inner thighs, groin, and axillae. The characteristic blisters are pruritic and appear on either normal-appearing or erythematous, urticarial base. When blisters rupture, denuded areas may become crusted and occasionally invaded by bacterial pathogens.

The course and prognosis of BP varies. Most treated patients go into a clinical remission within several months without need for further treatment.

CICATRICIAL PEMPHIGOID This is a relatively rare condition characterized by chronic blistering and scarring of mucosal surfaces covered by stratified squamous epithelium. Involved

organs include the ocular conjunctiva, nasal pharynx, oral pharynx, larynx, upper esophagus, and anogenital mucosa. The marked tendency for scarring in this disorder leads to high morbidity secondary to loss of vision, esophageal strictures, and fibrotic scarring of other mucous membranes.

PEMPHIGOID GESTATIONIS Also known as herpes gestationis (HG), this is a relatively rare disease seen during pregnancy. The disorder often begins in the second or third trimester of pregnancy. It tends to recur in subsequent pregnancies and may be elicited by challenge with oral contraceptives. Lesions tend to involve the abdomen and then spread peripherally. The clinical appearance of the lesions is similar to that of BP.

DIAGNOSIS

HISTOPATHOLOGY Histopathologic examination of an early intact blister reveals a subepidermal blister with a mixed inflammatory infiltrate that is rich in eosinophils. The blister cavity contains serum, fibrin, and inflammatory cells.

DIRECT IMMUNOFLUORESCENCE The ideal substrate for this test is a biopsy of normal-appearing skin adjacent to a lesion (Fig. 89-3). A properly performed test from such a specimen is positive in 100% of BP patients. There is continuous linear deposition of C3 and IgG along the epidermal BMZ. Direct IF in HG and CP is similar to that of BP.

INDIRECT IMMUNOFLUORESCENCE The most commonly used substrate for this test is monkey esophagus. Other stratified squamous epithelia including normal human skin may also be used. Most patients with BP have circulating IgG autoantibodies against the BMZ. These antibodies bind to basement membrane molecules of stratified squamous epithelia.

Indirect IF is usually negative in most patients with HG by the standard methods. The anti-BMZ antibodies can, however, be detected by complement-fixation amplification (HG factor assay) or Western blotting. Approximately 25% of patients with CP have circulating anti-BMZ antibodies as detected by standard indirect IF.

IMMUNOELECTROMICROSCOPY (IEM) Direct IEM reveals the in vivo bound immune deposits (C3 and IgG) to be within the lamina lucida of the BMZ as well as basal-cell hemidesmosomes. Indirect IEM reveals that the circulating BP antibodies are directed against both the basal-cell hemidesmosomes as well as the lamina lucida. The findings in HG and CP are similar.

Table 89-1
The Pemphigoid Disorders

Disorder	Bullous pemphigoid	Cicatricial pemphigoid	Pemphigoid gestationis
Distribution of lesions	Flexures, neck, abdomen	Oral, ocular, anogenital	Abdomen, extremities
Tendency for scarring	–	+	–
Subepithelial blister	+	+	+
IgG and C3 at the BMZ	+	+	+
IgA at the BMZ	Rare	Occasional	–
Serum anti-BMZ antibodies detected by:			
Indirect Immunofluorescence	70%	25%	20%
Complement fixation	80%	?	50%
Western blotting or immunoprecipitation	95%	80%	80%
Target antigen in BMZ			
Location	Hemidesmosome and lamina lucida	Hemidesmosome, lamina lucida and lamina densa	Hemidesmosome and lamina lucida
Molecule	BP 180, BP 230	BP 180, BP 230, laminin 5, other	BP 180, rare BP 230

BMZ, basement membrane zone; BP 180, bullous pemphigoid antigen, mol wt 180 kDa; BP 230, bullous pemphigoid antigen, mol wt 230 kDa.

Figure 89-2   This is a close-up of the lesions revealing urticarial plaques and bullae.

PATHOPHYSIOLOGY

THE BULLOUS PEMPHIGOID ANTIGENS   It is established that there are two protein antigens recognized by autoantibodies in bullous pemphigoid. Recently it has also been established by use of a passive-transfer animal model that that interaction of these autoantibodies with one of these proteins in vivo is directly responsible for blister formation.

The first pemphigoid antigen to be cloned and sequenced has been called either the BPAg1 or the BP230 antigen, and has an estimated molecular weight of 230 kDa in sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). The hemidesmosome is an organelle that mediates a stable interaction between the keratin intermediate filament proteins of the basilar pole of the keratinocyte and transmembrane adhesion molecules that anchor the basal cell to the underlying lamina densa of the basement membrane. The BPAg1 is the major protein of the cytoplasmic plaque of the hemidesmosome, and its presumed (but not proven) function is to mediate this interaction. It is notable that the BPAg1 has approximately 30% sequence homology with desmoplakin I, the major plaque protein of the desmosome—an organelle that serves a similar function in mediation of cell—cell adhesion. BPAg1 has been mapped to chromosome 6 (6p12-p11) in the human and to the proximal region of chromosome 1 in the mouse.

The second pemphigoid antigen to be characterized is called the BPAg2 or the BP180 antigen, and has an estimated molecular
Figure 89-3 Direct immunofluorescence of perilesional skin of patient with bullous pemphigoid. Note the continuous linear deposition of complement (C3) along the epidermal basement membrane.

weight of 180 kDa in SDS-PAGE. The BPAg2 has been mapped to chromosome 10 (10q24.3) in the human and to the distal end of chromosome 19 in the mouse. It is a unique molecule, with many important structural features. It is a transmembrane molecule with a type 2 orientation, the carboxy-terminus being in the extracellular space and the amino-terminus being intracellular. The extracellular domain has lengthy collagenous domains, characterized by the presence of Gly-X-Y repeats, and this finding has led to an additional proposed name for the molecule, collagen type XVII. This portion of the molecule is presumed to interact with adhesion molecules of the lower lamina lucida/lamina densa to anchor the basal cell in place. The hypothesis that this molecule is important in normal epithelial adhesion is supported by the recent observation of kindreds in which a mutation of the BP180 gene results in a nonlethal, but generalized form of congenital epidermolysis bullosa. Immediately adjacent to the transmembrane domain of the BPAg2 there is a noncollagenous domain that contains the immunodominant epitope of the protein. Giudice and Diaz identified a polypeptide of 14 amino acids from this epitope that is recognized by the majority of human sera in bullous pemphigoid and herpes gestationis. Subsequently, they identified the corresponding region of the murine BPAg1 and found no significant homology between the human and murine epitope. This was a critical observation that allowed these investigators to subsequently develop a passive-transfer model in the mouse to define the immunopathologic events that lead to blister formation in vivo.

MECHANISMS OF BLISTER FORMATION For many years, it had been assumed that the sequence of events leading to blister formation in the human disease had been as follows: (1) Loss of tolerance to the BP antigens leads to autoantibody production and binding to the hemidesmosome. (2) Tissue-bound autoantibody activates the complement cascade. (3) Generation of chemotactic fragments of complement such as C3a and C5a recruit neutrophils and eosinophils to the site of bound autoantibody. (4) Release of proteolytic enzymes from the polymorphs degrades the BP antigens or other important adhesion molecules at the site. (5) Subepidermal blister formation ensues. This hypothesized sequence of events has now been confirmed and clearly defined in vivo by the use of an animal model. In this model, the 14-amino acid

polypeptide, encoding the immunodominant epitope of the murine BPAg2 was synthesized, and antibodies against it were raised in rabbits. These antibodies were then transfused into neonatal mice, and within 24 h, cutaneous inflammation and blister formation was apparent. The induced blisters showed subepidermal separation, deposition of rabbit IgG and murine C3 along the basement membrane zone, and infiltration of the base of the blister with polymorphonuclear leukocytes. Blister formation was not observed if the model was manipulated to inhibit complement activation by bound anti-BPAg2 antibody. This was demonstrated by transfusing the antibody into C5 deficient strains of mice, into Balb/c mice depleted of complement by pretreatment with cobra venom factor, or by the infusion of F(ab')2 fragments of the rabbit anti-BPAg2 antibodies into newborn mice. If the mice were depleted of circulating polymorphonuclear cells prior to antibody infusion, blister formation was also not observed. In related studies, the role of proteases released from eosinophils in the degradation of the BPAg2 was defined. Abundant message for a 92-kDa gelatinase was found in eosinophils at the base of blisters in humans with lesions of BP. In vitro studies confirmed that the eosinophil-derived gelatinase degraded the BPAg2 in the extracellular collagenous domains. In total, these studies provide compelling evidence for the proposed immunopathogenesis of lesions in BP.

It is not clear what role, if any, antibodies specific for the BPAg1 play in the development of lesions. Passive transfer of human antibodies against the BPAg1 do not produce any inflammation in the skin of mice. Rabbits that are immunized to the antigen and have circulating anti-BPAg2 antibodies do not develop any cutaneous lesions. These animals do exhibit an unusual inflammatory reaction to ultraviolet radiation. In this circumstance, erythematous doses of ultraviolet light produce marked epidermal inflammation and keratinocyte necrosis. This suggests that antibodies against the BPAg1 may cause some secondary inflammatory events in vivo, but it appears that antibodies against the BPAg2 are really of primary pathogenic importance. It is not clear why patients should simultaneously make autoantibodies against two completely unrelated protein antigens, although a similar phenomenon is observed in autoimmune thyroiditis, where autoantibodies develop against discrete but unrelated antigens that are related to each other only by close physical proximity.

MANAGEMENT

Pemphigoid is a disorder that results from an abnormal immune response and that has prominent inflammatory features. Therapy for pemphigoid should suppress inflammation and/or the immune response. If therapy fails, the elderly patient with extensive erosions may develop complications such as fluid loss, electrolyte imbalance, bacterial colonization with potential sepsis, scarring, and decubitus ulcers.

Most patients with generalized BP require systemic therapy. The most commonly used systemic agents are the corticosteroids. Immunosuppressive drug therapy with chemotherapeutic agents should be considered for patients who require high maintenance doses of corticosteroids, patients who develop corticosteroid side effects, and patients whose disease does not respond completely to corticosteroid therapy. The most commonly used immunosuppressive agents are azathioprine, cyclophosphamide, methotrexate, and cyclosporine. Treatment of CP and HG follows the same principles as that of BP.

FUTURE DIRECTIONS

In the past decade, extensive information has been derived about the molecular structure of BP antigens. A recent animal model confirmed the pathogenic role of BP antibodies in the induction of skin lesions. Future research should be directed toward understanding the mechanisms for the immune response that results in the production of BP antibodies.

90 Cutaneous Lupus Erythematosus

RICHARD D. SONTHEIMER

BACKGROUND

Lupus erythematosus (LE) is an extremely heterogenous autoimmune disease process that has the potential to involve every major organ system within the body. Involvement of internal organs is designated as systemic LE (SLE), whereas involvement of the skin is referred to as cutaneous LE. Some LE patients have only SLE and others only cutaneous LE, however, most will have features of both SLE and cutaneous LE. Polyclonal B-cell activation with resultant production of autoantibodies to a number of nuclear and cytoplasmic antigens is a hallmark of LE. Multiple genetic and environmental factors are thought to conspire to produce the mosaic of clinical and laboratory features that constitutes the LE disease process.

The skin is a major target in LE—cutaneous disease is the second most common overall clinical disease manifestation, and skin disease is the second most frequent way that this autoimmune disorder first presents itself. Unfortunately, the molecular basis of most forms of skin involvement in LE is poorly understood owing in large part to the absence of reliable in vitro or in vivo models of this pattern of cutaneous inflammation. Thus, a discussion of this subject must be allowed some degree of freedom concerning the extrapolations that naturally flow from an analysis of a diverse set of isolated clinical, pathological, and immunopathological observations as has been reported for LE. This overview will focus especially on the immunological effector mechanisms that might be responsible for the characteristic pattern of cutaneous inflammation that is seen in this disorder.

This chapter will review our current understanding of the etiology and pathogenesis of LE-specific skin disease (LESSD), the type of cutaneous involvement that is histopathologically unique to individuals having LE. Cutaneous vasculitis, a form of LE-nonspecific skin disease, can be seen in LE patients but also is seen in a number of other disease processes other than LE. Space does not allow discussion of the causal mechanisms of LE non specific skin disease. In its strictest sense, the term "cutaneous LE" might be used to refer to all forms of skin lesions that occur as the result of the underlying LE autoimmune process; however, in practice most use this term synonymously with LESSD.

CLINICAL FEATURES

The classification system popularized by James N. Gilliam divided LESSD (cutaneous LE) into three subgroups—acute

cutaneous LE (ACLE), subacute cutaneous LE (SCLE), and chronic cutaneous LE (CCLE) (a comprehensive color atlas illustrating the many ways that LE can be expressed in the skin can be found in Sontheimer RD et al.). Similarities and differences exist in the clinical and laboratory features associated with these three forms of cutaneous LE (Table 90-1). LESSD lesions can exist as an isolated event (e.g., localized classical discoid LE [DLE], which is the most commonly encountered variety of CCLE) or can accompany underlying SLE disease activity (e.g., ACLE). However, LESSD lesions that occur in the context of SLE are indistinguishable clinically and pathologically from those that occur as an isolated event. Although it is possible that each of these three major forms of LESSD has a unique etiopathogenesis, it is much more likely that each represents a variation on a common underlying theme with host factors such as genetic differences and environmental stimuli such as exposure to ultraviolet (UV) light accounting for the differences in phenotypic expression.

Several clinical observations concerning LESSD can serve as clues to the underlying pathogenesis of this pattern of cutaneous inflammation. When nonlesional skin of an LE patient is injured in any way, LESSD can be precipitated at the site of injury (i.e., the Köebner phenomenon). Autografting experiments have revealed LESSD to be recipient site dominant, i.e., grafts of nonlesional autologous skin transplanted into an area of LESSD inflammation assume the clinical and pathological features of the recipient site. In some patients, LESSD, especially SCLE, can be induced by exposure to certain drugs including hydrochlorothiazide, procainamide, D-penicillamine, sulfonylureas, oxyprenolol, griseofulvin, piroxicam, naproxen, PUVA, spironolactone, and diltiazem.

Photosensitivity is a clinical hallmark of LE occurring in as many as 80–90% of certain cutaneous LE subsets such as SCLE. In addition to precipitating or exacerbating cutaneous LE activity, exposure to UV light is also capable of aggravating the underlying systemic autoimmune abnormalities. The abnormal cutaneous response to UV light in LE patients is delayed in time, usually taking days to weeks to become fully apparent. The degree of abnormal sensitivity to sunlight and artificial sources of UV light can wax and wane over an individual patient's disease course. As previously mentioned, certain photosensitizing drugs such a hydrochlorothiazide and griseofulvin are capable of inducing some forms of LESSD such as SCLE. Some studies have indicated that circulating humoral factors may predispose to the development of cutaneous LE photosensitivity.

Most LE patients respond normally to minimal erythema dose testing, however, some reports have suggested decreased minimal

erythema doses in some individuals. In the classical phototesting studies, the action spectrum of LESSD appeared to be restricted to the ultraviolet B (UVB) spectrum; however, more recent studies have suggested that ultraviolet A (UVA) radiation can contribute to the photosensitive states experienced by some subsets of LE, especially SCLE. Single- and repeated-dose exposure of nonlesional skin to UV light can result in the production of typical cutaneous LE lesions. These UV light-induced lesions have identical histopathological features to idiopathic LE skin lesions. The earliest histopathological change in a UV light-induced skin lesion is perivascular accumulation of mononuclear cells—these changes clearly predate the appearance of immunoglobulin and complement deposits at the dermal–epidermal junction. Some photochallenge studies have suggested that UVB exposure preferentially induces the epidermal changes of LESSD, whereas UVA predominantly produces the dermal changes.

DIAGNOSIS

The diagnosis of LESSD is certain when the expected histopathological changes are seen in a skin lesion that is clinically consistent with a form of cutaneous LE. Dermatomyositis skin lesions can at times be difficult to distinguish from some forms of LESSD on routine histopathology alone. Whereas qualitative differences exist between ACLE, the pattern of pathological change in each of these forms of LESSD is that of a lichenoid tissue reaction. Experimental evidence suggests that other examples of the lichenoid tissue reaction such as lichen planus and graft-vs-host

skin disease are the result of T-lymphocyte–mediated autoimmune injury within the skin.

PATHOLOGY

EPIDERMAL CHANGES   Epidermal keratinocyte hyperproliferation in cutaneous LE lesions is associated with normal early differentiation and premature terminal differentiation. In addition, epidermal Langerhans cells are decreased in density and display a perturbed morphology.

However, the primary focus of change within the epidermis is at the basal cell layer with hydropic or liquefactive degeneration of basal keratinocytes being the most prominent change. Activated lymphocytes and macrophages can be seen admixed with these degenerating basal keratinocytes. The intimate association of activated lymphocytes with the degenerating epidermal basal cells has led to the speculation that autoantigen-specific lymphocytes might mediate keratinocyte cytotoxicity in LESSD. The presence of elevated serum levels of soluble interleukin (IL)-2 receptors in certain cutaneous LE subsets also indirectly supports a role for activated T cells in the pathogenesis of this form of LESSD. Epidermal keratinocytes in LESSD lesions express HLA class II antigen, ICAM-1, and the B7-3 costimulatory ligand. In addition, preliminary in vitro studies have suggested the existence of phenotypic variation in tumor necrosis factor (TNF)-α–induced ICAM-1 expression by epidermal keratinocytes from cutaneous LE patients.

DERMAL–EPIDERMAL JUNCTION CHANGES   There is thickening of the epidermal basement-membrane zone in chronic

LESSD lesions such as DLE. This appears to result from basal lamina reduplication that occurs as a result of the hyperproliferation and premature death that occurs within the epidermal basal-cell compartment.

DERMAL CHANGES Mononuclear-cell infiltration around blood vessels and dermal appendages is a constant feature of LESSD. CD4 T lymphocytes that express class II histocompatibility antigens comprise the majority of this infiltrate. These cells express other T-cell–activation markers such as the IL-2 receptor and thymidine incorporation to only variable degree. Monocytes and macrophages are seen to a lesser extent and B cells are quite rare. The infiltrating T cells are predominately of the helper-inducer, memory phenotype (CD4$^+$, CD45RA$^-$, CD45RO$^+$) and express CD28/CTLA-4. There do not appear to be significant qualitative differences in the inflammatory infiltrate seen in DLE and SCLE lesions. Some workers have reported that γ/δ T-cell receptor-positive T cells are virtually nonexistent in the epidermis and dermis of CCLE lesions, whereas others have suggested that T cells having a specific γ/δ receptor phenotype (V-γ2/V-δ2) are preferentially expanded within the epidermal and dermal T-cell infiltrates of CCLE lesions. The presence of γ/δ T cells would suggest the possibility of an antigen-specific response to stress proteins induced within the epidermis by environmental stimuli such as UV light.

The dermal microvasculature is a major focus of cellular inflammation within the dermis. Several studies have suggested that HLA-DR antigens are expressed at lower levels on dermal microvascular endothelial cells than is normal in DLE and SLE skin lesions. Dermal mucin deposition can be a prominent feature of LESSD lesions. Recent studies have suggested the possibility that circulating factors in LE patients that parallel SLE disease activity can stimulate exaggerated production of glycosaminoglycans by dermal fibroblasts.

SUBCUTANEOUS CHANGES Subcutaneous inflammation is relatively rare in LE; however, lupus panniculitis (profundus) can at times be the dominant cutaneous change. The histologic pattern is a lobular lymphocytic panniculitis. Perivascular infiltration with lymphocytes, plasma cells, and histiocytes in the deep dermis and subcutaneous fat is usually seen; this can extend to the point of lymphoid nodule formation. Vessel-wall thickening and invasion by mononuclear cells ("lymphocytic vasculitis") can also be observed. There is a distinct absence of polymorphonuclear leukocytes. Hyaline fat necrosis can be seen as well as prominent fibrinoid degeneration of collagen. Mucinous degeneration and calcification in established lesions occurs over time.

IMMUNOPATHOLOGY

Immunoglobulin (IgG, IgA, IgM) and complement (C3, C4, membrane-attack complex) components can be found in a band-like array along the dermal–epidermal junction of both lesional and nonlesional skin of LE patients. Elution of such immunoreactants from the skin of SLE patients has suggested that they contain antinuclear and anti–basement membrane zone reactivity. Ultrastructural studies have localized these deposits to structures below the lamina densa that are associated with type VII collagen (autoantibodies to type VII collagen are produced by some patients with SLE who develop vesiculobullous skin lesions ["vesiculobullous SLE"]). These deposits have been shown to follow the appearance of the perivascular mononuclear-cell infiltrate in UV-induced LE skin lesions by 4–6 weeks and thus are probably not causally involved as a primary factor in the pathogenesis of LESSD. Experimental studies in mice have shown that deposition of immunoglobulin at the dermal–epidermal junction can result from charge interaction alone when cationized antibody or immune complexes are present.

A pattern of IgG deposition different from the LE band has been observed to occur in SCLE patients. This dust-like array of IgG deposition is seen most prominently over the epidermal basal cells and has been suggested to correlate with the presence of circulating Ro/SS-A autoantibodies. The ability to detect this subtle immunofluorescence finding appears to vary somewhat between laboratories, suggesting that technical issues might be important to its detection.

In LE panniculitis/profundus, immunoglobulin and complement deposits are usually found in blood vessel walls of the deep dermis and subcutis by direct immunofluorescence.

ULTRASTRUCTURAL CHANGES

Early electron microscopic studies identified paramyxovirus-like structures within lesions of DLE; however, similar tubuloreticular structures have also been found in other settings such as dermatomyositis and Sjögren's syndrome. Considerable evidence now suggests that these "lupus inclusions" are not directly related to viral infection since they can be reproduced in cells in vitro as a result of excessive stimulation with interferon (IFN)-α or -β.

GENETIC BASIS OF DISEASE

HLA associations have been reported for several forms of LESSD. SCLE has been associated most strongly with HLA-B8, DR3, DRW6, DRW52, and DQW1/DQW2. This the HLA haplotype that is even more strongly associated with Ro/SS-A autoantibody production, the serological marker for SCLE. Nucleotide sequence analysis of DQW1/DQW2 alleles in patients who produce Ro/SS-A antibody have demonstrated that 100% have a glutamine residue at position 34 of the outermost domain in the DQA1 chain and a leucine at position 26 of the DQB1 chain. Partial or complete genetic deficiency of C2 and C4 is also associated with SCLE. CCLE (DLE) has been a found to correlate with the presence of HLA-B7, B8, Cw7, DR2, DR3, DQW1, and DQA1*0102. Like SCLE, DLE has been associated with genetic deficiency of C2, C4, and C5. There is no specific autoantibody marker for CCLE. No specific HLA associations have been reported for ACLE; however, ACLE lesions usually occur in the context of SLE and SLE has been most closely associated with HLA-DR2 and DR3.

Non-HLA genetic associations have also been reported for CCLE. DLE has been observed to be present at increased frequency in female carriers of X-linked chronic granulomatous disease, which is now known to result from genetic deficiency of reduced nicotinamide dinucleotide phosphatase (NADPH). In addition, IL-1 receptor antagonist and TNF-α gene polymorphisms have been associated with SLE; however, the role that this plays in the expression of cutaneous LE has not been fully determined. Preliminary evidence has argued against an association between SCLE and TNF-α polymorphism.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

The foregoing clinical and laboratory observations suggest that LESSD is the result of a genetically determined autoimmune
Figure 90-1 Modulation of Ro/SS-A autoantigen in epidermal keratinocytes following exposure to UVB irradiation. Lefeber, Norris, and coworkers first reported that UVB irradiation of human epidermal keratinocytes in culture resulted in the translocation of normally intracellular Ro/SS-A autoantigen to the surface of viable. Ro/SS-A antibody from the circulation would then be able to bind to these surface-expressed autoantigens, targeting the cells for injury through immune effector mechanisms such as antibody-dependent cell-mediated cytotoxicity. Golan et al. first presented data suggesting that greater degrees of Ro/SS-A autoantibody binding could be observed on the surface of cultured epidermal keratinocytes of LE patients following UVB compared to keratinocytes from normal individuals.

response to cutaneous autoantigens that is mediated by autoantibodies, immune complexes composed of autoantibodies and autoantigens, or autoantigen-specific T cells. The tempo and extent of this form of autoimmune inflammation can be impacted by various environmental stimuli foremost among which is exposure to UV light.

The photoreceptor for cutaneous LE has not been identified; however, some have argued that it might be DNA. Earlier work attempting to explain the molecular basis of photosensitivity in LE patients suggested that the pathologic immune response might be directed against neoantigens generated in the skin by the action of UV light on DNA. A murine model of some of the histopathological and immunopathological changes associated with cutaneous LE was produced by exposing the skin of mice that had been immunized to thymidine dimers to UV light. In addition, several investigators have argued that LE patients have abnormal UV light-altered DNA-repair capacity. However, the role played by UV-induced DNA injury and repair in the pathogenesis of human LESSD remains to be determined.

Most attention over the past decade has been directed to the idea that some forms of Ro/SS-A autoantibody-associated, photosensitive cutaneous LE such as SCLE and neonatal LE might result from the interaction of Ro/SS-A antibody from the circulation with Ro/SS-A antigen that has been transported to the surface of epidermal keratinocytes as a result of exposure to UVB (Fig. 90-1). The following observations support this hypothesis. Ro/SS-A autoantibodies are extremely prevalent in SCLE and there is a strong correlation between Ro/SS-A antibody levels and skin disease activity in neonatal LE. The dust-like pattern of IgG deposi-

tion seen in human SCLE lesions has been experimentally reproduced in nude mice bearing human skin explants by the passive transfer of Ro/SS-A autoantibody derived from LE patient sera.

UVB-induced Ro/SS-A antigen modulation in keratinocytes has now been confirmed by several groups, and it has been suggested that this phenomenon might be enhanced in keratinocytes from LE patients compared to those from normal individuals. It has not yet been determined whether differential UVB-induced expression of the molecular constituents of Ro/SS-A ribonucleoprotein particles (Ro60, Ro52, La/SS-B, calreticulin) might occur in the epidermal keratinocytes of LE patients compared to normal individuals. UVB-induced apoptosis might be responsible for the translocation of Ro/SS-A autoantigen to the cell surface. Autoantibody binding to the exposed antigens on the surface of keratinocytes could result in tissue injury through complement-mediated lysis or antibody-dependent cell-mediated cytotoxicity. Infection by alphaviruses such as sindbis also appears to be capable of inducing cell-surface expression of Ro/SS-A antigens as a result of virus-induced apoptosis. It is also possible that UV light might cause the expression of stress-related autoantigens in keratinocytes of LE patients that could then become the target of a pathological immune response.

Although quite attractive, the hypothesis that UVB-induced Ro/SS-A antigen modulation is a causative factor in photosensitive LESSD still remains unproven. Several arguments can be made against this hypothesis. Most Ro/SS-A antibody-positive Sjögren's syndrome patients do not develop SCLE or deliver infants with neonatal LE skin lesions, even though they have equally high levels of Ro/SS-A autoantibody (most studies have
Figure 90-2   Possible mechanisms of T-cell interaction with epidermal keratinocytes of an LE patient following exposure to UVB irradiation.
Figure 90-3   Events occurring in epidermal keratinocytes following exposure to UVB that could be relevant to the pathogenesis of LE-specific skin disease.

not found distinctive differences in the Ro/SS-A polypeptide specificities of the autoantibodies found in SCLE and Sjögren's syndrome). In addition, from the preliminary data that is available, there does not appear to be a positive correlation between Ro/SS-A antibody levels and disease activity in adults with SCLE. Also only a very small percentage of newborns exposed to maternal Ro/SS-A autoantibody production *in utero* develop either neonatal LE or congenital heart block. To date, no in vitro or in vivo experimental system involving UVB-induced Ro/SS-A autoantigen modulation in epidermal keratinocytes has reproduced the pattern of histopathological change that is typical of LESSD.

It is conceivable that Ro/SS-A antibodies in photosensitive cutaneous LE patients represent only a marker for Ro/SS-A antigen-specific T cells and that such autoreactive T cells may represent the primary immunological effector mechanism for photosensitive LESSD (Fig. 90-2). Increasing evidence suggests

that many of the autoantibodies seen in LE are antigen driven and preliminary studies have identified ribonucleoprotein autoantigen-specific T cells from LE patients, including 52-kDa Ro/SS-A-specific T cells. As previously mentioned, the pathology of LESSD shares many features with other T-cell–mediated skin disorders such as lichen planus and graft-vs-host skin disease. However, to date, Ro/SS-A antigen-specific T cells have not been identified in LESSD lesions. If such cells exist they might be expected to be increased in density in LESSD lesions compared to the peripheral blood.

In addition to modulating intracellular ribonucleoprotein autoantigens, UV light also has a number of other proinflammatory effects on epidermal keratinocytes (Fig. 90-3). UV light can upregulate proinflammatory molecules such as IL-1α, TNF-α, GM-CSF, IL-6, IL-10, IL-12, MIP-1 and 2, prostaglandin E, proteases, oxygen free radicals, and histamine. It is conceivable that genetically determined enhanced expression or defective meta-

bolic turnover of one or more of these products might occur in LE patients; however, there is currently little data that directly addresses this possibility. As previously mentioned, TNF-α polymorphism has been associated with SLE, and IL-1-receptor antagonist gene polymorphism has been implicated as a genetic factor in cutaneous LE.

UVB irradiation of murine and human skin can result in the generation of immunological tolerance to antigens applied to the skin at the site of irradiation. Increasing evidence suggests that UVB-induction of IL-10 by epidermal keratinocytes or recruited dermal macrophages might play an important role in the generation of this state of active tolerance. Since T-suppressor cell function has often been observed to be defective in SLE patients and murine models of SLE, one could question whether UVB induction of normal amounts of IL-10 within the epidermis of an LE patient might fail to produce an adequate state of physiological tolerance to epidermal autoantigens that are modulated by UVB exposure or epidermal neoantigens that are generated by UVB. Alternatively, genetically determined aberrations in IL-10 expression following UVB might also result in inadequate generation of tolerance signals leading to autoimmune responses to cutaneous autoantigens. At the moment there is no direct data to either support either of these speculations.

MANAGEMENT/TREATMENT

Effective treatment of LESSD usually requires systemic therapy with anti-inflammatory or immunosuppressive agents. Approximately 80% of patients respond to one or a combination of the aminoquinoline antimalarials such as hydroxychloroquine (Plaquenil), chloroquine (Aralen), or quinacrine. When antimalarial therapy is not successful in fully suppressing disease activity, alternative therapy with other anti-inflammatory drugs including dapsone, isotretinoin/etretinate, gold, clofazamine, and thalidomide can be beneficial. Long-term systemic corticosteroids and antimetabolite/cytotoxic immunosuppressives such as methotrexate, azathioprine, and cyclophosphamide are reserved for potentially disabling forms of cutaneous disease.

Aminoquinoline antimalarials have been associated with a diverse set of actions on cell physiology and pathways of inflammation. Which of their many molecular effects is most important to their value in LESSD is not at all certain. One of the few common actions shared by the aminoquinoline antimalarials and the rather diverse group of other drugs that are of value in cutaneous LE (e.g., dapsone, retinoids, auranofin) is their ability to scavenge oxygen free radicals, perhaps yielding a clue to an important mechanisms of cellular inflammation in LESSD. Thalidomide is another drug that can have a profoundly beneficial effect on LESSD. Recent studies have determined that thalidomide powerfully inhibits the production of TNF-α, a UVB-inducible epidermal cytokine that has been implicated in the pathogenesis of cutaneous LE.

FUTURE DIRECTIONS

The absence of a working in vivo or in vitro model of LESSD has greatly hindered our understanding of the molecular and genetic basis of this distinctive form of cutaneous inflammation. Whereas there are murine models of some of the clinical and immunological features of SLE, such animals, even when challenged with UV light do not reproducibly develop clinical skin lesions or develop the typical histopathological changes associated with LESSD. One exception is the MRL mouse. These mice, under some conditions, spontaneously develop patchy hair loss that is associated with very mild pathological and immunopathological changes typical of LESSD. It would be quite interesting to determine whether MRL mice that are crossed with transgenic mice that overexpress UVB-inducible proinflammatory cytokines such as IL-1α, TNF-α, or MIP in epidermal basal cells might more reliably express an LESSD pathology and thus provide a better model for cutaneous LE inflammation.

Much could also be done with the tools of modern molecular biology to determine whether variant expression of UVB-inducible proinflammatory cytokines might occur in the epidermal cells of LE patients compared to normal individuals. For example, RT-PCR and Northern blot analysis might be used to examine sequential suction blister-derived epidermal biopsies from UV light-challenged nonlesional skin of LE patients to determine whether the kinetics of UV light-induced cytokine production might be different in LE patients compared to normal individuals.

Systematic studies to detect evidence of oligoclonal T-cell-receptor gene rearrangement are also needed to determine whether T-cell expansion of the type associated with antigen-driven T-cell stimulation might be present in LESSD lesions. Efforts to clone Ro/SS-A autoantigen-specific T cells from SCLE skin lesions could also prove rewarding.

SUMMARY AND CONCLUSIONS

David Norris has proposed a four-step model for the pathogenesis of LESSD: (1) exposure to UV light induces the release of proinflammatory epidermal and dermal mediators such as IL-1 and TNF-α; (2) these mediators induce changes in epidermal and dermal cells including the induction of adhesion molecules and promotion of the translocation of normally intracellular autoantigen such as Ro/SS-A to the surface of epidermal cells; (3) autoantibody from the circulation binds to autoantigens such as Ro/SS-A that have been translocated to the surface of epidermal keratinocytes; and (4) keratinocyte cytotoxicity ensues as the result of lymphoid cells that have been recruited from the circulation, recognizing and responding to the Fc domains of autoantibody molecules bound to autoantigen expressed on the surface of keratinocytes (i.e., antibody-dependent cell-mediated cytotoxicity). Although this remains among the most attractive hypotheses for the explanation of Ro/SS-A antibody-associated forms of LESSD such as SCLE and neonatal LE, it does not address the pathogenesis of other forms of LESSD such as DLE that are not associated with Ro/SS-A antibody or other known autoantibody specificity. Better in vitro and in vivo experimental models will be required to more fully understand the molecular basis of all forms of LESSD.

91 Scleroderma (Systemic Sclerosis) and Morphea

Edwin A. Smith and E. Carwile LeRoy

BACKGROUND

The term "scleroderma," referring to dermal fibrosis, has been applied to two distinct illnesses. One of these, systemic sclerosis, is a generalized vascular and fibrotic autoimmune disease affecting multiple organs, including the lungs, gastrointestinal tract, heart, and kidneys. In contrast, localized scleroderma is limited to the skin. Because there is little evidence that localized scleroderma can become systemic sclerosis and with the likelihood that these represent different etiologies and pathogeneses, systemic sclerosis and localized scleroderma will be treated separately.

SYSTEMIC SCLEROSIS (SSc)

HISTORY   Notwithstanding a suggestive case report of scleroderma by Curzio of Naples in 1753, the earliest definitive clinical and pathological reports of scleroderma date from the mid-19th century, the same era in which Raynaud described the phenomenon bearing his name (1862) and associated it with scleroderma. That cardiac fibrosis can be of clinical significance was documented by Weiss in 1943, and the association of renal failure and scleroderma was made by Moore and Sheehan in 1952. Recent emphasis has been on understanding the pathophysiology of the disease with a hope that knowledge of the immunologic features as well as the causes of both the fibrosis and the vascular disease will lead to prevention or better treatment.

EPIDEMIOLOGY   The incidence of systemic sclerosis is estimated at between 4 and 20 per million per year, a broad range because of the likelihood of unrecognized and misclassified cases. Estimates of the prevalence of disease meeting the ACR (American College of Rheumatology) preliminary criteria (*see* Table 91-1) range from 50,000 to 300,000 in the United States. It has been estimated, using more liberal criteria (Raynaud's phenomenon, abnormal nailfold capillaries, and positive tests for antinuclear antibodies) to identify persons suffering from "scleroderma spectrum disorders," that the population prevalence ranges from 67 to 265 per 100,000.

Systemic sclerosis is unusual in children, but has its onset throughout adult years. There is a suggestion that African Ameri-

cans are at a moderately increased risk, but the illness is found in all racial groups and in all locales. Females are affected about three times more often than are males, and this difference is even more striking in young adult years. Associations have been made between the occurrence of systemic sclerosis and particular occupational exposures, including silica (gold and coal miners), vinyl chloride (industrial plastics workers), and organic solvents. Studies vary widely on the association of systemic sclerosis with HLA haplotypes, but several reports have found an association with HLA-DR5. Among selected scleroderma patients, the occurrence of certain autoantibody types has been associated with certain HLA class II alleles *(see below)*.

CLINICAL FEATURES   Systemic sclerosis has been divided into two distinct types, differing in clinical course, types of organ involvement, and autoantibody profiles (Table 91-2). These two types, diffuse cutaneous systemic sclerosis (dcSSc) and limited cutaneous systemic sclerosis (lcSSc), differ in the extent of maximal skin involvement. In lcSSc, the skin thickening is limited to the face and areas distal to the elbows and knees, whereas, in dcSSc, the sclerosis is proximal as well as distal, and frequently involves the trunk. The clinical differences between limited and diffuse cutaneous systemic sclerosis are outlined in Table 91-3.

LcSSc is the more insidious of the two forms of the disease with mild symptoms which may go unreported to a physician for years or decades. Raynaud's phenomenon in the typical lcSSc patient has often been occurring since teenage or young adult years with symptoms of esophageal reflux or dysphagia occurring at a later date. It is often only with the occurrence of digital ulcers, telangiectases, or symptoms of pulmonary hypertension and right-sided heart failure that the diagnosis is made. Anticentromere antibodies are associated with lcSSc in Caucasian patients and their occurrence in a patient whose only symptom is Raynaud's phenomenon suggests that this illness is likely to develop. However, these antibodies are found in only approximately 40% of patients with lcSSc and can occur in other diseases than SSc.

Early dcSSc is very different from lcSSc, with a much more abrupt onset of symptoms. Although Raynaud's phenomenon is also common in this form of the disease, it may follow other symptoms. The earliest skin manifestation is edema of the extremities followed over a period of months by progressive induration of the dermis. This induration usually proceeds from distal to proximal

Table 91-1
**Preliminary Criteria for Classification
of Systemic Sclerosis (Scleroderma)**

For the purposes of classifying patients in clinical trials, in population surveys, and for other studies, a person shall be said to have systemic sclerosis (scleroderma) if the one major or two or more minor criteria listed below are present. Localized forms of scleroderma, eosinophilic fascitis, and the various forms of pseudoscleroderma are excluded from these criteria.

   A. Major criterion
      1. Proximal scleroderma: Symmetric thickening, tightening, and induration of the skin of the fingers and the skin proximal to the metacarpophalangeal or metatarsophalangeal joints. The changes may affect the entire extremity, face, neck, and trunk (thorax and abdomen).
   B. Minor criteria
      1. Sclerodactyly: above-indicated skin changes limited to the fingers.
      2. Digital pitting scars or loss of substance from the finger pad: depressed areas at tips of fingers or loss of digital pad tissue as a result of ischemia.
      3. Bibasilar pulmonary fibrosis: bilateral reticular pattern or lineonodular densities most pronounced in basilar portions of the lungs on standard chest roentgenogram; may assume appearance of diffuse mottling of "honeycomb lung." These changes should not be attributable to other primary lung disease.

Table 91-2
Clinical Features of Systemic Sclerosis

Musculoskeletal
   Digital flexion contractures
   Tendon friction rubs
   Muscle weakness (when myositis present)
   Calcinosis
   Arthritis
Gastrointestinal involvement
   Esophageal reflux
   Dysphagia (diminished peristalsis or stricture)
   Delayed gastric emptying
   Malabsorption
   Alternating diarrhea and constipation
Pulmonary
   Interstitial fibrosis
   Pulmonary hypertension
Cardiac
   Pericarditis
   Myocardial fibrosis
   Tachyarrhythmias
   Conduction blockade
   Heart failure
Renal
   Hypertensive renal failure
Neurologic
   Entrapment neuropathies (including trigeminal neuralgia)

Table 91-3
Comparison of Clinical Features of Limited and Diffuse Cutaneous Systemic Sclerosis

	lcSSc	*dcSSc*
Onset	Insidious	Abrupt
Initial symptom	Raynaud	Raynaud or swelling
Skin involvement	Distal	Distal and proximal
Lung involvement	Pulmonary hypertension	Fibrosing alveolitis
Heart involvement	Secondary to pulmonary hypertension	Myocardial fibrosis
Renal involvement	Very unusual	Hypertensive renal crisis
ANA profile	Anticentromere	Anti-Scl-70 (antitopoisomerase I)
		Anti RNA polymerase

on the extremities and often involves the trunk. These dcSSc patients are more likely than the lcSSc patients to develop the more severe manifestations of SSc, including pulmonary fibrosis, hypertensive renal crisis, and heart failure or arrhythmias. Antibodies to topoisomerase I (30–50% of dcSSc patients) or to RNA polymerases I, II, and III (10–40%) are associated with dcSSc.

Vascular Manifestations   The vascular lesion in systemic sclerosis, luminal narrowing of small arteries and arterioles as a result of intimal proliferation, is widespread and similar in all involved organs. Microvascular involvement is seen in the form of dermal telangiectases and loss of capillaries in all vascular beds. This capillary loss can be demonstrated by in vivo widefield nailfold microscopic examination of the capillaries just proximal to the cuticle. The characteristic changes of systemic sclerosis seen by this technique are capillary loop dilatation and areas of avascularity. Because these changes are not seen in primary Raynaud's phenomenon, they are very useful from a prognostic point of view in evaluating persons who have recently developed symptoms. The vascular lesions are directly associated with sev-

eral distinct clinical problems, including Raynaud's phenomenon, pulmonary hypertension, and renal insufficiency.

Raynaud's Phenomenon   The nearly universal occurrence of Raynaud's phenomenon (a reversible decrease in digital blood flow on exposure to cold with subsequent postischemic vasodilatation) underscores the vascular nature of systemic sclerosis. Although this is a common complaint among otherwise healthy persons (occurring in approximately 5% of the general population), it is also the most frequent initial symptom of systemic sclerosis. Patients complain of color changes (blanching or cyanosis), numbness, and/or pain in response to a cold stimulus and there is often a reactive hyperemia with rewarming. Raynaud's phenomenon in systemic sclerosis results from the superimposition of physiologic cold-induced vasoconstriction on the already pathologically reduced luminal diameter.

The ischemia resulting from the digital vascular lesions can result in irreversible changes, including tapering of the palmar fingertip pad, ulcerations of the fingertips and over the proximal interphalangeal joints, and infarction of digital tips.

Renal Involvement The characteristic kidney involvement seen in systemic sclerosis is much more likely to occur in dcSSc than lcSSc, and usually occurs early in the illness when the skin is undergoing rapid fibrosis. A sudden onset of severe hypertension is followed by progressive azotemia. This "scleroderma renal crisis" results from secretion of large quantities of renin by the juxtaglomerular apparatus in response to the decreased blood flow caused by the arteriolar luminal narrowing. The resulting formation of angiotensin causes further vasoconstriction and reduction of renal blood flow, leading to severe hypertension and diminished glomerular filtration. Shearing of erythrocytes within the altered renal vasculature can result in a microangiopathic hemolytic anemia. Until the invention of angiotensin-converting enzyme inhibitors (*see* Management section, *below*), renal crisis led invariably to renal failure or death.

Pulmonary Hypertension Pulmonary hypertension in systemic sclerosis can be the result of either of two pathologic processes. Fibrosing alveolitis *(see below)* resulting in restrictive pulmonary mechanics can result in chronic hypoxemia with secondary pulmonary hypertension. However, an increase in pulmonary vascular resistance can occur without fibrotic parenchymal lung disease as a result of the intimal lesion in the pulmonary arterioles. This isolated pulmonary hypertension is seen almost exclusively in lcSSc, where it often remains silent for decades after the occurrence of the initial manifestations of the disease. The earliest clinical manifestation is usually exertional dyspnea with overt right-sided heart failure developing later in the course.

Telangiectasia The development of dilated cutaneous blood vessels in the skin is usually a later-developing manifestation of systemic sclerosis. These telangiectases are most common on the face, palms, fingers, and lips.

Fibrotic Manifestations **Dermal Fibrosis** The early edematous phase of skin changes is followed by progressive thickening and tightening of the skin as a result of deposition of extracellular matrix (primarily collagen) in the dermis. This usually proceeds from distal to proximal locations on the extremities. The skin becomes indurated, difficult to pinch into a fold, and tight over bony prominences. The patient may complain of itching or burning sensations. Involvement of underlying structures such as tendons and muscles gives rise to flexion contractures of the fingers and a diminished maximal oral aperture. The maximal extent of skin fibrosis is usually reached in the first 2 or 3 years of disease, followed by progressive atrophy that is perceived as improvement by the patient and clinical examiners. However, this improvement generally does not result in diminished digital contractures. This spontaneous regression of dermal sclerosis has led to many therapies being heralded as beneficial to the course of SSc, only to be later discounted in more rigorous trials.

Pulmonary Fibrosis The development of restrictive lung disease as a result of interstitial pulmonary fibrosis has become the most common factor accounting for increased mortality in systemic sclerosis. As stated above, it is much more common in patients with dcSSc than in limited disease. Symptoms (dyspnea on exertion, nonproductive cough) are often delayed until the disease is far advanced. Chest roentgenograms are insensitive to the detection of early lung disease, but show interstitial fibrosis when the disease has progressed. Less-advanced cases of restrictive lung disease may be established by pulmonary function testing in which decreases in vital capacity and gas diffusion are found. Computerized tomographic scanning of the pulmonary parenchyma by high-resolution techniques can identify both early fibrosis and the presence of alveolitis which gives a "ground glass" appearance to the areas of inflammation. This alveolitis presumably represents the prefibrotic stage of the illness.

Pulmonary fibrosis results in dyspnea, first on exertion and then at rest. The development of pulmonary hypertension followed by right heart failure frequently precedes death.

Cardiac Involvement Several types of heart involvement occur in SSc. Symptomatic pericarditis is less common than is an echocardiographic finding of increased pericardial fluid. Reversible myocardial ischemia as a result of the vascular disease in small vessels results in contraction band necrosis, followed by patchy myocardial fibrosis. Clinical manifestations include varying degrees of heart block, arrhythmias, and congestive heart failure. Left ventricular pressure overload may result from the systemic hypertension associated with renal crisis, and right ventricular hypertrophy followed by failure often results from pulmonary hypertension.

Digestive System Involvement Involvement of the gastrointestinal system in SSc follows only Raynaud's phenomenon as a common clinical manifestation. Diminished smooth muscle motor activity of the distal two-thirds of the esophagus is the most frequent problem and results in dysphagia and esophageal reflux. With chronic reflux esophagitis, stricture can develop. Diminished peristalsis also occurs throughout the remainder of the GI tract. Delayed gastric emptying may worsen esophageal reflux. Small-bowel involvement resulting in malabsorption with weight loss is uncommon, but may be severe in the individual patient. More frequently, stasis results in bacterial overgrowth within the small intestine with deconjugation of bile salts and subsequent development of diarrhea. Colonic involvement results in stasis and constipation. Thinning of the colonic mucosa results in wide mouth diverticuli, which are usually asymptomatic.

DIAGNOSIS The diagnosis of SSc rests on clinical grounds according to the preliminary classification criteria established by the American College of Rheumatology (ACR) (Table 91-1). Many persons have illnesses that do not fulfill these intentionally insensitive, but specific, criteria, yet clearly have either early or incomplete forms of SSc.

GENETIC BASIS OF SSc As for all autoimmune diseases, the pathogenesis of SSc is felt to involve interacting genetic and environmental factors, although the precise nature of neither is completely understood. Whereas SSc is not inherited in the classical Mendelian sense, some reproducible serological manifestations are regulated by immune-response genes. DNA methods of typing HLA alleles have demonstrated close associations with disease-specific autoimmune manifestations. This link of the immunogenetic profile is much closer to the autoantibody profile than it is to the subset of SSc (lcSSc or dcSSc) or to any specific clinical or outcome parameter. The genetic hypothesis of SSc has been bolstered by rare reports of familial occurrence and by the fact that the autosomal-dominant animal model, the Tsk/+ mouse, expresses disease-specific autoantibodies (anti-topo I and anti-RNAP I) in addition to dermal fibrosis.

Whereas understanding of direct links between immune events and the vascular, cutaneous, or visceral fibrosis of SSc remains elusive, the presence of distinct autoimmune features in Ssc permits hypotheses similar to those for other autoimmune disorders. These hypotheses include: (1) an altered T-cell repertoire that fails to discriminate certain antigens as "self;" (2) one or more key

immune events initiated by these self antigens and involving the trimolecular complex (MHC, TCR, antigen) that leads to the expansion and activation of self-reactive T cells; and (3) the elaboration of cytokines to provide help for B cells that express surface Ig molecules that recognize specific autoantigens such as centromere proteins, topoisomerase I, or RNA polymerase. In the specific case of SSc, these elaborated cytokines are also hypothesized to activate fibroblasts and cause endothelial cell damage and proliferation. When fully understood, many specifics of this general autoimmune paradigm should provide the basis for therapeutic immune intervention.

Antigen-presenting cells employ HLA molecules to present MHC-restricted epitopes to the heteromultimeric T-cell receptor (TCR). The expression of both the HLA and TCR are under genetic control. TCR genes utilize combinatorial mechanisms (V-J-D) to express a remarkable diversity. Most epitopes are recognized by T cells containing α/β chains in their TCRs. To date, no clonal selection of α/β T cells has been observed in either the blood or target organs (gut or lung) of SSc patients. A less prevalent subset of T-cells expresses only γ/δ chains in their TCRs. These cells seem to favor intestinal subepithelial sites and can be clonally expanded by either antigens or superantigens, the latter being microbial products that activate and expand T cells by ligating TCRs outside the cleft in which they receive MHC-restricted antigens. Normally, individuals express 10–20 different types of delta chains on their γ/δ TCRs. In groups of Ssc patients, however, γ/δ TCRs from blood, lungs, or gut biopsies display five or fewer junctional region sequences, indicating oligoclonal expansion. These studies by White et al. show expanded Vd1 ⊕ γ/δ T cells and lead to the hypothesis that the gut serves as a reservoir of γ/δ T cells where they are exposed to external influences (e.g., toxic oil, conjugated tryptophan, trichloroethylene in drinking water, possibly viruses) in response to which they expand, perhaps migrate, and potentially respond to similar influences in inhaled air. The function of this oligoclonal expansion of γ/δ T cells, including cytokine secretion and B-cell help, is poorly understood in general, and particularly, in SSc. Because T lymphocytes respond to short peptides, precise epitope mapping of these Vd ⊕, γ/δ TCRs might be a fruitful future area of study to design peptides that engage this particular T cell but block its expansion.

Both afferent (i.e., related to antigen processing or recognition) and effector (e.g., null complement haplotypes or differences in other immune-inflammatory mediators) immune-response genes have been shown to be associated with SSc to a statistically, but perhaps not clinically, significant degree. No conclusive link between class I HLA types and SSc has been demonstrated. Several class II associations have been made with different results, depending on ethnic origin of the population being studied. Positive associations with DR 3 and 5 (now 11) and negative associations with DR 2 (now 15), 7, and 9 have been made. Logistic-regression analysis has identified the primary class II HLA association to be with DQA1*0501, with the DR associations being explainable by linkage dysequilibrium. Ethnic differences between Europeans, Japanese, African Americans, and Native American Indians are substantial, but generally mirror autoimmune disease associations in those populations.

When HLA molecules and autoantibody types are examined in groups of SSc patients regardless of clinical pattern (lcSSc or dcSS), impressive associations between serology and HLA alleles can be demonstrated. For example, in one study of 42 SSc patients

with anticentromere antibodies, 100% were either heterozygous or homozygous for Gly or Tyr (polar residues) rather than leucine (a nonpolar residue) at position 26 of the DQB1 molecule (a position in the peptide-binding groove of the HLA-DQ molecule). However, that 71% of the healthy population and 69% of SSc patients without anticentromere antibodies also have either one or two alleles containing such a polar residue at position 26 makes the likelihood of having anticentromere antibodies if one has such an allele very low. This indicates a major environmental influence. In the case of SSc patients expressing antitopoisomerase I autoantibodies, the polar residue in DQB1 conferring "susceptibility" is at position 30. These intriguing observations both indirectly strengthen the case that the autoimmune serology may be playing a pathogenetic role in the disease and raise the possibility of ultimately immunizing the highly susceptible individual to a blocking peptide. It should be noted that these susceptibility residues reside in the second hypervariable region of the DQB1 chain in contrast to the situation in rheumatoid arthritis or type I diabetes mellitus in which "shared epitopes" reside in the third hypervariable region of the DRB1, highlighting the lack of present understanding of functional differences between DQ and DR HLA molecules in antigen presentation. These class II HLA-autoantibody associations are strong, even if at present they are poorly understood.

Class III HLA molecules, which influence effector functions such as complement activation and tumor necrosis factor (TNF)-α cytokine secretion, are encoded by genes located between those of classes I and II on chromosome 6. A null genotype for one of the isoforms of the fourth component of complement, C4A (tightly linked to the general autoimmune haplotype [B8, DR3]) is characterized by a large gene deletion in the class III region, and is associated with several autoimmune disorders, particularly lupus and SSc. In English patients with SSc, C4A null alleles are present in 50% of patients studied. The functional implications of this gene deletion are unknown but nonetheless intriguing.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE   The pathophysiology of systemic sclerosis is incompletely understood, and the primary etiology(ies) remains completely obscure. Because evidence of the vascular lesion is seen so early in the course of the illness, theoretical constructs that attempt to explain all features of the illness as being secondary to the vascular lesion have been made. However, it is possible that both the vascular and fibrotic features of the illness result from some other cause, possibly immunologic or toxic. That the immunologic and microvascular lesions are already evident when the first clinical manifestations occur makes understanding the seminal event very difficult.

The Vascular Lesion   The marked abnormalities seen in the blood vessels prompted searches for the cause of the endothelial-cell damage and proliferation. It is not clear whether alterations in platelet function (elevated plasma β-thromboglobulin levels and increased circulating platelet aggregates) are a cause or result of the vascular disease. Injury to or activation of the endothelium is supported by the elevated circulating levels of von Willebrand factor and endothelin (both synthesized and released by endothelial cells) and loss of endothelial reserve by diminished levels of angiotensin-converting enzyme. It has been proposed that the T lymphocytes found infiltrating the perivascular areas in early dermal lesions are the cause of the endothelial injury. Clearly, these interstitial lymphocytes leave the circulation by way of the endothelial cells. Increased expression of intercellular adhesion molecule 1 (ICAM-1) on endothelial cells of active dermal lesions

Table 91-4
Antinuclear Antibodies in Systemic Sclerosis

Antigen recognized	Incidence (all SSc)	SSc Type (incidence)
Centromere	10–20%	lcSSc 40%
Topoisomerase I (Scl-70)	15–25%	dcSSc 25–50%
RNA polymerase I, II, III	10–25%	dcSSc 20–45%
U3RNP (fibrillarin)	5–45%	dcSSc 5%
Th	5%	lcSSc
U1RNP	5–35%	lcSSc

and the demonstration that infiltrating lymphocytes bear cell surface leukocyte adhesion factor 1 (LFA-1), the ligand for ICAM-1, indicate a mechanism for the presence of T cells in the perivascular infiltrates. The endothelial cells also express increased amounts of endothelial leukocyte adhesion molecule 1 (ELAM-1 or E-selectin). That T cells may be important in causing endothelial injury is supported by the finding of elevated levels of granzyme-1 and antibodies to granzyme-1 in sera of SSc patients. This enzyme is able to lyse endothelial cells possibly in association with perforin and via a programmed cell death (apoptosis) pathway.

Immunologic Aspects   Integral immunologic features of SSc include the presence of specific autoantibodies (*see* Table 91-4), infiltration of the skin by lymphocytes and macrophages, and the demonstration of abnormal amounts of certain cytokines in the blood, lungs, and dermis. Nests of lymphocytes (primarily T cells) and macrophages are found in the dermis, particularly in the deeper reticular area, where fibrosis is most intense. Subset analysis shows these infiltrating lymphocytes to be CD4$^+$ cells bearing α/β T-cell receptors.

The occurrence of antinuclear antibodies in the sera of patients with systemic sclerosis approaches 100%. All types of staining patterns may be seen, but nucleolar patterns are more specific. Associations have been made between the presence of antibodies to certain purified nuclear antigens and clinical manifestations of SSc. Antibodies to centromeres (kinetochore plates) occur in approximately 40% of patients with lcSSc, but in only 2–5% of patients with dcSSc. On the other hand antibodies to topoisomerase I (also known as Scl-70) are present much more frequently in dcSSc (30–40%). The presence of these latter antibodies is therefore also associated with rapid skin thickening, pulmonary interstitial fibrosis, and renal crisis.

Antibodies to RNA polymerase types I, II, and III are also seen frequently in dcSSc, and account for the frequent occurrence of antinucleolar ANA staining. There are marked racial differences in the occurrence of the various autoantibodies in the clinical subsets of SSc, making the regulation of expression of these specific antibodies of interest. Linkage of certain autoantibody types with specific HLA loci has been demonstrated (*see above*).

Inflammatory Aspects   SSc, with only moderate elevations of circulating acute-phase reactants, is not an overwhelmingly inflammatory condition. The only area in which polymorphonuclear leukocytes have been demonstrated to be present in increased numbers is in pulmonary lesions. When alveolar cells are obtained for analysis by bronchoalveolar lavage, increased numbers of PMNs, eosinophils, and macrophages are seen. These macrophages are activated, as evidenced by increased production of fibronectin in cell culture. Analysis of the fluid obtained by

BAL has demonstrated increased levels of several cytokines. The PMN chemoattractant IL-8 is present in increased quantities in such fluid. Cytokines that increase fibroblast proliferation (platelet-derived growth factor, PDGF) and matrix synthesis (transforming growth factor type 1, TGF-1) are also present in increased concentrations.

Systemic Sclerosis (SSc) and the Extracellular Matrix (ECM)   Many abnormalities of the ECM have been documented in SSc, and it is likely that many more will be forthcoming. Recent awareness that cells derive informational signals directly from ECM via integrins as well as from cytokines and growth factors bound to ECM has both substantially increased the momentum to define ECM components and placed ECM modular motifs in a central position in the study of cell behavior in fibrosis (Fig. 91-1). As an example, skin fibroblasts behave quite differently with regard to collagen secretion and metalloproteinase production when cultured on three-dimensional collagen lattices in contrast to monolayer tissue-culture plastic.

A detailed review of the components of the ECM is beyond the scope of this discussion. Suffice it to say that there are 19 collagens composed of 33 genes, 8 laminins, 5 thrombospondins, alternatively spliced fibronectins and cytotactins, and wide variations in the charge and size of a family of proteoglycans that have recently been completely renamed. That collagens are the most diverse of the modular protein families thus far characterized can be appreciated visually from Fig. 91-1. The common structural characteristic of collagens is the primary structure Gly-X-Y, which, by virtue of the absence of a side chain on glycine in peptide linkage, folds into a tight and strong α helix. When this helix is uninterrupted for 1000 or more residues, collagen fibrils with impressive tensile strength are formed, characteristic of skin, bone, tendon, and blood vessels. Collagens with interrupted helices and specialized globular modules may participate in other ways in ECM function. Collagens, fibronectins, and proteoglycans may interact with cells in adhesive ways, cytotactins and thrombospondins may function in antiadhesive ways. Cell–matrix interactions via a large number of integrin surface cell membrane receptors trigger signaling cascades and, via reorganization and clustering of intracellular cytoskeletal elements, can direct cell shape, movement, division, and secretion. The cell–matrix interactions of fibroblasts and endothelial cells are under intense study presently and understandings of direct relevance to SSc can be anticipated.

The SSc lesional skin fibroblast has been known since 1972 to differ from normal fibroblasts, with overproduction of collagen being the first abnormality described. Whereas its in vitro proliferative response to PDGF is less than that of control fibroblasts, it proliferates in response to TGF-β1, whereas control cells do not, and it does not see bFGF as a mitogen, whereas control cells do. When control cells are exposed to TGF-β1, they express some of the phenotypic traits of the activated SSc fibroblast, including the heightened expression of the PDGF receptors α and β.

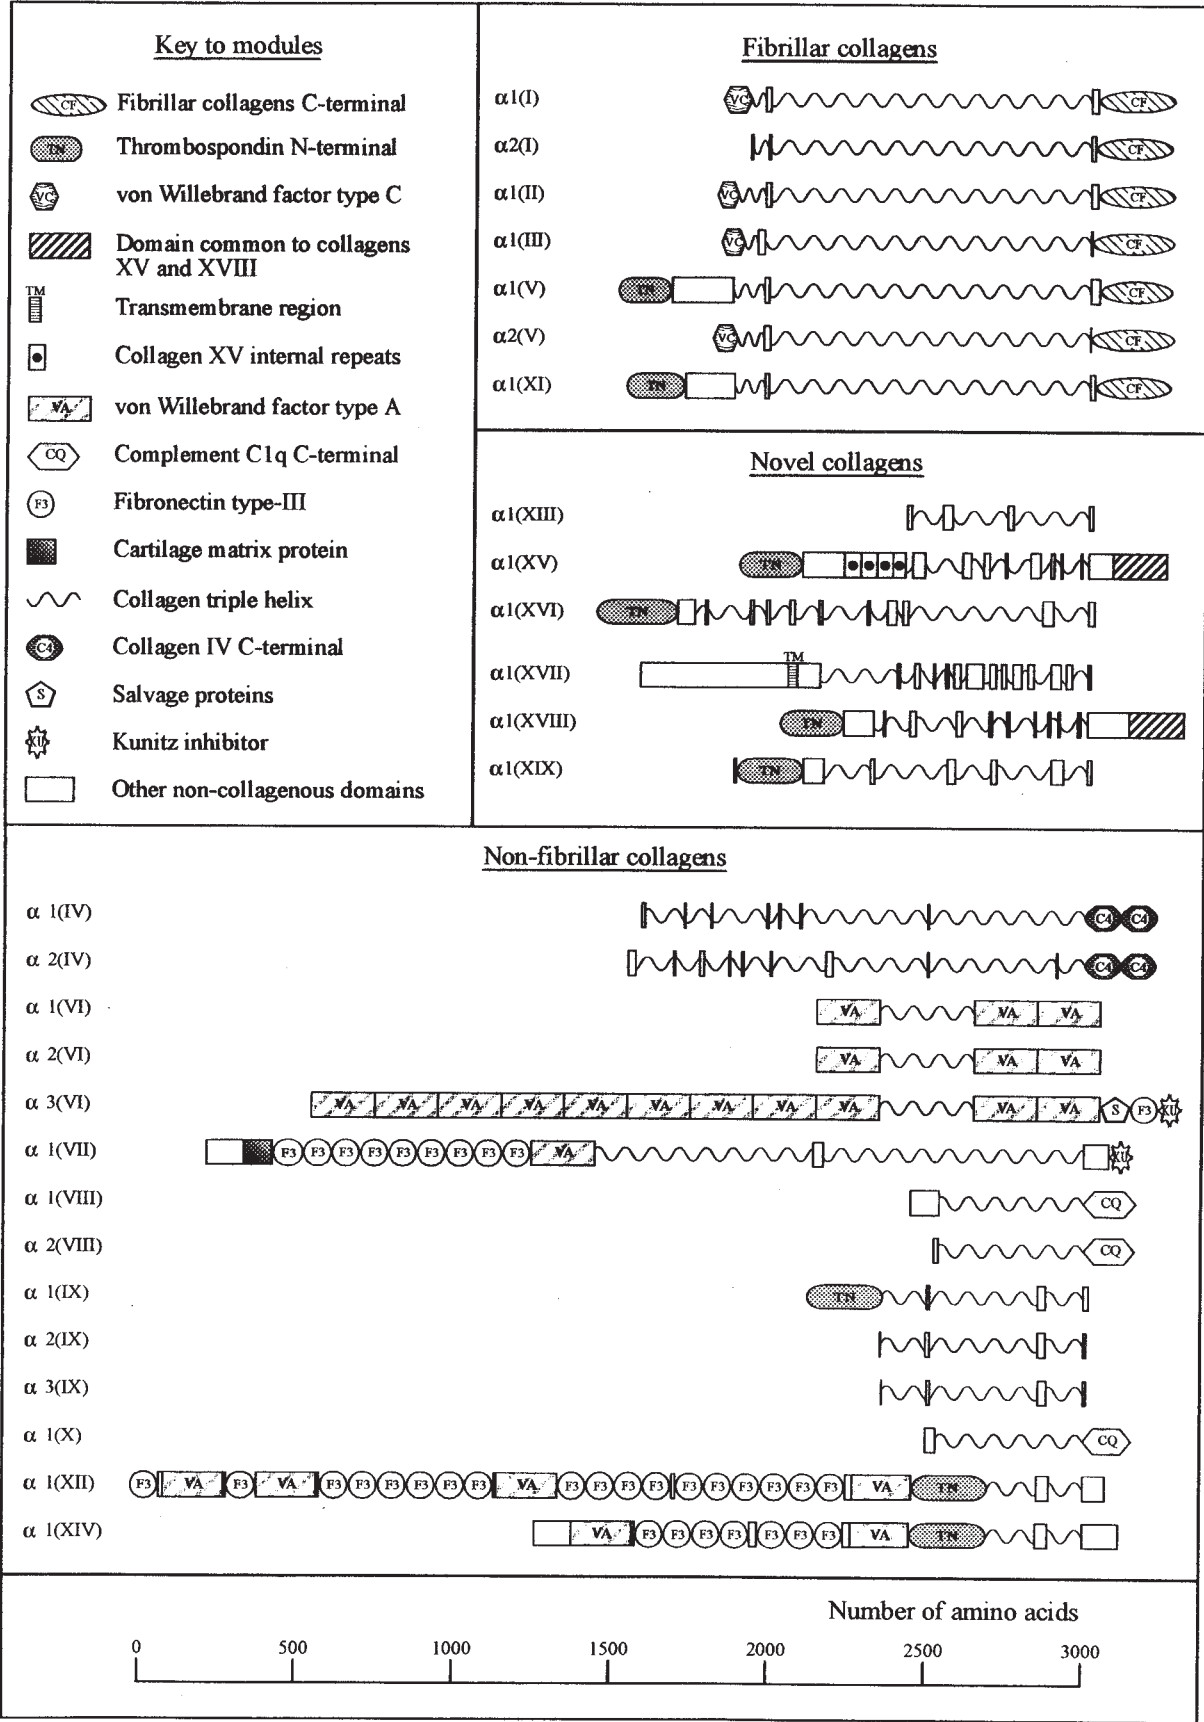
In vivo healthy skin fibroblasts rarely express collagen α1(I) mRNA but, in SSc lesions, fibroblasts in the vicinity of mononuclear-cell perivascular inflammatory infiltrates express this message. Immunolocalization studies of this same microenvironment can identify TGF-β1 and PDGF AA. It is also the site of microvascular endothelial-cell abnormalities and presumably of perivascular fibrosis as well. Using a combination of in vitro and in vivo techniques, the matrix molecules shown to be overexpressed in the Ssc microlesion are collagens type I, III, V, VI, and VII,


Figure 91-1 A graphic presentation of the diversity of collagens. (Reproduced with permission from Karger S, Basel AG. The collagen superfamily. Int Arch Allergy Immunol 1995;107:484–490.)

Endothelin
Fibroblast
Fibronectin, IL-6, VEGF (vascular endothelial growth factor)

fibronectin, and cytotactin (tenascin). Fibroblast exposure to TGF-β1 upregulates these same matrix molecules in a prolonged fashion. The data to-date suggest that the molecular site of upregulation of these matrix molecules is pretranslational in that there is an increased level of steady-state mRNA present. Evidence also exists that suggests both an increased rate of mRNA synthesis and a decreased rate of mRNA decay, in the case of the best-studied collagen, type I. Regarding mRNA synthesis, directed by 5' promoter elements, at least 4 *cis*-acting DNA response elements can be shown to bind at least three distinct protein-transcription factors, including a collagen-binding factor (CBF) binding a CCAAT motif, the ubiquitous Sp1 binding a series of G-C–rich boxes, and a c-Krox factor binding several G rich motifs. How these interactions combine to initiate transcription and which ones are critical to the fibrosis of Ssc remains to be elucidated. Nonetheless, the area of the transcriptional control of ECM synthesis, the interruption of the widespread and prolonged stimulation by TGF-β1, and ultimately the modulation of ECM production in SSc remains a potentially important area for therapeutic intervention.

Cytokines   Several cytokines have been implicated in the pathogenesis of systemic sclerosis (Table 91-5). Elevations of IL-2, IL-4, IL-6, and IL-8 have been demonstrated in the sera of patients. Both IL-2 and IL-2-receptor levels seem to mirror the activity of fibrosis that is occurring and therefore indicate involvement of the immune system. IL-2 has no direct effects on fibroblasts, but has been reported to increase TGF-β release by macrophages. Cytokines that directly affect fibroblast proliferation and matrix synthesis are involved in fibrotic lesion.

Platelet-Derived Growth Factor (PDGF)   PDGF, which exists as either homo- or heterodimers of A and B chains, is a potent mitogen for fibroblasts. Rich sources of this protein include platelet α granules and macrophages, both cell types known to be activated in SSc. PDGF α receptors, which recognize all PDGF isoforms, are increased by TGF-β in scleroderma fibroblasts but not in normal dermal fibroblasts. That PDGF AA, which signals only via α receptors, is found in scleroderma lesions makes it likely that this cytokine is important in fibroblast proliferation in systemic sclerosis. Both PDGF AA and BB are found in increased concentration in fluid removed from the lungs of systemic sclerosis patients by bronchoalveolar lavage.

Transforming-Growth Factor β (TGF-β)   TGF-β has quite contrasting effects on cells depending on cell type and on their state at the time of study. Interest in TGF-β in SSc stems from the fact that this is the most potent stimulator of fibroblast synthesis of extracellular matrix known. TGF-β is produced by megakaryo-

cytes, macrophages, and T cells, particularly TH-2 type. Whereas no increases in blood levels of TGF-β are seen in systemic sclerosis patients, other evidence implicates this cytokine in the areas of occurring lesions. *In situ* expression of TGF-β mRNA in dermal lesions has been demonstrated. As mentioned above, TGF-β causes dermal fibroblasts of scleroderma lesions to proliferate via increased expression of PDGF α receptors and response to PDGF A ligand. In the lung lesion, increases in TGF-β type 1, but not type 2, have been measured in bronchoalveolar lavage fluid and increases in TGF-β mRNA are seen in mononuclear cells obtained by this means.

Interleukin-6   IL-6, a product of macrophages and fibroblasts, has been shown to be produced in vitro by scleroderma fibroblasts at levels up to 30 times that of normal fibroblasts. Although IL-6 is a stimulator of collagen synthesis only at very high concentrations, it inhibits fibroblast synthesis of tissue inhibitor of metalloproteases (TIMP). Produced locally, IL-6 may therefore promote fibrosis by inhibiting collagenase activity.

Basic Fibroblast Growth Factor (bFGF)   bFGF, a stimulator of fibroblast proliferation, has been found in dermal lesions. Fibroblasts themselves produce bFGF and it may thus be involved in an autocrine role in fibroblast proliferation in systemic sclerosis.

Interferon-γ   A product of T cells, interferon (IFN)-γ actively suppresses fibroblast collagen synthesis. Serum levels of IFN-γ have been found to be depressed in systemic sclerosis and in vitro stimulation of peripheral blood T cells fails to elicit the increase in interferon gamma production seen in normal T cells. Therefore, a defect in T cells of systemic sclerosis patients resulting in an inability to suppress fibrosis may exist.

Interleukin-1   IL-1, primarily a product of macrophages, is able to stimulate fibroblast extracellular-matrix synthesis. Increased sensitivity of systemic sclerosis fibroblasts in culture to stimulatory effects of IL-1β has been demonstrated. There has been recent evidence that systemic sclerosis fibroblasts from clinically involved dermis are able to produce IL-1α and that this cytokine is responsible for increases in PDGF-A and IL-6 production by these cells. This intriguing possibility would link several of the abnormal cytokine productions seen in systemic sclerosis together into a pathogenetically meaningful cytokine "cascade."

Endothelin   Endothelin is the potent smooth muscle contracting peptide derived from endothelial cells. Increased blood levels of endothelin have been described in both primary Raynaud phenomenon and in SSc, and some evidence indicates that levels are further increased with exposure to cold. Elevated levels are found in patients with pulmonary hypertension and also fibrotic lung involvement. There is evidence indicating that endothelin can increase fibroblast collagen-synthetic rates, a finding that links the vascular and fibrotic lesions seen in SSc.

MANAGEMENT   Because the etiology of SSc remains so obscure, treatment is directed to each of the clinical problems presented by the disease. It is hoped that with better understanding, treatment directed at the underlying disease processes can be developed.

Skin Involvement   Because spontaneous skin softening almost always occurs with time, uncontrolled trials are difficult to interpret, and enthusiasm over proposed therapies must be tempered. There are many reports of dramatic improvements, but these therapies have often failed when studied in a prospective and randomized fashion.

D-Penicillamine is widely used to treat the dermal thickening, based on its inhibition of collagen crosslinking and facilitation of collagen degradation. Several uncontrolled studies have demonstrated improvement in the extent of skin thickening. A multicenter, randomized trial comparing high-dose and low-dose D-penicillamine is currently underway, and not until its results are known can one assuredly state that D-penicillamine is an effective therapy for SSc. If therapy with D-penicillamine is undertaken, the dose should be gradually increased to 1–1.5 g/d, a dose that must be maintained for 6 months to a year to see any clinically important improvements. Many patients experience side effects with gastrointestinal symptoms being the most common. Renal (hematuria, proteinuria) and hematological (leukopenia, thrombocytopenia) adverse reactions are of greater concern and close monitoring is required.

Immunosuppression with glucocorticoids and/or cytotoxic chemotherapy is not effective in changing the skin disease. Chlorambucil and 5-fluorouracil has been shown to be ineffective. IFN-γ, which decreases fibroblast collagen synthesis, has been reported to decrease skin thickening in patients with SSc in uncontrolled trials, but has been associated with some exacerbation of vascular problems.

Raynaud's Phenomenon (RP)   Modifications of both behavior and environment are necessary to avoid cool temperatures. β-blockers may worsen RP by allowing unopposed α-adrenergic stimulation. Behavioral therapy with biofeedback may reduce the frequency or severity of attacks, although the evidence suggests that this is more effective in primary than in secondary Raynaud's phenomenon.

Calcium-channel blockers are the most commonly used pharmacologic therapies, but there is no definitive proof of their efficacy in SSc. The sustained release form of nifedipine is prescribed most commonly. Calcium-channel blockade causes inhibition of gut smooth muscle contraction and may therefore increase esophageal reflux or delay peristalsis in the stomach or gut. Prazosin (an α-adrenergic blocker) can be used instead of, or in addition to, calcium-channel blockers. Platelet inhibitors (low-dose aspirin and dipyridamole) are used, although there is no definitive proof of their efficacy. Nitroglycerin paste can be applied at the bases of the most affected digits to promote arterial dilatation.

Stellate ganglion blockade to bring about temporary sympathectomy may greatly alleviate pain and induce vasodilatation. Infection of a digital ulcer requires local cleansing, and application of an antibacterial ointment may be helpful. Occasionally infection is so rapidly progressive or advanced to the point of osteomyelitis that therapy with parenteral antibiotics is indicated. Surgical therapy has been used to treat severe RP. Whereas cervical sympathectomy may reduce attack frequency and severity for a short time, symptoms usually recur and it is, therefore, not recommended. Digital sympathectomy has been promoted as more selective and having longer-lasting effects than cervical sympathectomy, but this procedure is still investigational. Amputation of a phalanx or digit may quickly relieve pain, and is sometimes the most effective means of dealing with infection.

Renal Involvement   The development of hypertensive renal disease in a SSc patient is a medical emergency because irreversible loss of renal function may result. The discovery of angiotensin-converting enzyme (ACE) inhibitors has changed the natural history of SSc. Any elevation in blood pressure should be taken quite seriously, and when persons who have had low-to-

normal pressures develop elevations that are still within the normal range of < 140/90 mmHg, they should be evaluated for renal disease. During the early stages of treatment, captopril rather than other ACE inhibitors is recommended because its shorter half-life allows greater flexibility in dosing. For those who remain hypertensive, captopril should be maintained and other hypotensive agents added using whatever combination of drugs allows normal blood pressures to be obtained. Antihypertensive therapy should be continued, even if renal failure ensues, since there are reports of return of sustained renal function even after dialysis.

Pulmonary Disease   No controlled, prospective trial has shown any drug to alter the course of SSc interstitial lung disease. All patients should be vaccinated for *Streptococcus pneumoniae* and influenza. Patients with severe fibrosis may benefit symptomatically from oxygen. Because fibrotic interstitial lung disease is associated with alveolar inflammation, therapy to reduce this inflammation has been undertaken in uncontrolled trials. Daily oral cyclophosphamide (100 mg/d) significantly increased the forced vital capacity (FVC) of patients with alveolitis. This treatment must be undertaken advisedly, however, as no controlled trial has been undertaken. Pulmonary hypertension remains a difficult problem in the management of SSc, and is often involved in the demise of these patients.

Pulmonary hypertension may occur either as a complication of interstitial fibrosis or as isolated pulmonary hypertension in the absence of interstitial lung disease. This latter form of severe pulmonary hypertension occurs almost exclusively in patients with limited cutaneous SSc. Echocardiography with Doppler allows estimation of peak systolic pulmonary artery pressure by a noninvasive means. Results of treatment studies of pulmonary hypertension complicating SSc have been quite variable. The long duration of pulmonary vascular disease before it becomes symptomatic leads to fixed vascular lesions that may not be amenable to vasodilation. Calcium-channel blockers may lower pulmonary artery resistance, but their effect on survival is unknown.

Cardiac Disease   Pericarditis usually responds to nonsteroidal antiinflammatory drugs or to low-dose corticosteroids. Treatment of left-ventricular dysfunction involves the use of digoxin, diuretics, and afterload-reducing agents. Long-term therapy with captopril has been shown to improve systolic and diastolic function in some patients. Nifedipine has been shown to improve myocardial perfusion and cold-induced myocardial ischemia, but no information is available on long-term clinical effects. Antiarrhythmic drugs are used to treat symptomatic ventricular arrhythmias.

Gastrointestinal Manifestations   Antireflux measures (small, frequent meals; avoiding recumbency after eating; elevation of the head of the bed) are recommended for all SSc patients because of the universal occurrence of esophageal reflux. Damage to the esophageal mucosa from acid reflux can be reduced by use of acid lowering drugs such as H_2-blockers or proton-pump inhibitors. Cisapride, which increases gastrointestinal motility by enhancing acetylcholine release at the myenteric interface, has improved upper gastrointestinal symptoms in clinical trials. Esophageal strictures are sought by barium studies and respond to dilation.

Malabsorption with diarrhea, weight loss and malnutrition, bloating, distention, and abdominal pain may result from hypoperistalsis of the small bowel. A 2-week treatment with antibiot-

ics—e.g., tetracycline, amoxicillin, or metronidazole—may help by diminishing bacterial overgrowth and relieve symptoms of recurrent diarrhea. The occurrence of pseudoobstruction is associated with vomiting and radiographic evidence of dilated bowel. Any precipitating causes (opioid narcotics, electrolyte abnormalities) should be corrected. Surgical exploration should be avoided as the outcome is usually very poor.

LOCALIZED SCLERODERMA (MORPHEA)

EPIDEMIOLOGY The incidence and prevalence of localized scleroderma are unknown, but minor types are quite common and may not come to medical attention. It occurs primarily in young adults and children, with a slight predominance in females. All races are affected. There is no known occupational or exposure risk.

CLINICAL FEATURES There are several varieties of morphea, including guttate, plaque, generalized, and linear. These can occur either singly or as several types in the same patient. Guttate morphea are small (few millimeter), oval lesions occurring on the neck and chest. Plaque morphea are a few centimeters to a few inches in diameter and can become generalized with widespread involvement. Initially lesions are erythematous or violaceous lesions that evolve into waxy, ivory-colored skin thickening with a surrounding violaceous border. If these lesions become generalized, the appearance can resemble that of systemic sclerosis, but there is no sclerodactyly, Raynaud's phenomenon, or internal organ involvement. Linear scleroderma occurs most commonly in children and appears as band-like areas of induration along a particular myotome. There is atrophy of the skin, underlying subcutaneous tissue, muscle, and even osseous involvement. When involving the face (*en coup de sabre* lesion), facial hemiatrophy may result. This lesion is similar to (or may be the same as) the Parry-Romberg syndrome. Linear scleroderma, when involving a limb, often results in shortening, severe contractures, and considerable disability.

Histologically, morphea does not differ from the findings in systemic sclerosis, with a chronic inflammatory cell infiltrate in the inflammatory border, and monotonous increase in dermal collagen.

The clinical course of most morphea is to spontaneously soften, but to leave areas of atrophy and depigmentation. Occasionally there can be complete resolution. Progression to systemic sclerosis has been reported, but is so extraordinarily rare as to be reportable. Morphea is not associated with Raynaud's phenomenon, esophageal dysmotility, interstitial lung disease, or renal involvement.

Various nonspecific immunological abnormalities have been reported in morphea, including hypergammaglobulinemia, antinuclear antibodies, anti–single-stranded DNA antibodies, antihistone antibodies, and rheumatoid factor. Systemic sclerosis specific antibodies (antitopoisomerase, anticentromere, anti-RNA polymerase) are not found in patients with linear scleroderma. Although there was initial enthusiasm, when many patients with morphea were found to have antibodies to *Borrelia burgdorferi*, that this signified the cause of morphea, later studies using PCR to search for this organism's DNA in morphea lesions have been unsuccessful. It is now felt that *Borrelia* infection plays no role in causing morphea.

GENETIC BASIS OF DISEASE The occurrence of multiple family members with localized scleroderma is very unusual. No predisposing genetic lesion or HLA type has been associated with the occurrence of lesions.

MOLECULAR PATHOGENESIS The increases in dermal collagen are of the same types seen in systemic sclerosis—I and III. Immunohistochemically determined increases in TGF-β have been described in the active margins of the lesion in close association with fibroblasts shown to be secreting procollagen. Very few other details concerning the molecules involved in pathogenesis have been described.

TREATMENT No treatment has been demonstrated to alter the course of localized scleroderma. Often morphea lesions are self-limiting, running a course from initiation to disappearance in several years. D-penicillamine has been applied to more progressive lesions, and in those individuals who may go on to generalized morphea. No controlled study regarding use of this medication has been completed. Deforming linear scleroderma may require plastic surgery. When a limb has become so deformed as to inhibit function, amputation with prosthetic replacement should be considered.

92 Muscle Development and Differentiation

Eric N. Olson

INTRODUCTION

Vertebrate species contain dozens of different skeletal muscles, each with unique positions, sizes, shapes, contractile properties, and patterns of innervation. In recent years, dramatic progress has been made toward understanding the genetic pathways that control the formation and patterning of skeletal muscle during embryogenesis. The discovery of several families of genes that act at different steps in the developmental pathway leading to skeletal muscle formation has provided a framework for understanding the complexity of this tissue and will undoubtedly yield insight into the causes of several neuromuscular disorders, as well as provide the potential for therapeutic intervention into such diseases.

REGULATION OF MUSCLE DIFFERENTIATION IN VITRO

Much of the progress in understanding muscle development can be attributed to the fact that many of the events associated with muscle differentiation in vivo can be recapitulated in tissue culture. Immortalized muscle cell lines or skeletal myoblasts isolated from embryos proliferate in vitro in the presence of fetal bovine serum and other mitogens such as fibroblast growth factor (FGF). Myoblasts are committed to the myogenic lineage, but they do not express muscle structural genes until they are forced to exit the cell cycle. Myoblast differentiation is accompanied by irreversible withdrawal from the cell cycle, fusion to form multinucleate myotubes, and expression of a large array of muscle-specific genes whose products are required for the specialized contractile, excitable, and metabolic properties of the differentiated muscle fiber.

Several early studies suggested the existence of myogenic regulatory factors with the potential to activate muscle gene expression. Experiments in which heterokaryons were formed between skeletal muscle cells and various nonmuscle cells demonstrated that muscle genes became activated in nonmuscle cell nuclei and suggested the existence of *trans*-acting factors in muscle cells that could activate muscle gene expression. Genetic evidence for such myogenic factors was provided by experiments in which the fibroblast cell line 10T1/2 was shown to form skeletal muscle following treatment with the demethylating agent 5'-azacytidine. The frequency of conversion of 10T1/2 cells to muscle (up to 50%) suggested that one gene was responsible for establishing the myogenic phenotype following its activation by demethylation. This hypoth-

esis was confirmed by DNA transfection experiments in which genomic DNA from myoblasts or 5'-azacytidine-treated 10T1/2 cells was shown to convert 10T1/2 cells to myoblasts with a frequency consistent with a single regulatory gene.

THE MyoD FAMILY OF MUSCLE-SPECIFIC TRANSCRIPTION FACTORS

The first myogenic regulatory gene to be cloned was *myoD*, which was isolated by cloning mRNAs that were expressed in myoblasts, but not 10T1/2 fibroblasts. When a cDNA clone encoding MyoD was expressed ectopically in fibroblasts, it was found to activate skeletal muscle gene expression (Fig. 92-1). Subsequently, three related genes, myogenin, Myf5, and MRF4 (also called Myf6 and herculin) were discovered. These genes, which are referred to as the MyoD family, are expressed exclusively in skeletal muscle; there is no detectable expression in cardiac or smooth muscle, despite the fact that these three muscle cell types express many of the same muscle-specific genes.

Members of the MyoD family exhibit distinct expression patterns during differentiation of muscle cells in culture. Most established muscle cell lines express either MyoD or Myf5 when they are proliferating as undifferentiated myoblasts. When induced to differentiate by exposure to growth factor-deficient medium, myogenin is rapidly upregulated immediately prior to activation of muscle structural genes. MyoD and Myf5 also continue to be expressed in differentiated myotubes. MRF4 is not expressed until late in the differentiation program.

Members of the MyoD family can induce skeletal muscle gene expression when they are introduced into a wide variety of cell types including fibroblasts, melanoblasts, chondroblasts, smooth and cardiac muscle cells, and osteoblasts. In some cell types, these factors activate the entire myogenic program, resulting in formation of multinucleate myotubes and expression of the full array of muscle-specific genes, whereas in other cell types, only a subset of muscle genes is expressed. There are other cell types, such as adipocytes, in which forced expression of the myogenic factors represses the endogenous program of cell-specific gene expression, while in other cell types the skeletal muscle program is coexpressed with the endogenous program. There are also cell types, such as hepatocytes and several types of transformed cells, in which the myogenic factors are unable to activate muscle gene expression. The failure of the myogenic factors to activate muscle gene expression in these cell types suggests either that they lack certain cofactors required by the myogenic factors or they contain inhibitors of muscle gene expression or both.
Figure 92-1 Activation of MHC expression in fibroblasts expressing exogenous MyoD. 10T1/2 fibroblasts were transfected with a MyoD expression vector. Cells were then stained using antibodies specific for MyoD (red) and myosin heavy chain (green). MyoD can been seen within the nuclei of transfected cells and myosin is expressed only in the cells that express MyoD. Figure provided by S. Tapscott, Fred Hutchinson Cancer Research Center. (*See* color insert following p. 684.)

In addition to activating the expression of muscle structural genes, members of the MyoD family regulate one anothers expression. For example, if MyoD is introduced into fibroblasts, it activates the endogenous MyoD gene as well as the myogenin and MRF4 genes. These autoregulatory interactions have been proposed as a mechanism whereby these factors amplify and maintain their expression and thereby commit cells to a myogenic fate.

THE BASIC HELIX-LOOP-HELIX FAMILY OF TRANSCRIPTION FACTORS

Members of the MyoD family share about 80% amino acid identity within a 70-amino acid segment that encompasses a region rich in basic amino acids, followed by a region postulated to adopt a helix-loop-helix (HLH) conformation in which two amphipathic α-helices are separated by an intervening loop (Fig. 92-2). Related, but more divergent, basic-HLH (bHLH) motifs are found in members of a superfamily of proteins that regulate cell proliferation and differentiation in species ranging from yeast to humans. Among these are members of the c-myc family of oncoproteins and the products of several *Drosophila* genes that regulate embryonic cell fates, including the *achaete-scute* gene products, which regulate neurogenesis, and twist, which regulates mesoderm formation.

The HLH motif mediates protein dimerization and brings together the basic regions of bHLH proteins to form a bipartite DNA binding domain that recognizes the consensus sequence CANNTG (N = any nucleotide), known as an E-box (Fig. 92-3). This DNA sequence motif is found in the control regions of numerous muscle-specific genes, where it binds the myogenic factors and mediates transcriptional activation.

The myogenic bHLH factors homodimerize inefficiently, but they readily form heterodimers with members of a family of ubiquitous bHLH proteins, known as E-proteins. There are also HLH proteins that lack basic regions and inhibit the activity of bHLH proteins by forming heterodimers incapable of binding DNA. Among this class of HLH proteins are members of the Id family.

Mutagenesis studies have revealed several functional domains in the myogenic bHLH proteins (Fig. 92-4). These factors contain transcription activation domains in their amino- and carboxyl-termini that are important for efficient activation of muscle-specific transcription. The basic regions of the myogenic factors play a dual role in the control of muscle gene expression by mediating DNA binding and by conferring muscle specificity to transcriptional activation. Fine mapping of individual amino acids in the DNA-binding domains of the myogenic factors has shown that two clusters of basic amino acids are required for binding to the E-box consensus sequence (Fig. 92-4). In addition, two adjacent amino acids, alanine-threonine, in the center of the DNA binding domains, are required for activation of muscle gene expression. These residues are conserved in the basic regions of all known myogenic bHLH proteins in species ranging from *Drosophila* and sea urchins to humans and they are absent from the basic regions of the more than 40 other bHLH proteins described to date. The specificity and conservation of these residues suggest that they represent part of an ancient mechanism for activation of muscle gene expression.

If the alanine-threonine residues in the basic region of a myogenic bHLH protein are replaced with the amino acids found at that position in the basic regions of E proteins, the resulting mutant protein will bind DNA normally, but is unable to activate muscle gene expression. Conversely, if these residues along with a third amino acid between the basic region and helix-1 of the myogenic factors are introduced in the corresponding positions in E proteins, they confer on the E proteins the ability to activate muscle gene expression.

The exact mechanism whereby amino acids in the basic region direct muscle-specific transcription is unclear. However, one possibility is that these amino acids induce an allosteric change in the myogenic factors following DNA binding, which might expose a protein interface that can interact with accessory factors required for the activation of muscle gene expression. In this regard, the crystal structure of a MyoD homodimer binding to an E-box DNA sequence has been deduced. The structure of the complex confirms that the basic region and first helix of the HLH region form a continuous *a*-helix. Alanine-threonine in the MyoD basic region lie within the major groove of the DNA binding site and are therefore inaccessible to other proteins. However, the interaction of these residues with the DNA appears to induce a conformational change in the protein, which may influence the proteins with which it can interact.

GROWTH FACTOR CONTROL OF MYOGENESIS

As in many cell types, differentiation of myoblasts is coupled to withdrawal from the cell cycle. Whereas many cell types can reenter the cell cycle when stimulated with mitogens, skeletal muscle cells lose the ability to reinitiate DNA synthesis when they differentiate and therefore become irreversibly committed to the postmitotic state. Because myoblasts express MyoD or Myf5
Figure 92-2 Diagramatic representation of the four myogenic bHLH proteins. A linear representation of each myogenic regulatory factor is shown. The basic (+++) and HLH regions are indicated. The number of amino acids in each protein is shown at the end of each box.
Figure 92-3 A Schematic representation of a MyoD/E12 hetero-dimer is shown. The basic region and helix-1 form a contiguous α-helix separated from helix-2 by an intervening loop. Each basic region recognizes half of the palindromic sequence CANNTG. E12 is represented in blue and MyoD in red. (*See* color insert following p. 684.)

(these factors are unable to induce muscle gene expression when cells are exposed to growth factors, however), there must be post-translational mechanisms that inhibit their activities. There appear to be multiple mechanisms whereby growth factors prevent myogenic bHLH proteins from activating muscle-specific genes. For example, Id proteins are expressed at high levels in proliferating undifferentiated myoblasts and are downregulated when myoblasts are induced to differentiate. Because Id proteins dimerize preferentially with E proteins, they sequester the dimerization partners for myogenic bHLH proteins in myoblasts. The down-regulation of Id has been proposed to release E proteins so that they can dimerize with myogenic bHLH proteins and activate muscle-specific genes. Consistent with this model, forced expression of Id from an expression plasmid is sufficient to prevent myoblast differentiation under conditions that would normally promote differentiation. In the embryo, Id expression is also downregulated in regions of skeletal muscle differentiation.

The nuclear oncogene products Fos and Jun, which are upregulated by mitogens, can also block muscle differentiation by interfering with the activities of myogenic bHLH proteins. The inhibitory activities of Fos and Jun appear to be mediated by competition with the myogenic factors for interaction with a common cofactor required for myogenesis and by direct interactions with the myogenic factors.

Members of the MyoD family have also been shown to be targets for several protein kinases. Protein kinase C, which is activated by growth factors, can substitute for growth factors and block myoblast differentiation. The threonine residue in the center of the DNA-binding domains of the myogenic factors, which mediates muscle-specific gene activation, has been shown to be efficiently
Figure 92-4 Schematic representation of the myogenin protein. Myogenin is a 224-amino acid protein with the bHLH motif near the center. The 12 amino acids within the basic region are required for sequence-specific DNA binding in conjunction with bHLH motif. The alanine-threonine in the center of the basic region are conserved in and specific to all members of the MyoD family and are important for activation of muscle-specific transcription. This threonine is also a protein kinase C phosphorylation site, which inhibits DNA binding when phosphorylated. S, S/T, serine- and serine/threonine-rich regions, respectively.

phosphorylated by PKC in vitro and in vivo. In the case of myogenin, this phosphorylation prevents DNA binding, presumably because it introduces a negative charge into the center of the DNA-binding domain, resulting in electrostatic repulsion from the DNA. FGF can induce phosphorylation of this threonine in cultured cells, resulting in repression of myogenin's ability to activate muscle gene expression. The ability of this threonine to serve as a target for growth factor-dependent phosphorylation pathways that block myogenesis demonstrates that this single amino acid plays a dual role in the control of muscle development; it is structurally important for transcriptional activation, and it serves as a target for growth factor signal transduction pathways under control of PKC.

Type-β transforming growth factor (TGF-β) also inhibits muscle differentiation by blocking the activities of the myogenic factors. In myoblasts exposed to TGF-β, myogenic bHLH proteins are expressed, and they can bind to their target DNA sequences associated with muscle-specific genes but are unable to activate expression of those genes. It has been proposed that TGF-β interferes with the expression or activity of a cofactor required by the myogenic factors to activate myogenesis.

The linkage of muscle differentiation to cell cycle withdrawal suggests that the cell cycle machinery interfaces with the mechanism for muscle gene activation. The retinoblastoma protein (Rb) has been shown to be an important regulator of cell cycle progression. Rb is a nuclear phosphoprotein that is phosphorylated in a cell cycle-dependent manner. In cycling cells, Rb is phosphorylated in a specific domain known as the "pocket," whereas in growth-arrested cells Rb is dephosphorylated. When quiescent cells are stimulated to reenter S phase, Rb becomes phosphorylated during the G1/S phase transition prior to initiation of DNA synthesis. The pocket of Rb interacts with a variety of nuclear proteins to control cell cycle progression. Among these is the transcription factor E2F, which activates the expression of several genes involved in cell proliferation. Binding of E2F to dephosphorylated Rb inactivates E2F and results in a block to proliferation (Fig. 92-5). Conversely, phosphorylation of Rb releases E2F so that it can activate cell growth. The oncoproteins encoded by several DNA tumor viruses, such as SV40 large T antigen and adenovirus E1A, also bind to the pocket of Rb, which prevents interaction between Rb and E2F, resulting in uncontrolled proliferation. These oncogenes are potent inhibitors of myogenesis and when expressed in terminally differentiated myotubes can lead to reinitiation of DNA synthesis.

MyoD has also been shown to bind to the pocket of dephosphorylated Rb. This interaction requires the basic region and first helix of MyoD and is dependent on the alanine-threonine residues in the basic region that are required for activation of muscle gene expression. Because MyoD and E2F bind the same region of Rb, they must interact with separate molecules of Rb. Exactly how MyoD binds DNA and Rb simultaneously is unclear. The role of Rb in the MyoD-DNA complex also remains to be determined.

Rb is upregulated during myogenesis and is required for irreversible exit of muscle cells from the cell cycle. Myoblasts lacking Rb are able to form myotubes and express muscle-specific genes, but they do not irreversibly exit the cell cycle and can resynthesize DNA in response to mitogenic stimulation.

The pocket of Rb is phosphorylated by cyclin-dependent protein kinases (CDKs). The CDKs are expressed constitutively throughout the cell cycle but are activated by association with regulatory proteins called cyclins. Cyclin D1 is induced during the G1 to S phase transition and activates CDK4, resulting in phosphorylation of Rb. Forced expression of cyclin D prevents activation of muscle gene expression by MyoD, presumably because it leads to inactivation of Rb, although a more direct role of the cyclin D1/CDK4 complex in phosphorylating MyoD has not been ruled out.

There is also a family of CDK inhibitors (CKIs) that act as inhibitors of cell growth by blocking CDK activity. One of these CKIs, called p21/WAF1/CIP1, is upregulated during myogenesis and is likely to play a role in locking cells out of the cell cycle. When CKI is expressed in proliferating myoblasts, it can inhibit growth and induce muscle differentiation even in the presence of high concentrations of mitogens (Fig. 92-5); p21 is also expressed in differentiating muscle cells during embryogenesis. Upregulation of p21 expression is also observed in several differentiated cell types in the embryo, suggesting it may be part of a common mechanism linking cell cycle withdrawal to activation of cell differentiation.

EMBRYONIC ORIGINS OF SKELETAL MUSCLE

The formation of skeletal muscle during embryogenesis involves the commitment of mesodermal stem cells to the skeletal muscle lineage and the subsequent differentiation of myoblasts to form multinucleate myotubes, which mature into skeletal muscle fibers. Skeletal muscle is derived from the somites, which form in a rostral-to-caudal gradient by segmentation of the paraxial mesoderm along the neural tube (Fig. 92-6). Newly formed somites
Figure 92-5 Model depicting the interaction between the cell cycle machinery and the myogenic regulatory pathway. MyoD or Myf5 are expressed in myoblasts and induce the expression of the CDK inhibitor p21 in the absence of growth factors. p21 induces growth arrest, which results in myogenin expression. Myogenin in turn activates muscle differentiation. Growth factor signals induce cyclin D1, which activates CDK4, resulting in phosphorylation of the Rb pocket, as well as inhibition of MyoD function. Phosphorylated Rb is unable to bind E2F and is therefore inactive as a growth suppressor. In the absence of growth factor signals, Rb is dephosphorylated and binds to E2F. E2F normally activates expression of genes required for cell proliferation, but it is inactivated when bound to Rb.
Figure 92-6 Diagrammatic representation of somite maturation. Schematic representation of an early chick embryo is shown on the left. Somites form in a rostral-to-caudal progression by segmentation of the segmental plate mesoderm. Right: cross-sections of the embryo at the indicated level. **(A)** Paraxial mesodermal cells in the segmental plates have not yet formed somites. **(B)** Newly formed somites appear as epithelial spheres. **(C)** Immature somites have become compartmentalized to form the dermamyotome and sclerotome. **(D)** Mature somites have formed the dermatome, myotome, and sclerotome.
Figure 92-7 Expression pattern of a *myogenin-lacZ* transgene in an 11.5-day mouse embryo. The *myogenin* promoter was linked to a β-galactosidase reporter gene and introduced into transgenic mice. The expression of β-galactosidase activity was detected by a colorimetric assay and is shown in blue. The expression pattern of the transgene is identical to that of the endogenous gene. (*See* color insert following p. 684.)

appear as an epithelial sphere, which subsequently becomes compartmentalized to form the dermamyotome and the sclerotome. The sclerotome gives rise to the ribs and vertebrae. The dermamyotome gives rise to the myotome and dermatome, which form axial muscles of the back and the dermis, respectively. Myf5 is the first member of the MyoD family to be expressed during mouse embryogenesis, appearing in the somite at embryonic day 8 (E8). Myogenin transcripts appear in the myotome by E8.5 and MRF4 and MyoD are expressed at E9 and E10.5, respectively.

Muscle cells in the limbs arise from cells that emigrate from the ventrolateral edge of the dermamyotome. These migrating cells are committed to the myogenic lineage, but they do not express the myogenic bHLH factors until they reach the limbs. The homeobox gene *Pax3* is expressed in the migrating myogenic precursor cells. Evidence that Pax3 is involved in migration or commitment of these cells to the myogenic lineage has been provided by analysis of a mouse mutant called *Splotch*. The *splotch* mutation maps to the *Pax3* gene and results in the absence of limb muscles. Pax3 may mediate activation of MyoD and Myf5 in response to muscle-inducing signals from overlaying ectoderm. Interestingly, a chromosomal translocation resulting in structural rearrangement of the human *Pax3* gene has been associated with alveolar rhabdomyosarcoma, a malignant tumor of skeletal muscle (*see* Chapter 3).

Whereas limb muscles are derived from myogenic precursor cells that migrate from the ventrolateral edge of the dermamyotome, the axial muscles of the back are derived from the myotomal compartment of the somites. The neural tube and notochord have been shown to play important roles in somite maturation by serving as a source for signaling molecules that induce patterning of the somites. In the absence of neural tube, the myotome fails to form. In contrast, the formation of limb muscles is independent of the neural tube or notochord.

Several of the myogenic bHLH genes have been analyzed for *cis*-acting DNA sequences that direct expression in the early somites and subsequently during skeletal muscle formation. The best characterized of these genes is *myogenin*, which is controlled by DNA sequences in the proximal promoter region. When these sequences are linked to the β-galactosidase gene as a marker and are introduced into transgenic mice, they direct the expression of β-galactosidase in the exact pattern as the endogenous *myogenin* gene (Fig. 92-7). Within the *myogenin* gene control region is an E-box that binds the myogenic bHLH proteins with high affinity and a binding site for the myocyte enhancer binding factor-2 (MEF2) family of transcription factors. Together, these two families of regulators control the expression of myogenin in the somites and limb buds.

A GENETIC PATHWAY FOR2 MUSCLE DEVELOPMENT REVEALED BY GENE TARGETING IN TRANSGENIC MICE

To determine the specific roles of the myogenic bHLH genes in muscle development in vivo, these genes have been deleted from the genome of transgenic mice by homologous recombination. Remarkably, mice lacking MyoD are fully viable and show no obvious muscle abnormalities. The only apparent consequence of *MyoD* inactivation is a twofold increase in expression of Myf5. Paradoxically, mice homozygous for a null mutation of *Myf5* also develop normal skeletal muscle, but die at birth because of the absence of ribs, which results in an inability to breathe. It is unclear why Myf5, which is expressed exclusively in skeletal muscle cells, affects the formation of ribs, which are derived from the somite. One possibility is that Myf5 controls the expression of growth factors or extracellular matrix molecules by muscle cells, which are involved in regulating the behavior of adjacent rib precursor cells in the somite. When both *MyoD* and *Myf5* are inactivated in the same animal, there is a complete absence of skeletal muscle and there are no detectable myoblasts. These findings suggest that MyoD and Myf5 play overlapping roles in the generation of myoblasts. This type of genetic redundancy could occur if MyoD and Myf5 were expressed in the same cells or if they were expressed in separate cells, either of which could support normal muscle development if the other cell population were eliminated. When lacZ expression is driven by the Myf5 locus in Myf5 null embryos, muscle progenitor cells migrate aberrantly. Thus, Myf5 protein appears to be necessary for cells to respond correctly to positional cues and to adopt a myogenic fate. The phenotype of mice lacking myogenin suggests that myogenin acts in a genetic pathway downstream of MyoD and Myf5. In myogenin-null mice, myoblasts are normally specified and positioned, but there is a near-complete absence of differentiated skeletal muscle fibers. The undifferentiated myoblasts that populate the presumptive muscle forming regions of myogenin-null mice express MyoD and Myf5, indicating that these myogenic factors do not require myogenin for their expression and suggesting that they cannot direct the formation of normal skeletal muscle in the absence of myogenin.

During normal muscle development, myogenin is downregulated at birth as MRF4 becomes upregulated to high levels. MRF4 is not expressed above background levels in myogenin-null mice, which suggests that it lies downstream of myogenin in the
Figure 92-8 The genetic pathway for skeletal muscle development. According to this model, either MyoD or Myf5 become expressed when mesodermal precursor cells from the somite become committed to the myogenic lineage. Myoblast-specific genes are regulated by MyoD and Myf5. When the extracellular concentration of growth factors is reduced, MyoD or Myf5 activate the expression of myogenin, which in turn activates myotube-specific genes. Myogenin is normally downregulated when MRF4 is upregulated after birth. In MRF4-null mice, myogenin continues to be expressed at a high level, suggesting that MRF4 is normally required for its downregulation.

myogenic pathway. MRF4-null mice have normal skeletal muscle and are fully viable. However, myogenin is overexpressed in these mice, which suggests that it may compensate for the lack of MRF4. This upregulation of myogenin in the absence of MRF4 also suggests that MRF4 is required for the downregulation of myogenin that normally occurs in postnatal skeletal muscle.

Together, the results of gene knockout experiments suggest that muscle cell determination and differentiation are controlled by the type of genetic cascade shown in Fig. 92-8.

MEF2 FACTORS AND MYOGENESIS

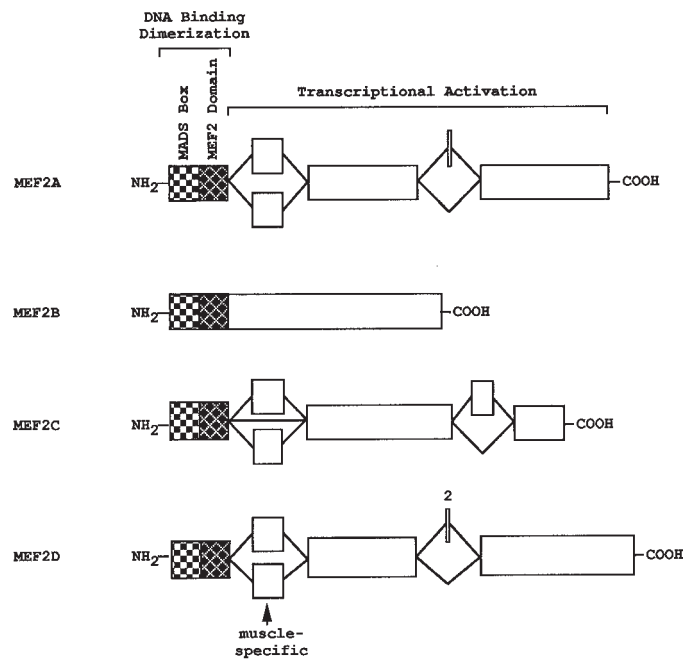
The majority of skeletal muscle genes contain E-boxes in their control regions and are therefore probably directly activated by the myogenic bHLH factors. However, there are also skeletal muscle genes that lack E-boxes. Many of these genes are controlled by the myogenic bHLH factors through a cascade of events in which the myogenic factors induce the expression of intermediate regulators, which in turn activate muscle-specific genes. MEF2 proteins are among these intermediate regulators. MEF2 factors are unable to activate muscle gene expression alone, but they potentiate the transcriptional activity of bHLH proteins. This potentiation appears to be mediated by direct interactions between the DNA-binding domain of these different types of transcription factors. The MEF2 factors belong to the MADS box family of transcription factors, named for MCM1, which regulates mating type-specific genes in yeast, Agamous and Deficiens, which act as homeotic genes to control flower development in plants, and Serum Response Factor (SRF), which controls several serum-inducible and muscle-specific genes. There are four MEF2 genes in vertebrates: MEF2A,-B,-C, and -D (Fig. 92-9). The proteins encoded by these genes are nearly identical within the MADS domain, which is located at their amino-termini. The MADS domain mediates homo- and heterodimerization and DNA binding to the sequence CTA(A/T)$_4$TAG, which is found in the control regions of nearly every skeletal as well as cardiac muscle gene. Immediately adjacent to the MADS domain is a region known as the MEF2 domain, in which the MEF2 factors also share extensive homology. The function of the MEF2 domain has not yet been determined. The carboxyl-termini of the MEF2 factors are required for transcriptional activation and are subject to complex patterns of alternative splicing, which generates enormous complexity of this family.


Figure 92-9 Diagrammatic representation of the proteins encoded by the four MEF2 genes. A linear representation of each MEF2 factor is shown. The MADS and MEF2 domains are indicated and alternative exons are shown.

In addition to regulating muscle structural genes, MEF2 factors have been shown to regulate the myogenic bHLH genes. The promoters of the myogenin, MyoD, and MRF4 genes have been shown to contain MEF2 sites that are essential for transcription of these genes in vivo and in vitro. During mouse embryogenesis, the MEF2 factors are expressed in the somite myotome after Myf5 and myogenin, which suggests that they do not play a role in the initial activation of these genes, but they are likely to be required for amplification and maintenance of the expression of these genes once their expression has been initiated.

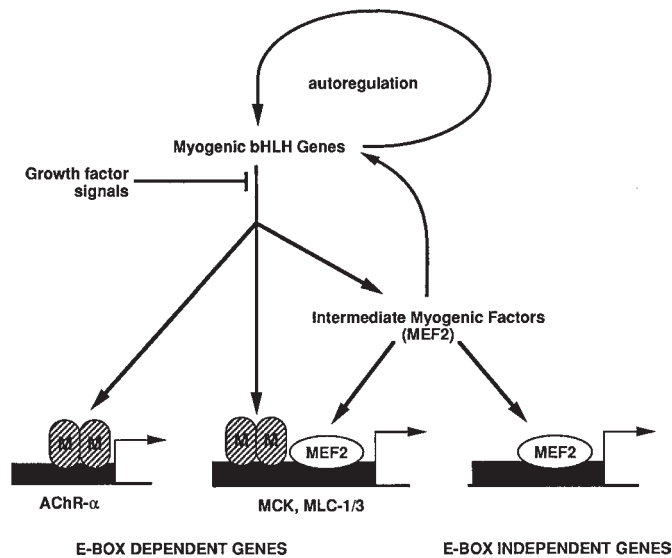
MEF2 expression can be induced in nonmuscle cells by forced expression of myogenic bHLH proteins, which suggests that the


Figure 92-10 Activation of muscle gene expression by myogenic bHLH and MEF2 factors. Members of the MyoD family positively autoregulate their own expression and directly activate transcription of muscle-specific genes containing E-boxes in their control regions. MEF2 factors are induced in response to myogenic bHLH proteins and can in turn activate the expression of muscle-specific genes that lack E-boxes in their control regions. MEF2 proteins also bind the control regions of several myogenic bHLH genes and therefore participate in a positive feedback loop that amplifies and maintains the myogenic program. Myogenic bHLH proteins are shown in black, designated M.

Mef2 genes lie in a genetic pathway downstream of the myogenic bHLH genes. However, forced expression of MEF2 in fibroblasts has been shown to induce the expression of the myogenic bHLH genes and to activate muscle differentiation. This suggests that MEF2 factors and myogenic bHLH proteins function within a complex regulatory network in which members from either family of factors can autoregulate one another and crossregulate the other family members (Fig. 92-10). In this way, these two families of regulators reinforce one another's expression and drive cells toward differentiation.

The four *Mef2* genes are also expressed at the earliest stages of heart development, as well as in smooth muscle cells, suggesting that MEF2 factors may regulate muscle gene expression in multiple muscle cell types. The functions of MEF2 have been analyzed genetically in *Drosophila*, which contains only a single *Mef2* gene, called *D-mef2*, which encodes a protein that is virtually identical to the vertebrate MEF2 proteins in the MADS and MEF2 domains. The *Drosophila* MEF2 protein also binds the same DNA sequence as the mammalian factors and can activate transcription through the MEF2 site in mammalian cells. Like its vertebrate relatives, D-MEF2 is expressed specifically in myogenic precursors and their descendants during embryogenesis. *Drosophila* embryos lacking *D-mef2* contain myoblasts that are normally specified and positioned, but these cells are unable to differentiate. The severe muscle defect in these mutant flies suggests that *Mef2* provides a function required for activation of muscle gene expression in multiple muscle cell types and suggests that the genetic functions of *Mef2* have been conserved since flies and humans evolved from a common ancestor over 600 million years ago.

RELATIONSHIP OF SKELETAL MUSCLE TO OTHER TISSUES

There are several reasons to expect that networks of cell type-specific bHLH proteins may control cell determination and differentiation in cell types other than skeletal muscle. The presence of E-boxes in the control regions of numerous tissue-specific genes suggests that these genes are controlled by specific bHLH proteins. The ubiquitous expression of E-proteins also suggests the existence of cell type-specific dimerization partners for these proteins. Id proteins are also expressed in many types of undifferentiated cells. Indeed, in recent years, several cell type-specific bHLH proteins have been identified in *Drosophila* and vertebrate species. Further investigations into their mechanisms of action seems likely to reveal fundamental mechanisms for the control of tissue-specific gene expression during development.

93 Skeletal Muscle Structure and Function

Henry F. Epstein

INTRODUCTION

Skeletal muscle provides unparalleled examples of the interrelationships between structure and function in a biological tissue. Moreover, recent advances in molecular genetics of both humans and experimental organisms have provided models of the perturbation of structure and function in inherited disease. Three distinct systems of molecular machinery are organized to interact with one another to produce a normally contracting muscle:

1. The sarcomere with its interdigitating arrays of protein filaments that actually generate tension and perform work.
2. The sarcoplasmic reticulum and transverse-tubule system with their specialized membranes that couple the electrical signals arising from neuronal excitation with the contraction of the sarcomeres.
3. The membrane-cytoskeleton system that anchors the other two systems to the plasma membrane and to the extracellular protein matrix.

Remarkably, each of these systems is not only important for understanding muscle physiology but contains molecules whose genetic alteration is responsible for at least one specific human disease.

MYOFIBRIL STRUCTURE AND ASSEMBLY

THE SARCOMERE   Skeletal muscle is composed of long fibers that were formed by the fusion of committed cells during differentiation. Each multinucleated fiber contains many microfibers or myofibrils that may be considered the units for muscle contraction. Each myofibril contains repeating assemblies of myosin and actin filaments called sarcomeres (Fig. 93-1). The sarcomeres are the physical basis of the alternating dark and light bands seen in polarized light microscopy that give striated muscle its name.

The Myosin Filament   Myosin is the principal protein of the thick or myosin filaments of skeletal muscle. The sarcomeric myosin molecule of approximately 500,000 mol wt was the first multifunctional protein to be recognized, consisting of two globular head regions of about 115,000 mol wt each and a long rod-like tail region comprising the rest of the molecule. Each myosin molecule contains three pairs of distinctly encoded polypeptide chains: two heavy chains, two regulatory light chains, and two essential light chains. One of each kind of light chain and the globular

portion of each heavy chain constitute each myosin head. The myosin rod contains the α-helical regions of both heavy chains supercoiled about each other.

About 300 myosin molecules assemble to form each myosin filament. The assembly has several interesting structural features. The filament is bipolar, divided in half along its long axis by a twofold axis of symmetry. In the central region, rods of myosin molecules from each half pack with another in an antiparallel manner. These interactions may represent the first steps in the assembly of the filaments. On each side of this zone, successive myosin molecules pack in parallel, staggered by about 14.5 nm, to form a right-handed helix. Myosin assembly continues until an exact filament length, 1550 nm, is reached, and then stops abruptly. This precise regulation of myosin assembly is not well understood either in molecular or physical–chemical terms.

Several additional proteins are capable of complexing with myosin and become associated with the myosin filaments. The proteins C protein and titin are among the best studied examples. The 140-kDa C protein binds to seven sites in each half-filament. These sites are separated by approximately 44 nm, skipping two myosin repeats. This observation implies that different myosins must be in nonequivalent environments within the filament. Titin is a very large (3000-kDa) protein that creates its own filament which serves as a bridge between the myosin filament and the Z line. Titin shares many structural features with C protein, including myosin binding sites, and contains a protein kinase domain with potential specificity toward myosin light chains. Other titin domains appear to form elastic springs and interact with the Z structures. Myosin filaments are separately anchored by M structures (*see below*).

The Actin Filament   Actin is the principal protein of the thin or actin filaments of skeletal muscle. The actin polypeptide is 42 kDa, but it can reversibly polymerize to form long right-handed double helical filaments approximately 1.0 nm long. The assembly is coupled to the hydrolysis of ATP. The three-dimensional structure of the actin monomer has been determined, and it is a bilobed structure of 7 nm long, oriented in the direction of the polar filament axis (Fig. 93-2). The pitch of the filament axis is 36 nm with seven actin monomers per turn in each strand.

Two additional proteins are major components of actin filaments, tropomyosin and troponin. Tropomyosin is a dimer of 35-kDa polypeptides that may be identical or closely similar isoforms. The two polypeptides are highly α-helical and supercoil about one another in a very similar manner to the coils of myosin rods. Tropomyosin dimers bind to the deep groove on either side
Figure 93-1   Sarcomere of skeletal muscle. Note the thick filaments that are crosslinked at the M line and thin filaments that are crosslinked at the Z line. The M and Z lines are anchored by the cytoskeleton. The vertical lines visible on the thick filaments represent the positions of myosin heads (fine lines) and of myosin-associated C-type proteins (heavier lines at every third fine line). (Courtesy of Professor Hugh E. Huxley.)

of the actin helix. Troponin is a complex of three distinct polypeptides: troponin-T, troponin-I, and troponin-C. Troponin-T, 37 kDa, is elongated and interacts with tropomyosin. Troponin-C, 18 kDa, binds to calcium and is highly similar in three-dimensional structure to other small calcium-binding proteins, including calmodulin, parvalbumin, and the regulatory myosin light chains. Troponin-I, 24 kDa, is necessary for the formation of a functional complex with troponins T and C.

The M and Z Structures   Each sarcomere contains multiple myosin and actin filaments, each kind aligned in a regular array. Within each array, the filaments are in register without any stagger and are parallel to one another. The myosin filament array is central and is flanked on each side by actin filament arrays. The symmetry of the sarcomere is similar to that of the bipolar myosin filament.

The precise alignments of these arrays require additional structures to crosslink the filaments. The myosin filaments are crosslinked in their central zones by M structures. Myomesin, a homolog of C protein and titin, is part of the M structure and is a 165-kDa myosin-binding protein. The actin filaments are crosslinked by Z structures at their distal ends. Alpha-actinin, a dimer of 100-kDa polypeptides, is an actin-binding protein, which can crosslink filaments and is a major component of the Z structure. Cap Z protein is also found in the Z structures and interacts with actin.

It is likely that more proteins will be discovered in the sarcomere that function in the assembly or alignment of the myosin and actin filaments.

THE SARCOPLASMIC RETICULUM AND TRANSVERSE TUBULE SYSTEM   Because skeletal muscle fibers are large multinucleated syncytia up to $100\,\mu M$ in diameter and millimeters to centimeters in length, a specialized membrane system, the transverse tubules and sarcoplasmic reticulum, couples the depolarizing signal originating from motor neurons to each of the myofibrils, even those deep within the fibers. For each of the myofibrils within the fibers and for each sarcomere unit of the myofibrils, there is a sleeve of membrane, the sarcoplasmic reticulum, which is connected via the transverse tubules to the outer plasma membrane of each fiber.

The Calcium Pump   The calcium pump molecule, a 115-kDa protein, is the principal protein of the sarcoplasmic reticulum (SR). This molecular pump translocates calcium from the myofibril to the lumen of the SR. Two calcium ions are translocated per ATP

Figure 93-2   Structure of a thin filament with actin and tropomyosin present that has been saturated with myosin heads (S1 fragments). Note the helical arrangements of the proteins (From Stryer L. Biochemistry, 4th ed., New York: W H Freeman, after drawing by Drs. Ronald Milligan and Paula Flicker, with permission.)

hydrolyzed by the pump. The active intermediate of the pump molecule is phosphorylated. The functioning of the pump is determined by the myofibrillar calcium concentration, the availability of ATP, and the sequestering capacity of the SR. This latter function relies on the 55-kDa protein calsequestrin, which binds 40–50 calcium ions at the relatively low affinity of 1 m*M*.

The Calcium-Release Channel   The calcium-release channel, also known as the ryanodine receptor, because the binding of that drug was critical to the original identification, is a giant oligomeric molecule composed of four 565-kDa subunits (Fig. 93-3). These channel complexes have multiple transmembrane domains that span the junctional sarcoplasmic reticulum membranes and foot domains that extend into the lumen between the transverse tubules and the sarcoplasmic reticulum. Additional proteins, including a 95-kDa junctional protein, may be important for the interaction of the calcium release channels and the voltage-sensitive channels of the transverse tubules.

Voltage-Sensitive Channel   The voltage-sensitive channel of the transverse tubules is a multisubunit protein that was isolated through its interaction with the drug dihydropyridine. It was originally termed the dihydropyridine receptor and is also called the voltage sensor. The α1-subunit has a mass of 212 kDa and may be
Figure 93-3 Interaction of the calcium release and voltage sensitive channels. The voltage-sensitive or sensor channel with its multiple subunits spans the transverse tubule (t-tubule) membranes and may interact with both the extracellular and cytoplasmic compartments. The calcium-release channel with its four giant subunits spans the sarcoplasmic reticulum (SR) membranes and may interact with the cytoplasm and the lumen of the SR. The voltage sensor and calcium-release channels are shown physically in the SR lumen. (Courtesy of Professors Susan L. Hamilton and Wah Chiu.)

proteolytically cleared to a 175-kDa form. The higher molecular weight form is activated by phosphorylation, whereas the smaller form has lost three phosphorylation sites and the related activation. Additional 15-kDa $\alpha2$, 55-kDa β, 30-kDa γ, and 27-kDa ϵ subunits complex with the $\alpha1$ protein. The γ-subunits are glycoproteins. A 95-kDa junctional triadic protein may be necessary for functional interactions between the tubular voltage-sensitive channel and the reticular calcium release channel (Fig. 93-3).

An interesting property of the tubular channel is that it permits calcium influx from extracellular fluids. It must be emphasized that this calcium is not directly involved in the release of calcium from the sarcoplasmic reticulum nor the subsequent activation of contraction.

THE MEMBRANE CYTOSKELETON SYSTEM The regular organization of myofibrils, sarcoplasmic reticulum, and transverse tubules in skeletal muscles suggest the existence of an underlying framework. Furthermore, the contractile action of the myofibrils necessitates their anchoring to specific sites on the plasma membranes of their muscle fibers so that the force that they produce is transmitted to the tendons and then to bone. Both of these requirements may be met by the network of protein assemblies called the membrane cytoskeleton system. The importance of this system to muscle function is emphasized by the fact that there are at least three independent membrane associated systems that anchor the actin cytoskeleton of muscle. These systems, named after the first of their constituent proteins to be identified, include the dystrophin, spectrin, and integrin-based systems.

The Dystrophin System The dystrophin system was discovered by its alteration in Duchenne-Becker muscular dystrophy. Dystrophin is actually a family of protein isoforms that are produced by alternative splicing of the transcript or alternative starts of transcription of the Duchenne genetic locus. The 427-kDa isoform functions as an integral part of a membrane-cytoskeleton system in skeletal muscle.

Muscle dystrophin is actually a member of a larger superfamily of proteins that includes α actinin and the spectrins. These proteins share an actin-binding domain near their amino terminals and a long coiled-coil rod domain. Nearer the carboxyl terminal, dystrophin has a special cysteine-rich domain and then a separate carboxyl-terminal domain.

The cysteine-rich domain is responsible for anchoring dystrophin to a complex of transmembrane glycoproteins including the 25-kDa dystrophin-associated protein, the 35- and 43-kDa dystrophin-associated glycoproteins, the 50-kDa glycoprotein adhalin, and the 43-kDa β-dystroglycan (Fig. 93-4). This complex in turn binds the extracellular 156-kDa glycoprotein α-dystroglycan, which in turn binds the 40-kDa muscle-specific laminin isoform merosin. As other laminins, merosin is a component of the extracellular basal lamina and binds to lung fibrillar protein assemblies of the extracellular matrix.

The carboxyl-terminal domain interacts with a complex of 50- to 60-kDa cytosolic proteins: α, $\beta1$, and $\beta2$ syntrophins. The syntrophins also bind to utrophin, a dystrophin homolog that may take part in a fourth membrane-cytoskeletal system and may functionally link the two systems.

The Spectrin System The earliest membrane-cytoskeletal system to be discovered was the spectrin-based complex, originally in red blood cell membranes washed free of hemoglobin or ghosts (hence spectrin-ghost protein). Spectrin exists as a dimer of an ubiquitous 284-kDa α spectrin isoform and a 270-kDa β spectrin. The β spectrin amino-terminal domain, homologous to those of α actinin and dystrophin, binds actin filaments. Both spectrin subunits contain the characteristic, long, coiled-coil rod domain, and β spectrin contains a specific domain in the rod near the carboxyl terminal that binds the 215-kDa transmembrane protein ankyrin. A muscle-specific isoform is produced by alternative splicing in the carboxyl-terminal domain. Spectrin, ankyrin, and various cytoskeletal proteins are located at specific sites on the plasma membrane including costameres which are aligned with the myofibrils, and triadic junctions (and thus appear striated) and adhesion sites near muscle-tendon junctions.

The Integrin System The integrins are a large family of protein isoforms that form tissue-specific complexes. They are transmembrane proteins that bind a variety of extracellular matrix proteins including various collagen isoforms. The integrins do not directly interact with the actin cytoskeleton, but are functionally linked to the protein vinculin and the cytoskeletal α-actinin isoform that binds actin filaments.

In the experimental organisms, *Caenorhabditis elegans* and *Drosophila*, muscle-specific β integrin isoforms are localized near the sites of apposition of Z-band-like structures and the plasma membrane. Null or "knockout" mutations of this β integrin produces a lethal disruption of membrane and myofibril organization and even of filament assembly in either organism. In *C. elegans*, nulls for vinculin have the same deleterious effect. Thus, the integrin-based system may be even more fundamental to the organization of muscle structures, especially early in development, then either the dystrophin or spectrin-based systems. Recently developed "knockout" mutations in mice cannot even form mesoderm.

CONTRACTILE FUNCTION AND REGULATION

FUNCTION

The Sliding Filament Model Contraction in skeletal muscles occurs by the sliding of actin filaments past myosin filaments (Fig. 93-5). Since myosin filaments are bipolar, the heads on each half are oriented 180° from the other half. Therefore, in contraction, the myosin heads bind and pull the polar actin filaments toward their
Figure 93-4 The dystrophin membrane cytoskeleton system. Dystrophin is shown interacting with the actin cytoskeleton, a complex of membrane-spanning proteins, and a complex of cytoplasmic proteins. Indirectly, dystrophin interacts with extracellular proteins and structures. This complex set of interactions is necessary for normal muscle development and function. (From Campbell KP. Cell 1995;80:675–679, with permission.)

center and that of the sarcomere at the M line. In relaxation, the actin filaments move away from the sarcomere center.

In this model, the backbones of the myosin and actin filaments do not undergo significant structural changes during contraction. That is, the filaments themselves do not shrink or expand sufficiently to explain contraction and relaxation. The critical interactions and structural changes involve the association of the myosin heads and actin filaments.

The Actomyosin ATP Cycle   The interactions of myosin heads with actin and ATP are the critical molecular events in muscle contraction. Actin activates myosin to bind ATP and hydrolyze it to ADP and phosphate. This activation occurs by a cycle (Fig. 93-6). Since the binding of actin, ATP, and ADP to

myosin are mutually exclusive, the myosin must be placed into a special high-energy conformation (Fig. 93-7) with a finite lifetime following ATP hydrolysis. The highly transient complex of this special myosin state with actin is believed to be when actual force is generated by myosin upon actin. The cycle is completed when ADP dissociates from the actomyosin complex.

The actual muscle, the 600 heads on each myosin filament, interact with 12 neighboring actin filaments. Each actin filament can interact with three myosin filaments. With this arrangement, the probability of myosin and actin finding each other is markedly enhanced over a random distribution. At any time during
Figure 93-7 Mechanism of force generation. The biochemical events are matched to molecular structure and the power stroke of muscle contraction in this more detailed version of the actomyosin-ATP cycle. Note that movement occurs. (From Stryer L. Biochemistry, 4th ed. New York: WH Freeman, with permission.)

active contraction, every actin and myosin filament in the sarcomere is very likely to be participating in multiple actomyosin interactions.

The Myosin Head as a Protein Motor   In order to accomplish the sliding of filaments and the actomyosin-ATP cycle, the myosin head must be a very specifically designed protein motor. In fact, the heads tethered artificially without their rod domains and filament organization can induce motility and tension on free actin filaments. The myosin heads are truly the business ends of thick filaments.

The three-dimensional structure of myosin heads has been determined by X-ray diffraction of protein crystals (Fig. 93-8). The head itself is a 15-nm long structure. At one end, the head has two sides, each of which contains a special site. One site binds actin in a large cleft and the opposite site binds and hydrolyzes ATP. The sites are separated by 3–4 nm. Therefore, a structural change in the region between the sites must occur in order for the binding of ATP and actin to affect one another. The opening and closing of the actin binding cleft may be part of this mechanism (Fig. 93-9).

The actual distance that a myosin head may move an actin filament has been measured. It can be as large as 10 nm. Where does this distance arise? The carboxyl terminal region of the heavy chain in the myosin head is a long α helix to which the myosin light chains attach (Fig. 93-8). This complex may serve as a lever arm where the fulcrum is either of the rod domain of the myosin molecule assembled into the backbone of a thick filament or an equivalent tether (Fig. 93-7). Evolutionarily, the myosin light chains had regulatory or modulatory functions with respect to motor functions.

REGULATION   The key steps in the regulation of muscle contraction are the coupling of the excitation of muscle to the release of calcium from the sarcoplasmic reticulum and the action of calcium on the interaction of myosin and actin filaments. The uptake of calcium from the myofibril into the sarcoplasmic reticulum is the mechanism directly controlling relaxation in skeletal muscle.

Calcium Release and Uptake   The contraction and relaxation of skeletal muscle ultimately is controlled by the action of motor neurons. Their release of acetylcholine presynaptically and the depolarization of the skeletal muscle plasma membrane following the binding of acetylcholine to specific receptors within specialized membrane sites postsynaptically induce muscle contraction. The absence of motor neuron input and the repolarization of the skeletal muscle plasma membrane are associated with muscle relaxation.

The depolarization of the plasma membrane directly affects the voltage-sensitive channels of the transverse tubules. Direct molecular interaction between these channels and the foot domains of the calcium-release channels of the sarcoplasmic reticulum occurs in the junctional region (Fig. 93-3). Allosteric changes in this interaction as a result of transverse tubule membrane depolarization induces a change in conformation of the calcium-release channel. This channel switches from its closed to open state, and calcium is released from the sarcoplasmic reticulum into the myofibrils.

A potential source of controversy or confusion, depending on one's viewpoint, is that both the voltage-sensitive channel of the transverse tubules and the calcium-release channel of the sarcoplasmic reticulum are themselves activated by calcium. Theoretically, calcium ions could trigger calcium-release by their action on these two molecules. However, these effects are considered to be secondary to the allosteric mechanism discussed because extracellular and junctional calcium can be eliminated without inhibition.

The allosteric interaction between the two channels is modulated by the action of other proteins. For example, activation of the voltage sensitive channels are markedly enhanced by phosphorylation of the major α1-subunits. Junctional proteins such as 95-kDa protein and other proteins of both the tubules and the reticulum may also influence the interactions of the two major channel proteins.
Figure 93-8 Three-dimensional structure of myosin head. Note that the balls represent individual atoms derived from X-ray diffraction of crystals of proteolytically derived S1 or myosin head. RLC is the regulatory light chain; ELC is essential light chain. (From Stryer L. Biochemistry, 4th ed. New York: WH Freeman, adapted from Ivan Rayment, with permission.)
Figure 93-9 Detail of myosin head interacting with actin or thin filament. Note structural changes within myosin head and between myosin and actin. (From Stryer L. Biochemistry, 4th ed. New York: WH Freeman, after Rayment I, Holden HM, Whittaker M, Yohn CB, Lorenz M, Holmes KC, and Milligan RA, Science 1993;261:58–65, with permission.)

The uptake of calcium is controlled primarily by the calcium pump molecules of the sarcoplasmic reticulum. These molecules act as classical transport pumps; ATP is hydrolyzed by the pump in order to transport calcium ions into the reticulum lumen against an electro-chemical gradient. Secondarily, the binding of the transported calcium ions by the lumenal protein calsequestrin aids in the uptake. Essentially these processes are continuous; they are overwhelmed by the activated calcium release processes and predominate when release is deactivated.

Regulation by Calcium of Actin and Myosin Interaction The release of calcium from the sarcoplasmic reticulum into the myofibrillar space activates the cycle of actomyosin-ATP interactions (Figs. 93-6 and 93-7) and the subsequent sliding of actin filaments past myosin filaments (Fig. 93-5). The key interaction of calcium is with the troponin complexes of the actin filaments. Each actin filament with its full complement of tropomyosin and troponin may be considered as a single allosteric unit (Fig. 93-2). The binding of calcium to troponin anywhere on the actin filament changes the potential interactions of all the actin monomers.

This remarkable effect of calcium binding by troponin is mediated by two levels of conformational change. First, calcium induces a change in the troponix complex: tropomyosin interaction. Second, the activated tropomyosins rotate about each actin strand. This rotation is propagated along both strands of actin up and down the filament. The net effect of these conformational changes is the opening of sites on actin subunits for interaction with myosin heads.

The allosteric interactions of the actin filaments may also be sensitive to the binding of myosin heads.

The uptake of calcium into the sarcoplasmic reticulum leads to reversal of actomyosin activation and the conformational changes in the actin filaments.

THE MYOFIBRIL IN HEALTH AND DISEASE

Three areas of muscle biology are medically significant. First, the actin and myosin filaments of skeletal muscles represent the body's largest store of amino acids that may be mobilized for metabolic needs. Skeletal muscle, therefore, plays a necessary role

in nutrition and metabolism. Second, hormones and neuronal action control the metabolic functions of muscle. Skeletal muscle is a critical tissue in the effects of diabetes. Injury or dysfunction of motor neurons leads to skeletal muscle atrophy. Third, an increasing number of inherited diseases have been traced to specific proteins of the myofibril. Many of these disorders affect both heart and skeletal muscle, consistent with the sharing of both proteins and their functions between these tissues.

MUSCLE PROTEINS AND NUTRITION   Myosin and actin are the principal proteins of skeletal muscles. Although relatively stable, these proteins are continuously being degraded and synthesized. Since virtually all myosin and actin are assembled into filaments in muscle, the filaments must also be continuously assembled and disassembled. Skeletal muscle can degrade these proteins to free amino acids and, in certain cases, can oxidize the amino acids in order to synthesize ATP.

The amino acids may be reutilized by muscle or may be secreted. Nearly every tissue of the body may take up amino acids and utilize them for protein synthesis. The liver takes up alanine and can utilize it for gluconeogenesis. The glucose may be used by the liver itself or be secreted and used by other tissues. A potential cycle exists between liver and muscle. Amino acids from myofibrillar protein breakdown are secreted by skeletal muscle, taken up by liver, and used in synthesizing glucose. The glucose is secreted, taken up by muscle, and used for contraction or stored as glycogen.

Lactate from anaerobic muscle contraction may also be used by the liver for gluconeogenesis (Cori cycle). In addition to amino acids and carbohydrates, skeletal muscle oxidizes fatty acids to produce ATP.

Well-nourished persons will use fatty acid oxidation for aerobic contraction and glycolysis/glycogenolysis for anaerobic work. The utilization of protein amino acid stores becomes significant under conditions of fasting or in uncontrolled diabetic states in which glucose and fat utilization are both impaired. Prolonged starvation shuts off protein degradation, and oxidation of ketone bodies derived from prior lipid oxidation predominates.

HORMONAL AND NEURONAL CONTROL

Insulin and Diabetes   The major hormone that regulates both energetics and synthetic metabolism in skeletal muscle is insulin. Insulin stimulates uptake of glucose, amino acids, and fatty acids into skeletal muscle. The synthesis of glycogen and of myofibrillar proteins is markedly increased. In diabetes mellitus of either primary β-cell pancreatic origin or a result of insulin resistance, all of these positive effects of insulin can be decreased. In severe diabetic states, they are markedly reduced. Free fatty acids are mobilized to produce ketone bodies, and the oxidation of ketone bodies becomes a major contributor to energetics in muscle and other tissues that ordinarily require insulin.

Neuronal Control   Skeletal muscles require functional interactions with both motor neurons and specialized proprioceptive neurons of muscle spindles, not only for proper contractile function but also in the development and maintenance of myofibrillar proteins and structures. Muscle fibers are of two major types. Type I fibers are slow twitch, and their contraction is dependent on aerobic metabolism. Type II fibers are fast twitch, and the contraction is primarily dependent on glycogenolytic (anaerobic) metabolism. There are multiple differences in gene expression between the two fiber types, including metabolic enzymes, membrane channel protein isoforms, and myofibrillar protein isoforms. Most skeletal muscles in humans contain mixtures of the two fiber

types. Some fibers show intermediate properties and represent minor subtypes.

The differentiation of and maintenance of Type I and II muscle fibers are dependent on the appropriate innervation by "slow" and "fast" motor neurons, respectively. Functional, pathological, or physical deinnervation of either type of muscle fiber leads to atrophy. Reinnervation will lead to development of a fiber of type specificity dependent upon the type of motor neuron.

The mechanism of this dependence of skeletal muscle on nerve is not fully understood. In part, skeletal muscle may respond developmentally and metabolically to its own functioning. On the other hand, neurons actively secrete various protein factors and peptides in addition to neurotransmitters such as acetylcholine. Such factors include agrin, an extracellular protein that organizes acetylcholine receptors into special membrane sites and ciliary neurotrophic factor that may stimulate skeletal muscle development and growth more generally.

Inherited Muscle Diseases   Chapter 94 will discuss much of the exciting new research in inherited diseases of skeletal muscle. Also, inherited diseases of the heart may affect proteins shared with skeletal muscle. It is important to note here that there are genetic alterations of specific proteins of the myofibril, sarcoplasmic reticulum/transverse tubules, and membrane cytoskeleton that lead to alterations of skeletal muscle structure and function.

Central core disease in which the myofibrillar compartment becomes selectively depleted in affected skeletal muscle fibers can be associated with specific mutations of the β-cardiac myosin heavy-chain isoform that is shared by slow skeletal muscle fibers. The responsible genetic locus is on human chromosome 14q. The skeletal muscle defects may be associated with or independent of the development of hypertrophic cardiomyopathy in these patients.

Malignant hyperthermia in which volatile anesthetics produce uncontrollable muscular contraction and generation of heat during surgery is a result of mutations of sarcoplasmic reticulum calcium release channel. The responsible genetic locus for this disorder is on human chromosome 19q.

Duchenne and Becker muscular dystrophies are produced by a variety of mutations in the dystrophin 427-kDa isoform (Fig. 93-4). These disorders affect males primarily because the responsible genetic locus is on human chromosome Xp2.1. As discussed, dystrophin participates in one of several protein systems that anchor cytoskeletal actin filaments to the membrane and the extracellular matrix in skeletal muscle. Although primarily thought of as skeletal muscle diseases, Duchenne-Becker dystrophy patients and even female carriers may have significant cardiomyopathies because of the shared expression of dystrophin.

94 Muscular Dystrophies

ERIC P. HOFFMAN

OVERVIEW

Mutations of nine different genes have been shown to be causative of specific types of muscular dystrophy, and linkage studies have shown the existence of approximately six additional genes. The most common cause of muscular dystrophy is mutations of the dystrophin gene on the X chromosome: absent dystrophin results in Duchenne muscular dystrophy in males (>95% of childhood onset lethal dystrophy in males), present but abnormal dystrophin in Becker muscular dystrophy (50% adult ambulatory dystrophy in males), and 10% of isolated female dystrophy patients show symptoms as a consequence of carrier status and skewed X-chromosome inactivation. The pathophysiology of dystrophin abnormalities involves an instability of the plasma membrane of myofibers with a chronic deterioration of the muscle leading to weakness. Myotonic dystrophy is the next most frequent dystrophy, and is extremely variable, showing presentations ranging from neonatal lethality, to childhood mental retardation, adult distal weakness with myotonia, or early onset cataracts. It is dominantly inherited, with considerable variation in phenotype within families. This disease is caused by an increase in size of a trinucleotide repeat (CTG) in the 3' untranslated region of a protein kinase. The size of the expansion generally correlates with disease severity. The mechanism by which the expansion mutation causes the observed multisystemic and variable clinical features is not well-understood. Very recently, mutations of six additional genes have been identified. Mutations of calpain III, a muscle-specific membrane-bound protease, may be a relatively common cause of dystrophy in patients with normal dystrophin. Four different genes encoding specific "sarcoglycans" (transmembrane proteins that are components of the dystrophin-based membrane cytoskeleton) have recently been shown to cause relatively rare cases of Duchenne/Becker-like muscular dystrophy. Approximately 40% of neonatal onset disease, congenital muscular dystrophy, has been shown to be a result of deficiency of α2 laminin (merosin), a protein involved in attachment of myofibers to the extracellular matrix (basal lamina). In addition to profound weakness at birth, these patients show marked abnormalities of white matter by MRI studies, yet are intellectually normal. Finally, a rare X-linked recessive muscular dystrophy distinguished clinically from Duchenne/Becker muscular dystrophy by early prominent contractures and cardiac

conduction defects has recently been found to be caused by mutations of a gene of unknown function in Xq28 (emerin). Additional dystrophies for which genes have been genetically mapped but not yet identified include dominantly inherited limb-girdle muscular dystrophy (chromosome 2p), fascioscapulohumeral dystrophy (4q), and oculopharyngeal muscular dystrophy (15p).

INTRODUCTION

Of the nine genes for which mutations have been shown to cause subtypes of muscular dystrophy, six result from abnormalities of the plasma membrane and adjacent basal lamina. Myofibers undoubtedly have a very stringent requirement for a durable and resilient plasma membrane based on two features of its normal physiology and function. First, each contraction of the myofibrils leads to a rapid and dramatic redistribution of the cytoplasm, resulting in changes of the shape of the myofiber. These shape changes would be expected to impart considerable stresses on the plasma membrane. Second, the force generated by the myofibrils must be transduced to the extracellular matrix so that the muscle group can contract and generate force as a single coordinated unit. Thus, this force transduction must be transmitted through the plasma membrane, which must be strongly reinforced to withstand these sheer forces. The study of human disease has been critical in both identifying components of the myofiber membrane cytoskeleton and in determining the relative functions of many of the components. To date, six distinct human inherited muscular dystrophies have been identified that are caused by deficiencies of the membrane cytoskeleton: one intracellular component (dystrophin; Duchenne muscular dystrophy), four transmembrane components (α, β, γ, and δ-sarcoglycans), and one extracellular component (α2 laminin). The muscular dystrophies caused by deficiency of dystrophin or any of the four sarcoglycans are quite similar histologically and clinically. This observation suggests that the progressive muscle diseases caused by these proteins may all share a similar pathogenesis, namely chronic membrane instability leading to progressive dysfunction of the muscle, and that all of the sarcoglycans and dystrophin are required for membrane stability. The deficiency of the extracellular component, α2 laminin, results in a more complicated and severe phenotype (congenital muscular dystrophy), with apparent involvement of the immune system in tissue pathology, and also abnormalities of myofiber regeneration.
Figure 94-1 Schematic of proteins involved in muscular dystrophies. Shown is a segment of a myofiber plasma membrane, with the intracellular dystrophin-based membrane cytoskeleton, transmembrane sarcoglycans and dystroglycans, and extracellular basal lamina with laminin 2. Male Duchenne/Becker muscular dystrophy and isolated female dystrophinopathy patients are the result of abnormalities of the dystrophin protein, a common X-linked recessive disease. Rare autosomal recessive childhood-onset dystrophies are caused by mutations in any one of the sarcoglycan proteins (α sarcoglycan [adhalin], β sarcoglycan, γ sarcoglycan, and δ sarcoglycan). Many cases of neonatal onset severe congenital muscular dystrophy are caused by deficiency of $\alpha2$ laminin (merosin), which is the large subunit of laminin in the myofiber basal lamina. (Reprinted with permission from Duggan et al. NEJM, 1997).

DISORDERS OF THE MEMBRANE CYTOSKELETON: DEFICIENCY OF DYSTROPHIN OR THE SARCOGLYCANS

Duchenne muscular dystrophy is one of the most common inherited disorders of humans and is the most frequent muscle disease (1/3500 live born males). Its high frequency in all world populations is a result of the high mutation rate of the gene, which in turn is largely a consequence of the enormous size of the gene (2.5 million bp). Affected children are predominantly male, because of the X-linked recessive inheritance pattern, and appear normal until about 4 or 5 years of age, when muscle weakness becomes obvious. Thereafter, there is a relentless progression of weakness and muscle wasting, leading to confinement to a wheelchair by age 14 years, and death due to respiratory failure by age 20 years (unless the patient is mechanically ventilated).

The biochemical deficiency causing the disorder remained obscure until 1987, when the Duchenne muscular dystrophy gene was identified by positional cloning techniques. The gene, which has remained 10 times larger than the next largest gene, encodes a 427-kDa protein dubbed "dystrophin," and dystrophin-deficiency is recognized to define Duchenne muscular dystrophy at the biochemical level. Mutations of the gene are deletions (55%), duplications (5%), and point mutations (40%). Partial dystrophin-deficiency, often the result of in-frame deletion mutations compatible with production of dystrophin that lacks segments of amino acids, is diagnostic of the milder and more variable Becker muscular dystrophy. Presentations of Becker dystrophy include proximal weakness, myoglobinuria, myalgias, hyperCKemia, and cardiac failure, and some patients may remain asymptomatic at advanced ages.

Female homozygotes do not exist because of the relative rarity of the disorder; females generally act as heterozygous gene carriers. However, approximately 10% of isolated female dystrophy patients express their symptoms as a consequence of heterozygosity for a dystrophinopathy. Most of these females show preferen-

tial inactivation of the X chromosome containing the normal dystrophin gene (skewed X inactivation). Presentations of isolated female carriers are as variable as in Becker muscular dystrophy in males, although the progression is often mitigated in the female patients.

Molecular diagnosis, genetic counseling, and prenatal diagnosis are well established in the dystrophinopathies. Dystrophin protein analysis of muscle biopsy, gene deletion mutation analysis, and gene linkage analysis are all routinely used. The large size of the gene complicates molecular genetic counseling and prenatal diagnosis: There is 10% recombination within the gene, and the high mutation rate leads to many "new mutations," which may effect a single egg or sperm or may cause the gonads of a parent to be a carrier but not the parent him/herself (gonadal mosaicism).

The identification of dystrophin as a major component of the membrane cytoskeleton of muscle fibers permitted use of the dystrophin protein as a probe to isolate and characterize other components. Recent research has identified three complexes of proteins that interact with dystrophin near the plasma membrane and appear to provide one type of connection between the intracellular contractile myofibrils and the extracellular matrix (Fig. 94-1). Rare childhood-onset muscular dystrophies with autosomal recessive inheritance patterns have been shown to be caused by mutations of four of the sarcoglycan proteins (Table 94-1; Fig. 94-1). No disorders have been associated with the primary defects in any of the syntrophins or dystroglycan components.

The clinical and histopathological consequences of primary disorders of dystrophin and the sarcoglycans are quite similar, and it can be safely assumed that they share a common molecular pathogenesis. Current models suggest that deficiencies of these proteins lead to membrane instability, which initiates both acute responses (hyperCKemia, myofiber necrosis) and chronic responses (progressive fibrosis, failure of myofiber regeneration, and muscle wasting/weakness). The immune system may play a role in both the acute and chronic responses, and immune suppressants such as prednisone have shown some effect in slowing the progression of

Table 94-1
Molecular Basis of the Muscular Dystrophies

Protein defect	Disease	Onset of symptoms	Frequency	Characteristic clinical features	Gene mutations	Molecular diagnosis
Dystrophin-deficiency	Duchenne muscular dystrophy	Childhood	1/3500 males (>90% of childhood-onset dystrophy)	Proximal weakness, calf hypertrophy, cardiomyopathy, 30% MR	55% deletions	Mutation, linkage analysis, protein analysis of muscle biopsy
Abnormal dystrophin	Becker muscular dystrophy	Childhood-adult	1/20,000 males (50–70% of male teen/adult-onset dystrophy)	Proximal weakness, high CK, cardiomyopathy	70% deletions	Mutation, linkage, protein of biopsy
Dystrophin mosaicism	Isolated female dystrophinopathy	Childhood-adult	1/100,000 females (10% of female dystrophy)	Proximal weakness, high CK, cardiomyopathy	60% deletions (heteroxgote)	Protein, X inactivation, mutation, linkage
α Sarcoglycan (adhalin)	SCARMD/LGMD[a]	Childhood	<1/200,000	Proximal weakness, high CK	Missense	Protein followed by mutations[b]
β Sarcoglycan	SCARMD/LGMD[a]	Childhood	<1/200,000	Proximal weakness, high CK	Missense	Protein followed by mutations[b]
δ sarcoglycan	SCARMD/LGMD[a]	Childhood	<1/200,000	Proximal weakness, high CK	Missense	Protein followed by mutations[b]
β Sarcoglycan	SCARMID/LGMD	Childhood	<1/200,000	Proximal weakness, hyperCKemia	Nonsense	Protein followed by mutations
α2-Laminin (merosin)	Congenital muscular dystrophy	Neonatal	<1/200,000	Floppiness, high CK, white matter changes by MRI	Deletion[c], nonsense	Protein, prenatal of chorionic villi
Calpain III[d]	LGMD	Childhood-adult	1/50,000?	Proximal weakness	Missense	Mutation
Emerin	Emery-Dreifuss muscular dystrophy	Childhood	<1/200,000	Contractures, proximal weakness, cardiac conduction defects	Missense	Mutation
DM kinase[e]	Myotonic dystrophy	Extremely variable	1/8,000	Neonatal floppiness, childhood MR, adult distal wasting, cataracts, frontal balding	Expansion of a CTG trinucleotide repeats	Mutation

[a]Severe childhood-onset autosomal recessive muscular dystrophy (SCARMD) and limb-girdle muscular dystrophy (LGMD) are generic descriptive diagnoses often used to describe these patients.

[b]Many muscular dystrophy patients show secondary deficiencies of sarcoglycan proteins. Thus, biochemical detection of a deficiency of a sarcoglycan protein most often does not reflect a primary deficiency (mutations) of that protein. For this reason, mutation analysis is suggested for a definitive diagnosis.

[c]Only a few mutations of the very large merosin gene have been identified to date.

[d]The clinical and molecular features of dystrophy associated with Calpain III mutations have not yet been well-defined. A multiple gene (digenic) inheritance has been proposed.

[e]The molecular pathogenesis of myotonic dystrophy is not well-understood. The disease is clearly caused by the expansion mutation in the 3' UTR of the kinase gene; however, it is not clear what genes, RNAs, or proteins are altered by this expansion.

the disease. Efforts at gene therapy are underway, although the refractory nature of mature myofibers to viral delivery systems, and the unique nature and large amount of the target muscle tissue, are hurdles currently facing this approach.

α2 LAMININ (MEROSIN) DEFICIENCY

In 1994, Tome and colleagues identified a subset of congenital muscular dystrophy patients that showed complete lack of immunostaining for the α2-laminin chain in their muscle biopsy. The α2-laminin gene (LAMA2) has been mapped to chromosome 6q22-23, and mutations have been identified in affected patients. Merosin-deficient patients are relatively uniform in clinical presentation and progression: patients are floppy at birth, with the infant unable to raise limbs against gravity. Serum creatine kinase are elevated to 2000–10,000 IU/I (normal <200 IU/I). The muscle biopsy shows a dystrophic process, with degeneration of myofibers, and a marked increase in endomysial and perimysial connective tissue with fatty infiltration. Importantly, one recent study found that 3 of 10 merosin-deficient patients studied were initially given the diagnosis of infantile polymyositis because of the presence of significant populations of inflammatory cells. This study documented focal inflammatory reaction in a young patients muscle, with concentrations of B and T cells resembling primary follicles, generally seen in spleen. These results suggested that earlier reports of the diagnosis of infantile polymyositis, with a presumed autoimmune etiology, could in fact represent a possible histological finding in inherited α2-laminin deficiency. Both CD4+ and CD8+ cells are seen in large numbers, both distributed throughout the biopsy and in focal aggregates.

α2 laminin is one of the three components of the heterotrimeric muscle laminin molecule (Fig. 94-1). The α2-subunit is present in muscle, the central nervous system (CNS), and schwann cells, and replaces the more ubiquitous α1 chain during the development of muscle tissue. The other two components, laminin β1 and γ1, are not tissue-specific. Laminin is a major constituent of basal lamina of most cells, where it complexes with collagen IV and other proteins to anchor cells in their tissue environment. α2 laminin is involved in neurite outgrowth in the peripheral and central nervous system. Interestingly, patients with α2 laminin deficiency show dramatic white-matter changes by MRI, although there is no overt CNS dysfunction or intellectual impairment. There is a mouse model for merosin deficiency, *dy/dy*, and the mutation in the milder of two alleles has been identified. These mice show a phenotype similar to the human disease.

Another congenital muscular dystrophy for which linkage data exist is Fukuyama congenital muscular dystrophy. This congenital muscular dystrophy is most frequently seen in Japan and shows very high serum creatine kinase levels at birth and atrophic brain. Japanese families with have been used for gene linkage studies, which have localized the gene to chromosome 9q31-33. No specific gene or gene mutations have been identified to date.

CALPAIN III DEFICIENCY   A recent study has shown mutations in a gene corresponding to a muscle-specific protease, calpain III, associated with a relatively large number of childhood-adult onset muscular dystrophy inherited in an autosomal recessive pattern. The pathogenesis of the disease is not clear, and there are features of the genetics that are enigmatic and require further explanation before a strict relationship between calpain III mutations and muscular dystrophy can be assumed.

EMERY-DREIFUSS MUSCULAR DYSTROPHY   A rare X-linked recessive disorder, Emery-Dreifuss muscular dystrophy, is clinically distinct from the dystrophinopathies as a result of the early presence of contractures and cardiac conduction defects requiring placement of a pacemaker. Linkage studies had shown the responsible gene to be located in Xq28, and the gene was recently identified. The novel protein (emerin) encoded by this gene shares features with other proteins involved in vesicular transport. It is localized to the nuclear membrane of skeletal and cardiac muscle cells. The molecular pathogenesis of the disorder is not clear.

MYOTONIC DYSTROPHY   Myotonic dystrophy is the term used to describe one of the most common, and certainly the most variable, of the myopathic disorders. The moniker is more historical than descriptive: Only a subset of patients show myotonia or muscular dystrophy. Patients with this dominantly inherited disorder can present in the neonatal period (congenital myotonic dystrophy) with floppiness often requiring ventilatory support, in childhood with mental retardation and characteristic facies (hatchet jaw, lowset ears), in adolescence with distal weakness and wasting, or in older age with cataracts and frontal balding. The disease and corresponding severity have been strongly associated with an unstable trinucleotide repeat on the short arm of chromosome 19: Repeats of many thousands of basepairs are associated with early onset severe disease and shorter repeats associated with later onset milder disease. The repeat length changes between parent and offspring (meiotic instability), as well as within a patient (mitotic or somatic instability), such that muscle tissue has longer repeats than are present in other tissues.

The (CTG) repeat expansion is in the 3' untranslated region of a novel cAMP kinase gene (DM kinase), and an obvious assumption is that the repeat alters the expression of the kinase protein, leading to expression of disease. However, the dominant inheritance (patients are heterogotes, with a normal kinase gene in addition to the one containing the expansion mutation) and lack of sequence alterations in protein expressed by the mutant gene seem inconsistent with the dramatic variability of the clinical disease. The molecular pathogenesis is not resolved; however, three models are currently being tested: the expansion may have long-range effects on adjacent genes in the chromatin; RNA molecules containing the expansion may cause abnormalities of RNA metabolism; or the disorder may result from haploinsufficiency of the kinase or a second neighboring homeobox gene. These three mechanisms may not be mutually exclusive.

GENETICALLY DEFINED DOMINANTLY INHERITED DYSTROPHIES   Three dominantly inherited, late-onset muscular dystrophies have been mapped to specific chromosome locations: limb-girdle muscular dystrophy (chromosome 2p), fascioscapulohumeral dystrophy (4q), and oculopharyngeal muscular dystrophy (15p). Fascioscapulohumeral muscular dystrophy is one of the more common dominantly inherited muscular dystrophies and shows preferential involvement of facial and upper-girdle muscles. The disorder is variable in severity, although most patients present in late teenage or adult years. The disease is strongly associated with alterations of the telomore of the long arm of chromosome 4. However, no specific gene has been implicated in the disease pathogenesis. Most patients carrying the descriptive diagnosis of limb-girdle muscular dystrophy have a recessively inherited disease, although rare families with late-onset dominant inheritance have been described. Oculopharyngeal dystrophy shows onset in later decades of life and shows progressive weakness of ocular and pharyngeal musculature. The disease is most common in French-Canadian populations.

95 Rhabdomyosarcomas

Stephen J. Tapscott

BACKGROUND

Rhabdomyosarcomas are the most common of the soft tissue sarcomas in childhood, yet they are still a relatively rare tumor, with an incidence in the United States of 1.3–4.5 per million children per year. The histologic classification of rhabdomyosarcoma has historically relied on the expression of genes associated with skeletal muscle in some of the tumor cells, giving a subset of cells the appearance of skeletal muscle cells or myoblasts. Several histologic subcategories of rhabdomyosarcomas have also been recognized. Embryonal rhabdomyosarcomas are characterized by round or spindle-shaped cells, mixed with a variable number of eosinophilic myoblasts, sometimes showing cross-striations. Embryonal rhabdomyosarcomas occur most frequently during the first three years after birth and account for about 50–60% of rhabdomyosarcomas. Additional distinctions can be made within the group of embryonal rhabdomyosarcomas; for example, there are the botyroid and spindle-cell variants. Alveolar rhabdomyosarcomas are distinguished from embryonal rhabdomyosarcomas histologically by characteristic open spaces in pathology sections, reminiscent of alveoli in the lungs. Alveolar rhabdomyosarcomas account for approximately 20% of rhabdomyosarcomas and have a bimodal incidence distribution with peaks at approximately ages 3 and 15. A third group of pleomorphic or primitive rhabdomyosarcomas is not easily distinguished from other small round-cell tumors of childhood, such as neuroblastoma, Ewing's sarcoma, primitive neuroectodermal tumors, and non-Hodgkin's lymphoma, based on standard histology. For these primitive tumors, classification as rhabdomyosarcomas can be confirmed using antibodies or other molecular probes to genes characteristically expressed in skeletal muscle, such as desmin, myosin, or muscle creatine kinase.

RHABDOMYOSARCOMAS EXPRESS MyoD OR RELATED MYOGENIC FACTORS

Expression of the myogenic regulatory protein, MyoD, or one of the related members of this group of myogenic basic-helix-loop-helix (bHLH) proteins, which consists of MyoD, Myf5, Myogenin, and MRF4, can be used to categorize less differentiated tumors as rhabdomyosarcomas, since almost all rhabdomyosarcomas express one or more of this group of proteins. The myogenic bHLH proteins are transcription factors that orchestrate the expression of the genes that characterize skeletal muscle. Gene

knockout experiments demonstrate that these genes are necessary for skeletal myogenesis, and the ability to convert nonmyogenic cells to skeletal muscle by expressing one of the myogenic bHLH proteins indicates that in many cell types, they are sufficient to mediate differentiation. In addition to activating expression of muscle structural genes, MyoD has been shown to mediate withdrawal from the cell cycle and induction of p21 expression. The role of these proteins in normal development is discussed (Chapter 92).

Given the ability of the myogenic bHLH proteins to activate transcription of skeletal muscle genes, the expression of MyoD in rhabdomyosarcomas can account for the low level of muscle differentiation seen in the tumor. In the tumors that have been analyzed, however, most of the cells in the tumor express MyoD, but very few cells express muscle structural genes and withdraw from the cell cycle, indicating that the activity of the myogenic bHLH proteins has been partially blocked. Analysis of the myogenic bHLH proteins in several tumors has demonstrated that they are not mutant, yet they are inefficient activators of muscle genes. Therefore, in the generation of rhabdomyosarcomas, the tumor cells have acquired mechanisms of preventing the normal activity of the myogenic bHLH proteins, thereby escaping cell differentiation and cell-cycle withdrawal.

Several molecular mechanisms have been identified that can prevent MyoD and related myogenic bHLH genes from activating transcription:

1. Heterodimerization with a member of the E-protein subfamily of bHLH genes (E12, E47, E2-5, E2-2) is a requirement for high-affinity DNA binding, since MyoD has a low affinity for DNA binding as a homodimer. Therefore, limiting amounts of E protein or high levels of the HLH protein Id, which competes with MyoD for heterodimerization with E proteins, could limit heterodimer formation and DNA binding.
2. A threonine residue in the DNA binding region of the MyoD protein, as well as in Myogenin, is subject to a PKC-dependent phosphorylation that can be induced by fibroblast growth factor (FGF). Phosphorylation prevents DNA binding and transcriptional activity.
3. TGF-β also blocks transcriptional activity of the myogenic bHLH proteins but does not prevent heterodimer formation or DNA binding based on in vitro binding assays.
4. Sequences adjacent to the MyoD binding sites can negatively regulate MyoD activity, possibly through interaction with other factors that can inhibit MyoD activity.

5. Oncogenes have been demonstrated to inhibit MyoD transcriptional activity, which could represent a direct interaction, such as with c-jun, or be mediated by other factors, such as increasing Cyclin D1 which then inhibits MyoD activity. In rhabdomyosarcomas, amplification of MDM@ has been shown to inhibit MyoD activity.

These examples represent several different basic mechanisms of preventing myogenesis mediated by MyoD and related myogenic bHLH proteins, and it remains to be determined which, if any or all, of these mechanisms play a role in the inhibition of myogenesis in rhabdomyosarcomas.

MOLECULAR GENETICS OF ALVEOLAR RHABDOMYOSARCOMAS

Cytogenetic studies identified multiple abnormalities in cells from rhabdomyosarcomas; however, alveolar rhabdomyosarcomas had a characteristic translocation between chromosome 2 and 13, t(2;13)(q35;q14). Fine mapping of the breakpoint identified *PAX3* as a candidate gene on chromosome 2, leading to the demonstration that the rearrangement occurred within the *PAX3* gene and ultimately identifying a novel chimeric transcript encoding the amino-terminal portion of the PAX3 protein from chromosome 2 and the carboxyterminal portion of a gene on chromosome 13, with homology to the fork head family of genes.

PAX3 is a transcription factor that is expressed in the neural tube, neural crest derivatives, and in the muscle precursor cells that migrate from the somites into the limb bud. Dominant, or semidominant, mutations of *PAX3* in mice, the *splotch* mutant, and humans, the Waartenberg syndrome, are noted for defects in neural crest and neural tube development. Embryos homozygous for some alleles of *splotch* have deficient limb muscle formation that can be attributed to the inadequate generation or migration of limb muscle precursor cells. This may partly be the basis for limb deformities in human variations of the Waartenberg syndrome that are homozygous for *PAX3* mutations.

The t(2;13) in alveolar rhabdomyosarcomas creates a novel gene with the transcription start site and 5-prime coding region of the *PAX3* gene and the 3' region of a gene called *FKHR* (fork head homolog rhabdomyosarcoma), a member of the fork head family of transcription factors, so-called because the prototype gene of the family was described as a mutation in Drosophila melanogaster that produced two spiked head structures (*see* Chapter 3). Additional vertebrate members of the fork head family include the hepatocyte nuclear factors (BNF-3α, BNF-3β, BNF-3γ) and brain factor-1 (BF-1). The fusion protein includes the two DNA binding domains in the carboxy-terminal half of the PAX3 protein, a paired box DNA-binding domain and a homeodomain, but disrupts the DNA-binding region of the FKHR protein. The carboxy-terminal portion of FKHR maintained in the fusion protein is rich in prolines and acidic amino acids, attributes consistent with an acidic activation domain, and transfection experiments demonstrate that the fusion protein is more potent than PAX3 as transcriptional activator of reporter constructs driven by PAX3 binding sites. Further, DNA-binding studies show that the fusion protein binds to PAX3 binding sites, but that it has a mildly altered DNA-binding affinity compared to PAX3. Therefore, the PAX3-FKHR fusion protein may have oncogenic activity based on enhanced activation of genes regulated by PAX3 or through altered binding affinity to specific DNA sequences.

While PAX3 is apparently expressed in the early migrating muscle progenitor cells, its role in development is only beginning to be understood. PAX3 expression inhibits myogenesis in cultured muscle cell lines and inhibits the ability of MyoD to activate the myogenic program in fibroblasts. The PAX3-FKHR fusion protein is a more potent inhibitor of myogenesis and MyoD activity in this system. Based on these observations and the developmental expression of PAX3 in the migrating muscle precursor cells, but not in skeletal muscle, it is possible that the normal function of PAX3 is to prevent myogenic differentiation during precursor cell migration and the fusion protein either enhances this activity or loses an element necessary to suppress this activity.

Although much less frequent than t(2;13), a t(1;13)(p36;q14) translocation has been described in some alveolar rhabdomyosarcomas. This translocation creates a fusion protein between PAX7 on chromosome 1 with the FKHR gene that is structurally very similar to the PAX3-FKHR fusion protein. PAX7 is also expressed in muscle precursor cells and is capable of binding to PAX3 sites either as a homodimer or as a heterodimer with PAX3. Therefore, each fusion protein, PAX3-FKHR and PAX7-FKHR, is expressed in myogenic precursor cells and has shared gene targets.

MOLECULAR GENETICS OF EMBRYONAL RHABDOMYOSARCOMAS

Most rhabdomyosarcomas are sporadic; however, the appearance of rhabdomyosarcomas in families with the Li-Fraumeni syndrome or the Beckwith-Wiedemann syndrome have provided valuable insights into the genetics of this tumor (*see* Chapter 7). Beckwith-Wiedemann syndrome (*see* Chapter 116) is associated with growth excess and a high incidence of tumors, including Wilms' tumor, hepatoblastoma, adrenal carcinoma, and rhabdomyosarcoma. Because of the association of Wilm's tumor with a locus on chromosome 11p13, this region was analyzed for loss of heterozygosity (LOH) in both rhabdomyosarcomas and in the Beckwith-Wiedemann syndrome. LOH of chromosome 11 was detected in a large portion of rhabdomyosarcomas, but the common region of LOH mapped to 11p15.5, similar to the mapping of the region of LOH for the Beckwith-Wiedemann syndrome. A preferential retention of the paternal allele in both embryonal rhabdomyosarcomas and in the Beckwith-Wiedemann syndrome has led to the suggestion that LOH alters the level of gene expression maintained by an imprinted allele, either decreasing expression of a tumor suppressor gene by loss of the nonimprinted allele or increasing expression of a growth-promoting gene by duplication of the nonimprinted allele.

The presence of a tumor growth suppressor gene at 11p15 has been supported by transfer of subchromosomal fragments to rhabdomyosarcoma cells. Fragments of chromosome 11 that contain 11p15 suppress growth and xenograft tumor formation in embryonal rhabdomyosarcomas, although similar experiments have not been performed in alveolar rhabdomyosarcomas, nor has parental origin of the suppressing allele been analyzed.

The gene relevant to rhabdomyosarcoma formation at 11p15 has not been clearly identified, although some candidates have been studied. Insulin-like growth factor II (IGF-2) is a maternally imprinted gene that maps to 11p15, transcriptionally silent on the maternal allele and expressed from the paternal allele. Elevated levels of IGF-2 resulting from paternal disomy associated with LOH may give a growth advantage to cells and has been postulated as the cause of the somatic hypertrophy in the Beckwith-

Wiedemann syndrome. IGF-2 has been shown to act as an autocrine growth factor in some rhabdomyosarcomas and loss of imprinting (LOI), i.e., expression of IGF-2 from both alleles has been demonstrated in alveolar rhabdomyosarcomas and embryonal rhabdomyosarcomas that do not have LOH at 11p15. The growth-promoting activity of increased IGF-2 levels may play a critical role in the generation of rhabdomyosarcomas; however, this model would not explain the somatic cell genetic experiments that implicate a tumor suppressor gene at 11p15.

A second, somewhat unusual, candidate gene that maps to 11p15 is *H19*, unusual because the *H19* transcript does not contain a conserved open reading frame and may function as a regulatory polyadenylated RNA. *H19* is imprinted in the opposite manner to *IGF2*, expressed from the maternal allele and silent on the paternal allele; therefore, loss of the maternal allele decreases *H19* expression. Transfection of *H19* into rhabdomyosarcoma cell lines suppresses both growth and tumorigenicity, making it a candidate for the 11p15 tumor suppressor gene.

Implicating imprinting as a critical factor in the LOH at 11p15 means that the transcription of numerous genes in the region might contribute to the transformed phentoype, and both *H19* and *IGF2* may contribute to the generation of rhabdomyosarcomas. Many additional genes have been mapped to the 11p15.5 region, including the cyclin-dependent kinase inhibitor $p57^{KIP2}$, the nucleosome assembly protein *hNAP2*, and the retinoblastoma-associated protein *RbAp48*. Mutations of the *p57* gene have been reported in Beckwith-Wiedemann syndrome and cause developmental abnormalities in mice that are similar to the Beckwith-Widemann syndrome, indicating that *p57* has a critical role in this syndrome. It remains to be determined whether altered expression of *p57* or other genes in this region contribute to the generation of rhabdomyosarcomas.

Rb, p53, AND ONCOGENES

Just as the association of rhabdomyosarcomas with the Beckwith-Wiedemann syndrome focused attention on 11p15, the appearance of rhabdomyosarcomas in families with Li-Fraumeni syndrome suggested that *p53* inactivation may be important for tumor formation. Analysis of *p53* abnormalities, without respect to alveolar or embryonal histologic types, indicated that approximately half of the tumors had abrogated normal *p53* function. When histologic subtype is considered, then it appears that the frequency of *p53* mutations is higher in the embryonal rhabdomyosarcomas. Differences between embryonal and alveolar rhabdomyosarcomas are further suggested by a higher frequency of *N-myc* amplification in alveolar rhabdomyosarcomas, whereas mutations in *N-ras* or *K-ras* appear to be more frequent in embryonal rhabdomyosarcomas. In contrast to *p53*, mutations in the *Rb* gene are rare in rhabdomyosarcomas.

ORIGIN OF RHABDOMYOSARCOMAS

While it is commonly believed that rhabdomyosarcomas originate from transformed muscle precursor cells, the appearance of rhabdomyosarcomas in regions that contain few muscle progenitors suggests that another mechanism may also contribute to their generation. A defining molecular feature of rhabdomyosarcomas is the expression of *MyoD* or another member of the myogenic bHLH group. *MyoD* transcription is actively suppressed in nonmuscle cells, an attribute that may be general to genes such as *MyoD* that positively autoregulate their transcription and commit a cell to a specific fate. Therefore, a cell that loses suppression of

MyoD transcription may activate the positive feedback circuits and commit to the muscle lineage. If this happens in a nascent tumor cell, then the sufficiency of MyoD to activate terminal differentiation might eliminate that cell from the replicating population. In this regard, the loss of the suppression of *MyoD* transcription could be thought of as a protection against growth. However, if the activity of MyoD was prevented by the expression of an oncogene, such as *PAX3-FKHR*, or by the loss of other factors necessary for myogenesis, then tumor growth would continue and MyoD would not be able to induce terminal differentiation. While this model is speculative, it would account for mixed tumor phenotypes, such as the myomedulloblastoma or the rhabdomyomatous nephroblastoma.

TREATMENT AND FUTURE DIRECTIONS

The current approach to therapy of rhabdomyosarcomas combines chemotherapy, radiation therapy, and surgery. The most recent Intergroup Rhabdomyosarcoma Study (IRS-III) utilized a risk-based design that increased therapeutic intensity in groups with marginally poorer prognosis. In addition to tumor staging based on invasiveness, involvement of lymph nodes, metastasis and degree of surgical excision; tumor histology is a significant variable in predicting response to treatment. In IRS-II, the 5-year survival rate was 95% for the favorable category of botyroid, 67% for embryonal, and approximately 50% for alveolar and undifferentiated. IRS-III included therapy intensification for the groups with the less favorable prognosis and has achieved survival rates for alveolar tumors comparable to embryonal.

One challenge for the future is to determine if survival can be improved and therapy-related complications minimized by using the available molecular markers to further refine risk-based therapy. One clear question is whether tumors that are histologically classified as embryonal but have t(2;13) should be treated as alveolar or embryonal tumors. Further, is there an outcome distinction between those tumors with t(2;13) or t(1;13), or tumors with amplified *N-myc*, activated *ras*, or *p53* mutations that will help direct therapeutic decisions. The availability of rapid PCR methods to identify fusion transcripts or LOH should greatly facilitate these studies.

It would be very satisfying if further understanding of the molecular biology of rhabdomyosarcomas eventually led to rationally designed therapies. Perhaps the development of drugs that inhibit *PAX3* expression or increase *H19* expression, or ribozymes and antisense oligonucleotides that degrade the *PAX3-FKHR* fusion transcript, would be useful adjuvants to therapy.

GENERAL APPROACHES FOR IDENTIFYING GENES RELEVANT TO NEUROLOGICAL DISORDERS

Recent advances in gene mapping and cloning strategies have led to the discovery of genes responsible for many neurological disorders. These disorders are often characterized by considerable phenotypic or biochemical complexity. Successes and failures of efforts to clone genes responsible for neurological disorders highlight the crucial role of skilled clinical assessment. Identification of disease-related genes is a critical step in the elucidation of the underlying disease mechanism, provides a basis for a more logical classification of disease entities, and, it is hoped, will lead to new therapies. The general principles for identifying disease-related genes are described in Part I of this textbook; in this chapter we will focus on approaches relevant to neurological disorders.

The power of the cloning strategies can be appreciated from a general quantitative perspective of the human genome (*see* Chapter 5). The genome consists of 3×10^9 base pairs (bp), and less than 5% of the entire genome encodes the estimated total of 60,000–100,000 expressed genes. These estimates predict an average of one gene every 30–50 kb throughout the genome. The average gene covers approximately 20 kb; a large gene such as the Duchenne muscular dystrophy (DMD) gene can extend for several hundred kilobases, whereas a relatively small gene can be encoded by less than 5 kb.

A typical search for a disease gene encompasses mapping the gene to a physical chromosomal location and then isolating clones containing fragments of DNA that encode all or part of the gene. One commonly employed cloning strategy consists of using probes genetically linked to the disease locus to screen libraries of yeast artificial chromosome (YAC) clones containing fragments of human DNA of 0.1–2.0 Mb (1 Mb = 1 million bases) in length. A 1-Mb segment of human genomic DNA may contain some 50 genes. Since DNA sequencing remains a tedious procedure in which a medium-sized laboratory may be capable of sequencing only several thousand base pairs per week, it would require several years to sequence one YAC clone. Thus, methods of selecting YAC clones are crucial, and after selection the search for a gene must be narrowed even further before direct DNA sequencing becomes productive. Several physical characteristics of genomic DNA can be used to guide the search for clones containing the disease-causing gene.

About 70% of the genome is unique-sequence DNA and contains both coding and noncoding regions. The remaining 30% is composed of repetitive DNA sequences. Some of these are clustered in a few locations (such as the telomeres), and some are dispersed throughout the genome amid short stretches of single-copy sequence of several kilobases or less. The association of these interspersed repeats with expressed genes has led to their use as crucial markers for cloning approaches. Minisatellite repeats contain repeat units of some 10–15 nucleotides, which are present with variable copy numbers in different individual genomes such that the length of the minisatellite varies across individuals. If DNA is cut using a restriction endonuclease and analyzed by Southern blot, a fragment that contains a minisatellite will also demonstrate size variation across individuals; this variation is termed a VNTR (variable number of tandem repeats) polymorphism.

Microsatellite repeats contain a repeat unit of only two, three, or four nucleotides, most commonly the dinucleotide (CA)n or variable-length runs of a single nucleotide. The high degree of polymorphism in microsatellite markers compared with restriction fragment length polymorphisms (RFLPs) and VNTR markers significantly increases the chances that a marker located near a disease locus will be informative in linkage studies. Variation in a microsatellite repeat number results in only a small change in the overall length of a microsatellite-containing DNA fragment and is therefore difficult to detect by Southern blot analysis. However, using the polymerase chain reaction (PCR), primers flanking the microsatellite can be used to amplify the DNA segment containing the repeats, and variations in repeat length of only two or three nucleotides can be detected by electrophoresis of the PCR product. Microsatellite alleles of different lengths (one microsatellite can have more than 10 different alleles) can easily be identified. Since microsatellites are typically flanked by unique-sequence DNA, a specific pair of PCR primers will usually identify a unique locus and therefore serve as a useful marker. The development of PCR and microsatellite markers has made available genetic markers that are more evenly distributed throughout the genome and more polymorphic than the previously used RFLP and VNTR markers. For most cloning approaches, several hundred evenly spaced microsatellite markers located at 10-Mb intervals are adequate for screening the entire human genome.

The goal of identifying and determining the location of all human genes is based on developing both physical and genetic linkage maps of the genome. Physical maps identify the position of a gene or locus in terms of chromosomal location. Giemsa staining of chromosomes reveals a banding pattern unique to each

chromosome. The designation that the gene for myotonic dystrophy (DM) is at 19q13.3 indicates that the gene is on the long arm (q = long arm; p = short arm) of chromosome 19 at band 13.3. Cytogenetic analyses such as Giemsa banding provide a mapping resolution of several megabases. Linkage maps are derived from the establishment of genetic linkage between specific markers with distances expressed in units (centimorgans [cM]) that are a function of recombination frequency. On average, 1 cM is equal to approximately 1 Mb. The ongoing integration of physical and genetic linkage maps, which is the first stage of the Human Genome Project, will result in a comprehensive, high-density map of the human genome.

FUNCTIONAL CLONING   Functional cloning (also known as "forward genetics") consists of identifying a defective enzyme or protein by standard biochemical methods based on knowledge of the disease phenotype. This approach has most commonly been used for isolating genes coding for defective enzymes associated with inborn errors of metabolism. Our meager understanding of the mechanisms underlying most neurological disorders has limited the number of disease-related genes isolated by functional cloning. Examples of genes derived by functional cloning include Lesch-Nyhan syndrome, metachromatic leukodystrophy, and Fabry's disease. Purification of the protein of interest allows antibody and oligonucleotide probes to be produced, which are used for screening DNA libraries. Oligonucleotide probes can be used to screen cDNA or genomic libraries by hybridization or PCR-based methods. Genomic or cDNA clones isolated by library screening can then be used to derive the full-length DNA sequence by isolating additional clones. The chromosomal location of the gene of interest can be established by using the clone as a probe for fluorescent *in situ* hybridization (FISH) to a resolution of 1–20 Mb.

POSITIONAL CLONING   Positional cloning (also known as "reverse genetics") in a purely conceptional sense requires no knowledge of disease mechanism or underlying biochemical defects. Identification of the gene responsible for the disease of interest is established by its map position as determined by linkage analysis in affected families. The principal difficulty with this approach is that a genomic region defined by current high-resolution mapping with microsatellite markers can extend for several centimorgans (several megabases) and contain more than 50 genes. In many cases, cytogenetic rearrangements such as deletions, translocations, or the presence of trinucleotide repeats for diseases demonstrating anticipation (defined as the earlier appearance of a more severe phenotype in successive generations) have provided the necessary additional clues for gene localization. Neurological disorders for which the responsible gene was discovered primarily by positional cloning include DMD, neurofibromatosis types 1 and 2, DM, and tuberous sclerosis. Currently, the number of disease genes identified by positional cloning strategies in which phenotypic features, suspected biochemical deficits, or chromosomal rearrangements were not used to select likely gene candidates is less than 10. Lander and Schork pointed out that the only two human disease genes with point mutations (rather than rearrangements, deletions, or trinucleotide repeats) that had been identified solely by positional cloning were cystic fibrosis and diastrophic dysplasia. More recently, the gene responsible for a majority of early onset cases of Alzheimer's disease (AD), presenilin 1 *(S182)*, was also identified by positional cloning. The fact that few neurological disease genes have been identified to date purely by positional cloning points to the crucial role of a combination of clinical, phenotypical, and biochemical studies.

CANDIDATE GENE APPROACH   In contrast to positional cloning, the candidate gene approach requires no knowledge of gene location. It can be used if knowledge of the disease phenotype suggests gene candidates. For example, accumulation of amyloid plaques in familial and sporadic AD raised the possibility that mutations in the β-amyloid precursor protein (APP) gene might cause some forms of familial Alzheimer's disease (FAD). Studies have shown that some 15–25% of FAD is associated with mutations in the APP gene and that these mutations can alter APP processing and contribute to amyloid formation. APP mutations have not been detected in sporadic AD. The discovery that the transmissible spongiform encephalopathies such as kuru and Creutzfeldt-Jakob disease involve aberrant metabolism of the prion protein raised the possibility that inherited spongiform encephalopathies might involve mutations in the prion protein gene. DNA sequencing demonstrated that various point mutations in this gene cause several inherited prion diseases including Gerstmann-Sträussler-Scheinker syndrome, Creutzfeldt-Jakob disease, and fatal familial insomnia. Significant genetic linkage between specific mutations in the prion protein gene and each phenotype further supported the role of these mutations in causing prion disease.

POSITIONAL CANDIDATE APPROACH   The positional candidate approach uses mapping to define a genomic locus linked to the disease followed by selection of gene candidates from the identified region based on biological or phenotypic knowledge of the disease. For example, the Huntington's disease (HD) gene was mapped to 4p16.3, and YAC contigs (overlapping DNA clones) from this region were established which included many candidate transcripts. The phenotypic observation that anticipation occurs in HD families had raised the possibility that the HD gene might contain a trinucleotide repeat; thus, efforts were focused on a transcript (IT15) that contained cytosine-adenine-guanine (CAG) repeats. Expansion of the IT15 CAG repeats was established to be the mutation causing HD *(see below)*. The presence of anticipation also guided efforts to pinpoint genes with trinucleotide expansions in DM and spinocerebellar ataxia (SCA). A positional candidate approach also identified the Xq28 gene responsible for X-linked hereditary hydrocephalus. In this instance, the morphology suggested a disorder in neuronal migration as a possible explanation for the developmental defect. One of the many genes present in the linkage-derived 2-Mb candidate interval was *L1*, a cell surface protein with amino acid sequence motifs characteristic of cell adhesion molecules (CAMs). Sequencing of the *L1* gene in normal controls and in patients with hereditary hydrocephalus demonstrated several disease-associated mutations. Since there are numerous CAMs and other categories of proteins modulating neural morphogenesis, studies that focused on the *L1* gene sequence would have been difficult to justify without mapping studies first pointing to the *L1* region.

The discovery that specific apolipoprotein E *(APOE)* alleles are associated with early versus late onset of AD also resulted from a combination of gene mapping and biochemical studies. Late-onset FAD was found to be linked to chromosome 19q markers located in a region containing *APOE* and other candidate genes. Biochemical investigation showing that APOE bound to amyloid β-peptide led to studies focusing on the potential relationship between *APOE* alleles and AD. The number of disease genes found by the combined strategies of positional cloning and candidate genes will continue to increase as the locations of human transcripts are mapped at an increasing rate and microsatellite markers with finer mapping resolution are made available.

TYPICAL STEPS
IN A POSITIONAL CANDIDATE APPROACH

1. DETERMINE CHROMOSOMAL LOCATION BY GENETIC LINKAGE ANALYSIS Genetic loci of disease-relevant genes are determined by establishing significant linkage between the disease phenotype and a particular form of a genetic marker at a known locus within one or more pedigrees. Significant linkage is formally determined by calculation of logarithm of odds (lod) scores. Three features of genetic linkage studies are especially crucial for successful gene mapping: (1) accurate clinical diagnosis, (2) the availability of large families, and (3) the use of informative genetic markers.

With respect to neurological disorders, the first point is of particular interest. The tremendous phenotypic complexity and the large number of overlapping features of many neurological and neuropsychiatric diseases limit the accuracy of many clinical classification systems. The phenotype of ataxia illustrates the problems of clinical nosology. Familial neurodegenerative diseases that cause ataxia can be associated with a plethora of other features such as dementia, retinitis pigmentosa, myelopathy, or neuropathy. Different combinations of these features have been used to create specific categories of hereditary ataxia. As Harding pointed out, purely clinical classification of hereditary ataxias can prove to be quite fallible. Members of the same family have been assigned to different disease categories, and individuals from families with mutations in different genes can have indistinguishable phenotypes. The latter point is of particular importance since misdiagnosis of only one individual within a pedigree or the inadvertent mixing of pedigrees with different diseases can invalidate lod scores. Fortunately, classification of inherited ataxias is becoming clearer as genotypes are established. It is important to note that the astonishing progress made in determining the genetic loci of neurological disorders has been possible because of the careful attention neurologists have given to the identification and classification of patients with familial neurological disorders.

2. ESTABLISH A GENETIC MAP AND NARROW THE CANDIDATE REGION WITH FLANKING MARKERS By using several microsatellite markers from one candidate region and multipoint linkage analysis, one can identify markers most closely flanking the disease gene and narrow the candidate region to 1–3 cM. However, the presence of chromosomal regions with lower- or higher-than-average rates of recombinations can result in up to a fivefold variation in distances determined by genetic versus physical methods. Fifty or more expressed genes may be present in a 1-Mb segment of genome.

3. ESTABLISH A PHYSICAL MAP OF THE CANDIDATE REGION Closely flanking microsatellite markers can be used to screen YAC libraries. By isolating overlapping contiguous YAC clones, a contig map is created that contains the loci of flanking microsatellite markers and therefore the candidate gene region. Contigs covering most of the human genome are now available. To narrow further the physical candidate region, clones with shorter fragments of human DNA can be derived either by subcloning fragments of YAC clones into smaller vectors or by screening cosmid or bacteriophage P1 libraries, which contain DNA fragments of up to 50 kb (cosmids) or 50–100 kb (P1) in length.

4. IDENTIFY CANDIDATE GENES IN THE REGION DEFINED BY THE CONTIG MAP Often, the most challenging step in the positional candidate approach is the identification of candidate genes interspersed over hundreds of kilobases of noncoding DNA. Presently, there is no accurate way to identify expressed genes merely by sequencing DNA. In order to isolate individual genes present in a YAC or P1 clone, DNA fragments derived from YAC or P1 clones can be used to screen cDNA libraries that contain DNA inserts derived only from expressed genes. Another method of gene isolation is known as exon trapping, or amplification, in which exons are selectively cloned based on their association with exon/intron splice junction sites. Sequencing of a candidate gene may result in several possible outcomes: the gene may be a previously discovered gene with known function, it may be a novel gene with significant sequence similarity to genes of known function and therefore may have a similar function, or the sequence may have no previously known motifs to offer a clue to function.

5. IDENTIFY DISEASE-ASSOCIATED ALTERATIONS IN DNA SEQUENCE OR STRUCTURE Once candidate genes are identified, several different strategies can be used to look for disease-associated mutations. In most cases, direct DNA sequencing of dozens of candidate genes derived from normal and disease DNA would not be feasible with current DNA-sequencing technology. Alternative strategies include focusing on genes with known or suspected functions that are likely to be relevant to the disease phenotype; screening for mutations by the technique of heteroduplex analysis or single-stranded conformation polymorphism (SSCP) analysis; and selecting genes with potentially relevant elements such as a trinucleotide repeat if one characteristic of the phenotype is anticipation.

6. PROVE THAT AN IDENTIFIED DNA ALTERATION IS THE CAUSE OF THE DISEASE DNA is highly polymorphic; for example, DNA sequence differs by 1–2 bp in every 1000 bp between two unrelated individuals. Thus, an altered DNA sequence in a candidate gene might constitute either a wild-type allele that does not cause disease, or a disease-causing mutant allele. It is possible that the "mutation" is a DNA polymorphism that is tightly linked to the disease locus but does not constitute the disease locus itself. DNA polymorphisms not causing altered phenotype are more likely not to affect transcription or protein structure and therefore are more likely to occur outside of transcription-relevant elements and open reading frames or in the third base of a codon. In contrast, disease-causing mutations often lead to nonconservative amino acid substitutions, open reading frame shifts, stop codons causing premature truncation of protein translation, disruption of transcription elements, or disruption of RNA splice sites.

Increasingly stringent criteria can be used to support the hypothesis that a given mutation is the cause of the disease phenotype: (1) all affected individuals, but none of the unaffected individuals, within a pedigree should have the mutation; (2) the mutation should not be present in a large series of unrelated controls; (3) in a case where the mutation has appeared *de novo*, the affected individual, but neither of the unaffected parents, should have the mutation; (4) protein expressed from DNA constructs containing the mutation should demonstrate altered function in vitro; or (5) transgenic animals expressing the mutant genotype should show some phenotypic features of the disease.

COMPLICATIONS AND LIMITATIONS
OF GENETIC MAPPING

Many diseases or phenotypes, including those of the nervous system, have a hereditary component yet do not exhibit classical mendelian inheritance that can be attributed to a single genetic

locus (*see* Chapter 4). These diseases or phenotypes have been referred to as "complex traits" and include susceptibilities to cancer, heart disease, hypertension, and diabetes. Complex traits manifesting in the nervous system may include dementia, migraine, Tourette-like syndromes, schizophrenia, and manic-depressive illness. Neurological diseases illustrate the point that genetic linkage approaches become more problematic with more complex phenotypes.

Many mechanisms can obscure modes of inheritance. Different mutations in the same gene can result in different phenotypes (allelic heterogeneity) and mutations occurring in different genes can result in the same phenotype (nonallelic genetic heterogeneity). Other features of genetic diseases that complicate mapping efforts include phenocopies, incomplete penetrance, variable expressivity, age-dependent onset of phenotype, polygenic inheritance, mitochondrial inheritance (Chapter 103), and dynamic mutations (trinucleotide repeats).

Characteristics of neurological diseases that may compound these uncertainties include the complexity of disease manifestations, common phenotypic overlap of different diseases, the lack of laboratory studies that confirm clinical diagnosis, and late age of onset. Some of the mechanisms that limit the use of linkage analysis for inherited disorders are listed below.

NONALLELIC GENETIC HETEROGENEITY   Nonallelic genetic heterogeneity describes the phenomenon of individuals or families with similar clinical syndromes who have mutations in different genes. One important implication of this phenomenon is the effect on genetic linkage analysis. The calculation of lod scores often involves pooling of multiple families with the same phenotype because statistical significance is difficult to achieve with one family. If families with mutations at different loci are pooled, positive and negative lod scores may cancel each other out and linkage will be missed. For this reason, the most conservative linkage analyses are limited to one large family. One example of nonallelic genetic heterogeneity is the multiple axonal forms of Charcot-Marie-Tooth disease (CMT). The locus for CMT type 1A is 17p11.2, and the disease mutation is in the peripheral myelin protein *(PMP-22)* gene. CMT type 1B, which is less common but clinically similar to CMT type 1A, is associated with a mutation on chromosome 1q. Other neurological diseases in which similar or indistinguishable phenotypes are caused by mutations in different genes include FAD, with loci at 14q24.3, 1q31–42, and 21q21.3, and the phenotypically similar SCA types 1, 2, and 3, with loci at 6p23, 12q23–24.1, and 14q24.3–31, respectively. Retinitis pigmentosa can be caused by mutations in more than 10 different genes. Nonallelic genetic heterogeneity is likely to be one of several factors that have limited successful genetic linkage studies of schizophrenia and manic-depressive illness. The lack of distinguishable clinical subcategories and/or the clinical complexity of these diseases makes accurate phenotypic analysis difficult and is likely to lead to inappropriate pooling of different genotypes.

ALLELIC HETEROGENEITY   Different phenotypes can result from different mutations in the same gene (allelic mutations). Unlike the process of nonallelic genetic heterogeneity, allelic heterogeneity is unlikely to complicate the calculation of lod scores. Examples of neurological diseases demonstrating phenotypic heterogeneity include Duchenne/Becker muscular dystrophy (dystrophin gene, Xp21.2), infantile/juvenile-onset spinal muscular atrophy (5q11.2–13.3), and familial Creutzfeldt-Jakob disease/fatal familial insomnia/Gerstmann-Sträussler-Scheinker

disease (prion protein gene, 20pter–p12). Each of these mutations results in different aberrant protein isoforms or alterations in expression that apparently trigger distinct disease mechanisms and phenotypes.

PHENOCOPIES   Individuals may have a clinical presentation that resembles a particular disease phenotype but has a nongenetic cause. Examples include vascular dementia appearing as FAD and toxin- or drug-induced chorea mimicking HD.

VARIABLE EXPRESSIVITY   Variable expressivity occurs when the severity of a trait resulting from a mutant allele varies from mild to severe. Expression of the disease phenotype can be modified by other factors such as predisposing alleles of other genes, environmental agents, sex, and age. Variation in expression can also occur following somatic variations in trinucleotide repeats as occurs in myotonic dystrophy.

INCOMPLETE PENETRANCE   Penetrance refers to the all-or-none expression of a mutant genotype. If a disease is expressed in less than 100% of individuals carrying the abnormal allele, it is said to have incomplete penetrance.

POLYGENIC INHERITANCE   Some diseases are caused by concomitant mutations in multiple genes. Polygenic inheritance has been observed in a form of retinitis pigmentosa that results when mutations in both the RDS/peripherin and *ROM1* genes are present. Similarly, some forms of Hirschsprung's disease may be caused by simultaneous mutations located at 13q22 and 10q11.2. Polygenic inheritance complicates mapping studies because a mutation at one locus may not always produce an abnormal phenotype.

More advanced mapping approaches have recently been reviewed. In allele-sharing methods, one demonstrates by polymorphic marker analysis that identical copies of a candidate chromosomal region are present in affected relatives of a pedigree more often than expected by chance. This type of approach was used to establish linkage of late-onset AD to chromosome 19 even though conventional linkage studies resulted in equivocal results. A second alternative mapping strategy consists of association studies, which do not require the availability of disease pedigrees because they compare allotypes of a gene of interest across unrelated affected and unaffected individuals from one population. Association studies demonstrated that *APOE* gene allotype has a significant association with age of onset of AD and implicated the *APOE* in the underlying mechanism of AD.

If an allele or a marker is close enough to a disease-causing gene and most cases of the disease in the population arise from a small number of ancestral mutations, then association studies will demonstrate linkage disequilibrium between the marker and the disease-causing gene. Linkage disequilibrium studies are particularly useful for genetically isolated populations. The power of linkage disequilibrium analysis was demonstrated by Nikali et al, who identified a locus for infantile-onset SCA in an isolated Finnish population by using DNA samples from only four affected individuals.

NON–DISEASE-BASED APPROACHES FOR CLONING NERVOUS SYSTEM GENES

An important source of candidates for disease genes are those cloned in the context of studies elucidating basic neurobiological mechanisms. Common cloning approaches are described below.

FROM PROTEIN TO GENE   As described above, purification of a protein responsible for a biological function of interest allows

oligonucleotide or antibody probes to be made, which are used to screen genomic or cDNA libraries. The resulting clones can be used for FISH to determine the chromosomal localization of the gene. FISH analysis with multiple probes can define interprobe relationships with a resolution as precise as 40 kb or less. Hundreds of genes cloned in this manner have contributed to physical maps of cloned genes with known functions. As illustrated in the example of X-linked hydrocephalus and the *L1* cell adhesion molecule gene, the availability of physical maps with genes of identified functions can contribute significantly to genetic linkage studies in discovering disease-causing genes.

FROM FUNCTION TO GENE In some cases, low abundance or other properties of a protein with known function make its purification difficult. In other cases, nothing is known about the nature of the protein responsible for a specific well-characterized function. If an assay is available that quantitatively detects the function of the protein of interest, this assay can be used to clone the corresponding gene. In one functional approach known as expression cloning, 5 or 10 randomly divided fractions of cDNA clones made from messenger RNA derived from tissue normally expressing the protein are each injected into frog oocytes in which proteins encoded by cDNA clones are expressed. Oocyte protein derived from one of the cDNA fractions will contain the specific activity of interest; that cDNA fraction can be further divided, injected again into oocytes, and the activity assayed. This cycle can be repeated until one cDNA clone responsible for the activity of interest is identified.

Expression cloning has been used to identify several genes likely to be critical in our understanding of neurological disease mechanisms. A gene encoding a vesicular amine transporter that suppresses MPP+ toxicity was isolated by screening Chinese hamster ovary fibroblasts transfected with pools of cDNA derived from MPP+-resistant cells, for MPP+ resistance. In another expression cloning study, a gene expressing a cocaine- and antidepressant-sensitive human noradrenaline transporter was found by screening COS cells, transfected with pools of cDNA derived from neuroblastoma cells, for noradrenaline accumulation. The availability of clones expressing neurotransmitter transporters will be critical for determining whether neurotransmitter transport has a significant role in neurodegenerative disease.

Another function-based approach for cloning genes is the yeast two-hybrid system. This system can be used to screen libraries for proteins that bind with a known target protein of interest. A plasmid containing the gene encoding the target protein and plasmids containing cDNAs derived from a tissue of interest are used to transform yeast cells such that each transformant expresses the target protein and a protein encoded by one cDNA. The plasmids also encode a DNA binding site, a transcription activating domain, and a reporter protein such as β-galactosidase. If the target protein binds with a protein expressed by cDNA inserts, the DNA binding site and transcription activation domains are brought into close proximity, causing the reporter gene to be expressed and the transformed cell to turn blue. Blue cells are likely to contain a cDNA encoding a protein that binds to the target protein. PCR-based sequencing of the identified cDNA reveals whether it represents a known or novel gene. In a search for proteins regulating the cell cycle, the cyclin-dependent kinase Cdk2 was used as a target protein to identify a new protein, Rbr2, which is related to the retinoblastoma protein. The yeast two-hybrid system was also used to discover the huntingtin-associated protein 1 (HAP1). HAP1 binds

to the N-terminal region of normal and mutant huntingtin, the protein expressed by the Huntington's disease gene.

CLONING ADDITIONAL MEMBERS OF GENE FAMILIES Different members of gene families often have similar functions. In order to discover additional genes coding for proteins with a desired function, several methods have been developed for cloning related family members. A cDNA probe corresponding to a previously cloned gene (the prototype family member) can be used to screen cDNA or genomic libraries under low stringency conditions, which allow identification of clones with similar as well as identical sequences. Clones with significant overall sequence similarity can then be used to express protein, and the protein can be assayed to establish if it has a function similar to the prototype protein. If two or more members of a gene family have been cloned, PCR primers corresponding to domains conserved across the known family members can be used to screen libraries for novel family members. This method has been used to discover three novel members of the neurotrophin gene family. Neurotrophins such as brain-derived neurotrophic factor (BDNF) are undergoing clinical trials for motor neuron disease and peripheral neuropathies. Homology of the presenilin 1 gene to one of several candidate genes in the 1q31 region contributed to the discovery of the presenilin 2 gene as an additional gene causing FAD.

CLONING HUMAN ANALOGS OF GENES CAUSING DISORDERS IN OTHER SPECIES The powerful methods of Drosophila genetics have led to the discovery of hundreds of mutations leading to phenotypes affecting the nervous system. In cases where the Drosophila phenotype has some resemblance to a human disease phenotype, probes based on the mutation-containing Drosophila gene can be used for low-stringency screening of human libraries to clone the human analog. A much smaller number of mutations have been found in mice, which have also been used to guide efforts for cloning human genes and identifying human mutations. For example, the discovery that the myelin-deficient trembler mouse contains point mutations in the *PMP-22* gene contributed to the hypothesis that CMT type 1A may be caused by mutations in human *PMP-22*.

GENOME SCANNING Two recently described techniques are being used to compare genomes from individuals with and without a given genetic disease with the hope of identifying chromosomal regions that do not match and therefore may be responsible for the phenotype. Methods such as genomic mismatch scanning (GMS) and representational difference analysis (RDA) may be particularly useful for multigene diseases.

RANDOM CLONING Several groups are conducting partial sequencing of randomly selected cDNA clones with the goal of having partial sequence (a minimum of one sequencing reaction or several hundred base pairs) from all expressed human genes. Partial cDNA sequences are generally specific to a given expressed gene and have been termed expressed sequence tags (ESTs). Some groups are focusing on human brain cDNA libraries, while others have targeted cDNA libraries made from cells relevant to pathologic processes to increase the chances of cloning disease-relevant genes. Partial sequence is often sufficient to assign a cDNA to a known gene family. Several thousand ESTs are being deposited in databases every week. Within the next 2 years virtually all expressed human genes are likely to be at least partially sequenced. Expanded cDNA sequence databases and integration with physical and genetic maps will contribute significantly to evaluation of candidate genes located in regions defined by mapping studies.

CLINICAL AND GENETIC CLASSIFICATION OF GENE DISORDERS

Genetic neurological disorders have traditionally been classified on the basis of clinicopathologic concepts of disease. Typical of classification schemes are those applied to hereditary ataxias, hereditary neuropathies, and myotonic dystrophies. Phenotypic classification criteria have also been used to establish subtypes of disorders such as Duchenne/Becker muscular dystrophy, neurofibromatosis types 1 and 2, and tuberous sclerosis types 1 and 2. The complexity, variability in phenotype, and overlapping features of these diseases limit the resolution of phenotype-based classification and complicate disease nosology. Accordingly, as new clinical studies have been undertaken these categories have been revised and continue to evolve. The derivation of tightly linked disease markers, identification of disease-causing mutations, and molecular genetic mechanisms responsible for these diseases have introduced new methodologies for disease categorization. For example, the phenotypic distinction between neurofibromatosis types 1 and 2 has been reinforced by the discovery that they are caused by mutations in different genes belonging to distinct gene families: GTPase-activating protein and the merlin cytoskeletal protein, respectively. In contrast, the finding that Duchenne and Becker muscular dystrophies are both caused by mutations of the dystrophin gene blurs the traditional distinction between these diseases. A comparison of the clinical categorization of the inherited ataxias with the identification of distinct genotypes has confirmed that mutations in different genes can lead to indistinguishable clinical syndromes. In other cases, diseases that would not have been viewed as related clinically have been found to be caused by mutations in the same gene. Both X-linked hereditary hydrocephalus and X-linked spastic paraparesis are caused by mutations in the *L1 CAM* gene. Perhaps the most dramatic example of a novel disease category evolving from discovery of new genes is the group of trinucleotide repeat diseases. To date, nine previously characterized and ostensibly largely unrelated disorders can now be considered in the context of the shared mechanism of unstable trinucleotide repeats (discussed *below*).

Hereditary neurological disorders with known gene localization are organized primarily by clinicopathologic phenotype in Table 96-1. In some cases, organization is influenced by genotype. The first group is the neurodegenerative disorders, which implies that deterioration and death of neurons occurs after normal development. These diseases may affect any portion of the nervous system. The second group is the epilepsy syndromes. The third group is the neuromuscular diseases, which affect the peripheral nervous system, the neuromuscular junction, or muscle. The fourth group is tumors of the central nervous system (CNS). The fifth group is abnormalities of development characterized by defects in neuronal development and migration. The availability of testing by DNA diagnostic laboratories is indicated in the far right column.

Different modes of inheritance occur in each of these categories. Neurological genetic disorders inherited in a mendelian autosomal dominant fashion include HD, FAD, amyotrophic lateral sclerosis (ALS), DM, CMT, familial hyperkalemic periodic paralysis, and tuberous sclerosis. Disorders with autosomal recessive traits include Friedreich's ataxia, Wilson's disease, Tay-Sachs disease, and other lysosomal disorders. X-linked recessive disorders include DMD, spinobulbar muscular atrophy (Kennedy's syndrome), Kallmann's syndrome, and fragile X syndrome.

The types of mutations causing neurological genetic disorders include gene deletions (the most common finding in DMD), translocations that interrupt the gene (neurofibromatosis type 1), and point mutations (e.g., in the superoxide dismutase gene in ALS). Point mutations can substitute an alternative base and thereby alter the amino acid sequence (missense mutations) or introduce stop codons leading to premature truncation of protein translation (nonsense mutations). These classical forms of DNA alterations are considered "static" mutations, because they generally remain stable during meiosis and provide the basis for classical mendelian inheritance. The discovery of unstable trinucleotide repeats has introduced the more recent concept of "dynamic" mutations, which account for some forms of non-mendelian inheritance such as the clinical phenomenon of anticipation.

THE CONTRIBUTION OF GENE CLONING TO ELUCIDATION OF NEUROLOGICAL DISEASE MECHANISMS

One of the strongest arguments for cloning disease genes and large-scale human genome projects is that the discovery of a disease gene leads to elucidation of pathogenetic mechanisms of disease and possible therapeutic approaches. It is important to note, however, that for a large number of the disorders listed in Table 96-1, cloning and sequencing of the gene responsible for the disease have not established the function of the gene product or fundamental principles regarding mechanisms of cell dysfunction or death. It is clear that identification of the disease gene and its product are just one part of the constellation of biological and clinical studies required to elucidate disease mechanisms. Highlighting this point of view is one of the most puzzling features of genetic neurological disorders including familial ALS and trinucleotide repeat diseases: in many diseases the mutant gene is widely expressed in many tissues, yet pathological manifestations are limited to subpopulations of cells. In some cases the nature of the protein encoded by the disease gene fits well into existing knowledge of the pathological process. Neurofibromatosis type 1 and tuberous sclerosis type 2 involve abnormal cell growth and are caused by mutations in GTPase-activating proteins, consistent with the fundamental role of GTPase in regulating cell growth.

One of the important outcomes of gene discovery is the development of tools such as antibody probes to launch the search for physiological function. Antibodies raised against the HD gene protein revealed that it is a cytoplasmic protein also associated with intracellular vesicles and therefore raised the possibility that abnormal vesicular function might contribute to the phenotype. Availability of clones with and without mutations can be used to express normal and aberrant forms of the protein to test hypotheses of protein function. An elegant example of this application is the demonstration of abnormal electrophysiologic properties of sodium channels containing specific and distinct mutations characteristic of hyperkalemic periodic paralysis and paramyotonia congenita respectively.

GENETICALLY INDUCED MECHANISMS OF CELL DEATH

The mechanism of cell death in genetic disorders remains unknown for most conditions. Three general mechanisms of mutation effects have been proposed: (1) loss of function, (2) dominant-negative effects, and (3) gain of function.

In loss-of-function disorders, the mutation leads to a deficiency in an enzyme or protein, resulting in cellular dysfunction. The best-defined examples are the lysosomal storage disorders, in which enzymatic deficiencies in complex lipid metabolism lead to accumulation of normal or abnormal cellular constituents. The

mode of inheritance in these disorders can be autosomal recessive, X-linked (as for example in DMD), or the result of a combined germ cell and somatic mutation that affects both alleles (such as the removal of a growth suppressor effect as occurs in tumors like retinoblastoma or neurofibromatosis type 1).

In the case of a dominant-negative effect, the abnormal mutation competes with or abolishes the normal allelic function at either the DNA, RNA, or protein level. Although this mechanism has been postulated to be an important example of cellular dysfunction in yeast, its role in neurological disorders remains speculative. True dominant disorders such as HD and SCA1, in which the heterozygote genotype elicits the full spectrum of the disease phenotype, could be the result of either dominant-negative or true gain-of-function effects. In the latter case, the abnormal cellular function exerted by the mutation at one allele in some way renders the cell susceptible to toxic effects, whether or not the normal allele is expressed.

DISORDERS ASSOCIATED WITH TRINUCLEOTIDE REPEATS

Nine neurological disorders are now recognized to be associated with abnormal expansions of trinucleotide repeats (Table 96-2). This section will provide an overview of trinucleotide repeat disorders; additional chapters will focus on HD and the SCA trinucleotide diseases. A convenient way of organizing repeat diseases and understanding their mechanisms can be based on the location of the repeat expansions within the gene. Expansions can occur in the 5' untranslated region (UTR), within the open reading frame (translated portion) of the gene, within the 3' UTR, or within introns.

Four fragile X sites (FRAXA, FRAXE, FRAXF, and FRA16A) are associated with expansions of CGG or CCG trinucleotide repeats located on the long arm of the X chromosome. Expansion of CGG trinucleotides is associated with hypermethylation of nearby CpG islands and chromosomal fragility. The FRAXA site is associated with the fragile X syndrome, the most common cause of inherited mental retardation syndromes. FRAXA is located in the 5' UTR of the *FMR1* gene, which encodes a protein identified as FMRP. Loss of FMRP is responsible for the fragile X phenotype. One model to account for the defect in fragile X syndrome is that expanded CGG repeats become methylated and become targets of methyl CpG-binding proteins that act to inhibit transcription. Studies showing decreased *FMR1* RNA and FMRP protein in fragile X patients support this loss-of-function model. In expansions of more than 200 repeats, inhibition of transcript translation also affects FMRP levels. Expansions at the FRAXE locus are associated with a milder form of mental retardation.

The second category of trinucleotide expansion diseases consists of five neurodegenerative disorders in which expansion of an open reading frame CAG repeat would be expected to lead to expanded polyglutamine tracts. The stretches of CAG repeats, which vary between 5 and 37 in the normal alleles of each condition, are increased by two- to fourfold in the mutation; increased severity of the neurological disorder demonstrates a striking correlation with larger numbers of repeats. Normal alleles identified to date never contain more than 38 CAG repeats. One possible disease mechanism is that the expanded polyglutamine tract causes a loss of protein function. The observations that deletions causing the loss of the HD and spinobulbar muscular atrophy (SBMA) genes do not lead to disease phenotypes and that HD patients homozygous for the disease allele have phenotypes similar to heterozygous patients argue against loss-of-function models. Instead,

these observations suggest a gain-of-function model in which the gained function is toxic to neurons. For example, expanded polyglutamine tracts might lead to the gained function of excessive protein transglutamination. Expanded polyglutamine tracts could also acquire the function of "polar zippers" due to hydrogen bond formation between main-chain and side-chain amides of interacting proteins. In both models, loss of the function of a crucial protein(s), inhibited or depleted by aberrant interaction with expanded polyglutamine tracts, would lead to neuronal degeneration. Recent studies showing that apparent open reading frame CAG repeats are indeed translated into protein and that expanded polyglutamine tracts in the HD protein lead to a potentially deleterious interaction with the glycolysis enyzme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) further encourage toxic gain-of-function models.

Gain-of-function mechanisms of polyglutamine tract diseases must also account for the findings that even though proteins associated with these neurodegenerative diseases are widely expressed by most neurons, each disease affects only a regionally specific, small subpopulation of neurons. One possibility is that each of these polyglutamine tract proteins interacts with proteins that are indeed cell type specific. Another potential mechanism of cell type specificity is that somatic instability of CAG repeats leads to greater expansions in specific cell populations. The relatively small variations of three to five in the number of triplet repeats in the HD gene occurring in different regions of the brain makes this explanation less likely.

A third category of trinucleotide repeat disorders consists of repeat expansion in the 3' UTR. So far, only one disease demonstrates expansion in this region. In DM, a GTC (CAG in the antisense) repeat in the 3' UTR of the DM kinase gene expands manyfold, from 5–40 repeats in normal alleles to several kilobases in severe cases. The DNA expansion is variable in different tissues, indicating that errors in DNA replication can occur during meiosis, as well as during subsequent somatic-cell mitosis. Since DNA sequence motifs in the 3' UTR of genes are thought to regulate transcript processing, expansions in this region might affect transcript levels and thereby alter DM kinase protein levels. Quantitative messenger RNA analysis of muscle biopsies demonstrated dramatic disease-specific decreases in DM kinase RNA in adult-onset myotonic dystrophy patients. Interestingly, levels of both the mutant and normal DM transcripts were decreased, suggesting a novel mechanism of a dominant-negative mutation occurring at the RNA level.

A second potential novel disease mechanism occurring in myotonic dystrophy is that expansion of the GTC repeat could also affect expression of nearby genes. The *DMR-N9* gene is located immediately upstream from the DM kinase gene and is expressed in neural tissue and testis. Interestingly, Jansen and colleagues have noted that in spite of characteristic cognitive impairment and testicular atrophy in DM patients, little or no DM kinase protein is present in these tissues. In contrast, the highest expression of *DMR-N9* is neural tissue and testis; therefore, alterations in its expression might better account for pathology at these sites. Studies showing that repeat expansion disrupts adjacent chromatin structure offer one mechanism by which expression of adjacent genes could be inhibited. The possibility that repeat expansions at one locus could affect expression of more than one gene by a *cis*-acting effect and that expansion-containing transcripts can affect levels

Table 96-1
Classification of Inherited Neurological Disorders

	Disorder	Chromosomal localization	Principal clinical findings—phenotype	Mode of inheritance	Genotype/gene products/functions/ disease mechanisms	OMIM[a] number(s)
Neurodegenerative diseases	Alzheimer's disease, early onset	AD4: 1q31–42	Dementia, memory loss, typical Alzheimer's disease	AD	Mutations in presenilin 2 gene *(SM2)*; product is a putative membrane protein that may be involved in intracellular protein transport	600759
	Alzheimer's disease, early onset	AD3: 14q24.3	Dementia, memory loss, typical Alzheimer's disease	AD	Mutations in presenilin 1 gene *(S182)*; product is a putative membrane protein that may be involved in intracellular protein transport	104311
	Alzheimer's disease, late onset familial and sporadic	AD2: 19q13.2	Memory loss, dementia	Codominant	Apolipoprotein E4 associated with increased risk and earlier age of onset; in vitro, APOE3 promotes and apo E4 inhibits neurite outgrowth; APOE4 binds to Aβ peptide less avidly than APOE3, and may promote fibrillogenesis	104310
	Familial Alzheimer's disease with amyloid precursor protein mutation	AD1: 21q21.3–22.05	Rare cause of early-onset Alzheimer's disease	AD	Point mutation in *APP* gene	104760
	Huntington's disease[b]	4p16.3	Chorea, dementia, rigidity, epilepsy in juvenile patients	AD	CAG triplet repeats 5' end of gene that encodes a novel protein huntingtin → expanded polyglutamate tract in protein may cause partial loss of some physiologic functions and gain of other functions	143100
	Familial Creutzfeldt-Jakob disease	20pter–p12	Spongiform encephalopathy with dementia, myoclonus	AD	Prion protein gene mutation	123400
	Fatal familial insomnia	20pter–p12	Adult-onset insomnia	AD	Prion protein gene mutation	600072
	Gerstmann-Straüssler-Scheinker disease	20pter–p12	Spongiform encephalopathy with dementia, myoclonus	AD	Prion protein gene mutation	137440
Movement disorders	Ataxia telangiectasia	11q22.3	Cerebellar degeneration, choreoathetosis, ocular apraxia oculocutaneous telangiectasia, immunodeficiency, endocrinopathy	AR	Mutations in *ATM* gene, which codes for protein with domains similar to phosphatidylinositol 3' kinase, an intracellular growth and differentiation factor signal transduction mediator, and rad3, a DNA repair monitor/cell cycle checkpoint regulator protein; mutations found in the same gene in all complementation groups suggest intragenic complementation	208900
	Autosomal dominant cerebellar ataxia with pigmentary macular dystrophy (ADCAII)	3p12–21.1	Cerebellar ataxia, decreased vision, ophthalmoplegia, decreased vibration sense, increased deep tendon reflexes	AD	Unknown; mapped to within 8 cM	164500

Dentatorubropallido-luysian atrophy (DRPLA)	12p12.3-13.1	Ataxia, choreoathetosis, dementia, progressive myoclonus epilepsy (PME), psychiatric disorder	AD	CAG repeat expansions in *DRPLA* gene—unknown function; PME more common with larger expansions	125370
Episodic ataxia type 1 (EA-1)	12p13	Ataxic episodes lasting seconds to minutes, myokymia, paroxysmal kinesogenic choreoathetosis, acetazolamide and phenytoin responsive	AD	Potassium channel *(KCNA1)* gene mutations	160120
Episodic ataxia type 2 (EA-2)	19p13	Ataxic episodes lasting hours to days, down gaze nystagmus, headache, progressive cerebellar signs and atrophy, acetazolamide responsive	AD	Unknown	108500
Friedreich's ataxia	9q13–21.1	Onset during puberty; ataxia, dysarthria, absent reflexes, decreased vibration, joint position sense cardiomyopathy, diabetes mellitus	AR	Unknown	229300
Ataxia with vitamin E deficiency, Friedreich-like (AVED)	8q13	Same as Friedreich's ataxia but with severe vitamin E deficiency	AR	Mutations in α-tocopherol transfer protein gene *(αTTP)* → impaired binding of vitamin E to VLDL	277460
Hereditary progressive dystonia with marked diurnal fluctuation (HPD)	14q22.1–22.2	Distal lower extremity dystonia in first decade, spreads to other limbs over years; symptoms greatest in evening, decreased in morning; responds markedly to levodopa	AD? female predominance	Mutations in GTP cyclohydrolase I gene → biopterin deficiency → decreased tyrosine hydroxylase activity → decreased dopamine	128230
Machado-Joseph disease (MJD)	14q24.3–31	Ataxia, ophthalmoparesis, corticospinal signs, dystonia-rigidity, amyotrophy	AD	CAG repeat expansions in *MJD1* gene	109150
Spinocerebellar ataxia 1 (SCA1)	6p23	Ataxia, progressive dementia, spasticity, onset 3rd or 4th decade; anticipation in successive generations	AD	Expansion of trinucleotide repeat (CAG) in ataxin 1	164400
Spinocerebellar ataxia 2 (SCA2)	12q23–24.1	Features extensively overlap with SCA1, but more common hypotonia and ophthalmoplegia	AD	Unknown; anticipation observed suggesting possibility of trinucleotide repeat expansion	183090
Spinocerebellar ataxia 3 (SCA3)	14q24.3–31	Similar to Machado-Joseph disease	AD	Allelic at Machado-Joseph disease locus	183085
Spinocerebellar ataxia 4 (SCA4)	16qter-24	Ataxia, axonal neuropathy, corticospinal signs, normal eye movements	AD	Unknown	600223
Spinocerebellar ataxia 5 (SCA5)	11 centromeric	Ataxia, dysarthria	AD	Unknown	600224
Torsion dystonia	9q34	Early onset, generalized dystonia, occurs in both Ashkenazi Jewish (AJ) and non-Jewish pedigrees	AD	Unknown	128100

(continued)

Table 96-1 *(continued)*

	Disorder	Chromosomal localization	Principal clinical findings—phenotype	Mode of inheritance	Genotype/gene products/functions/ disease mechanisms	OMIM[a] number(s)
	Wilson's disease	13q14.3	Disorder of copper transport into liver: extrapyramidal signs, psychiatric disorders	AR	Mutations in gene *ATP7B*, encoding a putative copper transporting P-type membrane ATPase, 57% similar to that associated with Menkes' syndrome (MNK)	277900
Retinitis pigmentosa	Retinitis pigmentosa 1	3q21-q24	Night blindness, peripheral field loss, blindness, abnormal ERG	AD	Mutations in gene that encodes rhodopsin → interference in maturational processing of wild-type protein	180100
	Retinitis pigmentosa, peripherin-related	6p21.1–cen	Night blindness, peripheral visual loss leading to blindness	AD	Mutations in RDS/peripherin gene, a rod photoreceptor membrane protein	179605
Spastic paraplegia	Autosomal dominant familial spastic paraplegia (SPG3, SPG4, SPG6)	SPG3: 14q SPG4: 2p21–24 SPG6: 15q11.1	Pure spastic paraplegia	AD	Unknown	SPG3: 182600 SPG4: 182601 SPG6: 600363
	Autosomal recessive familial spastic paraplegia	8q	Pure spastic paraplegia	AR	Unknown	600146
	X-linked familial spastic paraplegia 2 (SPG2)	Xq21–22	Initial pure spastic paraplegia; involvement of entire CNS over years	X-LR	Myelin proteolipid protein gene mutation; allelic with Pelizaeus-Merzbacher	312920
Vascular diseases	Cerebral autosomal dominant arteriopathy with subcortical infarcts (CADASIL)	19p12	Multiple subcortical infarcts, dementia	AD	Unknown	125310
	Familial cerebral amyloid angiopathy (Dutch type)	21q21.3–22.05	Cerebral hemorrhage	AD	Point mutations in *APP* gene	104760
	Familial hemiplegic migraine	19p13	Onset 5–30 years, aura with unilateral paresis and other focal symptoms lasting 30–60 min; followed by headache, may have persistent cerebellar signs	AD	Unknown, may be related to episodic ataxia type 2	141500
	Hereditary cystatin C amyloid angiopathy (HCCAA) (Icelandic)	20p11.2	Cerebral hemorrhage	AD	Mutations in cystatin C gene, product is a cysteine protease inhibitor; forms amyloid, which deposits in the walls of cerebral vessels	105150
Miscellaneous	Abetalipoproteinemia (Bassen-Kornzweig syndrome)	4q24	Vitamin E deficiency; neuropathy, ataxia, retinitis pigmentosa, acanthocytosis	AR	Mutations in gene coding large subunit of microsomal triglyceride transfer protein (MTP) → impairment of synthesis of VLDL	200100
	Adrenoleukodystrophy	Xq28	Leukodystrophy, hypoadrenalism, mild neuropathy, baldness, hypogonadism	X-LR	Mutations in ALD protein gene, a peroxisomal membrane transporter; associated with impaired β-oxidation of unbranched saturated very long chain fatty acids in peroxisomes	300100
	GM1 gangliosidosis	3p21.33	Mental retardation, seizures, blindness	AR	Mutations in gene encoding β-galactosidase, which cleaves the terminal saccharide of GM1; mutations → enzyme deficiency → cellular GM1 accumulation	230500

	Hypobetalipoproteinemia	2p24	Vitamin E deficiency; neuropathy, ataxia, retinitis pigmentosa, acanthocytosis	AR	Mutations of apolipoprotein β100 → low serum betalipoprotein → altered VLDL and chylomicron function	107730
	Menkes' syndrome (kinky hair disease, steely hair disease)	Xq13.3	Abnormal whitish kinky hair, growth and mental retardation, spastic quadriparesis, seizures	X-LR	Mutations in *ATP7A*, encoding MNK, a protein very similar to P-type cation-transporting membrane ATPases; may be involved in copper transport across membranes; mutations may lead to copper deficiency → copper dependent enzyme dysfunction	309400
	Pelizaeus-Merzbacher disease	Xq21–22	CNS dysmyelination; progressive neurologic deterioration	X-LR	30% have mutation in coding region of myelin proteolipid protein gene; allelic with X-linked familial spastic paraplegia 2	312080
	X-linked cutis laxa (occipital horn syndrome)	Xq13.3	Mild mental retardation, skin and joint laxity, skeletal deformities, bony horns projecting from occipital bone	X-LR	Allelic with MNK	304150
Epilepsy syndromes	Benign neonatal epilepsy 1 (EBN1)	20q13.2–13.3	Generalized seizures, neonatal onset, benign course, usually resolving at 6–12 mo, 10–15% have seizures later in life	AD	Mutations in the α-4 subunit of the neuronal nicotinic acetylcholine receptor gene	121200
	Benign neonatal epilepsy 2 (EBN2)	8q	Clinically indistinguishable from EBN1	AD	Unknown	121201
	Familial partial epilepsy	10q	Simple partial seizures, normal intelligence	AD, reduced penetrance	Unknown; mapped to within 10 cM	600512
	Juvenile myoclonic epilepsy (JME)	6p11–21.2	Onset in adolescence, myoclonic jerks, generalized tonic-clonic seizures	Uncertain	Gene locus named *EJM1*	254770
	Nocturnal frontal lobe epilepsy (ADNFLE)	20q13.2–13.3	Nocturnal seizures	AD	May be allelic with *EBN1*, also with a normal low-voltage electroencephalogram variant	600513
	Progressive epilepsy with mental retardation (EPMR)	8pter-p22	Normal at birth, generalized seizures onset age 5–10 years, severe mental retardation 2–5 years after seizure onset	AR	Unknown; mapped to within 7 cM	600143
	Progressive myoclonus epilepsy, Unverricht-Lundborg type (EPM1)	21q22.3	Generalized seizures, stimulus-reactive myoclonus, onset age 6–15, progressive	AR	Mutations in cystatin B gene	254800
Neuromuscular disorders Motor neuron diseases	Familial amyotrophic lateral sclerosis, adult, dominant (ALS1)	21q22.1	Weakness, muscle atrophy, spasticity, increased deep tendon reflexes; about 10% of cases are familial, indistinguishable clinically from sporadic form	AD	Point mutations in Cu,Zn-superoxide dismutase *(SOD1)* in some families (20%); heterogeneity exists → possible motor neuron injury due to defective detoxification of reactive oxygen species	105400
	Familial amyotrophic lateral sclerosis, juvenile recessive (ALS2)	2q33–35	Earlier onset and slower progression than ALS1	AR	Unknown	205100
	Familial amyotrophic lateral sclerosis, adult, dominant (ALS3)	11	Similar to ALS1	AD	Mutations in neurofilament protein heavy chain gene → disruption of neurofilament crosslinking	Not cited

(continued)

Table 96-1 *(continued)*

Disorder	Chromosomal localization	Principal clinical findings—phenotype	Mode of inheritance	Genotype/gene products/functions/ disease mechanisms	OMIM[a] number(s)
	Spinal muscular atrophy (SMA) I–III	5q11.2–13.3	SMAI: infantile (Werdnig-Hoffman) disease—present by 3 months of hypotonia, proximal limb weakness, areflexia SMAII: childhood onset, limb/girdle weakness, areflexia, 70% never ambulate independently SMAIII: juvenile (Kugelberg-Welander) disease—onset after age 2, slowly progressive symmetric proximal muscle weakness sparing bulbar muscles	AR	Mapped to about 1-Mb region; region is unstable and highly polymorphic making reconciliation of mapping data difficult; two candidate genes have been identified: neuronal apoptosis inhibitory protein *(NAIP)* gene, with amino acid homology to baculovirus apoptosis inhibitory proteins, and survival motor neuron *(SMN)* gene, coding a novel 294-aa protein	SMAI: 253300 SMAII: 253550 SMAIII: 253400
	Spinobulbar muscular atrophy (Kennedy's syndrome)	Xq12	Muscular weakness and atrophy	X-LR	Trinucleotide repeats in androgen receptor gene → expanded polyglutamate tract in protein may cause partial loss of some physiologic functions and gain of other functions	313200
Muscle diseases	Becker myotonia (recessive myotonia congenita)	7q35	Similar to myotonia congenita	AR	Known *ClC-1* mutations present in about 16% unrelated cases	255700
	Central core disease (CCD)	19q13.1	Nonprogressive primarily proximal myopathy, onset in infancy	AD	Mutation in ryanodine receptor gene *(RYR1)*; allelic with MHS1	117000
	Congenital muscular dystrophy (merosin deficient) (CMD)	6q2	Weakness and hypotonia at birth, limb contractures at birth or later	AR	Probable mutations in merosin gene	156225
	Congenital myasthenic syndromes/slow-channel syndrome (SCS)	2q,17p	Weakness, fatigability, hypotonia, muscle atrophy	AD (?)	Mutations in genes encoding subunits of the acetylcholine receptor → altered channel kinetics	100690
	Duchenne/Becker muscular dystrophy (DMD/BMD)	Xp21.2	DMD: onset of muscular weakness early in life, progressive; BMD form is later onset, less severe	X-LR	Mutations in dystrophin gene resulting in complete absence or major deletions of dystrophin (DMD), or less severe derangements of dystrophin structure (BMD) → disruption of linkage between microfilaments and the trans-sarcolemmal glycoprotein complex mediating adhesion to the extracellular matrix protein merosin → may lead to membrane damage with contraction	310200
	Emery-Dreifuss muscular dystrophy	Xq28	Childhood onset, benign course with early contractures, progressive muscle wasting with humeral/peroneal predominance, cardiac conduction defects-arrhythmias, heart block	X-LR	Mutations in emerin gene; codes a 254-aa serine-rich protein, which may be membrane-anchored and has unknown function	310300

Disease	Location	Clinical features	Inheritance	Molecular defect	OMIM
Facioscapulohumeral dystrophy	4q35	Weakness, atrophy; face and shoulder muscles	AD	Unknown; exhibits anticipation, which may be associated with successive deletions in a region of tandem repeats	158900
Fukuyama-type congenital muscular dystrophy (FCMD)	9q31-33	Weakness and hypotonia at birth, cerebral and cerebellar polymicrogyria and cerebellar cysts, ocular anomalies; overlaps with Walker-Warburg syndrome	AR	Unknown; proposed allelic with Walker-Warburg syndrome	253800
Hereditary myoglobinuria	1p32	Episodic myalgia, rhabdomyolysis, myoglobinuria presenting 2nd and 3rd decade	AR	Mutations in gene coding carnitine palmitoyltranserase II $\rightarrow$ diminished import of long-chain fatty acids into mitochondria $\rightarrow$ mitochondrial dysfunction	600650
Hyperkalemic periodic paralysis (HYPP)	17q23.1–25.3	Myotonia, periodic areflexic paralysis	AD	Point mutation in α-subunit, sodium channel (SCN4A) $\rightarrow$ impairment of sodium current inactivation; normokalemic variants occur (normoPP)	170500
Hypokalemic periodic paralysis (HOKPP)	1q32	Similar to HYPP, but attacks accompanied by hypokalemia, triggered by insulin and epinephrine, last longer and patients have no myotonia	AD	Loss of function mutations in α-1 subunit of the dihydropyridine (DHP) receptor gene, a slow voltage-gated L-type calcium channel $\rightarrow$? dominant negative disruption of channel function (decreased Ca^{2+} current); predominant expression in males may be hormone effect	170400
Limb-girdle muscular dystrophy, autosomal dominant 1A (LGMD1A)	5q22.3–31.3	Late (3rd decade) onset muscular dystrophy, sparing the face; slow progression	AD	Unknown; mapped to within 7 cM	159000
Limb-girdle muscular dystrophy, autosomal recessive 2A (LGMD2A)	15q15.1–21.1	Progressive symmetrical atrophy of proximal limb muscles, beginning in first two decades	AR	Mutations in calcium-activated neural protease 3 (CANP3), large subunit gene important, but probably requires another as yet unidentified mutation for disease expression (digenic model)	253600
Limb-girdle muscular dystrophy, autosomal recessive 2B (LGMD2B)	2p13–16	Pelvic girdle affected earliest; onset in late 2nd decade	AR	Unknown	253601
Malignant hyperthermia (MHS1)	19q13.1	Sensitivity to volatile anesthetics, muscle contraction	AD	Mutation in ryanodine receptor gene (RYR1) at 19q13.1 $\rightarrow$? disturbance of Ca^{2+} flux cells; when mild $\rightarrow$ excessive contraction; when severe (as in CCD?) $\rightarrow$ Ca^{2+}-mediated mitochondrial toxicity	145600
Malignant hyperthermia (MHS2,3,4)	MHS2: 17q11.2–24 MHS3: 7q21–22 MHS4: 3q13.1	Sensitivity to volatile anesthetics, muscle contraction	AD	Unknown	MHS2: 154275 MHS3: 154276 MHS4: 600467

Table 96-1 *(continued)*

	Disorder	Chromosomal localization	Principal clinical findings—phenotype	Mode of inheritance	Genotype/gene products/functions/ disease mechanisms	OMIM[a] number(s)
	Myotonia congenita (dominant MC, Thomsen's disease)	7q35	Onset 1st decade, muscle stiffness/myotonia, muscle hypertrophy without weakness	AD	Known mutations in the chloride channel gene *(ClC-1)* account for about 15% of MC cases. Mutations cause loss of function and functional channel is likely homo-oligomer → "dominant negative" mechanism	160800
	Myotonic dystrophy	19q13.3	Multisystem disorder: cataracts, myotonia, weakness, frontal baldness, mental retardation	AD, anticipation	CTG repeats at 3' end of myotonin protein kinase gene—product is membrane associated and localized primarily to neuromuscular and myotendinous junctions; expression of adjacent genes may also be affected	160900
	Nemaline myopathy	1p13–q25	Most commonly congenital non- or slowly progressive myopathy; forms range from severe congenital to mild adult	AD (other forms AR)	Dominant form associated with α-tropomyosin gene *(TPM3)* mutation. Met9Arg mutation may increase tropomyosin-actin affinity → rod body formation	256030 (general); 161800 (dominant)
	Oculopharyngeal muscular dystrophy (OPMD)	14q11.2–13	Onset usually after age 50, ptosis, dysphagia	AD	Gene unknown; maps near cardiac β-myosin	164300
	Paramyotonia congenita (PC)	17q23.1–25.3	Cold-induced muscle stiffness (myotonia) and weakness, occasional periodic paralysis	AD	*SCN4A* mutations; allelic with HYPP	168300
	Potassium-aggravated myotonia (PAM)	17q23.1–25.3	Potassium sensitive muscle stiffness (myotonia) and weakness, occasional periodic paralysis	AD	*SCN4A* mutations; allelic with HYPP (other variants occur ("sodium-channel myotonias")	170500
	Severe childhood autosomal recessive muscular dystrophy (SCARMD, LGMD2C, LGMD2D)	13q12, 17q21	Similar to DMD or BMD	AR	17q21-linked form: mutations of adhalin gene; adhalin is a component of the membrane glycoprotein complex noted above 13q12-linked form: gene unknown	LGMD2C: 253700 LGMD2D: 600119
	Startle disease (hyperekplexia)	5q33–35	Exaggerated startle, neonatal hypertonia, nocturnal myoclonus	AD, AR	Mutations in the α-1 subunit of the inhibitory glycine receptor → mechanisms unknown, though Arg271 mutations seen in some human cases; causes decreased agonist sensitivity in a mouse model	149400
	X-linked myotubular myopathy	Xq28	Severe neonatal hypotonia, apnea, common perinatal death	X-LR	Unknown	310400
Peripheral neuropathies	Charcot-Marie-Tooth disease type 1A (CMT1A)	17p11.2–12	HMSNI: Variable onset, motor > sensory neuropathy, distal muscle atrophy, absent reflexes, high arches in feet, decreased nerve conduction velocities, ± nerve enlargement	AD	Mutations or 1.5-Mb duplication in peripheral myelin protein gene *(PMP-22)*, product is a component of compact myelin	118220
	Charcot-Marie-Tooth disease type 1B (CMT1B)	1q22	HMSNI	AD	Mutations in *MPZ* gene, product is a component of compact myelin	118200

	Charcot-Marie-Tooth disease type 1, X-linked (CMTX1,2,3)	CMTX1: Xq13.1 CMTX2: Xp22.2 CMTX3: Xq26	HMSNI	X-linked dominant	CMTX1: mutations in connexin32 gene coding a gap junction protein localized to uncompacted peripheral myelin at the nodes of Ranvier and Schmidt-Lanterman clefts; CMTX2,3: genes unknown	CMTX1: 302800 CMTX2: 302801 CMTX3: 302802
	Charcot-Marie-Tooth disease type 2A (CMT2A)	1p35–36	HMSNII: Later onset, sensorimotor axonal neuropathy, near normal nerve conduction velocities	AD	Unknown	118210
	Charcot-Marie-Tooth disease, type 4A (CMT4A)	8q13–21.1	HMSNI	AR	Unknown	214400
	Dejerine-Sottas disease type A (DSDA)	17p11.2–12	HMSNIII: Onset birth/infancy, slowly progressive sensorimotor deficits, high arches, scoliosis, ataxia, enlarged nerves, markedly decreased conduction velocities	AD	*PMP-22* mutations *(see above)*	601097 (PMP22); 145900 (Dejerine-Sottas)
	Dejerine-Sottas disease type B (DSDB)	1q22–23	HMSNIII	?	Mutations in *MPZ* gene coding P_o protein *(see above)*	145900 (Dejerine-Sottas); 159440 (P_o mutation)
	Familial amyloidotic polyneuropathy (FAP)	18q11.2–12.1	Sensory/autonomic peripheral neuropathy, cardiomyopathy	AD	Mutations in transthyretin gene $\rightarrow$ formation of amyloid	176300
	Hereditary neuropathy with pressure palsies type A (HNPPA)	17p11.2	Recurrent entrapment/pressure neuropathies, segmental demyelination	?AD	*PMP-22* deletions; CMT1A and HNPPA may be reciprocal products of unequal crossover	162500
Central nervous system tumors	Neurofibromatosis type 1 (Von Recklinghausen) (NF1)	17q11.2	Multiple neurofibromas, 1:3500 individuals, *café au lait* spots, malignant gliomas, Lisch nodules in iris	AD	Encodes neurofibromin, a member of the Ras-GTPase-activating protein (GAP) family	162200
	Neurofibromatosis type 2 (NF2)	22q12.2	Acoustic neuromas, bilateral meningiomas	AD	Deletions in the gene that encodes for merlin/schwannomin, a tumor suppressor protein with sequence similarity to tyrosine phosphatase and cytoskeleton linkage protein	101000
	Retinoblastoma	13q14.1–14.2	40% hereditary, 60% nonhereditary, multiple tumors in inherited form	AR	Rb gene mutations or deletions cause disease; Rb protein is 105-kDa tumor suppressor, DNA-binding protein	180200
	Von Hippel-Lindau type 1, 2 (VHL1, VHL2)	3p25–26	Type 1: retinal angiomas, CNS hemangioblastomas, pancreatic cysts in some; type 2: identical to type 1 plus pheochromocytoma	AD	Type 1: 56% microdeletions, deletions, insertions, nonsense mutations in VHL gene, a tumor suppressor of otherwise unknown function; type 2: 96% missense mutations in VHL gene	193300
Defects of neuronal migration and differentiation	Familial cavernous malformations of the brain	7q11.2–21	Seizures, headache, intracerebral hemorrhage, neurologic deficits	AD	Unknown	116860

(continued)

Table 96-1 *(continued)*

Disorder	Chromosomal localization	Principal clinical findings—phenotype	Mode of inheritance	Genotype/gene products/functions/ disease mechanisms	OMIM[a] number(s)
Familial dysautonomia, Riley-Day syndrome	9q31–33	Onset in infancy, autonomic dysfunction, taste, pain and temperature loss; seen in Ashkenazi Jewish populations	AR	Unknown	223900
Fragile X syndrome A (FRAXA)	Xq27.3	Mental retardation, decreased head size, large forehead, macro-orchidism	X-LR	CGG trinucleotide repeat expansions in 5' region of *FMR1* → transcriptional inhibition of gene due to overmethylation, as well as translational inhibition; *FMR1* product contains KH domains and RGG box, motifs found in RNA binding proteins	309550
Fragile X syndrome E (FRAXE)	Xq28	Mild mental retardation	X-LR	CGG/CCG repeat expansions, 600 kb distal to FRAXA site; developmentally regulated transcript recently found in region	309548
Hirschsprung's disease 1 (HSCR1)	10q11.2	Neonatal megacolon due to absence of Messner and Auerbach plexuses	AD	Mutations in *ret* proto-oncogene. Product (c-ret) is a receptor tyrosine kinase with extracellular domain similar to cadherins; thought to be involved in enteric neuronal migration or differentiation; mutations in *ret* also associated with multiple endocrine neoplasia type 2A	142623
Hirschsprung's disease 2 (HSCR2)	13q22	Very similar or identical to HSCR1	Dose-dependent expression homozygotes 74%, heterozygotes 21%	Mutations in the endothelin B receptor (EDNRB) gene; product is a G-protein-coupled receptor which mediates cellular calcium fluxes; mutations → loss of function; disease expression probably requires participation of other loci	600155
Hydrocephalus due to stenosis of the aqueduct of Sylvius (HSAS)	Xq28	Hydrocephalus with moderate to severe mental retardation, adducted hypoplastic thumbs (25% of cases), spastic paraparesis, aplasia or hypoplasia of the corticospinal tract and corpus callosum	X-LR	Mutations in *L1* gene—product is a multifunctional/multidomain cell adhesion molecule	307000
Kallmann syndrome	Xp22.3	Anosmia with hypogonadism (GnRH deficiency), syndrome due to failure of olfactory neuronal migration	X-LR	Mutations in gene *(KALIG-1)* which encodes protein with homology to neural-cell adhesion molecules (N-CAM)	308700
MASA syndrome (Gareis-Mason syndrome)	Xq28	Mental retardation, aphasia, shuffling gait (due to spastic paraparesis) and adducted thumbs (due to absent or hypoplastic extensor pollicis brevis and/or longus), may also have hydrocephalus	X-LR	*L1* mutations	303350

Miller-Dieker lissencephaly syndrome	17p13.3	Microcephaly, micrognathia, epilepsy, agyria due to failure of cortical neuronal migration	AD	Mutation in *LIS-1* gene coding the 45-kDa (regulatory) subunit of platelet-activating factor (PAF) acetylhydrolase; part of heterotrimeric enzyme, which inactivates PAF; PAF proposed to modulate neuronal differentiation or migration; effect of mutation on PAF unknown	247200
Norrie disease (ND)	Xp11.4	Retinal malformation, hearing loss, mental retardation	X-LR	Mutations in *ND*; sequence comparisons and modeling suggest similarity to transforming growth factor–β family/cysteine-knot motif growth factors	310600
Tuberous sclerosis type 1	9q34	1:10,000 births, mental retardation, seizures, adenoma sebaceum	AD	Unknown; may be a growth suppressor	191100
Tuberous sclerosis type 2	16p13.3	Hamartomas, epilepsy, mental retardation	AD	Gene encodes tuberin, which has homology to GTPase activating protein GAP3; effects of mutations on gene function unknown	191092
Waardenburg syndrome 1 (WS1)	2q35	Deafness, white forelock, dystopia canthorum, pigmentary abnormalities	AD	Mutation in paired box-containing *(PAX)*–3 gene; product is a transcription factor involved in embryonic patterning/neural crest migration; heterozygotes have WS1, homozygotes have WS3, which is more severe and includes upper limb abnormalities	193500
Waardenburg syndrome 2 (WS2)	3p12.3–14.1	Deafness, white forelock, dystopia canthorum, heterochromia irides, early greying	AD	Mutations in microphthalmia (MITF) gene encoding a putative basic helix-loop-helix-leucine-zipper transcription factor	193510
Walker-Warburg syndrome (WWS)	9q31–33	Lissencephaly, ocular anomalies, hydrocephalus, callosal hypoplasia, septal agenesis, congenital muscular dystrophy	AR	Unknown; proposed allelic with FCMD	236670
X-linked spastic paraplegia type 1 (XLSP or SPG1)	Xq28	Spastic paraplegia, ataxia, absent extensor pollicis longus	X-LR	*L1* mutations	312900

Abbreviations: AD, autosomal dominant; APP, amyloid precursor protein; AR, autosomal recessive; CNS, central nervous system; ERG, electroretinogram; GnRH, gonadotropin-releasing hormone; Rb, retinoblastoma; SCA, spinocerebellar ataxia; VLDL, very low density lipoprotein; X-LR, X-linked recessive.

[b]HD causes both dementia and movement disorder.

Table 2
Neurological Diseases Caused by Expansion of Trinucleotide Repeats

Disorders	Site of repeat	Effect on gene expression
Fragile X-A	CGG repeat 5' to translation initiation site; point mutation identified in some patients	Failure of expression of *FMR1*
Fragile X-E	CGG/CCG repeats; relationship to genes unknown	Unknown
Dentatorubropallidoluysian atrophy (DRPLA)	CAG repeat in open reading frame (ORF)	Normal gene expression
Huntington's disease	CAG repeat in ORF	IT15 transcript shows normal expression without cellular selectivity; expanded polyglutamine tract may alter huntingtin protein intersection with huntingtin-associated protein 1 (HAP1) or GAPDH
Kennedy's syndrome	CAG repeat in ORF of androgen receptor gene	Normal gene expression; polyglutamine tract in androgen receptor
Spinocerebellar ataxia type 1 (SCA1)	CAG repeat in ORF	Normal gene expression
Spinocerebellar ataxia type 3 (SCA3)/Machado-Joseph disease	CAG repeat in ORF	Unknown
Myotonic dystrophy	CTG repeat in 3' untranslated region of *DM-1* gene, 5' end of dystrophia myotonia-associated homeodomain protein gene; cases without repeats also described	Gene expression decreased; possible dominant-negative effect at RNA level
Friedreich's ataxia	GAA repeat in the first intron of the *X25* gene	Gene expression decreased

of transcripts derived from a separate allele by a *trans*-acting effect point to many new potential scenarios for the mechanism of DM.

A fourth category of trinucleotide repeat diseases is caused by expansion of a repeat in an intron. Friedreich's ataxia (FA) is caused by the expansion of a GAA triplet in intron 1 of the *X25* gene leading to decreased mRNA levels due to either inhibition of transcription or disrupted RNA splicing. The majority of FA patients tested thus far demonstrate homozygosity for expanded alleles, while some are heterozygous with a combination of one expanded allele and point mutations in the other allele. These genotypes are consistent with an autosomal recessive pattern of inheritance and a loss-of-function disease mechanism.

The discovery of triplet repeats and analysis of the ages of onset of affected individuals has given a molecular precision to old concepts such as anticipation (earlier onset of the disease in successive generations, which is associated with further expansion of the abnormal repeats in persons who are more severely affected) and has helped to account for variations in gene expression. Variations in trinucleotide repeats in HD (and particularly in DM) have given a molecular explanation for concepts of variable expressivity, in which variations in repeats occurring among individual members of the family can lead to earlier onset, or more severe symptoms and signs, as occurs in juvenile HD. Variations in the numbers of repeats in somatic cells resulting from further expansions of repeats in cells undergoing mitotic divisions, as in DM, can also explain differences in tissue involvement. Studies suggesting that other neurological and psychiatric disorders involve anticipation and the identification of other genes with trinucleotide repeats raise the possibility that additional trinucleotide repeat diseases will be discovered.

DNA-BASED DIAGNOSIS OF NEUROLOGICAL DISORDERS   Many of the disorders listed in Table 96-1 have been mapped to specific chromosomes or chromosomal regions; however, the particular genes affected by mutations have yet to

be identified. For some of these diseases, DNA diagnosis or presymptomatic testing is possible by family linkage analysis. Successful family linkage analysis requires that family relationships (such as paternity) are accurately established, that the clinical status of affected or unaffected individuals is accurate, that a sufficient number of family members can be genotyped, and that informative markers are available. For many patients, these requirements often rule out application of DNA diagnosis.

The rapid rate at which disease genes are being identified is rendering direct DNA diagnosis more widely applicable. In genetic diseases in which the pathological phenotype is caused by only one or a small number of well-defined mutations within a given gene, detection of the mutation is an extremely useful tool in clinical diagnosis. Methods of detecting DNA mutations for diagnostic purposes include direct sequencing of patient DNA, allele-specific oligonucleotide hybridization, differential restriction endonuclease patterns of PCR products, and analysis of single-stranded conformation polymorphisms (*see* Chapters 2 and 4).

The limitations of DNA testing in the context of neurological disorders should be emphasized. First, if the clinical diagnosis being considered is in error or if the phenotype overlaps with other disorders, the detection of normal alleles of the gene tested is of no diagnostic value. For example, in cases of suspected hereditary spinocerebellar ataxia, investigators have suggested concomitant analysis of multiple SCA genes.

Second, some diseases such as DM, neurofibromatosis, and hereditary amyloid polyneuropathy can be caused by dozens of different mutations within one gene (allelic heterogeneity). Most methods of DNA analysis focus on point mutations or relatively short segments of DNA; therefore, assessment of numerous loci scattered over a wide area of DNA becomes impractical for most clinical applications. Mutations are identified in only about two-thirds of DMD/Becker muscular dystrophy (BMD) and neurofi-

bromatosis type 2 patients and in less than half of those with neu-rofibromatosis type 1. Recent advances in multiplex PCR and single-stranded chain polymorphism analysis have improved this yield; however, it is essential that the clinician be aware of the "sensitivity" of each DNA analysis.

It is also possible that focused DNA analysis could miss the presence of a novel mutation in the relevant gene. For these reasons, particularly for many genes involved in metabolic diseases, diagnostic methods based on protein properties or function are more effective and efficient than DNA-based tests. For example, dystrophin antibodies may show decreased expression or aberrant distribution of dystrophin expression in a muscle biopsy of a patient in which no DNA mutations were detected.

DNA testing can be performed by commercial laboratories, hospital-based laboratories set up for clinical applications, or academic laboratories studying a gene of interest in a research context. It must be emphasized that DNA testing should only be conducted in the context of comprehensive genetic counseling in which the implications of potential test results are fully understood and adequate support services are available. The practical and ethical implications of neurogenetic testing have recently been reviewed. A computerized directory of diagnostic and research DNA laboratories (known as Helix) is accessible by phone and fax at no cost to registered health care professionals. Laboratories are encouraged to list their services with Helix, also at no cost. Information on access and/or listing new laboratories may be obtained at the Helix office (tel: 206-528-2689; fax: 206-528-2687).

97 Huntington's Disease

MARCY E. MACDONALD

INTRODUCTION

In 1872 George Huntington reported a perplexing and fatal disease that afflicted some of his patients who were members of the same East Hampton Long Island families cared for by his physician father and grandfather in previous generations. The ailment, an unremitting, adult-onset "hereditary chorea," became known as Huntington's chorea but is now called Huntington's disease (HD) (OMIM 143100), to reflect the constellation of motor, psychiatric, and cognitive deficits that attend the disorder.

Huntington emphasized the familial nature of the disease, reporting that it was frequently transmitted by either affected mothers or fathers to their children, never skipping a generation, a pattern that was subsequently attributed to the inheritance of an autosomal dominant mendelian gene defect. He thought that the disorder must represent "an heirloom from generations away back in the dim past," a conjecture later supported by Vessie's observation that many of the Long Island families were descendants of immigrants from Bures, England, who arrived in New England in 1649.

The disorder is not restricted to Long Island, as Huntington believed, but is found worldwide, with the lowest prevalence in Blacks and Asians, and the highest, approximately 4–7 cases per 100,000, in populations of Western European ancestry. Finland, with its distinct genetic origin, has a lower disease prevalence than the rest of Europe. However, the frequency of the genetic defect, *HD*, is 2.5 to 3-fold higher, because at any given time an estimated two out of three gene carriers are too young to exhibit disease symptoms, which typically do not strike until middle age.

The unique clinical symptoms arise from a progressive and graded loss of neurons, primarily in the basal ganglia, that is triggered mysteriously by the *HD* gene defect. The biochemical basis for the cell loss remains an enigma, but HD is yielding to a molecular genetic approach; in 1983 *HD* was the first defect mapped to a chromosomal location using only genetic linkage to DNA markers, and a decade later it was found to be an elongated, unstable CAG trinucleotide repeat in a novel 4p16.3 gene. The nature of the mutation clarifies many of the puzzling genetic features of the ailment, and its discovery reveals that HD is one of a number of neurodegenerative diseases whose distinct pathologies are caused by the shared theme of an expanded triplet repeat.

CLINICAL FEATURES

Huntington's original report, a classic description of the manifestations of HD, remarked on the three disorders that together make HD a distinct clinical entity: progressive motor impairment, cognitive decline, and emotional deterioration. The majority of patients become symptomatic in midlife, as was the case in Huntington's families, but the disease can strike at any age, and approximately 10% of cases exhibit symptoms before the age of 20 (juvenile onset) or after the age of 55 (late onset).

The severity of the movement disorder, which involves both voluntary and involuntary systems, is variable, changing during the course of the disease and being more or less pronounced depending on the age of the patient when symptoms first begin. Typically, it starts subtly in midlife with clumsiness, motor restlessness, and slight adventitious movements, and progresses to frank chorea, sudden unintended movements of almost any part of the body. Although chorea is a prominent feature in most midlife and late onset-adult patients, it may not be seen in juvenile-onset HD, which follows a more aggressive course, featuring seizures, rigidity, myoclonus, or dystonia. At all ages, there is a progressive loss of voluntary motor function that is evident from abnormal eye saccades and an inability to perform tasks demanding fine motor control. Walking is also affected and patients usually assume a wide-gaited stance. As the disease steadily worsens over a period of 15–20 years, patients inevitably become incapacitated, unable to communicate by word or gesture, and incapable of eating and walking without assistance. Near the end most patients are bedridden, and, for many, death results from asphyxiation or infection arising from inhalation of food particles.

The cognitive and psychiatric deficits of HD often precede the onset of neurologic symptoms and manifest as dementia, memory loss, apathy, and bouts of deep depression. The most commonly reported initial symptoms are irritability and restlessness. Patients are unable to change easily from one task to another, job performance cannot be maintained, and most become periodically depressed and lose interest in family and work. The disease is also associated with an increased risk of suicide. Although the severity of the psychiatric and cognitive symptoms is variable, these aspects of the disease pose significant challenges for the care of HD patients.

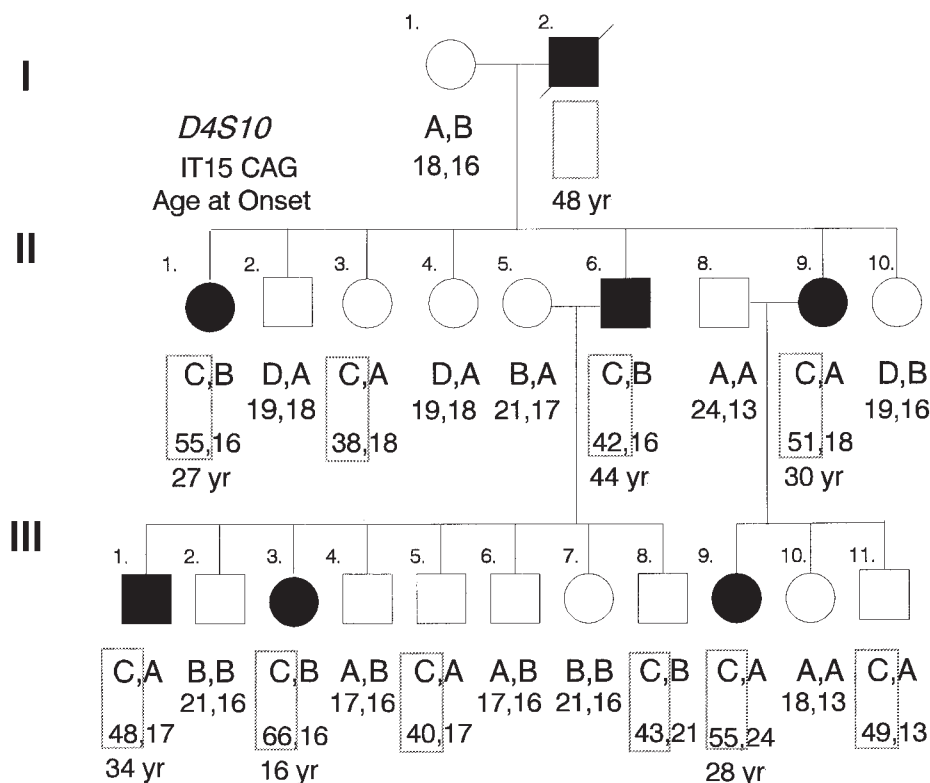
HD is almost invariably present within a family and it is usually possible to establish the inherited nature of the disease by asking the patient or related family members for genealogical information (Fig. 97-1). The disease is transmitted by both males and females in an autosomal dominant manner, and both sexes have a


Figure 97-1 Genetic characteristics of HD. An idealized three generation **(I–III)** HD pedigree is depicted with family members—males (circles) and females (squares)—numbered sequentially. Filled symbols, clinically diagnosed members; slashed symbol, a deceased individual. Genotyping results for *D4S10* marker alleles (A,B,C,D) and the *HD* CAG repeat length measurement (IT15 CAG) at both alleles (larger shown first by convention) are shown below each symbol, with the marker alleles on the disease chromosome given within a box. The age at onset (yr) is also shown below symbols of symptomatic family members. The disease is segregating with the C allele of *D4S10*, a linked marker that exhibits 4% recombination with HD. Individuals who have inherited the C allele from their affected parent (II-1, II-3, II-6, II-9, III-1, III-3, III-5, III-8, III-9, III-11), therefore, have a 96% chance of having inherited the *HD* defect. Direct determination of the length of the *HD* CAG repeat demonstrates that all of these individuals have inherited the *HD* defect. One child (III-3) had juvenile onset due to a CAG allele of 66 repeat units but many other individuals are not yet old enough to have become symptomatic (II-3, III-5, III-8, III-11) including an elderly individual in generation II (II-3) who inherited a disease chromosome that has 38 CAG repeats.

50–50 chance of inheriting the defect, although the relatively rare juvenile form of the disease occurs most frequently as a result of transmission through the male germline. The *HD* defect is highly penetrant, and individuals who have inherited it will develop symptoms if they live a normal life span. Sadly, because HD generally strikes in middle age, the defective gene is often passed on to children before the parent is aware of his or her disorder.

PATHOLOGY

Huntington's disease-associated pathology appears to be confined to the brain. The basal ganglia, especially the striatum, is in the course of time ravaged by the disease, and the dramatic cell loss becomes evident on magnetic resonance imaging (MRI) and positron emission tomography (PET) scans. The atrophy is due to the progressive loss of one of the major striatal neuronal cell populations, the γ-aminobutyric acid (GABA)-, enkephalin-, and substance P-containing medium-sized spiny projection neurons. There is also neuronal cell loss in the globus pallidus. However, with the exception of the cortex, other brain regions are not obviously affected, and other striatal neuronal populations, such as the large acetylcholine-rich or smaller somatostatin- and neuropeptide Y-containing aspiny interneurons, are spared by the gene defect. The death of striatal neurons begins in the medial dorsal region of the caudate and progresses along posteroanterior, dorsoventral, and mediolateral axes, producing a characteristic gradient of cell loss that forms the basis of the neuropathologic evaluation of HD.

The cerebral cortex, another primary target of the gene defect, consistently exhibits a diffuse pattern of neuronal cell loss rather than the focal pathology found in the basal ganglia. Total brain weight is reduced about 20–30% in end-stage disease, a consequence of massive cell death that is especially apparent in juvenile-onset cases. Inconsistent alterations involving almost every cell population and brain region, including the thalamic and subthalamic nuclei, brain stem, and spinal cord, have been reported, but it is likely that these changes are secondary features of the disease rather than primary effects of the *HD* defect.

The obvious striatal degeneration provides an explanation for the motor and perhaps the cognitive and emotional features of HD as the basal ganglia receives inputs from cortical areas serving these functions. Loss of the striatal input to the globus pallidus probably results in the choreiform movements of HD because of increased inhibitory pallidal input to the subthalamic nucleus, a region whose destruction by other means elicits chorea. Similarly, loss of striatal input to the frontal cortex and the superior colliculus is likely to be involved in the loss of control over voluntary movements such as eye saccades.

Glutamate is the major excitatory neurotransmitter of the cortical-striatal pathway but a variety of neurotransmitters and neuropeptides are found in both regions. Indeed, these biologically active molecules appeared to be good targets for treatment schemes that are based on the idea that rectification of a neurochemical imbalance caused by the gradual loss of neuronal cells could slow or prevent the progression of disease pathology. However, a selective neurotransmitter deficit has not been found in HD, and therapeutic strategies arising from these neurochemical surveys have been ineffective.

The biochemical lesion that precipitates the apparently specific neuronal cell loss in HD remains elusive despite increasingly sophisticated cellular and neurochemical descriptions of the disease pathology. Changes in a myriad of neurotransmitters, amino acid receptors, and metabolites have been reported, and some may contribute to the clinical symptoms of HD, but these alterations are likely to be a consequence of the cell death rather than a direct effect of the disease gene. Some changes that are seen in HD, including reduced numbers of N-methyl-D-aspartate (NMDA) receptors, decreased glucose utilization, and elevated lactose concentration, are consistent with a currently favored hypothesis that is emerging from animal studies. This model proposes that neuronal cell death is a consequence of NMDA receptor-mediated glutamate excitotoxicity that occurs via either an acute direct mechanism or a subtle route such as a defect in energy metabolism.

CLINICAL DIAGNOSIS

Diagnosis of HD based on neurologic or psychiatric examination is relatively straightforward despite the variable age at onset and age-dependent differences in clinical presentation. In many cases the clinical diagnosis is strengthened by evidence of HD neuropathology at autopsy in a previously diagnosed family member. Because the disease almost always presents in someone with a family history of the disorder, inheritance is a commonly used diagnostic criterion, but this information may not be available when dealing with very late onset cases or adoptees, making diagnosis more difficult in these individuals.

The differential diagnosis of HD theoretically includes disorders involving voluntary and involuntary motor dysfunctions and many forms of mental illness; in practice, however, few diseases are confused with HD clinically. Some disorders with overlapping symptoms, including cortical stroke, schizophrenia, and cortical dementias, are relatively common and consequently may be initially confused with HD but are ultimately distinguished as the disease progresses. Familial diseases that exhibit HD-like symptoms, such as choreo-acanthocytosis, benign hereditary chorea, and dentatorubropallidoluysian atrophy, are very rare and also can be distinguished from HD by a variety of means including neurological examination, neuropathology, and, most recently, direct DNA testing.

GENETIC LINKAGE

In 1983 *HD* was the first gene defect mapped to a human chromosome using a genetic strategy that exploits naturally occurring DNA sequence variation (polymorphism) to search the human genome for chromosomal segments that are coinherited with the defect in disease families. Genetic linkage to polymorphic DNA markers is used first to discover the approximate chromosomal location of the defect and then to narrow progressively the amount of chromosomal DNA that must be searched to identify the muta-

tion itself. This strategy, which does not require any knowledge of the disease gene, its function, or its mechanism of pathogenesis, is now widely used to isolate mutant genes that cause inherited human disease.

HD was an ideal candidate for pioneering this approach because it exhibits high penetrance, unique clinical manifestations, and midlife onset, which conspire to produce large, identifiable families with the disease. Genetic linkage was quickly discovered by tracing the inheritance of restriction fragment length polymorphisms (RFLPs) detected by anonymous DNA probes in HD kindred. No crossover events were observed between two *Hin*dIII RFLPs, detected by the probe G8, and the disease gene in two large pedigrees (one of American and the other of Venezuelan ancestry) producing odds of greater than 100 million to one in favor of genetic linkage between *D4S10* and *HD*. Assignment of G8 to the short arm of chromosome 4 placed *HD* close to 4p16.3, the terminal cytogenetic band of the short arm of chromosome 4.

The discovery of genetic linkage provided the means to test whether the same gene defect that resides on chromosome 4 was responsible for causing disease symptoms in all HD families. Indeed, this was proven to be the case, as all HD families genotyped exhibited linkage to *D4S10* regardless of ethnic or genetic background. The absence of nonallelic heterogeneity meant that, for the first time, an accurate predictive test could be offered to some asymptomatic individuals who are "at risk" for the disorder because a parent has the disease (*see* Fig. 97-1).

Family studies with the linked DNA markers also revealed the complete phenotypic dominance of the disorder. Rare HD homozygotes, individuals with two copies of the *HD* defect, one inherited from each affected parent, were found to be clinically indistinguishable from their affected heterozygous siblings, who have only one copy of the mutation. This surprising finding argues that the normal *HD* gene does not help delay or otherwise influence the clinical features of the disorder and demonstrates that two copies of the disease gene are not significantly more damaging than a single copy.

ISOLATION OF THE *HD* MUTATION

Genetic linkage set the stage for the isolation of the *HD* defect from the vicinity of *D4S10* (Fig. 97-2). Genotyping of a large number of HD families demonstrated that *HD* and *D4S10* displayed about 4% recombination, and linkage analysis with DNA markers located centromeric to *D4S10* revealed that the defect was located within 4p16.3 between *D4S10* and the telomere, a distance of about 6 Mb of DNA. The location cloning strategy that progressively refined the candidate region and ultimately led to the discovery of the *HD* mutation then progressed through a number of stages. Initial efforts were aimed at the generation of somatic cell and radiation hybrid mapping panels that were required for the generation of a large number of polymorphic RFLPs, variable number of tandem repeat (VNTR), and simple sequence repeat (SSR) genetic markers from 4p16.3. As new markers were cloned they were placed on the emerging genetic and physical maps of the region, and they were used for genetic linkage in HD pedigrees in an effort to find critical crossover events that would bracket the defect.

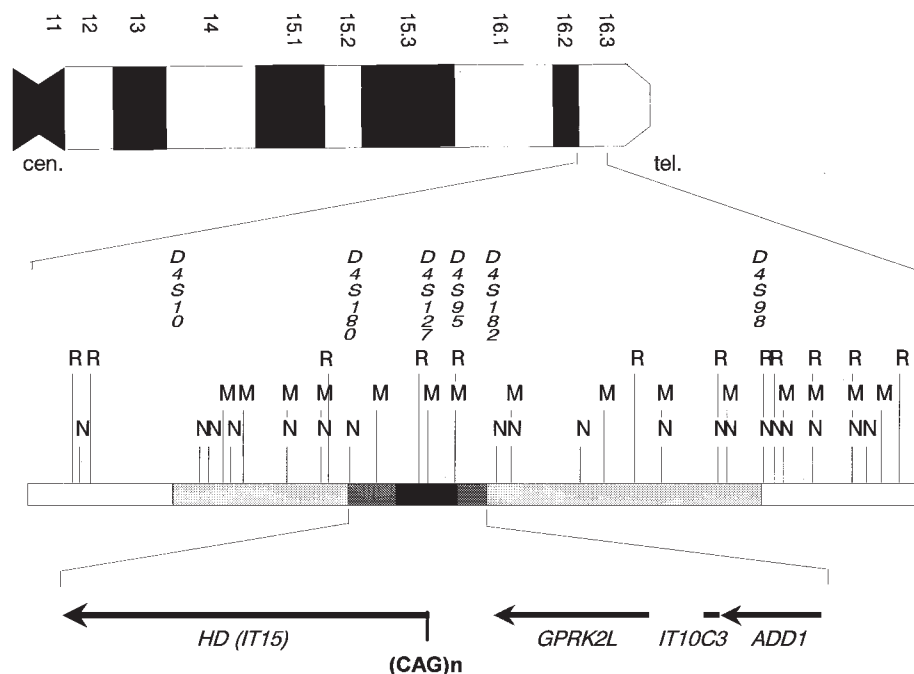
A hot spot of recombination located approximately 300 kb telomeric to *D4S10* quickly became the proximal boundary, but localization of the defect within the remaining 3.5 Mb of 4p16.3 was problematic because several crossover events within well-


Figure 97-2 Isolation of the HD gene from 4p16.3. The long-range restriction map (R, *Nru*I site; M, *Mlu*I site; N, *Not*I site; brackets, sites that are partially cut) of about 3×10^6 bp of 4p16.3, the terminal cytogenetic band, is depicted under a schematic of the short arm of chromosome 4 (cen., centromere; tel., telomere). The unshaded region was eliminated by recombination events in HD families, placing the defect within the ~2-Mb region between *D4S10* and D4S98 (light shading). The ~500-kb region between *D4S180* and *D4S182* (darker shading) was implicated by linkage disequilibrium and initial haplotype studies, and continued haplotype analysis placed the defect within the ~150-kb region between *D4S180* and *D4S127* (darkest shading). This segment is further expanded below the restriction map to depict gene transcripts that were eliminated as candidates (ADD1, IT10C3 GPRK2L), thereby targeting the search to the 5' end of *IT15*, where the *HD* defect, an unstable and expanded CAG repeat, is located ([CAG]n).

characterized HD pedigrees yielded contradictory locations for the gene. A few clinically diagnosed members of HD families had inherited DNA markers from the affected parents' normal chromosome 4, suggesting that the defect must be located in the telomeric 100 kb of the chromosome. But other crossover events predicted a nonoverlapping internal location of about 2.5 Mb of DNA closer to *D4S10*. Isolation of the telomeric region as a yeast artificial chromosome (YAC) demonstrated that it was unlikely to contain the disease gene, and a few rare recombination events that favored the internal region were identified. The individuals with apparent crossover chromosomes that predicted the telomeric location were explained ultimately only by the cloning of the *HD* defect.

Linkage disequilibrium, the nonrandom association of certain marker alleles with HD chromosomes, at *D4S95* initiated a search across the entire internal candidate region with highly polymorphic VNTR and SSR markers, and highlighted a subregion that exhibited maximal linkage disequilibrium with the defect. The construction of 4p16.3 haplotypes across this relatively small segment yielded a plethora of marker haplotypes, a surprising finding that revealed for the first time that the current pool of *HD* chromosomes has arisen from more than one independent *HD* mutation or primordial chromosome. Moreover, these results suggested that the identification of a minimum collection of 4p16.3 marker alleles shared by *HD* chromosomes likely to be related by mutational ancestry might pinpoint the location of the disease gene.

A region of about 2 Mb of DNA was ultimately mapped and isolated in overlapping clone sets and candidate genes from a 500-kb segment of 4p16.3 between *D4S180* and *D4S182* were scanned for DNA sequence alterations that were unique to disease chromosomes. Several genes with sequence homology to known proteins, including the gene encoding α-adducin, *ADD1*, a novel small molecule transporter, IT10C3, a G-protein-coupled receptor kinase, *GPRK2L*, and several genes with novel DNA sequence were eliminated as *HD* gene candidates, and a rare Alu repeat insertion within an intron of *ADD1* in two affected individuals was incorrectly interpreted as being causative of HD.

Continued haplotype analysis using new polymorphic markers finally targeted a very small (150-kb) portion of the candidate region that contained the 5' end of a novel interesting transcript (IT). Cloning and sequencing of this region of the *IT15* gene revealed a polymorphic CAG trinucleotide repeat that was found to be expanded and unstable on HD chromosomes signaling the isolation of the *HD* mutation.

THE *HD* MUTATION

A plethora of studies involving individuals from HD families worldwide have confirmed the IT15 CAG repeat expansion as the universal cause of HD and serve to further delineate the characteristics of the *HD* defect. The length of the IT15 CAG repeat (Figs. 97-2 and 97-3) on normal chromosomes is variable, ranging from 6 to 35 U, and these arrays are inherited in a mendelian fashion. Immediately adjacent is a polymorphic, stably transmitted stretch of CCG codons that on normal chromosomes varies in length from 6 to 12 repeat units, while more than 90% of disease chromosomes carry 7 CCG repeats. By contrast, the CAG repeat
Figure 97-3 Distribution of CAG repeat lengths on HD and normal chromosomes. The frequency of CAG allele sizes reported in the literature for 2885 normal (light shading) and 3484 disease (dark shading) chromosomes, shown as a percentage of the total, is plotted against the estimated number of CAG units. These CAG repeat length determinations represent the distribution of repeat lengths at the *HD* locus in populations of disparate genetic and ethnic backgrounds from around the world. The very rare chromosomes displaying an intermediate-sized allele, overlapping with the upper end of the normal and the lower end of the disease chromosome distribution, that have been identified in families with a member who represents a new mutation to HD are not included in this data set.

on HD chromosomes ranges from 37 to more than 100 U, alleles that almost invariably change in length, increasing or decreasing in size, when transmitted from parent to offspring. In most cases, the alteration is small (<6 U), with a bias toward increases in length, but paternal transmission can result in very large increases in the number of CAG repeats. This striking intergenerational instability appears to occur during spermatogenesis, and different *HD* allele sizes among children of an *HD* gene carrier are reflected in a similar variation in sperm DNA. Moreover, identical monozygotic twins with HD develop clinical symptoms at the same time and display identical expanded CAG repeat lengths, strengthening the argument that the intergenerational instability occurs during gametogenesis rather than during embryonic development. The unstable behavior of the expanded CAG repeat during maternal transmission suggests that instability, albeit of reduced magnitude, also occurs during oogenesis. The cellular and molecular mechanisms leading to changes in CAG repeat length and the parameters that affect it, including parental age, disease status, repeat length, and a host of other biological factors, have yet to be defined.

In contrast to the evident gametic instability, the vast majority of expanded CAG repeats exhibit very limited somatic instability. Somatic variation is exhibited by some long expanded CAG repeats (>60 U), but these alterations are most evident in the cerebellum and do not correlate with the neuropathology of HD.

CLINICAL CORRELATES

Studies reporting the IT15 repeat lengths observed on the disease chromosomes of several thousand HD patients from around the world reveal that all but a few exceptional individuals have a CAG repeat in the expanded size range, confirming the universality of this mutation in diverse races, nationalities, and ethnic

groups. It is apparent that rare patients with HD-like symptoms who do not have an expanded CAG allele can be explained as sample mix-ups, lab errors, or erroneous diagnoses based on atypical features. Indeed, the low rate of misdiagnosis of the disorder is also revealed by the small number of postmortem brains from patients with a clinical diagnosis of HD that do not have HD-like neuropathology.

Huntington's disease almost always occurs in individuals with a family history of the disorder, and only rarely do sporadic cases satisfy the rigorous criteria for new mutation status: living unaffected elderly parents, proof of paternity, and transmission of the disease to a child. Nonetheless, evidence that new mutation to HD does occur is provided by the identification of a few such families and the finding of a multiplicity of different 4p16.3 haplotypes on HD chromosomes, a result that was consistent with multiple origins of the mutation. Discovery of the *HD* mutation has confirmed that sporadic cases of HD are due to new mutations at the *HD* locus. These individuals, like familial HD cases, have CAG repeat lengths in the expanded disease range but their unaffected relatives with the same 4p16.3 haplotype possess a CAG repeat of intermediate size, repeats that span the gap between the normal and disease causing ranges. Indeed, many new mutations occur on the same 4p16.3 haplotype found in about one-third of unrelated HD families, suggesting that these traditional disease families share a common ancestor who was not affected by the disorder. Thus, it is likely that these intermediate allele-bearing chromosomes serve as a reservoir that can give rise to new sporadic HD cases.

The vast majority of postmortem brains assessed for HD neuropathology have an expanded CAG repeat, and the few anomalous cases (<1%) can be ascribed to atypical clinical features suggesting a distinct disorder. Because all cases of HD that have been confirmed neuropathologically display an expanded IT15
Figure 97-4 Inverse correlation between CAG repeat length and age at onset. The association of any given CAG repeat length with the age at onset of neurologic disease symptoms for 1070 HD patients reported in the literature is shown. The mean age at onset (filled squares) and the range of onset ages (shaded area) for any given CAG repeat length is depicted and the line represents the curve obtain by power regression analysis. The correlation between age at onset and CAG repeat length is highly significant across all HD allele sizes ($r = -0.87$, $p < 0.00001$), but the wide range of possible ages of onset associated with any given repeat length precludes an accurate estimate of when the disease will strike any single individual.

CAG repeat, it is unlikely that another mutation, either at the *HD* locus or elsewhere in the genome, is able to produce the constellation of clinical and neuropathological features that makes HD a unique clinical disorder.

The nature of the *HD* mutation explains much of the variation in the clinical manifestations of the disorder, including the paternal inheritance of juvenile-onset HD. The longest expanded CAG repeat lengths (>55 U) give rise to juvenile-onset HD and the shortest (35–39 U) tend not to trigger disease until very late in life (Figs. 97-1 and 97-4). CAG repeat length, therefore, is inversely correlated with age at onset of disease symptoms. Coupled with the propensity of the expanded CAG repeats occasionally to increase dramatically in length during spermatogenesis, this inverse correlation accounts for the observation that most juvenile-onset HD is inherited from fathers.

The inverse correlation between the length of the expanded IT15 CAG and age at onset of neurologic and psychiatric symptoms as well as age at death is extremely strong, even when clinical data are contributed by many different physicians. Repeat length, however, accounts for only about 50% of the variation in age at onset of clinical symptoms that is observed between individual patients with identical expanded CAG repeat lengths. Thus, it is evident that other factors, perhaps interacting genes, environmental influences, or stochastic events, are involved in determining the precise age at which the disease strikes any given individual. It has not yet been established whether the length of the CAG expansion is associated with the rate of progression of the disorder, as these studies have yielded conflicting results.

THE *HD* GENE

The polymorphic CAG repeat is located 17 amino acids from the initiator ATG codon in the first exon of a novel gene whose 67

exons span about 185 kb of 4p16.3 DNA (Fig. 97-2). The *HD* gene encodes a protein, dubbed huntington, that is more than 3140 amino acids in length including the variable segment of glutamine residues and the adjacent polyproline segment encoded by the polymorphic CAG and CCG repeats, respectively. Huntingtin's normal activity is not known, but the high degree of sequence conservation exhibited by the mouse, rat, and pufferfish *HD* homologs suggests that it performs an essential cellular function. The most divergent segment is the polyglutamine/polyproline segment at the N-terminus of the protein. The normal human gene has 12–36 glutamines, whereas the rat has 8, the mouse 7, and the pufferfish 4 consecutive polyglutamine residues at this position, strongly suggesting that the exact composition or length of the amino acid sequence of this portion of the N-terminus is not critical for huntingtin's normal activity.

Huntingtin is expressed in the cytoplasm of a wide variety of neuronal and nonneuronal tissues and cells, but its distribution does not immediately explain the distinct pattern of HD neuropathology. As a consequence of the extended N-terminal polyglutamine segment encoded by the expanded CAG repeat, the products of the normal and HD chromosomes can be distinguished in extracts of HD cells and tissues, but these two isoforms of huntingtin do not differ in their pattern of expression or intracellular location. Preliminary biochemical analysis supports the notion that both isoforms are primarily cytosolic rather than being integrally associated with particular organelles. A similar distribution of huntingtin expression is revealed by immunohistochemistry in sections of rat, monkey, and human brain tissue. Huntingtin, in both normal and HD tissue, is found in the cell bodies, dendrites, axons and terminals, but not in the nuclei, of neurons and other cell types in the brain. Thus, the primary targets of the CAG mutation, the medium-sized striatal projection neurons, are only a subset

of the neuronal and nonneuronal cells that express the mutant isoform of huntingtin.

MOLECULAR MECHANISM

The means by which the expanded IT15 CAG repeat causes the pathology of HD is not evident from the sequence of the normal or mutant versions of the *HD* gene products or their apparently identical patterns of expression. Indeed, the *HD* gene is widely expressed and yet only particular populations of neuronal cells appear to be sensitive to its effects. The mutation may provoke the pathological changes by a direct action on the mature striatal neurons, it may first trigger an as yet undetected alteration within another cell type(s), or it may act during development to generate a compromised tissue that is susceptible to neuronal cell loss later in life.

At the molecular level, several modes of action can be formulated, but some of these have been eliminated by studies of the gene products. The mutation does not alter transcription of the *HD* gene, as the mRNA is expressed at comparable levels from the disease and normal alleles. It also does not prevent translation of the mRNA from the disease allele, implicating the altered structure of huntingtin, and its extended polyglutamine segment, in the pathogenesis.

The lengthened polyglutamine stretch does not cause HD by elimination of huntingtin's normal activity, because disruption of the gene does not produce disease symptoms. In humans, individuals with an *HD* gene translocation that eliminates 50% of huntingtin production do not develop HD, and mice with one copy of the *HD* gene homolog *(Hdh)* inactivated by targeted mutagenesis show no HD-like abnormality. Notably, expression of a novel truncated version of murine huntingtin's NH_2-terminus in transgenic mice appears to cause restless behavior, learning deficits, and pathology in the subthalamic nucleus, suggesting that abnormal versions of huntingtin can have neuronal and behavioral consequences. By contrast, complete inactivation of the mouse *Hdh* gene results in early embryonic death, prior to development of the nervous system, and severely reduced levels of huntingtin produce perinatal lethality and an abnormal brain phenotype, indicating that huntingtin activity is essential for normal embryonic development. Thus, the existence of HD homozygotes who make only mutant huntingtin cannot be simply explained if the mutation acts to eliminate huntington's normal activity.

The most likely hypothesis is that the expanded CAG repeat causes pathology via a gain of function mechanism in which the extended polyglutamine stretch confers a new property on huntingtin. If it increased, rather than decreased, huntingtin's normal activity, this gain of function could act through the protein's normal physiological role. Alternatively, huntingtin's inherent activity may remain intact, but the elongated polyglutamine segment may promote a new interaction of huntingtin or one of its breakdown products with a biochemical pathway unrelated to its normal physiological role. This novel interaction, the protein's gain of function, could cause either activation or inactivation of the target pathway. It has been shown that huntingtin is cleaved by a proapoptotic cysteine protease and that the rate of cleavage increases with the length of the polyglutamine tract. The role of inappropriate apoptosis in HD therefore warrants further study.

Any hypothesized mode of action of the expanded CAG repeat must explain the complete dominance of the defect, the cellular specificity, and the association of repeat length with disease severity. Dominance is expected in the gain of function model because huntingtin would probably not interfere with the new property of the HD protein, and complete dominance would be expected if a critical effective threshold for the new property was achieved with a single dose of the disease gene. The specificity could be the result of the restricted distribution of a critical interacting target protein, and the correlation with disease severity could derive from an increasing effectiveness of the interaction with lengthening of the polyglutamine stretch. Indeed, a recent study reports the cloning of a gene encoding a novel protein, HAP1, whose expression is confined to the brain and whose association with huntingtin in vitro is influenced by the length of the polyglutamine segment.

Thus, the gain of function model provides an attractive working hypothesis that emphasizes investigation of the peculiarities of the mutant isoform with its extended N-terminal polyglutamine segment. Additional protein partners for normal and HD huntingtin will emerge from a variety of biochemical and genetic studies, and the challenge will be to determine whether these candidate interactor proteins play a role in the pathogenesis of HD.

OTHER CAG REPEAT DISORDERS

Huntington's disease is one of a growing number of neurodegenerative disorders that are known to be caused by expanded and unstable trinucleotide repeats that encode extended polyglutamine segments (*see* Chapter 100). In all of these diseases, a normally polymorphic CAG repeat is expanded and unstable on disease chromosomes, and the CAG repeat is located within the coding sequence of the gene, predicting an altered protein with an extended stretch of consecutive glutamine residues.

In Kennedy's syndrome (OMIM 313200) or spinobulbar muscular atrophy (SBMA), the expanded CAG lengthens a polyglutamine segment in the androgen receptor at Xq11.2–q12, resulting, in males, in a progressive loss of anterior horn cells in the spinal cord causing progressive muscular weakness and sometimes mental retardation and mild androgen insensitivity. Reduced androgen receptor function may underlie the endocrine abnormalities, including gynecomastia and testicular atrophy that usually occurs before onset of muscle weakness, but there is no abnormal development of the genitalia. Inactivation of the androgen receptor gene, therefore, does not mimic the pathology of SBMA but rather produces testicular feminization, indicating that the expanded CAG repeat does not trigger the degeneration of the anterior horn cells by causing androgen insensitivity.

Spinocerebellar ataxia type 1 (SCA1) (OMIM 164400), a fatal progressive cerebellar ataxia characterized by muscle atrophy, decreased deep tendon reflexes, and proprioception, is caused by the loss of neurons in the cerebellum (Purkinje's cells and dentate nucleus), in the inferior olive, and in cranial nerve nuclei III, IV, IX, X, and XII. This disorder, which, like HD, is inherited as an autosomal dominant trait, is due to an expanded CAG repeat in a novel chromosome 6p gene that encodes ataxin 1, an 87-kDa protein of unknown function. Ataxin is found in the cytoplasm of nonneuronal tissues, in the nuclei of neurons from various brain regions, and in both the cytoplasm and nuclei of cerebellar Purkinje's cells. Interestingly, the *SCA1* alleles found on normal chromosomes do not encode a pure CAG stretch, as occurs at the *HD*, SBMA, and other loci; rather, the repeat is interrupted by CAT codons not found in the expanded CAG segment of the disease allele.

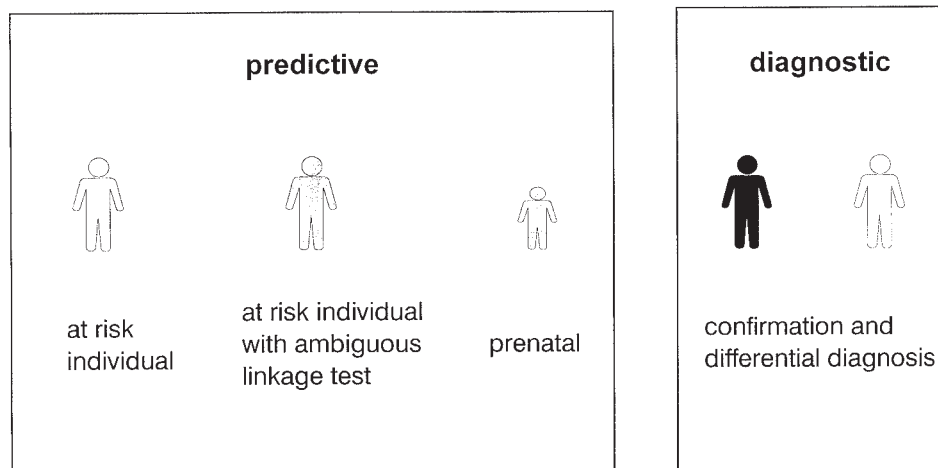
Machado-Joseph disease (MJD) (OMIM 109150), originally described in an Azorean Portuguese family, is one of the most frequent inherited spinocerebellar degenerative disorders. Its


Figure 97-5 Molecular diagnosis. A diagram illustrating the uses of direct CAG repeat length measurement is shown. The direct DNA test distinguishes between normal and HD chromosomes in predictive testing of at-risk individuals, including those who have received an ambiguous result from the HD linkage test perhaps because of a crossover event between the linked markers and the disease gene and in prenatal diagnosis in at-risk pregnancies. The test is also of diagnostic value in confirming or refuting the clinical diagnosis of HD in atypical cases.

pathology involves a progressive degeneration of the spinocerebellar tracts, but the inferior olive and cerebellar cortex are not as affected, as they are in SCA1. The disorder manifests with progressive cerebellar ataxia and pyramidal and extrapyramidal signs, external opthalmoplegia, facial and lingual fasciculation, and bulging eyes. It is also autosomal dominant and is caused by an expanded CAG repeat in a novel gene encoded at 14q32.1. Spinocerebellar ataxia type 3 (SCA3), which is clinically very similar to MJD, is caused by expansion of this same CAG repeat on chromosome 14 and is therefore an allelic disorder.

Dentatorubropallidoluysian atrophy (DRPLA) (125370) is a rare autosomal dominant neurodegenerative disorder involving loss of neurons in dentatofugal and pallidofugal systems. It is a progressive motor disorder whose hallmarks are ataxia, choreoathetosis, and myoclonus, associated with epilepsy and dementia. DRPLA is due to an expanded CAG repeat located in the coding sequence of a novel gene on chromosome 12p. This expansion causes the extension of a polymorphic polyglutamine stretch in a 190-kDa cytoplasmic protein of unknown function. Haw River syndrome, a DRPLA-like disorder observed in a single African-American family in North Carolina, is an allelic disorder caused by expansion of this same CAG repeat.

The range of CAG repeat sizes on both normal and disease chromosomes is similar in each of the disorders (approximately 6–34 on normal and approximately 35–100 on disease chromosomes), and in each case CAG instability is most obvious during gametogenesis, although somatic mosaicism in the expanded alleles has been observed. In all of the disorders, the length of the CAG repeat on disease chromosomes is inversely correlated with age at onset of symptoms, so that the most severe cases, juvenile onset, are due to the longest CAG repeat lengths. The inverse correlation of age at onset of symptoms and repeat length, and the observation that striking increases in the size of the expanded CAG repeat most often occur during spermatogenesis clarify the tendency for inheritance of the earliest-onset cases from fathers.

The expanded CAG repeat at each of the disease loci produces an elongated stretch of polyglutamine in the corresponding protein resulting in structurally distinct normal and abnormal proteins, providing support for the idea that the defect is operating at the level of the altered protein in each disease. Similarly, in each disease the primary pathology is progressive neurodegeneration, albeit of different neuronal populations in different brain regions, suggesting that the neuronal cell death is caused by a common mechanism. In this scenario, the pattern of neuronal cell susceptibility would be determined by the protein context with which the extended polyglutamine stretch is presented to the cell. If the expanded CAG repeat is acting via a gain of function at the protein level in all of these neurodegenerative disorders, it may be possible to develop interventions for many of these diseases by unraveling the biochemical steps between the mutation and the cellular pathology in any one of them.

PROSPECTS

In 1983 predictive testing for HD became a reality when the discovery of the linked DNA marker, G8, made it possible to offer presymptomatic or prenatal diagnostic testing to some individuals. The linkage test, however, was only applicable to at-risk individuals for whom several family members, including a clinically diagnosed affected relative, were able and willing to donate their DNA. The ability to test a currently unaffected individual for the presence of a gene defect that will eventually cause an untreatable neurologic disease raised numerous ethical dilemmas, and pilot programs began cautiously, with an emphasis on counseling both before and after delivery of the test result. Formal guidelines, sanctioned by the International Huntington Association (IHA) and by the World Federation of Neurology (WFN), have been established to ensure high ethical standards in HD predictive testing. It is hoped that this precedent will become an important guide for predictive testing programs in other untreatable late-onset neurologic diseases.

Predictive testing in HD and the other triplet repeat expansion disorders can now be performed by measurement of CAG repeat length (Fig. 97-5). This assay provides an inexpensive method that can be applied to any at-risk individual and to prenatal testing, for confirmation of a clinical diagnosis of HD and for differential diagnosis in difficult cases. This direct DNA test is more accurate and of broader applicability than the linkage test, but the informa-

tion that can be imparted to the individual undergoing testing is essentially the same. Therefore, the formal guidelines, revised to take into account the peculiar features of the assay method, are still valid, and it is recommended that they be followed for the direct test that makes use of CAG repeat length measurement.

Several inherent features of the CAG repeat complicate the interpretation of the molecular DNA test in predictive testing situations. The range of repeat sizes on normal and HD chromosomes does not overlap but may differ by as few as three repeat units. In addition, chromosomes with CAG repeat lengths that span the gap between these two distributions, intermediate alleles, are found in unaffected members of rare HD new-mutation families. These alleles can also overlap with the lower end of the HD size range, and it is not clear whether these individuals are truly "normal" or will develop HD if they have a sufficiently long life-span. It is probable that a discrete border between CAG repeat lengths that cause HD and those that do not cannot be drawn but rather that other genetic, environmental, or stochastic modifying factors become of primary significance in determining the age at onset for repeat lengths at the low end of the HD range. In addition, the intergenerational stability of the intermediate repeat lengths is also not well-established, making it difficult to assess accurately the risk of transmitting to children an allele that has expanded into the disease range.

The strong inverse correlation between age at onset and the length of the expanded CAG repeat raises an additional counseling dilemma. The number of CAG repeats can be precisely measured, and an allele size that falls within the established disease range is diagnostic of the future onset of the disease. However, the broad range of ages at onset observed for any given repeat length makes the number of CAG repeat units a dubious predictor of when symptoms of the disease will begin (*see* Fig. 97-4).

The discovery of the *HD* mutation has made the molecular diagnosis of the disease more accessible to at-risk individuals, but the availability of an accurate predictive test is a mixed blessing without a cure or effective treatment for the disorder. The gain-of-function hypothesis, in which the extended polyglutamine segment bestows a new property on the huntingtin protein, suggests that development of a therapy will require modulation or elimination of the impact of mutant huntingtin's novel property rather than simply replacing or augmenting its normal activity. For example, a specific toxic breakdown product from mutant huntingtin that inhibits another cellular process may cause neuronal cell death that could perhaps be reversed by replacing the lost activity. Alternatively, if the new property was simply an augmentation of huntingtin's normal activity, producing "too much of a good thing," the protein's normal pathway would have to be targeted to eliminate neuronal cell death. These are only two of the numerous gain of function scenarios that can be imagined to explain how the expanded CAG repeat kills neuronal cells. It is also conceivable that studies on the underlying cellular mechanisms causing neuronal cell loss in the other polyglutamine expansion diseases could generate therapeutic strategies that can be effectively applied to HD. It is clear that this devastating disorder is yielding to the molecular genetic approach, and there is little doubt that therapies based on a knowledge of the actual disease mechanism will be forthcoming. The next major advance, a therapeutic intervention that will prevent or even slow the onset of HD, will refute George Huntington's contention that this devastating disease is "one of the incurables."

98 Molecular Genetics of Alzheimer's Disease

P. H. St. George–Hyslop

INTRODUCTION

Alzheimer's disease (AD) (OMIM 104300) is a common degenerative disorder of the human central nervous system. The disease is characterized clinically by the onset of a slowly progressive impairment of memory and most other higher cognitive functions during mid to late adult life. The illness, which typically follows a progressive course over 5–15 years, ultimately renders the patient bedridden, and eventually results in death from intercurrent illness such as pneumonia. The neuropathological hallmarks of AD include the widespread loss of neurons from many areas of the brain, but especially from the cerebral cortex and hippocampus. In addition, many neurons in the cerebral cortex and hippocampus show the presence of an intracellular aggregate of fibrillary proteins composed of hyperphosphorylated Tau, which at the level of electron microscopy appear as aggregates of paired helical filaments (PHF), and at the level of light microscopy appear as neurofibrillary tangles (NFTs). Some neurons also show evidence of granulovacuolar degeneration. The final conventional neuropathological hallmark of AD is widespread and often severe extracellular deposition of the amyloid β (Aβ) peptide. These deposits of Aβ peptide, which are derived from proteolytic cleavage of the full-length precursor protein known as β-amyloid precursor protein (βAPP), may occur as amorphous spherical deposits with little associated reaction in the surrounding neuropil (diffuse or pre-amyloid plaques). Alternatively, the Aβ peptide deposits may be associated with swollen dystrophic neurites containing paired helical filaments, with activated microglia and reactive astrocytes (mature or senile plaques). It is thought, but not proven, that the mature senile plaques represent a progression from earlier diffuse plaques.

The etiology of AD appears complex. Multiple epidemiological studies have repeatedly shown that the risk for acquiring AD is age-dependent and is increased in the presence of a family history of this disease. There is also evidence from some but not all epidemiological studies that risk for AD may be increased with a prior history of significant head trauma and with lower levels of education. Less clear-cut risk factors include exposure to heavy metals such as aluminium, depression, hyperthyroidism, and a family history of Down's syndrome.

The repeated observation in multiple epidemiological surveys that a positive family history is a strong risk factor for AD clearly suggests that genetic factors play a role in this disease. Attempts to dissect the nature of this genetic contribution using epidemiological techniques have been difficult to interpret for a variety of technical reasons including the fact that the disease has a late onset that allows censoring from death (by other disorders), and the absence of definitive antimortem diagnostic tools. Thus, early studies reported risks to first-degree relatives (parents, siblings, or children) that varied between 3 and 14%. More recent studies using life-table techniques suggest that the risk to first-degree relatives is much higher and varies from 24% to over 50% by age 90. Studies of twins, which are also affected by the same confounding factors, suggest concordance rates amongst monozygotic twins of 40–50% compared with a lower concordance rate in dizygotic twins (10–15%). More recently, attempts at segregation analysis using information on family members of probands with AD have also been applied. These studies suggest that pedigrees with an early age of onset cumulatively show a pattern of segregation compatible with autosomal dominant inheritance with age-dependent penetrance. Conversely, late-onset families have a more complicated pattern of inheritance, which could be compatible with one of several genetic models including a high-frequency, low-penetrance single gene disorder or a multifactorial model in which several genes and/or nongenetic factors interact. Nevertheless, despite the apparent complexity of the general model of etiologic factors causing AD derived from the epidemiological surveys, there is clear evidence that some cases of AD are inherited through families as a simple autosomal dominant trait with complete or very high age-dependent penetrance. These families, although somewhat rare, have recently been used for molecular genetics studies, which have led to the discovery of four different genes that confer inherited risk for AD.

THE β-AMYLOID PRECURSOR PROTEIN GENE

The β-amyloid precursor protein gene (βAPP) (OMIM 104760) was the first gene found to bear mutations capable of causing early-onset familial AD (FAD). The βAPP gene, which has been mapped to chromosome 21, encodes an alternatively spliced single spanning transmembrane protein. The longer isoform, which contains 770 amino acids, contains two exons, which encode a Kunitz protease inhibitor domain and a 19–amino acid sequence homologous to the *ox*-2 antigen, and is expressed in most tissues. In contrast, a shorter isoform containing 695 amino acids is predominantly expressed in brain (Fig. 98-1). Several other rare splice forms are known. The immature protein undergoes O- and N-glycosylation and phosphorylation, and a complex pattern of
Figure 98-1　Cartoon of the functional domains of the βAPP gene. The N-terminus is located in the extracellular domain and contains a signal peptide (not shown), a cysteine-rich region (white box), and several putative O- and N-glycosylation sites (CHO). Exons 7 and 8 of the βAPP gene are alternatively spliced at residue 289 and encode the Kunitz protease inhibitor (KPI) and ox-2 domains, respectively. The Aβ peptide (black box) spans the end of the extracellular domain and part of the transmembrane domain. The location of the transmembrane domain is depicted by the lipid bilayer cartoon. The short C-terminal domain is intracellular. Open-headed arrows, the sites of the secretase cleavages; solid arrows, the sites of the pathogenic mutations.

Table 98-1
Missense Mutations in the βAPP Gene[a]

Codon	Mutation	Phenotype
665	Gln→Asp	Late-onset AD, no segregation
670/671	Lys-Met→Asn-Leu	FAD; increased Aβ production
673	Ala→Thr	No disease phenotype
692	Ala→Gly	FAD + cerebral hemorrhage; increased Aβ
693	Glu→Gly	Late onset AD, no segregation
	Glu→Gln	HCHWA-D
713	Ala→Val	Schizophrenia, no segregation
	Ala→Thr	AD, no segregation
717	Val→Ile	FAD; increased long Aβ isoforms
	Val→Phe	FAD
	Val→Gly	FAD

[a]Some mutations have been found in elderly asymptomatic subjects or have not been present in all affected subjects, raising the question as to whether these mutations are simple benign polymorphisms or pathogenic mutations with incomplete penetrance.

metabolism through the trans-Golgi network before passage to the cell surface *(see below)*. The Aβ peptide is a proteolytic cleavage product of the full-length protein derived from residues 672 to 711 that spans the last 28 residues of the "extracellular" domain and the first 14 residues of the transmembrane domain (encoded by exons 16 and 17). The function of the βAPP gene is unknown, although roles in cell adhesion, synaptic growth, or neural repair have been proposed. The βAPP gene may also function as a G-coupled receptor linked through an interaction in the C-terminus to $G_{o\alpha}$-protein (this putative linkage may have several levels of significance, including signal transduction and regulation of intracellular protein trafficking).

The candidacy of βAPP as the site of mutations causing AD was supported by four observations. First, a 40- to 43-amino acid proteolytic cleavage product of βAPP, termed the Aβ peptide, is a major component of the amyloid plaque of AD. Second, genetic linkage studies had implicated the existence of an FAD gene in some pedigrees in approximately the same region of chromosome 21 as the βAPP gene. Third, patients with trisomy 21, who would be expected to carry an extra copy of the βAPP gene, almost invariably develop at least the neuropathological attributes of AD by age 40. Finally, a glutamate to glutamine missense mutation at codon 693 of the βAPP gene had been discovered in subjects with a rare

cerebral vascular disorder known as hereditary cerebral hemorrhage with amyloidosis (Dutch-variant) (HCHWA-D), which is characterized by severe deposition of Aβ within blood vessel walls and with modest numbers of diffuse amyloid plaques within the brain parenchyma. Subsequent analysis of the βAPP gene in some pedigrees with FAD led to the discovery of missense mutations at three other codons (Table 98-1). In addition, several other missense amino acid substitutions have been discovered, but their relationship to disease states is less clear-cut, either because they have also been observed in elderly subjects without disease or because they were not present in all AD-affected members of the kindred in which the mutation was discovered.

An examination of the position of pathogenic mutations in the βAPP gene revealed that their locations were probably nonrandom and appeared to be positioned around residues that are important in the cleavage of full-length βAPP into the 40- to 43-amino acid Aβ peptide (*see* Table 98-1). A number of studies conducted on cultured cell lines and a more limited analysis of homogenates of brain tissue suggested that βAPP is metabolized through two different routes (Fig. 98-2). The first route, known as the α-secretase pathway, involves cleavage of the full-length βAPP molecule between residues 687 and 688 (using numbering of the 770 isoform), which in effect cleaves βAPP within the residues that would form the Aβ peptide (at residues 16 and 17 of the Aβ peptide). This pathway, therefore, leads to the release of a large soluble N-terminal fragment equivalent to protease nexin II, and the retention in the membrane of a C-terminal fragment of approximately 10 kDa in size, which is then further processed by γ-secretase to render a short 20–amino acid peptide termed p3. It appears that the α-secretase (nonamyloidogenic) cleavage can occur both at the cell surface and in the secretory pathway on the way to the cell surface.

The alternate pathway for cleavage of βAPP occurs in the endosome-lysosome network either after reinternalization of surface of βAPP or during passage through the endoplasmic reticulum and trans-Golgi network. This β-secretase pathway gives rise to the Aβ peptide through N-terminal cleavage at residues 671 and 672 (770 isoform numbering) by β-secretase, and C-terminal cleavage by γ-secretase at residues that have not been clearly defined. The Aβ peptide, or rather the range of peptides with sizes varying from 40 to 43 amino acids in length, that is produced by this pathway is a normal physiologic secretory product of many cell types. However, this pathway is also thought to be the principal source of Aβ peptide forming the amyloid plaque.
Figure 98-2 Processing pathways for βAPP. The immature βAPP protein undergoes O- and N-terminal glycosylation in the Golgi, and then either it is transported to the cell surface, where it may be cleaved within the Aβ peptide by α-secretase (nonamyloidogenic pathway) to release the soluble N-terminus while the C-terminus is cleaved by γ-secretase to generate the p3 fragment, or the mature βAPP can be cleaved in the post-Golgi endosome-lysosome pathway at the N-terminus and C-terminus of Aβ by β-secretase and γ-secretase, respectively, to liberate Aβ (amyloidogenic pathway).

While both the α-secretase and the β-secretase pathways appear to be physiological, the relative balance of the two pathways seems to be controlled by a number of events including the phosphorylation state of the cell. In addition, the pathogenic mutations in the β*APP* gene also appear to influence the relative activities of these βAPP processing pathways. Thus, the double mutation at codon 670 and 671 which substitutes the lysine-methionine residues with asparagine-leucine (Swedish mutation) is a better substrate for β-secretase, which, as noted earlier, cleaves at the N-terminus of the Aβ peptide between residue 671 and 672 of βAPP. The Ala692Gly (Flemish) mutation and the HCHWA-D mutation at codon 692 are both located close to the putative α-secretase cleavage site between residues 687 and 688. The Ala692Gly mutation appears to inhibit normal α-secretase cleavage and therefore promotes passage through the β-secretase pathway, thus leading to a higher relative production of Aβ peptide. The Ala692Gly mutation also increases the N-terminal heterogeneity of the Aβ peptide, which may result in the production of slightly hydrophobic peptides, which could aggregate more easily into insoluble β-pleated sheet conformations.

Constitutively secreted Aβ normally terminates at residue 711 (residue 40 of the Aβ peptide). Smaller proportions of the Aβ peptide are secreted in longer isoforms with 42 or 43 amino acids ending at position 713 or 714 of βAPP. The mutations at codon 717, which are located three residues outside the C-terminus of the Aβ peptide, appear to increase the relative proportion of Aβ peptides with 42 amino acid residues. These longer isoforms are more hydrophobic and may therefore also be more prone to aggregate into β-pleated sheet conformation.

Cumulatively, the observations on the physiological processing of βAPP, and on the effects of pathogenic mutations in the β*APP* gene have led to the thesis that the aberrant processing of full-length βAPP into the Aβ peptides is one of the central biochemical events leading to AD. One potential mechanism by which the apparent production of Aβ peptide might lead to neurodegeneration is provided by the observation that the Aβ peptide, while a physiologic product of cells, can undergo a conformational change that renders the Aβ peptide neurotoxic. As noted above, the longer isoforms (e.g., $A\beta_{1-42}$) are particularly prone to undergoing this conformational change and become neurotoxic, whereas shorter isoforms like the normally secreted $A\beta_{1-40}$ tend to be more soluble. The exact mechanisms by which cell death occurs after exposure to neurotoxic Aβ isoforms is unclear but might involve potentiation of excitotoxic injury, alterations in intracellular calcium homeostasis, and activation of apoptotic cell death pathways. Nevertheless, attempts are now being made to generate compounds that will inhibit either Aβ peptide production, Aβ peptide aggregation, or its neurotoxic effects.

APOLIPOPROTEIN E

Studies implicating the apolipoprotein (APOE) (OMIM 107741) gene as an AD susceptibility locus derived from several intersecting lines of investigation. First, genetic linkage studies conducted on a large series of late-onset AD families provided evidence suggesting the presence of genetic linkage and/or association to a region of chromosome 19q13. Second, APOE immunoreactivity had been detected in senile plaques and NFTs of patients with AD. Third, analysis of proteins in the cerebral spinal fluid that were able to bind to immobilized Aβ peptide revealed the presence of APOE. Finally, association studies revealed that inheritance of the ε4 allele (Cys112Arg) of the APOE gene is associated with 1) a copy number–dependent increase in risk of both sporadic and late-onset FAD and 2) a decrease in the age of onset for late-onset AD. Conversely, the ε2 allele confers a protective effect against late-onset AD. It also seems likely that the genotype at APOE can modify the age of symptom onset in subjects carrying certain βAPP mutations (especially Val717Ile) and perhaps the mutations in the presenilin 2 *(PS2)* gene *(see below)*.

While the association between increased risk for AD with inheritance of the ε4 allele and decreased risk for AD associated with inheritance for the ε2 allele has now been confirmed in multiple studies in many different racial groups, there remains some controversy as to whether the inheritance of the ε4 allele is sufficient by itself to cause this disease. Furthermore, while the association with AD is unambiguous, some but not all studies have suggested that the ε4 allele may also be associated with a variety of other neurodegenerative diseases including Creutzfeldt-Jakob disease, Lewy body variant of AD, and multi-infarct dementia, as well as with a poorer outcome after head injury and stroke. The latter observations suggest that the apo E ε4 allele might act as a modulator of the regenerative response to selected types of neural injury. Moreover, unlike the missense mutations in the β*APP*, *PS1*, and *PS2* genes, the predictive value of the presence of an ε4 allele in presymptomatic subjects is unclear. Nevertheless, the discovery of the presence of the ε4 allele in a subject with a clinical picture compatible with AD may have some usefulness as an ancillary diagnostic test when performed in conjunction with the usual battery of clinical tests used in the work-up of patients presenting with dementia.

The mechanism by which the inheritance of the ε4 allele of APOE increases risk for AD, and how this might be addressed therapeutically, is unclear. It has been suggested that APOE is a chaperon for Aβ and that the ε4 allele more avidly binds Aβ and either promotes assembly into pathologic fibrils or inhibits its
Figure 98-3   Cartoon of a putative structure of the presenilin genes. Thin lines, sequences that are poorly conserved between the presenilin 1 and presenilin 2 genes; bold lines, conserved domains. The region depicted by asterisks is alternatively spliced in some tissues.

clearance possibly through competition for the low-density lipoprotein receptor–related protein, LRP. Conversely, it has been proposed that the unphosphorylated microtubule-associated protein, Tau, which is involved in the formation of the paired helical filaments, is bound avidly by ε3 but not by ε4, thereby, in the presence ε4, more easily allowing the formation of PHF. Finally, it is possible that the different APOE alleles might exert their effects through different mechanisms of lipid recycling and/or on neural repair.

THE *PRESENILIN* GENES ON CHROMOSOME 14q24.3 AND CHROMOSOME 1

Genetic linkage studies using large numbers of pedigrees with early onset autosomal dominant FAD mapped a common locus *(AD3)* (OMIM 104311) to chromosome 14q24.3. It has been estimated that the *AD3* locus, which is associated with a particularly aggressive form of early onset AD (onset between 30 and 60 years of age), accounts for up to 50% of cases of early onset FAD. Subsequent positional cloning studies led to the isolation of a novel gene termed presenilin 1 *(PS1)* because of its association with presenile dementia of the Alzheimer type. Although the function of the *PS1* gene is unknown, the predicted amino acid sequence for the *PS1* cDNA implies that it is probably an integral membrane protein with at least seven hydrophobic membrane-spanning domains and two acidic hydrophilic domains located at the N-terminus and between transmembrane domain 6 and transmembrane domain 7 (Fig. 98-3). The amino acid sequence of the presenilin 1 protein shows strong homology to a *C. elegans* gene, sel12. Loss-of-function mutations in *sel12* suppress developmental phenotypes arising from activating mutations in the *lin12/notch* gene. While the mechanism by which *sel12* suppressed *lin12/notch* mutations is unclear, the role of notch in intercellular signaling during cell fate determination in development has suggested that the human presenilins may also have a function within signal transduction pathways. However, the amino acid sequence of presenilin 1 also shows weaker homology to that of another *C. elegans* protein, SPE-4, which is thought to be involved in membrane budding and fusion events in a membrane-bound cytoplasmic organelle derived from the Golgi network in spermatocytes of *C. elegans*. In addition, weaker amino acid sequence similarities are also present

Table 98-2
Missense Mutations in the Presenilin Genes

Codon	Location	Mutation	Phenotype
Presenilin 1			
82	TM1	Val→Leu	FAD, onset 55 years
96	TM1	Val→Phe	FAD
115	TM1→TM2 loop	Tyr→His	FAD, onset 37 years
136	TM2	Met→Thr	FAD, onset 49 years
143	TM2	Ile→Thr	FAD, onset 35 years
146	TM2	Met→Leu	FAD, onset 45 years
163	TM3 interface	His→Arg	FAD, onset 50 years
171	TM3	Leu→Pro	FAD, onset 35 years
210	TM4 interface	Ile→Thr	FAD
231	TM5	Ala→Thr	FAD, onset 52 years
246	TM6	Ala→Glu	FAD, onset 55 years
260	TM6	Ala→Val	FAD, onset 40 years
264	TM6	Pro→Leu	FAD, onset 45 years
285	TM6→TM7 loop	Ala→Val	FAD, onset 50 years
286	TM6→TM7 loop	Leu→Val	FAD, onset 50 years
del291-319	TM6→TM7 loop	Ex10 splice defect	FAD
384	TM6→TM7 loop	Gly→Ala	FAD, onset 35 years
392	TM6→TM7 loop	Leu→Val	FAD, onset 25–40 years
410	TM7	Cys→Tyr	FAD, onset 48 years
Presenilin 2			
141	TM2	Asn→Ile	FAD (Volga German), onset 50–65 years
239	TM5	Met→Val	FAD (Florence), onset variable

between presenilin 1 and a number of ion channels, and there is some structural similarity to G-coupled receptors, which also have seven membrane-spanning domains. Finally, studies of cDNA sequences capable of rescuing lymphocytes from apoptosis led to the isolation of a cDNA that was capable of suppressing apoptosis in T cells, and which contained the C-terminus of the *PS1* homolog called *PS2 (see below)*. As a result, three putative functions have been proposed. The first proposes a role in membrane budding and fusion events during protein trafficking in the endoplasmic reticulum or Golgi apparatus (which significantly is the site of βAPP metabolism). The second putative function is either a role in intracellular ion homeostasis (particularly calcium metabolism, which is thought to be abnormal in AD) or intracellular signaling pathways. Finally, there may be a role in modulation of cell death mechanisms. Mutational analysis of the *PS1* gene has led to the discovery of at least 12 different mutations in residues that are highly conserved in evolution (Table 98-2). Unlike the mutations in the β*APP* gene, the *PS1* mutations have not been focused on a single domain, but are placed in the hydrophobic membrane spanning domains as well as in the hydrophilic exposed domains.

Immediately following the isolation of the *PS1* gene, causing the *AD3* subtype of FAD, a second gene (termed presenilin 2) was discovered on the basis of its strong nucleotide and amino acid

sequence homology to the *PS1* gene. The *PS2* gene (OMIM 600759), which is located on chromosome 1, encodes a protein of 448 amino acids and has a structural organization very similar to that of *PS1*, including at least seven transmembrane domains and two large acidic hydrophilic domains at the N-terminus and between transmembrane domain 6 and 7. The strong amino acid sequence homology (greater than 60% amino acid sequence identity) and the obvious structural similarities suggest that the *PS1* and the *PS2* genes are members of a gene family. The principal differences between these genes are in the amino acid sequence of the acidic hydrophilic domains of their respective proteins, and in the patterns of tissue specific expression. The *PS1* gene is expressed at moderate levels in most tissues, whereas the *PS2* gene is expressed at somewhat lower levels in most tissues, including brain, but is expressed at quite high levels in pancreas, skeletal muscle, and cardiac muscle. Mutational analysis of the *PS2* gene in pedigrees with FAD in which mutations in the βAPP and *PS1* genes had been excluded led to the discovery of two different mutations in the *PS2* gene; one in a pedigree of Italian origin, the other in a group of related families of Volga German ancestry. The clinical phenotype associated with mutations of the PS2 gene has a later onset than the phenotype associated with mutations in the *PS1* gene or βAPP genes (onset 50–70 years). Furthermore, it appears that the age of onset of clinical symptoms in carriers of *PS2* mutations can be dramatically modified over a range of 40 years by as yet unidentified genetic or environmental factors. A similar phenomena has been discovered with some mutations in the βAPP gene where age of onset is reduced by the presence of an APOE ε4 allele and delayed by the presence of an APOE ε2 allele, but is not observed with mutations in the *PS1* gene. A potential explanation for the differences in the clinical phenotypes associated with mutations in the different presenilin genes may arise from differences in their levels of expression or perhaps differences in their specific functions.

OTHER ALZHEIMER'S DISEASE GENES

Although four different genetic loci associated with inherited susceptibility to AD are now known, it has become clear that they do not account for all cases of FAD. Thus, while the APOE ε4 allele is a relatively common risk factor for late-onset AD, at least 40% of subjects with late onset AD (particularly those with onset after age 70 years) do not have the ε4 allele. Mutations in the presenilin 1 gene probably account for up to 70% of very early onset AD (onset before age 60). However, mutations in the βAPP and the presenilin 2 genes, which are respectively associated with onsets at 45–60 years and 50–70 years, account for only a small proportion of familial cases with ages of onset between 50 and 70 years of age. Consequently, it seems highly likely that at least one, and possibly several, other genes causing inherited susceptibility to AD must exist elsewhere in the genome. A late-onset form of AD may be caused by mutations in the mitochondrial cytochrome-c oxidase 1 and 2 genes (*see* Chapter 103). Attempts to identify these other AD susceptibility genes are currently underway using both conventional genetic linkage strategies and nonparametric association methods.

ANIMAL MODELS

In addition to providing a known starting point for biochemical studies designed to elucidate the biochemical pathophysiology of this disease, the discovery of AD susceptibility genes also provides a means to generate animal models. Such animal models would be useful both in the molecular dissection of this disease and in the preclinical testing of potential treatments. Several transgenic lines have been created using a variety of βAPP constructs, and have met with varying degrees of success. The most successful model to date has been a transgenic line in which a mutant human βAPP minigene has been placed under the control of the platelet-derived growth factor receptor β-subunit promoter. This animal model developed severe cerebral Aβ amyloidosis with abundant amyloid plaques, which showed some neuritic dystrophy and synaptic pathology. Classical NFTs, however, were not observed. The reason why this particular transgenic line was more successful in recapitulating at least part of the AD phenotype is unclear but may reflect either the strong promoter employed or a special vulnerability of the strain of mouse used. If the latter hypothesis were proven correct, mapping of other loci within the mouse genome that are capable of altering susceptibility of the mouse to AD amyloidosis could provide a rapid means to identify other human genes that would modify human susceptibility to this disease. Manipulation of the expression of these modifier genes could potentially be used therapeutically to treat human AD.

99 Amyotrophic Lateral Sclerosis and Related Motor Neuron Diseases

Meret E. Cudkowicz and Robert H. Brown, Jr.

INTRODUCTION

The last decade has witnessed considerable progress in elucidating the genetic and molecular basis of inherited motor neuron diseases. Determination of specific gene defects causing motor neuron illness provides insights into the neurobiology of the motor neuron and into the pathogenesis of both inherited and sporadic forms of motor neuron disease. These insights are critical in guiding the development of treatment strategies. This chapter provides an overview of motor neuron disorders, with a particular focus on recent studies of amyotrophic lateral sclerosis.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

AMYOTROPHIC LATERAL SCLEROSIS (ALS) It is convenient to classify motor neuron diseases anatomically into three groups that involve: (1) both motor neurons in brainstem and spinal cord (lower motor neurons), and corticospinal and corticobulbar motor neurons (upper motor neurons); (2) only lower motor neurons; and (3) only upper motor neurons (Table 99-1). Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease that falls into the first group. The prevalence of ALS is 4–6 cases per 100,000 with an incidence of 0.4–1.8 per 100,000. The majority of ALS cases are sporadic. However, 10–15% of cases are inherited as an autosomal dominant trait (familial ALS, autosomal dominant: FALS-AD; OMIM 105400); very rare cases have an autosomal recessive inheritance pattern. The sporadic and FALS-AD forms of ALS are clinically and pathologically identical. Age and sex are the only ALS risk factors repeatedly documented in epidemiological studies. The median age of onset is 55, and the median survival is less than five years. Ten percent of cases begin before age 40 and only rarely before age 30. There is a slight male predominance (3:2 male-to-female ratio).

The distinctive clinical and pathological features of ALS were first described in 1869 by Charcot. Clinical signs of both lower and upper motor neuron involvement are necessary for a definitive diagnosis. The former include weakness and muscle atrophy, usually beginning asymmetrically and distally in one limb, and then spreading within the neuraxis to involve contiguous groups of motor neurons. Upper motor neuron involvement is heralded by weakness with spasticity or muscle stiffness. Symptoms can begin either in bulbar or limb muscles. In this and most other motor neuron diseases, there is relative sparing of muscles of eye movement and of urinary sphincters. Respiratory failure may be an early manifestation in patients with bulbar onset. It is usually a later development in limb-onset cases and ultimately proves fatal in virtually all cases of ALS.

DISORDERS OF LOWER MOTOR NEURONS Several diseases are characterized by selective involvement of lower motor neurons. These are distinguished from ALS by the absence of corticospinal or corticobulbar tract involvement and, in many instances, a slower rate of progression. Multifocal motor neuropathy with conduction block (MMNCB) is a treatable lower motor neuropathy characterized by multifocal disruption of motor nerve conduction. This disease often begins asymmetrically in the upper extremities. In most instances focal onset, absence of corticospinal findings, and slow progression (several years) distinguish MMNCB from ALS. The diagnostic test for MMNCB is electromyography (EMG), which reveals focal motor conduction failure, defined by a loss of greater than 50% of the amplitude of the compound motor action potential. This disease is thought to be autoimmune, both because many affected individuals have high titers of antibodies to GM1 ganglioside and because many respond dramatically to treatment with intravenous immunoglobulin (iv Ig). Some individuals fail to respond to iv Ig but improve with high-dose cyclophosphamide therapy. Lymphoma-associated motor neuron disease is a rare disorder described in patients with both Hodgkin's and non-Hodgkin's lymphoma. Laboratory tests often reveal a monoclonal gammopathy, elevated cerebrospinal fluid (CSF) protein and the presence of oligoclonal bands in the CSF. Postpoliomyelitis muscular atrophy is a slowly progressive motor neuropathy that arises several decades after partial or complete recovery from acute, paralytic poliomyeltis. The course is slow and progressive.

Three disorders of the lower motor neuron are inherited. X-linked spinal bulbar atrophy (OMIM 313200) affects males in early adulthood and presents with slowly progressive limb weakness with prominent bulbar muscle involvement. Tendon reflexes are lost and upper motor neurons signs are absent. There are often active fasciculations about the face. Associated findings include gynecomastia, testicular atrophy, and diminished fertility. Electromyography and muscle biopsy findings show chronic denervation and reinnervation.

Table 99-1
Inherited Motor Neuron Disorders

Disease	Defect	Locus
Upper and lower motor neurons		
Amyotrophic Lateral Sclerosis		
Dominant, adult onset		
	Superoxide dismutase 1	21q
	Neurofilament heavy subunit	11
Dominant, juvenile onset		9
Recessive, juvenile onset		2q33–35
Lower motor neurons		
Spinal muscular atrophy		5q11.2–13.3
SMA I	Survival motor neuron protein	
SMA II		
SMA III		
SMA IV		
X-linked spinobulbar muscular atrophy	Androgen receptor	Xq11
GM2 gangliosidoses		
Late-onset Tay-Sachs	Hex A deficiency (α subunit)	15q23–24
Sandhoff disease	Hex A+B deficiency (β subunit)	5q11.2–13.6
AB variant	GM2 activator protein	5q
Upper motor neurons		
Familial spastic paraplegia		
Dominant		2p
		14q
		15q
Recessive		8q
X-linked	Proteolipid protein	Xq22
		Xq28

The spinal muscular atrophies (SMAs) are a group of neuromuscular disorders characterized by progressive degeneration of motor neurons in the spinal cord and brainstem. The majority of familial cases have an autosomal recessive mode of inheritance. A smaller number have an autosomal dominant or X-linked inheritance pattern. The most severe form of SMA (type I or Werdnig-Hoffmann disease; OMIM 253300) is a fulminant denervating disease of infants. With an incidence of 1 in 20,000 live births and a carrier frequency of 1:80, this is a relatively common disorder. The other forms (*see* Table 99-1) begin later in life and have a more chronic course. In type I SMA, clinical signs may be evident prenatally, as indicated by diminished fetal movements in the last two or three weeks before birth. In the neonatal period, the infants are severely weak and hypotonic. Problems with nursing and respiratory function are common. The majority of children die before age two, usually from respiratory infections and pulmonary insufficiency. Type II SMA (OMIM 253550) is a childhood form that usually appears before 18 months of age and is associated with survival of several years. Type III, or Kugelberg-Welander disease (OMIM 253400), is also a childhood form, typically beginning after 18 months of age. One may rarely encounter a late childhood or adult-onset form, which produces more pronounced distal weakness. However, it is striking that in these chronic forms, progressive, symmetric weakness is typically more proximal than distal, with leg greater than arm involvement. Indeed, before EMG studies are obtained, the severity of the proximal weakness may erroneously suggest the diagnosis of a primary muscle disease.

At least three forms of GM2 gangliosidosis (type 1, or adult-onset Tay-Sachs disease, OMIM 272800; Sandhoff disease, OMIM 268800; AB variant, OMIM 272750) may have a clinical phenotype that resembles SMA. Affected individuals usually have lifelong incoordination. In the teen or early adult years, they develop progressive proximal weakness with fasciculations, mild denervation atrophy, and EMG abnormalities indicating dysfunction of spinal motor neurons. There may be mild dysarthria and difficulty swallowing. Some patients also develop spasticity and Babinski responses attesting to corticospinal tract involvement. The primary defect in this disease is accumulation of GM2 ganglioside, a consequence of defects either in one of the two enzymes, *N*-acetyl-hexosaminidase A and B (hex A and hex B), which normally metabolize this substrate, or in the protein "GM2 activator," which normally enhances the activity of these two enzymes.

PATHOLOGY

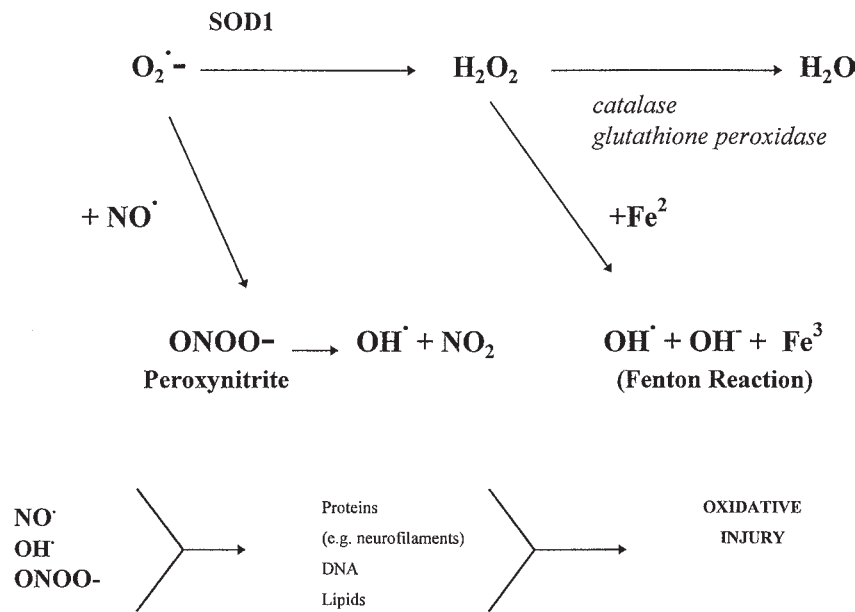
In ALS, the pathological hallmark is selective atrophy and death of corticospinal and corticobulbar neurons in the motor cortex and motor neurons in the brainstem and spinal cord. There is an associated mild proliferation of glial cells. Affected neurons and axons often have cytoskeletal pathology with accumulations of neurofilaments and aggregates of ubiquinated proteins. There is thinning of the anterior roots of the spinal cord with preservation of the posterior sensory roots. As Charcot first noted, the lateral columns of the cord, consisting primarily of long tracts of the descending corticospinal system, may be shrunken and sclerotic. The pathological hallmark of the spinal muscular atrophies is degeneration and loss of anterior horn cells. Affected motor neurons can be strikingly chromatolytic, with swelling of the cell body, dispersion of the endoplasmic reticulum, displacement of the nucleus to an atypical, peripheral position in the soma, and nucleolar hyper-


Figure 99-1 Selected normal reactions of superoxide. Top: Superoxide is normally detoxified by SOD1 to hydrogen peroxide, which is then converted to water by catalase and glutathione. Combined with nitric oxide (NO·), superoxide can also form peroxynitrite (ONOO-), which breaks down nonenzymatically to produce hydroxyl radicals (OH·). These may also be generated from hydrogen peroxide via Fe²⁺ (Fenton reaction). Bottom: These reactive oxygen species may oxidatively damage DNA, lipids, and proteins.

trophy. In any disease targeting spinal motor neurons, muscle biopsy may reveal evidence of both active denervation, in the form of isolated, angulated, atrophic fibers, and chronic denervation, with either successful reinnervation (fiber-type grouping) or reinnervation followed by successive denervation (atrophy of groups of fibers with identical fiber type). The major pathological abnormality in FSP is corticospinal tract degeneration, which is more pronounced caudally.

FAMILIAL SPASTIC PARAPLEGIAS Familial spastic paraplegias (FSPs) are usually transmitted as autosomal dominant traits and characterized by progressive, spastic weakness beginning in the distal legs (OMIM 182600). Recessive (OMIM 270088) and X-linked (OMIM 312900) forms are also recognized. The age of onset in FSPs varies widely. Because respiration is largely spared, most FSP patients survive several decades. Weakness of the upper extremities is distinctly unusual, as is involvement of the posterior columns and anterior horn cells. FSP may infrequently arise in "complicated" forms associated with involvement of other regions of the nervous system; for example, there may be amyotrophy, mental retardation, sensory neuropathy, and, in some infantile-onset cases, hydrocephalus.

PATHOGENESIS AND GENETICS

AMYOTROPHIC LATERAL SCLEROSIS Many causes of ALS have been proposed including atypical poliovirus infection, prion-mediated neuronal death, intoxication by exogenous metal-toxins (lead, aluminum, and other metals), autoimmune processes targeting motor neurons, and toxicity from excess excitation of the motor neuron by transmitters such as glutamate. The latter is suggested by several observations: brain levels of glutamate are reduced in ALS; glutamate transport is diminished in brains of ALS patients at autopsy; and CSF glutamate levels may be elevated. Moreover, there is growing literature documenting that glutamate is pathological for motor neurons in vitro.

In some cases of FALS, genetic studies have established that the primary defects are mutations in the gene for cytosolic, copper-zinc superoxide dismutase (SOD1). Currently, more than 50 different mutations in SOD1 have been reported exclusively in FALS. Copper-zinc superoxide dismutase is a metalloenzyme of about 153 amino acids that is expressed in all eukaryotic cells. It is one of a family of three SOD enzymes, which include manganese-dependent mitochondrial SOD (SOD2) and copper-zinc extracellular SOD (SOD3). Encoded by five exons, the SOD1 protein functions as a homodimer. Each monomer contains an active site with one ion each of copper and zinc. The primary function of the SOD1 enzyme is to detoxify the superoxide anion by conversion to hydrogen peroxide (Figure 99-1). Hydrogen peroxide is subsequently detoxified by glutathione peroxidase or catalase to form water. Hydrogen peroxide can generate free radicals by reacting with ferric ions to form the hydroxyl radical. Superoxide is potentially toxic by itself, and also can produce the more toxic hydroxyl radical either through formation of hydrogen peroxide or by reaction with nitric oxide. Superoxide interacts with nitric oxide to form the peroxynitrite anion, which may be directly toxic to cells and also generates hydroxyl radicals. An important implication of these biochemical properties of SOD1 is that FALS may arise as a consequence of abnormalities of free radical homeostasis and resulting cellular oxidative stress.

The effects of the FALS mutations on SOD1 function are not fully understood. Whether motor neurons degenerate because SOD1 activity is reduced or because the mutant protein has gained a novel, adverse function remains to be determined. In patients with these SOD1 mutations, but not in sporadic cases or in normal controls, SOD1 activity is reduced by 25–50% in red blood cell lysates, lymphoblastoid cell lines, and brain. The loss of function appears to be due to diminished stability of the mutant protein rather than a loss of intrinsic specific activity or a dominant negative interaction of mutant and wild-type protein in SOD1 hetero-

dimers. Recently, it has been shown that in chronic, organotypic spinal cord cultures partial reduction of activity of SOD1 triggers apoptotic nerve cell death, including fulminant motor neuron death. This death process, in vitro, is reversed by agents that enhance intracellular antioxidant defenses (e.g., *N*-acetylcysteine).

These observations are somewhat enigmatic, as most diseases arising from decreased protein activity, or "loss of function," are recessive. Dominantly inherited diseases, like FALS, are thought to arise because a single mutant allele produces a mutant protein with a novel property that is in some way toxic to the cell. Three arguments indicate that the primary effect of the SOD1 mutations is gain of a toxic function. First, to date, no true null mutations have been identified in SOD1 in FALS patients. If haplo-insufficiency (50% reduction in activity from loss of the product of one allele) triggers the disease, one would anticipate some mutations that block protein expression from the mutant allele (e.g., via premature stop codons or deletions). Such null mutants are conspicuously absent. Second, in most studies, there is not a correlation between the extent of inactivation of SOD1 and any clinical measures of disease severity. The third observation, suggesting that SOD1 mutations may be cytotoxic, is that mice that overexpress high levels of mutant SOD1 protein reportedly develop a lethal, denervating, paralytic disease that resembles ALS clinically and pathologically. In these animals, dendritic processes in motor neurons show microvacuolization, resulting from defects in rough endoplasmic reticulum and mitochondria. Because the total or aggregated SOD1 activity in these animals is above normal, it is difficult to argue that the disease arises from loss of function. The possibility that the high levels of SOD1 activity in the animals triggers the neuronal degeneration is unlikely, as mice overexpressing normal SOD1 to a similar extent do not develop motor neuron disease. These findings support the hypothesis that the primary effect of the SOD1 mutations is a gain of a toxic function. The mechanisms of cytotoxicity of the mutant SOD1 molecule are unclear at this time. It is possible that: (1) the mutant enzyme precipitates to form toxic, cytoplasmic aggregates; (2) the mutant SOD1 molecule has an enhanced affinity for peroxynitrite and, consequently, produces elevated levels of nitronium ions, which catalyze nitration of tyrosines on proteins such as neurofilaments and tyrosine kinase receptors; (3) there is subnormal copper or zinc binding by the enzyme and resulting neurotoxicity from these metals; and (4) some mutant SOD1 proteins are cytotoxic because reduced detoxification of superoxide anion causes an increased level both of this anion and secondarily, peroxynitrite. The latter may nitrate protein tyrosine groups or decompose enzymatically to produce nitrogen dioxide and hydroxyl radical. Studies have also shown that certain mutations in SOD1 (A4V; G93A) catalyze oxidation by hydrogen peroxide at a higher rate than that of the wild-type enzyme, supporting the idea that oxidative reactions may be involved in the pathology of ALS.

More recently, a second genetic defect has been associated with isolated cases of ALS. Two different mutations have been identified in the heavy subunit of neurofilament in five different patients. Because these mutations were not detected in more than 300 DNA samples from normal controls, they are unlikely to be polymorphisms. It remains to be established whether these neurofilament mutations will be present in large series of either familial or sporadic ALS patients. It is pertinent, however, that transgenic mice overexpressing either normal or mutant neurofilament develop a motor neuron disease phenotype. Moreover, mice that express a

point mutation in the light neurofilament subunit even more fully reproduce aspects of human ALS pathology. Further, animals intoxicated with the agent β-β-imino-diproprionitirle (IDPN) develop severe neurofibrillary pathology, particularly in the proximal axon, which disrupts axonal transport and thereby impairs motor neuron function. Together, these findings in humans and experimental animals underscore the importance of cytoskeletal protein function for motor neuron viability.

X-LINKED SPINOBULBAR MUSCULAR ATROPHY   The genetic defect underlying X-linked spinobulbar muscular atrophy (SBMA) is an expansion of a normally occurring CAG trinucleotide repeat within the coding region of the gene for the androgen receptor on the X chromosome. This leads to an expanded polyglutamine tract within the receptor. The length of the repeated CAG sequence correlates with the severity of the disease. Although first identified in SBMA, this primary defect, an expanded CAG repeat domain, has now been identified in other neurodegenerative disorders including Huntington's disease (OMIM 143100), spinocerebellar ataxia (OMIM 164400), and a rare disorder known as dentatorubopallidoluysian atrophy (DRPLA) (OMIM 125370). As discussed in the chapter on Huntington's disease (Chapter 97), it remains to be established why this defect is so selectively neurotoxic, and why its pathological effect may not be evident until adult life.

FAMILIAL SPASTIC PARAPLEGIAS   In the last 2 years, genetic linkage analyses have clearly documented genetic heterogeneity in FSPs. Large FSP pedigrees with dominant inheritance patterns have been linked to loci on chromosome 2p, 14q, and 15q. Other large FSP families are not linked to these loci, indicating there must be yet another locus for dominantly inherited FSP. The observation that there is genetic anticipation in some families has prompted the speculation that FSP may be a trinucleotide repeat disease. A childhood-onset form of uncomplicated FSP has recently been linked to chromosome 8q. In addition, there are both complicated and uncomplicated forms of FSP transmitted as X-linked recessive traits. Genetic studies have detected at least two loci for X-linked FSP at Xq28 and Xq22. In some families the Xq22-linked form arises from mutations in the gene for the central nervous system myelin constituent, proteolipid protein (PLP). Strikingly, different mutations in the same PLP gene cause Pelizaeus-Merzbacher disease, indicating that this disease and some forms of X-linked FSP are allelic variants.

SPINAL MUSCULAR ATROPHIES   In 1990 the defect causing spinal muscular atrophies (SMA) was genetically mapped to the proximal portion of the long arm of chromosome 5 (5q11.2–13.3). Most cases of SMA are linked to this locus; it is likely that these disorders all result from mutations within the same gene (allelic heterogeneity). While the specific gene has not yet been definitively identified, two candidate genes were recently reported. Strikingly, one has homology to a viral protein known to inhibit apoptosis. This suggests that SMA might result from loss of antiapoptotic proteins normally required in critical stages of motor neuron differentiation to prevent motor neuron death. It is fortunate that, even in the absence of a definitive gene defect, prenatal testing is now available for SMA using linked polymorphisms; the accuracy of prenatal predication is 90% or greater depending on the individual family.

ANIMAL MODELS

There are currently several mouse models of hereditary motor neuron disease. These include the wobbler (wr), progressive mo-

tor neuropathy (pmn), wasted (wst), tumbler (tb) motor neuron disease 1 (mnd1), motor neuron disease 2 (mnd2), transgenic mice overexpressing mutant SOD1, and transgenic mice overexpressing light and heavy neurofilaments subunits (NF-L and NF-H). The motor neuron disease in the mnd1 and transgenic SOD1 mice are inherited as autosomal dominant and are relevant models for ALS. The NF-L and NF-H mice develop progressive weakness and muscular atrophy secondary to denervation. The spinal neurons show extensive neurofilamentous swellings that are prominent in proximal axons and within dorsal root ganglia. The remaining animal models have a lower motor neuropathy with a recessive inheritance pattern, possibly more relevant to the spinal muscular atrophies. The specific genetic defects in these animals have not yet been defined. Therapeutic trials of potential new agents for ALS are already underway in the SOD1 transgenic mice. It is hoped that this model will be a useful method to screen novel therapeutics and a tool to better understand the underlying disease process.

THERAPEUTIC OPTIONS

There is no known therapy for ALS. However, three recent therapeutic trials have been cautiously promising. Riluzole, a drug that inhibits release of glutamate at presynaptic terminals, is reported to extend survival in ALS, although there is no concomitant improvement in strength. Insulin-like growth factor 1 has been reported in preliminary communications to improve strength in ALS patients in a dose-dependent manner. It has been suggested that brain-derived neurotrophic factor (BDNF) augments respiratory function in ALS. To date, full reports of the latter two studies have not been published; it remains to be established how clinically meaningful these drugs will be in ALS. As noted above, multifocal motor neuropathy with conduction block is often effectively treated with immunosuppressive agents such as intravenous gammaglobulin or cyclophosphamide.

Currently, there are no specific treatments for X-linked SBMA, the SMAs, post-polio muscular atrophy, or the FSPs. Prevention and early treatment of respiratory infections, rehabilitation measures, bracing, and treatment of scoliosis are critical to improving and optimizing motor function.

FUTURE DIRECTIONS

Molecular biology has had a profound effect on our understanding of the motor neurons disorders—in particular, familial and sporadic ALS and the spinal muscular atrophies. The investigations of motor neuron diseases summarized here give significant insights into factors important for motor neuron viability. Exactly how important each of these factors is should hopefully become apparent in the near future. The development of several animal models of motor neuron disease should enhance our understanding of these disorders and increase our ability to screen quickly many potential therapeutic agents. One hopes that insights gained from the study of these diseases will enhance our understanding not only of motor neuron diseases but also of other neuron-selective degenerative diseases. Finally, and most importantly, one hopes that the investigation of these issues will lead to effective strategies for treating these diseases.

100 Spinocerebellar Ataxia and Other Disorders of Trinucleotide Repeats

HUDA Y. ZOGHBI

INTRODUCTION

Expansion of trinucleotide repeat sequences is now known to be the mutational mechanism in at least seven neurological disorders. These include fragile X syndrome, myotonic dystrophy (DM), spinobulbar muscular atrophy (SBMA), Huntington's disease (HD), spinocerebellar ataxia type 1 (SCA1), dentatorubro-pallidoluysian atrophy (DRPLA), and Machado-Joseph disease (MJD). The discovery of trinucleotide repeat expansions provides a biological explanation for "anticipation," a poorly understood clinical phenomenon frequently observed in these disorders. So far, only trinucleotide repeats with cytosine-guanine-guanine (CGG), cytosine-adenine-guanine (CAG), or cytosine-thymidine-guanine (CTG) have been associated with disease states, although other polymorphic trinucleotide repeat sequences are widespread in the human genome (please *see* Addendum).

The mechanism underlying the expansion, and occasionally the contraction, of these repeats remains unresolved. It is intriguing that the number of repeat units within the murine homologs of the genes involved in the above human disorders is relatively small, ranging from 2 to 5 repeats, and the repeats are frequently not polymorphic. This raises the question of whether dynamic mutations involving trinucleotide repeat instability are unique to humans and whether the mechanism involving pathologic expansions is influenced by the length and variability within a particular repeat.

The disorders caused by trinucleotide repeat expansions can be divided into three groups based on clinical and molecular distinctions. Five diseases have later onset and are progressively neurodegenerative. These include SBMA, HD, SCA1, DRPLA, the allelic Haw River syndrome (HRS), MJD, and the allelic spinocerebellar ataxia type 3 (SCA3). The expanding repeat in each of these disorders is $(CAG)_n$, which lies within the coding region of the respective gene, and is predicted to encode for glutamine in the protein. The number of repeats on the expanded alleles is not very large, usually about twice the number on normal chromosomes, and ranges between 37 and 121 repeats. All five diseases display a dominant inheritance pattern (modified by the effects of X inactivation in SBMA), suggesting that the phenotype cannot be simply explained by loss of the normal function of the protein after repeat expansion.

The clinical and molecular features of the second group of disorders include a stable nonprogressive neurologic deficit, mainly mental retardation, and large expansions (200–2000 U) of a $(CGG)_n$ repeat. The CGG repeat responsible for fragile X syndrome (FRAXA) is located in the 5' untranslated region of the *FMR1* gene and is not predicted to encode for a peptide. Expansions of the repeat in excess of 200 U result in methylation of the promoter region, shutdown of *FMR1* transcription, and absence of the FMR1 protein. FRAXE, a molecularly defined syndrome characterized by a fragile site in Xq28 and occasionally accompanied by mental retardation in some kindreds, has been shown to be caused by large expansions of a (CGG vs CCG) repeat that has not been associated with a gene thus far.

Myotonic dystrophy is in a unique category in that the mutation involves large expansions, ranging from 50 to 4000 U, of a CTG repeat that is located in the 3' untranslated portion of a gene encoding myotonin protein kinase. Myotonic dystrophy is a dominantly inherited neuromuscular disorder characterized by muscle weakness, myotonia, and several associated findings. The mechanism by which the repeat expansion leads to the phenotype in DM is unknown at this time, and it is not clear whether the repeat expansion leads to loss of normal function or to a new detrimental function in myotonin protein kinase.

Table 100-1 summarizes the salient clinical and genetic features of the various disorders caused by trinucleotide repeat expansions, and Fig. 100-1 shows the range of repeat sizes in both the normal and expanded alleles.

This chapter will focus on SCA1 and will provide a brief overview of the other trinucleotide repeat disorders.

SPINOCEREBELLAR ATAXIA TYPE 1 (SCA1)

CLINICAL FEATURES AND LABORATORY FINDINGS

The dominantly inherited SCAs are clinically and genetically a heterogeneous group of neurologic disorders characterized by variable degrees of degeneration in the cerebellum, spinal tracts, and brain stem. SCA1 (OMIM 164400) is one subtype that has been classified based on its genetic localization to the short arm of human chromosome 6.

The main clinical features in SCA1 include gait ataxia, dysarthria, and dysmetria. As the disease progresses, brain-stem involvement results in facial weakness, tongue atrophy, severe dysarthria, and dysphagia. Hyperreflexia may be detected early in the course of the disease, but in later stages the patients develop

Table 100-1
Inherited Disorders Caused by Trinucleotide Repeat Expansions

Disease	Clinical features	Pathology	Inheritance	Gene locus	Repeat sequence and location	Protein
Spinal and bulbar muscular dystrophy	Proximal muscle weakness, bulbar dysfunction, partial loss of secondary sexual characteristics	Loss of motor neurons in the spinal cord and cranial nerves	X-linked	Xq11–q12	CAG-coding	Androgen receptor
Huntington's disease	Chorea and intellectual deterioration; juvenile onset with dystonia seizures and cognitive dysfunction	Atrophy of caudate and putamen; loss of spiny neurons	AD	4p16.3	CAG-coding	Huntingtin
Spinocerebellar ataxia type 1	Ataxia, dysarthria, and brain stem dysfunction	Purkinje's cell degeneration and loss of neurons in the dentate nucleus, inferior olive, and cranial nerve nuclei	AD	6p22–p23	CAG-coding	Ataxin-1
Dentatorubro-pallidoluysian atrophy/Haw River syndrome	Progressive ataxia, myoclonus, epilepsy, chorea, and dementia	Neuronal loss in the dentate nucleus, globus pallidus, thalamus, and subthalamic nuclei	AD	12pter–p12	CAG-coding	Atrophin
Machado-Joseph disease/ spinocerebellar ataxia type 3	Ataxia, amyotrophy, bulging eyes, faciolingual fasciculations, and dystonia	Neuronal loss in the dentate nucleus, substantia nigra, and cranial nerve motor nuclei	AD	14q32.1	CAG-coding	
Fragile X syndrome (FRAXA)	Mental retardation, macrocephaly, enlarged ears, macro-orchidism, and mild skeletal anomalies	Edema and generalized increase of connective tissue in adult testes	X-linked	Xq27.3	CGG-5'UTR	FMR1
FRAXE	Possibly mental retardation	X-linked	Xq28	CGG-?		
Myotonic dystrophy	Myotonia and muscle weakness, cataracts, cardiac involvement, endocrine dysfunction, and baldness	Relative loss of type 1 muscle fibers; increased internal nuclei and degeneration of microfilaments	AD	19q13	CTG-3'UTR	Myotonin protein kinase

Abbreviations: AD, autosomal dominant; UTR, untranslated region.

muscular atrophy, hypotonia, and hyporeflexia. Other, less consistent findings observed in some patients include optic nerve atrophy, ophthalmoparesis, and loss of proprioception and vibration sense. The disease typically manifests in the third to fourth decade, progresses over 10–15 years, and results in death due to brain stem dysfunction. Earlier age of onset and increase in the severity of the phenotype in later generations, a phenomenon known as *anticipation*, has been observed in some SCA1 kindreds.

Computerized tomography and magnetic resonance imaging studies in SCA1 patients reveal atrophy of the brachia pontis and anterior lobe of the cerebellum, and enlargement of the fourth ventricle. Typical neuropathologic findings in SCA1 include cerebellar atrophy with loss of Purkinje cells and dentate nucleus neurons, presence of "torpedoes," which are swollen axons of degenerating Purkinje cells, and severe neuronal degeneration in the inferior olive and to a lesser degree in cranial nerve nuclei III, IV, IX, X, and XII. Demyelination in the restiform body, brachium

conjunctivum, spinocerebellar tracts, and posterior columns is frequently noted.

The clinical and laboratory findings in SCA1 are also observed in patients with other genetically distinct hereditary SCAs, including spinocerebellar ataxia type 2 (SCA2), which maps to the long arm of chromosome 12 (12q23–24); SCA3, which maps to chromosome 14q24.3–q32; and several SCA kindreds for which the gene locus is not yet mapped.

MOLECULAR MECHANISMS   **CAG Repeat Expansion in SCA1**   The candidate region for the SCA1 gene was determined to span approximately 1 Mb of DNA using a combination of genetic and physical mapping approaches. Genomic cosmid clones from this candidate region were screened for the presence of trinucleotide repeats given that expansion of such sequences proved to be the mutational mechanism in three other disorders that display anticipation, fragile X syndrome, DM, and HD. This approach resulted in the identification of a CAG repeat that was unstable and expanded in SCA1. Using the polymerase chain reaction (PCR),
Figure 100-1 Ranges of repeat sizes in normal, premutation, and expanded alleles for eight trinucleotide repeat disorders. SBMA, spinobulbar muscular atrophy; DRPLA, dentatorubropallidoluysian atrophy; HRS, Haw River syndrome; MJD, Machado-Joseph disease; SCA1, spinocerebellar ataxia type 1; HD, Huntington's disease; FRAXE, mental retardation associated with the FRAXE chromosomal fragile site; FRAXA, fragile X syndrome; DM, myotonic dystrophy. the repeat was amplified from DNAs of unaffected and affected individuals to determine the sizes of alleles. The SCA1 CAG repeat is highly polymorphic, with a heterozygosity rate of 84%. Normal

individuals displayed 18 alleles, ranging from 6 to 39 repeat units, whereas individuals with SCA1 had two alleles, one within the normal range and one within a range of 40–81 CAG repeat units (Fig. 100-2). The number of trinucleotide repeat units on SCA1 chromosomes was inversely correlated with the age of onset of symptoms (Fig. 100-3). A linear correlation coefficient of –0.815 was obtained, indicating that the number of repeat units accounts for 66% of the variability in the age of onset.

Analysis of the SCA1 CAG repeat in families known to have the chromosome 6–linked form of SCA demonstrated an expanded allele cosegregating with disease in affected individuals, suggesting that expansion of this repeat is the mutational mechanism in all SCA1 families examined to date.

Features of the SCA1 CAG Repeat DNA sequence analysis of genomic and cDNA clones at the SCA1 locus revealed the following repeat configuration: $(CAG)_{12}CATCAGCAT(CAG)_{15}$. Because of the finding of CAT interruption in these clones, the configuration of the repeat on normal and SCA1 chromosomes was examined by sequence analysis and a combination of PCR and restriction analysis using *Sfa*NI, which cleaves $GCATC(N)_5$, allowing the identification of CAG tracts with CAT interruptions. These data revealed that in greater than 98% of normal chromosomes the CAG repeat is interrupted with 1, 2, or 3 CAT units. The four normal chromosomes with a contiguous CAG repeat configuration had very short repeat tracts (one with 6, one with 19, and two with 21 repeats). All SCA1 individuals examined to date, from several independent kindreds, were found to have a contiguous repeat configuration. This finding led to the hypothesis that the CAT interruptions, which break the repeat into two smaller tracts (typically less than 18 U each), may stabilize alleles with 21 or more repeats, and that the loss of the CAT interruption renders the CAG repeat unstable on SCA1 chromosomes. Studies of over 700 germline transmissions of normal alleles containing one or more CAT interspersions failed to identify instances of repeat instabil-
Figure 100-3 Distribution of the *SCA1* CAG repeat length versus the age of onset in year. The linear correlation coefficient is –0.8145. (Reprinted with permission from The University of Chicago Press, Chicago.)
Figure 100-4 Immunoblot analysis of ataxin 1 expression in lymphoblasts from normal (NL) and SCA1 individuals. Lanes 1, 2, and 9–11, extracts from normal individuals; lanes 3–8, extracts from SCA1 patients. The number of CAG repeats on both alleles is shown. Normal and expanded alleles are translated, with the latter varying according to the number of repeat units. (Reprinted with permission from Nature Genetics, a MacMillan Publication, Washington, DC.)

ity. In contrast, expanded alleles with perfect CAG tracts are very unstable and expand or contract in 70% of transmissions. The majority of the expansions occur in paternal transmissions resulting in larger alleles and earlier age of onset, whereas contractions mostly occur in maternally transmitted alleles. Chong and colleagues demonstrated gametic and somatic heterogeneity of the expanded *SCA1* CAG repeat using single sperm and low-copy genome analysis establishing mitotic instability at this locus. Comparative low-copy genome analysis of a large interrupted normal allele ($n = 39$) and a small uninterrupted disease allele ($n = 40$) revealed somatic instability of the latter, suggesting a role of the CAT interruption in stabilizing longer repeat tracts.

Characterization of Ataxin 1, the *SCA1* Gene Product
Northern blot analysis revealed that the CAG repeat is within an 11-kb transcript that is expressed in a wide variety of tissues including brain, muscle, kidney, lung, leukocytes, and placenta. Sequence analysis allowed the development of a composite sequence spanning 10,660 bp and identified a putative coding region which encodes 792–826 amino acids depending on the size of the repeat. The *SCA1* protein product, ataxin 1, appears to be a novel protein that does not share any homology with previously identified proteins. The CAG repeat is predicted to encode glutamine, and it is located 588 bp from the first methionine. The *SCA1* transcript is transcribed from both the wild-type and the expanded alleles in lymphoblasts from SCA1 patients.

The expression of ataxin 1 was evaluated in tissues from normal and SCA1 individuals using immunoblot and immunohistochemical analyses. Using ataxin 1 antiserum, lymphoblasts extracts from unaffected individuals revealed a single ataxin 1 band with an estimated molecular weight of 100 kDa (Fig. 100-4, lanes 1, 2, 9, 10, and 11). Extracts from SCA1 patients contained the 100-kDa band as well as a band showing slower electrophoretic mobility (Fig. 100-4, lanes 3–8). The size of the higher molecular-weight band in the patients varied according to the size of the expanded allele (*see* Fig. 100-4). The wild-type and expanded alleles were also translated in cerebellar tissue as well as in other brain tissues. Ataxin 1 is expressed in a variety of both neuronal and nonneuronal cells. Immunolocalization studies revealed that ataxin 1 is cytoplasmic in nonneuronal tissues and nuclear in neuronal cells, the only exception being cerebellar Purkinje cells, where it has both nuclear and cytoplasmic localization. The staining and localization of ataxin 1 was similar in regional brain tissues from SCA1 patients and controls.

PATHOGENESIS OF NEURODEGENERATION IN SCA1
SCA1 is a member of a growing family of neurodegenerative disorders caused by expansion of CAG repeats that lie within the coding portion of the involved genes and encode a glutamine tract.

A gain-of-function pathogenic mechanism has been proposed for these disorders based on numerous observations that argue against a loss-of-function mechanism. These observations include the lack of SBMA and HD phenotypes in patients with deletions of the androgen receptor and *HD* genes, respectively, and the embryonic lethal phenotype in mouse mutants lacking both copies of the murine *hd* gene. The gain-of-function model may involve cell-specific protein–protein or protein–DNA interactions, given the selective neuronal loss in face of a broad tissue expression pattern of the gene products. Alternatively, the mutated protein or its degradation products may become toxic to the cell, leading to neurodegeneration. The specificity of the degenerating neurons could be determined by the level and/or localization of the protein within those cells. The findings that the expanded alleles are translated into mutant proteins and that the sizes of the mutant proteins correlate with the number of repeats and age of onset support a gain-of-function model at the protein level. The unique expression pattern of ataxin 1 in Purkinje cells, the primary site of pathology in SCA1, may have a role in determining the specificity of the neuropathologic phenotype in this disease. To test the gain-of-function hypothesis, Burright and colleagues generated transgenic mice harboring the human *SCA1* gene with either a normal or expanded CAG tract containing 30 or 82 repeats, respectively. Expression of the transgenes was directed to the Purkinje cells using the regulatory elements of the Purkinje cell-specific gene *Pcp*-2. All transgenic mice expressing the unexpanded human *SCA1* gene were normal, whereas animals expressing the expanded *SCA1* allele developed ataxia and Purkinje cell degeneration like the human disorder. These data indicate that the expanded CAG tract within the *SCA1* gene is sufficient to produce Purkinje cell degeneration and ataxia consistent with a gain-of-function pathogenic mechanism. The availability of this mouse model will allow further studies aimed at understanding the exact molecular mechanisms leading to neurodegeneration in disorders caused by CAG repeat expansions.

It is interesting to note that both the normal and expanded repeat tracts were stable in over 125 parent to offspring transmissions. These data suggest that there may be basic differences between mice and humans with respect to DNA repair and/or replication. Alternatively, repeat instability may be affected by the chromosomal milieu and may be difficult to reproduce in the context of cDNA transgenes.

OTHER TRINUCLEOTIDE REPEAT DISORDERS

The following section will briefly review the main clinical and molecular features of the disorders caused by trinucleotide repeat expansions. Huntington's disease will not be discussed since a more detailed discussion is provided in Chapter 97.

SPINOBULBAR MUSCULAR ATROPHY Spinobulbar muscular atrophy (OMIM 313200) is an X-linked disorder characterized by proximal muscle weakness, bulbar dysfunction, and partial loss of secondary sexual characteristics. The clinical findings of lower motor neuron disease, gynecomastia, and impotence led to the hypothesis that SBMA may result from dysfunction of the androgen receptor (AR) given that this receptor is expressed in spinal and cranial motor neurons. Fischbeck and colleagues mapped the SBMA locus to the long arm of the X chromosome and subsequently determined the mutation in SBMA to be an expansion of the CAG repeat within the first exon of the AR gene. Normal alleles contain 12–30 repeats, and expanded alleles contain

40–62 repeats. The AR is a transcriptional regulatory protein, and it is proposed that the CAG repeat expansion confers a new regulatory activity that is harmful to motor neurons. Transgenic mice harboring a human AR cDNA failed to develop motor neuron disease in spite of transcription of the transgene. This lack of phenotype could be due to the low level of expression of the transgene compared with the endogenous gene, or may be due to the relatively short CAG repeat tract (45 repeats). New transgenic lines using different promoters and longer repeats are currently being generated to address these issues.

DENTATORUBROPALLIDOLUYSIAN ATROPHY Dentatorubropallidoluysian atrophy (OMIM 125370) is a rare autosomal dominant neurodegenerative disorder, characterized by progressive ataxia, myoclonus, epilepsy, chorea, athetosis, and dementia. The mutation causing DRPLA was identified using the candidate gene approach and was determined to involve an expansion of a CAG repeat within a novel gene that maps to human chromosome 12p. DRPLA patients have an expanded allele in the 54–75 repeat range in addition to the normal allele, which typically contains 7–34 repeats. The size of the expanded allele typically increases when paternally transmitted, with larger alleles causing juvenile-onset cases.

Burke and colleagues found the DRPLA mutation in an African-American family with HRS. Haw River syndrome differs from DRPLA in the absence of myoclonic epilepsy and presence of demyelination of the subcortical white matter.

The DRPLA protein is a novel protein whose function is unknown at this time; it is localized within the cytoplasm of neurons. As in SCA1, SBMA, and HD, the mutant alleles are translated into proteins of expanded length.

MACHADO-JOSEPH DISEASE AND SCA3 Machado-Joseph disease (OMIM 109150) is characterized by progressive ataxia, external ophthalmoplegia, bulging eyes, facial and lingual fasciculation, muscle atrophy, dystonia, and spasticity. Neuropathologic findings include severe neuronal loss in the striatum and substantia nigra, with moderate abnormalities in the dentate nucleus and red nucleus. The mutational mechanism in MJD involves the expansion of a CAG repeat that lies within a novel gene on chromosome 14q32.1. Normal alleles contain 14–34 repeats, whereas expanded alleles contain 61–84 repeats. SCA3 (OMIM 183085), which is clinically distinct from MJD and resembles SCA1, is also caused by CAG expansions within the *MJD* gene.

MYOTONIC DYSTROPHY Myotonic dystrophy (OMIM 160900), the most common muscular dystrophy affecting adults, is an autosomal dominant disorder with a wide range of severity from a frequently lethal form in newborns (congenital DM) to almost asymptomatic expression in adults. Clinical features include muscle weakness, myotonia, cataracts, cardiac arrhythmias, endocrine dysfunction, male-pattern baldness, and male infertility. The disease typically increases in severity and occurs earlier with successive generations, a phenomenon known as anticipation. Congenital DM, the most severe form of the disease, is characterized by severe hypotonia, respiratory insufficiency, and feeding difficulties. Congenital DM is usually transmitted from mothers, who often have mild to undetectable symptoms.

Myotonic dystrophy is caused by expansion of a CTG repeat that is located in the 3' untranslated region of a gene predicted to encode a protein kinase. The number of repeats varies from 5 to 20 in the normal population, whereas in DM families it ranges from 50 to 4000.

The DM gene product, myotonin protein kinase (Mt-Pk), was confirmed to be a serine/threonine kinase using in vitro assays of the recombinant protein. Controversy still exists as to the effects of the CTG repeat expansion on the mRNA/protein in DM. Mice lacking the myotonin protein kinase gene develop a late onset progressive myopathy, but lack other features of myotonic dystrophy, including myotonia and male infertility. Thus, the exact pathogenic mechanism of this mutation remains unclear.

FRAGILE X SYNDROME AND OTHER FRAGILE SITES

Fragile X syndrome (OMIM 309550) is the most common single cause of inherited mental retardation, with an estimated incidence of 1 in 2000 live births. The main clinical feature in preadolescent males is mental retardation; in postpubescent males additional features include increased head size, enlarged ears, macroorchidism, narrow and elongated facies, and mild skeletal defects. FRAXA, which was initially mapped to Xq27.3 based on the finding of a fragile site at this location, is an X-linked disorder with unusual penetrance. Approximately 30% of female carriers have borderline IQ, and 20% of males with genetic risk for FRAXA are normal. These observations led to the "Sherman paradox," which describes increasing penetrance in successive generations. The FRAXA gene known as *FMR1* was isolated using a positional cloning approach, and the mutation was determined to be an expansion of a CGG repeat within the 5' untranslated portion of the gene. Symptomatic males have 200 or more repeat units, whereas nonpenetrant males and carrier females have 70–150 repeats, which are referred to as premutational. Females with mental retardation typically have repeats with 200 or more units, but, in general, only 30% of females with repeats over 200 have mental retardation, presumably due to the effects of X-inactivation patterns. The identification of the mutational basis of FRAXA clarified the Sherman paradox and, like other trinucleotide repeat mutations, provided a molecular basis for anticipation.

The *FMR1* CGG repeat is highly unstable in premutation alleles transmitted through a female meiosis. Females with 80 or more repeats have a virtual 100% mutation rate to a disease-causing expansion with more than 200 repeats. Sequence analysis of normal and FRAXA alleles showed that the CGG repeat is interrupted by AGG trinucleotides at regular intervals. These interruptions, which are lost in premutation alleles, may provide stability in normal alleles.

The FMR1 gene product is found in many tissues, with highest levels being observed in brain and testis. The precise function of the protein remains unknown, but it has been shown to bind RNA. The RNA-binding property of FMR1 suggests that it might be involved in regulating the expression of other genes.

The CGG expansion in FRAXA leads to methylation of the promoter region and decreased levels of the mRNA and protein. Although the majority of FRAXA cases are caused by CGG repeat expansions, a few cases have resulted from mutations that lead to the complete absence of the FMR1 protein (Fig. 100-5). A mouse mutant that is null for *Fmr1* was generated by gene targeting and was found to have learning deficits. These data clearly demonstrate that, in FRAXA, the disease results from loss of the normal function of *FMR1*.

Two additional fragile sites have been identified on the X chromosome: FRAXE (OMIM 309548) and FRAXF (OMIM 600226) in Xq28. Both of these have been associated with CGG repeat expansions. A gene (FMR2) adjacent to the FRAXE site has been cloned, and there is loss of FMR2 expression in association with
Figure 100-5 Immunoblot analysis for the FMR1 protein. NF, normal female cell line; FxM, cell line from a male with fragile X syndrome caused by a typical CGG expansion mutation; P, cell line from a patient with a nucleotide deletion in exon 5 of *FMR1* resulting in premature termination of translation; FMR1 protein cannot be detected in the cell lines from the males with mutation (P) or expansion (FxM). (Figure kindly provided by David Nelson and reprinted with permission from Nature Genetics, a MacMillan Publication, Washington, DC.)

CGG expansion at FRAXE. At this time there is no clinical phenotype associated with FRAXF.

CGG repeat expansions have been observed in two autosomal fragile sites, FRA16A (OMIM 136580) and FRA11B (OMIM 600651), on human chromosomes 16 and 11, respectively. FRA16A has not been associated with a gene yet, but the expanding CGG repeat in FRA11B is within the 5' end of the protooncogene *CBL2* and results in methylation of sequences in this region. It is interesting that FRA11B has been associated with Jacobsen syndrome (OMIM 147791), a disorder characterized by dysmorphic features, mental retardation, and deletions of 11q23–qter. This association has been observed in some families where the 11q deletion has been noted to occur on a parental chromosome carrying the expanded CGG repeat.

CLINICAL IMPLICATIONS

The finding that expansion of trinucleotide repeats is the mutational mechanism in the neurological disorders described above greatly facilitates the diagnosis of these diseases and provides options for genetic counselling. In the case of dominantly inherited ataxias, the identification of these mutations allows a rational classification of this highly heterogeneous group of diseases in addition to facilitating diagnosis. Molecular testing for trinucleotide repeat expansions should be considered as the leading diagnostic test in trying to evaluate patients with dominantly inherited ataxia, progressive degenerative disorders characterized by chorea, dementia with or without seizures, X-linked patterns of lower motor neuron disease, congenital muscle disorders and suspected DM, and mental retardation. SCA1 and MJD/SCA3 are currently estimated to account for approximately 30–40% of dominantly inherited ataxias. Thus, analysis of the CAG repeats at those two loci will provide a molecular diagnosis in a substantial number of patients. It is important to emphasize that testing for the HD, DRPLA, and SCA mutations in asymptomatic individuals who are at risk should be restricted to adults who have undergone extensive psychological and genetic counseling, given the devastating nature of these diseases. In children these tests should be limited to those already symptomatic. In the case of FRAXA, the molecu-

lar analysis of the CGG repeat is superior to the cytogenetic approach traditionally used for identifying the fragile site, owing to its sensitivity and accuracy. However, chromosomal analysis in patients with mental retardation is still extremely valuable given the relative high likelihood of identifying other cytogenetic abnormalities.

The finding that CAG repeat expansion is the mutational mechanism in several late-onset neurodegenerative disorders suggests that this will prove to be the mutational mechanism in most of them. This will facilitate the identification of the genes/mutations in several dominantly inherited ataxias and will eventually lead to understanding the pathogenesis of these diseases.

ADDENDUM

Since the submission of this chapter, several new research developments have occurred in the field of trinucleotide repeats. These mainly include the identification of new disease genes and new insight into disease pathogenesis. The following section will highlight some of the key recent developments.

The CGG repeat which expands in the fragile XE syndrome has been demonstrated to reside in the 5' UTR of a new gene termed FMR2. The expansion of an AAG repeat which resides in the first intron of a novel gene was demonstrated to be the most common mutation in Friedreich ataxia (FRDA). Normal alleles typically contain 7–32 repeats, whereas expanded alleles have more than 66 repeats. The expansion leads to lower levels of the gene product and most likely causes disease through a loss-of-function mechanism. The FRDA gene product frataxin localizes to the mitochondria and has homologs in yeast and round worm. Loss of function of the yeast frataxin homolog results in mitochondrial dysfunction and iron accumulation. These findings, together with the finding of iron deposits in heart tissue from FRDA patients, suggest that frataxin is involved in mitochondrial iron export and homeostasis.

The gene for spinocerebellar ataxia type 2 (SCA2) was identified, and the mutation involves the expansion of a translated CAG repeat within the novel protein ataxin-2. Normal alleles contain 15–29 repeats and expanded alleles contain 35–59 repeats. The SCA2 CAG repeat is interrupted by 1–3 CAA units on normal chromosomes but is a pure CAG repeat tract on expanded disease alleles. Ataxin-2 is a cytoplasmic protein of an apparent molecular weight of 150 kDa and no known homology to previously identified molecules.

Using the candidate gene approach, a small expansion in the CAG repeat located in the C-terminal portion of the α_{1A} voltage-dependent calcium channel was demonstrated to cause spinocerebellar ataxia type 6 (SCA6). The SCA6 CAG repeat contains 4–18 repeats on normal chromosomes and 21–30 repeats on disease chromosomes. It is intriguing that these small expansions, which are well within the normal range for other polymorphic CAG repeats, are pathogenic in SCA6. This finding suggests that the protein context of the CAG repeat is important and may modulate the pathogenicity of the toxic glutamine tract. Alternatively, the small expansion of the CAG repeat in the α_{1a} calcium channel may disrupt its normal function, leading to abnormal calcium homeostasis and neuronal degeneration.

Lastly, the gene for spinocerebellar ataxia type 7 (SCA7) has been identified and the mutational mechanism was demonstrated to be the expansion of a translated CAG repeat within a novel nuclear protein ataxin-7. Normal alleles contain 7–17 repeats and expanded alleles contain 38–130 repeats.

The importance of the length of the polyglutamine tract in the phenotype of each of the neurodegenerative diseases caused by CAG repeat expansion has been demonstrated by the fact that longer repeats cause earlier and typically more severe disease. New insight into the pathogenesis of neurodegenerative diseases caused by CAG repeat expansion has recently emerged from immunohistochemical studies of patient tissues and studies of transgenic mouse models.

Immunohistochemical staining of brain tissues from HD, SCA3, and SCA1 patients using the respective antisera demonstrated the presence of nuclear inclusions in affected brain regions but not in neurons spared in the disease. Transgenic mice harboring a truncated form of the huntingtin protein with an expanded polyglutamine tract, as well as SCA1 transgenic mice, had neuronal inclusions similar to those seen in patients. It is interesting that the nuclear inclusions stain positively with ubiquitin antibodies in both patient and mouse tissues. These findings point to the nucleus as the site where disease pathogenesis is mediated and raise the possibility that protein ubiquitination and the degradation pathway may be involved. Factor(s) that lead to selective neuronal loss in each of these diseases remain unknown. In the case of SCA1, the strong interaction between mutant ataxin-1 and the leucine-rich acidic nuclear protein (LANP), a protein with highest expression levels in cerebellar Purkinje cells, suggests that LANP is a candidate to be one of the factors mediating cell specificity in SCA1. Additional factors for SCA1 and other diseases could include levels of expression of the mutant proteins in the various neuronal types, as well as protein modifications that may be cell-specific.

In summary, the identification of expansion of unstable trinucleotide repeats as a mutational mechanism in human disease has proven to be one of the most exciting and clinically relevant discoveries in this decade. To date, over 12 diseases can be easily diagnosed, and families can be offered effective genetic counselling. The identification and characterization of the mutant gene products are likely to lead to better understanding of disease pathogenesis and hopefully to potential therapeutic choices in the future.

101 Charcot-Marie-Tooth Disease and Related Peripheral Neuropathies

JAMES R. LUPSKI

INTRODUCTION

Charcot-Marie-Tooth disease (CMT) is the most common inherited peripheral neuropathy, affecting at least 1 in 2500 individuals. Charcot-Marie-Tooth disease represents a heterogeneous collection of disorders of the peripheral nerve. It can be inherited as an autosomal dominant, autosomal recessive, or X-linked trait, and, in addition, isolated cases occur. The autosomal dominant segregation pattern is the most frequently observed, and recent molecular studies have identified an exciting novel mutational mechanism for this form—the CMT1A duplication. It is intriguing that, for one of the most common dominant disorders affecting humans, there is no mutant gene involved in the majority of cases. Instead, the disease phenotype results from having three copies of a normal non-mutated gene or a gene dosage effect secondary to an inherited or *de novo* DNA duplication. Furthermore, an intrinsic structural property of the human genome, a repeat sequence (CMT1A-REP) flanking the duplicated region, acts as a substrate for homologous recombination and an unequal crossover event. This recombination between misaligned flanking CMT1A-REP repeats appears to have a sex predilection and to occur preferentially during male gametogenesis. The identification of the CMT1A duplication has potent implications for clinical diagnosis, clinical management with respect to prognosis, counseling regarding recurrence risk, and the rational design of therapy geared at normalizing the levels of gene expression.

Hereditary neuropathy with liability to pressure palsies (HNPP) (OMIM 162500) is a less frequently diagnosed autosomal dominant peripheral neuropathy, which usually presents with a milder clinical phenotype than CMT. The patient inherits a tendency to nerve injury after mild trauma; it is likely that most affected individuals remain undiagnosed because they are either clinically asymptomatic or only minimally aware of functional disabilities. Carpal tunnel syndrome and other entrapment neuropathies are frequent manifestations of HNPP, making it difficult to distinguish from an acquired neuropathy. In the majority of cases, HNPP results from DNA deletion of the same genetic region duplicated in CMT1A. Molecular detection of the HNPP deletion secures a diagnosis suspected clinically and can be useful for distinguishing HNPP from acquired neuropathies.

The Dejerine-Sottas syndrome (DSS) (OMIM 145900) is a rare and severe neuropathy. Though it was initially thought to be an autosomal recessive trait, molecular studies have identified mutations in only one copy of the two homologues of the same genes that when mutated can lead to a CMT phenotype. These heterozygous mutations presumably represent dominant alleles. Thus, instead of being two completely distinct entities, DSS and CMT may more accurately represent a spectrum of related clinical findings due to allelic heterogeneity underlying the disorders; many DSS cases may result from new mutation dominant alleles.

In the past few years, molecular analyses have identified three genes: *PMP22*, *MPZ*, and *Cx32*, wherein mutations, or altered dosage of the normal gene in the case of *PMP22*, lead to inherited neuropathies. These genes provide critical reagents to study the biology of the peripheral nerves. Each gene product is important for proper structure or function of the myelin. The inherited peripheral neuropathies CMT, HNPP, and DSS thus represent "myelinopathies." Molecular genetic studies of CMT and related neuropathies have given new insights into the biology of the human peripheral nervous system and have important implications for patient care.

CLINICAL FEATURES AND PATHOGENESIS

Charcot-Marie-Tooth polyneuropathy syndrome, or the hereditary motor and sensory neuropathies (HMSN), are genetically and clinically heterogeneous disorders of the peripheral nerves characterized by an insidious onset and slowly progressive weakness of the distal muscles and mild sensory impairment. Symptoms typically appear in the first or second decade but may appear later. Children with CMT often walk on their toes, and adults consult a physician because of abnormalities of gait from a dropped foot due to dorsiflexor weakness, foot deformities such as pes cavus, or loss of balance. Cramps are a frequent complaint, are worse after long walks, and are sometimes exacerbated by cold weather. The most frequent complaint concerning hand function that may occur later in the disease is difficulty with fine finger movements. Deep tendon reflexes disappear early at the ankle and later at the patella and the upper limb.

Electrophysiologic and neuropathologic studies distinguish two major forms. Charcot-Marie-Tooth disease type 1 (CMT1) (OMIM 118200), also known as HMSNI, is a demyelinating neuropathy with moderately to severely decreased motor nerve con-

duction velocities (NCVs, usually <42 m/s). The conduction deficit is uniform from nerve to nerve and from nerve segment to nerve segment, suggesting a cell-autonomous defect involving the Schwann's cell. Charcot-Marie-Tooth disease type 1 is characterized by hypertrophic nerves, which may be visualized in some patients under the skin (greater auricular nerve) or palpated (ulnar and peroneal nerves).

Peripheral nerve pathology shows segmental demyelination and remyelination and frequent "onion bulb" formation, which consists of circumferentially directed Schwann cells and their processes. Charcot-Marie-Tooth disease type 1 has been characterized further with genetic linkage studies, which demonstrate the involvement of at least three loci in different families: CMT1A at 17p11.2–p12, CMT1B on 1q21.2–q23, and CMTX1 at Xq13.1. Charcot-Marie-Tooth disease type 2 (CMT2) (OMIM 118210), also called HMSNII, is characterized by normal or slightly reduced motor NCVs with decreased amplitudes and neuropathology that shows axonal loss with few if any onion bulbs. Dejerine-Sottas syndrome (HMSNIII) is a demyelinating neuropathy with clinical electrophysiologic and histopathologic features similar to, but of more severe and earlier onset than, CMT1. These classifications appear to reflect primary pathological involvement of the myelin (CMT1 and DSS) or the axon (CMT2) of the peripheral nerve.

Hereditary neuropathy with liability to pressure palsies may manifest clinically as periodic episodes of numbness, muscular weakness, atrophy, and in some cases palsies that follow relatively minor compression or trauma to the peripheral nerves. Electrophysiologic studies sometimes show mildly slowed NCV in clinically affected individuals as well as in asymptomatic "carriers." Conduction blocks can also be observed. Peripheral nerve pathology shows segmental demyelination and remyelination with tomacula or "sausage-like" focal thickenings of the myelin sheath. Ultrastructural studies reveal frequent occurrence of uncompacted myelin, particularly in the inner lamellae, due to separation of the major dense line with widened islands of cytoplasm in the Schwann cell.

MOLECULAR MECHANISMS

DNA DUPLICATION ASSOCIATED WITH CMT1A The CMT1A duplication (OMIM 118220) was identified initially in multiple US and European CMT1 families, where it was found to cosegregate with the disease in familial cases and as a new mutation in an isolated or sporadic case. The segregation of marker genotypes from within the duplicated segment in the new mutation individual suggested a mechanism of unequal crossover or nonsister chromatid exchange for the duplication. Demonstration of the CMT1A duplication in affected individuals was carried out by the following methods: detection of three alleles at a highly polymorphic dinucleotide repeat locus, dosage differences at restriction fragment length polymorphic (RFLP) alleles, detection of a duplication-specific junction fragment of 500 kb with pulsed field gel electrophoresis (PFGE) to separate large-molecular-weight fragments of *Sac*II digested genomic DNA from the affected individual, and microscopically by two-color fluorescent *in situ* hybridization (FISH) of interphase nuclei. Failure to recognize the molecular duplication can lead to misinterpretation of marker genotypes for affected individuals, identification of false recombinants, and incorrect localization of the disease locus. The CMT1A duplication was confirmed subsequently by many laboratories in patients from varied ethnic background, was shown to

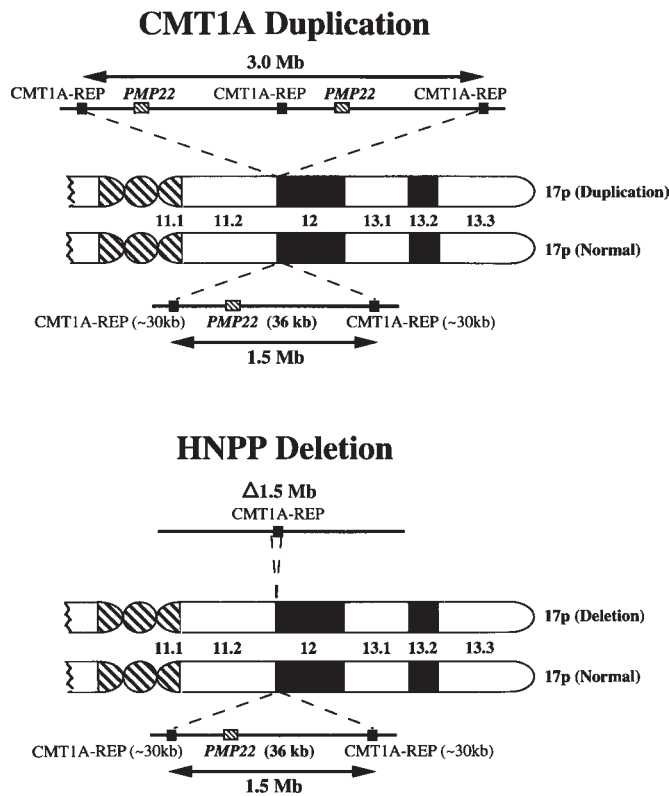
occur in approximately 70% of unrelated CMT1 cases, and was found in 9 out of 10 sporadic CMT1 cases. The junction fragment appeared to be identical in multiple CMT1A duplication patients of varied ethnicity, suggesting a precise recombination event to generate the duplication. Taken together, these observations suggested that the CMT1A duplication was a frequent cause of CMT that appears to have occurred *de novo* multiple and independent times in different genetic backgrounds.

Patients with the CMT1A duplication exhibit typical neuropathology of CMT1. Electrophysiologic studies in families segregating the CMT1A duplication demonstrated a clear bimodal distribution of abnormally decreased motor NCV in individuals with the CMT1A duplication, while normal NCVs appeared in those shown not to have inherited the CMT1A duplication. However, a remarkable range of motor NCV was observed in CMT1A duplication patients that was not related to age or clinical severity. Longitudinal electrophysiologic studies performed 22 years apart in one family segregating the CMT1A duplication demonstrated little change in NCV and only mild increased motor impairment. Thus, the CMT1A duplication is a good biological marker for the disease with clinical utility for diagnosis and prognosis.

Molecular studies showed that the duplication was 3 Mb in size, consisting of a tandem arrangement of a 1.5-Mb monomer unit, and that the region duplicated was flanked by an approximately 30-kb repeat called CMT1A-REP (Fig. 101-1). Physical mapping studies showed that CMT1A-REP was present in two copies on the normal chromosome as a direct repeat but in three copies on the CMT1A duplication chromosome. Probes to CMT1A-REP were shown to detect specific junction fragments in CMT1A duplication patients. These observations are consistent with a model of unequal crossover whereby misalignment between the proximal copy of CMT1A-REP and the distal copy of CMT1A-REP during meiosis and a homologous recombination event involving these misaligned repeats result in the CMT1A duplication. This model predicts a reciprocal recombination that would result in a 1.5-Mb deletion.

***PMP22* GENE DOSAGE AS A NOVEL MECHANISM FOR CMT1A** Several models were proposed to explain how the CMT1A duplication might alter the expression of a "CMT gene" to result in the disease phenotype. To investigate the gene dosage model, patients with a cytogenetically visible duplication of the short arm of chromosome 17 (17p) were subjected to electrophysiologic studies. Four patients with different cytogenetic duplications had the decreased NCV consistent with CMT1. That these patients had different breakpoints and yet, as long as they duplicated the CMT1A region, they manifested motor NCV abnormalities consistent with CMT1 lends strong support to the gene dosage model even prior to the identification of a dosage-sensitive gene that maps within the CMT1A duplication.

The identification of the dosage-sensitive gene was aided greatly by concurrent studies on the basic neurobiology of peripheral nerve regeneration and an animal model for CMT1, the *Trembler (Tr)* mouse. A subtractive hybridization strategy, using cDNA libraries constructed from crushed sciatic nerve vs noncrushed nerve to investigate genes important to nerve regeneration, identified a peripheral myelin-specific gene that was not expressed after crush injury but was expressed at a high level during nerve regeneration and maintenance. This gene mapped to mouse chromosome 11, which is syntenic to human chromosome 17p, encoded a protein of approximately 22 kDa, and was called peripheral

CMT1A Duplication


HNPP Deletion

Figure 101-1   Structure of CMT1A duplication and HNPP deletion. The CMT1A duplication is a submicroscopic tandem duplication of a 1.5-Mb DNA region while the HNPP is a 1.5-Mb deletion of the same region in chromosome 17p11.2–p12. The regions on chromosome 17p are depicted, with the normal chromosome shown below and the segmentally duplicated or deleted chromosome above. Cross-hatched circles, the centromere. The normal chromosome 17p contains a 1.5-Mb region on 17p11.2–p12 flanked by homologous CMT1A-REP sequences (filled boxes in blown-up region) of approximately 30 kb in length (our unpublished observations). The *PMP22* gene (crosshatched boxes) maps within this 1.5-Mb critical region, which is duplicated in most patients with CMT and deleted in most patients with HNPP. The 1.5-Mb HNPP deletion is not detected by standard cytogenetic G-banding, and results in deletion of *PMP22* and one copy of CMT1A-REP on one chromosome. CMT1A results from three copies of *PMP22*, while HNPP results from one copy of *PMP22*. The 3.0-Mb CMT1A duplication is not detected cytogenetically, and results in two copies of *PMP22* and three copies of CMT1A-REP on the duplicated chromosome.

myelin protein–22, *Pmp*-22. *Pmp*-22 was shown to contain a mutation causing different missense amino acid substitutions in the *Tr* and allelic *Tr*^{J} mice. *Trembler* had been proposed as an animal model for CMT and for DSS based on similar electrophysiologic findings of decreased motor NCV and neuropathologic findings including onion bulb formation.

The human *PMP22* gene was isolated, shown to be expressed at a high level specifically in the peripheral nerve, and mapped within the CMT1A duplication (Fig. 101-1). Subsequently, a human *PMP22* missense mutation leading to the identical amino acid substitution identified in *Tr*^{J} mouse was found to cosegregate with the CMT1 phenotype in a nonduplication family, whose disease locus was linked to 17p11.2–p12. Similarly, a *de novo PMP22* mutation was identified in a sporadic nonduplication case of CMT1.

The identification of *de novo* and inherited *PMP22* point mutations in DSS further supports the role of *PMP22* in demyelinating peripheral neuropathies. These observations, in conjunction with the findings that rare CMT1 patients with smaller or larger duplications each include the *PMP22* gene, strongly support the hypothesis that *PMP22* is the dosage-sensitive gene in the CMT1A duplication. Further proof for the dosage hypothesis was obtained with the demonstration of elevated *PMP22* mRNA expression in biopsied peripheral nerves from CMT1A duplication patients.

A transgenic rat model of CMT1A has been created by overexpression of *PMP22*. The transgenic rats develop gait abnormalities, peripheral hypomyelination, onion bulb formation in Schwann cells, and muscle weakness. This model may facilitate the evaluation of potential treatment strategies for CMT1A

DNA DELETION ASSOCIATED WITH HNPP   The HNPP deletion was identified initially in two families segregating autosomal dominant HNPP and as a *de novo* mutation in a sporadic case. The deletion was demonstrated in affected individuals by loss of RFLP alleles and by FISH. It was shown to segregate in a dominant fashion, to contain all the markers known to be duplicated in patients with the CMT1A duplication, to measure 1.5 Mb in size, and to have junctions that overlapped those of the CMT1A duplication (Fig. 101-1). Because the deletion resulted in lack of transmission of deleted alleles to affected offspring, failure to recognize the deletion could lead to erroneous exclusion of paternity or maternity. The *PMP22* gene was shown to be deleted in patients with the HNPP deletion. It was proposed as the gene whose underexpression or haploinsufficiency was responsible for HNPP. This hypothesis was substantiated by the subsequent identification of a *PMP22* frameshift mutation, leading to a nonsense codon and to a premature termination likely resulting in a null allele, in a nondeletion HNPP family.

Although some evidence exists to suggest genetic heterogeneity, the majority of patients appear to have HNPP by the deletion. The identification of similar junction fragments in multiple unrelated families suggests that a precise recombination event is involved in generating the HNPP deletion.

THE CMT1A DUPLICATION AND HNPP DELETION RESULT FROM A RECIPROCAL RECOMBINATION   Physical mapping studies of the CMT1A duplication showed that CMT1A-REP was present in three copies on the duplicated chromosome. This finding led to a model for generating the duplication that predicted a reciprocal recombination product of a 1.5-Mb deletion with only one copy of CMT1A-REP remaining on the deleted chromosome. The HNPP deletion was proposed as the anticipated reciprocal recombination product. Molecular analysis in multiple patients detected three copies of CMT1A-REP on both inherited and *de novo* CMT1A duplication chromosomes, and one copy of CMT1A-REP on the deleted chromosome in both inherited and *de novo* HNPP. Furthermore, the predicted HNPP junction fragments with a CMT1A-REP probe were identified. Obviously, these two diseases cannot coexist in the same family lineage because the mutation event must cause a duplication and a deletion gamete, only one of which will appear in the fertilized egg and thus be transmitted into subsequent generations. These observations support the hypothesis that a reciprocal recombination mechanism involving CMT1A-REP is responsible for the generation of both the duplicated and deleted chromosomes. Moreover, they document the first examples in humans of mendelian syndromes resulting from the reciprocal products of unequal
Figure 101-2 Reciprocal recombination resulting in Charcot-Marie-Tooth disease type 1A (CMT1A) or hereditary neuropathy with liability to pressure palsies (HNPP). Open boxes, CMT1A-REP; solid boxes, *PMP22*; A, B, C, and D, and A', B', C', and D', unique sequences flanking CMT1A-REP on the two chromosome homologs, respectively; circled numbers 1 and 2, the crossovers that lead to the different DNA rearrangements: CMT1A duplication or HNPP deletion; jct, specific junction fragments for the CMT1A duplication and HNPP deletion detected using a CMT1A-REP probe. Distribution of major myelin proteins in Peripheral Nerve

Figure 101-3 Myelin protein components and organization in the peripheral nervous system (PNS). Note that one Schwann cell myelinates a single axon in the PNS. A crosssection illustrates compact myelin organization indicating the major dense line and the intraperiod line, which are formed by apposed intracellular and extracellular membranes surfaces, respectively. The proposed structures of the major PNS myelin proteins are shown; PMP22, peripheral nerve myelin protein, 22-kDa M_r; P_0, myelin protein zero; Cx32, connexin 32. Boxes, the inherited myelin disorders associated with mutations in each myelin protein; CMT1A, Charcot-Marie-Tooth disease type 1A; HNPP, hereditary neuropathy with liability to pressure palsies; CMT1B, Charcot-Marie-Tooth disease type B; DSS, Dejerine-Sottas syndrome; CMTX, X-linked CMT. The gap in the membrane indicates the different locations of the Cx32 proteins. Bottom, the distribution as determined by immunostaining of the major PNS myelin proteins PMP22 (A), P_0 (B), and Cx32 (X) in the peripheral nerve. (Adapted from Roa and Lupski, Adv Hum Genet 1994;10:128–133.)

exchange involving large intrachromosomal segments, and provide the first example of two distinct human diseases associated with reciprocal products of the same mutational event (Fig. 101-2). Interestingly, there is a recombination hot spot within CMT1A-REP associated with the unequal crossover responsible for the CMT1A duplication and HNPP deletion, and this hot spot is located near a *mariner* insect transposon-like element.

***MPZ* AND *CX32* MUTATIONS ASSOCIATED WITH MYELINOPATHIES**   The *MPZ* gene encodes myelin protein P_0, which is expressed uniquely by myelinating Schwann cells and is a major structural protein of peripheral myelin. P_0 is an integral myelin membrane protein with a single transmembrane domain and an extracellular domain consisting of an immunoglobulin-like structure. The latter domain is important for homophilic adhesion molecule interactions and is proposed to play a significant role in myelin compaction. Homozygous P_0 knockout mice have clinical features similar to CMT1, including hypomyelination and uncompacted myelin.

The locus for the human P_0 gene was mapped to 1q22–q23 by FISH, the same region implicated in CMT1B. Heterozygous *MPZ* mutations have been identified in CMT1B, isolated CMT1, and DSS (Fig. 101-3). Many mutations are in regions that encode the extracellular domain and may result in a perturbation of homophilic interactions necessary for myelin compaction.

The *Cx32* gene encodes the gap junction protein, connexin 32. *Cx32* mRNA is expressed at high levels in the peripheral nerve but also in the liver. Multiple *Cx32* mutations were identified in families with X-linked CMT1 (CMTX1). Immunohistochemical staining of connexin 32 at the nodes of Ranvier and at Schmidt-Lanterman incisures suggests that it may form the intracellular gap junctions that connect the folds of Schwann's cell cytoplasm (*see* Fig. 101-3). These junctions have been proposed to allow transfer of ions, nutrients, and small molecules around and across the compact myelin to the innermost myelin layers, indirectly providing sustenance to the axon as well. This could explain the combination of myelin disruption and axonal degeneration that occurs with *Cx32* mutations in CMTX1.

PATHOPHYSIOLOGY

The three genes identified to date, *PMP22*, *MPZ*, and *Cx32*, involved in the inherited myelinopathies CMT1, HNPP, and DSS,

each encode highly expressed integral myelin membrane proteins. The biology of protein P_0 is perhaps the best understood, because of extensive structural studies, the analysis of the properties of adhesion molecules in cell culture systems, the availability of a P_0 knockout mouse, and the multiple *MPZ* mutations in CMT1 and DSS, which are enabling genotype/phenotype correlations. All evidence points to an important role for P_0 in the maintenance of proper myelin compaction by acting as a homophilic adhesion molecule facilitating the tight compaction of apposed extracellular membrane faces along the intraperiod line of peripheral nerve myelin.

The exact biological function of *PMP22* remains unknown. However, by analogy to *MPZ* and mutational alterations leading to CMT1 and DSS, and in combination with ultrastructural studies showing loss of myelin compaction in HNPP patients where the phenotype is now known to result from haploinsufficiency of *PMP22*, it is likely that the PMP22 protein plays a role in maintaining myelin compaction. One proposed hypothesis regarding *PMP22* function is that it may be involved in the intramembrane contact important to myelin integrity, since many of the mutations associated with inherited neuropathies occur in regions encoding the transmembrane domains. Whatever the exact function for

PMP22, it is clear that a critical amount of the protein is required, since either overexpression or underexpression by only 50% results in a disease phenotype. The studies on the role of *PMP22* inherited neuropathies delineate the concept of a "gene expression window" for a dosage-sensitive gene. This concept has potent implications for gene therapy.

The underlying pathophysiology in CMT1 and related demyelinating neuropathies may therefore be related to a disturbance of myelin compaction, resulting in the abnormal motor NCV, which then leads to the clinical manifestations. The identification of other genes wherein mutations result in a CMT1 phenotype would facilitate a better understanding of the biology of the normal peripheral nerve.

CLINICAL IMPLICATIONS

MOLECULAR DIAGNOSIS   The CMT1A duplication is the causative mutation for the majority of autosomal dominant CMT1 and occurs as a new mutation in 90% of sporadic CMT1 cases. Given its high frequency, the detection of the CMT1A duplication is a useful diagnostic test in patients with inherited as well as sporadic peripheral neuropathy. In a patient with an electrophysiological diagnosis of CMT1, detection of the CMT1A duplication establishes the exact molecular form of the disease in that family. This makes it possible to diagnose or exclude with a simple blood test other family members who are at risk of developing the disease, enables prenatal diagnosis to be offered, and may provide prognostic information.

The HNPP deletion appears to be the causative mutation in the majority of autosomal dominant and sporadic HNPP cases. Hereditary neuropathy with liability to pressure palsies is a milder disease than CMT, and, because the symptoms can be episodic and transient, individuals may be less likely to seek medical attention. It can be a difficult clinical diagnosis to make and requires a high index of suspicion. Therefore, molecular testing can be very helpful. The HNPP deletion should be suspected in the following clinical situations: (1) any family showing dominantly inherited pressure palsies, (2) families with multiple members affected with carpal tunnel syndrome or other entrapment neuropathies, and (3) all patients with a recurrent demyelinating mononeuropathy or polyneuropathy of undetermined etiology, since electrophysiological studies can show evidence for conduction block. The detection of the HNPP deletion establishes a precise molecular diagnosis, enables presymptomatic diagnosis in family members at risk, can be useful for prognosis, and will promote preventive measures to avoid nerve pressure or trauma to susceptible areas such as the elbows, wrists, and at the fibular neck of the legs. Although the exact prevalence of HNPP is unknown, sporadic cases should be nearly as common as sporadic CMT1A, since the HNPP deletion and CMT1A duplication represent reciprocal recombination products.

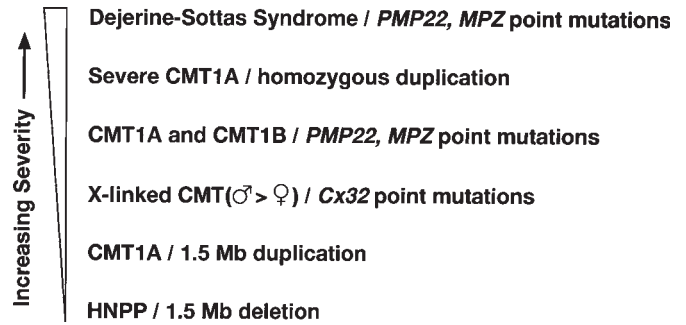
Molecular diagnostic testing is available commercially for the detection of the CMT1A duplication and the HNPP deletion in the United States and is also performed in molecular diagnostic laboratories throughout the world. In the first 18 months of testing in the United States, the CMT1A duplication was detected in 21% of 2421 individuals with a clinical suspicion of CMT. Intriguingly, 20 suspected CMT patients were found to have the HNPP deletion even prior to launching of the molecular assay for HNPP. This emphasizes the extreme variability of clinical expression of these inherited peripheral neuropathies, the limitations of a clinical


Figure 101-4 Clinical neuropathy phenotype/genotype correlations. Left, clinical phenotypes with the trend toward increasing severity listed from bottom to top; right, are shown the types of mutations found. The inherited primary demyelinating peripheral neuropathies are clinically heterogeneous with a wide variability of clinical expression and can have overlap of symptoms. However, molecular analysis enables recognition of some trends for phenotype/genotype correlations.

diagnosis when evaluating these patients, and the diagnostic value of molecular testing. During the 6 months since the launch of molecular testing for the HNPP deletion, 28% of 166 individuals suspected clinically of having HNPP have tested positive for the deletion.

Molecular diagnostic testing for *Cx32* mutations is also available commercially in the United States. Mutation in *Cx32* appears to be the most common alteration found in nonduplication CMT1. Detection of these mutations has important clinical implications for genetic counseling regarding recurrence risk, since it establishes the X-linked form of the disease in the family.

PHENOTYPE/GENOTYPE CORRELATIONS   Charcot-Marie-Tooth disease is well-established as a disorder with extreme variability of clinical expression. Some of this variability may have reflected genetic heterogeneity. However, not only is there interfamilial clinical heterogeneity but there is also significant intrafamilial clinical heterogeneity. Families segregating the CMT1A duplication may have substantive variability among affected individuals; the degree of motor NCV decrease can also vary. Clinical variability can even be observed in identical twins with the CMT1A duplication. It has been proposed that this clinical variability may reflect the gene dosage phenomena underlying CMT1A. Patients with the CMT1A duplication have no abnormal gene product, but, instead, their disease reflects abnormally increased expression of *PMP22*. Altered gene expression levels may be more susceptible to modifier gene and/or environmental effects than gene mutations resulting in aberrant proteins.

There is a wide variability of clinical expression for each of the inherited demyelinating neuropathies and clinical diagnostic categories may overlap. Nevertheless, molecular analyses enable some phenotype/genotype correlations as guidelines. Patients with the HNPP deletion usually have a milder disease than those with the CMT1A duplication. The point mutations in *PMP22* and *MPZ* give missense amino acid substitutions, which result in aberrant proteins that will usually lead to a more severe clinical CMT1 or DSS phenotype than the duplication form (Fig. 101-4). The severity of the disease likely reflects the extent of the mutation's effect on the protein function in myelin compaction. Missense amino acid substitutions may be more detrimental than null mutation by having a dominant-negative effect in a multimeric structure.

CONCLUSIONS

Molecular genetic analysis of the demyelinating neuropathies CMT1 and HNPP has uncovered a novel mutational mechanism whereby a reciprocal recombination involving a misaligned flanking repeat sequence results in both the CMT1A duplication and HNPP deletion. These studies have illuminated the role that gene dosage may play in causing a disease phenotype, which has important implications for therapeutic strategies, and which may underlie the basis of the extreme clinical variability. The identification of these specific molecular lesions has resulted in the availability of molecular procedures for establishing or excluding a secure diagnosis, enabling presymptomatic and prenatal diagnosis, and providing prognostic information.

The identification of the myelin genes *PMP22*, *MPZ*, and *Cx32*, wherein structural gene alterations can result in demyelinating neuropathy phenotypes, has led to a better understanding of the molecular basis of CMT1, HNPP, and DSS, and has provided important tools to investigate further the biology of the peripheral nerve. Multidisciplinary approaches have enabled us to understand the molecular bases for and pathophysiology of CMT and other myelinopathies, and they highlight the importance of myelin compaction for proper nerve function. These findings provide a clear focus for efforts to elucidate the cascade of events beginning with a mutation in a gene or altered gene dosage leading ultimately to recognizable diseases phenotypes. This knowledge will be instrumental to the design of rational therapies for these diseases.

102 Molecular and Genetic Basis of Prion Diseases

STANLEY B. PRUSINER

INTRODUCTION

Prions cause a group of human and animal neurodegenerative diseases that are now classified together because their etiology and pathogenesis involve modification of the prion protein (PrP). Prion diseases are manifest as infectious, genetic, and sporadic disorders (Table 102-1). These diseases can be transmitted among mammals by the infectious particle designated "prion." Despite intensive searches over the past three decades, no nucleic acid has been found within prions; yet, a modified isoform of the host-encoded PrP designated PrP^{Sc} is essential for infectivity. In fact, considerable experimental data argue that prions are composed exclusively of PrP^{Sc}. Earlier terms used to describe the prion diseases include transmissible encephalopathies, spongiform encephalopathies, and slow virus diseases.

The quartet of human prion diseases are frequently referred to as kuru, Creutzfeldt-Jakob disease (CJD) (OMIM 123400), Gerstmann-Sträussler-Scheinker (GSS) (OMIM 137440) disease, and fatal familial insomnia (FFI) (OMIM 600072). Kuru (OMIM 245300) was the first of these diseases to be transmitted to experimental animals, and it is likely that kuru spread among the Fore people of Papua New Guinea by ritualistic cannibalism. The experimental and presumed human-to-human transmission of kuru led to the belief that prion diseases are infectious disorders caused by unusual viruses similar to those causing scrapie in sheep and goats. Yet, a paradox was presented by the occurrence of CJD in families; it appeared to be a genetic disease. The significance of familial CJD remained unappreciated until mutations in the protein coding region of the *PrP* gene on the short arm of chromosome 20 were discovered. The earlier finding that brain extracts from patients who had died of familial prion diseases inoculated into experimental animals often transmitted disease posed a conundrum that was resolved with the genetic linkage of these diseases to mutations of the *PrP* gene.

CJD is a rare disorder with an annual worldwide incidence of about 1 case per 10^6 people. Less than 1% of CJD cases are infectious, and most of those appear to be iatrogenic. Between 10 and 25% of prion disease cases are inherited, while the remaining cases are sporadic. Patients with CJD frequently present with dementia, but approximately 10% of patients exhibit cerebellar dysfunction

initially. Kuru was once the most common cause of death among New Guinean women in the Fore region of the Highlands but has virtually disappeared with the cessation of ritualistic cannibalism. Patients with either kuru or GSS usually present with ataxia, while those with FFI manifest insomnia and autonomic dysfunction.

Scrapie is the most common natural prion disease of animals. One outbreak of scrapie followed the vaccination of sheep for looping ill virus with formalin-treated extracts of ovine lymphoid tissue unknowingly contaminated with scrapie prions. Two years later, more than 1500 sheep developed scrapie from this vaccine. While the transmissibility of experimental scrapie became well established, the spread of natural scrapie within and among flocks of sheep remained puzzling. Parry argued that host genes were responsible for the development of scrapie in sheep. He was convinced that natural scrapie is a genetic disease which could be eradicated by proper breeding protocols. He considered its transmission by inoculation of importance primarily for laboratory studies and communicable infection of little consequence in nature. Other investigators viewed natural scrapie as an infectious disease and argued that host genetics only modulates susceptibility to an endemic infectious agent.

The offal of scrapied sheep in Great Britain is thought to be responsible for the current epidemic of bovine spongiform encephalopathy (BSE) or mad cow disease. Prions in the offal from scrapie-infected sheep appear to have survived the rendering process that produced meat and bone meal (MBM). The MBM was fed to cattle as a nutritional supplement. After BSE was recognized, MBM produced from domestic animal offal was banned from further use. Since 1986, when BSE was first recognized, more than 150,000 cattle have died of BSE. Whether humans will develop CJD after consuming beef from cattle with BSE prions is of considerable concern.

As our knowledge of the prion diseases increases and more is learned about the molecular and genetic characteristics of prion proteins, these disorders will undoubtedly undergo modification with respect to their classification. Indeed, the discovery of PrP and the identification of pathogenic *PrP* gene mutations have already forced us to view these illnesses from perspectives not previously imagined.

THE PRION CONCEPT

Once an effective protocol was developed for preparation of partially purified fractions of scrapie agent from hamster brain, it

Table 102-1
Human Prion Diseases

Disease	Etiology
Kuru	Infection
Creutzfeldt-Jakob disease	
Iatrogenic	Infection
Sporadic	Unknown
Familial	*PrP* mutation
Gerstmann-Sträussler-Scheinker disease	*PrP* mutation
Fatal Familial Insomnia	*PrP* mutation

became possible to demonstrate that those procedures which modify or hydrolyze proteins produce a diminution in scrapie infectivity. At the same time, tests done in search of a scrapie-specific nucleic acid were unable to demonstrate any dependence of infectivity on a polynucleotide, in agreement with earlier studies reporting the extreme resistance of infectivity to ultraviolet irradiation at 254 nm.

Based on these findings, it seemed likely that the infectious pathogen capable of transmitting scrapie was neither a virus nor a viroid. For this reason the term prion was introduced to distinguish the proteinaceous infectious particles that cause scrapie, CJD, GSS, and kuru from both viroids and viruses. Hypotheses for the structure of the infectious prion particle included: (1) proteins surrounding a nucleic acid encoding them (a virus), (2) proteins associated with a small polynucleotide, and (3) proteins devoid of nucleic acid. Mechanisms postulated for the replication of infectious prion particles ranged from those used by viruses to the synthesis of polypeptides in the absence of nucleic acid template to posttranslational modifications of cellular proteins. Subsequent discoveries have narrowed hypotheses for both prion structure and the mechanism of replication.

Considerable evidence supporting the prion hypothesis has accumulated over the past decade. Furthermore, the replication of prions and their mode of pathogenesis also appear to be without precedent. After a decade of severe criticism and serious doubt, the prion concept is now enjoying considerable acceptance.

DISCOVERY OF THE PRION PROTEIN

Once the dependence of prion infectivity on protein was clear, the search for a scrapie-specific protein intensified. While the insolubility of scrapie infectivity made purification problematic, we took advantage of this property, along with its relative resistance to degradation by proteases, to extend the degree of purification. In subcellular fractions from hamster brain enriched for scrapie infectivity, a protease-resistant polypeptide of 27–30 kDa, later designated PrP 27–30, was identified; it was absent from controls. Radioiodination of partially purified fractions revealed a protein unique to preparations from scrapie-infected brains.

Purification of PrP 27–30 to homogeneity allowed determination of its NH_2-terminal amino acid sequence. These studies were particularly difficult because multiple signals were found in each cycle of the Edman degradation. Whether multiple proteins were present in these "purified fractions," or a single protein with a ragged NH_2 terminus was present, was resolved only after data from five different preparations were compared. When the signals in each cycle were grouped according to their intensities, of strong, intermediate, and weak, it became clear that a single protein with a ragged NH_2 terminus was being sequenced. Determination of a

single, unique sequence for the NH_2 terminus of PrP 27–30 permitted the synthesis of an isocoding mixture of oligonucleotides that was subsequently used to identify incomplete PrP cDNA clones from Syrian hamster (SHa) and mouse (Mo). cDNA clones encoding the entire open reading frames (ORF) of SHa and Mo PrP were subsequently recovered.

PrP is encoded by a chromosomal gene and not by a nucleic acid within the infectious scrapie prion particle. Levels of PrP mRNA remain unchanged throughout the course of scrapie infection—an unexpected observation, which led to the identification of the normal PrP gene product, a protein of 33–35 kDa, designated PrP^C. PrP^C is protease-sensitive and soluble in nondenaturing detergents, while PrP 27–30 is the protease-resistant core of a 33- to 35-kDa disease-specific protein, designated PrP^{Sc}, which is insoluble in detergents. Progress in the study of prions was greatly accelerated by the discovery of PrP and determination of its N-terminal sequence. Indeed, all of the elegant molecular genetic studies in humans and animals as well as many highly informative transgenetic investigations have their origin in the purification of PrP 27–30 and the determination of its N-terminal sequence.

PrP GENE STRUCTURE AND ORGANIZATION   The entire ORF of all known mammalian and avian *PrP* genes is contained within a single exon (Fig. 102-1). This feature of the *PrP* gene eliminates the possibility that PrP^{Sc} arises from alternative RNA splicing; however, mechanisms such as RNA editing or protein splicing remain a possibility. The two exons of the *SHaPrP* gene are separated by a 10-kb intron: exon 1 encodes a portion of the 5' untranslated leader sequence, while exon 2 encodes the ORF and 3' untranslated region. The Mo and sheep *PrP* genes are comprised of three exons with exon 3 analogous to exon 2 of the hamster. The promoters of both the SHa- and *MoPrP* genes contain multiple copies of G-C-rich repeats and are devoid of TATA boxes. These G-C nonamers represent a motif that may function as a canonical binding site for the transcription factor Sp1.

Mapping *PrP* genes to the short arm of human (Hu) chromosome 20 and the homologous region of Mo chromosome 2 argues for the existence of *PrP* genes prior to the speciation of mammals. Hybridization studies demonstrated fewer than 0.002 *PrP* gene sequences per ID_{50} unit in purified prion fractions, indicating that a nucleic acid encoding PrP^{Sc} is not a component of the infectious prion particle. This is a major feature that distinguishes prions from viruses, including those retroviruses that carry cellular oncogenes and from satellite viruses that derive their coat proteins from other viruses previously infecting plant cells.

Although *PrP* mRNA is constitutively expressed in the brains of adult animals, it is highly regulated during development. In the septum, levels of *PrP* mRNA and choline acetyltransferase were found to increase in parallel during development. In other brain regions, *PrP* gene expression occurred at an earlier age. *In situ* hybridization studies show that the highest levels of PrP mRNA are found in neurons.

HUMAN PRION DISEASES

CLINICAL MANIFESTATIONS OF HUMAN PRION DISEASES   The human prion diseases are manifest as infectious, inherited, and sporadic disorders, and are often referred to as kuru, CJD, GSS, and FFI, depending on the clinical and neuropathological findings (*see* Table 102-1).

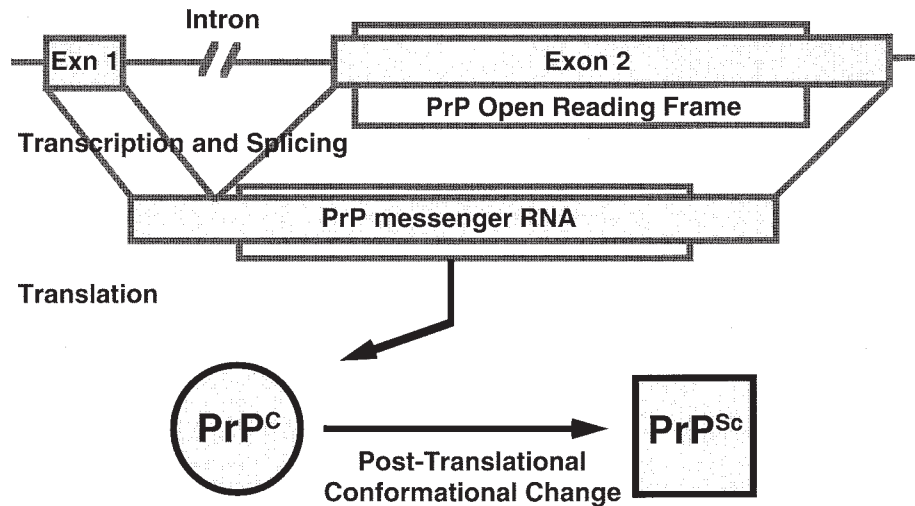
Infectious forms of prion diseases result from the horizontal transmission of infectious prions, as occurs in iatrogenic CJD and


Figure 102-1 Structure and organization of the chromosomal *PrP* gene. In all mammals examined the entire ORF is contained within a single exon. The 5' untranslated region of the *PrP* mRNA is derived from either one or two additional exons. Only one *PrP* mRNA has been detected. PrP^{Sc} is thought to be derived from PrP^C by a posttranslational process. The amino acid sequence of PrP^{Sc} is identical to that predicted from the translated sequence of the DNA encoding the *PrP* gene, and no unique posttranslational chemical modifications have been identified that might distinguish PrP^{Sc} from PrP^C. Thus, it seems likely that PrP^C undergoes a conformational change as it is converted to PrP^{Sc}.

kuru. Inherited forms, notably GSS, familial CJD, and FFI, constitute 10–15% of all cases of prion disease. A mutation in the ORF or protein coding region of the *PrP* gene has been found in all reported kindreds with inherited human prion disease. Sporadic forms of prion disease comprise most cases of CJD and possibly some cases of GSS. How prions arise in patients with sporadic forms is unknown; hypotheses include horizontal transmission from humans or animals, somatic mutation of the *PrP* gene ORF and spontaneous conversion of PrP^C into PrP^{Sc}. Numerous attempts to establish an infectious link between sporadic CJD and a preexisting prion disease in animals or humans have been unrewarding.

DIAGNOSIS OF HUMAN PRION DISEASES Human prion disease should be considered in any patient who develops a progressive subacute or chronic decline in cognitive or motor function. Typically adults between 40 and 70 years of age, patients often exhibit clinical features helpful in providing a premorbid diagnosis of prion disease, particularly sporadic CJD. There is as yet no specific diagnostic test for prion disease in the cerebrospinal fluid. A definitive diagnosis of human prion disease, which is invariably fatal, can often only be made from the examination of brain tissue. Over the past decade, knowledge of the molecular genetics of prion diseases has made it possible to diagnose inherited prion disease in living patients using peripheral tissues.

A broad spectrum of neuropathological features in human prion diseases precludes a precise neuropathological definition. The classic neuropathological features of human prion disease include spongiform degeneration, gliosis, and neuronal loss in the absence of an inflammatory reaction. When present, amyloid plaques that stain with α-PrP antibodies are diagnostic.

The presence of protease-resistant PrP (PrP^{Sc} or PrP^{CJD}) in the infectious and sporadic forms and most of the inherited forms of these diseases implicates prions in their pathogenesis. The absence of PrP^{CJD} in a biopsy specimen may simply reflect regional variations in the concentration of the protein. In some patients with inherited prion disease, PrP^{Sc} is barely detectable or undetectable; this situation seems to be mimicked in transgenic (Tg) mice, which

express a mutant *PrP* gene and spontaneously develop neurologic illness indistinguishable from experimental murine scrapie.

In humans and Tg mice that have no detectable protease-resistant PrP but express mutant PrP, neurodegeneration may, at least in part, be caused by abnormal metabolism of mutant PrP. Because molecular genetic analyses of PrP genes in patients with unusual dementing illnesses are readily performed, the diagnosis of inherited prion disease can often be established where there was little or no neuropathology, atypical neurodegenerative disease, or misdiagnosed neurodegenerative disease, including Alzheimer's disease.

Although horizontal transmission of neurodegeneration to experimental hosts was for a time the "gold standard" of prion disease, it can no longer be used as such. Some investigators have reported that transmission of the inherited prion diseases from humans to experimental animals is frequently negative when using rodents, despite the presence of a pathogenic mutation in the *PrP* gene, while others state that this is not the case with apes and monkeys as hosts. The discovery that Tg(MHu2M) mice are susceptible to Hu prions promises to make feasible transmission studies that were not practical in apes and monkeys.

The hallmark common to all of the prion diseases, whether sporadic, dominantly inherited, or acquired by infection, is that they involve the aberrant metabolism of the prion protein. Making a definitive diagnosis of human prion disease can be rapidly accomplished if PrP^{Sc} can be detected immunologically. Frequently, PrP^{Sc} can be detected by either the dot-blot method or Western immunoblot analysis of brain homogenates, in which samples are subjected to limited proteolysis to remove PrP^C prior to immunostaining. The dot-blot method exploits enhancement of PrP^{Sc} immunoreactivity following denaturation in the chaotropic salt, guanidinium chloride. Because of regional variations in PrP^{Sc} concentration, methods using homogenates prepared from small brain regions can give false-negative results. Alternatively, PrP^{Sc} may be detected *in situ* in cryostat sections bound to nitrocellulose membranes followed by limited proteolysis to remove PrP^C and guanidinium treatment to denature PrP^{Sc}, and thus enhance its

avidity for α-PrP antibodies. Denaturation of PrP^Sc *in situ* prior to immunostaining has also been accomplished by autoclaving fixed tissue sections.

In the familial forms of the prion diseases, molecular genetic analyses of *PrP* can be diagnostic and can be performed on DNA extracted from blood leukocytes antemortem. Unfortunately, such testing is of little value in the diagnosis of the sporadic or infectious forms of prion disease. Although the first missense *PrP* mutation was discovered when the two *PrP* alleles of a patient with GSS were cloned from a genomic library and sequenced, all subsequent novel missense and insertional mutations have been identified in PrP ORFs amplified by the polymerase chain reaction (PCR) and sequenced. The 759 bp encoding the 253 amino acids of PrP reside in a single exon of the *PrP* gene, providing an ideal situation for the use of PCR. Amplified PrP ORFs can be screened for known mutations using one of several methods, the most reliable of which is allele-specific oligonucleotide hybridization. If known mutations are absent, novel mutations may be found when the PrP ORF is sequenced.

When PrP amyloid plaques in brain are present, they are diagnostic for prion disease as noted above. Unfortunately, they are thought to be present in only about 10% of CJD cases, and by definition all cases of GSS. The amyloid plaques in CJD are compact (kuru plaques). Those in GSS are either multicentric (diffuse) or compact. The amyloid plaques in prion diseases contain PrP. The multicentric amyloid plaques, which are pathognomonic for GSS, may be difficult to distinguish from the neuritic plaques of Alzheimer's disease except by immunohistology. In the GSS kindreds the diagnosis of Alzheimer's disease was excluded because the amyloid plaques failed to stain with β-amyloid antiserum but stained with PrP antiserum. In subsequent studies, missense mutations were found in the *PrP* genes of these kindreds.

In summary, the diagnosis of prion disease may be made in patients on the basis of (1) the presence of PrP^Sc, (2) mutant PrP genotype, or (3) appropriate immunohistology, and should not be excluded in patients with atypical neurodegenerative diseases until one or preferably two of these examinations have been performed.

INFECTIOUS PRION DISEASES

KURU   For many decades kuru devastated the lives of the Fore Highlanders of Papua New Guinea. The high incidence of the disease among women left a society of motherless children raised by their fathers (Table 102-2). It was unusual in the Fore region to see an older woman. With the cessation of traditional warfare, older men are now found. Many of these older men have had a succession of wives, each dying of kuru after leaving several children. Because contamination during ritualistic cannibalism appears to have been the mode by which kuru spread among the Fore people, and since cannibalism had ceased by 1960 in the Fore region, the patients now developing kuru presumably were exposed to the kuru agent more than three decades ago. In many cases, histories from patients and their families of the episode in which they cannibalized the remains of a near relative who had died of kuru have been obtained, presumably providing the source of infection. That the kuru prions could remain apparently quiescent in these patients for periods of three decades and then manifest in the form of a fatal neurological disease is supported by incubation periods of over 7.5 years in some monkeys inoculated with kuru agent.

Table 102-2
Infectious Prion Diseases of Humans

Diseases	No. of cases
A. Kuru (1957–1982)	
1. Adult females	1739
2. Adult males	248
3. Children and adolescents	597
Total	2584
B. Iatrogenic Creutzfeldt-Jakob disease	
1. Depth electrodes	2
2. Corneal transplants	1
3. Human pituitary growth hormone	90
4. Human pituitary gonadotropin	5
5. Dura mater grafts	65
6. Neurosurgical procedures	4
Total	167

IATROGENIC CREUTZFELDT-JAKOB DISEASE   Accidental transmission of CJD to humans appears to have occurred by corneal transplantation, contaminated EEG electrode implantation, and surgical operations using contaminated instruments or apparatus (*see* Table 102-2). A cornea unknowingly removed from a donor with CJD was transplanted to an apparently healthy recipient, who developed CJD after a prolonged incubation period. Corneas of animals have significant levels of prions, making this scenario seem quite probable. The same improperly decontaminated EEG electrodes that caused CJD in two young patients with intractable epilepsy were found to cause CJD in a chimpanzee 18 months after their experimental implantation.

Surgical procedures may have resulted in accidental inoculation of patients with prions during their operations, presumably because some instrument or apparatus in the operating theater became contaminated when a CJD patient underwent surgery. Although the epidemiology of these studies is highly suggestive, no proof for such episodes exists.

Since 1988, 65 cases of CJD after implantation of dura mater grafts have been recorded. All of the grafts were thought to have been acquired from a single manufacturer whose preparative procedures were inadequate to inactivate human prions. One case of CJD occurred after repair of an eardrum perforation with a pericardium graft.

Thirty cases of CJD in physicians and health care workers have been reported; however, no occupational link has been established. Whether any of these cases represent infectious prion diseases contracted during care of patients with CJD or processing specimens from these patients remains uncertain.

HUMAN GROWTH HORMONE THERAPY   The possibility of transmission of CJD from contaminated human grown hormone (HGH) preparations derived from human pituitaries has been raised by the occurrence of fatal cerebellar disorders with dementia in more than 90 patients, ranging in age from 10 to 41 years (*see* Table 102-2). While one case of spontaneous CJD in a 20-year-old woman has been reported, CJD in patients under 40 years of age is very rare. These patients received injections of HGH every 2–4 days for 4–12 years. Interestingly, most of the patients presented with cerebellar syndromes which progressed over periods varying from 6 to 18 months. Some patients became demented during the terminal phases of their illnesses. This clinical course resembles kuru more than ataxic CJD in some respects. Assuming

these patients developed CJD from injections of prion-contaminated HGH preparations, the possible incubation periods range from 4 to 30 years. The longest incubation periods are similar to those (20–30 years) associated with recent cases of kuru. Many patients received several common lots of HGH at various times during their prolonged therapies, but no single lot was administered to all the American patients. An aliquot of one lot of HGH has been reported to transmit CNS disease to a squirrel monkey after a prolonged incubation period. How many lots of the HGH might have been contaminated with prions is unknown.

Although CJD is a rare disease with an annual incidence of approximately 1 out of a million people, it is reasonable to assume that CJD is present with a proportional frequency among dead people. About 1% of the population dies each year, and most CJD patients die within one year of developing symptoms. Thus, we estimate that 1 in 10^4 dead people have CJD. Since 10,000 human pituitaries were typically processed in a single HGH preparation, the possibility of hormone preparations contaminated with CJD prions is not remote.

The concentration of CJD prions within infected human pituitaries is unknown; it is interesting that widespread degenerative changes have been observed in both the hypothalamus and the pituitary of sheep with scrapie. The forebrains from scrapie-infected mice have been added to human pituitary suspensions to determine if prions and HGH copurify. Bioassays in mice suggest that prions and HGH do not copurify with currently used protocols. Although these results seem reassuring, especially for patients treated with HGH over much of the last decade, the relatively low titers of the murine scrapie prions used in these studies may not have provided an adequate test. The extremely small size and charge heterogeneity exhibited by scrapie and presumably CJD prions may complicate procedures designed to separate pituitary hormones from these slow infectious pathogens. Even though additional investigations argue for the efficacy of inactivating prions in HGH fractions prepared from human pituitaries using 6 M urea, it seems doubtful that such protocols will be used for purifying HGH, since recombinant HGH is available.

Molecular genetic studies have shown that most patients developing iatrogenic CJD after receiving pituitary-derived HGH are homozygous for either methionine (M) or valine (V) at codon 129 of the PrP gene. Homozygosity at the codon 129 polymorphism has also been shown to predispose individuals to sporadic CJD. Interestingly, valine homozygosity seems to be overrepresented in these HGH cases compared with the general population.

Five cases of CJD have occurred in women receiving human pituitary gonadotropin.

INHERITED PRION DISEASES

FAMILIAL PRION DISEASE The recognition that approximately 10% of CJD cases are familial posed a perplexing problem once it was established that CJD is transmissible. Equally puzzling was the transmission of GSS to nonhuman primates and mice, since most cases of GSS are familial. Like sheep scrapie, the relative contributions of genetic and infectious etiologies in the human prion diseases remained a conundrum until molecular clones of the PrP gene became available to probe the inherited aspects of these disorders.

PrP MUTATIONS AND GENETIC LINKAGE The discovery of the PrP gene and its linkage to scrapie incubation times in mice raised the possibility that mutation might feature in the

hereditary human prion diseases. A proline (P)→leucine (L) mutation at codon 102 was shown to be linked genetically to development of GSS with a logarithm of odds (LOD) score exceeding 3 (Fig. 102-2). This mutation may be due to the deamination of a methylated CpG in a germline PrP gene resulting in the substitution of a thymine (T) for cytosine (C). The P102L mutation has been found in 10 different families in nine different countries, including the original GSS family. Amyloid plaques isolated from patients with GSS (P102L) were found to be composed of PrP molecules with an L at residue 102 based on protein sequencing of purified peptides. Patients with GSS who have a P→L substitution at PrP codon 105 have also been reported.

Some patients with a mutation at codon 117 have a dementing or telencephalic form of GSS, while others have an ataxic form of the disease. In both forms of GSS (A117V), PrP amyloid plaques were found as well as spongiform degeneration. The factor or factors that determine the different phenotypes of this disease are unknown.

Patients with PrP mutations at codons 198 and 217 were once thought to have familial Alzheimer's disease but are now known to have prion diseases, on the basis of PrP immunostaining of amyloid plaques and PrP gene mutations. A genetic linkage study of this family produced a LOD score exceeding 6. Patients with the codon 198 mutation resulting in a phenylalanine (F)→serine (S) substitution have numerous neurofibrillary tangles (NFT) that stain with antibodies to tau (τ) protein and have amyloid plaques that are composed largely of a PrP fragment extending from residues 58 to 150. Since the F198S mutation is not contained within the major PrP peptide of the amyloid plaques, patients heterozygous at codon 129 were chosen to determine whether this peptide is derived from the mutant protein. Like the results of studies with GSS (P102L) and GSS (Y145Stop), protein sequencing showed that the PrP peptides are derived exclusively from the mutant protein. Similar results were found with PrP peptides from a patient of Swedish ancestry with the codon 217 mutation resulting in a glutamine (Q)→arginine (R) substitution. The neuropathology of patients with the codon 217 mutation was similar to that of patients with the codon 198 mutation.

One patient with a prolonged neurologic illness spanning almost two decades who had PrP amyloid plaques and NFTs was found to have an amber mutation of the PrP gene resulting in a stop codon at residue 145. Staining of the plaques with α-PrP peptide antisera suggested that they might be composed exclusively of the truncated PrP molecules. That a PrP peptide ending at residue 145 polymerizes in amyloid filaments is to be expected since an earlier study noted above showed that the major PrP peptide in plaques from patients with the F198S mutation was an 11-kDa PrP peptide beginning at codon 58 and ending at approximately 150. A synthetic PrP peptide containing residues 90–145 was found to adopt an α-helical or β-sheet structure depending on the solvent as determined by 2D-NMR, FTIR spectroscopy, and fiber diffraction.

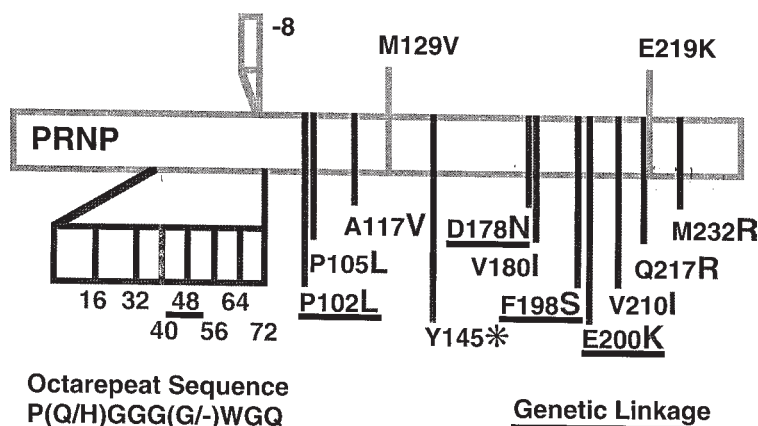
An insert of 144 bp at codon 53 containing six octarepeats has been described in patients with CJD from four families all residing in southern England (*see* Fig. 102-2). This mutation must have arisen through a complex series of events since the human PrP gene contains only five octarepeats, indicating that a single recombination event could not have created the insert. Genealogic investigations have shown that all four families are related, arguing for a single founder born more than two centuries ago. The LOD score


Figure 102-2   Human prion protein gene (PRNP). Large gray rectangle, the open reading frame; above the rectangle, human PRNP wild-type coding polymorphisms; below the rectangle, mutations that segregate with the inherited prion diseases. Single letter code for amino acids is as follows: A, Ala; D, Asp; E, Glu; F, Phe; I, Ile; K, Lys; L, Leu; M, Met; N, Asn; P, Pro; Q, Gln; R, Arg; S, Ser; T, Thr; V, Val; Y, Tyr. The wild-type human *PrP* gene contains five octarepeats [P(Q/H)GGG(G/-)WGQ] from codons 51 to 91. Deletion of a single octarepeat at codon 81 or 82 is not associated with prion disease; whether this deletion alters the phenotypic characteristics of a prion disease is unknown. There are common polymorphisms at codons 117 (A→A) and 129 (M→V); homozygosity for M or V at codon 129 appears to increase susceptibility to sporadic CJD. Octarepeat inserts of 16, 32, 40, 48, 56, 64, and 72 amino acids at codons 67, 75, or 83 are designated by the small rectangle below the ORF. These inserts segregate with familial CJD, and genetic linkage has been demonstrated where sufficient specimens from family members are available. Point mutations are designated by the wild-type amino acid preceding the codon number and the mutant residue follows, e.g., P102L. These point mutations segregate with the inherited prion diseases, and significant genetic linkage (underlined mutations) has been demonstrated where sufficient specimens from family members are available. Mutations at codons 102 (P→L), 117 (A→V), 198 (P→S), and 217 (G→A) are found in patients with GSS. Point mutations at codons 178 (A→A), 200 (G→L), and 210 (V→I) are found in patients with familial CJD. Point mutations at codons 198 (P→S) and 217 (G→A) are found in patients with GSS who have PrP amyloid plaques and neurofibrillary tangles. Additional point mutations at codons 145 (Y→Stop), 105 (P→L), 180 (V→I), 208 (A→H), and 232 (M→A) have been recently reported.

for this extended pedigree exceeds 11. Studies from several laboratories have demonstrated that two, four, five, six, seven, eight, or nine octarepeats in addition to the normal five are found in individuals with inherited CJD, whereas deletion of one octarepeat has been identified without the neurologic disease.

For many years the unusually high incidence of CJD among Israeli Jews of Libyan origin was thought to be due to the consumption of lightly cooked sheep brain or eyeballs. Recent studies have shown that some Libyan and Tunisian Jews in families with CJD have a *PrP* gene point mutation at codon 200 resulting in a glutamate (E)→lysine (K) substitution. One patient was homozygous for the E200K mutation, but her clinical presentation was similar to that of heterozygotes, arguing that familial prion diseases are true autosomal dominant disorders. The E200K mutation has also been found in Slovaks originating from Orava in northern Slovakia, in a cluster of familial cases in Chile, and in a large German family living in the United States. Some investigators have argued that the E200K mutation originated in a Sephardic Jew whose descendants migrated from Spain and Portugal at the time of the Inquisition. It is more likely that the E200K mutation has arisen independently multiple times by the deamidation of a methylated CpG as described above the codon 102 mutation. In support of this hypothesis are historical records of Libyan and Tunisian Jews indicating that they are descended from Jews living on the island of Jerba off the southern coast of Tunisia where Jews first settled around 500 BC and not from Sephardim. Although genetic linkage was established for the P102L mutation, some investigators continued to hold the view that an environmental cofactor was necessary and that mutant *PrP* genes render individuals susceptible to the ubiquitous "scrapie virus." This "virus"

was also provided as an explanation for what was mistakenly interpreted as incomplete penetrance of the codon 200 mutation in familial CJD. From life-table analyses, we now recognize that if carriers with the codon 200 mutation live long enough they eventually develop prion disease (Fig. 102-3).

Many families with CJD have been found to have a point mutation at codon 178 resulting in an aspartate (D)→asparagine (N) substitution. In these patients as well as those with the E200K mutation, PrP amyloid plaques are rare; the neuropathologic changes generally consist of widespread spongiform degeneration. Recently, a new prion disease called fatal familial insomnia, which presents with insomnia, was described in three Italian families with the D178N mutation. The neuropathology in these patients with FFI is restricted to selected nuclei of the thalamus. It is unclear whether all patients with the D178N mutation or only a subset present with sleep disturbances. It has been proposed that the allele with the D178N mutation encodes an M at position 129 in FFI while a V is encoded at position 129 in familial CJD. The discovery that FFI is an inherited prion disease clearly widens the clinical spectrum of these disorders and raises the possibility that other degenerative diseases of unknown etiology may be caused by prions. The D178N mutation has been linked to the development of prion disease with a LOD score exceeding 5. Studies of PrP^{Sc} in FFI and familial CJD caused by the D178N mutation show that after limited proteolysis the M_r of the FFI PrP^{Sc} is about 1 kDa smaller. Whether this difference in protease resistance reflects distinct conformations of PrP^{Sc} that give rise to the different clinical and neuropathologic manifestations of these inherited prion diseases remains to be established.
Figure 102-3 Cumulative probability of developing CJD (1-S$_i$) as a function of age in the *PrP*-E200K carriers. Intervals are the ages of the carriers in decades.

A valine (V)→isoleucine (I) mutation at PrP codon 210 produces CJD with classic symptoms and signs. The V210I mutation is thought to be incompletely penetrant, as the E200K mutation was previously thought to be. It seems likely that, if a sufficiently large number of people with the V210I mutation could be analyzed, complete penetrance that is age-dependent would be found.

Other point mutations at codons 208 and possibly 232 also segregate with inherited prion diseases. The codon 208 mutation results in the substitution of arginine (R) for histidine (H). The patient presented with a progressive dementia and widespread myoclonus was subsequently observed. The diagnosis of CJD was conformed at autopsy. Patients with the codon 232 mutation present with dementia; this mutation is particularly notable since it lies within the C-terminal signal sequence that is removed from *PrP* when the GPI anchor is attached.

PRP GENE POLYMORPHISMS

POLYMORPHISMS AT CODONS 129 AND 219 At PrP codon 129, an amino acid polymorphism for the M→V has been identified (*see* Fig. 102-2). This polymorphism appears able to influence prion disease expression, not only in inherited forms, but also in iatrogenic and sporadic forms of prion disease. A second polymorphism resulting in an amino acid substitution at codon 219 (E→K) has been reported in the Japanese population, in which the K allele occurs with a frequency of 6%.

DOES HOMOZYGOSITY AT CODON 129 PREDISPOSE TO CJD? Studies of Caucasian patients with sporadic CJD have shown that most are homozygous for M or V at codon 129. This contrasts with the general population, in which frequencies for the codon 129 polymorphism in Caucasians are 12% V/V, 37% M/M, and 51% M/V. In contrast, the frequency of the V allele in the Japanese population is much lower and heterozygosity at codon 129 (M/V) is more frequent (18%) in CJD patients than the general population, where the polymorphism frequencies are 0% V/V, 92% M/M, and 8% M/V.

While no specific mutations have been identified in the *PrP* gene of patients with sporadic CJD, homozygosity at codon 129 in sporadic CJD is consistent with the results of Tg mouse studies.

The finding that homozygosity at codon 129 predisposes to CJD supports a model of prion production which favors interactions between PrP molecules that are homologous in the H1 and H2 regions. Structural prediction studies suggest that PrP has four regions of secondary structure denoted H1, H2, H3, and H4. The H1 and H2 regions are thought to undergo a conformational change when PrPC is converted into PrP^{Sc}.

CODON 129 MAY INFLUENCE IATROGENIC CJD Susceptibility to infection may be partially determined by the PrP codon 129 genotype, analogous in principle to the incubation-time alleles in mice. In 16 patients (15 Caucasian, 1 African-American) from the United Kingdom, United States, and France with iatrogenic CJD from contaminated growth hormone extracts, 8 (50%) were V/V, 5 (31%) were M/M, and 3 (19%) were M/V. Thus, a disproportionate number of patients with iatrogenic CJD were homozygous for valine at PrP codon 129, and heterozygosity at codon 129 may provide partial protection. Whether these associations are strongly significant awaits statistical analysis of larger samples. Thousands of children who received pituitary growth hormone extracts are still at risk for the development of CJD. Fortunately, the use of genetically engineered growth hormone will eliminate this form of iatrogenic CJD in the future.

Approximately 15% of patients with sporadic CJD develop ataxia as an early sign, accompanied by dementia. Most, but not all, patients with ataxia have compact "kuru" plaques in the cerebellum. Patients with ataxia and compact plaques exhibit a protracted clinical course, which may last up to 3 years. The molecular basis for the differences between CJD of shorter and longer duration have not yet been fully elucidated; however, some preliminary analyses have suggested that patients with protracted, atypical clinical courses are more likely to be heterozygous at codon 129.

CODON 129 AND INHERITED PRION DISEASES Homozygosity at codon 129 has been reported to be associated with an earlier age of onset in the inherited prion disease caused by the 6 octarepeat insert, but not by the E200K mutation, in Libyan Jews. As noted above, the FFI phenotype is found in patients with the D178N mutation who encode a Met at codon 129 on the mutant allele, while those with dementing illness (familial CJD) encode a V at 129. Homozygosity for either M or V at codon 129 is thought to be associated with an earlier age of onset for the D178N mutation.

BOVINE SPONGIFORM ENCEPHALOPATHY

EPIDEMIC OF MAD COW DISEASE Beginning in 1986, an epidemic of a previously unknown disease appeared in cattle in Great Britain. This disease was initially named bovine spongiform encephalopathy (BSE) but is frequently called "mad cow" disease. BSE was shown to be a prion disease by demonstration of protease resistant PrP in brains of ill cattle. Based mainly on epidemiologic evidence, it has been proposed that BSE represents a massive common source epidemic that has caused more than 150,000 cases to date. In Britain, cattle, particularly dairy cows, were routinely fed meat and bone meal (MBM) as a nutritional supplement. The MBM was prepared by rendering the offal of sheep and cattle using a process that involved steam treatment and hydrocarbon solvent extraction. The extraction process produced protein- and fat-rich fractions; the protein, or greaves, fraction contained about 1% fat, from which the MBM was prepared. In the late 1970s, the price of tallow prepared from the fat fraction fell, making it no longer profitable to use hydrocarbons in the rendering process. The resulting MBM contained about 14% fat, and it is postulated
Figure 102-4 Annual incidence of bovine spongiform encephalopathy in Great Britain. All cases were confirmed clinically and neuropathologically. Statistics compiled by John Wilesmith of the Central Veterinary Laboratory at Weybridge, England.

that the high lipid content protected scrapie prions in the sheep offal from being completely inactivated by steam.

Since 1988 the practice of using dietary protein supplements for domestic animals derived from rendered sheep or cattle offal has been forbidden in the United Kingdom. By 1992 the BSE epidemic seems to have reached a peak, with over 35,000 cattle afflicted (Fig. 102-4). In 1993 less than 32,000 cattle were diagnosed with BSE, and in 1994 the number was approximately 22,000. The recent statistics argue that the epidemic is now under control as a result of the 1988 food ban.

CROSSING A SPECIES BARRIER Assuming the above postulate is correct, then only sheep prions were present initially in the contaminated MBM. Since the species barrier depends, at least in part, on the amino acid sequences of PrP in the donor host and recipient, the similarity between bovine and sheep PrP was probably an important factor in initiating the BSE epidemic. Bovine PrP differs from sheep PrP at seven or eight residues depending on the breed of sheep. As the BSE epidemic expanded, infected bovine offal began to be rendered into MBM which contained bovine prions.

TRANSMISSION OF BSE TO EXPERIMENTAL ANIMALS Brain extracts from BSE cattle have transmitted disease to mice, cattle, sheep, and pigs after intracerebral inoculation. Transmissions to mice and sheep suggest that cattle preferentially propagate a single "strain" of prions. Seven BSE brains all produced similar incubation times as measured in each of three strains of inbred mice.

Of particular importance to the BSE epidemic is the recent transmission of BSE to the nonhuman primate marmoset after intracerebral inoculation followed by a prolonged incubation period. The potential parallels with kuru of humans, confined to the Fore region of New Guinea, are worthy of consideration. While it seems likely that kuru was transmitted orally, as proposed for BSE among cattle, some investigators argue that other than oral routes were important since oral transmission of kuru prions to apes and monkeys has been difficult to demonstrate.

There is no example of zoonotic transmission of prions from animals to humans based on many epidemiological studies that have attempted to implicate scrapie prions from sheep as a cause of CJD. Whether BSE poses any risk to humans is unknown, but four farmers with BSE-afflicted cattle have died of CJD during the past 2 years.

PRION PROPAGATION

The concept of the species barrier for prion transmission was introduced three decades ago based on transmission studies of experimental scrapie in sheep, goats, and rodents. The initial molecular studies of the prion species barrier were performed using Tg(*SHaPrP*) mice. The *SHaPrP* transgene rendered mice susceptible to SHa prions, implying that the species barrier between Syrian hamsters and mice is due to one or more of the 16 amino acid substitutions that distinguish *SHa* from *MoPrP*. Like SHa prions, Hu prions inoculated into non-Tg mice produced disease infrequently after a prolonged incubation period. Based on our experience with Tg(*SHaPrP*) mice, we produced Tg(*HuPrP*) mice, but surprisingly they remained refractory to Hu prions. When the Tg(*HuPrP*) were crossed with Prnp$^{0/0}$ mice in which the MoPrP was disrupted, the resulting Tg(*HuPrP*)Prnp$^{0/0}$ mice became susceptible to infection with Hu prions (Table 102-3). This indicates that MoPrP^C inhibited the conversion of HuPrP^C into HuPrP^{Sc}. These findings and others described here make it likely that, besides PrP^C and PrP^{Sc}, a third component participates in the formation of nascent PrP^{Sc}. We presume that this third component is a macromolecule and that it is a protein; though it remains as yet unidentified, we have provisionally designated this third component "protein X."

The site at which PrP^C binds to protein X must be within the Mo-encoded residues of chimeric PrP^C, since Tg(*MHu2M*) mice were found to be susceptible to Hu prions irrespective of the presence of endogenous MoPrP^C (Table 102-4). We interpret these results to mean that the Mo sequences in chimeric PrP^C enable it to compete effectively with MoPrP^C for binding to protein X.

We envision that, during the propagation of prions, a complex of homotypic PrP^{Sc} and PrP^C binds to protein X. This pairwise interaction of PrP^{Sc} with PrP^C and the stoichiometry of the conversion reaction make it doubtful that PrP^{Sc} itself is protein X. Although the function of protein X in the formation of PrP^{Sc} is unknown, it seems likely that protein X acts in some manner to facilitate the formation of nascent PrP^{Sc}.

PrP^{Sc} FORMATION The formation of nascent PrP^{Sc} is a posttranslational process that seems to occur after PrP^C reaches the cell surface. Transgenetic studies argue that PrP^C and PrP^{Sc} form a complex during the conversion of PrP^C into nascent PrP^{Sc}. Although SHa transgenes provided considerable information about some of the features of PrP^{Sc} formation, use of the more divergent *HuPrP* transgene has greatly extended our understanding. Tg(*MHu2M*)Prnp$^{0/0}$ mice that express only chimeric PrP^C were resistant to Mo prions; whereas Tg(*MHu2M*)FVB mice expressing both chimeric and MoPrP^C were susceptible to Mo prions but the incubation time was prolonged. In contrast, Tg(*MHu2M*)Prnp$^{0/0}$ mice inoculated with either Hu or chimeric MHu2M prions exhibited similar incubation times (*see* Table 102-4).

To assess the specificity of PrP^C binding to PrP^{Sc} in the central domain delimited by codons 96 to 167, we studied the influence of pathologic mutations and a polymorphism. Tg(*MHu2M*) mice were resistant to Hu prions from a patient with GSS who carried the P102L mutation but were susceptible to prions from patients with familial CJD who harbor the E200K mutation (*see* Table 102-4C). Engineering the P102L mutation into the chimeric transgene rendered the Tg(*MHu2M*-P101L) mice susceptible to the GSS prions from the brain of a patient who died of GSS and carried the P102L mutation (Fig. 102-5). Studies of Tg(*HuPrP*)Prnp$^{0/0}$ mice expressing M or V at the polymorphic codon 129 demonstrated the

Figure 102-5 Spontaneous and transmissible neurodegeneration in Tg(*MHu2M*-P102L)69/Prnp$^{0/0}$ mice. Uninoculated Tg(*MHu2M*-P102L)69/Prnp$^{0/0}$ mice were observed for the spontaneous development of neurologic disease (squares). At ~70 days of age, Tg(*MHu2M*-P102L)69/Prnp$^{0/0}$ mice were inoculated intracerebrally with brain homogenate prepared from either a patient with GSS who carried the P102L mutation (diamonds) or another patient who died of sporadic CJD (triangles).

influence of this residue within the central domain on prion propagation (Fig. 102-6). When the 129 residue within the central domain was the same in PrP^{Sc} of the inoculum and PrP^C of the recipient mouse, incubation times were substantially shortened. These findings demonstrate that single amino acid mismatches at codon 102 or 129 prolong the incubation time; whereas, a mismatch at codon 200 does not. Although the results reported here argue that prion propagation is facilitated by homology within the central domains of HuPrP^C and HuPrP^{Sc}, other investigations with *SHa/MoPrP* transgenes demonstrate that the requirements for sequence similarity may vary with different species and strains of prions.

Since MoPrP^C can inhibit the formation of HuPrP^{Sc} in the presence of a substantial excess of HuPrP^C, this contends that Mo protein X has a higher affinity for MoPrP^C than it does for HuPrP^C (*see* Table 102-3B,C). MoPrP^C prevented HuPrP^{Sc} formation whether the inoculum contained amorphous aggregates of PrP^{Sc} or ordered arrays of prion rods composed of PrP 27–30 molecules

Figure 102-6 Amino acid mismatches at the codon 129 polymorphism prolong the incubation times of Tg(*HuPrP*)/Prnp$^{0/0}$ mice. Tg(*HuPrP*-M129)440/Prnp$^{0/0}$ mice were inoculated intracerebrally with a case of iatrogenic CJD (364A, triangles). Tg(*HuPrP*-V129)152/Prnp$^{0/0}$ mice were inoculated with iatrogenic CJD (364A, diamonds) and sporadic CJD (EC, squares; RG, circles). All the CJD cases were from individuals homozygous for M/M at codon 129.

(*see* Table 102-3A). If MoPrP^C had been more inhibitory when the prion rods were inoculated, then we would suppose that a single MoPrP^C molecule could bind to multiple HuPrP^{Sc} molecules and prevent the formation of nascent HuPrP^{Sc}, but this is not the case.

We assume that the stoichiometry of PrP^C and PrP^{Sc} that form a complex is approximately 1:1. Whether this complex is composed of two or more PrP molecules is uncertain. Although some investigators have argued that the formation of nascent PrP^{Sc} involves the formation of PrP amyloid fibrils, there is much evidence to the contrary. Purified preparations of PrP^{Sc} from brain possess an amorphous ultrastructure and do not form amyloid polymers except when PrP^{Sc} undergoes partial proteolysis to produce PrP 27–30 in the presence of a nondenaturing detergent. Isolated PrP amyloid plaques contain primarily fragments of PrP, and several synthetic PrP peptides spontaneously polymerize into amyloids when dispersed in water. In vitro conversion of PrP^C into a protease resistant form that is presumed to be equivalent to PrP^{Sc} by mixing a greater than 50-fold excess of PrP^{Sc} with labeled PrP^C has been reported. Interestingly, the binding of PrP^C to PrP^{Sc} was found to be dependent on the same residues that render Tg(*MH2M*) mice susceptible to SHa prions, and it seems to be strain dependent. Whether PrP^C actually undergoes a conformational change that is characteristic of PrP^{Sc} or the binding of PrP^C to PrP^{Sc} renders it protease resistant without actually undergoing this conformational transition remains to be established.

EVIDENCE FOR PROTEIN X BINDING TO THE C-TERMINUS OF PrP^C Since truncation experiments show that the N-terminal 67 residues of mature PrP are dispensable, it seems likely that the site at which PrP^C binds to protein X is at the C-terminal end of PrP^C. A comparison of predicted amino acid sequences shows sufficient variation from codon 167 to 231 between Hu and Mo as well as similarity between SHa and Mo to account for our results. The location of residue 215 is particularly interesting; in HuPrP, it is an I, while in MoPrP it is a V and in SHaPrP a T.

In contrast to SHaPrP, HuPrP differs from MoPrP at four additional amino acids that lie C-terminal to residue 215. Any or all of these substitutions besides residue 215 could explain the difference in susceptibility between Tg(*HuPrP*)FVB and Tg(*SHaPrP*)FVB mice to Hu and SHa prions, respectively. Two of the four additional residues that distinguish HuPrP from MoPrP lie at positions 219 and 220. While these residues might participate in the binding of PrP^C to protein X, it seems unlikely that residues at 228 or 230 are involved in the binding to protein X since they are adjacent to the GPI anchor which is attached to an S residue at 231. The proposed model is consistent with our findings that chimeric MHu2MPrP^C but not HuPrP^C is converted into PrP^{Sc} in the presence of MoPrP^C, and HuPrP^C is converted into PrP^{Sc} in the absence of MoPrP^C (*see* Table 102-3).

DOES PROTEIN X FUNCTION AS A MOLECULAR CHAPERONE? How PrP^C unfolds and refolds into PrP^{Sc} is unknown, but the profound change in protein structure that occurs during this process is likely to be associated with a large activation barrier. Whether protein X functions as a molecular chaperon that lowers this barrier remains to be established; consistent with such a role for protein X is the apparent lack of PrP^{Sc} binding. Changes in the inducibility of heat shock proteins (Hsp) as well as their subcellular distribution, some of which function as molecular chaperones, have been found in scrapie-infected cells and raise the possibility that protein X might be an Hsp. Alternative possibilities for protein X include scaffolding or assembly proteins that provide a milieu for the PrP isoforms to interact as well as the *bcl-2* protein, which was found with the yeast two-hybrid system to bind PrP. Another possibility is that protein X features in the transient or as yet undetected chemical modification of PrP^C that facilitates its refolding into PrP^{Sc}.

MODELING OF GSS IN TRANSGENIC MICE

The codon 102 point mutation found in GSS patients was introduced into the *MoPrP* gene and Tg(*MoPrP*-P101L)H mice were created expressing high (H) levels of the mutant transgene product. The two lines of Tg(*MoPrP*-P101L)H mice designated 174 and 87 spontaneously developed CNS degeneration, characterized by clinical signs indistinguishable from experimental murine scrapie and neuropathology consisting of widespread spongiform morphology and astrocytic gliosis and PrP amyloid plaques (Fig. 102-7). By inference, these results contend that *PrP* gene mutations cause GSS, familial CJD, and FFI.

Brain extracts prepared from spontaneously ill Tg(*MoPrP*-P101L)H mice transmitted CNS degeneration to Tg196 mice and some Syrian hamsters. The Tg196 mice express low levels of the mutant transgene product and do not develop spontaneous disease. Many Tg196 mice and some Syrian hamsters developed CNS degeneration between 200 and 700 days after inoculation, while inoculated CD-1 Swiss mice remained well. Serial transmission of CNS degeneration in Tg196 mice required about 1 year, while serial transmission in Syrian hamsters occurred after about 75 days. Crossing the Tg196 mice with Prnp$^{0/0}$ mice produced recipient Tg196/Prnp$^{0/0}$ mice that developed CNS degeneration in more than 95% of the inoculated animals in approximately 190 days. Serial transmission of CNS degeneration in Tg196/Prnp$^{0/0}$ mice required about 220 days, while serial transmission in Syrian hamsters occurred after approximately 75 days. These findings and those from other studies suggest that mutant and wtPrP interact, perhaps through protein X, to modify the pathogenesis of the dominantly inherited prion diseases.
Figure 102-7 Neuropathology of Tg(*MoPrP*-P101L) mice developing neurodegeneration spontaneously. The mice harbor transgenes carrying the PrP point mutation found in GSS(P102L) of humans. **(A)** Vacuolation in cerebral cortex of a Swiss CD-1 mouse that exhibited signs of neurologic dysfunction at 138 days after intracerebral inoculation with ~10^6 ID_{50} units of RML scrapie prions. **(B)** Vacuolation in cerebral cortex of a Tg(*MoPrP*-P101L) mouse that exhibited signs of neurologic dysfunction at 252 days of age. **(C)** Kuru-type PrP amyloid plaque stained with periodic acid Schiff in the caudate nucleus of a Tg(*MoPrP*-P101L) mouse that exhibited signs of neurologic dysfunction. **(D)** PrP amyloid plaques stained with α-PrP antiserum (RO73) in the caudate nucleus of a Tg(*MoPrP*-P101L) mouse that exhibited signs of neurologic dysfunction. Bars: in B (also applies to A) = 50 μm; in D (also applies to C) = 25 μm.

THERAPEUTIC APPROACHES TO PRION DISEASES

There is no known effective therapy for treating or preventing CJD. There are no well-documented cases of patients with CJD showing recovery either spontaneously or after therapy, with one possible exception. Since people at risk for inherited prion diseases can now be identified decades before neurologic dysfunction is evident, the development of an effective therapy is imperative.

PRENATAL SCREENING FOR PrP MUTATIONS The inherited prion diseases can be prevented by genetic counseling coupled with prenatal DNA screening, but such testing presents ethical problems. For example, during the childbearing years, the parents are generally symptom-free and may not want to know their own genotype.

GENE THERAPY AND ANTISENSE OLIGONUCLEOTIDES Unexpectedly, ablation of the *PrP* gene in Tg(Prnp$^{0/0}$) mice has not affected the development of these animals, and they remain healthy at almost two years of age. Since Prnp$^{0/0}$ mice are resistant to prions and do not propagate scrapie infectivity, gene therapy or antisense oligonucleotides might ultimately provide an effective therapeutic approach. Mice heterozygous (Prnp$^{0/+}$) for ablation of the *PrP* gene had prolonged incubation times when inoculated with mouse prions. This finding is in accord with studies on Tg(*SHaPrP*) mice in which increased SHaPrP expression was accompanied by diminished incubation times.

INHIBITORS OF β-SHEET FORMATION Because the absence of PrP^C expression does not provoke disease, it seems reasonable to conclude that scrapie and other prion diseases are a consequence of PrP^{Sc} accumulation rather than an inhibition of PrP^C function. The function of PrP^C remains unknown to date. These findings suggest that perhaps the most effective therapy

may evolve from the development of drugs that block the conversion of PrP^C into PrP^{Sc}. Since the fundamental event in both the formation of PrP^{Sc} and the propagation of prions seems to be the unfolding of α helices and their refolding into β sheets, drugs targeting this structural transformation would seem likely to be efficacious.

Whether dyes like Congo red that bind to PrP amyloid will be effective in vivo in preventing the formation of PrP^{Sc} remains to be established. Congo red has been reported to inhibit the formation of PrP^{Sc} in cultured scrapie-infected mouse neuroblastoma cells, but the mechanism by which this occurs is unknown.

Dextran sulfates have been used to delay the onset of scrapie in laboratory animals; however, these compounds are only effective when given before or concurrently with the prion inoculum. The inhibitory effect of dextrans on prion propagation has been most pronounced in animals inoculated intraperitoneally. The mechanism by which the sulphated sugar polymers inhibit PrP^{Sc} formation in cultured cells and animals is unknown.

Injection of corticosteroids into mice at the time of intraperitoneal inoculation of prions resulted in the prolongation of the incubation time. These results suggested that the immune system played a role in the initial phase of scrapie infection as did studies with spleenless mice. Studies with nude mice and more recently SCID mice showed that incubation times were unaltered compared with controls after intracerebral inoculation; in contrast, SCID mice were not susceptible to prions inoculated intraperitoneally. Studies of lymphoid tissues after intraperitoneal inoculation of prions showed that the follicular dendritic cells that are thought to function in the presentation of antigens selectively accumulated PrP^{Sc}. In SCID mice no focal accumulations of PrP^{Sc} in lymphoid tissues have been found.

Chronic treatment with the antifungal drug amphotericin started at the time of intracerebral inoculation prolonged incubation peri-

ods in mice and hamsters. Administration of amphotericin to humans with CJD had no therapeutic effect; likewise, the antiviral drug amantidine was also ineffective. HPA-23 is an inhibitor of viral glycoprotein synthesis. When given to scrapie-infected animals around the time of inoculation, but not later, it profoundly extends the length of the incubation period. The effects in human CJD are uncertain. Interferon was used in experimental scrapie of rodents, but the incubation times were unaltered.

Although antibodies have been raised against the scrapie prion protein and these crossreact with prion proteins in CJD human brains, passive immunization or even vaccination would seem to be of little value. CJD and scrapie both progress in the absence of any immune response to the offending prions; however, neutralization of scrapie prion infectivity was accomplished when the infectious particles were dispersed into detergent–lipid–protein complexes.

RESISTANT BREEDS OF SHEEP   With the discovery that QQ homozygosity at codon 171 appears to render Suffolk sheep susceptible to scrapie while QR and RR sheep are resistant, the notion of breeding scrapie-resistant sheep as Parry proposed seems quite reasonable. The screening procedures for identifying QQ sheep are simple and could be applied in an agricultural setting with ease.

CONCLUDING REMARKS

PRIONS ARE NOT VIRUSES   The study of prions has taken several unexpected directions over the past few years. The discovery that prion diseases in humans are uniquely both genetic and infectious has greatly strengthened and extended the prion concept. To date, 19 different mutations in the human *PrP* gene all resulting in nonconservative substitutions have been found either to be linked genetically to or to segregate with the inherited prion diseases (*see* Fig. 102-2). Yet, the transmissible prion particle is composed largely, if not entirely, of an abnormal isoform of the prion protein designated PrP^{Sc}. These findings argue that prion diseases should be considered pseudoinfections, since the particles transmitting disease appear to be devoid of a foreign nucleic acid and thus differ from all known microorganisms as well as viruses and viroids. Because much information, especially about scrapie of rodents, has been derived using experimental protocols adapted from virology, we continue to use terms such as infection, incubation period, transmissibility, and end-point titration in studies of prion diseases.

PRION BIOLOGY   If, as recently suggested, several yeast proteins induce alternative metabolic states through a prion-like mechanism, then perhaps PrP^{C} also exists in more than one physiologic state. The transformation of PrP^{C} to an alternative metabolic isoform might be facilitated by protein X. Interestingly, one prion-like protein in yeast (Sup 35) seems to require intermediate levels of the molecular chaperone (Hsp 104) to undergo transformation to [PSI^{+}]. In the filamentous fungus *Podospora anserina*, the *het-s* locus controls the vegetative incompatibility; conversion from the S^{s} to the s state seems to be a posttranslational, autocatalytic process.

Might protein X function as a chaperone that mediates a conformational change in PrP^{C} that alters its cellular function in the absence of PrP^{Sc} or a pathologic *PrP* gene mutation? In the presence of PrP^{Sc}, protein X might catalyze the conversion of PrP^{C} into PrP^{Sc}. Whatever the mechanism of PrP^{Sc} formation, this process seems to be unprecedented in biology, and its elucidation promises to have implications far beyond the prion diseases.

103 Genetic Basis of Mitochondrial Disease

Donald R. Johns

INTRODUCTION

Structural, biochemical, or genetic derangement of mitochondria is the common feature of the mitochondrial encephalomyopathies. This diverse group of disorders has a wide spectrum of clinical manifestations (Tables 103-1 and 103-2) that affect the eye, central nervous system, peripheral nervous system, and the somatic organs. The differential dependence of nearly all organ systems on oxidative metabolism is reflected in the variable, protean clinical manifestations of mitochondrial disorders. There is also a wide array of ages and modes of onset, course, and progression, ranging from severe infantile diseases to chronic neurodegenerative diseases of the elderly.

Establishment of the molecular genetic basis of many of the mitochondrial diseases has occurred at a rapid pace since the first human mitochondrial DNA (mtDNA) mutations were discovered in 1988. A number of different types of pathogenetic mtDNA mutations have been associated with a variety of clinical phenotypes, and the roster of mtDNA mutations and phenotypes continues to grow. The potential role of mtDNA mutations is also being investigated in the pathogenesis of more prevalent diseases, in addition to the traditional mitochondrial diseases.

Our emphasis will be on the molecular genetic basis and clinical features of mitochondrial encephalomyopathies with known pathogenetic mtDNA mutations.

STRUCTURE AND FUNCTION OF MITOCHONDRIA AND MITOCHONDRIAL DNA

Mitochondria contain a complex array of biochemical pathways that are involved in intermediary metabolism. The inner mitochondrial membrane encompasses the matrix space, which is the site of the tricarboxylic acid cycle and fatty acid oxidation. The five polypeptide complexes of the respiratory chain and ATP synthase are assembled in the inner mitochondrial membrane. The oxidation of a variety of substrates produces reducing equivalents that are sequentially transferred via the electron transport chain to reduce molecular oxygen to water. An electrochemical gradient is produced by the coupled translocation of protons and the redox potential is used by ATP synthase to produce ATP. The mitochondrial production of ATP for energy requiring cellular processes by this process is known as oxidative phosphorylation.

Mitochondria are the only animal cellular organelles that contain their own extrachromosomal DNA, distinct from the overwhelming majority of cellular DNA found in the nucleus. Human mtDNA is a small (16,569-nucleotide) double-stranded, circular molecule that encodes 13 protein subunits of four different biochemical complexes of oxidative phosphorylation. MtDNA also encodes the 24 structural RNAs (2 ribosomal RNAs and 22 transfer RNAs) required for the intramitochondrial translation of these subunits. The mtDNA-encoded tRNAs are also involved in the cleavage of the polycistronic transcript into individual messenger RNAs and tRNAs, and the tRNA$^{Leu(UUR)}$ has a unique role in transcription termination. The noncoding D (displacement)-loop is the site of regulatory regions that control transcription and replication. MtDNA mutations are found in each type of mitochondrially encoded gene (Fig. 103-1).

Mitochondria probably evolved from independent organisms that became endosymbiotically incorporated into the cell. Consequently, they replicate, transcribe, and translate their DNA independently of nuclear DNA. However, cellular and mitochondrial function are interdependent. The nuclear DNA-encoded proteins that are subunits of oxidative phosphorylation and all of the other myriad macromolecular compounds required for mitochondrial structure and function (e.g., mitochondrial DNA replication, transcription, and translation) must be imported from the cytoplasm into the correct position within the mitochondria.

Several unique features of mtDNA help explain its role in the pathogenesis of disease. mtDNA has no introns (so that a random mutation will usually strike a coding DNA sequence), has no protective histones, has no effective DNA repair system, is exposed to oxygen free radicals generated by oxidative phosphorylation, and mutates more than 10 times more rapidly than nuclear DNA. mtDNA is strictly maternally inherited and does not recombine; thus, mitochondrial DNA mutations sequentially accumulate along maternal lineages. This property has made mtDNA sequence variation an invaluable tool for evolutionary biologists and forensic scientists, and has provided important normative data to help determine the pathogenetic significance of newly discovered mutations.

A number of other mtDNA characteristics are central to understanding mitochondrial disease. Each mitochondrion contains 2–10 mtDNA molecules, and each cell contains multiple mitochondria (polyplasmy). Thus, normal and mutant mtDNA can coexist within the same cell, a condition known as heteroplasmy, which allows an otherwise lethal mutation to persist. The presence of either completely normal or completely mutant mitochondrial DNA is known as homoplasmy. During cell division, mitochondria are unevenly

Table 103-1
Neurological Manifestations of Mitochondrial Diseases

Ophthalmoplegia	Sensorineural hearing loss
Stroke-like episodes	Ataxia
Seizures	Dementia
Myoclonus	Peripheral neuropathy
Optic neuropathy	Vascular headache
Myopathy	Myelopathy

Table 103-2
Systemic Manifestations of Mitochondrial Diseases

Cardiac conduction defects	Fanconi proximal nephron dysfunction
Cardiomyopathy	Glomerulopathy
Diabetes mellitus	Hepatopathy
Short stature	Intestinal pseudo-obstruction
Pigmentary retinopathy	Pancytopenia
Lactic acidosis	Psychiatric disease (depression)

Figure 103-1   Schematic diagram of human mitochondrial DNA and the most prominent pathogenetic mutations. Inside the circle, point mutations in structural and protein-coding genes, with the clinical phenotype and the nucleotide position of the mutation; arcs outside the circle, the position of the most common single deletion, which is 5 kilobases in length, and the multiple deletions; *MERRF*, myoclonic epilepsy with ragged red fibers; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes syndrome; LHON, Leber's hereditary optic neuropathy; *NARP*, neuropathy, ataxia, and retinitis pigmentosa; Leigh, maternally inherited Leigh's disease. (Reproduced with permission from NEJM 1995;333:638–644.)

partitioned into the daughter cells through the process of replicative segregation, and the proportion of mutant and normal mtDNA molecules can thereby shift. Thus, population genetics, as opposed to mendelian genetics, govern mtDNA. Selection pressures apply at the molecular, cellular, and organismal levels. The critical proportion of mutant mtDNA required for deleterious phenotypic expression is known as the threshold effect, and varies among individuals, among organ systems, and within a given tissue depending on the delicate balance of oxidative supply and demand.

The dual genetic input into the complexes of oxidative phosphorylation by both the nuclear and mitochondrial genomes, as well as complex intergenomic communication and the reactions required for import of proteins into the mitochondria, provides a wide variety of sites at which mitochondrial function can be altered.

The classic mitochondrial phenotypes described below are caused by both gross structural rearrangements (single deletions, multiple deletions, duplications) and by mtDNA point mutations. Mutations that are likely to cause a severe, lethal impairment of oxidative phosphorylation (gross structural defects, point mutations in critical regions) are only viable if they are heteroplasmic. In contrast, the majority of the milder, missense mtDNA mutations in protein-coding genes are homoplasmic. Pathogenetic mtDNA point mutations have been found in each type of mtDNA gene, but tRNA mutations predominate in mitochondrial encepha-

lomyopathy phenotypes and protein-coding gene mutations predominate in Leber's hereditary optic neuropathy (LHON). A point mutation in the 12S ribosomal RNA gene is associated with both spontaneous and antibiotic-associated sensorineural deafness (OMIM 561000) (*see* Fig. 103-1).

CLASSIC MITOCHONDRIAL ENCEPHALOMYOPATHY PHENOTYPES

Many diseases were provisionally classified as mitochondrial disorders on the basis of abnormal mitochondrial morphology, biochemistry, or a pattern of maternal inheritance. The first direct proof that mtDNA was involved in disease pathogenesis was the finding of large deletions in the mtDNA of patients with mitochondrial myopathies and the description of a missense mutation in the mtDNA of patients with LHON. Over the next several years, the molecular genetic basis of the classic mitochondrial encephalomyopathies was elucidated. Although these disorders are relatively uncommon, they were the first molecularly defined examples of many cardinal neurological diseases, including stroke: mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome; seizures: MELAS and myoclonic epilepsy with ragged red fibers (MERRF) syndrome; and optic neuropathy: LHON.

CHRONIC PROGRESSIVE EXTERNAL OPHTHALMOPLEGIA   This disease (OMIM 258450) is characterized by ptosis, ophthalmoplegia, and limb myopathy. Additional clinical features (*see* Tables 103-1 and 103-2) may also occur, as may the laboratory abnormalities characteristic of mitochondrial disorders (Table 103-3). Patients with chronic progressive external ophthalmoplegia (CPEO) have abnormal skeletal muscle biopsies, with abnormal proliferating mitochondria that cause "ragged red fibers," a histological hallmark of the severe biochemical defects in oxidative phosphorylation found in many mitochondrial encephalomyopathies. The occurrence of a number of somatic and central nervous system findings with CPEO are known as the CPEO-plus syndromes. Kearns-Sayre syndrome (OMIM 530000) is a subset of CPEO-plus that begins before age 20 and is characterized by CPEO and atypical pigmentary retinopathy, with the ancillary features of elevated cerebrospinal fluid protein, ataxia, or heart block.

Most patients with CPEO have large, single deletions in mtDNA, and the presence of a pigmentary retinopathy is a strong predictor of a deletion. Almost all single mtDNA deletions occur sporadically and the mechanism of deletion formation is unknown, but recombination or slippage during replication are plausible. The junction of most deletions contains directly repeated sequences, including a 13/13 nucleotide direct repeat "hot spot" that accounts for about 25% of all deletions. Approximately half of all deletions are bounded by other direct repeats, and one-quarter have no apparent direct repeat. A few patients have partially duplicated mtDNA molecules. Many patients who lack an mtDNA deletion or duplication have a point mutation at nucleotide position 3243.

AUTOSOMALLY TRANSMITTED MULTIPLE MITOCHONDRIAL DNA DELETIONS   The autosomal inheritance of multiple mtDNA deletions implies a primary defect in a nuclear DNA gene that has secondary qualitative effects on mtDNA and thus typifies a defect in intergenomic communication. Multiple mtDNA deletions have diverse manifestations, but most are variants of CPEO with specific additional features. This syndrome

Table 103-3
Possible Laboratory Findings in Mitochondrial Diseases

"Ragged red fibers" on skeletal muscle biopsy
Elevated serum and cerebrospinal fluid lactate concentration
Myopathic potentials on electromyography
Axonal and demyelinating peripheral neuropathy on nerve conduction studies
Sensorineural hearing loss on audiogram
Cardiac conduction defects
Basal ganglia calcification or focal signal abnormalities on magnetic resonance imaging studies
Altered phosphorus magnetic resonance spectroscopy
Defects in oxidative phosphorylation on biochemical studies
Molecular genetic demonstration of mtDNA mutation

(OMIM 550000) is characterized by multiple deletions that differ from single deletions in their inheritance pattern, their location within the mitochondrial genome, and their molecular structure. Multiple mtDNA deletions can be transmitted in both autosomal dominant and autosomal recessive patterns. The identity of the nuclear encoded gene(s) that influences the regulation and function of normal mtDNA in a *trans*-acting manner is not known but has been linked in Finnish families to chromosome 10q23.3–24.3. Tissue-specific autosomally transmitted depletion of mtDNA, which represents a quantitative mtDNA defect caused by an intergenomic communication error, has also been described. mtDNA deletions can be detected reliably by molecular genetic methods, but require skeletal muscle as the source of DNA.

MITOCHONDRIAL ENCEPHALOMYOPATHY, LACTIC ACIDOSIS, AND STROKE-LIKE EPISODES   The mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) syndrome (OMIM 540000) is characterized by seizures and stroke-like events that cause subacute brain dysfunction, cerebral structural changes, and several other common clinical and laboratory features (*see* Tables 103-1 through 103-3). The maternal inheritance of the MELAS syndrome may be obscured because of mild or oligosymptomatic clinical features in relatives. In 80% of cases, a point mutation at nucleotide 3243 in the transfer RNA[Leu(UUR)] gene is the cause. Other mutations in this gene, which appears to be a common site of pathogenetic mutations, have also been found in MELAS probands. The 3243 mtDNA mutation appears to be the most pleiomorphic pathogenetic mutation and is also associated with nondeletion CPEO, myopathy, deafness, diabetes, and dystonia.

MYOCLONIC EPILEPSY WITH RAGGED RED FIBERS SYNDROME   The myoclonic epilepsy with ragged red fibers (MERRF) syndrome (OMIM 545000) consists of myoclonus, seizures, cerebellar ataxia, and mitochondrial myopathy. Pathogenetic mutations have been demonstrated at nucleotide positions 8344 and 8356 in the tRNA[Lysine] gene. Neurological (*see* Table 103-1) and laboratory (*see* Table 103-3) features common to other mitochondrial encephalomyopathies are seen. Maternal relatives may be asymptomatic or may have partial clinical syndromes, including lipomas in a characteristic "horse-collar" distribution and hypertension.

NEUROPATHY, ATAXIA, AND RETINITIS PIGMENTOSA/ MATERNALLY INHERITED LEIGH'S DISEASE   The syndrome of neuropathy, ataxia, and retinitis pigmentosa (NARP) (OMIM 551500) is characterized by proximal weakness, sensory neuropathy, developmental delay, ataxia, seizures, dementia, and retinal

Table 103-4
Pathogenetic mtDNA Point Mutations

Nucleotide position	mtDNA gene	Clinical phenotype	Nucleotide change	Amino acid substitution
1555	12S rRNA	Deafness	A to G	NA
3243	tRNA$^{Leu(UUR)}$	MELAS Diabetes	A to G	NA
3260	tRNA$^{Leu(UUR)}$	Cardiomyopathy	A to G	NA
3271	tRNA$^{Leu(UUR)}$	MELAS	T to C	NA
3303	tRNA$^{Leu(UUR)}$	Cardiomyopathy	A to G	NA
3460	ND-1	LHON 1°	G to A	Ala 52 Thr
8344	tRNA^{Lys}	MERRF	A to G	NA
8356	tRNA^{Lys}	MERRF	T to C	NA
8993	ATPase 6	NARP/Leigh's	T to G[a] T to C	Leu 156 Arg Leu 156 Pro
11778	ND-4	LHON 1°	G to A	Arg 340 His
13708	ND-5	LHON 2°	G to A	Ala 458 Thr
14484	ND-6	LHON 1°	T to C	Met 64 Val
15257	Cytochrome-*b*	LHON 1°/2°	G to A	Asp 171 Asn

Note: The numeral in the amino acid substitution column refers to the position of the mutant codon in the mtDNA-encoded protein. ND-1, ND-4, ND-5, and ND-6—1st, 4th, 5th, and 6th subunits of NADH dehydrogenase; ATPase 6—6th subunit of ATP synthase; MELAS—mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes syndrome; MERRF—myoclonic epilepsy and ragged red fibers; NARP/Leigh's—neuropathy, ataxia, and retinitis pigmentosa/maternally inherited Leigh's disease; cardiomyopathy—hypertrophic cardiomyopathy and skeletal myopathy; LHON—Leber's hereditary optic neuropathy; 1°—primary, 2°—secondary LHON-associated mtDNA mutation; NA—not applicable since mutations are in ribosomal or transfer RNAs; Ala—alanine; Thr—threonine; Leu—leucine; Arg—arginine; Pro—proline; His—histidine; Met—methionine; Val—valine; Asp—aspartic acid; Asn—asparagine.
[a]Only pathogenetic mtDNA point mutation that is a transversion mutation.

pigmentary degeneration. This maternally inherited disorder is associated with two different heteroplasmic missense mutations at nucleotide position 8993 in the ATPase 6 gene. High proportions of the same mutations are also seen in maternally inherited Leigh's disease. The point mutations associated with these and other mitochondrial disorders are readily detected by molecular genetic analysis of mtDNA extracted from muscle, blood, and urine.

LEBER'S HEREDITARY OPTIC NEUROPATHY Leber's hereditary optic neuropathy (OMIM 535000) was the first disease in humans pathogenetically linked to heritable point mutations in mtDNA, and it may serve as a paradigm for homoplasmic missense mutation-mediated mitochondrial diseases. The core clinical phenotype is painless, subacute, bilateral visual loss with central scotomas and dyschromatopsia. The mean age of onset is 23 years, and three to four times as many males are affected as females.

LHON bears little clinical resemblance to the other mitochondrial diseases but was first classified as such on the basis of its maternal inheritance pattern. The pathophysiology of visual loss appears to involve both genetic and epigenetic factors. The mtDNA mutations exhibit a great deal of genetic heterogeneity with mutations in at least eight genes that encode subunits of three biochemical complexes. Four mutations, at nucleotide positions 11778, 3460, 15257, and 14484, are thought to have primary pathogenetic importance in multiple probands (Table 103-4; *see also* Fig. 103-1).

Several other mtDNA mutations have been associated with LHON that may have secondary pathogenetic roles in LHON. The prevalence of a secondary mutation at nucleotide position 13708 in the ND-5 gene is significantly increased in association with four different primary mutations. An X-linked nuclear DNA factor has been postulated to explain the marked male predominance, but the evidence has been conflicting. The most important epigenetic factors are exposure to alcohol and tobacco.

The diversity of the primary LHON-associated mtDNA mutations is reflected in genotype-specific clinical phenotypes. The most outstanding differential feature is the prognosis for visual recovery, which varies nearly 10-fold depending on the mutation. The causative mtDNA mutations of some variants of LHON, such as LHON plus dystonia (OMIM 516006.0002) and subacute optic neuropathy and myelopathy, have also been determined.

Analysis of the pathogenetic importance of LHON-associated mtDNA mutations illustrates the issues involved in determining the pathogenicity of any mtDNA mutation. A definitive cause-and-effect relationship between an mtDNA mutation and a clinical phenotype can be difficult to establish. MtDNA is highly polymorphic, there is dissociation of genotype and phenotype, different mutations can be associated with the same phenotype, the same mutation can be associated with different phenotypes, and epigenetic factors can affect clinical manifestations.

PATHOPHYSIOLOGY OF MITOCHONDRIAL DNA MUTATIONS

There is a complex, poorly understood relationship between the various mtDNA mutations, the resulting impairment of oxidative phosphorylation, and the associated clinical phenotypes. One important experimental system that has made major contributions to the understanding of mtDNA mutations is the rho° cell line. Recipient cell lines are rendered devoid of endogenous mtDNA and are fused with donor cytoplasts that harbor the mtDNA mutation of interest. The resultant cybrid contains the nucleus of the recipient cell line and the cytoplasm (including the mitochondria and mtDNA) of the diseased cell line. This system can be used to study the mitochondrial protein synthesis and the biochemical phenotype of oxidative phosphorylation defects in cybrid cell lines with variable proportions of mutant and normal mtDNA. There are

no animal models of mitochondrial disease, and there is a large gap between detailed data at the molecular and cellular level, and the complex clinical observations in patients.

All well-characterized mtDNA deletions eliminate at least one tRNA gene, and the deleted region appears to be transcribed but not translated. Indeed, there is a severe, generalized defect of translation that causes impaired mitochondrial protein synthesis and oxidative phosphorylation defects. The limited clinical expression of mtDNA deletions may reflect both heteroplasmy and differential tissue distribution. Clinically sporadic single deletions must have arisen in the oocyte or early in development, prior to the divergence of the three primary germ cell layers.

Pathogenetic tRNA mutations also impair mitochondrial messenger RNA translation and cause deficits in mitochondrial protein synthesis and in oxidative phosphorylation. The different clinical phenotypes seen in mutations in different tRNA genes imply some subtle functional differences among them, although impairment of oxidative phosphorylation must be a central feature of their pathogenicity. Age-related decline in oxidative metabolic capacity, differential tissue susceptibility, heteroplasmy, and interaction with tissue-specific nuclear DNA-encoded isozymes of oxidative phosphorylation subunits explain some of the intra- and interfamilial clinical heterogeneity, as well as the progressive course of the mitochondrial diseases.

The primary LHON-associated missense mtDNA mutations are usually homoplasmic and may occur alone or in combination with a number of secondary mutations. The LHON-associated mutations studied to date cause subtle, complex-specific impairment of oxidative phosphorylation. Many characteristic features of LHON, such as the long latency to onset, the acute nature of the vision loss, and clinical involvement confined to the optic nerve, are not explained adequately by such a mechanism. The allelic missense mutations in the ATPase 6 gene associated with NARP and Leigh's disease mutate a highly conserved leucine residue and impair ATP production via blockage of the ATPase proton channel. These mutations show a unique trait among pathogenetic mtDNA mutations in that the clinical phenotype appears to be dependent on the proportion of mutant to wild-type mtDNA.

A mouse model of mitochondrial myopathy has been created by generating a knockout of the heart/muscle isoform of the adenine nucleotide translocator (Ant 1). The null mice exhibit mitochondrial proliferation, a defect in coupled respiration, and increased serum lactate levels. Adult mice also had severe exercise intolerance.

ORGAN SYSTEM MANIFESTATIONS OF MITOCHONDRIAL DNA MUTATIONS

Virtually all tissues of the body are dependent to some extent on oxidative metabolism and thus can be affected by mtDNA mutations. The somatic manifestations listed in Table 103-2, first noted in association with the classic mitochondrial diseases, may be the dominant or initial clinical symptom and may provide the first opportunity for consideration of a mitochondrial diagnosis. These somatic manifestations may be important comorbid features.

The neurological manifestations of mitochondrial disorders, involving both the central and peripheral nervous systems, have dominated the literature and have been reviewed elsewhere. Less well known are the nonneurological manifestations of mtDNA mutations. The ophthalmological manifestations of mtDNA mutations are very prominent, with involvement of virtually the entire visual axis from lids, cornea, and extraocular muscles to the occipital cortex. The cardinal eye findings include ptosis, ophthalmoplegia, optic neuropathy, pigmentary retinopathy, and cortical visual field defects.

Cardiovascular manifestations are also common in the mitochondrial disorders and can be life-threatening, comorbid features. These manifestations include dilated and hypertrophic cardiomyopathy (OMIM 510000), conduction disease and heart block, Wolff-Parkinson-White syndrome, and most recently hypertension. Cardiomyopathy has been the dominant clinical feature in association with several tRNA mutations, particularly in the tRNA$^{Leu(UUR)}$ gene, which harbors a disproportionately large number of mutations.

Endocrine manifestations are frequent, and the prevalence of diabetes mellitus is higher than expected in the mitochondrial encephalomyopathies (*see* Chapter 47). The islet cells of the pancreas are extremely metabolically active and are susceptible to disruption of oxidative phosphorylation. The diabetes mellitus associated with mtDNA mutations is mainly due to a defect in insulin secretion. Diabetes mellitus has been linked with a heteroplasmic point mutation in the tRNA$^{Leu(UUR)}$ gene at nucleotide position 3243, usually, but not exclusively, in association with sensorineural hearing loss (OMIM 520000). Diabetes mellitus is a treatable, co-morbid feature of a number of mitochondrial diseases and can be the dominant, presenting manifestation of an mtDNA mutation. Hypoparathyroidism and symptomatic hypocalcemia have been noted in association with Kearns-Sayre syndrome.

Gastrointestinal manifestations of mtDNA mutations include colonic pseudo-obstruction, hepatopathy, chronic diarrhea, and weight loss. The most prominent renal manifestation of mtDNA mutations has been a Fanconi type of nonselective proximal nephron dysfunction, with consequent aminoaciduria, phosphaturia, and glycosuria. A glomerulopathy and the lactic acidosis associated with mitochondrial disorders may also bring these patients to the attention of the nephrologist. Pearson's syndrome (OMIM 557000) of exocrine pancreas dysfunction and a sideroblastic hypoproliferative anemia and pancytopenia occurs in association with large-scale single mtDNA deletions. Other forms of sideroblastic anemia or aplastic anemia may also be associated with acquired or inherited mtDNA mutations. Psychiatric manifestations, most notably depression, have been noted in association with multiple mtDNA deletions.

ROLE OF MITOCHONDRIAL DNA MUTATIONS IN COMMON DISEASES

The role of mtDNA mutations in common, socioeconomically significant diseases is under active investigation. The genetic basis of many prevalent diseases is complex, and does not follow simple, single-gene mendelian inheritance. The study of mitochondrial diseases such as LHON has illustrated the potential for complex pathophysiological interaction between genetic and epigenetic factors. As a result of these interactions, mtDNA mutations may be involved in subsets of common diseases, such as diabetes mellitus, in which the maternal inheritance pattern is not prominent.

The tissue-specific accumulation of somatic (noninherited) mtDNA mutations may be more relevant to late-onset degenerative disorders than are inherited mtDNA mutations or gross structural derangements that occur at the gametic level. The high mutation rate and poor repair capacity of mtDNA contributes to the buildup of mtDNA mutations in postmitotic tissues or those

with a slower turnover rate. Environmental factors may also affect mtDNA; the antiretroviral drug azidothymidine depletes muscle mtDNA and causes an acquired mitochondrial myopathy.

The accumulation of mtDNA mutations and the consequent deficit in ATP production beyond a threshold level in certain critical neuronal subpopulations may contribute to the pathogenesis of neurodegenerative diseases, particularly those that become more common with age, such as Alzheimer's disease and Parkinson's disease. Mitochondrial energy deficits have been postulated to contribute to neuronal injury via an excitotoxic mechanism that implicates many of the currently identified mediators of cell injury and death. These mechanisms may also contribute to arguably the most prevalent human condition, aging (OMIM 502000) itself. Ames and colleagues have outlined an elegant scenario that incorporates a rapidly accumulating body of data about the role of mitochondria in animal and human aging. They posit that cumulative, age-dependent mitochondrial dysfunction, mediated to a significant degree by oxidative damage to mtDNA and other mitochondrial macromolecules, is a major contributor to aging at the cellular, tissue, organ-system, and whole-organism level.

FUTURE STUDIES

Data about the role of mtDNA mutations in the pathogenesis of human disease has accumulated rapidly since 1988. The availability of the complete human mtDNA sequence and a wealth of knowledge about variations in that sequence have been crucial to our nascent understanding of the pathogenetic role of mtDNA mutations. Detailed study of mitochondrial disease has also provided insight into fundamental biological processes such as oxidative phosphorylation and aging.

There are a number of fertile areas for future work on the molecular genetic basis of mitochondrial disease, based in part on our knowledge of the complex interaction of nuclear and mitochondrial genes. The majority of oxidative phosphorylation subunits are encoded by nuclear genes, and pathogenetic mutations in these genes will be discovered. There are multiple nuclear genes involved in the coordinate regulation of mtDNA, and the identification of one such defect in intergenomic communication is underway. The discovery of the nuclear gene defect underlying the mtDNA depletion phenotype, which may involve the control of mtDNA replication, is technically more difficult, because of the autosomal recessive inheritance and the small sibships. The complex pathway by which nuclear DNA-encoded proteins reach their ultimate destination in the correct intramitochondrial compartment affords a number of vulnerable points for mutations, including the chaperon proteins.

mtDNA mutations appear to be pathogenetic in an expanding array of human conditions and diseases, and the repertoire of mtDNA mutations is by no means exhausted. The phenotypic borders of the mitochondrial diseases will broaden, and novel clinical syndromes will be described, at least partially on the basis of newly discovered pathogenetic mtDNA mutations. Pathogenetic mtDNA mutations have been discovered in each type of mtDNA gene, and there does not appear to be any constraint to prevent all 37 (22 tRNAs, 13 proteins, 2 rRNAs) mtDNA genes from harboring them. The role of mtDNA mutations in more prevalent neurological diseases, such as multiple sclerosis and Parkinson's disease, will continue to be an active area of investigation. In multiple sclerosis, for instance, there may be a dominant nuclear DNA gene mutation(s) that interacts with and is modified by mtDNA mutations.

Advances in our understanding of the molecular genetic basis of mitochondrial diseases have already had a profound impact on their detection and evaluation. A set of sensitive and specific molecular genetic tests has been developed for a number of the mitochondrial encephalomyopathies. The unequivocal establishment of the diagnosis of a mitochondrial disease by such molecular genetic methods is a prerequisite for proper genetic counseling and, ultimately, treatment. To date, the advances in diagnosis of these diseases have not been paralleled by therapeutic advances, but at least we are now aware of the biochemical target for such therapy and are able to avoid ineffective or inappropriate therapy. For example, using in vitro replication run-off assays, it has been possible to selectively inhibit the replication of mutant mitochondrial DNA by using peptide nucleic acids complementary to the mutant sequence. Mitochondrial gene therapy for these disorders must overcome a number of obstacles (e.g., the unique mtDNA genetic code and the requirement for specific targeting to the correct intramitochondrial compartment) from those encountered in the search for effective nuclear gene therapy, but it is not beyond the realm of possibility in the future.

104 Malignant Hyperthermia and Central Core Disease

David H. MacLennan and Beverley A. Britt

MALIGNANT HYPERTHERMIA

BACKGROUND   The recorded history of malignant hyperthermia (MH) began in 1900, when several, often fatal, cases of unexpected fever and "convulsions" during anesthesia in the operating room were reported. It was not until Denborough and colleagues (1961) reported 10 cases in a single Australian family, however, that it was realized that MH is inherited as an autosomal dominant abnormality. In 1966 it was discovered that pigs afflicted with porcine stress syndrome also develop MH reactions that are virtually identical to human MH, providing an excellent experimental model for MH. By 1970 the site of the primary defect could be assigned to skeletal muscle rather than brain. Muscle fascicles from MH-susceptible (MHS) patients were shown to be more sensitive than normal to the contracture-inducing properties of caffeine and halothane, providing the basis for the caffeine/halothane contracture test for MH susceptibility. In a landmark paper, Harrison (1975) showed that dantrolene sodium is an effective antidote, reversing the symptoms of an MH reaction. In the early 1980s the Ca^{2+}-release channel of skeletal muscle sarcoplasmic reticulum from both humans and swine was shown to be hypersensitive to Ca^{2+}-, caffeine-, and halothane-induced channel opening. Subsequent genetic analysis has shown that abnormalities in the Ca^{2+}-release channel of skeletal muscle sarcoplasmic reticulum (the ryanodine receptor, OMIM 180901) are linked to MH in a large proportion of MH families.

CLINICAL FEATURES

Individuals susceptible to malignant hyperthermia (OMIM 145600) may respond to the administration of potent inhalational anesthetics and depolarizing skeletal muscle relaxants with a rising end tidal CO_2, skeletal muscle rigidity, tachycardia, unstable and rising blood pressure, hyperventilation, cyanosis, a falling arterial oxygen tension (PaO_2), an increasing arterial carbon dioxide tension ($PaCO_2$), lactic acidosis, and, eventually, fever. Cellular damage brings about electrolyte imbalance with an early elevation in serum of K^+, Mg^{2+}, and Ca^{2+} and a later rise in the serum and urine of muscle proteins such as creatine kinase and myoglobin. If therapy is not initiated immediately, the patient may die within minutes from ventricular fibrillation, within hours from

pulmonary edema or coagulopathy, or within days from neurological damage (postanoxic cerebral edema or encephalopathy) or obstructive renal failure, the latter resulting largely from the release of muscle proteins such as myoglobin into the circulation and thence into the renal tubules. During convalescence, acute muscle soreness, and muscle edema may develop.

Central core disease (CCD) (OMIM 117000) is a rare, nonprogressive myopathy, presenting in infancy, and characterized by hypotonia, proximal muscle weakness, and susceptibility to malignant hyperthermia. Additional variable clinical features include pes cavus, kyphoscoliosis, foot deformities, congenital hip dislocation, and joint contractures. Although signs may be severe, up to 40% of patients demonstrating central cores may be clinically normal. Diagnosis is made on the basis of the lack of oxidative enzyme activity in central regions of skeletal muscle cells, observed upon histological examination of muscle biopsies. Electron microscopic analysis shows disintegration of the contractile apparatus, ranging from blurring and streaming of the Z lines to total loss of myofibrillar structure. The sarcoplasmic reticulum and transverse tubular systems are increased in content and are, in general, less well structured. NADH-tetrazolium reductase reactions reveal pale circular areas designated as central cores. Mitochondria are depleted in the cores but may be enriched around the surfaces of the cores. The disorder is inherited as an autosomal dominant trait with variable penetrance, and it is tightly linked to defects in the Ca^{2+}-release channel gene.

The King-Denborough syndrome (OMIM 145600) is characterized in children by particular congenital abnormalities such as short stature, scoliosis, pectus deformity, delay in motor development, ptosis, low-set ears, antimongolian slanted eyes, cryptorchidism, and susceptibility to malignant hyperthermia. This syndrome is inherited as an autosomal dominant trait, but it is not yet known whether it is linked to defects in the Ca^{2+}-release channel gene.

EPIDEMIOLOGY   MH crises develop most commonly in individuals between the ages of 3 and 30, and the number of MH reactions declines progressively in age groups above 30. Reactions are rare before the age of 3 or after the age of 78. Males are slightly more affected, in terms of both incidence of reactions and positive biopsies, perhaps because of their larger and stronger musculature. Many individuals experiencing MH reactions have had previous uneventful general anesthetics, often of long duration and with known triggering agents.

INCIDENCE The incidence of MH is about 1 in 15,000 anesthetics in children and about 1 in 50,000 to 1 in 100,000 anesthetics in adults. These reported incidences are probably marked underestimates of the true incidence of MH susceptibility because of the incomplete penetrance of the gene and the difficulty in defining mild reactions, including masseter muscle spasm. The incidence of masseter muscle rigidity in children in the United States is about 1 in 100 anesthetics. The corresponding figure for masseter muscle rigidity in Canada is only about 1 in 1000 to 1 in 2000 anaesthetics, perhaps due to different protocols for anesthesia. Of those US children who have had anaesthetic-induced masseter muscle rigidity and, subsequently, had muscle biopsies, 50% were positive in the caffeine/halothane contracture test for MH susceptibility. If these frequencies were truly indicative of MH susceptibility, then the incidence of MH in the general population would be as high as 1 in 200.

DIAGNOSTIC TESTS

MH episodes may occur in individuals who have inherited muscle diseases with deleterious phenotypes such as central core disease, King-Denborough syndrome, Duchenne muscular dystrophy, myotonia fluctuans, and, possibly, other myopathies. MH susceptibility is seldom associated with ill health, although serum creatine kinase is often elevated and potential associations with chronic muscle pain, chronic fatigue, and muscle weakness are being investigated. Accordingly, one of the most important goals of MH research is to prevent MH episodes through identification of MHS individuals in advance of anesthesia. The in vitro caffeine/halothane contracture test (CHCT and IVCT) was developed as a diagnostic test for MH susceptibility on the premise that muscle fibers from MHS individuals might be more sensitive than normal to these agents, which induce contractures. The North American test protocol and the European test protocol have been standardized on this premise.

The CHCT and IVCT have been devised to be a valuable clinical test, assuring that appropriate anesthetics are administered to those patients who are MHS, while permitting those diagnosed as normal to be treated with normal anesthetic routines. Sensitivity approaching 100% is crucial to avoid false negative diagnoses, since failure to detect MH susceptibility can result in a serious or fatal outcome. Specificity should also be high to avoid false positive diagnoses, but false positive diagnosis will not result in life-threatening anesthetic reactions.

The current CHCT is carried out under strict protocols, and those who perform the tests should be experienced and highly competent. Under these conditions, the CHCT and IVCT currently achieve 97–99% sensitivity, and only 78–92% specificity (Ørding et al. 1997; Allen et al. 1998). The tests detect abnormal responses to caffeine- and halothane-induced rises in intracellular Ca^{2+}. This is a complex process, because the outcome of the contracture test depends on the interplay among a very large number of competing reactions within muscle cells, including, as a minimum, Ca^{2+} release and reuptake, and muscle contraction and relaxation. The multifactorial nature of the regulation of the contracture response could, occasionally, give a test result that is discordant with genetic evidence. While a false-positive test result does not pose any significant problem for clinicians, inaccurate diagnoses create serious difficulties for geneticists attempting to link the inheritance of MH susceptibility to inheritance of a specific allele. In any case where the CHCT has been positive, it is strongly recommended that non-triggering anesthetic routines be followed.

MOLECULAR GENETICS

LINKAGE OF THE *RYR1* GENE TO MALIGNANT HYPERTHERMIA
Early studies of porcine MH established a linkage group for the porcine *HAL* gene, the glucose phosphate isomerase gene *(GPI)*, and the gene for 6-phosphogluconate dehydrogenase *(PGD)*, located near the centromere of pig chromosome 6. The homologous region around the human *GPI* locus was found to be on the long arm of chromosome 19, making this a candidate region for human MH. Cloning of the human skeletal muscle ryanodine receptor *(RYR1)* cDNA led to the localization of *RYR1* to human chromosome 19q13.1, in the same region as human *GPI*. Linkage studies showed cosegregation of MH in 23 meioses in nine families, leading to a lod score (the logarithm of the odds favoring linkage vs nonlinkage) of 4.2 for a recombinant fraction of 0.0. The probability of linkage of more than 10,000 to 1 identified *RYR1* as a candidate gene for MH in humans.

PORCINE MALIGNANT HYPERTHERMIA MUTATION
The demonstration of linkage of *RYR1* to MH led to parallel searches in both pigs and humans for sequence differences in the *RYR1* gene between MH and normal individuals. In a comparison of the cDNA sequences of MH (Pietrain) and normal (Yorkshire) pigs, the substitution of T for C at nucleotide 1843, leading to the substitution of Cys for Arg at amino acid residue 615, was the only amino acid sequence alteration found. Tight linkage between inheritance of the mutation and inheritance of MH was established in a study of backcrosses between British Landrace heterozygous animals of the *N/n* genotype and homozygous MH animals of the *n/n* genotype. A lod score of 102, favoring linkage, was found for a recombinant fraction of 0.0 in tests of 376 animals, including 338 informative meioses.

HUMAN MALIGNANT HYPERTHERMIA MUTATIONS
The demonstration of linkage between MH and a mutation in porcine *RYR1* led to a search for the corresponding mutation in human MH families. The equivalent human mutation, Cys for Arg[614], was first found in a single family of five members, in which it segregated with MH. This mutation has been found in about 4% of MH families worldwide. In many of these MH families, it segregated with individuals who have been diagnosed by the CHCT as MHS, but, in a few of these MH families, linkage has not been observed. If linkage cannot be demonstrated, at least three alternatives explanations must be considered: (1) the Arg[614]-to-Cys mutation may not be causal of MH; (2) a second MH allele may be segregating in the family; or (3) the phenotypic diagnosis, based on the CHCT, may result from factors other than genetic MH.

The assignment of the Arg[614]-to-Cys mutation as causative of human MH has a strong genetic and biochemical basis. First, the corresponding mutation is linked to porcine MH with a lod score of 102, favoring linkage for a recombinant fraction of 0.0. Second, the mutation has been found across a species barrier, between swine and humans, where it frequently segregates with MH. Third, in biochemical studies of the porcine channel, a measurable defect has been observed in the closing of the Ca^{2+}-release channel. Finally, when expressed in muscle cells, the mutant form of the ryanodine receptor has been shown to release Ca^{2+} in response to lower levels of added caffeine or halothane than the normal channel. Accordingly, explanation (1) cannot be readily accepted.

By contrast, explanations (2) and (3) can be more readily accepted as a cause of linkage discordance. The segregation of two MH mutations in a single family could lead to apparent discordance, if only one mutation were being analyzed, even though

Table 104-1
***RYR1* Mutations Associated with Human MH and CCD**

Mutation	Exon	Association	Occurrence
Cys35Arg	2	MH	1 Family
Arg163Cys	6	MH, CCD	2%
Gly248Arg	9	MH	2%
Gly341Arg	11	MH	6%
Ile403Met	12	MH, CCD	1 Family
Tyr522Ser	14	MH, CCD	1 Family
Arg552Trp	15	MH	1 Family
Arg614Cys	17	MH	4%
Arg614Leu	17	MH	2%
Arg2162Cys	39	MH, CCD	4%
Arg2162His	39	MH	1 Family
Val2167Met	39	MH	8% (6 Swiss)
Thr2205Met	40	MH	1 Family
Gly2434Arg	45	MH	4%
Arg2435His	45	MH, CCD	1 Family
Arg2458Cys	46	MH	4%
Arg2458His	46	MH	4%

concordance might exist for each mutation. Since the sensitivity and the specificity of the CHCT and IVCT are less than 100%, it is highly probable that the occasional discordance between the CHCT- and the DNA-based diagnoses, at least for the Arg[614]-to-Cys mutation, arises from inaccuracy in the CHCT. The phenotype determined from the CHCT may have resulted from genetic factors not related directly to MH susceptibility and might be attributed to variation arising from the multifactorial nature of the contracture response.

Continued analysis of the DNA sequence of ryanodine receptors from probands from MH families has associated MH with 17 mutations at 14 sites present in 40% of MH families (Table 104-1). Thus, the causal MH mutations in 60% of MH families have yet to be found. The search for additional MH mutations in *RYR1* is hampered largely by the size of the gene. The coding sequence in the cDNA is over 15,000 bp long. The gene is 161,000 bp long and contains 106 exons. The MH mutations found to date have clustered in exons 2–17 and 39–46 (*see* Table 104-1). If additional mutations continue to cluster in a few exons, mutant searches will be much less onerous than might be anticipated, considering the length of the coding sequence in the gene.

CENTRAL CORE DISEASE MUTATIONS An important feature of CCD is its close association with susceptibility to malignant hyperthermia. This association has led investigators to establish linkage between CCD and markers in the long arm of chromosome 19, including markers in *RYR1*. Analysis of *RYR1* cDNA sequences in several CCD families has led to the discovery of five mutations that are linked to CCD and MH (*see* Table 104-1).

SEARCHING FOR ADDITIONAL MHS LOCI Linkage of MH to chromosome 17q (OMIM 154274) in several families has been reported, making candidates of the sodium channel α-subunit gene *(SCN4A)* and two subunits of the dihydropyridine receptor, *CACNLB1* and *CACNLG,* located on chromosome 17q11.2-q24. In subsequent studies, however, linkage of MH to chromosome 17q and to the candidate genes was ruled out in other nonchromosome 19-linked European families. Vita et al. (1995) have suggested that paramyotonia congenita and other demonstrated defects of the sodium channel α-subunit protein might

have been associated with abnormal responses to succinylcholine, including muscle rigidity.

MH has also been linked to chromosome 7q (OMIM 154276), with a lod score less than 3 in a single family. The presence of the gene encoding the α2/δ subunit of the dihydropyridine receptor (CACNL2A OMIM 114204) on chromosome 7q21-22 established it as a candidate gene for MH, but sequencing of this candidate gene has not led to the identification of a causal mutation.

Several large, non-chromosome 19-linked European MH families have been included in a systematic linkage study using a set of polymorphic microsatellite markers covering the entire human genome (Robinson et al., 1997). A single family was first linked to chromosome 3q3.1 (OMIM 600467) with a lod score of 3.22, and two more candidate loci were identified. The first was chromosome 1q (OMIM 601887 1q32), the site of a candidate gene, *CACNL1A3,* encoding the α1-subunit of the DHP receptor (CACNA1S OMIM 114208); the second resides on chromosome 5p (MHS6 OMIM 601888), where no known candidate has been mapped; the third provides evidence for at least one other unspecified locus.

Analysis of the chromosome 1q-linked family led to the discovery of the mutation of G3333 to A in the *CACNL1A3* gene (OMIM 114208), leading to the mutation of Arg1086 to His in the α1-subunit of the L-type voltage-dependent calcium channel. This mutation segregated with MH in a large pedigree, yielding a two-point lod score of 4.38 at a recombination fraction of 0 (Monnier et al., 1997). This mutation is located in the loop between domains III and IV of the channel, where it is spatially separated from other mutations in the gene, previously shown to be causal of hypokalemic periodic paralysis, and which are not associated with MHS. This study suggests that there is a direct functional interaction between the III-IV loop of the α-subunit of the DHP receptor and the ryanodine receptor, which can lead to susceptibility to MH, probably through defective regulation of the Ca^{2+}-release channel. The DHP receptor mutation does not lead to any other symptoms of ion channel disease, suggesting that it does not affect L-type calcium channel function.

It is still difficult to project the proportion of MH families that will eventually be linked to causal mutations in *RYR1* and in other gene loci. At least 50% of MH families are now linked to *RYR1*. A significant number of true MH families show a high correlation with inheritance of *RYR1* markers, but are not fully concordant. Evidence that in vitro contracture tests have less than complete specificity will require re-evaluation of the role of *RYR1* in these high correlation families. Other MH loci clearly exist, but only one or a few families have been linked to each of the other MH loci identified to date, indicating that MH mutations in these loci are rare. Causal mutations in *RYR1* will most likely be found in a large proportion of families when linkage problems are worked out.

PHYSIOLOGICAL BASIS

Examination of the early and late events in the development of a halothane-induced MH reaction in swine have proven very informative. Blood chemistry studies have revealed that lactic acidosis, presumably originating in glycogenolysis and glycolysis, and the release of K^+, Mg^{2+}, and Ca^{2+} from muscle, the target tissue, occur within seconds of the time that halothane reaches the muscle. Observed rises of serum K^+ to as high as 7–8 m*M* have been considered to be sufficient to cause cardiac arrest in at least some

patients. A rise in body temperature usually occurs only after 15 or 20 min, and perhaps even substantially longer. On the basis of measurements of oxygen uptake, the major source of heat production has been shown to be anaerobic, arising from the breakdown of creatine phosphate and ATP. The neutralization of bicarbonate in the blood by lactic acid and the direct production of CO_2 by the tricarboxylic acid cycle gives rise to CO_2 in the blood and expired air. The release of Ca^{2+} into the blood from the muscle was the first indication that a disturbance in Ca^{2+} homeostasis in muscle was the primary defect in MH.

Studies of the mechanisms controlling changes in muscle tension have revealed that the interaction of actin and myosin is regulated by Ca^{2+} and that Ca^{2+} regulation is mediated through the Ca^{2+}-binding protein, troponin. Muscle Ca^{2+} concentrations are regulated by the activities of Ca^{2+} pumps and channels located in the sarcoplasmic reticulum and transverse tubular systems. Ca^{2+} also plays a role in the control of glycolysis in muscle through its activation of phosphorylase kinase.

Higher rates of Ca^{2+}-induced Ca^{2+} release, particularly at low levels of inducing Ca^{2+}, were observed in membrane vesicle preparations from both human and porcine muscle and closure of single porcine MH channels at high Ca^{2+} concentrations has been shown to be inhibited. In studies of single Ca^{2+}-release channels from humans, an abnormally high caffeine sensitivity was detected in MH individuals. In sarcoplasmic reticulum from MHS swine, ryanodine binding, which is dependent on the open state of the Ca^{2+}-release channel, was enhanced. Thus, comparative biochemical and physiological studies have implicated the Ca^{2+}-release channel as a potential causal factor for MH.

The Ca^{2+}-release channel has been isolated from skeletal muscle as a huge tetrameric complex. The complex consists of a relatively small transmembrane domain and a large, multidomain, cytoplasmic segment. Single, isolated Ca^{2+}-release channel proteins, when incorporated into planar lipid bilayers, form ligand-gated channels with a conductance greater than 100 pS in 50 mM Ca^{2+}. Ca^{2+} release is activated by μM Ca^{2+}, mM ATP, and mM caffeine, and is inhibited by mM Mg^{2+} and by mM calmodulin. In muscle cells, the primary activation of the Ca^{2+}-release channel probably occurs through its interaction with the dihydropyridine receptor.

DNAs encoding the Ca^{2+}-release channel of skeletal muscle sarcoplasmic reticulum have been cloned from rabbit and human muscle. They encode proteins containing about 5035 amino acids with masses of about 564,000 Dalton. Transmembrane sequences are located at the COOH-terminal end of the molecule. Predicted ATP, Ca^{2+}, and calmodulin-binding sites are clustered in two sites in the molecule. One lies in the proposed transmembrane domain in the COOH-terminal end of the protein, encompassing the region between amino acid residues 4253–4499, and the other lies between about residues 2400 and 3000.

It is of interest that six out of eight MH or CCD mutations lie between amino acids 163 and 614 (*see* Table 104-1), suggesting that this region of the molecule forms a third regulatory domain in the Ca^{2+}-release channel. The sequence surrounding Arg[614] is homologous to a sequence in the inositol 1,4,5-trisphosphate (IP_3) receptor, to which IP_3 binds to activate Ca^{2+} release. MH mutations are also found in residues 2433 and 2434. The second MH regulatory domain is also homologous to a sequence in the IP_3 receptor. Another interesting feature of the known MH mutations is that 13 of the 17 involve either loss or gain of arginine. This suggests that positive changes within the two MH domains are critical to regulatory function.

A defect in the Ca^{2+}-release channel giving rise to abnormal Ca^{2+} regulation within skeletal muscle could account for all of the signs of MH. If the Ca^{2+}-release channels had longer open times in the presence of anesthetic agents, intracellular Ca^{2+} might be chronically elevated, resulting in muscle contracture and activation of the first steps in glycogenolysis through activation of phosphorylase kinase. Muscle contracture and the pumping of excessive amounts of cytoplasmic Ca^{2+} back to the lumen of the sarcoplasmic reticulum would consume large amounts of ATP, thus generating high quantities of heat. The ADP formed would stimulate glycolysis and the mitochondrial oxidation of pyruvate derived from glucose. These hypermetabolic responses would lead to depletion of ATP, glycogen, and oxygen; to the production of excess glucose, lactic acid, CO_2, and heat; and, ultimately, to the disruption of cellular integrity and to intra- and extracellular ion imbalance.

MANAGEMENT

DIAGNOSIS   An acute MH episode is recognized by the presence of a number of nonspecific clinical indicators that illustrate muscle contracture, muscle breakdown, and hypermetabolism, including fever. A clinical grading scale (Larach et al. 1994) has been developed to assess the likelihood that each event represented acute MH. The CHCT is a widely used and valuable clinical test for diagnosis of MH status in families in which MH susceptibility is segregating. DNA-based diagnosis of MH susceptibility is currently possible in only about 10–15% of MH families. As more mutations are uncovered and linked to MH, DNA-based diagnosis should become the diagnostic method of choice.

ELECTIVE ANESTHESIA   Anesthesiologists identify many patients at risk through case histories, which include information on their kinship to individuals who have had an MH reaction and/or a combined history of a persistently elevated creatine kinase with chronic and incapacitating muscle pain and cramps. For patients known or suspected of having malignant hyperthermia, anesthetic routines are changed to any desired combination of nontriggering anesthetics (barbiturates, tranquillizers, narcotics, propofol, ketamine, nitrous oxide, and local anesthetics). Propofol is especially advantageous, not only because of the rapid reawakening, but also because propofol appears to normalize MH muscle. For this reason, however, propofol should not be used for muscle biopsies for the diagnosis of MH.

EMERGENCY TREATMENT FOR MH REACTIONS   Under present-day standard anesthetic practice, heart rate, blood pressure, end tidal CO_2 production, arterial oxygen saturation (SaO_2), and body temperature are monitored during the course of anesthesia. An increase in several of these may lead to the diagnosis of MH. When this occurs, the administration of the MH-triggering anesthetic is stopped immediately, without waiting for further confirmation of the diagnosis. The gas machine is replaced with a clean gas machine. If this is not possible, then at least the soda lime, the corrugated anesthetic tubing, and the ventilating bag are changed. The antidote, dantrolene, is administered at a dose of 1.0 mg/kg/min until muscle tone softens; fever, heart rate, and respiratory rate decline significantly toward normal; and blood gases normalize. Although internal and external cooling has been the usual practice, it no longer seems necessary, since dantrolene by itself effectively lowers body temperature. The patient is hyperventilated with 100% oxygen. Sodium bicarbonate is given for partial correction of metabolic acidosis. Regular insulin may

be infused if serum potassium and blood glucose are elevated. Furosemide and mannitol are infused to prevent the onset of acute renal failure. In addition, furosemide stops the sodium overload that may develop in the face of overly large doses of sodium bicarbonate, while mannitol helps to prevent muscle and brain edema. These practices have lowered the death rate from MH episodes from over 80% to less than 7% in recent years, but neurological, muscle, and kidney damage still contribute to the morbidity resulting from MH reactions.

FUTURE DIRECTIONS

Research over the past quarter century has led to partial understanding of the physiological and genetic basis for MH, but many goals are yet to be attained. Perhaps the most important immediate goal is to define all of the genes and all of the mutations in those genes that are causal of human MH. The development of DNA-based diagnostic tests for MH susceptibility, replacing the current invasive and expensive CHCT, should then permit accurate identification of those members of MH families who are MHS. This will assure that MHS individuals will receive a regiment of "safe" anesthetics, while normal family members can utilize more conventional anesthetics.

A second goal will be to understand the functional consequences of the structural alterations in the Ca^{2+}-release channel that lead to its involvement in MH episodes. Very little is known about the structural and functional domains of the Ca^{2+}-release channel and how mutations in the domains affect channel gating. MH mutations are clustered between residues 35 and 614 in a clear regulatory domain that corresponds to the IP_3 binding and activation domain for the Ca^{2+}-release function of the IP_3 receptor. MH mutations also appear between residues 2162 and 2458 in a second predicted regulatory domain. Future structure/function analyses will lead to the understanding of important regulatory domains in the Ca^{2+}-release channel and of their response to pharmaceutical intervention.

A third goal will be to understand, at the physiological level, how MH mutations in *RYR1* and possibly other genes relate to mutation-associated abnormalities in muscle cells. The question of how morphologically abnormal central cores form in muscle, from an *RYR1* mutation that also causes MH, raises another important question, of how chronic variation in Ca^{2+} levels in a muscle cell can affect its physiology. A corollary of this question is: How do mutations in alternate genes, leading to other myopathies, also affect Ca^{2+} regulation in muscle cells resulting in anesthetic-induced malignant hyperthermia? The answers to these and other questions will arise from ongoing investigations of the genetics and physiology of these interesting abnormalities.

105 Retinoblastoma

A Current Review

JOAN M. O'BRIEN

BACKGROUND AND HISTORY

Retinoblastoma (OMIM 180200) is the most common ocular tumor of childhood, occurring in 1 in 18,000 live births. In 1809 the disease was first recognized and described with careful anatomical drawings by James Wardrop, an ophthalmologist in Edinburgh. He maintained that retinoblastoma could be cured by early enucleation (removal of the eye involved with the tumor). His hypothesis was not confirmed in his own lifetime, since in that era children with this disease presented late, with widespread metastases. The advent of a cure for primary retinoblastoma coincided with the development of the ophthalmoscope. Once intraocular disease could be visualized and diagnosed, Wardrop's hypothesis was confirmed. Rudolph Virchow believed the tumor had a glial origin, and therefore, the malignancy was termed glioma retinae. Frederick Verhoeff defined retinoblastoma as an undifferentiated neuroblastic tumor of the retina, and this designation was soon adopted by the American Ophthalmological Society. Benign variants of retinoblastoma are termed retinoma and retinocytoma.

Retinoblastoma is a disease of infancy and early childhood, with the majority of cases diagnosed before the age of 4 years. In 1971 Alfred Knudsen proposed the "two-hit hypothesis," based on an epidemiological review of 48 cases of retinoblastoma. He analyzed the patient's disease with respect to unilaterality or bilaterality, age at diagnosis, sex of patient, and family history of disease. The author concluded that retinoblastoma could be caused either by a germinal mutation or a somatic mutation. Knudsen hypothesized that the number of new heritable cases decreases over time because the occurrence of a second event at a constant rate is less likely in a declining population of undifferentiated cells. David Comings elaborated upon Knudsen's hypothesis by suggesting that mutations responsible for the phenotype could occur to inactivate both alleles of a single responsible gene.

These hypotheses were confirmed by cloning of the retinoblastoma gene *(Rb)* (*see* Chapter 7). A close linkage of the tumor predisposition with the esterase-D locus was first described, placing the gene on chromosome 13q14. This was followed by Thaddeus Dryja's observation of overlapping deletions in familial cases, suggesting a more precise genetic locus. Subsequently, in collaboration with Stephen Friend and colleagues, *Rb* was cloned.

Shortly thereafter, using a strategy involving chromosomal walking in the region 13q14.1, Yuen Kai Fung and colleagues provided "structural evidence for the authenticity of the human retinoblastoma gene." Wen-Hwa Lee and coworkers published the gene's full sequence nearly simultaneously. Knudsen's hypothesis was specifically confirmed in the paper by Fung and colleagues; in a bilateral case a mutation at the *Rb* locus was detected not only in the tumor but also in fibroblast DNA, suggesting a germline initiating event. In a unilateral patient, both of two mutational events (a 3' deletion and a total deletion) were found in the tumor only, with the fibroblast DNA showing no deletion at the retinoblastoma locus. This suggested that the initiating event for unilateral retinoblastoma was somatic, occurring only within the transformed cells of the retina.

CLINICAL FEATURES

The clinical features of retinoblastoma are useful to predict the underlying genetic basis for the disease in individual patients. Children with germline mutations at the retinoblastoma locus generally present earlier in life, and because the initial event has occurred in every cell, the second event is a frequent one, resulting in bilateral and multifocal disease of the retina. In contrast, children with a somatic form of the disease have two mutations which occur sporadically within a single retinal cell. The likelihood of both events occurring within one retinal cell is low; therefore, these children present later with unilateral, unifocal disease.

Although such clinical observations generally correlate with genetic background, exceptions do exist. At least 15% of unilateral patients harbor germline mutations at the *Rb* locus. Any patient with a germinal mutation at this site has increased risk for the development of osteogenic sarcoma (OMIM 259500), soft tissue sarcoma, melanoma (malignant melanoma, OMIM 155600; uveal melanoma, OMIM 155720; malignant intraocular melanoma, OMIM 155700), breast carcinoma (familial, OMIM 114480; type 1, OMIM 113705), and gastrointestinal carcinoma (OMIM 175100). Additionally, 3–7% of children with bilateral disease develop primitive neuroectodermal tumors (PNETs) of midline structures of the brain. This disease entity has been described as trilateral retinoblastoma (cf., retinoblastoma, OMIM 180200), since a striking resemblance exists between the neuroblastic tumors arising bilaterally in the retina and in the brain.

Children with germline *Rb* mutations clearly have a lifelong neoplastic predisposition this requires careful surveillance.
Figure 105-1   Leukocoria. In this case, the white pupil is associated with persistent hyperplastic primary vitreous, a congenital anomaly of ocular development. This entity is in the differential diagnosis of retinoblastoma, but leukocoria and retinoblastoma need not be synonymous.

These children are also at risk for the development of multiple retinal tumors over the first 4 years of life. The major clinical challenge is to manage the recurrent primary tumors with as little risk to vision as possible, while minimizing iatrogenic inducers of second tumor development (e.g., treatment of primary tumors with external beam radiation, which has been associated with an increased rate of osteogenic sarcoma occurrence within the radiation field).

DIAGNOSIS

Children with retinoblastoma classically present with leukocoria or a white pupillary reflex (Figs. 105-1 and 105-2). However, patients with this disease may present with a wide variety of signs and symptoms and, in some cases, accurate diagnosis may be difficult. Retinoblastoma can be masked by hyphema (blood in the anterior segment of the eye, in front of the iris), a situation that is observed when the tumor has induced neovascularization of the iris. Children can present with orbital signs and symptoms that mimic preseptal cellulitis.

Retinoblastoma patients may also show signs of intraocular inflammation and may be thought to have vitritis. Coats' disease (exudative vitreoretinopathy/familial, OMIM 133780), an exudative retinopathy that can produce massive yellow white deposits, may be mistaken for retinoblastoma. Retinal dysgenesis syndromes, such as Norrie's disease (OMIM 310600), may also suggest retinoblastoma. Occasionally, the large ridges associated with retinopathy of prematurity appear mass-like, and retinoblastoma must be excluded. Myelinated nerve fibers, tuberous sclerosis with glial hamartomas of the retina and optic disc, and ocular staphylomas all may be confused with this tumor. A congenital anomaly of ocular development, persistent hyperplastic primary vitreous, also belongs in the differential diagnosis of this disease (*see* Fig. 105-1).

The diagnosis of retinoblastoma is made with retinal fundoscopy and imaging studies. Because calcification of the tumor is

Figure 105-2   Leukocoria. In this case, the child has bilateral retinoblastoma with the larger tumor on the right producing leukocoria.

common, ultrasound examination to identify pathognomonic calcification is frequently helpful in the diagnosis. Most other lesions considered in the differential diagnosis do not calcify. A computed tomography (CT) scan of the brain and orbits is essential to examine the extent of ocular involvement and to detect calcification within the tumor, as well as to evaluate midline structures to exclude the presence of a concomitant PNET. Magnetic resonance imaging (MRI) is rarely necessary, although in children with orbital signs at presentation or any suggestion of optic nerve invasion by CT scan, an MRI with gadolinium contrast enhancement can be useful in planning a surgical approach to the patient.

All children should be examined at birth to confirm a bilateral red reflex, and to exclude the diagnosis of retinoblastoma or other retinal disease. Any child under 6 years of age who presents with a white pupillary reflex should be considered to have retinoblastoma until an alternative diagnosis can be confirmed. If the retina cannot be clearly visualized by an ophthalmologist—for example, because of intraocular inflammation or intraocular blood—the child should undergo an imaging study. Retinoblastoma must be excluded prior to any surgical intervention because of the risk that occult tumor may be disseminated systemically. Even fine-needle aspiration biopsy is contraindicated in children suspected of having retinoblastoma.

GENETIC BASIS OF DISEASE

Prior to the identification of the retinoblastoma susceptibility gene, many researchers believed that malignancy resulted primarily from the activation of oncogenes. Experiments in which normal cells were fused with tumor cells, with resultant suppression of neoplastic features, suggested that normal cells could also contain genetic elements capable of suppressing malignant transformation. Cloning of the retinoblastoma locus provided the first unequivocal proof of this theory and permitted identification of the gene's function as a tumor suppressor. This discovery had important implications for the study of malignancy, leading to a search for other tumor suppressor genes. Mutations or deletions of tumor suppressor genes are associated with loss of function and with deregulated growth of cells. The *Rb* gene was thought to control an important point in the pathway of regulated cellular growth. Progression toward malignancy occurs in the absence of this gene product.

Inactivation of the *Rb* locus was subsequently recognized to occur not only in retinoblastoma and osteogenic sarcoma but also
Figure 105-3 Untreated unifocal, unilateral retinoblastoma. In general, unifocal lesions are not recognized until they are considerably larger than this. With unilateral retinoblastoma, visual decrement is not appreciated by the child or the parents until the disease is advanced, since the opposite eye is unaffected and has normal vision. Most children with unilateral disease have sporadic, somatic *Rb* gene alterations, and are at low risk for second-tumor development.

Figure 105-4 Treated multifocal, bilateral retinoblastoma associated with germline mutation at the Rb locus. The gray, diaphanous appearance of the superior lesion is associated with disease activity. The white, calcified lower lesion is treated and inactive.

in a number of other neoplastic processes, including breast carcinoma, small-cell lung carcinoma (OMIM 182280), bladder carcinoma (OMIM 109800), prostate carcinoma (OMIM 176807), and primary leukemia (OMIM 151390). It was discovered that the gene product was ubiquitously expressed in normal tissues. These observations suggested that *Rb* gene deletion or mutation could have a central role in transformation in a spectrum of histopathologically distinct malignancies.

In patients with germinal mutations at the *Rb* locus, every cell lacks one functional gene copy. The reason these children are predisposed to develop tumors of bone at an increased rate compared with tumors of other histologic origin is unclear. The risk for children with retinoblastoma to develop a second cancer of some type is approximately a 45%, 35-year risk. This risk may be increased after treatment with agents that damage DNA, such as irradiation or chemotherapy. Often, however, treatment options in children with retinoblastoma are limited. In many children, radiation therapy is required in order to retain vision and to treat the primary tumor. Figures 105-3 and 105-4 show, respectively, a unilateral and bilateral case of retinoblastoma. Treated and untreated forms are demonstrated.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

In some patients with retinoblastoma, the retinoblastoma gene is deleted in its entirety. An internal deletion of one exon or a point mutation at an important splice site may also occur, resulting in disruption of the gene product's function. The Rb protein (pRb) is known to play a key role in interacting with cell-cycle regulators (E2F and the

cyclins) in the regulation of transcription, and in producing terminal differentiation of particular cell types. The protein is phosphorylated in a cell cycle-dependent manner, and the phosphorylation state regulates the activity of pRb. A number of DNA tumor virus gene products, including SV40 T antigen, adenovirus E1A, and human papilloma virus E7, bind preferentially to the underphosphorylated form of pRb, and this binding may inactivate the protein, resulting in transformation of the cell toward malignancy.

NATURE OF GENE DEFECT The retinoblastoma gene is 180 kb in length and contains 27 exons. The normal message encoded by the gene is 4.7 kb in length: 2.7 kb represent coding sequence, and 2 kb represent noncoding sequence. The resultant protein contains 928 amino acids (Fig. 105-5). The promoter of the retinoblastoma gene contains a CpG island, and it is very GC rich. The promoter also contains consensus sequences for the transcription factors E2F-1, ATF, and SP-1. The 27 exons that comprise *Rb* range in size from 31 to 1889 nucleotides in length. The largest intron is greater than 60 kb long, and the smallest intron is less than 80 bp in length. Exon 1 contains 5' untranslated sequences and the first methionine, which correspond to the 5' end of the mRNA.

A number of mutations that have been observed in the retinoblastoma gene affect one of two conserved regions, areas that are also required for Rb gene product (pRb) binding to viral oncoproteins. Mutations have also been observed in the promoter region of the retinoblastoma gene in areas corresponding to recognition sequences for the ATF and SP-1 transcription factors. The identification of mutations in SP-1 and ATF sites in retinoblastoma
Figure 105-5 Retinoblastoma gene, mRNA, and protein structures.

families suggests that these sequences within the promoter may act as regulators of Rb gene transcription and are of phenotypic significance.

STUDIES OF mRNA AND PROTEIN The retinoblastoma protein is constitutively and ubiquitously expressed in human cells. The protein has a half-life of about 12 h. Regulation of Rb is accomplished posttranslationally (changes in expression and degradation are less important). pRb is activated and deactivated through phosphorylation events or through association with other cellular proteins. Compartmentalization within the nucleus may also play a role in the regulation of pRb.

In a number of cases where the retinoblastoma gene contains a mutation, its mRNA is truncated. The resultant protein loses function, particularly in the conserved domains where viral binding occurs, regions designated A and B. The amino acid sequence of the retinoblastoma protein suggests that it contains a number of globular domains and a hydrophilic tail. Of these, the A and B globular domains have been better defined, through mapping to the C terminus by deletion mutagenesis studies. These viral binding domains appear important to retinoblastoma protein function. Presumably, this localization of function explains why viruses have evolved to bind to this region and thereby to inactivate pRb. Activities that appear to be localized to the A-B region include suppression of growth in cell culture, adherence to nuclear components, and binding to transcription factors, as well as phosphorylation during the G1 phase of the cell cycle. Not surprisingly, these are the regions frequently observed to be deleted or to contain mutations in patients with retinoblastoma. Normal progression through the cell cycle is mediated by phosphorylation of pRb with consequent release of bound transcription factors, which act in a cascading fashion (Fig. 105-6). In cases in which the Rb gene is defective, the G1 block mediated by underphosphorylated pRb is missing, and division with cellular proliferation occurs in a less regulated fashion.

pRB: ROLE IN REGULATING TRANSCRIPTION To date, more than 30 separate cellular proteins have been identified that bind to pRb. This diverse group of proteins has been characterized to include transcription factors, regulators of growth, protein phosphatases, and protein kinases, as well as nuclear matrix proteins. Of these associated proteins, the best described is the transcription factor E2F-1. The E2F binding domain on pRb encompasses both the A and B regions involved in binding to viral oncoproteins and extends beyond these toward the carboxy-terminus. Apparently, the underphosphorylated form of pRb functions to bind and sequester members of the *E2F* family. Since E2F recognition sites are found in the promoters of a number of genes, the interaction between E2F and pRb is significant in growth regulation. The *E2F* consensus nucleotide sequence TTTCGCGC is found in the *TK* promoter, c-*myc*, b-*myb*, Cdc2, *E2F-1*, and, importantly, in the dihydrofolate reductase gene *(DHFR)*. E2F activates transcription of these downstream genes when it is released from binding to pRb. The dihydrofolate reductase gene is active in DNA synthesis which occurs during the S phase of the cell cycle. As indicated in Fig. 105-6, certain members of the E2F family bind to the Rb protein with greater affinity. Other E2F family members demonstrate greater binding affinity for p107 or p130, other members of the retinoblastoma family of genes.

In summary, when pRb is phosphorylated through the action of cyclin-Cdk complexes, E2F is released, which results in upregulation of transcription at targeted consensus sequences in the promoter regions of a variety of growth promoting genes. This includes genes such as the *DHFR* and *DNA polymerase*, which are necessary for DNA synthesis to occur in S phase. The presence of normal underphosphorylated pRb results in sequestration of E2F and its consequent inability to bind to the consensus sequence of numerous downstream genes. This binding may constitute a significant part the pRb-mediated G1 block. The Rb protein may also contain a transrepressor domain which mediates cell cycle arrest when bound to E2F.

pRB AND THE CELL CYCLE Studies investigating the role of the retinoblastoma gene in cell cycle progression have, in the majority of instances, focused on the phosphorylation status of the protein (*see* Chapter 6). Hypophosphorylated Rb protein predominates in G0 and G1, while in the S, G2, and M phases of the cell cycle the Rb protein is hyperphosphorylated. Phosphorylation events occur in at least three phases of the cell cycle: mid G1, S, and in the G2/M transition. Underphosphorylated forms of pRb mediate growth inhibition in G0 and G1 through binding of multiple transcription factors. The mid-G1 phosphorylation of pRb inactivates its tumor suppressor activity. Transcription factors and other proteins are freed to upregulate transcription and to allow the cell to progress through the cell cycle. The phosphorylation status of the retinoblastoma protein and its interactions with other gene products are demonstrated in Figs. 105-5 and 105-6. It appears that physical complex formation between cyclins D1, D2, and D3 with Cdk4, Cdk6, and cyclin E with Cdk2 results in phosphorylation of pRb. Cdks are catalytic subunits which are expressed at stable levels throughout the cell cycle; however, Cdk activity is modulated by cell cycle-dependent changes in the levels of different cyclins.

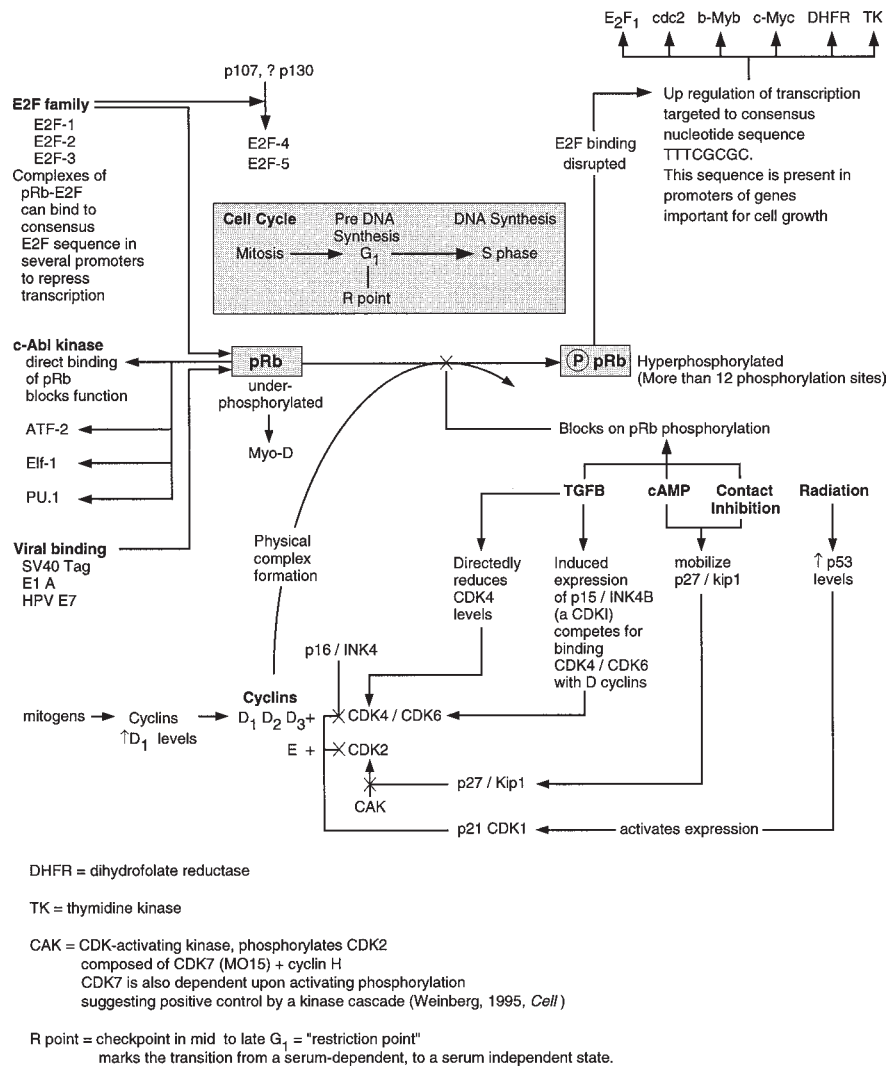
Eventually, the retinoblastoma gene product is restored to its dephosphorylated form, and this process may be mediated by protein phosphatase 1 (PP1). The catalytic subunit of PP1 binds to pRb in vitro. Other phosphatases will likely be identified that are


Figure 105-6 Function of the retinoblastoma gene product.

capable of dephosphorylating pRb. It is the hypophosphorylated form of pRb that binds most strongly to DNA. In addition, the hypophosphorylated form is "tethered" to nuclear structures, as demonstrated in experiments involving the extraction of cellular components through the use of salt and detergent solutions. Consistent with these findings, the hypophosphorylated form binds most specifically to other nuclear proteins. These observations suggest that the phosphorylation of pRb reduces its nuclear interactions, thereby allowing disassociation of Rb protein from the nuclear subcompartment during precise stages of the cell cycle.

In order for critical phosphorylations to occur in this complex protein, serine and threonine residues must be available for the phosphorylation event. The location of these residues is provided in Fig. 105-5. Furthermore, the protein must also contain binding sites for kinases and phosphatases. Given the complex interactions of this gene product with cell cycle proteins, it is reasonable to suggest that large deletions in the gene may have far-reaching effects upon its ability to regulate cell cycle progression.

pRB AND TERMINAL DIFFERENTIATION The role of retinoblastoma gene product in producing terminal differentiation has been carefully studied in muscle differentiation. The product of the retinoblastoma gene was found to bind directly to MyoD, a basic helix loop protein. MyoD appears to act as a muscle-specific transcription factor, capable of activating downstream structural genes in muscle, as well as mediating myogenic differentiation in different cell types. When pRb is inactivated, the progression from myoblast to myotube in culture is inhibited. Myotubes are generally felt to represent terminally differentiated structures; yet these will reenter the cell cycle in the presence of pRb inactivation. In a number of transgenic models, inactivation of the *Rb* gene appears to result in failure of terminal differentiation in neuronal tissues as well as in hematopoietic cells. These cell types are distinguished by the requirement for terminal differentiation in order to achieve full function. Interestingly, in these models muscular development is not affected.

RETINOBLASTOMA-RELATED PROTEINS The retinoblastoma gene is part of a larger family of genes that share homology. p107 and p130 inhibit E2F-mediated transcriptional activation and also appear to produce a G1 block. Whereas the retinoblastoma gene product binds preferentially to E2F-1, E2F-2, and E2F-3, p107 appears to bind preferentially to a distinct subset of the E2F family, E2F-4, and E2F-5. The sequence homology between these genes is greatest in the regions that correspond to the SV40 T antigen-binding domain in the retinoblastoma protein.

These E2F family members may exhibit a tissue-specific activity. For example, growth arrest in cervical carcinoma cells is mediated by p107 but not by pRb. If tissue specificity exists for this family, it could provide one explanation for the observation that patients with retinoblastoma gene mutations initially develop tumors of the retina, and subsequently develop bony tumors, particularly osteogenic sarcoma, at greatly increased frequency. Tissue-specific activity could suggest why children with the germline form of retinoblastoma are not more prone to tumors involving every cell that contains a retinoblastoma gene mutation. In certain tissues, other Rb family members could exert a protective function.

pRB AND CANCER   Study of the retinoblastoma gene and its product must initially focus on normal pathways for cell cycle progression and normal regulatory blocks on this progression. The absence of retinoblastoma gene product has cascading effects on regulation of downstream genes. Regulation of the cell cycle is an important process, which allows time for DNA repair before DNA synthesis occurs. Since the *Rb* gene is ubiquitously expressed, the tissue specificity of tumors that occur in children with retinoblastoma gene deletions has never been adequately explained. Recognition of the retinoblastoma family of genes and the potential for these genes to be tissue-specific in their action is a line of investigation that remains to be fully explored. Clearly, the pathway involving the retinoblastoma gene product is complex and interacts with many other pathways, including those involving cyclins, Cdks, transcription factors, growth factors, and nuclear DNA. As growth regulatory pathways are seen to converge, important points of intersection may be identified where crucial elements could be modified in the treatment of cancer.

MANAGEMENT/TREATMENT

Children with retinoblastoma are difficult to manage because the disease involves an extremely important sensory system, vision, and because in many cases the disease is inherited or is heritable. When families receive this diagnosis for their infant, they almost invariably experience feelings of guilt and responsibility. Siblings and offspring of patients with bilateral retinoblastoma need to be examined by an ophthalmologist early in life, which can place additional stress on the family. The major challenge in clinical management of children with retinoblastoma is to maintain their vision, while minimizing their exposure to second tumor-inducing effects of traditional treatment modalities. Because these patients are at risk for second-tumor development, they need to be monitored closely, including routine imaging of midline brain structures to exclude the development of PNETs. With early detection and treatment, retinoblastoma is a disease that is cured in its primary form in the majority of cases. Morbidity and mortality arise mainly when second tumors develop. Families of children with retinoblastoma require strong and consistent support from physicians committed to long-term tumor surveillance.

STANDARD TREATMENT MODALITIES   The treatment modality first recommended by James Wardrop, and subsequently found to be curative in many cases, is enucleation. This can be an extremely difficult treatment for patients with bilateral disease. In these cases, preservation of both eyes is attempted, if at all possible. Retinoblastoma invades the brain through the optic nerve; therefore, any tumor present at the surgical margin of the optic nerve is an undesirable clinical outcome. The surgical approach to enucleation must facilitate obtaining a long section of optic nerve. In general, when enucleation is performed in

children, the eye is removed with preservation of the conjunctiva, Tenon's capsule, and extraocular muscles. An orbital implant is placed, and this implant is usually integrated with the extraocular muscles so that it will move. The implant is covered completely with layers of Tenon's capsule and conjunctiva so that it is not readily visible. A prosthesis is then fitted over the orbital implant. An unfortunate side effect of enucleation in very small children is that orbital growth may be somewhat diminished in the absence of a viable globe.

External beam radiation is an extremely effective modality for the treatment of primary retinoblastoma. This modality avoids the necessity for enucleation and can provide useful vision in cases where tumors regress away from vital visual structures such as the macula and the optic nerve. Regrettably, external beam radiation therapy does increase the risk for second tumors within the radiation field, and has the unfortunate effect of producing mid-face hypoplasia, particularly in very young patients. Children who have received external beam radiation need to be carefully followed for the development of second tumors both within and outside the field of radiation. Furthermore, endocrine deficiencies can be observed if the hypothalamus and pituitary are in the radiation field, and children should be followed presumptively for endocrine and growth deficiencies. Precise radiation-therapy planning in children with retinoblastoma is extremely important. From an ophthalmologic perspective, the retinal disease needs to be followed carefully for the first 4–5 years of the child's life, as multiple recurrences of bilateral disease typically occur during this period. Lateral radiation ports sometimes can be designed to avoid the lens, eliminating cataract formation, which precludes viewing new neoplasms as these develop. Occasionally, anterior radiation ports are required in the treatment of large tumors, particularly when this is the only option for ocular preservation. In children who receive this treatment, cataracts almost invariably develop. Tumors are then followed for growth with serial ultrasound examinations.

Laser photoablation involves the use of an indirect laser on a head-mounted indirect ophthalmoscope. Tumors of less than 4 mm in basal diameter and less than 4 mm in height are generally amenable to this treatment. The tumor is covered with small laser burns, and the retinal surround is ablated with a lower-power setting. A precise treatment, laser photoablation can be used for tumors anywhere in the eye but is particularly useful for tumors near vital structures, which can be carefully avoided with this modality.

Cryotherapy involves placing a cryoprobe (a freezing metal instrument) on the sclera external to an observed focus of new tumor development. The sclera is indented to confirm the location of the cryoprobe with respect to the tumor with visualization through an indirect ophthalmoscope. The cryoprobe, properly situated, is then activated with a foot pedal. A triple freeze–thaw cryotechnique is performed, which ablates the tumor and the surrounding retina. Cryotherapy is useful in tumors of approximately 4 mm in basal diameter and height. Tumors at the equator or more-anterior locations may be more easily approached through cryotherapy. On the other hand, cryotherapy does incite more intraocular inflammation and produces more pain in children than laser photoablation.

Trials of primary chemotherapy for the treatment of intraocular retinoblastoma have recently been initiated. Preliminary results from groups in the United States, England, France, and Canada

suggest that chemotherapy, especially in combination with laser photoablation, may be useful in treating primary intraocular retinoblastoma. Chemotherapy is also useful as an adjunctive modality in children who have previously undergone external beam radiation therapy and who develop a tumor recurrence that is not amenable to any other treatment modality. Repeat radiation therapy is unlikely to result in good visual outcome, and in these cases, a course of chemotherapy may be considered.

An alternative method of delivering localized radiation directly to a tumor involves suturing a radioactive plaque on the sclera external to the region of tumor occurrence. This modality can be used to treat tumors that are larger than those amenable to laser photoablation or cryotherapy. Less localized than laser photoablation or cryotherapy, plaque therapy is effective in tumors in the far periphery of the eye, where structures vital to vision are not directly affected by the tumor or by the treatment. Complications including radiation vasculopathy and vitreous hemorrhage can occur, particularly if high doses of radiation are delivered through this modality. Furthermore, visual outcomes are not ideal if the plaque is placed posteriorly in the eye in proximity to the optic nerve or macula.

DEVELOPMENT OF NEW INTERNATIONAL CLASSIFICATION SYSTEM TO EVALUATE TREATMENT OUTCOMES The Reese Ellsworth classification system was based on the ophthalmologist's view of retinoblastoma using a direct ophthalmoscope. Since the advent of indirect ophthalmoscopy, tumors anterior to the ocular equator have been associated with better visual outcomes. Tumors at these anterior locations now can be easily visualized and are distant from important visual structures. Retinoblastoma is a rare disease, and, therefore, outcomes from a variety of centers need to be compared in order to provide useful information. At a meeting in Toronto, in July of 1994, consensus for the development of a new international classification system was achieved. Once implemented, this classification system will allow a tumor's size and location to be described uniformly among centers and across countries. This will permit more-objective evaluation of various therapeutic protocols as they emerge, as well as facilitating the assessment of combined modality therapy.

CURRENT STATUS OF GENETIC SCREENING The retinoblastoma gene is large, spanning 180,000 bp. In families where an informative polymorphism is available, restriction fragment length polymorphism (RFLP) analysis is a relatively rapid and straightforward method for genetic screening. This technique, however, is difficult to employ for the great majority of children with this disease, who do not have affected family members. Seventy percent of children with retinoblastoma do not have germline mutations but rather have sporadic somatic mutations occurring within a single retinal cell. Of the remaining 30% of children with the bilateral germinal form of retinoblastoma, only 10% have positive family histories. Genetic testing as it is currently employed with RFLP analysis requires an informative polymorphism, typically found when two or more affected family members' DNA is available for analysis. If blood and tumor DNA are available from only a single patient, the test becomes less informative. However, in these cases, if loss of heterozygosity is observed, the mutant allele often can be identified. An alternative method, sequencing the retinoblastoma gene, is time and labor intensive, and may not provide a result within the appropriate time frame for clinically relevant diagnosis. The need for a rapid test for germline mutation carriers is apparent, and this is a focus of ongoing research.

MONITORING OF CHILDREN FOR SECOND-TUMOR DEVELOPMENT For many years, children with an initial presentation of retinoblastoma were first evaluated with bone scan, lumbar puncture for cerebrospinal fluid cytology, and bone marrow aspirates and biopsies. The routine use of these tests has not yielded any earlier diagnoses of metastatic retinoblastoma, nor have serial bone scans proven to be useful in early diagnosis of osteogenic sarcoma. For this reason, a multidisciplinary clinic has been instituted at the University of California, San Francisco, in which experts with different perspectives and areas of expertise evaluate children with retinoblastoma for long-term cancer risk. In this clinic, children are monitored for endocrine deficiencies resulting from external beam radiation therapy. They are evaluated by a specialist in craniofacial plastics in order to ameliorate problems associated with mid-face hypoplasia in the setting of previous radiation. An ophthalmologist evaluates the patient's vision and retina to exclude the possibility of reactivations in the primary tumor, as well as to exclude radiation- and chemotherapy-related retinopathy and vasculopathy. In many cases, visual rehabilitation devices are recommended. An ocularist is present to refit the prosthesis over the orbital implant as the child grows. Pediatric oncologists perform complete histories and physical examinations on these children. To pinpoint any behavioral problems or learning difficulties, the children are also evaluated by school specialists and nurse specialists. Children are evaluated annually, and an attempt is made to see siblings on the same day. Having children seen in this clinic minimizes the number of physician visits required for each family and allows for discussion of patient problems from a multidisciplinary perspective.

The goal in reducing physician visits while maintaining comprehensive care is to minimize trauma to the child and to the family. This illness is lifelong, potentially familial, and requires surveillance, treatment, and genetic counseling. The emphasis, however, in a yearly clinic visit is on preventive care and on the high rate of cure. We have found that retinoblastoma families provide each other with strong support, and often families arrange to attend this clinic together so that ties established in infancy (when the children may be seen monthly for examinations under anesthesia) are maintained during childhood. Families with a new diagnosis of retinoblastoma are often best reassured by referral to this clinic, where it is apparent that older children with the same diagnosis are leading successful lives.

FUTURE DIRECTIONS

Since the cloning of the retinoblastoma gene, its complex role in regulating transcription and progression through the cell cycle has become the focus of intense research. In certain cells, the retinoblastoma gene product seems to be important in determining terminal differentiation. In many cancers, the retinoblastoma gene is altered or its pathway is deregulated, suggesting that this gene may act along one of several important pathways which should maintain the cell in a nonneoplastic state.

It is very likely that absence of functional retinoblastoma gene product results in deregulation of other downstream genes. When future treatment at the molecular level is considered, simple replacement of the retinoblastoma gene or its product may not completely reverse this cascade of downstream events. As the retinoblastoma gene pathway is clarified, however, important branch points may be identified and possibly reversed. Genetic intervention for this disease will require a more complete under-

standing of the role of the retinoblastoma gene in individual tissues, its normal regulation, and the multiple ways in which it can become deregulated to produce neoplasia.

Retinoblastoma, when it occurs in children, represents a highly penetrant, almost purely genetic cancer. Environmental factors that may act to increase predisposition to adult cancers play a very small role in this disease. If genetic therapy is contemplated, it may be best employed in diseases that are predominantly genetic in origin and that permit early intervention (as in children born of parents with the retinoblastoma phenotype).

Advances are required in genetic testing so that prenatal diagnosis of retinoblastoma can be routinely and reliably established. Early referral of retinoblastoma patients dramatically affects visual outcome and treatment options. When treatment is initiated, multimodality programs should minimize toxicity and second-tumor risk associated with individual modalities. Finally, evaluating treatment outcomes for this rare disease can best be accomplished through multicenter trials utilizing a uniform tumor classification system.

106 Neurofibromatosis

Type 1 and Type 2

JAIME O. CLAUDIO AND GUY A. ROULEAU

INTRODUCTION

Neurofibromatosis is a Mendelian genetic disorder that primarily affects the nervous system. It is characterized by an inherent predisposition to develop tumors of the brain and spinal cord, and a variety of neoplastic abnormalities involving tissues derived from neural crest cells or from the neural ectoderm. It consists of two major types that are genetically and phenotypically distinct: neurofibromatosis type 1 (NF1; OMIM 162200) and neurofibromatosis type 2 (NF2; OMIM 101000).

The first medical description of NF1 can be traced back in the 16th century to an Italian physician and naturalist, Ullise Aldrovandi; but the eponymous credit is ascribed to a German pathologist, Friedrich Daniel von Recklinghausen, who first described the cellular component of the tumors seen in this disease in 1882. However, von Recklinghausen made no distinction between NF1 and NF2 despite the fact that J. H. Wishart, then President of the Royal College of Surgeons of Edinburgh, reported in 1822 the first documented case of NF2; the patient, Michael Blair, suffered from tumors of the dura matter, brain, and both "auditory nerves." The genetic distinction between NF1 and NF2 became clear in 1987 when the genes responsible for these disorders were localized to separate chromosomes. The mapping of the *NF1* locus to the proximal long arm of chromosome 17 and *NF2* to the long arm of chromosome 22 established a precise classification and set the pace for the positional cloning of the *NF1* and *NF2* genes.

COMPARISONS BETWEEN NF1 AND NF2

DIAGNOSTIC CRITERIA The National Institutes of Health Consensus and Development Conference Statement in 1987 recommended the numerical classification of the neurofibromatoses and set up guidelines on diagnostic criteria for NF1 and NF2. This original set of criteria has been expanded for NF2 (Table 106-1) to accommodate diagnosis of individuals with no family history.

CLINICAL FEATURES Although NF1 and NF2 are distinct disorders, both show remarkable variable clinical expressivity. Both disorders usually present early; NF1 at about age 10 and NF2 in early teens or 20s. The major defining features of NF1 include *café au lait* spots, peripheral neurofibromas, and Lisch nodules. Additionally, an NF1 patient may suffer from orthopedic problems such as scoliosis and pseudoarthrosis, may develop plexiform neu-

rofibromas, or may be intellectually handicapped. A fraction of NF1 cases develop myeloid leukemia (OMIM 151410). Tumors such as rhabdomyosarcomas, optic gliomas, phaeochromocytomas, and neurofibrosarcomas may occur. By contrast, the hallmark of NF2 is the occurrence of bilateral vestibular schwannomas; however, schwannomas may occur on any cranial nerve, nerve root, or peripheral nerve. Meningiomas (OMIM 156100) occur in approximately 50% of patients, and ependymomas occur rarely. Optic gliomas do not occur in NF2 but juvenile subcapsular lenticular opacities are common, often presenting before tumors arise, and so may be a useful predictive test for at risk individuals. For NF2, *café au lait* spots and peripheral nerve schwannomas are infrequent, but when present may cause misdiagnosis as NF1. The most useful distinguishing feature for differential diagnosis between the two disorders is the absence of axillary freckling and Lisch nodules, and the lower number of *café au lait* spots in NF2. Furthermore, NF1 individuals never develop bilateral vestibular schwannomas.

There are two subtypes of NF2, often referred to by eponyms: the mild Gardner subtype and the severe Wishart subtype. Gardner is generally characterized by late onset (usually >25 years) of bilateral vestibular schwannomas and few associated brain or spinal tumors. Wishart is a serious and earlier onset subtype (usually <25 years) with rapid and progressive growth of bilateral vestibular schwannomas accompanied by multiple intracranial and spinal schwannomas, meningiomas, and ependymomas.

MOLECULAR GENETICS OF THE NEUROFIBROMATOSES

The predisposition to develop NF1 or NF2 is inherited as an autosomal dominant trait, but the diseases manifest as recessive traits at the cellular level. This genetic paradox is analogous to the two-hit mechanism in retinoblastoma (OMIM 180200), in which an individual inherits a mutant copy of the gene in an autosomal dominant pattern but develops tumors only when an inactivating somatic mutation occurs in the otherwise normal homolog. This results in the recessive expression of the disease phenotype in affected cells leading to tumor formation. Thus, the *NF1* and *NF2* genes are considered as recessive tumor suppressors.

NF1 is a more common disease than NF2, with a birth incidence of 1:3000, compared to 1:37,500 for NF2 (Table 106-2). However, NF2 is a more serious disease, with a mean actuarial survival of 15 years after diagnosis, whereas NF1 does not affect life-span.

Table 106-1
Diagnostic Criteria for NF1 and NF2

I. Neurofibromatosis Type 1

NF1 may be diagnosed in an individual when two or more of the following are present:

1. Six or more *café au lait* macules with diameters of more than 5 mm in prepubescent patients and more than 15 mm in postpubescent patients.
2. One plexiform neurofibroma or two or more neurofibromas of any type.
3. Freckling in the axillary or inguinal region.
4. A distinctive osseous lesion as sphenoid dysplasia or thinning of long-bone cortex, with or without pseudoarthrosis.
5. Optic glioma.
6. Two or more Lisch nodules (iris hamartomas).
7. A parent, sibling or child with neurofibromatosis 1 on the basis of the above criteria.

II. Neurofibromatosis Type 2

NF2 may be diagnosed when one of the following is present:

1. Bilateral eighth cranial nerve masses seen by magnetic resonance imaging with gadolinium.
2. A parent, sibling, or child with NF2 plus:
   a. Unilateral eighth cranial nerve mass or
   b. Any one of the following:
      i. Neurofibroma.
      ii. Meningioma.
      iii. Glioma.
      iv. Schwannoma.
      v. Posterior subcapsular cataract or opacity at a young age.
3. Unilateral vestibular schwannoma plus one or more of the following:
   a. Neurofibroma.
   b. Meningioma.
   c. Glioma.
   d. Schwannoma.
   e. Posterior subcapsular cataract or opacity at a young age.
4. Multiple meningiomas (two or more) plus unilateral vestibular schwannoma.
5. Multiple meningiomas (two or more) plus:
   a. Neurofibroma.
   b. Glioma.
   c. Posterior subcapsular cataract or opacity at a young age.

Table 106-2
Comparisons of NF1 and NF2

Characteristic	NF1	NF2
Other names	von Recklinghausen's disease	Bilateral acoustic neurofibromatosis
	Peripheral neurofibromatosis	Central neurofibromatosis
Chromosomal location	17q11.2	22q12.1
Inheritance	Autosomal dominant	Autosomal dominant
Expression	Recessive	Recessive
Age of onset	First decade	Second decade
Birth incidence	1:3000	1:37,500
Penetrance	Close to 100%	Close to 100%
Mutation rate	$3.0–5.0 \times 10^{-5}$	$1.0–8.0 \times 10^{-6}$

anonymous DNA sequences and cloned genes that detect restriction fragment length polymorphisms (RFLPs), both groups independently identified genetic markers near the centromere that are linked to the *NF1* locus. Fine genetic mapping by an international collaboration established a more precise localization of the *NF1* gene (Fig. 106-1A). Subsequently, two different chromosomal translocations in two NF1 patients, t(1;17) and t(17;22), were mapped to the *NF1* region. These chromosomal abnormalities served as key reagents for the identification of the *NF1* gene and provided evidence that NF1 is caused by loss of function mutations. To search for genes within the translocation breakpoint, screening was focused on genes lying within this region. The mouse leukemia gene, *Evi-2*, maps to the distal region of mouse chromosome 11, which is syntenic to the *NF1* region on human chromosome 17. Studies on the human homolog of *Evi-2* *(EVI2A)* indicated that it mapped in between the two translocation breakpoints, which are 50 kb apart. Subsequently, two other genes, *EVI2B* and oligodendrocyte-myelin glycoprotein *(OMGP)* were discovered within the 50-kb interval. All three genes were considered good candidates for the disease; *Evi-2* is a known proto-oncogene involved in murine myeloid tumors, whereas OMPG is a cell adhesion molecule in myelin of the nerve sheath and expressed only in schwann cells and oligodendrocytes. However, further analyses indicated that none of the three genes were disrupted by either translocation nor was there any sequence alteration within these genes in NF1 patients. Nevertheless, this strategy allowed the cloning of genomic DNA in the region. By searching for phylogenetically conserved DNA fragments and using these to screen cDNA libraries, a gene was identified that spanned the translocation breakpoint. On further analyses, deletions and point mutations within the cDNAs confirmed the identity of the *NF1* gene. Concomitantly, another group reported the insertion of a 500-bp sequence in an NF1 patient that, in subsequent studies, was shown to be an *Alu*I repeat that altered the splicing pattern of the *NF1* gene, thereby causing exon skipping during RNA processing.

The NF1 gene spans at least 350 kb and consists of 59 exons that are processed to yield a transcript of 11–13 kb. Transcription proceeds in telomeric direction opposite to the direction of transcription of the three genes (*EVIA2*, *EVI2B*, and *OMGP*) that are embedded within an intron of the *NF1* gene (Fig. 106-1A). The *NF1* gene encodes for a protein of 2818 amino acids with an estimated molecular weight of 250–320 kDa. The NF1 protein, called neurofibromin, has a central 381-amino acid domain with sequence

Both types share certain genetic features, such as high penetrance and high frequency of new mutations. For example, as many as 50% of cases are reported to have no family history and so represent new mutations. The penetrance for both diseases is close to 100%.

THE *NF1* AND *NF2* GENES   For diseases with no known biochemical abnormality, positional cloning now offers a way to isolate the primary gene defect. The *NF1* and *NF2* genes were identified using this approach. Thus, the search for the gene responsible for each disorder began by mapping the neurofibromatosis loci to specific chromosomes, narrowing down the region, and identifying genes within the defined critical interval. For *NF1*, two translocation breakpoints within the critical region helped identify the gene, whereas big chromosome deletions (which segregated with the disease in families) provided clues for the positional cloning of the *NF2* gene.

IDENTIFICATION OF THE *NF1* GENE AND ITS PROTEIN NEUROFIBROMIN   In 1987, two groups reported the localization of the *NF1* locus to the long arm of chromosome 17. Using

Figure 106-1 **(A)** The *NF1* locus in the pericentromeric region of chromosome 17. Fine genetic mapping by pulsed-field gel electrophoresis identified a 600-kb *Nru*I fragment within which two translocation breakpoints from two NF1 patients were identified. The translocation breakpoints, t(1;17) and t(17;22), were mapped 50 kb apart. Three CpG islands, known marker of the 5' region of a gene, are shown within the *Nru*I fragment. The organization of the 59 exons of the *NF1* gene, shown as black bars, and the three genes originally considered as good candidates (*EVI2A*, *EVI2B*, and *OMPG*) embedded in an intron of the *NF1* gene, are indicated. The three genes are transcribed in centromeric direction opposite to the direction of transcription of the *NF1* gene **(B)**. Regional map of the *NF2* locus on the long arm of chromosome 22. Cosmid contig shown as overlapping horizontal lines provided the path for the chromosome walk leading to the identification of the *NF2* gene. G1, G2, and G3 are gaps within the contig; the G2 and G3 are each spanned by yeast artificial chromosome (YAC). The location of 4 CpG islands is shown in between the markers D22S212 and D22S360. The two patients who showed abnormal fragments as detected by hybridization using C13 and C16 probes are indicated as R2399 and R2142 (the extent of the deletion in each patient is shown). The relative position of EWS, NEFH, NF2, and two unidentified genes are shown. Transcription of all the identified genes proceeds in telomeric direction except for pK1.3 and BAM22 (not shown), which are transcribed in centromeric direction. The NF2 gene is shown with its 17 coding exons in black bars. The position of C13 and C16 probes are also shown (modified from Rouleau et al., 1993).

similarity to p21-*ras* GTPase-activating proteins (GAP) and to IRA1 and IRA2, known yeast inhibitory regulators of the RAS signal transduction pathway. This domain, the NF1-GAP-related domain (NF1-GRD), may be alternatively spliced generating an additional 21-amino acid residue that retains GAP activity.

MUTATION ANALYSIS OF THE *NF1* GENE Deletions, insertions, base substitutions, and splice site mutations in the *NF1* gene have been described in a number of NF1 cases. No hot spot for mutations has yet been identified; however the majority of mutations result in a truncated and presumably nonfunctional protein. Mutations in the *NF1* gene have also been reported in a variety of malignancies and tumor syndromes from non-NF1 patients, including melanomas (OMIM 155600) and neuroblasto-

mas, colon adenocarcinomas, myelodysplastic syndrome, and anaplastic astrocytomas. NF1 patients with mosaicism for an *NF1* mutation have been reported and may explain some cases of "new" mutation in a sibship. A somatic mutation was identified in a benign neurofibroma from an individual with a known constitutional deletion of the other *NF1* allele. Homozygous inactivation of both *NF1* alleles has also been found in the leukemia cells of patients with neurofibromatosis type 1.

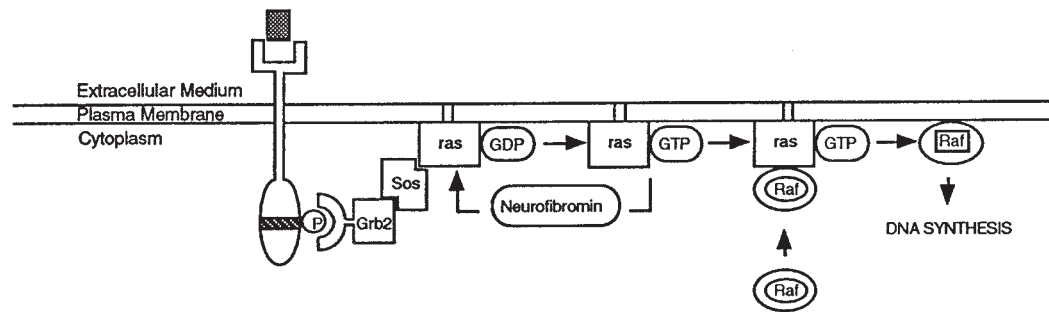
IDENTIFICATION OF THE *NF2* GENE AND ITS PROTEIN SCHWANNOMIN Molecular genetic studies in sporadic and NF2-associated meningiomas and schwannomas originally suggested a common pathogenic mechanism for these tumors by the loss of heterozygosity for distinct chromosome 22 loci. These

results were the starting point for genetic linkage analysis in NF2 pedigrees. An anonymous RFLP marker, D22S1, frequently reduced to hemizygosity in NF2-related tumors, was used to map the *NF2* gene to the long arm of chromosome 22. A combination of multipoint linkage analysis using a large kindred and molecular analysis of NF2 tumors with either interstitial or terminal deletions of chromosome 22 resulted in the exclusion of two possible candidate genes in the region. These genes include the "breakpoint cluster region" (BCR) implicated in the t(9;22) Philadelphia chromosome characteristically seen in chronic myelogenous leukemia (OMIM 151410) and the PDGF-β, the homolog of the *sis* oncogene that encodes the platelet derived growth factor (PDGF). As more closely linked polymorphic markers were developed, it became possible to analyze families for genetic heterogeneity. Such study led to the conclusion that NF2 is a genetically homogeneous disease involving only one major gene, distinct from the *NF1* gene on chromosome 17. Further segregation studies in affected families and characterization of large germline deletions in NF2 pedigrees narrowed the localization of the *NF2* locus to the interval flanked by D22S212 and D22S32, a one million-bp region small enough to positionally clone the *NF2* gene (Figure 106-1B).

As part of the cloning strategy, unrelated NF2 individuals were screened for chromosomal rearrangement within this 1-Mb interval using pulsed-field gel electrophoresis (PFGE) and single-copy DNA probes. Yeast artificial chromosome (YAC) and cosmid contiguous sequences, known as contigs, spanning the candidate region were constructed to provide the path for the chromosome walk to identify candidate genes (Figure 106-1B). This process uncovered two major probes for the identification of the gene. One probe, C16, detected an abnormal fragment in two individuals with NF2, whereas another probe, C13, located 40 kb centromeric to C16, was deleted in both patients (Figure 106-1B). Further characterization of the C13 probe showed that it is phylogenetically conserved, suggesting that a gene may be encoded within this DNA fragment. Using C13 to screen a fetal human cDNA library, a 2-kb cDNA clone (N1.1) was isolated that mapped backed by fluorescence *in situ* hybridization to the NF2 region. When the gene isolated was screened for mutations in NF2 individuals, sequence alterations were found that segregated with the disease. Independently, by chromosome walking and a combination of exon trapping and cDNA library screening, another group identified a candidate cDNA with a sequence identical to N1.1. Together, these data provided incontrovertible evidence that the cloned cDNA encodes for the protein mutated in NF2.

The *NF2* gene spans about 100 kb of genomic sequence and consists of at least 17 exons that encodes for a 595-amino acid protein called schwannomin (alternately merlin), with an estimated molecular weight of 69–80 kDa. In human tissue Northern blots, transcripts of different sizes (7.0, 4.4, and 2.6 kb) are expressed ubiquitously. It is uncertain whether these transcripts are generated by alternate polyadenylation signal or by alternative splicing of the *NF2* gene. Indeed, there are reports of different splicing patterns of the *NF2* gene, but the biological significance of the mRNA variants has not yet been understood.

Schwannomin belongs to a gene superfamily involved in linking plasma membrane protein to the cytoskeleton. This superfamily includes erythrocyte band 4.1, talin, a group of proteins known as the ezrin, radixin, and moesin (ERM) family and a rapidly expanding family of protein tyrosine phosphatases (Figure 106-2).
Figure 106-2 Schematic structural model of schwannomin and related proteins. Schwannomin belongs to a superfamily that includes erythrocyte band 4.1, talin, ERM family, and protein tyrosine phosphatase family. The members of this superfamily have common structural organization: a globular amino-terminal domain followed by a region rich in α-helical structure and a highly charged carboxy-terminal domain. The overall homology of schwannomin to the ERM proteins is 48% but the amino-terminal half of schwannomin is 62% identical to the same region in ERM family. Lower amino acid homology is seen between band 4.1, protein tyrosine phosphatases, and talin (~43% at the amino-terminus). The tyrosine phosphorylation sites for ezrin are conserved in the ERM family but not in schwannomin. The putative tyrosine phosphorylation sites of two of the tyrosine phosphatases are also shown. The last 32 amino acids at the carboxy-terminus of the ERM proteins are responsible for binding to actin; the amino terminal region binds to CD44. The actin-binding domain of the ERM family is not conserved in schwannomin. The amino-terminal domain of band 4.1 interacts with glycophorin C and its carboxy-terminal domain binds to the actin-spectrin complex in erythrocytes. Similarly, talin links integrins to vinculin through its amino- and carboxy-terminal domains, respectively.

MUTATION STUDIES OF THE *NF2* GENE Identification of inactivating mutations in tumors from NF2 patients, in sporadic schwannomas and meningiomas, and in other tumors not seen in NF2 provided evidence that the *NF2* gene is involved in the genesis of these tumors. Parallel mutation analyses of blood and tumor DNA had confirmed the two-hit mechanism of tumorigenesis in NF2 and proved that the *NF2* gene encodes for a recessive tumor suppressor. The observation that the *NF2* gene is mutated in the majority of sporadic meningiomas put to an end the controversy that another gene, closely linked to *NF2*, is implicated in the genesis of meningiomas. About 40% of meningiomas have no chromosome 22 abnormalities, suggesting that a yet-unidentified gene on another autosome must be involved. Evidence supporting a major role of the *NF2* gene in other tumors like melanomas, breast carcinomas, and mesotheliomas (OMIM 156240) has not been


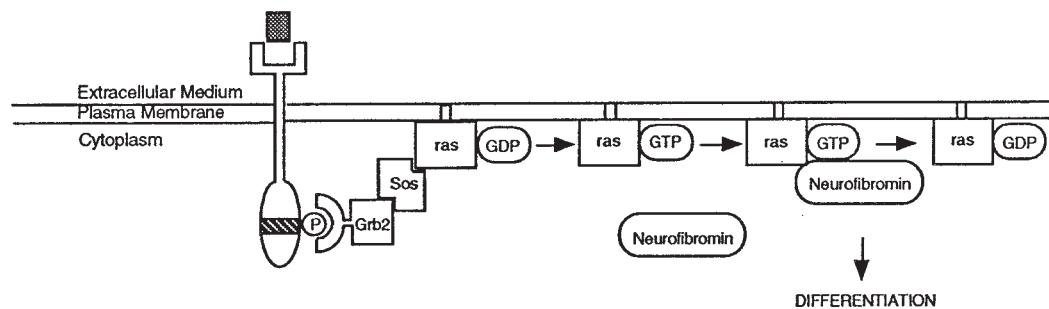


Figure 106-3 Models of neurofibromin function. **(A)** Upstream model depicting neurofibromin as downregulator of p21-*ras* activity. A growth factor interacting with its receptor initiates the signaling process through p21-*ras* protein. Binding of the growth factor results in phosphorylation of the receptor which, in turn, results in binding of Grb2/Sos to the receptor. This process activates p21-*ras* by promoting exchange of bound GDP for GTP. The level of accumulation of active p21-*ras*-GTP depends on the degree of activation by Sos and the degree of inactivation by neurofibromin, which promotes the hydrolysis of GTP. The activation of p21-*ras* leads to recruitment and activation of cytoplasmic Raf, thereby initiating a kinase cascade by a pathway that is not yet well-defined. This process results in DNA synthesis leading to cell division. **(B)** Downstream model of neurofibromin as an effector of differentiation, either alone or in complex with p21-*ras*. The binding of a growth factor to its receptor promotes phosphorylation of the receptor that, in turn, results in binding of Grb2/Sos to the receptor. The amino-terminal domain of Sos then activates p21-*ras* by exchange of GDP to GTP. The activation of p21-*ras* allows it to interact with neurofibromin; such interaction allows neurofibromin (or in complex with p21-*ras*) to act as an effector of the *ras*-mediated differentiation signal. Loss of function of neurofibromin would cause inhibition of the differentiation signal, and in effect promote cell division.

compelling, and no mutation of the *NF2* gene has been found in gliomas (OMIM 137800).

Most *NF2* gene mutations that have been identified result in truncated protein that is presumably nonfunctional. Missense mutations are rare and comprise only a minor percentage of mutations.

Germline mutation analyses correlating genotype to phenotype have not been conclusive. Three comprehensive studies have suggested that mild manifestations of the disease seem associated with mutations that preserve the C-terminus of the protein or with alterations involving missense or in-frame small deletions. Germline mutations have been identified in only about one-third of NF2 patients screened for alteration in the entire coding region of the *NF2* gene. However, because of the genetic homogeneity of *NF2*, it is unlikely that there is another gene involved. The most reasonable explanation for the unaccounted mutations is the possibility that mutations occur within the promoter and other regulatory sequences, and because large deletions affecting both intron and exons are not detected by polymerase chain reaction (PCR) screening method. No hot spot for mutation has been identified.

FUNCTIONAL ANALYSIS OF NEUROFIBROMIN AND SCHWANNOMIN

NEUROFIBROMIN   A clue to the function of neurofibromin came from the sequence homology of its central domain to mammalian GAP and to yeast IRA1 and IRA2. These proteins downregulate p21-*ras* by accelerating the hydrolysis of p21-*ras*-GTP to inactive p21-*ras*-GDP. Thus, a mutant neurofibromin is thought to be unable to control the continuous mitogenic signal brought about by the unrestricted activity of p21-*ras*. The first evidence supporting this paradigm known as the "upstream model" (Fig. 106-3A) came from experiments in yeast transfected with the NF1-GRD. Expression of the NF1-GRD in yeast promoted the hydrolysis of GTP by p21-*ras* and was able to complement the heat-shock sensitive phenotype of *ira1* and *ira2* yeast mutants. However, there are observations that contradict this model. For example, active p21-*ras* does not accumulate in mutant cells whose neurofibromin has been lost by mutation, such as neuroblastoma and melanoma cell lines; activated p21-*ras* can cause cell cycle arrest in rat schwann cells, and induce differentiation and block proliferation in rat phaeochromocytoma cell line PC12; and third, other members of the *ras* superfamily, like R-*ras* p23 protein, which

is regulated by neurofibromin and interacts with Bcl-2, a suppressor of programmed cell death (apoptosis), are expected to be affected by the loss of neurofibromin, thereby altering the apoptotic function of Bcl-2. These discrepancies can be explained by an alternate model known as the "downstream model," which postulates that neurofibromin receives a signal from activated p21-*ras* to promote differentiation (Fig. 106-3B). Therefore, a mutant neurofibromin would be unable to block cell proliferation because it can no longer affect cell differentiation from a p21-*ras* signal.

Further evidence supporting the model that neurofibromin may function as a negative regulator of p21-*ras* is derived from experiments on primary cell cultures of schwann cells, and neural crest- and placode-derived sensory neurons from *Nf1* (–/–) embryos. Whereas *Nf1* (–/–) neurons extend neurites and survive without neurotrophins in vitro, their wild-type counterparts die rapidly in the absence of NGF and BDNF. Schwann cells from null mutant embryos develop elaborate processes and, like the neurons from these mutant mice, have elevated levels of Ras-GTP. *Nf1* (–/–) neurons survive and acquire mature morphological characteristics in the absence of neurotrophins, just as if Ras signaling pathways were activated constitutively. Similarly, studies on hematopoietic cells from *Nf1* (–/–) mice showed that loss of the *Nf1* gene leads to an increased and prolonged rise in Ras-GTP levels in myeloid cells after granulocyte/macrophage colony stimulating factor (GM-CSF) stimulation, defining a role for neurofibromin in regulating GM-CSF signaling through Ras in hematopoietic cells.

Studies on the subcellular distribution of neurofibromin showed that it can associate with cytoplasmic microtubules. It is postulated that the interaction of neurofibromin to tubulin reduces its ability to downregulate p21-*ras*. This observation suggests that neurofibromin may suppress tumor formation in normal cells by an even more complex mechanism.

SCHWANNOMIN   The homology of schwannomin to a group of proteins known to function in maintaining cellular integrity provides evidence of a novel site of action of tumorigenesis. Although there is no current working model for the molecular basis of schwannomin in suppressing tumors of the nervous system, knowledge of its function has been based primarily on studies of members of the band 4.1 superfamily (Fig. 106-2). For example, schwannomin is postulated to normally act like erythrocyte band 4.1, which links transmembrane glycoproteins to the spectrin–actin complex of the cytoskeleton; or like talin, which interacts with vinculin and integrins, thereby regulating organization of cell shape. More closely related to schwannomin are ezrin, radixin, and moesin, which act as structural linkers between cell surface glycoprotein CD44 and actin-based cytoskeleton. These proteins are found preferentially in dynamic structures; ezrin is found in actin-containing cell-surface structures, moesin is found in microspikes, blebs, retraction fibers, filopodia, and lamellipodia; radixin is found in the cell-to-cell adherens junctions. Mutation of schwannomin may thus lead to unstable cell–cell and cell–matrix interactions leading to changes in cell shape, loss of contact inhibition, and cell migration. The transient phosphorylation of ezrin on tyrosine residues following exposure to epidermal growth factor, and of radixin in response to PDGF, provide insights into possible activation of schwannomin by a receptor-specific mechanism leading to a possible downstream signaling pathway. However, although schwannomin has several putative tyrosine phosphorylation sites, no phosphorylation site involved in a putative signaling pathway has been identified by in vivo or in vitro experiments.

Studies on the expression of schwannomin in human and mouse tissues show widespread but cell type-specific expression. It is expressed in neural crest-derived cells, endothelial cells, and erythrocytes. Functional studies of schwannomin in vitro have demonstrated that it can reverse the v-Ha-*ras*-induced anchorage-independent phenotype of NIH-3T3 cells. Additionally, when NIH-3T3 fibroblasts are transfected with the full-length NF2 cDNA, a concomitant one-third reduction of growth rate, as well as phenotypic changes (such as extension of varying number of thin processes) are observed compared to controls. These data support the tumor suppressor function of the *NF2* gene.

ANIMAL MODELS

Various breeds of domestic cattle are thought to develop multiple neurofibromas and schwannomas. Similarly, neurofibromas, schwannomas, and neurofibrosarcomas are known to develop in bicolor damsel fish. These are often cited as models of NF1 although they do not completely mimic the human disease. Several attempts to use chemical mutagens to introduce mutation and consequently generate mice with the neurofibromatosis phenotype have been unsuccessful in the past. Therefore, the technology of using embryonic stem cells to introduce mutations in mice, known as the "knockout" technique, remained the best recourse to model the disease. The identification and subsequent findings of high conservation of the mouse homologs of the *NF1* and *NF2* genes made it possible to study the genetic defect in mice using this strategy. Experiments to model *NF1* and *NF2* by gene targeting have generated mice that are genetically identical to neurofibromatosis patients. For *NF1*, a heterozygous mouse mutant has been generated by disruption of the gene by homologous recombination. Homozygous mutant embryos die *in utero* at around 14.5 days postcoitum due to severe malformation of the heart and hyperplasia of neural crest-derived sympathetic ganglia. This finding, not surprising since no human homozygote has been identified, suggests that neurofibromin plays an important role in cardiac organogenesis. Heterozygous animals do not develop the clinical abnormalities characteristic of the human disease, but they have increased predisposition to develop phaeochromocytoma and myeloid leukemia, two phenotypes that are seen, albeit infrequently, in NF1. They also exhibit learning and memory deficits. Similar efforts to generate NF2 mutant mice have confirmed that embryonic lethality defines the phenotype of homozygous mice. Although the exact clinical phenotype of both disorders are hardly reproducible in mice, these heterozygous mutant mice will be useful in understanding the molecular pathogenesis of the disorder and designing efficient therapeutic approaches.

MANAGEMENT AND THERAPEUTIC OPTIONS

Neurofibromatosis is an extremely difficult disease to manage because it involves the coordination of different health care professionals such as neurosurgeons, genetic counselors, otolaryngologists, opthalmologists, educational psychologists, and dermatologists, among others. The disfiguring defect, dermal neurofibroma, and learning disabilities in children with NF1 require strong psychosocial support. Similarly, NF2 patients may need social support from teachers of communication of the deaf. As at-risk individuals have a 50% chance of transmitting the disease to their offspring, proper management of neurofibromatosis patients includes genetic counseling. Currently, multidisciplinary centers in North America and Europe and several lay organizations are working as support

groups for neurofibromatosis patients. Information about the National Neurofibromatosis Foundation can be accessed through the internet at http://www.neurofibromatosis.org.

Because of the variable clinical expressivity of the disease, management and treatment vary with each patient, even within families. Surgery is still the mainstay of treatment for NF1 and NF2. Treatments for symptomatic patients with NF2 include radiotherapy, including gamma knife treatment, although surgery remains the treatment of choice. The prognosis for surgical excision is very good.

FUTURE PROSPECTS

The cloning of the genes for NF1 and NF2 has made the screening of at-risk individuals possible by molecular genetic analysis rather than by undergoing a series of neurological, ophthalmological, and audiometric tests. However, genetic testing is not yet readily available except in nonservice research laboratories studying the disease. Given the large size of both genes, especially *NF1*, direct DNA mutation screening will take a few years to become economically feasible and easily accessible. An alternative method to direct mutation screening by DNA analysis lies in the observation that the majority of mutations are predicted to result in truncated proteins. Thus a protein with altered size can be readily detected by a combination of reverse transcription-PCR and in vitro translation known as protein truncation assay. However, this method only predicts the site of mutation and thus still has to be complemented with a routine technique of DNA analysis.

The prospects of gene therapy are still uncertain. However, a better understanding of the molecular pathogenesis of the disease may provide clues in developing chemotherapeutic agents. This conventional approach may be a more practical method of providing more immediate therapeutic options for patients with neurofibromatosis.

107 Brain Tumors

Mark A. Israel

INTRODUCTION

Tumors of the central nervous system (CNS) are a remarkably diverse group of neoplasms and the diversity of their origins is reflected in their biological behavior and clinical manifestations. Primary CNS tumors occur infrequently compared to other tumor types, yet approximately 15,000–20,000 Americans are afflicted each year. In contrast to the relative rarity of these tumors in adults, brain tumors are the second most common type of tumor seen during childhood occurring with an incidence of 2.2–2.5 cases per 100,000 children per year. The incidence of brain tumors wanes during early adulthood, although they again occur with increasing frequency in the fourth decade of life, after which the incidence continues to increase. The incidence of brain tumors in the elderly is rising, although the reason for this is unknown.

CLINICAL PRESENTATION

Depending on the site of occurrence and the degree to which a tumor has progressed at presentation, an individual's signs and symptoms may be focal or diffuse. Small, slow-growing tumors deep in the brain may have few, if any, clinical manifestations, while a rapidly growing tumor of the motor cortex can have profound consequences early in its course. Since specific functions reside in characteristic locations in the brain, the site of a tumor can often be predicted by deficits identified during a neurological examination. Eventually symptoms attributable to increased intracranial pressure such as morning headache, vomiting, and lethargy predominate if the flow of cerebral spinal fluid is compromised. The most common presenting symptom in all age groups is headache, and seizures are the second most common. Other more subtle symptoms include personality changes and gastrointestinal disturbance. Typically symptoms develop over a subacute or chronic course. Rarely, the onset of symptoms is acute and may be associated with compression of critical brain regions in the temporal lobe or cerebellum against the skull (herniation), requiring immediate intervention.

Tumors that occur at CNS sites other than the cerebrum, such as the base of the skull, the cerebellum, or the brain stem may have distinctive clinical characteristics. Schwannomas occurring in the acoustic nerve may cause a cerebellopontine angle syndrome including disturbances of hearing, balance, taste, and sensation on the face. Posterior fossa tumors oftentimes lead to deficits of gait, coordination, and balance, while brain-stem lesions are associated with cranial nerve dysfunction. Tumors of the spinal cord may present with local symptoms attributable to a tumor's location along the spinal column or with symptoms that occur at a site distant from the tumor due to involvement of sensory and motor neuronal tracts.

Approximately 25% of tumors occurring outside the CNS eventually metastasize to the brain, although this is more common in adults than in children. Carcinomas of the lung, breast, and colon, as well as melanoma and renal cell carcinoma, are among the most common such tumors. Their signs and symptoms mimic those of primary brain tumors occurring at similar locations. Frequently there are multiple sites of metastatic involvement when a patient presents for treatment. While primary intracranial tumors of adults rarely metastasize, brain tumors of children more frequently spread throughout the neuroaxis and to distant sites, causing otherwise unexpected symptoms.

PATHOLOGY

Approximately 60% of primary brain tumors arising in adults exhibit cytological and immunohistochemical evidence of astrocytic lineage. Oligodendrogliomas are less frequent, accounting for only about 5% of glial tumors. Mixed tumors expressing evidence of both astrocytic and oligodendroglial differentiation are rather commonly seen. Brain tumors of adults very rarely exhibit evidence of neuronal differentiation. During childhood a different spectrum of brain tumors is observed. The most common childhood brain tumors are supratentorial, low-grade astrocytomas, although astrocytomas of the cerebellum and brain stem occur almost as frequently. Medulloblastoma is the third most common brain tumor that occurs during childhood.

Several different nosologies have been proposed for the pathological classification of brain tumors, since the pioneering work of Cushing and Bailey. The World Health Organization (WHO) classification of CNS tumors, now the most widely used, incorporates three separate types of criteria based on anatomical site, histologic type, and degree of malignancy (Table 107-1). The pathology of astrocytic tumors is particularly relevant to this text because most advances in our understanding of the molecular basis for the malignant behavior of CNS tumors have been in the characterization of astrocytomas. Typically these tumors are infiltrative, and they are morphologically and cytologically heterogeneous. Various grading schema for astrocytic tumors have been proposed. These share a focus on the degree of tumor cell anaplasia.

Table 107-1
Pathological Classification of Central Nervous System Tumors According to the World Health Organization

Tumors of neuroepithelial tissue	**Cysts and tumor-like lesions**
Astrocytic tumors	Rathke cleft cyst
Oligodendroglial tumors	Epidermoid cyst
Ependymal tumors	Dermoid cyst
Mixed gliomas	Colloid cyst of the third ventricle
Choroid plexus tumors	Enterogenous cyst
Neuroepithelial tumors of uncertain origin	Neuroglial cyst
Neuronal and mixed neuronal-glial tumors	Granular cell tumor
Pineal parenchymal tumors	Hypothalamic neuronal hamartoma
Embryonal tumors	Nasal glial heterotopia
Tumors of cranial and spinal nerves	Plasma cell granuloma
Schwannoma	**Tumors of the sellar region**
Neurofibroma	Pituitary adenoma
Malignant peripheral nerve sheath tumor	Pituitary carcinoma
Tumors of the meninges	Craniopharyngioma
Tumors of meningothelial cells	**Local extensions from regional tumors**
Mesenchymal, nonmeningothelial tumors	Paraganglioma
Primary melanocytic lesions	Chordoma
Tumors of uncertain histogenesis	Chondroma
Lymphomas and hemopoietic neoplasma	Carcinoma
Malignant lymphomas	**Metastatic tumors**
Plasmacytoma	**Unclassified tumors**
Granulocytic sarcoma	
Others	
Germ cell tumors	
Germinoma	
Embryonal carcinoma	
Yolk sac tumor	
Choriocarcinoma	
Teratoma	
Mixed germ cell tumors	

CLINICAL EVALUATION

Patients in whom a brain tumor is suspected should undergo imaging studies. Evaluation of such patients has been greatly facilitated by the development of sensitive and specific modalities of neuroimaging. Computerized tomography (CT) and magnetic resonance imaging (MRI) both with and without contrast enhancing agents are the mainstays of diagnosis and patient evaluation. Enhancing agents are of particular usefulness in high-grade tumors, as these typically increase contrast between normal and malignant tissue.

MRI is the preferred diagnostic technique because it gives a more accurate image of tumor margins and is more sensitive than CT in identifying hydrocephalus and in evaluating tumor associated edema and hemorrhage. MRI also provides multiplanar images that assist in treatment planning. Most CNS tumors are visible on MRI scanning, although as many as 50% of some tumor types, such as low-grade gliomas, do not enhance with gadolinium. Other tests, such as visual field evaluations and electroencephalography, may contribute to the evaluation of brain tumor patients.

MOLECULAR MECHANISMS AND GENETICS

The recognition of cancer as a disorder of genes has provided impetus for the molecular analysis of brain tumors and focused attention on the possibility of identifying new agents and new modalities of treatment. Cancer arises when mutations that provide a growth advantage to cells lead to their unregulated prolif-

eration within the CNS (Table 107-2). Tumor suppressor genes and oncogenes are two distinctive groups of genes that contribute to the development of brain tumors. Mutations in tumor suppressor genes can inactivate their ability to inhibit cell growth, whereas oncogenes contribute to cancer because inappropriate expression or expression of an altered protein stimulates cell growth. Tumor suppressor genes function recessively, and both alleles of a tumor suppressor gene must be inactivated for its phenotype to be manifest (*see* Chapter 105). Oncogenes act dominantly and mutation of one allele confers an altered phenotype on affected cells. Such a mechanism of dominant cellular activation has been found in Gds mutations in somatotropes (*see* Chapter 48).

CANCER PREDISPOSITION A predisposition for the development of brain tumors has been recognized as a part of several different complex inherited syndromes (Table 107-3). Some of these syndromes present with signs and symptoms attributable to multisystem disorders, and malignant tumors are only one of many disabling or life-threatening manifestations of the disorder. Other heritable syndromes have as their primary manifestation the development of malignant tumors. Tumor suppressor genes are responsible for some of these syndromes, a finding consistent with the model of tumorigenesis, first put forth by Knudson.

The familial occurrence of tumors is most evident when the inherited predisposition is widely expressed throughout the affected family. The Li-Fraumeni syndrome (OMIM 151623) is such a disorder that frequently results from the inheritance of a

Table 107-2
Frequently Occurring Cytogenetic and Genetic Alterations in Brain Tumors

Tumor	Cytogenetic changes	Genetic alterations
Astrocytoma	1p⁻,9p⁻,del10,13q⁻, 17p⁻,17q⁻,19q,22p⁻,DMs[a]	P53,RB1,NF1,EGFR, C-ros,met,gli,c-myc,ckd4,neu,ras
Oligodendroglioma	1p⁻,9p⁻,19q⁻	
Medulloblastoma	17p⁻,6q⁻,16q,DMs	
Meningioma	22q⁻	NF2

[a]DMs, double minute chromosomes.

Table 107-3
Hereditary Syndromes Associated with Brain Tumors

Hereditary disorder	OMIM no.	Prominently associated CNS malignancies
Syndromes with multisystem presentations		
Neurofibromatosis Type I	162200	Glioma
Neurofibromatosis Type II	101000	Meningioma, acoustic neuroma, schwannoma, ependymoma
Tuberous sclerosis	191100	Giant cell astrocytoma
von Hippel-Lindau	193300	Hemangioblastoma
Ataxia-telangiectasia	208900	Glioma
Common variable immunodeficiency	240500	Glioma
Syndromes with cancer as primary symptoms		
Turcot syndrome	276300	Medulloblastoma
Li-Fraumeni syndrome	151623	Glioma, medulloblastoma, ependymoma, choroid plexus
Hereditary retinoblastoma	180200	Retinoblastoma, pineablastoma
Gorlin syndrome	109400	Medulloblastoma, meningioma

mutated *p53* gene (*see* Chapter 7). Members of families affected by this syndrome typically have an increased frequency of many different tumors that occur earlier in life than is expected when they occur sporadically. Gliomas tend to be among the commonly occurring brain tumors, although medulloblastomas and choroid plexus tumors also occur. *p53* germline mutations have also been identified in young patients with glioblastoma who do not have a family history of brain tumors or increased tumor incidence. Patients with multifocal astrocytomas are also more likely than other glioma patients to have germline *p53* mutations.

Another cancer predisposition syndrome in which brain tumors are a particularly prominent characteristic and the molecular basis is known is Turcot's syndrome (OMIM 276300). Affected patients, who typically have both a malignant brain tumor and multiple colorectal adenomas, can carry germ-line mutations of either the *APC* gene or a DNA mismatch-repair gene (*see* Chapter 7). A predisposition for the development of brain tumors is clearly associated with other inherited disorders in which the development of malignancy may not be the first or primary manifestation of the inherited syndrome (Table 107-3). The two most widely recognized groups of such disorders are the phacomatoses and the immunodeficiency syndromes. Neurofibromatosis occurs in patients with mutations in the *NF1* gene, which functions in a signal transduction pathway important for cell growth. *NF1* (OMIM 162200) was cloned following localization of this locus to chromosome 17q11.2 by extensive linkage analysis and the identification of two neurofibromatosis patients with chromosomal translocation breakpoints at 17q11.2 (*see* Chapter 106). Using DNA from patients with these breakpoints, the *NF1* gene was identified as being interrupted by the rearrangement and recognized to encode a guanosine triphosphatase activating protein, neurofibromin. Brain tumors are the most lethal manifestation of neurofibromato-

sis. Tuberous sclerosis (OMIM 191100) also predisposes to CNS malignancies, and mutations have been identified recently in the TSC1 (tuberous sclerosis complex 1) gene on chromosome 9q34.

MOLECULAR PATHOLOGY OF BRAIN TUMORS
Astrocytomas The different histologic grades of astrocytomas in adults correspond to clonal populations of malignant cells that acquire sequential genetic alterations. Each mutation provides an additional growth advantage to the tumor cell leading to that cell becoming the predominant cell type and the most likely target for the next mutation. This model is consistent with clinical experience that documents highly malignant tumors arising within low-grade tumors. Other data relevant to this model come from the evaluation of tumors of different histologic grades for a number of different oncogenetic alterations. Genetic changes observed in low-grade tumors are also found in higher grade tumors, while other alterations seem to occur only in tumors of the highest malignant grades. To date, the study of astrocytic tumors has focused on the loss of DNA from chromosomes 1p, 9p, 10, 13q, two different loci on chromosome 17p, 17q, 19q, and the telomeric portion of 22q. At some of these loci, known or putative tumor suppressor genes are located. Deletions in 9p21-9p22 probably target *CDKN2*, which encodes a known tumor suppressor gene, *P16*. *P16* is an inhibitor of cdk4, a cyclin-dependent kinase that functions to promote cell growth. Interestingly, cdk4 is sometimes amplified in glioblastomas that have a normal *P16*.

p53, located on chromosome 17p, has been found to be mutated in approximately 30–40% of gliomas. The frequency of *p53* mutation does not vary among the different histologic grades of tumor. The retinoblastoma gene, *RB1* (OMIM 180200), is a well-characterized tumor suppressor gene located on chromosome 13q14 (*see* Chapter 105). Disruption of the *RB1* locus and mutations in the *RB1* gene have been found in all grades of astrocytoma

suggesting a role for *RB1* in the development of astrocytomas. The *NF1* locus at 17q is a likely candidate for being the gene altered in those tumors that show cytogenetic evidence of DNA loss in this chromosomal region, although *NF1* involvement in sporadically occurring gliomas has not been well-defined. No convincing evidence of the involvement of specific genes has yet emerged for other chromosomal sites altered in astrocytomas. Deletion of chromosome 10 occurs in up to 80% of glioblastomas and is seen rarely in low-grade astrocytomas. Loss of chromosome 10 occurs frequently, but smaller deletions suggest that different loci on 10p and 10q24 may be involved. A tumor suppressor gene *(PTEN)*, which encodes a putative protein tyrosine phosphatase gene, has been localized to chromosome 10q23. Mutations in *PTEN* have been found in one-third of glioblastoma cell lines and in 17% of primary glioblastomas.

Little is known regarding the oncogenes that may be important in the pathogenesis of astrocytic tumors. The oncogene most frequently implicated is *EGFR*, which encodes the epidermal growth factor (EGF) receptor. *EGFR* is amplified and mutated in glioblastomas. These altered forms of the molecule may contribute to unregulated growth by assuming a conformation corresponding to the activated form of the receptor. Other oncogenes activated in gliomas, albeit infrequently, include c-*ros*, *met*, and *Neu* (c-*erbB-2*), *MYC*, *HRAS*, and *NRAS*, which have all been observed to be highly-expressed in some glial tumors, although their contributions to tumorigenesis are unknown.

Pilocytic astrocytomas frequently have a rather benign clinical course, and their precise relationship to other astrocytomas is not understood. *p53* mutations are rare in pilocytic astrocytomas. Also, while the occurrence of these tumors in patients with neurofibromatosis strongly suggests that this gene will be involved in sporadic pilocytic astrocytomas, mutations in *NF1* have not yet been detected in pilocytic astrocytomas.

Oligodendrogliomas   Cytogenetic studies of oligodendrogliomas have shown frequent deletions of chromosomes 1p, 9p, and 19q13.2–13.4, although in none of these locations have specific tumor suppressor genes been implicated. The *p53* locus has been examined in a number of oligodendrogliomas and mixed oligoastrocytomas, although evidence for mutations was found in less than 10% of tumors examined. *EGFR* is not amplified in oligodendrogliomas, and other oncogenes have not been implicated.

Meningiomas   Most meningiomas (OMIM: 156100) arise from cells of the arachnoid membrane and are typically benign, although they have a distinct propensity to recur. These tumors occur frequently in patients with neurofibromatosis type 2 (NF2; OMIM 101000), which occurs as a result of mutations of the *NF2* gene on chromosome 22q. Since deletion of chromosome 22q is found frequently in both vestibular schwannomas and meningiomas, tumors that occur in patients with NF2, the *NF2* gene is likely to be inactivated in sporadic meningiomas, although this has not yet been documented. There is also preliminary evidence for a second tumor suppressor locus on 22q that contributes to the pathogenesis of meningiomas. No oncogenes are known to be amplified in meningiomas, and deletion or mutation of *p53* occurs infrequently. Deletions of loci on chromosomes 1p, 9q, and 17p have been observed in malignant meningiomas, which occur infrequently.

Medulloblastomas   Medulloblastomas (OMIM 155255) occur most commonly in children, and are seen frequently in two inherited cancer syndromes, the Turcot syndrome and Gorlin's syndrome (OMIM 109400). In Turcot syndrome, familial adenoma-tosis of the colon is combined with CNS tumors, including both glioma and medulloblastoma. The APC gene is mutated in the germ line of patients with Turcot syndrome, but this gene has not been found to be altered in sporadically occurring medulloblastomas. In Gorlin's syndrome, multiple basal cell carcinomas are associated with medulloblastoma. The gene for this syndrome is on chromosome 9q22.3–31, but evidence for the loss of genetic material at these loci is infrequently found in sporadic medulloblastoma. Although chromosome 17p is a frequent site of deletion in medulloblastoma, and medulloblastoma occurs in Li-Fraumeni families, *p53* mutations have not been found in sporadically occurring medulloblastoma. Several studies, however, have suggested the presence of a second tumor suppressor gene on 17p13 distal to *p53*. Other genetic changes rarely identified in medulloblastoma are deletions of chromosome 6q and 16q.

MOLECULAR PATHOPHYSIOLOGY   Mutations in genes important for the development of brain tumors manifest themselves by their effect on growth regulation and contribute to the invasive characteristics of malignant brain tumors. Probably the most important of these is the pathway mediated by the EGF receptor, which binds EGF or TGF-α and has tyrosine kinase activity when activated. The proliferation of some astrocytic tumors may occur as the result of autocrine stimulation, since some tumors that express the *EGFR* gene also synthesize and secrete EGF or TGF-α. Similarly, the platelet derived growth factor (PDGF) receptor and PDGF are sometimes found in the same tumor. Other growth factors that may contribute to glioma tumor cell proliferation include insulin-like growth factor I, basic fibroblast growth factor, and vascular endothelial cell growth factor, although the latter two seem to function primarily as angiogenic factors. Interestingly, several members of the TGF-β family of growth factors produced by some high-grade astrocytic tumors have immunosuppressant properties.

Extracellular matrix proteins and integrins, the cell surface receptors that recognize them, play key roles in mediating the production of tumor-derived proteases and the migration of tumor cells. Brain tumors produce several different types of proteases. The highest grade astrocytomas, glioblastoma multiforme (OMIM 137800), are unusual in that they contain high levels of the extracellular matrix protein vitronectin, which is not seen in the normal brain, as well as expressing the receptors for vitronectin, $\alpha_v\beta_3$ and $\alpha_v\beta_5$.

THERAPY

Therapy for malignant brain tumors is tumor-specific but typically involves surgery and radiation therapy. Neuro-oncology has been an important beneficiary of the technical advances that have characterized these two therapeutic approaches over the last several decades, and patients with localized, noninvasive tumors can frequently be cured. Radiosurgical techniques for precisely targeting tumor tissue with a very high dose of radiation are currently being evaluated. Some brain tumors, such as medulloblastoma, are sensitive to chemotherapy, which plays an important role in the management of some patients with this tumor. A role for adjuvant chemotherapy, in particular nitrosurea-based regimens, for the treatment of glial tumors is also widely recognized. Very high-dose chemotherapy utilizing combinations of drugs such as thiotepa and carboplatinum supported by autologous bone marrow transplantation or peripheral stem cell rescue are currently being evaluated.

FUTURE DIRECTIONS

The emerging description of a molecular basis for the pathogenesis of brain tumors and advances in molecular biology have led to new opportunities for improving the care of brain tumor patients. Evaluation of *EGFR* amplification or mutation of *p53* as prognostic markers may one day lead to new diagnostic and prognostic tools. Ongoing attempts to develop new anticancer drugs that target specific molecules in various growth regulatory pathways may prove useful against brain tumors, and this is especially true for tyrosine kinase inhibitors. Several different growth factor receptors implicated in the proliferation of brain tumors have tyrosine kinase activity, and drugs targeted at inhibiting this enzymatic activity will soon enter clinical trials.

Gene therapy for the treatment of brain tumors has also attracted considerable interest because of animal studies that suggest that at least two very distinct strategies are capable of curing animals with established brain tumors. One such strategy involved inoculation of rat C6 glioma cells transfected with an antisense mRNA for insulin-like growth factor 1 into nontransfected tumor. In association with an immune response, the established tumor disappeared. In other experiments the retroviral mediated transfer of the herpes simplex virus thymidine kinase gene to tumor cells has been pursued. Infected cells become sensitive to the cytotoxic effects of Ganciclovir, a guanine analog that disrupts cellular proliferation when it is phosphorylated by the viral thymidine kinase. Ongoing gene therapy trials for the treatment of brain tumor patients using such a viral prodrug strategy are currently ongoing and should provide insights important for the development of this new modality of treatment.

ACKNOWLEDGMENT

I wish to thank Dr. Jim Fick and Dr. Fred Barker for thoughtful comments and ideas in preparing this manuscript, and Ms. Lucy Avila for her editorial assistance.

108 Molecular Mechanisms and Regulating Behavior

PAUL M. PLOTSKY AND CHARLES B. NEMEROFF

INTRODUCTION

Elucidating the molecular genetic underpinnings of behavior represents the "Holy Grail" of neuroscience and is of particular interest to psychiatry. Despite the difficulty inherent in this ambitious goal, the past decade has witnessed promising strides toward this aim in large part because of the armamentarium of molecular, genetic, and imaging tools currently available. In studies on species ranging from aquatic snails (to worms to birds to rodents) to humans, increasing evidence indicates that there is a major heritable component to virtually every behavior in all organisms.

GENERAL CONSIDERATIONS IN GENETIC STUDIES OF BEHAVIORAL TRAITS

Several important assumptions are implicit in any genetic studies of behavior. First, although a given behavior may have a heritable component, this does not necessarily imply that a complex behavior is entirely attributable to an inherited gene or set of genes. Second, it is imperative to recognize that, even though genes probably do not code for behavior in a direct way, this does not exclude the possibility that an individual gene cannot play a critical role in the expression of a behavior. Third, it should be appreciated that most complex behaviors and behavioral dysfunctions are likely to be polygenetic and not regulated by a single gene. Fourth, the age-old nature versus nurture controversy must be replaced with the realization that the genetic/biological substrate with which an organism is born is modifiable by nongenetic factors or, put another way, the full expression of a behavioral phenotype is shaped by a complex interaction of genetic and environmental factors.

It is highly improbable that a gene encodes a single behavior. Individual genes code for specific proteins (i.e., enzymes, structural proteins, trophic factors, neurotransmitters, receptors, and so on). A given behavior is generated by neural circuits composed of multiple, interconnected neuronal elements. The development, differentiation, function, and connectivity of each neuron is dependent on the coordinated activity of a multitude of genes. The products of these genes interact with one another and their local environment, thus giving rise to coordinated neuronal activation subserving some particular behavior or set of behaviors. It follows from this reasoning that a particular gene does not explicitly code

for a behavior. For instance, if a particular molecule in the signaling cascade of a behavior-related neurocircuit is absent, it is easy to envision the disruption of the behavioral component that would normally be elicited by activation of that neurocircuit. Finally, there is a growing appreciation for the complexity of the interaction between the genetic endowment and nongenetic factors. For example, an individual may inherit a defective copy of a gene coding for a catabolic liver enzyme necessary for elimination of certain heavy metal complexes. If this individual accepts employment at a battery factory where exposure to heavy metal complexes occurs, the genetic vulnerability will be expressed as sickness and/or death as a result of the accumulation of these poisons. However, if the individual avoids such exposure, the potential vulnerability may ever be realized. This concept of a preexisting genetic vulnerability requiring some nongenetic trigger for expression of the phenotype has been readily adopted by developmental psychologists and psychiatrists to explain the acquisition of "released behaviors" or the etiology of psychiatric disease and substance abuse.

The foregoing exposition suggests that requisite to the successful investigation of the genetic basis of behavioral traits or etiology of psychiatric illness, it is necessary to: (1) develop replicable measurement techniques and methods to accurately define the target biological and behavioral phenomena, (2) demonstrate that the biological and behavioral measures are related to the normal or pathophysiology, and (3) establish an association between the biological and behavioral measures in human or animal studies.

TOOLS OF THE TRADE

It is now generally accepted that genetic factors contribute to the expression of various behavioral and psychiatric disorders in humans. From this, it follows that there must be underlying biological differences associated with differences in behavior. Unfortunately, there are currently few replicated findings that identify the specific biological substrates necessary for normal behavior in humans or lower animals (vide infra). Indeed, it is unlikely that the study of normal behaviors will lead to the identification of the underlying genetic determinants of behavior. The classic approach in human genetics has been and continues to be the study of abnormal or unusual phenotypes using family, twin, and adoption studies to assess the epidemiology of these phenotypes. By understanding the biological/genetic mechanisms responsible for

abnormal behavior, it should be possible to unravel the mechanisms involved in normal behavior. Clearly, the most convincing evidence for a genetic etiology of an illness or of a normal behavioral phenotype is the identification of a gene product that is always associated with the disorder and that can be established as necessary for expression of the phenotype.

Recent advances in molecular biology have provided geneticists with an increasing set of tools for such studies. In the past, linkage studies were not practical for humans because of the scarcity of available markers. However, in the past decade, the discovery of restriction fragment length polymorphisms (RFLPs), and the subsequent demonstration that RFLPs were inherited as simple Mendelian traits, have accelerated linkage mapping of loci responsible for many human diseases. The availability of these RFLP markers has ushered in the decade of genome mapping projects as well as making it at least theoretically possible to systematically screen families using these markers. Thus far, however, nearly all diseases mapped follow clear Mendelian, single-locus segregation patterns. In contrast, many common familial diseases such as diabetes, some forms of alcoholism, and many psychiatric diseases, such as schizophrenia and depression, are more complex; these diseases appear to be familial and clearly have a (poly)genetic component that may not display simple Mendelian transmission.

Complex behaviors and psychiatric diseases have yielded only slowly, if at all, to these approaches. This may be, in part, because of the polygenetic nature of these behavioral traits or to the important influence of nongenetic factors on the expression of these traits. Among the problems plaguing such studies are lack of sufficiently large genotypically or phenotypically pure populations, the relative inability of current diagnostic instruments to differentiate subcategories of these diseases, which probably occur on a continuum, and the lack of any convincing biochemical or anatomical marker.

In the past few years, a new class of human mutation, referred to as a trinucleotide repeat amplification, has been identified. Trinucleotide DNA repeats, which can expand to hundreds or even thousands of repeating triplets, have been found in many genetic diseases, including myotonic dystrophy, fragile X syndrome (types A and E), Kennedy's disease, Huntington's disease, and type 1 spinocerebellar ataxia. Interestingly, evidence indicates that the amplified DNA trinucleotide repeat underlies the clinical phenomenon termed genetic anticipation. Two components of genetic anticipation, greater severity and earlier age at onset in subsequent generations, are features of several psychiatric illnesses (i.e., schizophrenia and bipolar affective disorder). Furthermore, the concept of these trinucleotide repeats as regions of unstable DNA provides a compelling alternative to the traditional multifactorial polygenic theories: Many deviations from a single-gene mode of inheritance in psychiatric twin and family studies, which previously served as strong proof for more than one etiologic gene, can be easily explained by the non-Mendelian behavior of unstable DNA.

In animal studies, more interventionist strategies may be attempted to assess the relationship of a particular gene to behavior. It is now considered routine to create a series of transgenic animals. Usually, the initial studies are concerned with production of a "knockout" model, in which a particular gene or gene product is totally or partially inactivated. In some cases, an "overproduction" paradigm is created, as has been done to create a mouse model of Cushing's disease. The second stage is often the creation of a series of transgenic animals carrying target gene constructs, or promoter–reporter constructs, in which systematic mutagenesis of the promoter region has been performed. In each of these experimental paradigms, most commonly performed in fruit flies and mice, transfer of the construct into the organism is assessed, followed by biochemical, physiological, and/or behavioral testing.

NONGENETIC FACTORS

It is now abundantly clear that developmental windows exist during which the central nervous system (CNS) is extremely sensitive to environmental and emotional insults that shape how the organism will subsequently perceive and respond to its environment. This interaction between the organism's genetic endowment (e.g., genotype) and the local environment (i.e., uterine, intrinsic, extrinsic) suggests a high degree of plasticity during this critical period that may contribute to individual (phenotypic) differences, even among identical twins. It has been postulated that life experiences, especially those occurring during the pre- and neonatal periods of central nervous system development, exert a significant influence on phenotypic development at the cellular, as well as at the organismal, levels. Developing a comprehensive understanding of the nature and the mechanism(s) underlying this plasticity remains a major goal of biological psychiatry.

Communication between the genome and the environment is bidirectional. Development of the CNS proceeds along a fundamental genetic program that specifies the interrelationships among larger categories of neurons via mechanisms, including cell differentiation and chemoaffinity for the establishment of appropriate synaptic connections. As demonstrated in numerous species, the developing nervous system contains an excess number of synaptic connections, many of which will be lost during development. This process of synaptic sculpting or pruning occurs in response to the level of impulse activity along each connection and, thus, is environmentally mediated. Neuronal activity within a developing network selectively stabilizes only those emerging contacts (presynaptic) whose postsynaptic (receiving) cell is receptive to the process at a particular moment. The activation of a specific gene is not necessary for constructing a specific individual synaptic contact. Instead, the fine structuring of synaptic contacts follows a pattern determined by epigenetic factors, which build on a foundation of less finely structured neuronal networks that were specified by a basic genetic program. This high degree of flexibility leads to individual variability even among organisms sharing the same genes (i.e., identical twins). These responses to the external environment are capable of modifying gene expression within responsive cells at the microscopic level of fine structure and biochemistry as well as permanently altering the behavior of the central nervous system on a macroscopic level. The mechanistic aspects of this long-term "imprinting" by early experience remains to be fully elucidated, but is likely to involve alterations in gene expression via processes of DNA methylation or demethylation, activation of transcription factors, changes in protein phosphorylation state, as well as the participation of neurotrophic factors. It is particularly important to remember that these individual changes in neuronal circuitry may be either adaptive or maladaptive.

This preamble leads to the following questions:

1. To what degree is a particular behavioral trait or psychiatric disease determined by genetic and developmental factors?

2. To what degree is any given behavioral trait or psychiatric disease environmentally or socially determined?

We will attempt to address these questions in the remainder of this chapter through the presentation of specific examples primarily drawn from preclinical research. A comprehensive analysis of human studies of the genetic contributions to the development of major psychiatric illnesses is presented in Chapters 109–111 of this section.

OF SNAILS, FLIES, AND MICE: GENES AND BEHAVIOR

SENSITIZATION IN THE MARINE MOLLUSK Several invertebrate models have provided important insights into the effects of the genome on behavior. These invertebrate models offer the advantage of a more tractable central nervous system combined with comparatively simple, stereotyped behaviors. One such model system, which has been helpful in defining cellular and molecular events associated with simple forms of learning and memory, is the gill- and siphon-withdrawal reflex of the marine mollusk *Aplysia californica*. One simple form of nonassociative learning in this reflex is sensitization, which refers to an increase in the strength of the defensive withdrawal and the response to previously neutral stimuli after exposure to threatening stimuli. A single stimulus to the tail initiates the withdrawal and gives rise to a short-term sensitization that persists for minutes to hours. Repeated application of the stimulus results in a long-term sensitization that can persist for days to weeks. The deposition of this long-term memory is associated with the growth of synaptic connections, protein synthesis, and alterations in gene expression.

The fundamental mechanism underlying both short- and long-term sensitization is an increase in the synaptic strength of a monosynaptic connection between identified mechanoreceptor sensory neurons and effector motor neurons. An in vitro model of sensitization exists: Reconstructed synapses occurring in dissociated cell culture demonstrate the homologous phenomenon of facilitation. Biophysical studies suggest that the increase in synaptic strength observed in facilitation is secondary to an enhancement in transmitter release by the sensory neuron and an increase in postsynaptic excitability resulting from decreased potassium flux in the motor neuron.

Despite the similarity in the cellular processes of short- and long-term sensitization, the short- and long-term processes differ in important ways. The short-term change involves covalent modification of preexisting proteins and alteration of pre-existing intercellular connections. Short-term sensitization does not require *de novo* protein synthesis and is refractory to inhibition of transcription or translation. Conversely, long-term facilitation requires protein and mRNA synthesis, which must occur within a relatively narrow time window for facilitation to be manifest. Thus, the gene products required for short-term memory are pre-existing and turn over relatively slowly, whereas long-term memory requires the synthesis of new gene products. At least some of these new gene products drive structural changes in the synapse. Long-term, but not short-term sensitization, is associated with the formation of new synaptic contacts of the sensory cells onto the motor neurons.

The binding of serotonin to its receptor on the sensory neuron appears to be both necessary and sufficient to induce sensitization. Just as for physical stimuli, a single application of serotonin will produce short-term sensitization, whereas repeated or continuous application will induce long-term changes. Serotonin binding

activates an adenylyl cyclase that increases the intracellular concentration of cAMP, which in turn triggers the dissociation of the regulatory and catalytic subunits of protein kinase A (PKA). Activated catalytic PKA remains in the cytoplasmic compartment, primarily in presynaptic terminals, where it phosphorylates protein substrates, which contribute to prolongation of the presynaptic action potential and the enhancement of neurotransmitter release.

In contrast, long-term facilitation induces these as well as additional changes in the neurons; some of these changes impinge on the nucleus and result in alterations of gene expression. Stimuli producing long-term facilitation also induce a translocation of active catalytic PKA subunit to the nucleus, where proteins regulating transcription from cAMP response elements (CRE) are presumed to be phosphorylated. One family of proteins thought to be phosphorylated under these conditions are the CRE-binding (CREB) proteins. The necessity of PKA-driven expression from CREs for long-term facilitation is demonstrated by the fact that interference with the CRE expression prevents the establishment of long-term facilitation.

The identity of some of the genes induced by long-term facilitation has been elucidated. These are divided into two categories: early effectors and late effectors. Early effector products include N-terminal ubiquitin hydroxylase, which appears to effect the ubiquitin-mediated proteolytic cleavage of the regulatory subunit of PKA, thus maintaining the activity of the catalytic subunit, even in the absence of cAMP, clathrin, and an NCAM-related cell adhesion molecule. These latter two proteins, as well as many late effector products, appear to be involved in the structural elaboration of the synapse that occurs with long-term facilitation.

The dependency of long-term facilitation on transcription and translation displays a remarkably narrow temporal window. Inhibition of either transcription or translation at times greater than one hour after the last training session are without effect on the development of long-term facilitation. This critical period of sensitivity to transcription and translation is referred to as the consolidation phase. The existence of the *consolidation phase* suggests that there is a rapid initial expression of genes in response to the training regimen, and that the expression of these genes ultimately results in the establishment and stable maintenance of the increased synaptic strength associated with long-term facilitation and sensitization. The fact that mere covalent modification of existing transcription factors is not sufficient for the establishment of facilitation suggests that training starts a cascade of gene activation wherein constitutively expressed transcription factors induce temporally early genes that activate later effector genes; it is these later effector genes that are ultimately responsible for the morphological and biophysical changes associated with facilitation.

Several members of both early- and late-phase gene families have been identified. An Aplysia homolog of the mammalian C/EBP transcription factor family has been identified (ApC/EBP) and is known to possess an upstream CRE and to be regulated by cAMP. ApC/EBP is known to have the properties of an immediate–early gene: Its expression is not detected in unstimulated cells but is induced in stimulated cells, even in the presence of protein synthesis inhibitors. ApC/EBP expression is necessary for the establishment of long-term facilitation as shown by experiments blocking the expression or the actions of the protein. These interventions block the establishment of long-term facilitation without affecting short-term facilitation. Thus ApC/EBP represents at least one member of the early-phase gene family.

Other investigations have identified six proteins, the expression of which are altered during the acquisition of long-term facilitation. Two of these, clathrin and tubulin, increase in expression, whereas the other four, which appear to be immunoglobulin-related cell adhesion molecules displaying sequence homology to vertebrate NCAM and Drosophila fasiculin II, decrease in expression. The decreased expression of the cell adhesion molecules, designated apCAM, is thought to lead to a removal of adhesion molecules at sites of neuronal connections, promoting defasiculation and destabilizing adhesive contacts as a prelude to the synaptic remodeling and elaboration of long-term facilitation. Increased expression of the cytoskeletal proteins contribute to both the increased intracellular protein trafficking and the more extensive synaptic architecture resulting from synaptic remodeling.

The dissection of the molecular processes associated with long-term sensitization and facilitation in this seemingly simple monosynaptic reflex of Aplysia has yielded insights into the cellular and molecular events surrounding nonassociative learning. Additionally, we have seen that environmental events can influence (alter) the expression of genes, and that this altered gene expression results in altered behavior at both the synaptic and organismal level. The following corollaries are derived from these observations:

1. The seemingly simple process of learning in this reflex arc requires the coordinated expression of several genes, suggesting that the search for one gene/one behavior linkages may be futile.
2. Genetic defects along this pathway are likely to result in deficiencies in learning and memory processes.

THE SEX LIFE OF FLIES CNS regulation of sex-specific behaviors in Drosophila has been studied with great intensity, in the context of genetic factors that influence the development of sexually differentiated aspects of this insect. These studies have been particularly useful in strengthening the "single-gene" approach to behavior resulting from the availability of numerous mutant phenotypes. Three categories of genetic variations that can disrupt reproductive behaviors have been described:

1. Mutants isolated with regard to courtship defects.
2. General behavioral and neurological variants including sensory and learning mutants, whose defects include subnormal reproductive performance.
3. Mutations of genes within the sex-determination regulatory hierarchy of Drosophila.

Overall, these studies have clearly revealed that mutagenesis of genes, seemingly far removed from the regulation of behavior, can have direct consequences on it. Such studies have also highlighted the fact that the study of the genetic basis of behavior requires the study of genomes and their functional organization, rather than of single genes alone.

Drosophila males display a highly stereotyped courtship and mating behavior including orienting, following, tapping, singing, licking, mounting, and copulating behaviors toward receptive females. Mutations of a single gene, named period (*per*), result in alterations of the fly's circadian rhythms and, therefore, disrupt behaviors based on these rhythms. Males carrying a mutant *per* gene generate a courtship song that lacks the characteristic smooth sinusoidal pattern of frequencies and, hence, is much less effective in inducing receptivity in females. This demonstrates both that a single gene can influence multiple complex behaviors and that a single gene is capable of determining a single behavior. More recent work has mapped specific behavioral motifs within the *per* gene. Two species of flies, *D. melanogaster* and *D. simulans*, show similar 24-h circadian rhythms, but perform courtship songs with differing periods. When transgenic animals are constructed between these two species, a short region in the middle of the *per* gene was shown to control song period: *D. melanogaster* carrying the mid-region from *D. simulans* will sing with the period of *D. simulans* and vice versa.

The courtship behavior of *D. melanogaster* also illustrates the importance of regional gene expression in determining behavior. Sexual development in these flies is controlled by the complement of X chromosomes in each cell. Cells harboring one X chromosome give rise to male anatomical structures and behaviors in adult flies, while cells that have two X chromosomes lead to female anatomy and behaviors. Single-X male cells and double-X female cells activate separate but overlapping sets of sex-determining genes that give rise to the phenotypic differences. The generation of genetic mosaic flies carrying mixtures of male and female cells throughout the nervous system allowed the identification of those regions that are responsible for various components of the courtship ritual. Discrete regions of the fly brain have been identified in mosaic animals as being responsible for male pattern behavior in attraction to females (antennal lobe and mushroom body), initiating courtship (trigger zone) and orienting, tapping, following and licking (dorsocaudal brain), singing (rostral thoracic ganglion), and mounting and copulating (caudal thoracic ganglion). These observations suggest that the correct expression of sex-determining genes in several discrete anatomical loci are responsible for specific components of a complex suite of behaviors.

Drosophila have also contributed to our understanding of the molecular events of learning. Male flies react to pheromones from impregnated females with a prolonged cessation of mating behavior toward all females. Calcium/calmodulin-dependent protein kinase II (CaMKII) is another intracellular protein kinase that has been implicated in induction of molecular changes associated with learning, with mechanisms similar to those discussed for PKA in the case of the Aplysia (*vide supra*). Male flies engineered to express a thermosensitive CaMKII fail to remember their rejection by impregnated female flies when their CaMKII is inactivated. CaMKII-mediated learning in Drosophila bears additional similarities to PKA-mediated learning in Aplysia. The relevant substrate for CaMKII appears to be the potassium channel protein EAG. Mutations of the EAG protein produce learning impairment similar to CaMKII inactivation, and the EAG protein is a substrate of CaMKII in vitro. The full circuit appears to involve pheromone activation of neurons in the trigger region, which increases intracellular calcium levels. The increased calcium activates CaMKII, which phosphorylates the EAG potassium channel protein. Phosphorylation increases potassium efflux and decreases neuronal firing. The reduction in firing of trigger region neurons removes the stimulus to initiate the suite of courtship behaviors.

Drosophila behavior is rich and complex. As such, and similar to the case in higher vertebrates and mammals, early experience affects behavioral development of Drosophila. Therefore, Drosophila can be used to study the developmental mechanisms by which organisms optimize their behavioral repertoires to enhance their chances of survival. Female responsiveness to courting males is modified by early experience. This type of developmental plasticity permits adjustment of intrinsically determined responses to

visual targets, so that these insects can take into account the actual characteristics of the developing animal's environment. The "fine tuning" of basic genetic patterns of behavior introduces the possibility of inclusion of "cultural" and "social" elements into courtship and mate choice in insects. Conceptually, the role of developmental plasticity modification of genetic programs has broad theoretical and practical implications.

OF BIRD BRAINS AND MICE

HOW DO BIRDS SING? On any given morning, the sound of singing birds brings delight and pleasure. Birds sing to attract mates and, therefore, the development of mechanisms to produce and decode these songs is of reproductive and evolutionary importance. Several discoveries have shaped the recent study of brain substrates for birdsong. First, the failure of deaf birds to reproduce a song from memory supported the postulated existence of a song template. Attempts to test this idea led to the observation that song control is lateralized, as is language in humans. These observations stimulated the identification of brain sites of lateralization and auditory control of voice. Neurophysiological studies have shown that auditory information reaches the song control system. Lesions of the lateral magnocellular nucleus of the anterior neostriatum or area X affect song development in young birds, but not the maintenance of song in adults, which suggests this region acts as a site for song learning.

Isolation of behavioral components that contribute to the learning and production of song in birds has focused on the relationships between the vocal and respiratory systems. The temporal pattern of birdsong is primarily accomplished from the timing of activity in the bird's respiratory muscles. It appears that birds can simultaneously produce two different temporal patterns from the left and right halves of their vocal organ. The archistriatal and midbrain vocal nuclei in the brain innervate some of the respiratory centers in the medulla. Comparisons of the vocal and auditory systems between taxa indicate that different groups may use different neural circuits to achieve similar vocal–auditory behavior.

Now that the basic mechanisms of the actual control of birdsong learning and production are established, researchers will be able to perform interspecies comparisons of both the neurocircuitry and the genes involved in the generation of this complex behavior. Since this behavior is modifiable, analysis of birdsong at the genetic level may provide a model system for studies of the interaction between genetic and environmental factors.

HOW NOT TO BUILD THE BETTER MOUSE By studying a diverse set of gene mutations, important insights into the roles that the given gene product plays in the biological process may be gained. Gene mapping and gene manipulation studies in the mouse have yielded some of the most exciting findings in the genetic investigation of mammalian behavior. After years of studying various behavioral characters in the mouse using selective breeding techniques, it is clear that most are heritable and are specified by complexes of genes or quantitative trait loci (QTLs). The introduction of methods to perform highly efficient mutagenesis of the mouse germline has led to mutations that are of considerable value, including mutations of genes that have yet to be cloned or characterized. Once marked by such methods, these genes can be mapped to high resolution and then cloned. The use of primer templates based on a gene of interest that was characterized in another species has also provided a very productive method of cloning particularly important genes. Application of these approaches has

resulted in the identification of the mouse gene for circadian periodicity, numerous neurotransmitter receptors, channels, and reuptake transporters. Gene mutations or knockouts can also be induced to yield animal models of human heritable diseases, as demonstrated with the partial knockout of glucocorticoid receptor function, gene knockouts of serotonin receptors, and knockout of dopamine transporters. Such disease models permit research into the etiology of the given disease and evaluation of potential therapeutic regimens. However, the difficulties inherent in constructing valid models of psychiatric diseases or addictive syndromes in lower mammals must be appreciated.

WARRIOR MICE: THE MOLECULAR GENETICS OF AGGRESSION Building on data derived from mouse lines selected for either nest-building behavior or attack latency, researchers are focusing in on the gene or genes that contribute to aggressive behavior. Several molecular genetic mouse lines have recently been created that display increased aggression. The first of these was produced by knockout of the monoamine oxidase-A (MAOA) gene. These animals were characterized by elevated brain serotonin and norepinephrine concentrations as pups, and as adults they displayed enhanced intermale aggression, attempts to mount nonreceptive females, and reduced immobility in the forced swim test. Interestingly, rats treated prenatally with an MAO inhibitor have a reduced cortical serotonergic innervation as adults and various alterations in serotonin levels during development. A deficit of central serotonin has been associated with impulsive violence, depression, suicidality and alcoholism. Mice with knockout of the gene encoding for α-calmodulin–dependent protein kinase II (CaMKII), an enzyme necessary for activation of tryptophan hydroxylase required for serotonin biosynthesis, also leads to increased defensive aggression. The next target for gene knockout was the 5-HT1B receptor, as previous studies indicated that agonists of this receptor reduced aggressive behavior. Indeed, mice lacking this receptor exhibited greatly increased intermale aggression (decreased latency to attack, increased number of attacks, increased intensity of attacks) in classical tests. These observations are consonant with neurochemical and behavioral data from studies of monkeys and humans. Somewhat surprising have been reports of increased aggression and lack of social inhibition in null mutant mice lacking the neural nitric oxide synthase gene. Overall, these observations support the thesis that there are likely to be multiple routes, both genetic and environmental, to hyperaggressive behavior.

RODENT ADDICTS Considerable effort has been directed toward identifying the genetic contributions to substance abuse behavior. Psychostimulant drugs are believed to primarily interact with monoaminergic neurons. Most research efforts in this field have focused on the analysis of those central dopaminergic circuits believed to serve as the substrate for reward, leading to the dopamine hypothesis of psychostimulant addiction. This hypothesis proposes that enhancement of dopamine neurotransmission in the mesolimbic pathway is fundamental to the reinforcing properties of many drugs of abuse.

One approach to studies of the genetic basis of substance abuse is to construct congenic animal lines with different mesotelencephalic dopamine systems, using selective breeding techniques. Then, genomic markers (QTLs) associated with sensitivity to alcohol or cocaine can be identified, thus allowing the candidate genes that demonstrate linkage to markers associated with these behaviors to be cloned by position. In addition, Southern blot

hybridization techniques can be used to identify genetic polymorphisms of dopamine receptor subtype loci in mice and rats. In fact, polymorphisms of the D2, D3, and D4 dopamine receptor loci have been observed. The influence of the D2-like receptors in reward and addictive behaviors can be assessed by pharmacogenetic studies. Together, these approaches permit a molecular analysis of both known and previously unknown genes regulating various aspects (e.g., tolerance, sensitization, dependence, withdrawal) of substance abuse behavior. (An excellent review of the current status of this research area may be found in Self and Nestler.)

A common screening technique to assess sensitivity to cocaine is to measure locomotor responses to drug administration. In this way, it has been possible to characterize the effects of cocaine on the dopamine transporter. Thus, central dopaminergic system involvement has been studied in different strains of mice that exhibit differential sensitivity to cocaine. In these studies, C57BL/6 mice were less activated than DBA/2 mice after cocaine, though both strains had equivalent brain cocaine concentrations at the times and doses tested. Interestingly, treatment with a selective dopamine uptake inhibitor produced greater locomotor activation in DBA/2 mice than in C57BL/6 mice, even though binding studies with a selective dopamine uptake ligand revealed no between-strain differences, in caudate putamen or nucleus accumbens Kd or Bmax. Specific D1 or D2 antagonists produced dose-dependent decreases in locomotor activity, again showing no between-strain differences and the D2 antagonist completely reversed cocaine-induced activation in both strains. These findings demonstrate that C57BL/6 and DBA/2 mice differ in dopamine-related behaviors and suggest that dopaminergic processes may mediate genetic differences in cocaine sensitivity. Recent work in rats has confirmed the importance of dopamine receptors in substance abuse, as priming with a D2 agonist triggered relapse of self-administration behavior, whereas treatment with a D1 agonist inhibited this drug-seeking behavior.

The dopamine transporter represents an important regulator of dopaminergic activity. Cocaine, one of the best characterized of the psychostimulant drugs, fulfills the dopamine hypothesis by blocking the dopamine transporter and, thus, by preventing reuptake of the neurotransmitter, enhancing its synaptic concentration. A good concordance exists between binding of cocaine analogs to the dopamine transporter and changes in locomotor activity. Abundant data suggest that vulnerability to both the toxic and addictive effects of cocaine may be significantly influenced by genetic differences in both humans and animals. Even within the brain, differences in the dopamine transported are apparent. This difference may arise from differences in glycosylation of the polypeptide. The observation that cocaine is commonly abused along with other drugs has given rise to the hypothesis that common biochemical pathways may mediate the reinforcing or addictive properties of drugs of abuse. Of particular interest is the recent creation of a dopamine transporter knockout mouse line. Studies of these animals clearly demonstrate the importance of the dopamine transporter to overall function of central dopmaninergic circuits. In the knockout animals, evoked dopamine remains in the region of the synaptic cleft approximately 100 times longer than in normal mice. Furthermore, the knockout mice do not respond to cocaine, supporting the postulate that the primary site of cocaine's action is at the transporter. This animal model, along with those created with partial knockouts or transporter mutants, should be quite helpful in elucidating the basis for substance abuse, as well as for testing putative therapeutic approaches.

THE HYPOTHALAMIC-PITUITARY-ADRENAL AXIS, CUSHING'S DISEASE, AND DEPRESSION IN RODENTS

Patients with a number of psychiatric disorders exhibit profound disturbances of hypothalamic-pituitary-adrenal (HPA) axis function. Patients with severe depression often show evidence of increased HPA axis activity, such as a premature escape from the cortisol suppressant action of the synthetic glucocorticoid dexamethasone, elevations of cerebrospinal fluid levels of corticotropin releasing factor (CRF), and increased adenohypophysial and adrenal volumes. It is currently unknown whether these changes are primarily the result of defective glucocorticoid feedback inhibition or inappropriate secretion of CRF and/or arginine vasopressin. However, it is clear that normalization of the hyperactive HPA system occurs during successful antidepressant pharmacotherapy of depressive illness. Both elevation of CRF and of glucocorticoids are associated with signs and symptoms resembling depression in both humans and animals, giving rise to the idea that HPA axis dysfunction may precede the onset of depressive illness.

The connection between HPA axis dysfunction and depression has been tested in numerous animal models, including chronic exposure to stress, maternal separation, a transgenic model of CRF overexpression, and a transgenic model of partial glucocorticoid receptor knockout.

The hypothalamic peptide CRF is released in response to various stressors and increases pituitary adrenocorticotropin secretion, which then drives adrenal glucocorticoid production. Extrahypothalamic CRF serves as a neurotransmitter/neuromodulator and has been shown to play an important role in behavioral responses to stress. The transgenic mouse model of CRF overproduction was developed to examine the endocrine and behavioral effects of chronic CRF excess. These transgenic mice CRF display the expected endocrine abnormalities of the HPA axis, such as elevated plasma levels of ACTH and glucocorticoids. The CRF transgenics also exhibited an increase in anxiogenic behavior, an effect known to occur following central administration of CRF in animals, which was partially reversed by administration of a CRF antagonist. Continuing studies of these animals suggests that CRF transgenics and related transgenics such as CRF promotor mutants and CRF receptor mutants may provide a valuable tool for investigating the long-term effects of dysregulation of central CRF neurocircuits.

Another interesting transgenic mouse model was created by expression of a type II glucocorticoid receptor antisense RNA in the brain that results in impairment of glucocorticoid receptor function. These mice display endocrinological characteristics similar to those seen in depression, including hyperactivity of the HPA axis and resistance to dexamethasone negative feedback. When treated with the tricyclic antidepressant desipramine, hypothalamic glucocorticoid receptor mRNA concentration and binding activity increased. At the same time, circulating levels of adrenocorticotropin hormone and corticosterone decreased. These studies suggest that antidepressants affect HPA axis activity via modulation of glucocorticoid receptor gene expression; however, such studies do prove that this is a direct effect rather than an indirect action mediated through changes in other factors (i.e., neurotransmitters, G-proteins, neurotrophic factors) that secondarily alter glucocorticoid receptor expression. Nonetheless, this animal model represents an important advance in our understand-

ing of the interactions between the HPA axis and depression and certainly warrants further study.

DISCUSSION

Psychiatry, like much of the rest of medicine, has entered a new and exciting age demarcated by the rapid advances and the promise of molecular biology and neuroscience. This promise is presaged by the ability to generate knockout (e.g., null mutant) and overexpression transgenic organisms for the study of specific genes (*vide supra*). In addition, some success has been realized in the elucidation of molecular mechanisms underlying several brain disorders that lie at the intersection of neurology and psychiatry, including identification of mutations on chromosomes 1, 14, and 21, which appear to be associated with the early onset, dominantly inherited form of Alzheimer's Disease and a mutant gene on chromosome 4 associated with Huntington's Disease; unfortunately neither of these diseases is currently treatable.

Progress at the molecular level has furthered our understanding of phenylketonuria (PKU), a well-characterized disease that can be readily treated if identified by early screening. PKU, a classic example of success in the prevention of a genetic disease, is a genetic disorder in which an inborn error of metabolism (e.g., disruption of the hydroxylation of phenylalanine to tyrosine) leads to mental retardation if left untreated. Treatment is a relatively straightforward matter of removing phenylalanine from the diet beginning soon after birth. At least five known genes, which have been cloned, are involved in hydroxylation of phenylalanine, synthesis of tetrahydrobiopterin, and regeneration of this cofactor. More than 170 mutations of the human phenylalanine hydroxylase gene have been identified, and these account for approximately 99% of the mutations causing hyperphenylalaninemia. The aggregate PKU gene frequency is polymorphic in many human populations with the mutations highly stratified by region and population, thus reflecting a variety of mechanisms (i.e., founder effect, genetic drift, hypermutability, selection) for their occurrence and distribution. These studies have served notice that the relationship between genotype and clinical outcome is more complex than was originally suspected and is a function of multiple effects.

The enthusiasm for the promise presented by a molecular approach to understanding mechanisms of behavior and psychopathology, however, must be tempered by the recognition that the brain is an exceedingly complex organ shaped by more than the mere unfolding of a proscribed genetic program. Substantial evidence indicates that intrinsic and extrinsic environmental factors play a major role in the transition from genotype to phenotype. Perhaps the most compelling and well-documented example in neuroscience concerns the functional reorganization of the visual cortex in response to visual deprivation during development, a principle known as activity-dependent plasticity. Such activity-dependent plasticity fine tunes the basic genetically specified pattern of neuronal connectivity, thus assigning "weights" to particular neurocircuits in a process that may turn out to be either adaptive or maladaptive.

While the ability to engineer organisms that either over- or underexpress a particular gene has led to impressive advances in studies of the molecular basis of behavior and disease; these studies also highlight the remarkable adaptability of the brain to the absence of proteins that are believed to play critical roles in synaptic signaling. In the case of the null mutant paradigm, it must be appreciated that the knockout organism represents not only the absence of a single gene product, but potential compensatory alterations in a number of developmental, physiological, or even behavioral processes. These compensatory mechanisms might result in either the absence of an expected phenotypic change or the expression of phenotypic abnormalities, which then may be mistakenly attributed to the null mutation. Furthermore, these putative compensations depend, not only on the targeted gene, but also on the background genotype of the animal. Thus, studies that claim to demonstrate a linkage between a single gene mutation and a complex behavior, as recently claimed in studies suggesting that a polymorphism of the D4 dopamine receptor gene on the short arm of chromosome 11 accounted for approximately 10% of the genetic variation in the trait referred to as "novelty seeking," must be viewed with some degree of skepticism. The overall message, then, is that caution is warranted when inferring a tight relationship between a single gene and a particular behavioral phenotype or psychopathology, given the ability of the brain to compensate for deficits during development and its ability to modify synaptic connectivity as a function of experience.

Molecular forays into the basis of behavior and neural disorders is a very young field and is likely to hold many surprises. For instance, it has now been established that mutations and deletions of genes encoded in mitochondrial DNA cause heritable CNS disorders that do not follow simple Mendelian genetics. The extent to which genetic defects in mitochondrial DNA contribute to human disease is currently unknown. The mechanism of anticipation, a phenomenon in which each succeeding generation of affected individuals exhibits an earlier age of disease onset, eluded explanation for many years. This phenomenon is now attributed to the progressive expansion of trinucleotide repeats in mutant genes of successive generations.

The molecular genetic approach will undoubtedly yield important insights into the biological mechanisms underlying normal and abnormal brain function and behavior. However, it should be appreciated that the primary virtue of this approach lies in deciphering general principles of the biological organization of the brain and behavior rather than revealing the linkage between single genes and complex behaviors. Behavioral and neurobiological traits are complex, likely to be variable, and influenced by a large number of genes and environmental factors. In fact, it can be argued that the development of the CNS and emergent qualities, such as an individual organism's behavioral phenotype, are best described as complex nonlinear processes. This line of reasoning suggests that when contemplating complex functions such as behavior, we might need to look for fundamental units of organization larger than that of single genes alone. In fact, the precedent for such a paradigm shift is evident in the neuroscience where the focus has changed from the analysis of the characteristics of single neurons to neurocircuit analysis or the analysis of shifting populations of neurons when attempting to understand mechanisms underlying complex behaviors or processing tasks. The single gene, as the single neuron, represents a potentiality, the expression of which is highly dependent on its interactions with the local environment. Therefore, it would not be unreasonable to expect that groups of genes specified by some higher level of organization might represent the functionally relevant unit in determining a behavioral phenotype. In this scenario, some genes might belong to more than one functional gene group, much as a single neuron may belong to multiple neurocircuits. This sharing of "valence" genes or neurons might provide an intrinsic mechanism for integration of multi-

modal information. Furthermore, this type of organization, whether one is referring to neurons or to genes, implies a hierarchical organization of functional groups necessary for the generation of emergent qualities.

A number of interesting predictions may be made on the basis of such an organizational scheme. For instance, the mutation of a single gene within a functional gene group may be important as a trigger to alter expression levels of other genes within a group in a coordinated fashion. Identification of these cascades in gene expression might lead to insights into inherent features of CNS organization and of constellations of genes or gene groups that specify a complex phenotype, whether it be temperament or some other heritable aspect of behavior. As stated by Gerlai, "Genes, especially as they affect brain function, are not expressed in a vacuum but rather in the rich personal context of individual experience. Perhaps, the most important contribution of research in molecular aspects of psychiatry will be the characterization of the intrinsic vulnerabilities to psychiatric disorders so that we can, for the first time, have control over one variable in the complex simultaneous equation of Nature and Nurture that shapes brain and behavior." If the molecular genetic approach to studies of brain and behavior moves in this direction, then medicine and psychiatry are indeed headed into an exciting new age, likely to be characterized by tremendous advances leading to the reduction of needless human suffering — this represents the great promise and the beginning of a long journey.

109 Schizophrenia

Ming T. Tsuang and Stephen V. Faraone

INTRODUCTION

Psychiatry, with the rest of medicine, has entered the age of molecular genetics, but we are far from the stage of molecular diagnosis or treatment. Although schizophrenia researchers have produced suggestive evidence implicating specific chromosomal loci, the molecular genetic basis of the disease remains a mystery: Its mode of inheritance is unknown, and the loci that have been implicated are unlikely to account for a substantial proportion of the disease's etiology. In contrast, family, twin, and adoption studies have taught us much about the genetic epidemiology of schizophrenia. In doing so, they have provided a solid foundation for a new generation of molecular studies that promise to unravel the genetics of this complex disorder.

FAMILY STUDIES

Many of the studies from the first half of the twentieth century were completed prior to the creation of structured diagnostic criteria. These early studies showed the following risks for schizophrenia to relatives of schizophrenic probands: parents, 5.6%; siblings, 10.1%; offspring, 12.8%. Note that the risk to parents is less than the risk to siblings, yet most genetic models predict that these risks would be similar. It is relatively uncommon for schizophrenic people to marry and have children. When both parents had schizophrenia, the risk to children was much greater (36.6%). In the early studies, the risks to second-degree relatives ranged from 4.2% for half-siblings to 2.4% for uncles and aunts. First cousins had an average risk of 2.4%. Because the risk for schizophrenia in the general population was 0.8%, these familial risk figures are strongly suggestive of an important genetic component in the transmission of schizophrenia.

Compared with these early reports, more recent studies used more rigorous research methods and narrower, criterion-based definitions of schizophrenia. Overall, these studies confirm the familial nature of schizophrenia, but they report risk figures that are lower than those seen in earlier studies. For example, Tsuang, Winokur, and Crowe reported the risk of schizophrenia to first-degree relatives of schizophrenics to be 3.2%, compared with 0.6% for relatives of nonpsychiatric controls. Guze, Cloninger, Martin, and Clayton reported comparable figures of 3.6 and 0.56%, respectively. In both studies, the increased risk for schizophrenia among relatives of schizophrenics remained statistically significant despite the lower prevalence figures.

The reduced prevalence rates of schizophrenia in the more recent studies are probably because of differences in diagnostic procedures. For example, the figure of 3.2%, obtained when using stringent Washington University criteria, increases to 7.8% if the schizophrenia category is broadened to include atypical schizophrenics (e.g., schizoaffective disorder, psychosis not otherwise specified). Thus, the risk figures for schizophrenia based on modern criteria are similar to the figures obtained by the earlier European studies when atypical cases are included.

The exclusion of atypical schizophrenia cases from family studies may also explain why two family studies failed to find familial transmission in schizophrenia. Pope et al. found no cases of schizophrenia among first-degree relatives of their schizophrenic probands. Abrams and Taylor found the risk for schizophrenia to be only 1.6% among 128 first-degree relatives of schizophrenics. Although certain methodological problems may explain these results, it is also possible that they are because of diagnostic practices. Despite the caveats noted, contemporary figures as well as those reported in earlier studies suggest that the risk for schizophrenia in first-degree relatives exceeds the observed rate in the general population by 5–10 times. Of course, environmental factors can also cause familial transmission. Thus, twin and adoption studies must be examined to verify that genes—not the environment—underlie the familial transmission of schizophrenia.

TWIN STUDIES

After pooling the results of extant twin studies, Kendler found concordance rates of 53% for monozygotic (MZ) twin pairs and 15% for dyzygotic (DZ) twin pairs. This strongly implicates a genetic component for schizophrenia. Yet, the concordance rate for MZ twin pairs is not 100%; thus, environmental factors must play a crucial role in the etiology of schizophrenia. When concordance rates are translated into "heritabilities" (the proportion of the liability to schizophrenia resulting from genetic factors), 70% of the variance is attributed to genetic factors. Thus, there is a substantial role for environmental factors in the expression of schizophrenia. Several possibilities exist. Some forms of schizophrenia could be caused completely by environmental factors such as birth complications or viral infection. Alternatively, it may be that all cases of schizophrenia require a genetic susceptibility that is only expressed in some environmental circumstances.

A nongenetic explanation for the schizophrenia twin data is that MZ twins are exposed to more similar environmental factors than DZ twins. This hypothesis can be tested by looking at twins raised in different environments. A high concordance rate

for monozygotic twin pairs reared apart would refute the theory that sharing the same predisposing environment leads to the higher concordance rate in monozygotic twin pairs. Among the 17 such monozygotic twin pairs that have been observed, 11 (65%) were concordant for schizophrenia. This strengthens the hypothesis that both genes and environment play a causal role in the development of schizophrenia.

ADOPTION STUDIES

Adoption studies can disentangle genetic and environmental sources of etiology by showing if biological or adoptive relationships explain the familial transmission of disease. Heston examined 47 children who had been separated from their biological schizophrenic mothers within 3 days of birth. These children were raised by adoptive parents with whom they had no biological relationship. He also examined a control group of 50 persons who had been separated from nonschizophrenic mothers. Both groups studied were adults at the time of examination. If genes caused schizophrenia, then the biological children of schizophrenic mothers should have a higher risk for schizophrenia, regardless of who raised them as children. In contrast, if the parenting relationship caused schizophrenia, then separating children from a schizophrenic parent should prevent them from having schizophrenia. Heston's results supported a genetic etiology of schizophrenia: Five children of schizophrenic mothers became schizophrenic; in contrast, none of the children of nonschizophrenic mothers became schizophrenic.

Kety et al. carried out adoption studies of schizophrenia in Denmark. In the Greater Copenhagen area, 5500 children had been separated from their biological families by adoption between 1923 and 1947. Of these children, 33 who later became schizophrenic were studied along with 33 nonschizophrenic adoptees. The investigators examined the biological relatives of these schizophrenic and nonschizophrenic adoptees. They diagnosed 21% of the biological relatives of schizophrenic adoptees with schizophrenia or a related disorder. In contrast, only 11% of the biological relatives of nonschizophrenics had schizophrenia. There were no differences in rates of schizophrenia between the adoptive relatives of the schizophrenic and nonschizophrenic adoptees. One component of the Kety et al.'s study was similar to Heston's study. Children born to schizophrenic families but raised by nonschizophrenic families were compared with children born to, and raised by, nonschizophrenic parents. Schizophrenia and related disorders were found in 32% of the former group but only in 18% of the latter group.

Kety et al.'s sample also included some persons who had been born of nonschizophrenic parents but raised by a schizophrenic parent. If the fact of being reared by a schizophrenic parent caused schizophrenia, then these persons should be likely to suffer from schizophrenia. However, this was not so: Being raised by a schizophrenic parent did not predict schizophrenia in children who were not genetically predisposed to the disorder (i.e., who did not have a schizophrenic biological parent).

The adoption studies show that genetic factors mediate the transmission of schizophrenia. However, these studies also have some limitations. Most importantly, although the adopted children had been separated from the mother soon after birth, they had spent 9 months in the mother's uterus. During that time, the mother could have transmitted to the fetus some nongenetic biological or psychosocial factor that might have resulted in the child's schizophrenia 15 years later.

Fortunately, the Danish researchers could examine whether or not *in utero* influences might have explained their results. Kety et al. found that 13% of paternal half siblings of schizophrenic adoptees had schizophrenia compared with only 2% of paternal half siblings of nonschizophrenic adoptees. Paternal half siblings have different mothers. Therefore, these results cannot be explained by in utero effects. Indeed, the fact that a higher rate of schizophrenia was found among these half-siblings from the father's side, than in the half-siblings of the controls, is compelling evidence for the genetic basis of schizophrenia.

QUANTITATIVE MODELS OF GENETIC TRANSMISSION

A classic Mendelian model of inheritance will not adequately describe the genetic transmission of schizophrenia. Thus, more complex models are needed to describe the genetic transmission of the disorder. Quantitative or mathematical modeling studies provide a strategy for doing so. Such studies are discussed briefly below.

Single major locus models (SMLs) propose that the pair of genes present at a single locus is responsible for the transmission of schizophrenia. Results of SML analyses have not consistently supported single-gene transmission. SML models accurately predict the general population prevalence, the prevalence in offspring of schizophrenics, and the prevalence in siblings of schizophrenics. However, segregation analyses that provide statistical tests of model adequacy reject single-gene transmission. Those that cannot rule out the model note that the rate of schizophrenia among the MZ co-twins of schizophrenic patients and the offspring of two schizophrenics are underpredicted by the SML model.

The failure to find an SML model that unequivocally accounts for the familial transmission of schizophrenia has led to the testing of polygenic models. These models assume that genes found at more than one locus are responsible for the familial pattern of the disorder. There are two types of polygenic models. Oligogenic models postulate a relatively limited number of loci (e.g., less than 10), whereas multifactorial polygenic (MFP) models propose a large, unspecified number of loci (e.g., more than 100).

Studies that compared SML and oligogenic models agree that there are no dramatic differences between their abilities to account for the familial transmission of schizophrenia. Further, the oligogenic models are similar to the SML model in predicting that the majority of individuals with the schizophrenic genotype will not develop schizophrenia. Simulation studies by Risch suggest that multilocus models including gene interactions may be needed to account for the familial pattern of illness in schizophrenia. Notably, the rate of schizophrenia among the MZ co-twins of schizophrenic patients (which is underpredicted by SML models) is correctly predicted by oligogenic models that include a small number of genes that interact with one another.

Unlike oligogenic models, MFP models do not specify the number of loci involved in schizophrenia. Instead they assume that there are many interchangeable loci; genes at these loci have small, additive effects on the individuals predisposition for schizophrenia. This model assumes that all individuals have some unobservable "liability" or predisposition to develop schizophrenia. Gottesman and Shields noted five points in favor of MFP models. First, like other MFP disorders, schizophrenia is found with varying severities. Second, the risk for schizophrenia is greater for persons with many schizophrenic relatives than for persons with

few schizophrenic relatives. Third, the risk to a person increases as a function of the severity of a schizophrenic relative's illness. Fourth, nonschizophrenic individuals from the schizophrenia spectrum can be conceptualized as having a liability close to but not exceeding the threshold for schizophrenia. Finally, MFP disorders are expected to respond slowly to natural selection. Further, as discussed above, the SML model underpredicts the rate of schizophrenia among the MZ co-twins of schizophrenic patients. Thus, the twin studies of schizophrenia are consistent with the MFP model.

Overall, the MFP results are more promising than the SML results. In particular, path analytic MFP studies support the hypothesis that schizophrenia is to a large extent a disorder with a mostly genetic multifactorial etiology. Under this model, genetic factors account for 60–70% of the familial pattern of schizophrenia. Environmental factors are important to a much lesser degree. Overall, the results suggest that the MFP model deserves serious consideration. These results cannot rule out, however, the possibility of a mixed model in which an SML component and a MFP component both exist. However, attempts to fit such a mixed model have not been able to determine the mode of transmission.

THE SEARCH FOR GENES

In the 1980s, some preliminary findings implicated a gene on the short arm of chromosome 5. Interest in this area was initially motivated by the report of a single family in which two cases of schizophrenia each had a distinct abnormality of this chromosome. Subsequently, Sherrington et al. studied seven British and Icelandic families having schizophrenia in at least three generations. These investigators demonstrated genetic linkage to the part of chromosome 5 that had been previously implicated. Taken together, these two findings suggested that a schizophrenia gene would be found.

Unfortunately, other linkage studies could not replicate this linkage finding and some clearly excluded the chromosome 5 locus as being involved in schizophrenia. What can we make of these conflicting results? Some argued that, if more than one gene can cause schizophrenia, then both the positive and the negative findings can be correct. However, as more and more studies fail to find linkage to chromosome 5, it becomes more reasonable to conclude that the original positive finding may be a false result resulting from the play of chance. This now seems likely given that the group that produced the original finding of linkage found that evidence for it diminished when they extended their original sample.

Recent data implicated a pseudoautosomal locus in the etiology of schizophrenia. The pseudoautosomal region is a small portion of the Y chromosome that crosses over with the X chromosome during meiosis. If a gene from the pseudo-autosomal region causes schizophrenia, we would expect the following pattern of sex-specific transmission. Pairs of siblings with schizophrenia should be more likely to have the same sex if their father is schizophrenic but no such sex concordance is expected if the mother is schizophrenic. Since this pattern was found among schizophrenic families, the pseudoautosomal region was proposed to be the locus for a schizophrenia gene. In subsequent work, support for the pseudoautosomal hypothesis was inconsistent. Crow et al. showed that the estimated recombination fraction at the putative pseudo-autosomal locus was greater for females compared with males, a fact that was not consistent with the known greater recombination

fraction for males in the pseudoautosomal region. Thus, the same group suggested that a schizophrenia gene might reside in a nearby sex-specific region of the X and Y chromosomes. Their linkage analysis found some support for a dominant X-Y model of transmission in which homologous genes on X and Y contributed to the genetic susceptibility to schizophrenia.

A locus for schizophrenia on the sex chromosomes had also been suggested by cytogenetic studies. As reviewed by DeLisi et al., this work shows that schizophrenic patients have increased rates of the sex chromosome aneuploidies XXX and XXY. Other anomalies include long Y chromosomes, duplications in the heterochromatin regions of some chromosomes, inversion of a chromosome 9 region, fragile sites on chromosomes 9, 17, and 3, and trisomies of chromosomes 5 and 8. Since those reviews, Nanko et al. reported an association between schizophrenia and pericentric inversion of chromosome 9, Malaspina et al. described an association between schizophrenia and partial trisomy of chromosome 5p, and another study found a balanced 6:11 chromosomal translocation in a three-generation family with psychosis.

Although the available literature suggests that cytogenetic abnormalities cause some cases of schizophrenia, these abnormalities must account for only a small fraction of all schizophrenia. Some studies report no chromosome anomalies among patients with schizophrenia, and all positive studies report relatively low rates. For example, based on their review of ten studies that comprised 7519 patients, DeLisi et al. estimated the prevalence of sex chromosome anomalies among schizophrenic patients to be 0.5%.

A potential linkage to chromosome 22 has also generated much interest. Pulver et al. suggested the possibility of linkage to the long arm of chromosome 22, and consistent findings were reported by other investigators. However, a collaborative study reported by Pulver et al. excluded linkage to chromosome 22 loci, and another study could not find evidence of linkage. In addition, an association study to a marker at 22q12 found evidence for linkage disequilibrium with schizophrenia. Recently, Gill et al. reported a combined analysis of 11 schizophrenia linkage data sets. As a group, these data provided statistically significant evidence for linkage. However, their analyses also suggested that the putative schizophrenia gene would account for no more than 2% of the liability to develop the disorder.

The studies of chromosome 22 provide hope that the molecular genetic basis of schizophrenia will be uncovered. It seems likely that several genes in an oligogenic system may account for the genetic contribution to the disorder. In this regard, it is also notable that potential linkages have been reported to chromosomes 3p and 8p and also to the short arm of chromosome 5. Moreover, recent evidence implicated a schizophrenia gene on chromosome 6p in a series of 186 Irish schizophrenia families collected by Kendler et al. Findings consistent with their work have subsequently been reported, although not consistently.

SCHIZOPHRENIA-RELATED CONDITIONS

The available molecular genetic data suggest that multiple genes may cause schizophrenia. If so, then they might not be detectable without reducing measurement error and creating measures that more directly assess the genotype and its biological or behavioral consequences. Genetic epidemiological studies suggest that there are other disorders and conditions that are caused by the same genes that cause schizophrenia. Schizophrenia-related psychiatric disorders have been called "schizophrenia spectrum

disorders" to convey the idea of a spectrum of disorders related to schizophrenia. Likewise, we use the term "neurobiologic spectrum disorders" to refer to measures of brain functioning that are not psychiatric disorders, but can be considered to be evidence of abnormal brain function related to the schizophrenia genotype. The criterion for defining a disorder as in the schizophrenia spectrum is straightforward: It must occur more frequently among the biological relatives of schizophrenic patients than the relatives of people who do not have schizophrenia. This provides some evidence that their expression is mediated by one or more of the genes that also lead to schizophrenia.

PSYCHIATRIC SPECTRUM DISORDERS Approximately 9% of the first-degree relatives of schizophrenic patients will have a psychotic disorder that does not meet criteria for either schizophrenia or a mood disorder. The most common of these are "schizoaffective disorder" and "psychosis, not otherwise specified (NOS)." Notably, schizoaffective disorder is also found among the relatives of patients with bipolar disorder. This has led some investigators to conclude that schizophrenia and bipolar disorder may have genes in common. In this view, the two disorders are at opposite ends of a "continuum of psychosis" and the schizoaffective patients lie in the middle. This idea is controversial and is now the subject of much research.

In addition to these psychotic disorders, psychiatrists have observed for many years that the relatives of schizophrenic patients had "eccentric personalities." They also noticed poor social relations, anxiety in social situations, and limited emotional responses among the family members of schizophrenics. Less frequently observed were mild forms of thought-disorder, suspiciousness, magical thinking, illusions, and perceptual aberrations.

Psychiatric genetic researchers have focused on the familial prevalence of three disorders: schizotypal, schizoid, and paranoid personality disorders. Numerous studies have documented the increased prevalence of schizotypal personality disorder (SPD) in the biological relatives of chronic schizophrenic probands. These results have demonstrated consistency across family studies, adoption studies, and twin studies. Although two studies failed to find a higher rate of SPD among relatives of schizophrenic probands, most studies suggest that the biological relatives of schizophrenics demonstrate "subthreshold" pathology in the form of schizotypal personality disorder. The prevalence of such disorders in schizophrenic families has been estimated at between 4.2 and 14.6%. If "probable" SPD is included, estimates may run as high as 26.8%.

Results for schizoid and paranoid personality disorders (PDs) have been less consistent. Baron et al. found higher rates of paranoid PD in the relatives of schizophrenic probands (7.3%) versus control probands (2.7%). However, their results have been criticized for artificially inflating estimates of paranoid PD in relatives on the grounds that the sample of research diagnostic criteria (RDC)-defined schizophrenic probands may have also included delusional disordered probands. Moreover, family studies suggest that schizophrenia and delusional disorder are not genetically related to one another. For example, Winokur found paranoid traits in relatives of delusional disorder patients, but not in the relatives of schizophrenics. Kendler et al. showed that rates of DSM-III paranoid PD were not increased in the relatives of schizophrenics, but were increased in relatives of patients with delusional disorder. Thus, there is not strong evidence favoring paranoid PD as a member of the schizophrenia spectrum.

Regarding schizoid PD, Kety et al. and the Danish adoption studies are most frequently cited as providing the evidence which potentially refutes a schizoid-schizophrenia genetic link. A more recent replication in an adoption sample indicated findings similar to Kety and coworkers' earlier report. Also, Baron et al., reported that the relatives of schizophrenics had a slightly higher rate of schizoid PD than controls (1.6 vs 0%). Also, compared to family members of controls, the family members of schizophrenics demonstrated a significantly higher rate of probable SPD (12.1 vs 6.5%). Kendler et al. found an increased prevalence of a combined "schizotypal-schizoid" PD in biological relatives of schizophrenics, but their results did not allow for a distinction between "schizotypal" and "schizoid" traits. Thus, as with paranoid PD, strong evidence has yet to be presented in establishing a link between schizophrenia and schizoid PD. Clearly, among Axis-II disorders, Schizotypal PD is the strongest candidate for a relatively mild illness which is genetically related to schizophrenia.

NEUROBIOLOGIC SPECTRUM DISORDERS It seems unlikely that there will be a one-to-one correspondence between genetically influenced processes in the brain and the clinical phenomena that define diagnostic categories. Since psychiatric signs and symptoms may be relatively remote effects of the genotype, linkage studies might be more fruitful if they focus on measures more closely tied to brain function. Moreover, a putative indicator may measure only one component of the schizophrenia genotype. This would be likely if more than one gene caused the disorder— a very reasonable hypothesis for schizophrenia. To paraphrase Matthysse, minor genes for schizophrenia might be major genes for some index of central nervous system dysfunction. If so, these neurobiologic phenotypes could help clarify the genetic etiology of the disorder.

The search for neurobiologic phenotypes has previously uncovered several excellent candidates. These include eye-tracking dysfunction, attentional impairment, allusive thinking neurologic signs, neuropsychological impairment, and characteristic auditory-evoked potentials. A comprehensive review of each of these is beyond the scope of this chapter. However, an examination of neuropsychological studies will provide a useful example.

Studies of the children of schizophrenic patients provide consistent evidence for their poorer performance on perceptual-motor speed tests. Other studies found significant deficits in perceptual-motor speed tests among the adult relatives of schizophrenics. Tests of mental control/encoding (also referred to as measures of short-term memory or selective attention) are also impaired among relatives of schizophrenics. For example, several studies reported children of schizophrenic patients to have lower Wechsler arithmetic subtest scores than controls. Also, children of schizophrenic patients do poorly on digit span tasks when these tasks include a distraction component. Sorting tests (e.g., the Wisconsin Card Sorting Test) have implicated abstraction and concept formation as deficits among relatives of schizophrenic patients. Some studies found deficits in verbal learning and memory among relatives of schizophrenic patients; in contrast, visual–spatial general ability and visual–spatial learning and memory have usually not been impaired in these subjects. Impairments in motor function have been found consistently among the children of schizophrenic patients, usually as soft neurological signs such as disturbed gait, poor balance, incoordination, and motor impersistence.

In summary, studies of neuropsychological functioning among relatives of schizophrenic patients point to deficits in sustained attention, perceptual-motor speed, concept formation and abstraction and, to a lesser extent, mental control/encoding and verbal learning and memory. The domains impaired in relatives are

promising as potential indicators of the schizophrenia genotype because they are consistent with the cognitive dysfunctions thought to be central to schizophrenic patients themselves.

CLINICAL IMPLICATIONS

Psychiatric genetic research has not produced new diagnostic technologies or new therapies for schizophrenic patients. There is little doubt that, in the long run, the discovery of etiological genes will lead to treatments that are more effective, along with molecular genetic diagnostic markers that will identify high-risk individuals. Improved diagnostic technologies raise the possibility of designing primary prevention and other early intervention strategies for preschizophrenic individuals.

Although the major clinical contributions of genetic research in schizophrenia may be decades away, this line of research has led to advances in diagnosis, treatment, and genetic counseling that should be useful to the practicing clinician.

DIAGNOSIS Because schizophrenia is familial, the art of diagnosis should be extended from diagnosing patients to diagnosing entire families. Indeed, we have found that a comprehensive psychiatric family history is one of the most illuminating sources of information in a diagnostic interview. By determining what psychiatric illnesses occur in the patient's family, the clinician may be more precise in the diagnosis of the patient.

The psychiatric family history is most helpful for "atypical" patients who are not clearly schizophrenic or mood-disordered. It is also useful when little data about the patient are available. Nevertheless, such data should be routinely collected because, in all cases, it helps the clinician develop and test diagnostic hypotheses.

The use of family history data is straightforward and intuitive. For example, consider the case of a 30-year-old patient who is admitted to a hospital for the first time with the psychotic symptoms of both schizophrenia and the affective symptoms of bipolar disorder, without clearly meeting criteria for any disorder. If the patient has two schizophrenic siblings, a provisional diagnosis of schizophrenia would certainly be in order. If these siblings had bipolar disorder and/or major depression, the diagnosis of bipolar disorder would receive more consideration.

Of course, "familial diagnosis" should be used cautiously. It is an adjunct to—not a replacement for—clinical psychiatric diagnosis. Most importantly, the absence of schizophrenia among relatives should not be used to infer that the patient being diagnosed does not have schizophrenia. In fact, because of schizophrenia's complex mode of inheritance, many patients with schizophrenia will not have relatives with the disorder.

TREATMENT Knowledge of the genetics of schizophrenia should influence its therapy in three ways. First, if a patient has relatives with the disorder, their response to specific biological treatments should be considered in choosing a therapy for the patient. Although little is known about the pharmacogenetics of psychotropic drugs, clinical experience shows that, in some cases, biologically related schizophrenic patients may respond best to the same medication. However, controlled research is needed before practice guidelines can be established.

The second influence of genetic findings on treatment is in the area of medication compliance. Many schizophrenic patients refuse to take their medication; others do not actively refuse, but find it difficult to maintain their prescribed regimen. These problems can be reduced by discussing the genetic etiology of schizophrenia when teaching patients about their illness. Many still hold naive beliefs about the etiology of their disorder; they are quick to attribute it to events in the past, life circumstances, or their own psychological inadequacies. These beliefs (sometimes delusional) may make it difficult for a patient to accept the biological roots of their problems. For many psychiatric disorders, genetic data provide the quickest and most convincing means of showing patients how biology plays a role in their condition.

A third therapeutic use of genetic data relates to family therapy, especially for those that do assume that the illness was directly or indirectly caused by deviant family interaction. An educational component attempts to reduce the family's self-blame for the illness. Once families learn about the genetic and biological bases of the illness, they can discard guilty feelings and more productively cooperate in the treatment of their relative. Understanding biological bases also helps families accept the necessity of medication.

GENETIC COUNSELING Many patients, along with their relatives, are concerned about the potential recurrence of schizophrenia among family members. In the absence of knowledge of DNA markers from linkage analysis or risk figures from a known model of genetic transmission, we can use the available family study data to make predictions. For example, it is reasonable to tell a schizophrenic patient that the risk to siblings for severe psychotic illness is about 10%. The risk to an identical twin would be about 55%. Unfortunately, little is known about complicated family structures (e.g., the risk to a child who has a schizophrenic father and sibling).

When genes for schizophrenia are discovered, it will become possible to predict its onset in apparently healthy individuals. After a link has been confirmed, we can identify individuals within a pedigree who are marker-positive and disease-negative, but who have not yet passed through the period of risk for the illness. We would then predict that these individuals would later manifest the disorder. Thus, linkage analysis carries with it the promise of substantially increasing our understanding of etiology with hopes of providing leads toward primary prevention.

110 Affective Disorders

Francis J. McMahon and J. Raymond DePaulo, Jr.

BACKGROUND

In this chapter, we will attempt to outline the current state of knowledge about the genetics of affective disorders. The inclusion of this subject in a textbook of molecular medicine could be viewed as premature, since an understanding of the pathophysiology of the affective disorders on the molecular level is not yet in our grasp. Nevertheless, clinical research over the last century has established a major role for genetic factors in the etiology of the affective disorders. We will describe how molecular approaches to the affective disorders follow from this knowledge. We will also outline the major challenges in the path to a molecular understanding of the affective disorders.

The top–down approach of neuroscience, which attempts to fashion theories of pathogenesis out of an understanding of the component molecules of the nervous system, has so far not succeeded in establishing the molecular basis of the affective disorders. This is not surprising in view of the enormous complexity of receptors, ligands, second messengers, and synaptic connections in the brain. However, the impressive body of work in molecular neuroscience over the past 40 years has succeeded in establishing the context against which genetic findings may ultimately be interpreted.

The bottom–up approach of modern genetics is radically different. Instead of reasoning from component parts, the genetic approach first exploits the great wealth of genetic variation in an attempt to identify a gene or genes that are tied to the phenotype of interest in a predictable manner. This is the goal of linkage and association studies, which we will discuss in depth later. Once such a gene is identified, work can proceed logically to identifying a change in the gene's sequence of nucleotides that alters the structure and function of the protein product, that is, a mutation. At that point, the genetic approach may join hands with molecular neuroscience in formulating a theory of pathogenesis based on both genetic variation and biochemistry.

Affective disorders is the term applied to a range of illnesses manifested by pathologic changes in mood, one's attitude toward self, and the sense of bodily well-being. In this chapter we will not focus on the myriad illnesses that engender affective changes as a secondary feature of some larger disease process, such as cancer; rather, we will focus on those illnesses that, to the best of our knowledge and observation, constitute a primary change in the affective realm of mental life.

HISTORY

The affective disorders have been recognized in some form since antiquity. Galen and Aristotle write of patients suffering from melancholia and mania, whose symptomatology would be very familiar to modern psychiatrists. Later in Anatomy of Melancholy, Burton provided a bridge between the classical authors and medieval notions of mental illness, placing what we would now call affective disorders at the heart of his complex nosology of mental disorders. But it was the work of eighteenth- and nineteenth-century physicians, such as Benjamin Rush, Wilhelm Griesinger, and especially Emil Kraepelin, that provided the basis of our modern conceptualization of affective disorders as disease entities, distinct from schizophrenia or dementia, and characterized by cyclic or periodic changes that may be depressive or manic in character.

NOSOLOGY

UNIPOLAR VS BIPOLAR DISORDER The only major nosologic advance over these pioneers was introduced by Leonhard, who in the late 1950s showed that there were marked differences in age at onset and clinical course between patients with only depressions compared to those who also experienced mania at some time in their lives. This fundamental observation has been confirmed many times over in clinical studies, but has not yet been correlated with any robust differences in laboratory findings. Nevertheless, Leonhard's unipolar/bipolar distinction has become the basis of our clinical terminology. This chapter will focus on those studies undertaken since the adoption of the unipolar/bipolar distinction, reflecting its enormous impact on the field.

OTHER APPROACHES The Diagnostic and Statistical Manual of Mental Disorders, 4th ed. (DSM-IV) recognizes six major types of affective disorder (Table 110-1). In addition, several "specifiers" are listed for most of the major types, based on such things as the presence or absence of hallucinations or delusions, a seasonal pattern of episodes, or other clinical features. Calculation of all possible unique combinations of types and specifiers yields some 2655 subtypes of affective disorder. While all specifiers meet some minimum standard of reliability, validation of even the most widely recognized subtypes remains weak at best.

The International Classification of Diseases (ICD-10) contains a classification of major affective disorder that is very similar to that in the DSM. The exceptions are bipolar II disorder, which is not included as a separate category in the ICD-10, even though hypomania is included as a subtype of manic disorder. ICD-10 also

**Table 110-1
DSM-IV Classification
of Affective (Mood) Disorders, Major Subtypes**

Depressive disorders
    Major depressive episode
    Dysthymic disorder

    Bipolar II disorder
    Cyclothymic disorder
    Bipolar disorder NOS
Mood disorder NOS
Related condition listed under "Schizophrenia and other psychotic
    disorders":
    Schizoaffective disorder

provides fewer specifiers than DSM-IV. Finally, there are differences between the ICD-10 and the DSM-IV in the types of schizoaffective disorder and their clinical definitions.

The pragmatic value of such catalogs as DSM-IV and ICD-10 notwithstanding attempts to break down the affective disorder phenotype beyond the level of the unipolar/bipolar distinction have not proven very fruitful. There do appear to be differences in prognosis and possibly treatment response for some types of depression, and patients who experience distinct mood elevations less severe than those seen in mania (hypomanias) may be distinguished by family history, longitudinal course, and comorbidity from other patients. Still, the similarities among patients with unipolar or bipolar illness seem to far outweigh the differences. Further distinctions must likely await molecular discoveries of a fundamental nature.

CLINICAL FEATURES

CLASSIC DESCRIPTIONS The German psychiatrist Emil Kraepelin is widely viewed as the father of the clinical study of manic-depressive disorder. Based on his clinical observations, he advanced one of the broader concepts of manic-depressive disorder, encompassing modern bipolar and unipolar disorder as well as milder disturbances of the affective realm. As he states in the 8th edition of his classic textbook:

> *Manic-depressive insanity encompasses, on the one hand, the whole area of the so-called periodic and cyclic forms of mental illness, on the other hand, simple mania, the majority of illnesses designated as melancholia, and also a not insignificant proportion of cases of amentia (stupor). Finally, we also must include certain mild, even trivial colorings of mood—sometimes periodic, sometimes chronic—which can either be seen as prodromes of more serious disturbances or as phenomena that blend without sharp borders into the area of personal disposition.*

Whether Kraepelin's broad concept will prove valid must await the results of genetic research. But the clarity of his approach, his sharp differentiation between schizophrenia and manic-depressive disorder, and his appreciation for all of the clinical nuances of the illness, make his writings very valuable even for the modern reader.

DESCRIPTIVE VARIABLES **Age at Onset** Depression and mania can occur in children, although affective disorders are usually first diagnosed in adolescents and adults. However, the precise definition of the time when a mood disorder actually begins is often not possible on clinical grounds alone. The onset may be manifested in by the first treatment contact, the first clear episode, the first symptoms, or by some clinically occult process that bears no obvious relationship to symptoms.

Defining even these arbitrary markers of onset can be problematic. Age at onset data is usually collected retrospectively, which introduces some biases. Further, disease onset may be precluded by death from an unrelated cause, or onset may occur after the patient is examined and thus goes unobserved. Ascertainment biases can also significantly affect age at onset observations (e.g., clinical samples often contain more severe cases with earlier onset). In addition, several epidemiologic studies have described earlier onset of unipolar or bipolar disorder among persons born after 1945. This so-called cohort effect is of mysterious origin, but may result from several environmental and cultural phenomena, as well as recall bias.

Despite these issues, there is reasonably good agreement in the literature about age at onset for the affective disorders. The first episode of mania or major depression in bipolar I disorder tends to occur around the age of 20 years. For unipolar disorder, the first major depression occurs later, toward the early thirties, on average. Studies give conflicting results as to the onset of bipolar II (BPII) disorder. Some suggest an age at onset between that of bipolar I (BPI) and recurrent unipolar disorder, while other studies have suggested an age at onset for BPII that is very close, if not identical, to that of BPI.

Several points are clear. There are no marked differences in age at onset between males and females. In both bipolar and unipolar disorders, age at onset tends to be lower when there are many affected relatives, probably because of the increased burden of both genetic and nongenetic risk factors in such families.

Attempts to define clinical subtypes of affective disorder beyond the unipolar/bipolar level based on age at onset have, in general, produced a few striking differences. There is a remarkable clinical similarity between affective disorder beginning in young and late adulthood. However, people with early-onset bipolar disorder do appear to be more likely to experience psychotic symptoms (i.e., hallucinations or delusions).

Several disease that models account for the delayed onset of affective disorders have been proposed (for a review, *see* McMahon and DePaulo, 1996). Within families, several studies have suggested that age at onset declines in successive generations. Such anticipation may point to a role for genes with expanding triplet repeat sequences in affective disorders. Ultimately, however, a full understanding of age at onset in mood disorders must await discovery of the genetic factors involved.

Drug Response Treatment of affective disorders relies on two broad classes of pharmacologic agents: antidepressants and mood stabilizers, such as lithium.

The antidepressants are often classified according to their molecular structure or the major neurotransmitter systems they affect. However, it is not at all certain whether an antidepressant's known effects on neurotransmitter systems bears any direct relationship to its therapeutic action. Similarly, while the pharmacologic and side-effect profiles of the major mood stabilizers are well known, the mechanism of their therapeutic action remains mysterious.

Several investigators have attempted to classify persons with affective disorders according to their response or nonresponse to a particular drug or class of drugs. Unfortunately, this approach has revealed little. Aside from the methodologic difficulties inherent in classifying patients as "responders" or "nonresponders," a nosology based on treatment response embodies a logical fallacy. Simply stated, if a patient responds to a treatment that has been used successfully in disease X, then the patient must have had disease X. While morphine quickly relieves the symptoms of heart failure, we do not conclude that cancer patients who feel better when treated with morphine actually have heart failure.

Still, classification by treatment response may have some value in producing more homogeneous populations of patients for genetic linkage studies. For example, several studies have shown that a family history of bipolar disorder predicts response to lithium, and others have suggested that lithium-responsive bipolar disorder may fit a Mendelian model of inheritance better than bipolar disorder as a whole.

Comorbidity   The affective disorders are often complicated by other mental disorders, particularly substance abuse and anxiety disorders. That this comorbidity is more than just an understandable consequence of the impairments of depression or mania is shown by family studies. The same diagnoses that tend to co-occur with affective disorder also occur with increased frequency in the affectively well relatives of affectively ill probands. For example, Gershon et al. (1982) reported a greater lifetime risk of cyclothymic personality, generalized anxiety disorder, alcoholism, and drug abuse among first-degree relatives of probands with major affective disorder compared to unaffected control probands.

Comorbidity may also prove valuable as a means of differentiating different genetic forms of affective disorder. For example, MacKinnon et al. (1997) have shown an increased incidence of panic disorder only among the bipolar relatives of probands who suffer from both bipolar disorder and panic disorder. If particular comorbid illnesses occur in certain genetic subtypes of affective disorder, then the power and resolution of genetic linkage studies might be improved by partitioning family samples according to comorbid illnesses.

EPIDEMIOLOGY   Epidemiologic Catchment Area Study
While the high prevalence of the affective disorders has been suggested since antiquity, precise estimates of prevalence awaited the advent of modern epidemiologic methods. In 1978, the largest systematic study of the epidemiology of mental disorder in the United States was undertaken by investigators at five universities. Approximately 20,000 individuals aged 18 and older were selected for study out of a population that even included those living in institutions, such as nursing homes, psychiatric hospitals, and prisons. Face-to-face evaluations were carried out by nonclinicians using a structured interview, the Diagnostic Interview Schedule (DIS). Diagnoses were assigned based on the DSM-III. The ECA study clearly established that affective disorders, particularly major depression and dysthymia are quite prevalent in the community (Table 110-2). Females report more major depression and dysthymia than males, but similar rates of bipolar disorder, consistent with previous studies. The ECA found very little difference in prevalence between groups in different socioeconomic classes, races, or metropolitan areas. This would be expected if the prevalence of affective disorder is determined primarily by genetics. Furthermore, the ECA established the high rate of substance abuse comorbidity in affective disorder, particularly BPI, where over

Table 110-2
Lifetime Prevalence[a] of Affective Disorder

[a]Per 100 persons.
[b]NS, not specified.

60% of subjects with this illness reported abuse or dependence with alcohol and/or other drugs.

National Comorbidity Survey   This large epidemiologic study was undertaken to complement the ECA, collecting data on prevalence, comorbidity, and risk factors for mental disorders in a national sample of approximately 8100 respondents aged 15–54 years. Evaluations were carried out by nonclinicians using a modification of the DIS. Diagnoses were assigned based on the revised version of the DSM-III (DSM-III-R). The NCS results support the high prevalence of affective disorders in the community, with lifetime prevalence estimates that actually exceed those seen in the ECA for some diagnoses (Table 110-2). Like the ECA, the NCS also found more unipolar disorder among females and only small differences in prevalence between groups in different socioeconomic classes, races, or metropolitan areas. NCS data also revealed considerable comorbidity between substance use disorders and affective disorders. Comorbidity of alcohol use disorders and major depression was particularly striking, especially between alcohol dependence and major depression in females and blacks.

DIAGNOSIS

BASICS: MOOD, SELF-ATTITUDE, VITAL SENSE   Patients suffering from an affective disorder manifest a pathologic change in mood in at least two ways: in degree and responsiveness. The patient with major depression, for example, will experience a sad, low, or indifferent mood that fails to be dispelled by events that would usually be pleasurable or cheering. Similarly, the patient with mania will experience an elated, expansive, or irritable mood that does not change appropriately in response to disappointments or negative consequences of the patient's behavior. While a patient with an affective disorder will usually experience some variability of mood—for example, diurnal mood variation in major depression—this variability typically loses the close relationship to daily events and experiences characteristic of normal mood variability.

When we speak of a change in self-attitude, we mean a change in the way one views one's self in comparison to one's usual stan-

dards of personal worth. Self-attitude represents the aggregate of one's judgements about personal talents, achievements, character, and future. While sometimes difficult to examine, self-attitude is a diagnostically very important feature of affective disorder that can be helpful in distinguishing episodes of affective disorder from nonpathologic mood changes.

During an episode of affective disorder, the self-attitude typically changes in the same direction as the mood. Thus, the depressed patient will see himself as a failure, as unworthy of love, as reproachable. He may be preoccupied with guilt, past failures, or personal shortcomings. In severe cases, the future seems very bleak and thoughts of death or suicide may be present. All of these symptoms belong to the changes in self-attitude seen in affective disorder.

The vital sense is another aspect of the affective realm typically influenced by an affective disorder. The vital sense refers to one's feeling of physical well-being and bodily health. The vital sense encompasses changes in energy, stamina, sleep, and appetite, but is not restricted to these obvious bodily functions. For some patients, a change in vital sense will manifest only as a subtle change in subjective cognitive skills, such as concentration or memory. For other patients, vital sense changes will be the chief complaint at presentation, leading to the suspicion or diagnosis of a physical illness other than depression.

In major depression, vital sense is typically decreased, with feelings of exhaustion, fatigue, or achiness. Sleep may be increased or decreased, but is typically not perceived as refreshing or restful. Food may lose its appeal, leading to weight loss. All drives are decreased, with a loss of libido, appetite, and interest.

In mania, the opposite applies. Patients boast of limitless energy, strength, and stamina. The need for sleep is reduced, brief naps are perceived as completely restorative, and total sleeplessness may persist for days. All appetites are increased, which may lead to inappropriate sexual behavior or excessive use of alcohol.

In making the diagnosis of an affective disorder, it is important to examine all three aspects of the affective realm in detail. Changes may be subtle, may not be discovered unless enquired about, and may require skillful probing. Finally, it is difficult to overstate the value of longitudinal observation over time, particularly in milder cases of major depression. Longitudinal observation may also help identify rapid cycling, where patients may alternate quickly between mania and major depression, or mixed states, with simultaneous features of both mania and depression. These clinical features often call for particular treatment approaches.

CRITERION SYSTEMS   Rationale   Whereas the diagnosis of affective disorder is often not difficult for the skilled observer, variations in clinical practice and experience can lead to a lack of agreement among clinicians as to the correct diagnosis. For example, the US/UK diagnostic study found that, in 1972, the diagnosis of affective disorder was much less common among hospitalized patients in the United States than in the United Kingdom, raising concerns about diagnostic practices on both sides of the Atlantic. This finding added impetus to the movement to formulate and adopt standardized diagnostic criteria for the affective disorders and indeed for all mental illnesses. The Diagnostic and Statistical Manual of Mental Disorders (DSM) and its equivalent sections in the International Classification of Diseases (ICD) represent the current incarnation of this movement.

Reliability vs Validity   The value of standardized diagnostic criteria lies in their ability to increase the reliability with which a

diagnosis can be assigned. Reliability describes how often two different clinicians will make the same diagnosis when they examine the same patient. Thanks largely to the advent of standardized criteria, it is now safe to assume that most patients diagnosed with mania in New York would have been given the same diagnosis if they had been examined by psychiatrists in Iowa, London, or Frankfurt.

Diagnostic reliability is a necessary first step in discovering the molecular causes of any disease. Without reliability, there is no basis for assuming that any two people with the same diagnosis share any etiologic or pathogenic features in common. In this regard, the advent of reliable diagnostic criteria has been a major element in the progress toward understanding affective disorders on the molecular level. However, reliability can never be perfect, neither does perfect reliability assure validity. Until the genetic basis of the affective disorders is understood, we cannot be sure that the current diagnostic entities are valid disease entities, that is, that they bear a predictable relationship to events outside the affective realm, such as a change in the coding sequence of a gene.

Diagnostic and Statistical Manual of Mental Disorders   The DSM-IV lists operational criteria for diagnosing affective disorder. These criteria, while imperfect, do allow affective disorder to be diagnosed with high reliability by experienced clinicians. As discussed above, the DSM also delineates criteria for many related conditions, some of which are commonly seen among the relatives of probands with major affective disorders. The degree to which these conditions overlap with, or are distinct from, the major affective disorders, is another question that can best be answered once the genetic causes of the major subtypes are known.

GENETIC BASIS OF DISEASE

A genetic basis for the affective disorders, while long-suspected and supported by family, twin, and adoption studies, still awaits molecular elucidation. In this section, we will review the evidence supporting a genetic basis for affective disorders. We will also discuss the results of association and linkage studies, which, while still provisional, may lead to the identification of specific genes and mutations.

FAMILY STUDIES   Family studies have accomplished two important goals in the study of affective disorders. First, they have confirmed the familial nature of these illnesses—a necessary part of the genetic hypothesis. Necessary, but not sufficient: Many things, ranging from wealth to eating habits, are familial without being genetic. This is why twin and adoption studies, covered later, are also of great importance. Second, family studies have provided essential information about the range of disease phenotypes associated with the putative affective disorder genes, by revealing which types of illnesses run in the families of patients with affective disorder and which do not.

In other genetic disorders, family studies have also been a valuable tool for discerning the mode of inheritance, through segregation analysis. Segregation analyses have yielded conflicting results when applied to affective disorders, probably because the method does not readily accommodate etiologic heterogeneity, a fact of life likely to strongly affect the study of most psychiatric disorders. In addition, recent studies have suggested that transmission of bipolar affective disorder (BPAD) is influenced by the sex of the transmitting parent. Such parent-of-origin effects, which may reflect imprinting or mitochondrial inheritance, further obscure Mendelian transmission patterns.

Table 110-3
Lifetime Morbid Risks for Affective Disorders and Schizophrenia in Families

| Proband (N) | Risk (%) for first-degree relatives[a] | | | Study |

[a]Age-corrected by various methods.
[b]For studies that specify relatives diagnoses as bipolar I or bipolar II, includes both diagnoses.
[c]BPI includes probands and relatives with bipolar I and schizoaffective-manic disorders.
[d]Rates not age-corrected.

Classic The classic family studies of affective disorders were carried out in the early part of this century, before the advent of modern methodologic approaches. Despite this limitation, many of the classic family studies yielded conclusions that modern researchers have only confirmed, albeit with greater precision.

The 1936 study of Elliot Slater is perhaps the best example. Slater studied 315 probands with recurrent, major affective disorder collected from the cardfiles of the Munich Genealogical Institute, where he studied under the pioneering psychiatric geneticist Bruno Schulz. Slater calculated the lifetime risk for various mental illnesses among the parents and children of his probands. His paper was one of the first to use age-corrected estimates of lifetime risk, such as the Strömgren method, which adjusts for the fact that relatives of different ages have passed through different proportions of the period of risk.

Slater's main finding was that the parents and children of probands with manic-depressive disorder had a lifetime risk of developing the illness themselves (morbid risk) of about 15%. Although Slater did not collect unaffected control probands for comparison, based on contemporary prevalence estimates he concluded that "manic-depression" and suicide were increased among the parents and children of the probands, while schizophrenia "criminality" and "imbecility" were not. These results forced Slater to revise his own view that there existed a relationship between the predisposition to schizophrenia and to manic-depressive disorder. He concluded instead that "…such specula-

tions, however, appear to me now to be unjustified…" Although statistical and diagnostic approaches have changed, Slater's risk estimates are not very different from those obtained in more modern family studies, detailed below.

Modern Modern family studies are distinguished from most of the classic studies by three methodologic advances:

1. Use of operational diagnostic criteria.
2. Use of age-corrected risk estimates.
3. Use of control procedures, such as examination of relatives by investigators who were blind to the proband's diagnosis, and use of unaffected probands, allowing more precise estimates of relative risk of illness for relatives of affected probands.

The modern studies also incorporate the unipolar/bipolar distinction when selecting probands and reporting results.

The main findings of the modern family studies are presented in Table 110-3. These studies were selected based on proband sample sizes of over 100, diagnostic assessment by direct interview, and clinical evaluations performed blind to the diagnostic status of the proband. While absolute risks vary across studies, three conclusions are clear:

1. Major affective disorder is familial: There is an increased risk for major affective disorder among the relatives of affected probands compared to the relatives of unaffected probands.

2. Bipolar and unipolar disorder are distinct, but related: There is an increased risk of both unipolar and bipolar forms of affective disorder among the relatives of probands with bipolar disorder, while among the relatives of probands with unipolar disorder, risk is increased only for the unipolar form of the illness.

3. Major affective disorder is different from other major mental illnesses: The risk for other major mental illnesses such as schizophrenia, is not increased among the relatives of probands with major affective disorder. However, affective disorders and schizophrenia may still share etiologic determinants, as suggested by some authorities.

Family studies have clearly established the distinct familiality of major affective disorder and support the validity of the unipolar/bipolar distinction. However, as noted above, family studies alone cannot establish an unambiguous etiologic role for genetic factors. For this, lacking confirmed linkage reports or identified genes, twin and adoption studies remain the best source of data.

TWIN STUDIES The rationale of twin studies is simple: Since monozygotic (MZ) (identical) twins presumably carry the same genetic endowment, if one twin falls ill with a genetic illness, the other would be expected to fall ill as well, that is, be concordant. On the other hand, dizygotic (DZ) (fraternal) twins should have a lower concordance rate, since they share, on average, only half their genes. Concordance rates are usually calculated from the number of pairs where both co-twins are affected divided by the total number of pairs studied (pairwise concordance). Tetrameric correlations, which also take into account pairs where both co-twins are unaffected, are sometimes calculated as well. In probandwise concordance rates, the proportion of affected probands with an affected co-twin is reported.

It is important that the implicit assumptions of the twin method be borne in mind. First, it is assumed that ascertainment into the study is independent of concordance. For this reason, systematic ascertainment is important; nonsystematic studies usually overestimate concordance rates. It is also assumed that MZ and DZ twins differ only in the proportion of shared genes. We now know that MZ twins are not always genetically identical, because of somatic mosaicism, and may be more likely to experience similar environmental events than DZ twins. Still, high concordance rates among MZ twins, particularly if coupled with lower concordance rates among DZ twins, strongly suggest an etiologic role for genetic factors. Some researchers have developed biometrical models that, when applied to large samples of twins, provide estimates of the relative contributions of genes and environment to the variance in the phenotype, and in some cases distinctions can be made between shared (familial) and unshared environmental influences.

Classic The classic twin study of major affective disorders was published by Rosanoff, Handy, and Plesett (1935). In a retrospective chart-review study, 90 twin pairs were evaluated, at least one of whom suffered from "manic depressive syndromes." Although their methods were crude by today's standards, the authors obtained concordance estimates that are in good agreement with those of modern studies. Rosanoff et al. estimated a MZ pairwise concordance rate of 69.6% and a DZ concordance rate of 22.9%, based on same-sex twins. He concluded correctly that genetic factors play an important etiologic role, but, in some cases at least, nonhereditary factors are also required to cause the illness.

Modern The few modern twin studies of major affective disorder are distinguished by large, systematically ascertained samples. Some also have used operational diagnostic criteria and control procedures, such as blind assessment.

The largest study of bipolar disorder (110 twin pairs) was based on the Danish Twin Registry. In this study, MZ co-twins of probands with "manic-depressive disorders" had a probandwise concordance rate of 67%, significantly greater then the 20% seen in DZ twins. These figures were 79 and 19%, respectively, for MZ and DZ co-twins of probands with more narrowly defined bipolar disorder. Monozygotic co-twins of probands with unipolar disorder had a concordance rate of 54%, compared to a 24% rate seen in dizygotic twins.

These concordance rates are approximated by most other large, systematic twin studies. The results strongly support a major role for genetic factors in bipolar disorder, but offer less support for a major genetic role in unipolar disorder. Furthermore, the less than 100% concordance rate in bipolar disorder suggests that (barring undetected mosaicism) nongenetic factors are also important in the expression of the bipolar phenotype.

The largest twin sample studied for unipolar disorder comes from the Virginia Twin Registry. This population-based registry contains over 1700 female twins, with 742 complete pairs. Kendler et al. have studied these women using repeated self-report questionnaire assessments. Estimates of heritability of major depression ranged from 33 to 70%, depending on the reliability of the case definition: The more reliable case definitions were associated with higher heritability estimates. Kendler concludes that "major depression, as assessed over the lifetime, may be a rather heritable disorder of moderate reliability rather than a moderately heritable disorder of high reliability."

Twin studies have made a major contribution to our understanding of the role of genetic factors in affective disorders. While they certainly increase our confidence in a major etiologic role for genes in these illnesses, twin studies cannot provide data as to the particular genes involved. Still, future twin studies may help contribute to the refinement of our nosologic and disease-recognition strategies, which are critical steps in the road to the identification of disease genes.

ADOPTION STUDIES While twin studies lend strong support to a major role for genetic factors in major affective disorder, these studies do not readily distinguish between shared genes and shared environment. Twins generally share the same uterine environment and, being the same age, experience the same family environment at the same developmental stages. Moreover, MZ twins, perhaps owing to their similarity in appearance and temperament, may be exposed to more environmental similarity than DZ twins.

Adoption studies offer a way out of this conundrum. There are two basic designs:

1. The affected parent design, where the risk of illness is compared for the adopted versus biological offspring of affected parents; or

2. The affected adoptee design, where the risk of illness is compared for the biological vs adoptive parents of affected adoptees.

Even the best adoption studies cannot entirely exclude the environmental contributions of affected parents. For example, adoption usually occurs in the first days or weeks after birth, so that exposure to the biological mother's intrauterine environment is not eliminated. The advent of ovum donation and gestation by

surrogate mothers may eventually set the stage for an adoption study that avoids this problem.

The first adoption study in bipolar disorder was conducted by Mendlewicz and Rainer (1977), using the affected adoptee design with several different control groups. They found that the adoptive parents of affected adoptees had an observed rate of affective disorder that was not higher than that seen in the adoptive parents of unaffected adoptees or in the biological parents of children with poliomyelitis. In contrast, the biological parents of the adoptees with bipolar disorder showed a 16-fold increased rate of affective disorders. Several subsequent adoption studies of BPAD confirm these findings. Thus, while family environment probably plays a role in major affective disorders, there is little evidence that it is a major causative factor.

LINKAGE AND ASSOCIATION STUDIES   While family, twin, and adoption studies all support a major role for genes in the etiology of the major affective disorders, these study designs do not indicate in any way which genes are involved. Linkage and association studies, on the other hand, are designed to locate specific genes. In linkage studies, we assess the co-inheritance within a family of the disease phenotype and particular genetic markers whose location on the chromosomes is known. These can either be phenotypic markers, such as red-green color blindness, candidate genes, or anonymous polymorphic DNA markers.

In association studies, we assess the co-occurrence within a large population of the disease phenotype and a particular form (allele), of a gene of interest. A specialized type of association study, the linkage disequilibrium study, looks for fragments of ancestral founder chromosomes defined by associated DNA markers lying very near the actual disease allele.

Linkage Results   Over 50 linkage studies of BPAD have been performed to date. Although initial results were disappointing, more recent studies have yielded replicated findings that may ultimately lead to the identification of important disease genes. The major regions of interest are discussed below.

HLA   Two early reports of linkage between bipolar disorder and a particular set of human leukocyte antigens have never been replicated and probably represent a false-positive result.

The X Chromosome   An X-linked gene has been hypothesized to play an etiologic role in affective disorders since at least 1934, when Rosanoff hypothesized an X-linked "activating factor" to explain the higher prevalence of affective disorder among women. More direct evidence of X-linkage was suggested by Winokur, Clayton, and Reich's classic study of BPAD and protan/deutan color blindness (1968). The evidence of X-linkage seemed even stronger when two other groups reported linkage between BPAD and protan/deutan color blindness or glucose 6-dehydrogenase deficiency.

Despite these early results, X-linkage of BPAD, while not entirely disproven, has not been supported by the mass of molecular evidence. Ultimately, X-linkage was not supported in Baron's original pedigree set, when highly polymorphic DNA markers were used. The reliance on relatively uninformative phenotypic markers and large multigenerational families with few opportunities for male-to-male transmission may explain the failure to find support for X-linkage in many studies, but the early positive findings of X-linkage have never been fully explicated. While an X-chromosome locus for BPAD cannot be ruled out, if it exists, it must be a relatively "weak" locus or play a significant role in only a small minority of families.

Chromosome 11   The report of linkage of BPAD to the DNA markers HRAS and INS on chromosome 11 was greeted with great excitement. Following on the successful detection of the chromosome 4 linkage in Huntington disease, this report seemed to be further proof of the promise of polymorphic DNA markers in detecting linkages for complex neuropsychiatric disorders.

Although the initial report of chromosome 11 linkage, like that for the X chromosome, was not confirmed, the reasons for this failure were clear, and provided important lessons for the field. The linkage evidence rested on study of a large pedigree from the relatively inbred Old Order Amish. The rationale for studying the Amish in the first place was quite legitimate: It was hoped that this genetically isolated population, founded by relatively few initial settlers about three centuries ago, would be less likely to contain many different BPAD disease genes, and thus the power to detect linkage might be correspondingly greater.

Unfortunately, this same genetic isolation and in-breeding make the Amish population problematic in several ways: (1) in large, inbred kindreds, linkage evidence may rest disproportionately on data from one or a few individuals; (2) linkage evidence in large pedigrees with a few affected relatives is derived primarily from unaffected individuals, whose phenotype could change or who may carry the disease allele but not manifest the phenotype (incomplete penetrance); and (3) it is difficult or impossible to be sure that a large, inbred pedigree stems from a single ill founder, leading to genetic heterogeneity within the pedigree, decreasing the power to detect true linkage

The re-evaluation of the chromosome 11 linkage results in the Amish pedigrees indicated that each of these problems had a hand in the demise of the linkage finding. Previously missing genotype data on 10 individuals decreased the LOD score at HRAS from 4.08 to 2.36 ($\theta = 0$). The most dramatic effect on the LOD scores resulted from a phenotype change from unaffected to affected in one or two key individuals, lowering the LOD score to $-1.75(\theta = 0)$. Although these individuals may actually be phenocopies, they cannot be ignored, since there is, as yet, no way of identifying phenocopies independent of the linkage data. Extension of the original pedigree into right and left branches further reduced the LOD score well into the exclusionary range, probably as a result of multiple ancestral sources of illness in the Amish kindred leading to different disease genes segregating in different branches.

Based in part on the experience with the Amish study, linkage analysts now recommend that for complex phenotypes like affective disorder, several special precautions should be taken in the design and analysis of linkage studies. First, linkage results—particularly in large pedigrees—should be recalculated several times, each time changing the diagnosis (or genotype) of one person in the pedigree, to be sure that the results do not depend too heavily on any one individual. Second, it is important to detect multiple ancestral sources of illness and consider this fact in the linkage model. Third, affected-only linkage methods should always be part of a linkage study of diseases with late and variable age at onset or suspected incomplete penetrance. Results that are not supported by the affected-only analyses should be viewed with appropriate suspicion.

Recent   The results of the second generation of linkage studies of BPAD are beginning to appear, distinguished from the first generation by larger sample sizes, use of nonparametric (affected relative pairs) as well as parametric linkage methods, and the universal use of highly polymorphic DNA markers. A reported

linkage to chromosome 18p has been independently replicated. Other reports also suggest additional loci on the long arm of chromosome 18. New reports suggesting linkage to Xq26, and to chromosomes 4p and 21q have also appeared; the latter has been replicated in an independent series of pedigrees.

Berrettini et al. reported evidence of linkage between BPAD and polymorphic DNA markers within the pericentromeric region of chromosome 18. While overall LOD scores were not significant, several individual families yielded LOD scores consistent with linkage and affected sib-pair and affected pedigree-member results were statistically significant.

Stine et al. also reported evidence of linkage between BPAD and markers on 18p, within the same region implicated by Berrettini et al. On average, a highly significant 64% of sib-pairs affected with bipolar or recurrent unipolar disorder shared alleles of a DNA marker in this region. Stine et al. also found evidence of linkage to markers on 18q. Significant excess sharing of paternally, but not maternally, transmitted alleles was observed at three neighboring 18q markers. The evidence of linkage to loci on both 18p and 18q was strongest in the families with affected or transmitting fathers. In this set of families, the peak LOD score was 3.51 on chromosome 18q; LOD scores in the families with an affected or transmitting mother were negative. Similar results were seen in affected sib-pair analyses. Such a parent-of-origin effect for BPAD had been suggested by previous studies and has also been detected in a reanalysis of the Berrettini et al. data. Three other groups have since published weakly supportive evidence for an 18q locus in BPAD, and the group reporting the original 18q linkage has found further evidence of linkage to 18q in a new set of families.

Caveats and Outlook   Recent linkage reports suggest that, in contrast to earlier findings, linkage findings in BPAD, particularly on chromosomes 18 and 21, are not only detectable but replicable. Linkage methods work best when one or only a few genes underlie the phenotype of interest, while in complex phenotypes like BPAD, linkage results are more difficult to interpret, with many false positives and false negatives. The uncertainties inherent in the linkage study of BPAD mean that linkage findings, even when confirmed, are unlikely in themselves to provide fundamental insights. Such insights must await the identification of specific genes and mutations. While such an achievement is clearly visible on the horizon, very large sample sizes or the fortuitous discovery of an expanding triplet repeat, linkage disequilibrium effect, or cytogenetic abnormality will probably be necessary in order to localize linkage with the precision necessary for the commencement of gene-identification approaches.

The linkage studies of BPAD to date suggest that neither a single major locus nor a large number of genes, each of very small effect, will be found to underlie the phenotype. As has been shown for other complex phenotypes, like IDDM, it appears that a few genes of moderate effect (each conferring a relative risk of disease that is two to five times greater than that for persons not carrying the disease allele), probably acting in concert but with considerable heterogeneity in different populations, will ultimately be identified.

ASSOCIATION FINDINGS   The association approach is a method that complements linkage studies, typically by focusing on candidate genes, i.e., genes, the function of which makes them plausible candidates for a pathophysiologic role in BPAD. The association approach hypothesizes that when a gene underlies a given phenotype, certain alleles of that gene should be more commonly found in patients than in unaffected controls. Association methods look for a correlation between gene and phenotype in a population, while linkage methods look for this correlation within families. In linkage disequilibrium studies, association methods are used to detect marker alleles that lie so close to a disease gene that recombination between the marker and the disease gene occurs only rarely. Association approaches are more sensitive than linkage approaches in the face of significant genetic heterogeneity. But, like linkage approaches, association approaches are subject to false-positive findings, particularly when patient and control groups are not well-matched.

Tyrosine hydroxylase is the rate-limiting enzyme in the synthesis of catecholamine. An association between alleles of the gene encoding tyrosine hydroxylase, which maps to the tip of chromosome 11p, has been suggested by some studies, but the potential of a false-positive association has not been ruled out. Similarly, a few studies point to an association between BPAD or manic behavior and the gene for MAO-A, on Xp11. A number of studies have reported and association between affective disorder and polymorphisms near the serotonin transporter gene, but these may prove to be false-positive findings arising from population differences between cases and controls (for a review, *see* Greenberg et al.). Other reported associations have either proved to be spurious or have repeatedly failed to be replicated.

To date, only one study of BPAD has used the linkage disequilibrium approach across the genome. However, searching within a linked chromosome region for alleles associated with the phenotype is becoming a standard approach to narrowing the implicated chromosome region so that gene-identification studies can be accomplished efficiently. For this approach, genetically isolated populations are particularly useful.

Caveats and Outlook   Association studies have the potential to contribute significantly to the search for genes underlying BPAD. However, the selection of appropriate candidate genes is problematic. As pointed out by Crowe, all 20,000 genes expressed in the human brain are potential candidates. Even if it were possible to carry out the needed 20,000 association experiments, almost all of the positive findings would prove spurious, given the strong prior odds against any particular gene's being involved in BPAD. Narrowing candidate genes to those brain-expressed genes lying within areas of replicated linkage may offer a solution to this dilemma. Furthermore, the power of association methods to narrow linked regions via linkage disequilibrium may prove to be of great value in the identification of disease genes through physical mapping approaches. Once the first etiologic mutation is identified in BPAD, identification of the other important genes will be hastened. For example, sequence analyses have revealed that genes can be grouped into families or superfamilies, with similarities in sequence predicting similarity of function. A gene known to cause BPAD thus strongly implicates other genes in the same family as candidates.

MOLECULAR PATHOPHYSIOLOGY

HOW GENETIC DEFECTS COULD CAUSE MOOD DISORDER   Genetic studies of the affective disorders promise to revolutionize our understanding of molecular pathophysiology by implicating specific mutations as causal events leading to a mood disorder. But genetic findings alone will be insufficient. As stated at the beginning of this chapter, the genetic findings will

only be interpretable in the context of detailed knowledge about the structure and function of the brain.

One can speculate that genes encoding transcription factors (especially genes that regulate circadian rhythms, and the family of stress-induced immediate-early genes), neurotransmitter transporters, and second-messengers (such as G proteins) may ultimately be implicated by genetic studies of affective disorders. Data from family studies suggest that genes containing triplet-repeat sequences or genes in the mitochondrial genome are worthwhile candidates for study. Still, linkage and association methods offer the best hope for revealing which of the numerous good candidate genes actually play an etiologic role. Association methods are also the best way to identify genes that, while not themselves etiologic, play an important role in modifying the expression of the affective disorder phenotype. Indeed, when a disease is caused by many different highly pathogenic mutations, each of which is rare or uncommon, modifier loci may be the most important identifiers of those at risk for the disease. The apo E4 association with Alzheimer disease is a good example of a modifier locus that is of greater significance in the general population than any given causative disease allele.

MANAGEMENT/TREATMENT

HOW DISCOVERY OF A GENE WILL AFFECT MANAGEMENT AND TREATMENT The discovery of even one major gene underlying the affective disorders will revolutionize management and treatment. The identification of gene carriers among patients presenting for treatment will aid in accurate diagnosis using a much more valid method of disease classification—that based on the specific mutation involved—than is currently possible. It will also become possible to develop treatments that are truly rational, i.e., based on an understanding of the pathophysiology of the illness at the molecular level. Today, although currently available treatments are effective for the vast majority of patients with major affective disorders, we do not know why our treatments work when they work or why they fail when they fail. It is even possible that some of the mutations underlying major affective disorder will be amenable to gene therapy, raising the possibility of truly curative treatments for this devastating group of illnesses.

111   Alcoholism

ERIC J. DEVOR AND ARTHUR FALEK

INTRODUCTION

The many biochemical, familial/genetic, and molecular studies of alcoholism carried out in recent years are representative of the state of psychiatric genetics. This is to say that, despite the fact that there have been great advances made in each of these areas, the grail still eludes us; no precise mechanism has yet been elucidated to explain the transmission of risk, though there is ample evidence that vertical risk transmission does occur. On the other hand, it is also true that the gap in the ring is closing. As with nearly every major complex disease, including the psychiatric disorders, studies of the biochemistry, genetic epidemiology, and molecular biology of alcoholism are inexorably converging on a unifying model of pathogenesis. The exact nature of the model is unknown at present, but some of its general features have been defined, even though this has occurred primarily through discovering what is not included. Naturally, at this stage all knowledge is of value, and in this context it is useful to always keep in mind the great aphorism of Sherlock Holmes that, when all else is eliminated, whatever remains, however unlikely, must be the truth! In this chapter, therefore, we will give as much weight to negative evidence as we will to positive evidence and will use both to provide the general outlines of a model of the genetics of alcoholism.

One fact may be stated at the outset: that there is a plethora of evidence of the vertical transmission of risk in alcoholism; that is to say, the disease runs in families. Indeed, the familiality of alcoholism is one of its oldest and most robust features. The notion that heredity plays a significant role in alcoholism is an old one, dating perhaps back to the origins of alcoholic beverages themselves. References to the familiality of alcoholism and to the "passing on" of the disease from generation to generation may be found in the writings of the ancient Greeks, including both Aristotle and Plutarch, as well as those of the ancient Chinese. Moreover, it is clear in those writings that such ideas came to them from even more remote times. Interestingly, it was recognized, even in the oldest surviving records, that alcoholism was not a simple disease. Rather, complex and even contradictory patterns of inheritance were described. In some works, the scope of the inheritance of alcoholism was expanded to include presumed pleiotropic effects. For example, Long, reporting on his survey of the offspring of alcoholics in 1879, noted that 21% of the "inherited diseases" observed among these offspring could be attributed to alcoholism in the parents.

A classic early, systematic study of alcoholism was reported by Crothers in 1909. In that study, Crothers found that 70% of the more than 4000 alcoholics he had treated over a 35-year period had relatives whose own drinking habits could be described as moderate to excessive. Since then, virtually every study of alcoholics has confirmed of Crothers' conclusion that susceptibility of alcohol abuse/alcoholism is familial, and it can be accepted that "something that runs in families" is operating to produce at least part of the observed patterns of risk. The questions that still remain are: What is this something, and how does it operate?

A NATURAL HISTORY OF ALCOHOLISM

As with most psychiatric and neuropsychiatric disorders, a consensus definition of alcoholism is difficult to come by. However, the definition of alcoholism by Keller, quoted in Goodwin and Guze, is an acceptable working definition: "The repetitive intake of alcoholic beverages to a degree that harms the drinker in health or socially or economically, with indication of inability consistently to control the occasion or amount of drinking." This reference to so-called "loss of control" is an important feature in the discussion of heterogeneity among alcoholics, a topic we will take up later on.

Generally speaking, the epidemiology of alcoholism is also not well-defined. More is known about the patterns of drinking in general than about alcoholism *per se*. However, it is known that gender, age, education, socioeconomic status (SES), and ethnicity all play a role in the lifetime risk of alcoholism. Surveys of lifetime risk from Europe and a few from the United States agree that the reasonable "ballpark" figures are from 3 to 5% among males and from 0.1 to 1% among females. Taking these numbers as an average, it has been shown that African Americans in urban settings have higher rates of alcoholism than do Caucasians, whereas Orientals in all settings have consistently lower rates. Native Americans, who were frequently branded as ubiquitously heavy drinkers, display a great range of alcoholism prevalence and, in fact, some groups are now known to have very low rates. A further complication are the observations that women tend to begin heavy drinking at a later age than do men, and that African Americans begin to drink at younger ages than do whites of comparable SES. Clearly, there are complex interactions among epidemiologic variables that tend to make it difficult to do more than just describe these general tendencies.

Regardless of the patterns of occurrence, one thing is clear: Alcoholism is a behavioral disorder, and the behavior at the root of the disease is the consumption of large quantities of alcohol on

repeated occasions. The reasons for this consumption are often obscure and may be unknown. But as consumption progresses and the amounts consumed increase, there are some common behavioral sequelae. As problems related to drinking excessively become greater, the alcoholic often attempts to hide the condition by drinking alone, hiding bottles, and sneaking drinks. This behavior is almost always accompanied by feelings of guilt and remorse. Guilt and remorse, in their turn, lead to more drinking and a vicious circle is established.

Alcoholics often display symptoms of anxiety and depression. They attempt to relieve these symptoms in the short term by their drinking, but in the long term these same symptoms are exacerbated by that drinking. In addition to either inducing or enhancing low mood, irritability, anxiety, and violence, long-term alcohol consumption has the unusual capability of producing amnesia—the classic alcoholic "blackout." Beyond these behavioral effects of the prolonged use of alcohol in large amounts, there are also serious medical complications. Chief among these is, of course, cirrhosis of the liver but nearly every organ system is affected either directly or indirectly by years of heavy alcohol consumption.

One result of the years of study of end-organ damage in alcoholism is the evidence that the medical effects of alcohol consumption themselves appear to be under some genetic control. A classic alcoholic twin study in which concordance rates for alcoholism were assessed among 15,924 male twins also included data on alcoholic cirrhosis and psychosis. Concordance rates of 21.1% among monozygotic (MZ) twin pairs and 5.4% among dizygotic (DZ) twin pairs for psychosis and 14.6% among MZ twin pairs and 5.4% among DZ twin pairs for cirrhosis were reported. The authors of that study concluded that the alcoholism concordance rates among these twin pairs could not entirely account for the observed concordances of the medical and psychiatric sequelae, and that this constituted evidence that organ-specific complications themselves have an underlying genetic risk not associated with the overall alcoholism genetic risks. Other medical conditions for which some evidence of independent genetic risk is emerging include alcoholic cardiomyopathy and alcoholic pancreatitis.

THE GENETICS OF ALCOHOLISM

GENETIC EPIDEMIOLOGY We alluded early on to the evidence suggesting the vertical transmission of risk in alcoholism. Here, we will present some of this evidence in more detail because, as will become clear, the devil really is in the details.

Evidence of a genetic predisposition for any disease comes primarily from twin and adoption studies whereas the nature, or "architecture" of that genetic component comes mainly from family studies. Historically, the appeal of twin studies has been that they provide a means for assessing the relative contributions of genetic and nongenetic factors to the overall phenotype. The model twin paradigm asserts that, since MZ twins are genetically identical and DZ twins share only half of their genes on average, a greater similarity, or concordance, among MZ twins vs DZ twins for a particular trait can be taken as *de facto* evidence of a genetic component. The strength of that genetic component can thus be gaged by the degree of difference in MZ vs DZ concordance. This, of course, assumes that all other factors are equal!

Since 1960, a number of large twin studies of alcoholism, or of traits indicative of alcoholism, have been conducted. One of the most widely cited is the 1966 study of 902 male Finnish twin pairs in which three major components of drinking behavior were iden-

tified. These were frequency of drinking, amount of alcohol consumed, and loss of control over consumption. Among these three components, only loss of control failed to exhibit evidence of genetic control. The other two, frequency of drink and amount consumed, displayed modest heritabilities of 0.39 and 0.36, respectively for frequency. Subsequent studies of 11,500 Finnish twin pairs of both sexes and of 7500 Swedish twin pairs of both sexes confirmed these results by demonstrating heritability estimates for frequency of consumption and amount consumed in the range of 0.30–0.40.

One of the earliest twin studies that focused on alcohol abuse rather than upon consumption was the 1960 study of 174 Swedish male twin pairs by Kaij and colleagues. This study, along with a similarly focused examination of 850 American twin pairs, suggested that alcohol abuse itself had a heritability in the same 0.30–0.40 range as did consumption. This pattern was further supported by the classic twin study of clinically defined alcoholism conducted by Hrubek and Omenn mentioned previously. Thus, it appears clear from twin studies that overall, about one-third of the risk for consuming and abusing alcohol is a result of genetic factors.

One indication of a major advance in heritability studies in recent years is the trend toward separating risk by gender. Among the early studies of twin pairs, only one reported heritability estimates sexes separately. Those investigators noted that, based on their sample size, the difference in male-specific heritability of 0.37 and female-specific heritability of 0.25 for alcohol intake was statistically significant. In more recent studies, the evidence of heritable factors operating to differentially mediate risk of alcohol abuse and alcoholism among men and women has been compelling. Kendler and colleagues examined a sample of 1030 like-sex twin pairs using various definitions of alcoholism and found that, while all definitions provided evidence in favor of a genetic contribution to risk, only their broadest definition was conclusive in showing a concordance of 47% among MZ twins and 32% among DZ twins. Importantly, their data indicated alcoholism was under some genetic control in both sexes, though the nature of this genetic component was likely to be different among women than among men. This impression has been substantiated by the results of a large Australian twin survey. There, it was reported that probandwise concordance rates were 57% among male MZ twin pairs vs 33% among male DZ twin pairs. These rates compared to probandwise concordances of 29% among female MZ twin pairs vs 19% among female DZ twin pairs.

The Australian Twin Survey went further and examined concordances among opposite-sex twin pairs. It was found that the risk of alcoholism among the male co-twins of female affecteds was four times that among the female co-twins of male affecteds (60 vs 15%). In the terms of the classic formulation of the multifactorial model of disease risk, these findings suggest a substantially higher loading for risk among affected women than among affected men. That is, women have a much higher liability threshold than do men. A somewhat different conclusion was reached in an earlier study by of 114 male twin pairs and 55 female twin pairs. An observed proband-wise concordance of 76% among male MZ twin pairs compared to 53% among male DZ twin pairs and 39% among female MZ twin pairs compared to 42% among females DZ twin pairs. While these data would tend to deny the presence of a genetic contribution to risk among the female affected, they did not examine opposite-sex pairs in order to assess differential risk loads. Even so, when the details of the extant twin data are sorted

out, the overall evidence points toward a complex and interactive model of the genetic control of risk in which gender appears to play a major role. This should, of course, surprise no one.

A similarly complex set of phenomena are available in the results of the numerous, excellent adoption studies of alcoholism. The theory underlying the adoption study paradigm is a sound one. If the nature of liability transmission is substantially genetic, then at-risk adoptees, in whom the nongenetic familial milieu has been changed from high risk to low risk, should still develop the disorder in question at a higher rate than controls from a low-risk setting and nearly equal to their high-risk relatives in high-risk environments. However, if this paradigm is true, one of the earliest adoption studies of alcoholism was an inauspicious start. In the early 1940s, Roe reported that there were no differences in risk among adoptees compared with low-risk controls and, therefore, no genetic factors. The series of Danish adoption studies carried out in the early 1970s have served to relegate the Roe results to a less significant status. In the Danish series, a rigorous design selected subjects who were adopted away at an early age and had no subsequent contact with their biological relatives. The excellent records obtained through the Danish registries allowed comparison of both male and female adoptees of alcoholic parents, not only with matched controls from nonalcoholic parents but with their nonadopted same-sex siblings. This three-way comparison revealed that the adopted-away sons of alcoholic parents were four times as likely to become alcoholic than were the adopted-away sons of nonalcoholics, but nearly equal to their nonadopted male siblings. As before, however, the adopted-away daughters of alcoholic parents displayed no increased risk nor did their nonadopted same sex siblings. The rate for the adopted-away daughters of alcoholic parents was around 2% compared to 3% among their nonadopted siblings and 4% among the controls! In these studies, however, was an observation that was later to prove to be a key element in a massive record-linking Swedish adoption study. Investigators observed that not only were the adopted-away sons of alcoholic parents at much higher risk for becoming alcoholic than were the controls, but their alcoholism tended to be much more severe and had an earlier age of onset.

A research team headed by Bohman, Cloninger, and Sigvardsson set out in the late 1970s to make use of the excellent adoption registry data available in Sweden and also to use the gold mine of mandatory registrations of individuals with the government-run Temperance Board. Linking these databases together enabled the classification of 862 Swedish males adopted prior to age 3 on the basis of severity of alcohol abuse, not only among the adoptees themselves, but among both their biological and adoptive parents as well. This permitted the data to be subdivided among four groups; e.g., adoptees with and without a family history of alcohol abuse in either their biological or adoptive families, by level of severity of abuse, and to use both adopted and biological controls. A significant genetic heterogeneity and gene–environment interaction was demonstrated in these samples. The study showed that adoptees having both pre- and postnatal risks were more than four times as likely to become alcoholic as were adoptees from low-risk backgrounds (27 vs 6%). Making use of the same record-linking study design, the same pattern of risk was demonstrated among female adoptees. Beyond this, the wealth of information gathered in this study, including the crucial severity classifications, revealed in detail the pattern of greater severity and earlier age of onset among some male adoptees that was hinted at in other studies.

The results of the Swedish adoption study design led to the now famous formulation of Type I and Type II alcoholism. This formulation held that there were three clinical and etiologic subtypes of alcoholism. The first, termed Type I or milieu-limited alcoholism, in which both male and female subjects developed the disorder, is marked by adult onset and a less severe course, that was receptive to treatment. The Type II, or male-limited, form was expressed primarily among males and was marked by onset in the early teens, much more severe symptoms, including criminality related to alcohol abuse and low treatment success. Among the female relatives of these Type II alcoholics, there was an increased risk of somatization disorder rather than alcohol abuse. Somatization is characterized by numerous physical and emotional complaints, including pains, gastrointestinal disturbance, anxiety, sexual and marital maladjustment, and mood disorder for which no causes can be found. Such individuals have a long and florid medical history. This condition, also called Briquet's syndrome, was found in the female relatives of another type of alcoholism found in this study, in which males displayed severe antisocial, criminal behavior, and low treatment success. Among these female relatives, however, the somatization disorder appeared at a much higher frequency and was itself more severe than that seen in the female relatives of the Type II alcoholics.

In the years since the original presentation of the Type I/Type II alcoholism formulation there have been detractors and critics of the idea, but the weight of evidence from other investigators has tended to favor the view that alcoholism is not a unitary disorder, that there are in fact clinically and etiologically distinct subtypes of alcoholism. Recently, a much-anticipated replication of this earlier study was presented. This replication again employed the large-scale record-linking study design and was composed of 577 male and 660 female adoptees from Sweden. The results confirm the Type I/Type II dichotomy and reinforce the earlier conclusion that the more severe Type II form has a substantially greater genetic component of risk. The question remains, however, as to the architecture of that genetic component, and it is here that family studies have shed some light.

Familial/genetic studies of alcoholism have been conducted by many investigators for many years and, regardless of the definitions used, the ascertainment schemes employed, and the extent of the studies, it is clear that alcoholism aggregates in families. In one investigation, hospitalized alcoholics were studied, and it was found that 34% of their male relatives and 9% of their female relatives were themselves alcoholic. Even higher recurrence rates were found elsewhere. In another series, 54% of male relatives and 17% of female relatives of probands were also alcoholic compared to 20 and 4% of the male and female relatives of controls. Overall, the recurrence risks in relatives of alcoholics have been found in family studies to be as much as seven times higher than in relatives of nonalcoholics. Of course, as much, and more, data regarding the nature of recurrence risks have been gathered from the many twin and adoption studies of alcoholism. The true power of the family study design, however, emerged along with the sophisticated analytical methods of genetic epidemiology in the 1980s.

The methods of genetic epidemiology descend both analytically and philosophically from the multifactorial model of risk in complex, common diseases. These methods permit the investigator to decompose the genetic and nongenetic components of liability and to assess the genetic architecture of the heritable component. It is further possible to use these methods to determine the

relative contributions of major gene loci and of a polygenic background in shaping the heritable component. One of the earliest applications of the method of complex segregation analysis to the question of risk transmission in alcoholism was the 1987 family study by Gilligan and colleagues. Utilizing the pedigree information on a sample of 286 hospitalized alcoholics, the investigators determined that the families of male alcoholics were etiologically heterogeneous. Some of the families seemed to be like the families of the female probands. These were termed Type I-like in reference to the Cloninger typology scheme. Other families appeared to resemble Type II male-only families and were designated as Type II-like. Heritability estimates for alcoholism in the Type I-like families were in the range of 0.20. In the Type II-like families, it was found to be very high: 0.88. Segregation analyses of these families then revealed that there was significant genetic heterogeneity among male alcoholics, and that there were two distinct genetic architectures associated with the different levels of heritability. The less heritable Type I familial form was marked by a polygenic architecture, whereas the highly heritable Type II form was found to be under the control of a single dominant major gene effect. Two additional features of that study must be mentioned, however. The first is that no departures from purely Mendelian transmission were reported for the major locus but, second, in order for the major locus model to fit, the penetrances of the major gene conferring increased risk were required to be both gender-specific and quite low. Penetrance refers to the probability that an individual carrying a risk gene will actually express it in the form of the disease. An example of a completely penetrant disease gene is Huntington's chorea, wherein every person who inherits the gene eventually develops the disease if he or she lives long enough. Among males, penetrance estimates for alcoholism were less than 30% and, among females, penetrance estimates were less than 10%. The difficulty here is that these are penetrances that could look almost nongenetic in a family sample.

In a subsequent study using the same segregation analysis methods, another group reported that the genetic architecture of risk in a sample of 35 multigenerational families was indeed consistent with a major genetic effect, but that a single, major Mendelian genetic locus was not the basis of the effect. Recently, a reanalysis of these data using a more sophisticated model was reported. This third-generation technique indicated that non-Mendelian transmission of the major effect on risk was consistent with a genetic architecture involving the presence of a "few" major loci contributing to risk in a developmental progression. This newest result is completely in line with the developmental model of alcoholism risk summarized later in this chapter.

The genetic epidemiology of alcoholism has advanced our knowledge to a point where the useless notion of factors "versus" each other, whether they be genetic vs nongenetic, major gene vs polygenes, or shared vs nonshared, can be dispensed with. What has emerged is a more sophisticated view that all factors contribute to risk, and that their relative effects change over time. What remains to be done is to find these factors, especially the genetic factors, define them, and then build an understanding of how they work.

MOLECULAR AND BIOCHEMICAL GENETICS   One of the legacies of the single-factor era in alcoholism research, and of psychiatric genetics research in general, has been the notion of "the" gene. Whether it was the gene for alcoholism, or the gene for schizophrenia, or the gene for depression, the search was focused on finding that one gene that by its very presence conferred

increased risk to developing the disorder in question. This idea encouraged us to make hopeful-looking lists of potential candidate genes and to begin to assess their roles in "causing" our disease (*see*, for example, the impressive list of potential candidate genes for alcoholism provided by Devor and Cloninger, 1989:31). The result of this was that the single causal gene idea entered the molecular era nearly unchanged from the biochemical marker era.

An ideal example of this notion is the HLA-association study paradigm. In one investigation, Corsico and colleagues typed a sample of 30 alcoholics for 11 HLA-A antigens, 16 HLA-B antigens, and 9 HLA-DR antigens. They compared their HLA types with two different control groups with the result that significant associations for increased HLA-B40 and HLA-D3 frequencies and for decreased HLA-DR4 frequency were observed. The authors concluded from these statistical associations that alcoholism must have a significant genetic component, and that the HLA system is a major component of risk. Numerous investigators, including Gilligan and Cloninger, have noted that, for such studies, the number of markers tested and the sample sizes used can have a substantial influence on the chances of finding an association and that the statistical analyses must be corrected for the number of tests performed. This is to say, the more you look, the more chance you run of coming across a false-positive. Here, then, replication of an association would seem to be key, and it is worth noting that none of the HLA associations with alcoholism have survived this test.

In the molecular era, a scenario similar to the HLA studies has already occurred. In 1990, Blum and colleagues announced a statistically significant association between a restriction fragment-length polymorphism (RFLP) near the human D2-dopamine receptor gene (*DRD2*), on chromosome 11q22-q23 and alcoholism. An RFLP is a marker found in the DNA base sequence itself that appears to be linked to a risk gene.* The Blum et al. data showed that one of two variant DNA sequences, or alleles, of an RFLP revealed near the D2 dopamine receptor gene by the DNA restriction enzyme Taq I was present in a significantly higher number of alcoholics than controls. Their announcement of this association launched a flood of replication studies using a clone for the human *DRD2* gene that, for a time, resembled a virtual cottage industry. The field of psychiatric genetics was consumed by the debate as to whether or not *DRD2* played a role in alcoholism risk and whether or not it may act as a modifier of severity. To date, dozens of papers have been published addressing these and other questions about *DRD2*. While the arguments still continue in the psychiatric genetics literature, the importance of the *DRD2* gene in alcoholism has decreased.

Lost in the debate about the role that DRD2 may or may not play in alcoholism was an interesting aspect of the context of the initial claim of association. The clone of the *DRD2* gene was only one of nine markers selected and, among these, only three displayed polymorphisms for the enzymes used in the study. Several of the other markers had known RFLPs with other enzymes and yet these RFLPs were not screened. Thus, of the nine markers cited, only three polymorphisms were studied, but DRD2 was significant. The point of this digression is to note an interesting sociological aspect of such studies. Once the DRD2 association was reported everything else was ignored, including some odd methodology in the original paper. Over time, the weight of evidence has turned

---

*For many readers the RFLP may be only an historical phenomenon. A brief history and detailed description of the RFLP, its immediate successors, and their roles in the development of molecular genetic studies of disease, may be found in Devor (1992).

against an association of DRD2 with alcoholism, not in the least because no adequate functional mutation or pathophysiologic mechanism has been found to explain it. This is not to say, however, that DRD2 and the other dopamine receptors are irrelevant to the pathogenesis of psychiatric disorders. Indeed, credible evidence involving DRD2 in other forms of substance abuse is coming to light, and the D4 dopamine receptor, DRD4, has been tentatively associated with schizophrenia. Thus, research on the dopamine receptors continues and will do so for some time to come. However, the story of DRD2 and alcoholism is a perfect example of the single, causal gene paradigm.

It is interesting to note that one of the markers unsuccessfully studied in the original Blum et al. paper was monoamine oxidase (MAO). The relationship between the activity of MAO and alcoholism is one of the most replicated finding in all of psychiatric genetics. There are two isoforms of this enzyme, MAO-A and MAO-B, each having its own substrate affinities and kinetic properties. The two isoforms are encoded by separate genes located together on the X-chromosome (Xp11.3). The two genes appear to have arisen from a common ancestral form via a duplication. Interest in MAO and its role in alcoholism began with the 1977 study of Wiberg and colleagues who reported significantly lowered MAO-B activities among alcoholics when compared with controls. Since that report, the finding of decreased MAO activity among alcoholics has been replicated many times. Moreover, studies of MAO activity and the alcoholic subtypes defined by Cloninger have consistently found that the more severe and more genetically determined Type II alcoholics have the lowest activities among alcoholics and controls.

Reich proposed in 1988 that a marker of genetic susceptibility to a disease must pass three specific tests:

1. The marker itself must be highly heritable.
2. The marker must be present in as yet unaffected offspring of affecteds.
3. There must be demonstrable increase in risk among the relative of affecteds who carry the marker vs the relatives of affecteds who do not carry the marker.

The years of study of MAO would suggest that it passes all three of these tests. The activity of the enzyme has been shown to be under the influence of a single major gene. Familial studies of the sons of alcoholics showed that MAO meets the second criterion. Other family studies have demonstrated a greater risk of alcoholism and other psychopathologies among the relatives of alcoholics who have low MAO activities vs the relatives of alcoholics who have more normal enzyme activities. The weight of evidence would seem to support the conclusion that MAO activity is in fact a genetic marker of risk in alcoholism but, as has been the case for all other aspects of such research, some newer studies have cast some doubt on this conclusion. In one of these, the first molecular marker for *MAO-B*, a dinucleotide repeat located in one of the noncoding regions of the *MAO-B* gene itself was studied in a sample of 74 alcoholics and 34 nonalcoholic controls. No association of the molecular marker with alcoholism could be demonstrated in their data. Moreover, a follow-up family study has asserted that one of the findings of lowered MAO-B activities among alcoholics and alcoholic subtypes was confounded by gender differences in enzyme activities. Once these differences were accounted for, the statistical significance of the lower activity levels among the alcoholic subtypes could not be replicated. However, in that reanalysis, the investigators did find a significant difference in MAO activity, but only among males. Thus, even for an association as apparently robust as that between MAO and alcoholism, more work will be required to understand the nuances.

One marker that has also been studied among alcoholics for many years but for which the nuances do appear to be understood is the mitochondrial aldehyde dehydrogenase, *ALDH2*. A dominant mutation in the human *ALDH2* gene, located on chromosome 12q24, results in the loss of enzymatic activity in the liver. This defect reduces the conversion of acetaldehyde to acetic acid and is associated with the well-known "flushing" reaction in response to alcohol ingestion. This reaction is characterized by facial flushing, nausea, palpitations, and lightheadedness, and appears to be the consequence of slowed removal of acetaldehyde from the body. Historically, the flushing reaction has been associated with Asian populations and this correlates well with the distribution of the mutant allele ALDH2*2. Also, it is believed that the ALDH2*2 mutation represents a protective factor against alcoholism in populations in which it occurs, and this belief has been well-substantiated. In support of the allelic association, more detailed physiologic and psychologic analyses of the ALDH2*2 mutation phenotype have served to further reinforce the idea that it plays a protective role in alcoholism. Thus, ALDH2 represents the best known case of a genetic modifier of risk of alcoholism (*see* the discussion of secondary genotype/genotype interactions, *below*).

Finally, while there are many biochemical and molecular studies of alcoholism under way worldwide, few have produced potential markers of the status of MAO and ALDH2, by providing solid evidence that they do play some role in influencing risk, and none have passed the tests proposed by Reich. One that comes close is adenylate cyclase (AC). First reported by Tabakoff and colleagues, the activity of platelet AC in the presence of cesium fluoride was found to be significantly lower among alcoholics than among controls. This lowered activity was also found in lymphocytes of alcoholics. Subsequent familial/genetic studies of AC activity suggested that the phenomenon was under the primary control of a single major gene. The familial/genetic study suggested that the major gene involved in the regulation of AC activity and in the association with alcoholism was the G protein, G_s, that activates AC in response to receipt of a stimulus at a cellular receptor. This model has subsequently been verified by other investigators, and future studies of this phenomenon will finally determine the status of AC as a marker.

A DEVELOPMENTAL MODEL OF ALCOHOLISM

The information presented in this chapter forms a paradox of a sort. Given that the genetic epidemiology of alcoholism overwhelmingly supports the proposition that there is a substantial genetic component to risk, why has there not been one single gene identified as a true genetic risk locus? The answer lies in the nature of the methods used to look for risk genes and in the way that risk is understood or, better said, misunderstood. Twin studies and adoption studies are able to provide evidence that "something" is being transmitted in the families of alcoholics that burdens the relatives of affecteds with higher risk of becoming alcoholics themselves. These studies are also able to determine how much of this "something" is genetic in nature. Within this context, studies of the genetic epidemiology of alcoholics have performed brilliantly and have for once and for all time buried the utterly useless dichotomy of genetic vs environmental cause. The family studies have performed equally well in their appointed task of attempting
Figure 111-1   Graphic representation of a developmental genetic model of alcoholism. Part 1 indicates the existence of several primary risk genes. Part 2 demonstrates the possibility of interactions between these primary genes. Part 3 allows for other genes in the genome to interact with the primary genotype, further modifying it. Part 4 incorporates factors from the environment in the same interactive manner. Part 5 indicates that what is actually seen clinically is the end result that has been shaped by a lifelong process of interaction and modification. (Used with permission from Devor, 1993.)

to fashion a genetic architecture of the underlying risk. These studies have shown that, whatever the genetics may eventually turn out to be, the single major genetic locus with some or no multifactorial background will not be it. Accepting this interpretation of the state-of-the-field leads to an awkward question. Why is there no gene for alcoholism? The answer may be found in a cognitive dissonance that affects much of psychiatric genetics but one that is slowly abating. The field recognizes the multifactorial, oligogenetic nature of risk underlying common, complex disorders but has continued to approach it as if it were a single major gene phenomenon. The way to break out of this stalemate is simply to replace the single gene paradigm with a new one. This, obviously, is not easily accomplished, but a recent paper by Benjamin and Gershon acknowledges that this change is occurring and that thinking in psychiatric genetics has turned toward pursuit of genes of small effect that, together with the rest of the genome and the environment, both determine and influence risk.

In 1993, a dynamic developmental model of alcoholism was proposed as a heuristic device for abandoning the single gene mind-set. Later, specific implications of this model for linkage and association studies were outlined. The intellectual heritage of this developmental model can be traced to the seminal evolutionary genetics of Wright, to the concepts of canalization and epigenetics proposed by Waddington, and to the elegant multifactorial disease model formulated by Guze, Reich, and Cloninger. The philosophical impetus behind the model is eloquently summarized by Konner in *The Tangled Wing*:

> *Now that the discussion of heredity versus environment has transcended the "versus," passing beyond the question, Which? and the only slightly less use-*

> *less question, How much? to the mature question, How? we must prepare ourselves to face the fact that this last is not one question at all, but thousands. For each system, for each moment in development, we may have on our hands a different balance, a different division of labor, a different integration of the functions of the genes and of the world.*

Here, then, is the mind-set that is replacing the single-gene linkage analysis search for "the" gene for complex diseases.

A developmental model of alcoholism is presented in Fig. 111-1. The model is composed of five parts. The first part represents the fundamental, pristine state present at fertilization, in which there exists a set of alcoholism-specific genes that confer "primary risk" to developing the disease. These genes are representatives of a finite pool of risk gene loci that segregate alleles more or less independently in the human population, with each allele conferring a specific increase in liability on the individuals who inherit it. For schizophrenia, a disorder in which risk among relatives falls off precipitously with decreasing degrees of relatedness, Reich postulates that the pool may be as small as two or three loci. For alcoholism, it may not be many more and, in the absence of inbreeding or phenotypic assortative mating, the presence of any of the risk alleles in any particular combination could be essentially random. However, when two or more primary risk-enhancing alleles are present in any one individual the possibility of primary gene–gene interactions exists. This is shown in the second part of the model in Fig. 111-1.

The primary gene–gene interaction effects depend on which genetic combinations are present, and these could range from simple additive risk loading (in which each gene adds to the overall risk of developing the disease without regard to which other

genes are present) to true nonlinear epistatic effects (in which the increase in risk is greater than a simple sum of these effects and does depend on which other genes are present). Beyond this level of primary risk loading is a secondary level of gene–gene interactions (part 3), which recognizes the fact that the primary risk genotype exists in a developmental milieu composed of the rest of the genome. Thus, secondary gene–gene interactions may occur that involve genes that are not alcoholism-specific. Some of these secondary genes may exert a unique effect, affecting one or a few primary risk genotypes, or they may exert a common effect, affecting most or all primary risk genotypes. As was alluded to earlier in this chapter, such secondary interactions may increase the risk loading conferred by the primary genotype, or they may be protective and decrease the risk loading.

Part 4 of this model explicitly recognizes the role of nongenetic factors in modifying the entire relevant genotype. These environmental interactions may, as with secondary gene–gene interactions, be unique or specific to a small number of genotypes by acting through, for example, one particular secondary interaction pathway, or they may be ubiquitous, affecting most or all possible genic combinations. The overall effect of this interactive, developmental model is to precisely produce the types of clinical variations observed (e.g., age of onset, sex differences, response to treatment, severity, and familiality).

The practical experience with alcoholism to date does suggest that relatively few distinct alcoholic subtypes exist. This, in turn, permits us to speculate that the levels of interaction may be few, the actual number of primary risk loci and secondary modifying loci is small, or both. In this case the situation is manageable, and the search for these genes will ultimately be successful.

In closing, we refer to a sentiment written near the opening of the molecular era of alcoholism research that has proven to be prophetic, but remains true. In referring to the search for alcoholism risk genes, "the task is enormous, the pitfalls many, and the cost high, yet the payoff is staggering—a fundamental understanding of the genetics of an addiction and a realistic program of intervention based upon that understanding" Devor and Cloninger, 1989;29).

112 Waardenburg Syndrome

ANDREW P. READ

BACKGROUND

AUDITORY-PIGMENTARY SYNDROMES IN HUMANS AND OTHER ANIMALS   "What can be more singular than the relation between blue eyes and deafness in cats?" asked Charles Darwin in his *Origin of the Species*. In fact, the combination of hearing loss and pigmentary abnormalities is known in many other mammals, including dogs, horses, cattle, mink, mice, and humans. Most commonly, the skin or fur is white-spotted, sometimes white all over, and one or both eyes are blue. These syndromes are quite distinct from albinism. In albinos, melanocytes are present but produce no melanin as a consequence of an enzyme defect, usually lack of tyrosinase. In contrast, auditory-pigmentary syndromes are caused by a physical absence of melanocytes; this is associated with hearing loss but not with any visual problems. (Albinos suffer from poor eyesight because of a characteristic misrouting of optic nerve fibers.) Usually the absence is patchy, with areas of normal and depigmented tissue. In the inner ear, the stria vascularis of the cochlea contains melanocytes, and an absence of melanocytes correlates with a nonfunctioning cochlea, as judged by the lack of an endocochlear potential. Melanocytes are necessary for this function, but melanin is not, because albinos have normal hearing.

MELANOCYTES AND THE NEURAL CREST   Melanocytes are migratory cells, originating in the neural crest of the embryo. Thus the underlying cause of auditory-pigmentary syndromes is either a failure of neural crest differentiation, failure of melanocyte precursors to migrate correctly, or failure to differentiate and survive in their end location.

CLINICAL AND GENETIC HETEROGENEITY OF HUMAN AUDITORY-PIGMENTARY SYNDROMES   Human auditory-pigmentary syndromes have been described under many names and are undoubtedly highly heterogeneous. Autosomal-dominant, autosomal-recessive, and X-linked forms have been described, with or without other syndromic features. Waardenburg syndrome (WS) is a heterogeneous entity named after the Dutch ophthalmologist and geneticist who published the first comprehensive description in 1951. In this chapter I will review the classification of WS and describe the role of the *PAX3* and *MITF* genes in its etiology. Other related genes and syndromes will be discussed more briefly.

CLINICAL FEATURES

The subtypes of Waardenburg syndrome are listed in Table 112-1. Other related conditions are discussed in the section on Diagnosis.

WAARDENBURG SYNDROME TYPE 1   Waardenburg's original description was of "developmental anomalies of the eyelids, eyebrows and nose root with pigmentary defects of the iris and head hair and with congenital deafness." The eyelid abnormality is dystopia canthorum *(see below)*. Other features are summarized in Table 112-2. The incidence is about 1/40,000.

WAARDENBURG SYNDROME TYPE 2   Arias pointed out that families could be divided into two types, those in which all affected people had dystopia canthorum (Type 1) and those in which dystopia was never seen (Type 2). The remaining features are similar in both types (Table 112-2). Figure 112-1 shows the contrasting facial appearances. In most studies, WS2 is one to two times as frequent as WS1.

WAARDENBURG SYNDROME TYPE 3 (KLEIN-WAARDENBURG SYNDROME)   WS3 is extremely rare. The original patient described by Klein had very severe contractures and hypoplasia of her shoulders, arms, and hands, in addition to extensive depigmentation and other features of WS1. She resembled a WS1 homozygote reported by Zlotogora et al. (1995). Later reports have been of patients with WS1 plus mild contractures affecting the arms or fingers. These are probably a rare variant presentation of WS1. Some "WS3" patients have relatives with WS1; in several cases, PAX3 mutations have been described, and PAX3 is known to be expressed in the limb buds *(see below)*.

WAARDENBURG SYNDROME TYPE 4 (WAARDENBURG-SHAH SYNDROME)   Shah reported a series of Indian babies with depigmentation and Hirschsprung disease, who died before their hearing could be assessed. Recently, the genetic basis of this recessive combination of WS2 and Hirschsprung disease has been unraveled *(see below)*.

DIAGNOSIS

CRITERIA FOR DIAGNOSING WAARDENBURG SYNDROME   The label Waardenburg Syndrome is best confined to cases where the hearing loss is sensorineural, congenital, and nonprogressive, and where the inheritance is autosomal-dominant. Differential diagnoses include albinism (melanocytes are present but unpigmented, no hearing loss), vitiligo (postnatal onset and fluctuating course of depigmentation, no hearing loss), and piebaldism (extensive congenital depigmentation, no hearing loss, mutations in the *KIT* oncogene). Coincidental hearing loss can complicate the diagnosis.

Table 112-1
The Four Types of Waardenburg Syndrome

Type	MIM no.	Inheritance	Features
1	193500	AD	Dystopia canthorum
2	193510	AD	No dystopia
3 (Klein-Waardenburg)	148820	AD? (most cases sporadic)	Dystopia + limb abnormalities
4 (Waardenburg-Shah)	277580	AR	Hirschsprung disease

Table 112-2
Features of Waardenburg Syndrome Type 1 and Type 2

	Feature	WS1, %	WS2, %
Major criteria	Congenital sensorineural hearing loss >25dB	57	77
	Iris pigmentary abnormality		
	Heterochromia: eyes of different colors; or clearly demarcated segments of different colors in one eye;	20	50
	Isochromia: characteristic brilliant blue eyes	15	25
	White forelock in hair	45	25
	Dystopia canthorum	98	Absent
	Affected first-degree relative.		
Minor criteria	Several areas of congenitally hypopigmented skin	35	10
	Medial flaring of eyebrows with synophrys	65	Rare
	Broad high nasal root	75	Rare
	Hypoplasia of the alae nasi	Common	Rare
	Graying of the hair before age 30	Common	25

For Waardenburg syndrome, the Waardenburg Consortium defined an affected person as someone having two major, or one major and two minor criteria. The criteria are given in Table 112-2, along with estimated penetrances in WS1 and WS2, from the study of Liu et al. The apparently somewhat higher incidence of hearing loss and heterochromia in WS2 is probably an artefact of ascertainment: Without dystopia as a guide, patients are not diagnosed unless they show several other features of WS.

DIFFERENTIAL DIAGNOSIS OF TYPE 1 AND TYPE 2 WAARDENBURG SYNDROME Because dystopia is specific and highly penetrant, WS1 can be diagnosed with confidence and shows little or no genetic heterogeneity. The inner canthi are displaced outward so that the palpebral fissures are short, with little of the sclerae showing on the medial side of the pupil; the inferior lacrimal punctae lie in front of the cornea, and there is a broad high nasal root with synophrys (confluent eyebrows). Experience shows that dystopia canthorum needs to be assessed by measuring the inner canthal, interpupillary, and outer canthal distances (a,b,c respectively, in millimeters) with a rigid ruler held in front of the head, and then applying the formula

$$W = X + Y + a/b$$
$$\text{where}$$
$$X = (2a - 0.2119c - 3.909)/c$$
$$\text{and}$$
$$Y = (2a - 0.2479b - 3.909)/b$$

This rather abstruse measure (the numbers come from a discriminant analysis) has proved extremely effective for distinguishing WS1 ($W > 1.95$) from WS2 ($W < 1.95$). By contrast, clinical impression, even by skilled judges, has proved unreliable. The distinction is important to make because, as shown below, it holds the key to molecular diagnosis.

TYPE 2 WS AND OTHER RELATED SYNDROMES WS2 is not homogeneous. Clinical definition is arbitrary, and molecular studies show heterogeneity. About 20% of families have mutations in the *MITF* gene *(see below)*. Rare patients with Hirschsprungs disease plus features of WS2 (and thus describable as WS4) have an endothelin defect *(see below)*.

Many patients with auditory-pigmentary syndromes do not fall into any of the categories described above, and many other ill-defined auditory-pigmentary syndromes are listed in the literature, but little is known of the underlying genetics. In thinking about their clinical classification, it is useful to try to distinguish melanocyte-specific defects from more general neurocristopathies. Neurocristopathies arise early in embryonic development, whereas death of melanocytes can occur at any time. Nevertheless, this distinction is not always clear-cut. WS1 is mainly caused by dysfunction of the embryonic neural crest, but people with WS1 also often suffer premature graying of their hair 15–30 years after their neural crest completed its differentiation.

GENETIC BASIS OF WAARDENBURG SYNDROME

TYPE 1 WAARDENBURG SYNDROME Linkage to 2q35 and the Sp Mouse Model WS1 is relatively homogeneous genetically. Linkage was first demonstrated to the marker ALPP (alkaline phosphatase, placental isozyme) in 1989. ALPP maps to the distal long arm of chromosome 2. Recent collaborative studies using a microsatellite polymorphism from the *PAX3* gene suggest that all WS1 but no WS2 maps to this region. The map position was originally claimed to be 2q37, but more recent results suggest 2q35-q36. This region shows strongly conserved synteny with the proximal part of mouse chromosome 1, and a search of the corresponding mouse map suggested a likely homolog, *Splotch*. The heterozygous *Sp* mouse has no hearing loss, but nor do many

Figure 112-1 Facial appearance in **(A)** Type 1 and **(B)** Type 2 Waardenburg syndrome. Note dystopia canthorum in the patient in Panel A. This patient has a chromosomal deletion del(2)(q34q36.2) and is mentally retarded in addition to showing typical features of Type 1 WS. Neither Type 1 nor Type 2 WS is normally associated with any mental retardation.

Figure 112-2 PAX3 mutations seen in Manchester patients with WS1. The eight exons of the PAX3 gene are shown, with the paired box in exons 2–4 and the homeobox in exons 5–6 shaded. Mutations expected to truncate the gene product are above the gene diagram, those expected to produce a full-length product are below. Note that, whereas truncating mutations are distributed across most of the gene, amino acid substitutions are pathogenic only when located in the 5' part of the paired box and the 3' part of the homeobox. These regions are critical for DNA binding by the PAX3 protein.

humans with WS1, and phenotypes of orthologous mouse and human mutants are often somewhat different. On some genetic backgrounds, *Sp* mice have a broad snout, probably corresponding to dystopia canthorum in man.

The PAX3/pax-3 Gene A candidate gene, *pax-3*, mapped to this region in the mouse and was expressed in the developing nervous system of the early embryo in a pattern compatible with the pathology, both of *Sp* and of WS1. The human homolog is *PAX3*, originally called *HuP2*. Searches revealed mutations in both Sp and WS1.

PAX3 is a very interesting gene. PAX genes, in both mouse and man, form a family of nine closely related genes. All share a paired box, a highly conserved 128 amino acid DNA-binding domain found in organisms from *Drosophila* to man. As well as the paired box, *PAX3*, *PAX6*, and *PAX7* have a homeobox. All the PAX genes are believed to encode transcription factors; the expression pattern of PAX3 in the early embryo is described below. *PAX3* was the first human homeobox gene shown to carry mutations causing inherited disease.

Other PAX Genes in Human Syndromes *PAX6* mutations cause aniridia and other abnormalities of the anterior chamber of the eye. Mutations in *PAX2* have been seen in a few families with combinations of eye (e.g., optic nerve coloboma) and kidney problems. The molecular pathology of all these conditions appears to involve

haploinsufficiency. In each case there is a good mouse homolog, *sey* (small eye) and *krd* (kidney and retinal defects), respectively.

TYPE 2 WAARDENBURG SYNDROME In perhaps 20% of WS2 families the mutation maps to the proximal short arm of chromosome 3, and in some of these families mutations have been demonstrated in *MITF*, the human homolog of the mouse *microphthalmia* gene. The human *MITF* and mouse *mi* genes encode another transcription factor, a basic helix-loop-helix leucine zipper protein. Only about 20% of families with WS2 show evidence (by linkage or mutation screening) of involvement of *MITF*; the gene(s) responsible for 80% of WS2 have yet to be mapped or identified.

TYPE 3 WAARDENBURG SYNDROME In a few cases, *PAX3* mutations have been described. PAX3 is expressed in the developing limb muscles, and WS3 is probably a variant presentation of WS1.

TYPE 4 WAARDENBURG SYNDROME Mutations in the endothelin 3 or endothelin receptor B genes (on chromosomes 20 or 13, respectively) have recently been described in well-characterized affected patients with a combination of WS2-like pigmentary abnormalities and Hirschsprung disease.

MOLECULAR PATHOPHYSIOLOGY

EXPRESSION OF PAX3 In the mouse, *pax-3* is expressed in the developing nervous system starting at d 8–8.5 postcoitum. Expression occurs along the length of the neural tube, but only in the posterior part, including the neural crest. Expression is seen in various parts of the developing brain, and *pax-3* expressing cells migrate into the limb buds. The patterns of expression are described in more detail in the reviews cited at the end of this chapter. Preliminary studies in human embryos reveal a similar pattern. The expression pattern fits well with the observed features of WS1 and *Sp*, although as is usual in these cases, only a subset of expressing tissues is affected.

MOLECULAR PATHOLOGY OF PAX3 MUTATIONS *PAX3* mutations have been found in many families with WS1, but not in families with WS2. Figure 112-2 shows the mutations that
Figure 112-3   MITF mutations seen in Manchester patients with WS2. The gene has nine exons and encodes a DNA-binding basic domain (hatched in exon 6) and helix-loop-helix and leucine zipper dimerization domains (shaded, in exons 8–9). Mutations expected to truncate the gene product are above the gene diagram, those expected to produce a full-length product are below.

have been described in Manchester; similar mutations have been found by other groups within the Waardenburg Consortium. It is noteworthy that the mutations are very heterogeneous, including a complete deletion of the gene, truncating (nonsense or frameshifting) changes spread through exons 2–6, splice site mutations and amino acid substitutions. The substitutions are all of amino acids in the 5' part of the paired domain or the third (recognition) helix of the homeodomain. All of the amino acids involved are highly conserved across species and are known to take part in critical protein-DNA contacts in other PAX and homeodomain genes.

All of these changes produce the same clinical result, WS1. We conclude that WS1 is caused by a dosage effect in people heterozygous for a loss-of-function mutation.

As deaf people frequently marry, homozygotes may occur, and one case has been described. The child had severe depigmentation and limb contractures, but unexpectedly, considering the phenotype of homozygous *Splotch* mice, no neural tube defect. Nevertheless, it is likely that most *PAX3* mutations that cause WS1 in heterozygous people would be lethal in homozygotes.

Substitutions of asparagine 47 in the PAX3 paired domain may possibly produce a special phenotype. The mutation N47H was seen in the only known example of familial WS3, whereas a different substitution of the same amino acid, N47K, occurred in a family whose phenotype was described as craniofacial-deafness-hand syndrome (MIM 122880). Conceivably, these mutations represent a gain of function. Unambiguous (but somatic, not inherited) gain of function mutations of PAX3 are seen in the pediatric tumor alveolar rhabdomyosarcoma. In these tumors, a chromosomal translocation t(2;13)(q35;q14) creates a novel chimeric gene out of the 5' parts of *PAX3* and the 3' part of another transcription factor gene, *FKHR*.

MOLECULAR PATHOLOGY OF MITF MUTATIONS

Figure 112-3 shows human MITF mutations described in patients with WS2. All of these cases are dominant. In the mouse, both dominant and recessive alleles of *mi* are known. The difference can be explained by dominant negative effects of mutants that sequester the product of the normal allele in inactive dimers. Some of the human WS2 mutations would be predicted to be recessive in mice; however, maybe human homozygotes would be much more severely affected, as in mice. Transcripts and protein products of these mutant genes have not yet been studied.

MANAGEMENT AND TREATMENT OF WAARDENBURG SYNDROME

Apart from possible early graying of the hair, all features of Waardenburg syndrome are nonprogressive, and treatment is symptomatic. Early screening is important to identify hearing loss in infants.

FUTURE DIRECTIONS

For the known genes, *PAX3* and *MITF*, the major problem is the inability to predict the severity of symptoms of WS1 or WS2. Both conditions are variable even within families, so that severity must depend on the action of unidentified modifier genes. This makes genetic counseling difficult. Identifying the modifier genes and identifying the genes responsible for the bulk of WS2 are priorities. Although *PAX3* and *MITF* are known to be transcription factors, very little is known about their upstream regulators or downstream targets in the embryo. Knowing these might help identify genes for other auditory-pigmentary syndromes, as well as shedding light on an important part of embryonic development.

Gene therapy for WS seems problematic. *PAX3* and *MITF* have roles in basic pattern formation and differentiation in the embryonic neural crest. This makes them biologically interesting genes, but also makes it difficult to imagine effective postnatal gene therapy.

113 Greig Cephalopolysyndactyly Syndrome and Limb Disorders

KARL-HEINZ GRZESCHIK

INTRODUCTION

In the process of dissecting the factors governing the formation of hands and feet from the limb buds, human genetic disorders in which polydactyly or syndactyly occurs can provide clues to the genes involved in separating and defining the outline of limb elements in normal development. The identification by the positional cloning strategy of a gene believed to be responsible for Greig cephylopolysyndactyly syndrome, a rare developmental disorder, characterized by craniofacial abnormalities and malformations of hands and feet, can serve as a paradigm for the value of this approach, since it drew attention to GLI3, a gene not previously expected to be involved in regulation of human development. Greig syndrome appears to result from haploinsufficiency of this gene. *GLI3* is a member of a zinc finger gene family that includes *Krüppel*, a gene that was known to regulate development in Drosophila. Nevertheless, the involvement of a zinc finger gene in mammalian development had not been demonstrated earlier.

The identification of a candidate gene involved in human limb development called for the application of the powerful methods of genetic dissection of this gene in the mouse. Such a combination of candidate gene search in human developmental malformations and gene analysis in animal model systems holds the promise to teach how genes develop the human gestalt.

CLINICAL FEATURES OF GREIG CEPHALOPOLYSYNDACTYLY SYNDROME

Greig cephalopolysyndactyly syndrome (GCPS, OMIM 175700) is a rare developmental disorder characterized by craniofacial abnormalities and postaxial polydactyly of the hands, preaxial polydactyly of the feet, and syndactyly of the fingers and toes. It shows autosomal dominant inheritance with full penetrance but with marked inter- and intrafamilial variability.

Characteristic limb and skull manifestations observed in more than 50 patients are listed in Table 113-1. Hand and foot malformations are mostly bilateral. If unilateral, a hand is more often affected than a foot. Postaxial polydactyly is common in the hands and preaxial polydactyly in the feet: The thumbs are frequently broad with a broad nail and a malformed distal phalanx, sometimes

with a bifid tip. Radiographs of the hands can reveal preaxial polydactyly that is not noted on physical examination. Postaxial polydactyly of the hands usually manifests as a pedunculated postminimus, sometimes merely as a small cutaneous tag, with or without hypoplastic nail and a bony fragment as phalanx. The additional finger articulates at the ulnar side of the hand, mostly at the proximal or middle phalanx of the fifth finger; the fifth metacarpal bone is not affected (Fig. 113-1A).

In the feet, preaxial polysyndactyly is the most common malformation, including duplication of the distal phalanx of the hallux, of both phalanges, of both phalanges and metatarsus, and rarely of metatarsus alone (Fig. 113-1B). Broad halluces with broad nails are common. The fifth metatarsal bone, if not duplicated, is often broad and markedly altered in shape. Postaxial polydactyly of the feet has been observed occasionally resulting from duplication of the fifth toe (eventually only a single bony fragment is found) and broadening or duplication of the fifth metatarsal bone. Also in the feet, polydactyly sometimes was noted on radiographs only.

Syndactyly affects hands and feet as a constant feature but with some variability in its extent. It is mostly cutaneous in the feet, varying from mild webbing between the first two or three toes to complete cutaneous fusion, sometimes also with nail fusion. In the hands, bony fusion was reported on the distal phalanges of third to fourth fingers and of third to fifth fingers.

The craniofacial manifestations are variable and consist of a macrocephaly with a broad prominent forehead, a broad nasal root and brachycephaly (Fig. 113-1C). In individuals with large crania, the interpupillary distance will often be increased. The impression of hypertelorism is confirmed only rarely if canthal indices are used for correction. Prognosis for the mental and physical development of affected individuals is good. Advanced bone age seems to be a frequent finding in GCPS, suggesting an influence of the GCPS gene on bone development.

DIFFERENTIAL DIAGNOSIS

The wide variability of manifestations raised the question of whether or not other genetic entities thought to be distinct syndromes are not merely variants of the GCPS.

Acrocallosal syndrome (ACLS, OMIM 200990) is an autosomal recessive condition that shares manifestations with GCPS. However, neurological findings such as the severe mental retardation, hypotonia, and absence of corpus callosum in ACLS, are very

Table 113-1
Skull and Limb Manifestations in GCPS Patients[a]

Malformation	Number observed
Craniofacial	
Macrocephaly	23/44
High, broad forehead	25/36
Frontal bossing	21/36
Broad nasal bridge	30/38

Preaxial polydactyly	
Clinical	4/41
Radiological	8/22
Postaxial polydactyly	
Clinical	36/46
Radiological	10/22
Broad thumbs	37/40
Syndactyly	33/40
Feet	
Preaxial polydactyly	
Clinical	40/49
Radiological	21/26
Postaxial polydactyly	
Clinical	3/39
Radiological	3/26
Broad halluces	26/29
Syndactyly	43/47

[a]Data compiled from Ausems et al. 1994, according to references described therein. When radiographs were performed after surgical treatment in patients with polydactyly, this item is scored clinically (+) and radiologically (–).

rare in GCPS. Also, the type of polydactyly differs and the syndactyly is less severe in ACLS, generally affecting only the proximal portion between the second and third toes. Since no linkage was found on chromosome 7 in patients with acrocallosal syndrome, it is very unlikely that acrocallosal syndrome and Greig syndrome are allelic disorders.

Greig syndrome can be so mild as to be indistinguishable from the normal. Therefore, preaxial polydactyly type IV, or uncomplicated polysyndactyly (OMIM 174700), a dominant trait characterized by broad duplicated thumbs that are radially deviated and duplication of the halluces or second toes, with syndactyly of the second and third toes, may be Greig syndrome. Also, *crossed polydactyly*, a condition with autosomal dominant inheritance, characterized by polydactyly of the hands and feet with discrepancy of the axes of polydactyly between hands and feet, which occasionally shows syndactyly but no associated craniofacial abnormalities might be Greig syndrome.

THE MOLECULAR GENETICS OF GCPS

IDENTIFICATION OF A GCPS CANDIDATE GENE The genetic locus of GCPS had been assigned to chromosome 7p13 by three balanced translocations associated with GCPS in different families with one chromosome breakpoint in this band. This assignment was corroborated by the detection of three sporadic cases carrying overlapping deletions in 7p13, as well as by tight linkage of GCPS to the epidermal growth factor receptor gene in 7p13–p12.

In a positional cloning effort, the translocation breakpoint region was covered with a contiguous restriction map employing arbitrary DNA fragments and the cDNA of the gene *GLI3* as hybridization probes. *GLI3* had been isolated by homology to the zinc-finger gene GLI, which is amplified in gliomas, and mapped to 7p13. It was considered a potential candidate gene for Greig syndrome, both on the basis of its map position and its homology to the *Drosophila* gene *Krüppel*, which is involved in the regulation of development. Since the GCPS translocation breakpoints were found to interrupt the genomic segment coding for the distal half of the *GLI3* gene, and since the interstitial deletions of 7p observed in three Greig patients also eliminated the *GLI3* gene region, it could be postulated that haploinsufficiency of *GLI3* might evoke the developmental malformations in at least some of the Greig syndrome patients. The size of the *GLI3* gene could be determined as at least 280 kb. The transcribed *GLI3* sequence is composed of 15 exons with the most 3' exon spanning about 2.5 kb of continuously transcribed DNA. The gene is flanked by a CpG island that lies on the 5' side and that is in close proximity to the first exon detected by the cloned *GLI3* cDNA. The presence of other genes in this region that might be affected by deletions or positional effects resulting from the translocation events, however, still cannot be excluded. Two large introns of 70 kb each in the 5' region of the *GLI3* gene would leave ample room for additional genes.

PROPERTIES OF GLI3 The *GLI3* gene belongs to the human *GLI-Krüppel* gene family. It encodes a zinc-finger protein of 1596 amino acids and an apparent molecular mass of 190 kDa. Multiple regions of sequence similarity aside from the zinc-finger region suggest that other aspects of function are shared among the members of this gene family of DNA-binding proteins. The gene is expressed in a wide variety of human adult tissues. Because of their ability to bind specific DNA sequences, zinc-finger proteins are generally considered to be transcription factors. The high similarity between the binding specificities of the members of this family suggests, however, that these genes may assume their specific function only through their developmentally regulated expression or interaction of other nonhomologous protein domains with additional cellular factors.

ANIMAL MODELS FOR GCPS

Additional evidence for the influence of *GLI3* on the embryonal development of limbs and skull is derived from the allelic mouse mutations *extra toes* (*Xt*) *anterior digit deformity* (*add*), and possibly also from the mouse mutant *Polydactyly Nagoya* (*Pdn*). The spontaneous semidominant mouse mutation extra toes affects limb development with almost complete penetrance in heterozygotes but variable expressivity (Fig. 113-2). Several *Xt* alleles have been reported since and mapped to a region on mouse chromosome 13 homologous to human chromosome band 7p13.

The *Xt* mutation in a (C3Hx101)F$_2$ mouse was shown to be a deletion of at least 80 kb beginning at the 5' side of the *GLi3* gene. In a second *Xt* allele, *Xt^J*, a more downstream deletion was detected extending from the first zinc-finger motif towards the 3' end of the gene spanning at least 30 kb. The *Xt* heterozygotes show phenotypic peculiarities similar to GCPS patients: predominantly preaxial polydactyly of the hind limbs and a postaxial nubbin on the forelimbs. They also often have an enlarged interfrontal bone and some show hydrocephaly.

Brachyphalangy (*Xt^{bph}*) is a radiation-induced allele that has similar effects to *Xt* but is distinguishable in both heterozygotes and homozygotes. Unlike *Xt* heterozygotes, *Xt^{bph}* heterozygotes usu-

Figure 113-1 *(continued)* **(C)** Head from patient with Greig Cephalopolysyndactyly Syndrome. (Reproduced with permission from Gollop and Fontes, Am J Med Genet 1985;22:59–68.)

RNA expression level in homozygous *add/add* mice showed a reduction similar to that observed in heterozygous *Xt/+* mice but no alteration of the transcript size, it can be postulated that the insertion of foreign material disturbed a region important for transcriptional control of *Gli3*.

In homozygous *add/add* mice the forelimb is disorganized. The morphology of the thumbs is always altered, and sometimes the adjacent finger has an extra phalanx. The effect of the *Xt* and *add* mutants on the phenotype of the feet is summarized in Table 113-2. The anterior digit duplications in extra-toes mutants are similar to the phenotype of homozygous ci^w *Drosophila* flies, which are caused by a mutation in the *Drosophila Gli* protein *cubitus interruptus* (*Ci*). This homology in function throughout the animal kingdom suggests that *Gli* proteins are part of a very basic, conserved signaling pathway.

MOLECULAR PATHOPHYSIOLOGY OF GLI3 DEFICIENCY

GLI3 AS A TRANSCRIPTIONAL REGULATOR Based on the phenotypic similarities of *Xt* heterozygotes with GCPS and the molecular evidence that homologous genes are affected in both species, it is possible to analyze the physiological role of *GLI3* and the consequences of its deficiency by comparing *GLI3* expression in normal embryonic development with the effects in *Xt* mice in organs not readily available for analysis in Greig patients.

The consequence at the molecular level of both *Xt* deletions as well as the GCPS mutations detected so far is the complete absence of *GLI3* expression from the affected locus. This haploinsufficiency results only in a small number of minor malformations. *Xt/Xt* homozygotes on the other hand, despite the complete lack of expression from both genes, generally survive until birth; however, with a number of severe malformations. These stress the

Figure 113-1 **(A)** Right hand, **(B)** foot, from patients with Greig Cephalopolysyndactyly Syndrome. (Reproduced with permission from Gollop and Fontes, Am J Med Genet 1985;22:59–68.)

ally have an abnormal sternum and occasionally show syndactyly. All *Xt* alleles are homozygous lethal with more extreme limb and craniofacial defects as well as additional abnormalities of the brain, the central nervous system, and sense organs.

The *Pdn* mouse mutation is very likely to be allelic to *Xt*, but no effects on genomic structure nor expression of *GLI3* could be demonstrated yet.

The recessive mouse mutant add is an allele of the gene affected in *Xt*. This mutant was generated by insertional mutagenesis in mice. The *add* mutation originates from a transgene insertion within the segment deleted in Xt^(C3Hx101)F_2 at a maximal distance of about 44 kb from the transcription start of *Gli3*. The *add* insertion replaced only 1 bp of the wild-type sequence. Since the *GLi3*

general importance of the *Gli3* protein as a determinator of many parts of the body plan. At the same time, it appears that most of the development can occur without any *Gli3* protein. This may reflect the presence of other very similar *Gli* genes. Lethality may result from the lack of a functioning *Gli3* gene after birth rather than from developmental defects.

The spatial and temporal pattern of high *Gli3* expression in mouse embryos correlates well with the *Xt* phenotype. The highest level of *Gli3* expression is found in limb buds, the developing craniofacial mesenchyme, and the brain, the most severely affected structures in *Xt*/*Xt* homozygous mice. In addition, *Gli3* is highly expressed in the intercerebral disk anlage and in the sternal cartilage, both in regions affected by *Xt* mutations. Thus, the proper amount of *Gli3* product appears crucial in areas where it is particularly highly expressed.

Possible mechanisms for such a dosage-sensitive regulatory system have been elucidated by the analysis of other *Krüppel*-type zinc-finger genes. In *Drosophila*, the *Krüppel* product, the prototype, can both activate and repress gene expression through interaction with a single DNA-binding site. The opposite regulatory effects of the *Krüppel* protein are concentration-dependent, and they require distinct portions of the protein such as the N-terminal region for activation and the C-terminal region for repression. The

Krüppel zinc-finger-type transcription factor is able to form homodimers through sequences located within the C-terminus. The *Krüppel* monomer is a transcriptional activator. At higher concentration, *Krüppel* forms a homodimer and becomes a repressor that functions through the same target sequences as the activator.

Most important for the understanding of *GLI* function is the observation that during limb development in the *Drosophila Gli* protein Ci acts both as a repressor and activator of *decapentaplegic* (*dpp*) transcription in a concentration-dependent manner. The expression of *Dpp*, a homolog of the mammalian bone morphogenetic proteins (BMP), is normally repressed by low levels of *Ci*. An increase of *Ci* levels by *hedgehog protein* (*Hh*) signaling might overcome this regulation and result in *dpp* activation.

This dual function of a *Gli* protein during limb development in *Drosophila* might represent an evolutionarily conserved aspect of patterning by *Hh* family members. *Sonic Hh* plays an important role in mammalian limb development by specifying in conjunction with *BMP* pattern across the anteroposterior axis of the limb. A function for *GLI3* in the control of *SHH* signal production together with the control of *SHH* signal reception, may be consistent with the clinical observations in Greig Syndrome.

GLI3 IN LIMB DEVELOPMENT   A wealth of experimental results on the regulation of limb development allows to speculate on the role that *Gli3* might play in this context. Limb formation in the vertebrate embryo is initiated by local proliferations of mesenchymal cells forming a bulge under the ectoderm, which is induced to form an apical ectodermal ridge (AER) at the anterior-to-posterior (first-to-fifth digit) rim of the limb bud by maintaining undifferentiated proliferating mesenchyme in the immediately subjacent area (Fig. 113-3). The AER also elaborates pattern along the proximal-distal axis (i.e., humerus to digits). A region in the posterior mesenchyme, the zone of polarizing activity (ZPA), controls patterning in the anterior-posterior axis. Genes involved in the induction and maintenance of this process in vertebrates are indicated in Fig. 113-3. Distal skeletal morphogenesis is a late event in limb development. Mesenchymal condensations occur in a sequence to become adult skeletal elements.

Several steps in this developmental cascade seem to be sensitive to the proper amount of *Gli3* product: In mouse embryos, *Gli3* expression in the period from day 7 to 12 of gestation at first is strong in undifferentiated mesenchyme of the developing limb. Then it becomes confined to the interdigital mesenchyme between the precartilageous rays of the future digits and the interzonal mesenchyme. Later, *Gli3* is highly expressed in the perichondrium, a mesenchymal layer of cells surrounding the developing cartilageous intermediate of the bones to be formed.
Figure 113-3 Molecules involved in pattern specification during limb bud development. Dorsal view of the limb bud. AER, apical ectodermal ridge: The ridge releases factors from signal to the underlying cells to maintain a high mitotic state and patterning activities. PZ, progress zone: Cells in the underlying mesenchyme progressively acquire more distal fates in the course of limb outgrowth. ZPA, zone of polarizing activity: Posterior mesenchyme cells express *Sonic hedgehog* (*SHH*) and exhibit polarizing activity, i.e., an active role in coordinating pattern formation at the growing tip of the limb by establishing a dynamic system of positional values in three dimensions. SHH induces FGF4 expression, and its own expression is maintained by FGF4 and a dorsalizing factor from the dorsal ectoderm, WNT7a. The full names of the factors are given in Table 113-3.

The level of *Xt* expression inversely correlates with the number of digits formed (Table 113-2). There is no indication for a polarized *Gli3* expression along the anterior-posterior axis. However, it seems that the developmental field on the anterior side of the limb mesenchyme is more affected by a reduction of gene dosage than the posterior. This reduction may directly determine the additional digits. Alternatively, lack of transcriptional control by the *Gli3* protein may initially result in an increased size of the limb and AER that would induce formation of additional digits. Various additional consequences of *Gli3* reduction, such as bones with aberrant shapes, fused or elongated bones, and syndactylies suggest that also inducing steps further downstream, such as apoptosis separating digital elements, are influenced by the level of *Gli3* product.

CANDIDATE GENES FOR HUMAN LIMB DEVELOPMENT

Each of the genes organizing size and shape of individual bones and the separation of individual fingers by apoptosis and outgrowth can be altered resulting in oligo- or polydactyly, syndactylies, or ectrodactyly. As outlined for Greig syndrome, the hint for an association of a gene with a function can originate from the study of human malformations or from candidate genes detected in animal models.

Only a few of the many human syndromes associated with malformations of hands and feet could be linked to candidate genes on specific human chromosomes. In rare cases, distinct mutations of candidate genes are known to cause malformations. The rich collection of candidate genes originating from the study of limb development in animal models awaits its exploitation for the study of human development. Table 113-3 compiles the fragmentary information from these three sources.

CONCLUSIONS

PERSPECTIVE OF MOLECULAR DIAGNOSTICS *GLI3* spans at least 280 kb of genomic DNA. Little more than the cDNA and intron–exon boundaries have been sequenced so far. The upstream gene sequences that are potentially important for gene regulation still have to be analyzed in detail. The known intron–exon structure will stimulate the search for mutations in this gene; however, a clinical routine application is not readily available.

FUTURE RESEARCH The recessive mutation in *add/add* mice seems to reduce the expression of the *Gli3* gene and thus produce less of an otherwise normal protein. This reduction induces overgrowth only in the most sensitive developmental fields, mainly the most anterior part of the forelimbs (thumb and, eventually, digits). All other mutations analyzed so far on the molecular level in Greig patients or *Xt* mice are deletions or translocations, null mutations, probably eliminating transcription completely.

Whereas the mouse system provides advantages for studies of embryonal stages, of homozygotes, and gene rescue studies in transgenic animals, analysis of human developmental mutations holds the promise for a larger variety of mutations in individual unrelated Greig patients. These studies will show if only complete loss of one gene copy results in the Greig phenotype. If not, the position of mutations in the *GLI3* gene should indicate domains essential for functionality, the analysis of which in turn might

Table 113-3
Human Chromosome Regions Potentially Governing Limb Development

Gene	Name	Chromosomal location	Syndrome affecting limb development
LMX1	LIM homeobox transcription factor 1	1q22–23

help to identify other genes on which the *GLI3* product acts to regulate development and other factors cooperating with *GLI3* in this function.

The genomic sites upstream of the *Gli3* transcription start that are disturbed by the add insertion are candidates for promoter regions governing transcription of *Gli3* itself.

The variety of effects on different organ systems manifested by homozygous *Xt* mice encourages one to search systematically for mutations influencing *GLI3* expression or functionality in the multitude of human developmental defects other than the Greig syndrome.

114 Fibroblast Growth Factor Receptor-Related Skeletal Disorders

Craniosynostosis and Dwarfism Syndromes

MAXIMILIAN MUENKE, CLAIR A. FRANCOMANO,
M. MICHAEL COHEN, JR., AND ETHYLIN WANG JABS

BACKGROUND

Unique mutations in three human fibroblast growth factor receptors (FGFR1, FGFR2, and FGFR3) have been identified as causing various skeletal disorders that affect the skull (craniosynostosis syndromes) and the growth of the long bones (dwarfism syndromes). Craniosynostosis is the premature fusion of one or more cranial sutures. It is relatively common, with an estimated birth prevalence of 340 per million. More than 90 syndromes are associated with craniosynostosis, and the majority are inherited in an autosomal dominant manner. The best known of these include Crouzon, Jackson-Weiss, Pfeiffer, Apert, and Saethre-Chotzen syndromes. These syndromes have in common premature synostosis of the coronal sutures of the skull, underdevelopment of the midface, some cases having variable abnormalities of the extremities and other organ systems. All are inherited as autosomal dominant traits, most with complete penetrance and variable expressivity. Although viewed clinically as distinct entities, Crouzon, Jackson-Weiss, Pfeiffer, and Apert syndromes have now been shown to be allelic, with alterations in the same gene (*FGFR2*). Other craniosynostosis syndromes also shown to be caused by *FGFR* mutations include Beare-Stevenson cutis gyrata syndrome, Crouzon syndrome with acanthosis nigricans, and a craniosynostosis syndrome associated with a unique *FGFR3* point mutation. Interestingly, the two former conditions have dermatologic findings, but the first disorder is associated with *FGFR2* mutations, whereas the second is secondary to a *FGFR3* mutation. In contrast, there are two craniosynostotic conditions with mutations in transcription factors. Craniosynostosis, Boston type, is a result of a mutation in a homeobox gene, *MSX2*, and Saethre-Chotzen syndrome has been linked to mutations in the *TWIST* gene, a basic helix-loop-helix transcription factor. It has been suggested that the FGFRs are part of the same signaling pathway as TWIST.

Three dwarfing conditions—achondroplasia, hypochondroplasia, and thanatophoric dysplasia—have long been considered a family of skeletal dysplasias because of clinical and radiographic similarities. The phenotypic spectrum ranges from neonatal lethal thanato-

phoric dysplasia to mild hypochondroplasia, with achondroplasia somewhere in between. Overlap with the craniosynostosis syndromes is seen in thanatophoric dysplasia, in which cloverleaf skull occurs much more frequently in Type 2 than in Type 1. Recent observations have led to the delineation of a newly recognized syndrome in this family of disorders, which is more severe than achondroplasia but less so than thanatophoric dysplasia; the condition is called severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN). It is now recognized that all four of these disorders are caused by mutations in *FGFR3*.

Comparison of specific mutations in *FGFR*s and their phenotypes is providing new insights into the role of these receptors in normal and abnormal bone development. Furthermore, these mutations provide molecular signposts to complement clinical descriptions of this family of disorders. First, we will introduce the clinical features of these craniosynostosis and dwarfing syndromes and then discuss their genetic basis.

CLINICAL FEATURES

CROUZON SYNDROME Crouzon syndrome (OMIM 123500) is among the earliest described and most commonly inherited causes of craniosynostosis. In addition to premature fusion of the skull bones, this syndrome is characterized by shallow orbits, ocular proptosis, and midface hypoplasia (Fig. 114-1A). Craniosynostosis commonly involves the coronal suture leading to brachycephaly with shortening of the anteroposterior diameter of the skull. Additional findings include frontal bossing, hypertelorism, strabismus, beaked nose, mandibular prognathism, high arched palate, dental malocclusion, and conductive hearing loss. On occasion, mental deficiency has been observed. The most consistent finding is severe-to-moderate ocular proptosis because of shallow orbits. The hands and feet are not involved, in contrast to other craniosynostosis syndromes. Crouzon syndrome has a birth prevalence of 15.5 per one million newborns and accounts for approximately 4.5% of all cases of craniosynostosis. This syndrome has an autosomal dominant mode of inheritance with high penetrance and moderate variability in phenotypic expression. On occasion, families with extreme variability have been reported. New mutations represent 56% of all cases, and there is evidence of an advanced paternal age effect. Instances of two affected sibs

Figure 114-1 **(A)** Crouzon syndrome: Mother with ocular proptosis, divergent strabismus, hypertelorism, and midfacial hypoplasia. Note marked digital impressions on radiograms of the skull. (From Jones, Smith's Recognizable Patterns of Human Malformation, 1997, p. 421.) **(B)** Jackson-Weiss syndrome: two members of the Amish pedigree, one who is mildly affected with brachycephaly and hypertelorism and the other with turribrachycephaly. Feet anomalies of large great toes, syndactyly, and medial deviation. (From Fig. 1 of Jabs et al. Nature Genet 8:275–279,1994; Fig. 1C of Li et al. Genomics 22:418–424, 1994.) **(C)** Apert syndrome: Infant with severe brachycephaly, frontal bossing, ocular proptosis, hypertelorism, and midfacial hypoplasia. Note significant syndactyly. (From Fig. 2 of Park et al. Am J Hum Genet 57:321–328, 1995.) **(D)** Crouzon syndrome and acanthosis nigricans: female with brachycephaly, ocular proptosis, hypertelorism. Dermatologic manifestations of hyperpigmentation, hyperkeratosis, and melanocytic nevi. **(E)** Beare-Stevenson cutis gyrata syndrome: Note fine and coarse wrinkling of the skin with facial features of ocular proptosis and midface hypoplasia. (From Fig. 1 of Przylepa et al. Nature Genet 13:492–494, 1996; Fig. 12 of Hall et al. Am J Med Genet 44:82–89, 1992.) **(F)** SADDAN syndrome: Female with facial features similar to achondroplasia and hyperpigmentation.

born to unrelated parents with normal phenotypes raises the possibility of germline mosaicism.

CROUZON SYNDROME WITH ACANTHOSIS NIGRICANS A subgroup of patients with Crouzon syndrome have a dermatologic disorder—acanthosis nigricans and melanocytic nevi (Fig. 114-1D; OMIM 134934.0011). These skin findings with craniosynostosis breed true as an autosomal dominant condition. Acanthosis nigricans is characterized by verrucous hyperplasia of the skin, particularly in flexural areas. Histopathological findings include marked papillomatosis, the epidermis being thin and

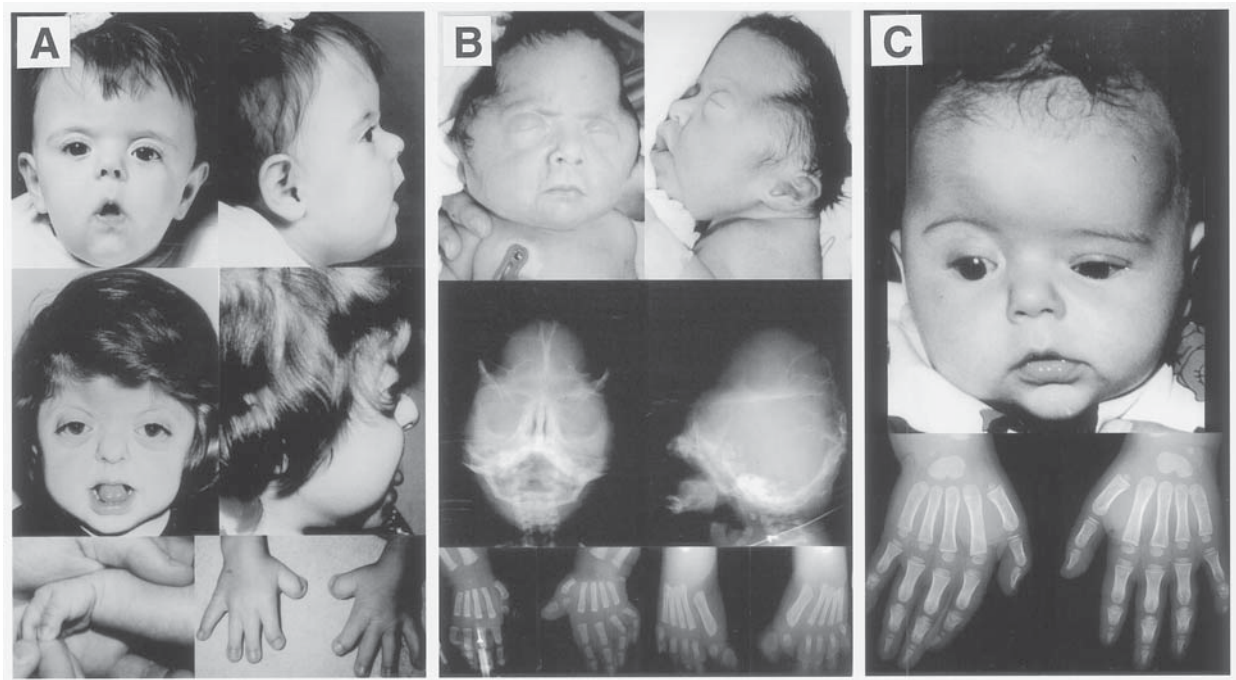
hyperpigmented. Acanthosis nigricans is heterogeneous, and many cases are associated with insulin resistance. This is of interest, since insulin binds to the classic insulin receptor and insulin-like growth factor receptors, which are expressed in keratinocytes. Other endocrine abnormalities (including obesity) and certain malignancies are known causes of acanthosis nigricans, and an association with certain congenital disorders, including Crouzon syndrome, is well-recognized. Acanthosis nigricans associated with Crouzon syndrome is rare and atypical in several ways. It usually occurs in females and its onset is often early, apparent in childhood


Figure 114-2 **(A)** Pfeiffer syndrome: Craniosynostosis of the coronal sutures, mild protrusion of her eyes, mildly broad thumbs, and great toes in a sporadic patient with the common *FGFR1* mutation. Craniosynostosis with more severe ocular protrusion, very broad thumbs and great toes and a splice mutation in exon 9 (IgIIIc) of *FGFR2* in a patient with familial Pfeiffer syndrome. (From Fig. 5 of Schell et al. Hum Mol Genet 4:323–328, 1995.) **(B)** Cloverleaf skull resulting from synostosis involving multiple sutures in a newborn with sporadic Pfeiffer syndrome and *FGFR2* mutation. Note the broad thumbs and broad medially deviated great toes on X-rays. **(C)** *FGFR3*-associated coronal synostosis: plagiocephaly resulting from unicoronal synostosis. Note the coned epiphyses and fused metacarpal bones on radiograms of the hands in the same patient with *FGFR3* 749C→G (Pro252Arg) mutation. (From Gripp et al., J Pediatr, in press.)

and always by puberty. It is distributed in a distinctive pattern, in the perioral, periorbital, and nasolabial areas as well as the neck, axillae, chest, breasts, and abdomen. Cementomas of the jaws have been found in a number of cases. Additional findings may include choanal atresia and hydrocephalus.

BEARE-STEVENSON CUTIS GYRATA SYNDROME Beare-Stevenson cutis gyrata syndrome (OMIM 123790) is a rare condition with only nine isolated cases reported to date. It is presumed to be autosomal dominant because of associated advanced paternal age. It is characterized by furrowed skin (cutis gyrata), acanthosis nigricans, craniosynostosis with craniofacial dysmorphism, digital anomalies, umbilical and anogenital anomalies, and early death (Fig. 114-1E). The most striking feature of this syndrome is the cutis gyrata with a corrugated appearance resembling the fine ribbing of corduroy. Large and deep folds are seen on the forehead, palms, soles, and perianal/genital regions. The craniofacial features of Beare-Stevenson syndrome are similar to the other craniosynostosis syndromes with downslanting of the palpebral fissures, ocular hypertelorism and proptosis, strabismus, dysmorphic ears, choanal atresia, and palatal anomalies. The majority have cloverleaf skull deformities with hydrocephalus, but some patients have a Crouzon-like appearance. In addition, a prominent umbilical stump, genital abnormalities (bifid scrotum, prominent scrotal raphe, rugose labia majora), and anal anomalies (anteriorly placed anus, tissue mounding of the anus) have been noted. Other unusual features include natal teeth, bifid or accessory nipples, pyloric stenosis, and a coccygeal tail.

JACKSON-WEISS SYNDROME Jackson-Weiss syndrome (OMIM 123150) is characterized by craniosynostosis and foot

anomalies (Fig. 114-1B). This condition was first reported in an Amish kindred with 88 affected individuals examined and another 50 reported to be affected. The condition is inherited in an autosomal dominant pattern with high penetrance and phenotypic expression so variable that the entire spectrum of dominantly inherited craniofacial dysostoses-acrocephalosyndactylies (e.g., Saethre-Chotzen and Pfeiffer syndromes, with the exception of Apert syndrome) appeared to be represented within this kindred. The facial features include proptosis, maxillary hypoplasia, and frontal prominence.

Unlike Crouzon syndrome, the degree of craniosynostosis and shallow orbits is mild to moderate, and none of the over 130 affected individuals in the Amish family are known to have undergone surgical intervention. Another distinguishing feature is that patients with Jackson-Weiss syndrome have the consistent manifestation of abnormal clinical and/or radiographic appearance of the feet, which can occur in the absence of any craniofacial features. Affected individuals have mild cutaneous syndactyly (especially of the second and third toes), broad great toes (broad metatarsal and proximal phalanges) with medial deviation, metatarsal and tarsal fusions (calcaneus, cuboid, navicular, and cuneiform), and/or abnormally shaped metatarsal and tarsal bones. Hand abnormalities are rare. The birth prevalence of this disorder is unknown, but several familial cases have been reported in the literature.

PFEIFFER SYNDROME Pfeiffer syndrome (OMIM 101600) is characterized by craniosynostosis, broad thumbs, and broad great toes (Fig. 114-2A,B). Craniofacial features are variable and secondary to synostosis, usually involving the coronal sutures.

Findings include a turribrachycephalic skull, midfacial hypoplasia with relative mandibular prognathism, beaked nose, low nasal bridge, hypertelorism, downslanting palpebral fissures, ocular proptosis, strabismus, highly arched palate, and crowded teeth. Anomalies of the hands and feet differ from any other craniosynostosis syndrome. Characteristically, the thumbs and great toes are broad and medially deviated (varus deformity). Brachydactyly is often present, as is partial soft tissue syndactyly of the fingers and toes. Radiographic findings of the hands include malformed and fused phalanges of the thumbs, short middle phalanges (brachymesophalangy) to complete absence, symphalangism (complete osseous fusion of proximal, middle, and distal phalanges that occurs over several years), and occasional fusion of the proximal ends of the fourth and fifth metacarpals. The distal phalanx of the great toe is broad, and the proximal phalanx is malformed. Broad and short first metatarsals and fusion of carpal and tarsal bones have been described. Additional manifestations may include cloverleaf skull (Fig. 114-2B), fusions of cervical and lumbar vertebrae, cubitus valgus, synostosis of the radio-humeral and ulnar-humeral joints, shortened humerus, abnormalities of the pelvis, coxa valga, and talipes calcaneovarus. Abnormalities affecting other organ systems are of low frequency and include hearing deficit, optic nerve hypoplasia, choanal atresia, bifid uvula, supernumerary teeth, gingival hypertrophy, widely spaced nipples, anal atresia or malpositioned anus, pyloric stenosis, umbilical hernia, and bifid scrotum. Intelligence is usually normal, although mental deficiency has been observed, particularly in sporadic cases. Rare CNS anomalies include hydrocephaly, Arnold-Chiari malformation, and seizures. The birth prevalence of Pfeiffer syndrome is not known. Its inheritance pattern is autosomal dominant with complete penetrance and variable expressivity. In addition to familial occurrence, sporadic cases resulting in new mutations are well-known.

FGFR3-ASSOCIATED CORONAL SYNOSTOSIS SYNDROME   This craniosynostosis syndrome has been defined in patients with a unique point mutation in *FGFR3* (OMIM 134934.0014). Clinical findings in over 70 patients from more than 30 unrelated families include bi- or unicoronal synostosis, midface hypoplasia, downslanting palpebral fissures, and ptosis (Fig. 114-2C). It is of note that some mutation carriers do not show any signs of craniosynostosis, having only macrocephaly or even normal head size. Sensorineural hearing loss is seen in some, as is developmental delay. Hand and foot anomalies are found in some, but not all, affected individuals and include brachydactyly with characteristic radiographic findings, such as thimble-like middle phalanges, coned epiphyses, and tarsal fusions. Some patients have broad halluces that are not deviated. It is of interest that this specific *FGFR3* mutation was identified in several affected individuals with unicoronal synostosis from a large prospective series, some of which were previously thought to be caused by intrauterine constraint. Height is normal, in contrast to FGFR3-associated dwarfism syndromes. The mode of inheritance is autosomal-dominant. Several previously reported families could be demonstrated to have this specific *FGFR3* mutation, one of which was called "craniosynostosis-type Adelaide." Based on results from an ongoing prospective study, it appears that the mutation associated with this syndrome may be common in sporadic or familial patients with uni- or bicoronal synostosis whose findings do not fit into any of the classic craniosynostosis syndromes.

APERT SYNDROME   Apert syndrome (OMIM 101200) is characterized by craniosynostosis, midface hypoplasia, and sym-metric syndactyly of the hands and feet, with a variety of other anomalies (Fig. 114-1C). Craniofacial features are characteristic for Apert syndrome and differ from those of other craniosynostosis syndromes. The cranium is disproportionately high, and the brain is megalencephalic. During infancy, a wide midline calvarial defect is present, extending from the root of the nose to the posterior fontanelle. Bony islands form and coalesce until the gap is completely covered by bone during the third year of life. Although the coronal suture is fused at birth, the anterolateral fontanelles are abnormally large, and both the lambdoid and squamosal sutures are patent. Turribrachycephaly is commonly observed with a flattened occiput and a steep forehead. The cranial base is malformed and often asymmetric. The anterior cranial fossa is very short. Additional craniofacial anomalies include hypertelorism, proptosis secondary to shallow orbits, downslanting palpebral fissures, and frequently strabismus. Hyperopia, myopia, or astigmatism can be found frequently. The nasal bridge is low, and the nose is beaked. Midfacial hypoplasia gives the impression of relative mandibular prognathism. Hearing deficit is secondary to otitis media and is related to the high frequency of cleft palate or bifid uvula. Furthermore, congenital fixation of the stapedial footplate has been reported in a number of cases. Dental anomalies include delayed and/or ectopic eruption, shovel-shaped incisors, and malocclusion. Upper-airway compromise is secondary to reduced nasopharyngeal and oropharyngeal space and poses a risk for obstructive sleep apnea, cor pulmonale, and even sudden death.

Characteristic abnormalities of the hands and feet are symmetric. The mid-digital hand mass minimally involves the second, third, and fourth fingers. The first and fifth fingers may be joined to the mid-digital hand mass or may be free. Similar patterns of syndactyly occur in the feet. Additional limb anomalies include limited mobility at the glenohumeral joint as a constant feature that progressively worsens with growth. Slight limitation of elbow extension and rotation occurs commonly, but is nonprogressive in nature. The humerus is commonly shortened to some degree. Radiographically, lack of segmentation of some joints in the hands cannot be observed at birth, but progressive ossification is found with time.

Vertebral anomalies particularly cervical fusions are common. Variable degrees of fusion may be observed involving the articular facets, the neural arch or transverse processes, or block fusion of the vertebral bodies. Ossification may not always be evident in early radiographs, although signs of impending fusion may include irregularity in vertical orientation of the vertebral bodies and narrowing of the involved intervertebral spaces. In childhood, the growth pattern in Apert syndrome consists of a slowing of linear growth so that most values fall between the 5th and 50th percentiles. From the onset of adolescence to adulthood, slowing becomes more pronounced. This two-step deceleration results in large measure from rhizomelic shortening of the lower limbs. The adolescent growth spurt takes place within the normal time frame.

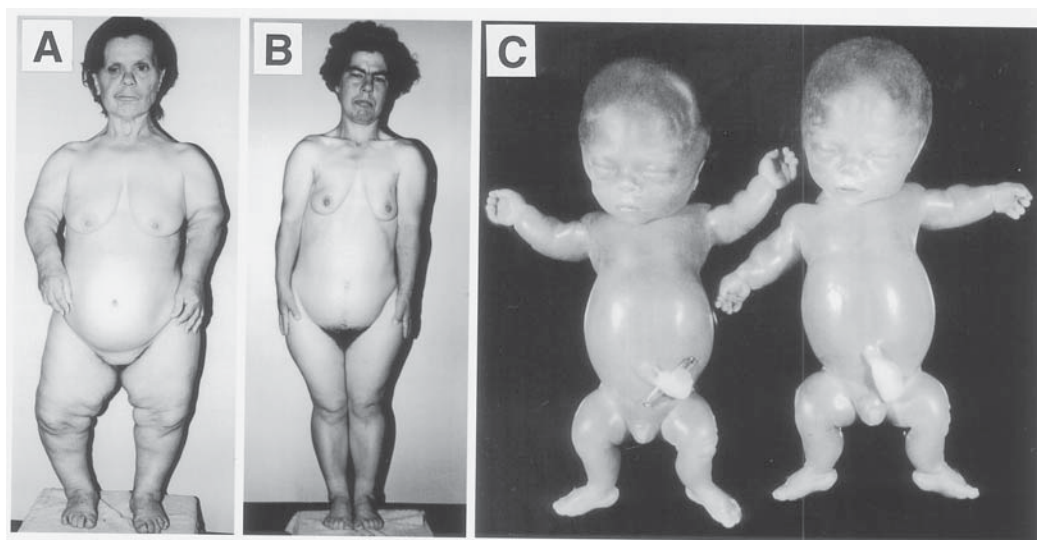
Intelligence in patients with the Apert syndrome varies from normality to mental deficiency. In patients who had craniectomies performed the first year of life, no significant differences in IQ were found between retarded and nonretarded outcome. It has been speculated that the mental deficiency is secondary to CNS abnormalities, such as malformations of the corpus callosum, the limbic structures, gyral abnormalities, hypoplasia of the cerebral white matter, and heterotopic gray matter. Gyral abnormalities, megalencephaly, and distortion ventriculomegaly are very com-


Figure 114-3 **(A)** Achondroplasia: Note macrocephaly, rhizomelic shortening, leg bowing (From Cohen MM, Jr. The Child with Multiple Birth Defects, 2nd ed., New York: Oxford University Press, 1997; p. 213). **(B)** Hypochondroplasia is associated with normal face and relatively proportional, short stature (From Cohen MM, Jr. The Child with Multiple Birth Defects, 2nd ed., New York: Oxford University Press, 1997; p. 213). **(C)** Thanatophoric dysplasia type 1 stillborn twins (Courtesy of MM Cohen, Jr.).

mon. Progressive hydrocephalus may occur on occasion but not nearly as frequently as in Pfeiffer or Crouzon syndromes or with cloverleaf skull deformities.

Cutaneous manifestations include skin dimples at the shoulders, elbows, and knuckles. Excess sweating is common. Acneiform lesions are particularly prevalent on the face, chest, and back. Additional skin findings include hyperkeratoses of the midplantar and lateral plantar surface, hypopigmentation of the skin, and paronychial infections with the feet being more commonly involved than the hands.

Apert syndrome is mostly sporadic, although over one dozen familial instances with autosomal-dominant inheritance pattern are known. Gonadal mosaicism has been postulated in a family with two affected sibs and unaffected parents. The rarity of familial cases can be explained by reduced genetic fitness of affected individuals because of the severe malformations and the presence of mental deficiency in many cases. Increased paternal age at the time of conception has been found in a large series of sporadic cases, and exclusive paternal origin of new mutations has been confirmed on a molecular level. Birth prevalence of Apert syndrome is 15.5 per one million births. The mutation rate is calculated to be 7.8×10^{-6} per gene per generation. Apert syndrome accounts for about 4.5% of all cases of craniosynostosis.

ACHONDROPLASIA   Achondroplasia (OMIM 100800) is the most common cause of human dwarfism, with an estimated birth prevalence of 25–66.7 per one million live births. It is inherited as an autosomal-dominant condition, but more than 80% of cases represent new mutations. The phenotype predominantly involves the skeletal system, although manifestations are seen in other organ systems as a result of bony compression. Affected persons are short, with rhizomelic (proximal) shortening of the arms and legs and a disproportionately long trunk (Fig. 114-3A). Often the hands exhibit a "trident" configuration, with separation between the fourth and third fingers resulting in a three-pronged appearance. True megalencephaly is seen, with absolute enlargement of the head circumference in more than 75% of cases. Typical facial characteristics include frontal bossing and midface hypoplasia.

Affected infants often have a thoraco-lumbar gibbus that is usually reducible and resolves as the child begins to sit and walk independently. Frequently, the gibbus is replaced by an exaggerated lumbar lordosis in early childhood, although the gibbus may persist into adulthood and may require surgical correction. Hypotonia is frequently observed in infancy and usually becomes less pronounced with age. Although major motor milestones are usually delayed, intelligence is generally normal unless hydrocephalus or other major complications involving the central nervous system intervene. Final adult height typically ranges from 118 to 145 cm for males and 112 to 136 cm for females.

The major medical complications of achondroplasia result from bony compression of the neuroaxis and the respiratory system. A small foramen magnum is found in almost all cases, and may lead to compression of the cervico-medullary junction and result in a high cervical myelopathy and/or central respiratory complications in early childhood, if the medulla is compromised. Small airway passages may lead to airway obstruction with potentially severe obstructive apnea. Recurrent otitis media is a frequent complication in early childhood and may require placement of pressure-equalizing tubes to minimize the risk of hearing loss.

Radiographic features of achondroplasia include short limbs with short, thickened tubular bones and short phalanges and metacarpals. The ribs are short with concave ends, and the growth plates are notched with a V-shaped appearance. Proximal fibular overgrowth is a frequent observation. The sternum is thick and wide. The vertebral bodies are typically short, flat and "bullet-shaped" in infancy. There is a decrease in the interpediculate distance as one progresses to the caudal end of the spine, in contrast to the increase in this dimension seen in persons who do not have achondroplasia. The vertebrae have short pedicles, which further compromise the dimensions of the spinal canal and contribute to symptoms of spinal stenosis in adulthood. Neuroradiologic evaluation of the brain and skull typically demonstrates enlarged ventricles and marked reduction in the size of the foramen magnum.

Morphologic evaluation of the growth plate in achondroplasia demonstrates normal, well-organized endochondral ossification

in many growth plates, but disruption of the growth plate in some weight-bearing joints, with short columns of chondrocytes and widening of the septa between the columns.

HYPOCHONDROPLASIA Hypochondroplasia (OMIM 146000) has many clinical similarities to achondroplasia, but is generally milder overall and typically has less craniofacial involvement. Short stature may not be recognized until the child is 2–3 years of age and is less pronounced than usually seen in achondroplasia (Fig. 114-3B). The height range may overlap with that of the general population, and the condition may be under-diagnosed. Hands and feet are broad and wide, but the trident appearance seen in achondroplasia is not usually apparent. At least one paper has reported an increased frequency of learning disabilities among this population.

The radiographic features of hypochondroplasia are also similar to, but milder than, those seen in achondroplasia. The long bones appear short and wide, with mild flaring of the metaphyseal-epiphyseal junctions. The skull is relatively normal in appearance, with only mild midface hypoplasia and frontal bossing. The interpediculate distance in the lumbar spine may stay constant or decrease as one progresses from rostral to caudal. The bone and cartilage in hypochondroplasia look relatively normal on morphologic evaluation, with minimal shortening of the chondrocytic columns and thickening of the matrix between the columns.

THANATOPHORIC DYSPLASIA Thanatophoric dysplasia (OMIM 187600) takes its name from the Greek "thanos," meaning death. Children affected with this condition almost invariably die in the perinatal period, with only a few survivors into early childhood documented in the literature. Early death is caused by severe respiratory compromise, secondary to an extremely small chest, perhaps exacerbated by medullary compression secondary to a small foramen magnum. Thanatophoric dysplasia is the most common of the neonatal lethal skeletal dysplasias. Clinical features include severe short-limbed dwarfism, curvature of the long bones, megalencephaly, and disproportionately long trunk with short ribs (Fig. 114-3C). The condition has been separated into two types, based on the presence or absence of curved tibiae and fibulae. The cloverleaf skull deformity is more often seen with straight tibiae and fibulae (Type 2). Type 1 is generally characterized by curved long bones and the absence of cloverleaf skull. Histopathology of the growth plate is typically irregular with few proliferative and hypertrophic chondrocytes. The hypertrophic zone of the growth plate is replaced by fibrous-appearing tissue, particularly at the periphery of the growth plate.

SADDAN Three patients have been recognized with a newly defined syndrome named SADDAN, for severe achondroplasia with developmental delay and acanthosis nigricans (Fig. 114-1F). All three patients were initially diagnosed as having achondroplasia, but were recognized as severe cases, with more profound dwarfism and bowing of the limbs than is typical for achondroplasia. All three cases exhibited acanthosis nigricans (an overlap with Crouzon syndrome with acanthosis nigricans and Beare-Stevenson syndrome) and had severe developmental delay, a highly unusual observation in achondroplasia. Radiographic features are intermediate between those of achondroplasia and thanatophoric dysplasia, and to date no chondro-osseous histopathology has been studied. One phenotypic case of thanatophoric dysplasia Type 1 with long-term survival and the R248C mutation associated with this diagnosis, and not SADDAN, has also been associated with acanthosis nigricans.

DIAGNOSIS

Patients with craniosynostosis syndromes are brought to medical and surgical attention because of abnormal head shape. Standard radiologic criteria are used to make the diagnosis of craniosynostosis. The three-dimensional CAT scan is the preferred tool for documentation of prematurely fused sutures and facial dysmorphism. Craniosynostosis cannot be diagnosed radiologically in adults because the sutures are normally fused. Associated increased intracranial pressure can be detected by radiological (*see* radiogram in Fig. 114-1A), ophthalmologic, and neurological examination, and CAT or MRI scan. A dysmorphology examination is required to detect the presence of associated features such as midface hypoplasia, and digital and anal anomalies. Clinical examination and dermatologic consultation with histologic examination of the skin can document such findings as acanthosis nigricans. Molecular diagnosis may involve analysis of the *FGFR1*, *FGFR2*, *FGFR3*, *MSX2*, or *TWIST* genes.

Diagnosis of dwarfism syndromes is still made predominantly on clinical and radiographic grounds. There are cases of intermediate severity between achondroplasia and hypochondroplasia, for whom molecular analysis may help to clarify the diagnosis. However, in the vast majority of cases, the diagnoses of achondroplasia, hypochondroplasia, and thanatophoric dysplasia can be made based on clinical observations and radiographic analysis. Unusual cases, such as those with acanthosis nigricans, unusually severe dwarfism, or mental deficiency, should be studied for the *FGFR3* mutation associated with SADDAN or other possible *FGFR3* mutations. The detection of the molecular basis of these disorders allows for prenatal as well as postnatal diagnosis. However, there are several problems in the application of molecular diagnostic testing, including the difficulty in predicting the severity of the phenotypic expression in affected individuals.

GENETIC BASIS OF DISEASE

The genetic bases of the craniosynostosis and short-stature syndromes described above have been elucidated very recently. The identification of the genes involved in these disorders has been a prime example of the so-called positional candidate gene approach. As an initial step toward gene identification, linkage analysis in large families aided in the mapping of the respective syndrome loci. Using microsatellite markers from throughout the genome, achondroplasia was mapped to DNA markers located in chromosome band 4p16. Both Crouzon and Jackson-Weiss syndrome were linked to chromosome 10q25–q26. Pfeiffer syndrome was shown to be heterogeneous with one locus on 8cen, a second locus on 10q25–q26. Because of the lack of large families with Apert syndrome, this disease could be excluded from 8cen markers and was shown to be consistent with linkage to 10q25–26. Similarly, a new autosomal-dominant craniosynostosis syndrome was excluded from the 8cen and 10q25–q26 regions, respectively, and was consistent with linkage to 4p16. Based on the chromosomal map position and the expression pattern, the *FGFR*s located in the same chromosomal regions were examined as candidate genes. Mutations were identified in *FGFR2* on chromosome 10q25–q26 as the cause for Crouzon, Jackson-Weiss, Pfeiffer, Apert, and Beare-Stevenson cutis gyrata syndromes. Mutations in *FGFR1* gene on 8p11.1 were identified in a subset of families with Pfeiffer syndromes. *FGFR3* on 4p16 is known to be involved in achondroplasia, hypochondroplasia, thanatophoric, and SADDAN, and was shown to cause Crouzon syndrome with acanthosis

nigricans and, most recently, FGFR3-associated coronal synostosis syndrome. Thus far, no human disorder has been associated with *FGFR4*, which is located in 5q35.

FIBROBLAST GROWTH FACTOR RECEPTORS   Four human FGFRs have been described, all coding for a cell-surface protein with an extracellular region with three immunoglobulin-like domains (IgI, IgII, IgIII), a transmembrane segment, and a split cytoplasmic tyrosine kinase domain (Fig. 114-4). The four FGFRs exhibit an amino acid identity of 55–72%, but differ in their ligand affinity and their tissue and temporal distribution. Structural diversity of the FGFRs is generated by alternative splicing (Fig. 114-4A), which leads to transmembrane receptors or secreted receptors consisting of one, two, or three Ig domains and different carboxyterminal halves of IgIII. IgII, the interloop region, and the N-terminus of IgIII are implicated in ligand binding. In addition, C-terminal sequences of IgIII appear to be important for ligand specificity, although they do not directly interact with their ligands, the fibroblast growth factors (FGFs). FGFs regulate cell proliferation, differentiation, and migration in many different tissues through complex signaling pathways. To date, 15 structurally related proteins of the mammalian FGF family have been identified and are associated with a wide spectrum of functions such as angiogenesis, wound healing, embryonic development, and malignant transformation. The ligand-induced activation of the FGFR kinase activity is mediated by receptor dimerization, which results in transphosphorylation of one receptor molecule by the other in the dimer. The autoactivated FGFR can then bind and phosphorylate intracellular signal transduction proteins and thus activate downstream pathways.

Xenopus, chicken, and mouse *FGFR*s encode proteins similar to human FGFR1 with a high amino acid identity of 78–98%. For the *Drosophila* (*DFR1*) and the *Xenopus* (*FGFR*) homologs, mRNA expression was shown in the mesoderm during embryogenesis. In *Xenopus*, posterior and ventral mesoderm development was blocked by a dominant-negative FGFR. Distinct spatial and temporal mRNA expression of *FGF*s and *FGFR*s, observed in the mouse, further supports roles for this group of ligands and receptors in embryogenesis. Whereas *FGFR1* and *FGFR2* mRNAs are coexpressed in prebone/precartilage structures, such as during craniofacial bone formation, *FGFR3* is expressed in the cartilage growth plates of long bones during endochondral ossification.

MUTATIONS IN *FGFR*s CAUSE CRANIOSYNOSTOSIS AND DWARFISM SYNDROMES   Both linkage and mutation analysis demonstrated genetic heterogeneity in Pfeiffer syndrome. Mutations have been identified in sporadic and familial Pfeiffer syndrome in *FGFR1* and *FGFR2*. A common mutation, a C-to-G transversion in exon 5 of *FGFR1* has been detected in all affected individuals of more than 20 unrelated families with Pfeiffer syndrome. This missense mutation, 755C→G, predicts a P252R substitution in the IgII-IgIII linker region, which is highly conserved in FGFRs through evolution as well as among the four human FGFRs. In this respect, it is of great interest that the 755C→G transversion predicting a P252R substitution in the IgII-IgIII linker region of *FGFR1* causing Pfeiffer syndrome is at an identical position to the 755C→G change in *FGFR2* in Apert syndrome and the 749C→G mutation in *FGFR3*, causing FGFR3-associated coronal synostosis syndrome (Fig. 114-4B,C; *see below*).

The second gene known to be involved in Pfeiffer syndrome is *FGFR2*. Approximately 18 different mutations have been shown in familial and sporadic cases, the majority of which either (1)

destroy a specific paired cysteine residue (C342) crucial for the formation of IgIII within the ligand binding region of FGFR2 or (2) introduce an additional unpaired cysteine, which likely interferes with the normal protein structure. Aberrant splicing of exon 9 (exon IIIc or exon B) in *FGFR2* was proposed to account for a subgroup of cases. The phenotypic consequences of mutations affecting exon 9 of *FGFR2* are remarkable for their pleiotropic effects resulting in three distinct craniosynostosis syndromes: Crouzon, Jackson-Weiss, and Pfeiffer syndrome (Fig. 4B; *see below*).

Molecular analyses of over 80 cases of Crouzon syndrome has revealed 30 different FGFR2 mutations. The majority of these mutations occur in IgIII, the ligand binding region of the extracellular domain. Over half of the mutations are in exon 9 (exon IIIc or exon B), which forms the second half of IgIII, with the others occurring primarily in exon 7 (exon IIIa or exon U), which forms the first half of IgIII (Fig. 114-4A,B). The mutations are missense, splicing, and small in-frame deletions and insertions. As in Pfeiffer syndrome, in the majority of cases, these mutations result in the loss or gain of the amino acid cysteine, and the most frequently mutated amino acid is C342. Mutation of this cysteine residue is predicted to affect the formation of the disulfide bond, which is critical to forming the tertiary structure of IgIII and determine its binding specificity and affinity.

FGFR2 normally undergoes alternative splicing resulting in isoforms with different spatiotemporal expression (Fig. 114-4A). The BEK or FGFR2 isoform that includes the product from exon 9 (exon IIIc or exon B) is expressed predominantly in primordial bone. The keratinocyte growth factor receptor (KGFR) isoform, which includes the product from exon 8 (exon IIIb or exon K), is expressed primarily in epithelial lined structures. *FGFR2* mutations that only affect exon 9 and the specific expression pattern of this isoform (BEK) in primordial bone are consistent with skeletal changes seen in Pfeiffer and Crouzon syndromes. In contrast, mutations in exon 7 present in both isoforms (BEK and KGFR) would be expected, not only to result in a skeletal phenotype but also in anomalies involving epithelial structures. Interestingly, there are documented cases of low imperforate anus and anorectal fistulas in Crouzon syndrome patients with exon 7 mutations. *FGFR2* mutations in both exon 7 and 9 have also been identified in Jackson-Weiss syndrome. In fact, Jackson-Weiss, Crouzon, and Pfeiffer syndromes share a common mutation, C342R. The original Amish family in the description of Jackson-Weiss syndrome had a mutation predicting an A344G substitution that was also found in Crouzon syndrome. The extensive phenotypic variability in this large kindred suggests the involvement of modifying gene(s). A number of these FGFR2 mutations, including C342R, have been demonstrated to cause constitutive activation of the receptor by aberrant intermolecular disulfide-bonding.

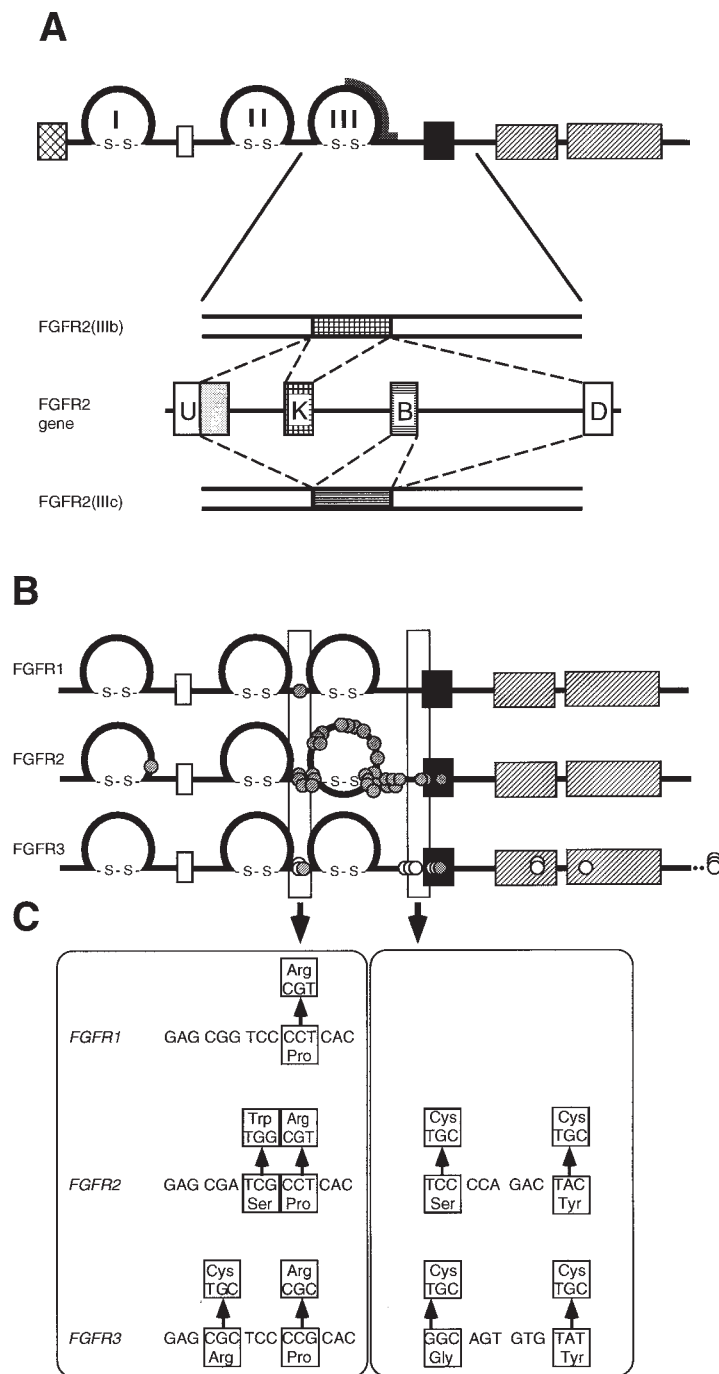
FGFR2 mutations were also detected in Beare-Stevenson cutis gyrata syndrome. In three sporadic cases, two novel missense mutations were identified predicting an amino acid to be replaced by a cysteine. Two patients had the identical Y375C substitution in the transmembrane domain, and one had a S372C change in the carboxyl-terminal end of the linker region between IgIII and the transmembrane domain (Fig. 114-4B,C). In two other patients, neither of these mutations as found suggesting further genetic heterogeneity. The phenotype of this syndrome is consistent with the mutations occurring in regions that would affect both the BEK (exon 9 or IIIc) and KGFR (exon 8 or IIIb) isoforms and their coexpression, because the BEK isoform is expressed normally in


Figure 114-4 **(A)** Schematic diagram of the mammalian fibroblast growth factor receptor (FGFR) putative protein structure with signal peptide (hatched box), three immunoglobulin-like (Ig) domains (loops), and an acidic region (open box) between first and second Ig-like domain, transmembrane domain (black box) and a split tyrosine kinase domain (striped box). Alternative splicing with differential exon use, as shown for the human *FGFR2* gene, generates receptor variants that differ in the second half of their third Ig-like domain and presumably their ligand-binding properties. Exons U (upstream, exon IIIa, or 7) and D (downstream containing transmembrane domain, exon 10) flank the alternatively used exons K (KGFR, exon 8) or B (BEK, exon IIIc, or 9) in the resulting mRNA, which constitute the IgIIIb or IgIIIc isoforms, respectively (*see text* for details). **(B)** Schematic diagram of the genes encoding FGFR1, FGFR2, and FGFR3 with the positions of the mutations reported in craniosynostosis (gray circles), including Pfeiffer, Apert, Crouzon, Crouzon with acanthosis nigricans, Beare-Stevenson cutis gyrata, and Jackson-Weiss syndrome, and short-stature syndromes (white circles) including achondroplasia, hypochondroplasia, thanatophoric, and SADDAN. **(C)** Nucleotide sequence of the interloop region between IgII and IgIII with three adjacent amino acids recurrently affected by unique mutations identified in Pfeiffer syndrome (*FGFR1*), Apert syndrome (*FGFR2*), *FGFR3*-associated craniosynostosis syndrome (*FGFR3*), and thanatophoric dysplasia (*FGFR3*). It is of note that the identical C-to-G substitution in *FGFR1*, *FGFR2*, and *FGFR3* predicting a proline to arginine change causes different craniosynostosis syndromes. The analogous amino acids in FGFR2 for Beare-Stevenson cutis gyrata syndrome and FGFR3 for thanatophoric dysplasia type 1 are mutated to produce an extra cysteine residue.

skeletal structures and the KGFR is expressed in tissues involved in the development of the skin, umbilicus, and anogenital organs.

In Apert syndrome, two recurring mutations in exon U (or exon 7) of *FGFR2* account for the overwhelming majority of several hundred cases studied worldwide. These are a 934C→G transversion resulting in a S252W substitution in the linker region between IgII and IgIII in about 70% and a 937C→G change resulting in a P253R substitution in 30% (Fig. 114-4B,C). These two distinct amino acid substitutions in FGFR2, which result in Apert syndrome, are both bulky substitutions that may alter the relative orientation of IgII and IgIII, thus affecting the binding of FGF ligands or dimerization with other FGFRs.

FGFR3-associated coronal synostosis is caused by a recurrent single-point mutation (749C→G) predicting a P252R substitution in the IgII/III interlinker region of FGFR3 in over 30 unrelated families. Interestingly, this common mutation occurs precisely at the analogous position within the *FGFR3* protein as the mutations in FGFR1 (P252R) in Pfeiffer syndrome and FGFR2 (P253R) in Apert syndrome (Fig. 114-4B,C). It has been speculated that the FGFR1 Pro252Arg and FGFR3 Pro250Arg mutations influence FGFR2 signaling, thereby causing the craniosynostosis phenotype. The observation that patients with FGFR1 or FGFR3 mutations tend to have a milder phenotype than those seen with FGFR2 mutations and that Apert syndrome, the most severe phenotype in the spectrum of FGFR2 mutations, is caused by the equivalent Pro252Arg mutation in FGFR2, is consistent with this possibility.

In Crouzon syndrome with acanthosis nigricans, a recurrent mutation predicting a A391E substitution occurs in the transmembrane domain of FGFR3 (Fig. 114-4B). The phenotypes associated with FGFR3 mutations are consistent with its spatiotemporal expression. FGFR3 is expressed in primordial bone, ectoderm, epithelial-lined structures, and skin. The majority of FGFR3 mutations are reported in dwarfism conditions, achondroplasia, thanatophoric dysplasia, and hypochondroplasia (Fig. 114-4B). The association of nondwarfism and even nonskeletal phenotypes with FGFR3 mutations reveals the potential for a wide range of pleiotropic effects as well as locus heterogeneity in Crouzon syndrome. Thus, the effects of the FGFR3 mutations in Crouzon syndrome with acanthosis nigricans, FGFR3-associated coronal synostosis syndrome, and those for the different dwarfism syndromes must be functionally distinct.

More than 95% of cases of achondroplasia are caused by one of two mutations in *FGFR3* (1138G→A is most common, 1138G→C is least common), both of which result in the substitution of an arginine residue for the normal glycine at amino acid 380 in the transmembrane domain of the protein. Interestingly, this alteration is one of the most frequent mutation in the human genome, with an estimated mutation frequency between 5.5×10^{-6} and 2.8×10^{-5} per gamete generation. The transmembrane domain affected by this mutation is important, not only as a cell-membrane anchor, but also in signal transduction.

Hypochondroplasia is less genetically homogeneous, with approximately 70% caused by a K540L substitution in the first tyrosine kinase domain of the FGFR3 protein. Mutations for the rest have not yet been identified. Several linkage studies have suggested that some cases of hypochondroplasia may be caused by mutations at a locus distant and distinct from *FGFR3*, but mutations at other gene loci have not yet been recognized.

Thanatophoric dysplasia (TD) Type 1 is caused by series of mutations in the *FGFR3* gene, one of which results in R248C,

located in the Ig II/II interloop region (Fig. 114-4B,C). In contrast, Type 2 (TD2; associated with straight limbs with or without cloverleaf skull) is associated with a unique recurring mutation predicting a K650N substitution in the second tyrosine kinase domain of FGFR3. The identical amino acid (K650M) is altered in three patients with SADDAN. In vitro studies have demonstrated that the G380R substitution in achondroplasia, the K540L change in hypochondroplasia, and the K650N alteration in TD2 all are associated with constitutive (ligand-independent) activation of FGFR3. The downstream effects of this constitutive activation and the mechanism whereby it is translated into the phenotypic effects of these mutations are not, as yet, understood.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

How these FGFR mutations alter the intracellular signaling pathway to cause the autosomal dominant phenotypes seen in the craniosynostosis and dwarfism syndromes is poorly understood. The abnormal phenotypes in the FGFR-related skeletal disorders are not simply caused by a deletion of one copy of the gene. This is supported by naturally occurring deletions in humans and also by gene knockout experiments in the mouse. Although individuals with a deletion of the short arm of chromosome 4 have one copy of *FGFR3* deleted, they do not have any of the characteristic findings of achondroplasia or thanatophoric dysplasia. Thus, the phenotypes in these skeletal disorders cannot be explained by the classic model of a mutation-induced haploinsufficiency. Further evidence for the unique nature of the identified *FGFR* mutations comes from knockout studies in transgenic mice. Heterozygous animals that are deleted for one copy of *Fgfr1*, *Fgfr2*, or *Fgfr3*, respectively, appear to be developmentally and anatomically normal. Recent studies provide further evidence that the abnormal phenotypes in FGFR-associated craniosynostosis and dwarfism syndromes are not a result of a loss-of-function, but rather from a gain-of-function of the mutated receptor molecule. This evidence comes from mutation-induced receptor activation and targeted *Fgfr* gene disruption experiments in the mouse. Biochemical studies have demonstrated that an *FGFR2* mutation (Cys342Tyr) found in Pfeiffer and Crouzon syndromes and *FGFR3* mutations in achondroplasia and types 1 and 2 thanatophoric dysplasia result in ligand-independent, constitutive activation of the receptor. This conclusion is supported by studies of *Fgfr3* knockout mice, which exhibit overgrowth of the long bones and axial skeleton suggesting that FGFR3 is a negative regulator of bone growth. However, individuals with FGFR3-associated coronal synostosis and Crouzon syndrome with acanthosis nigricans have normal long-bone growth. It is therefore doubtful that this mutation leads to constitutive FGFR3 activation in the same tissue distribution as the achondroplasia, TD-1, and TD-2 mutations.

MANAGEMENT AND FUTURE DIRECTIONS

Multidisciplinary team approach is required for the management of the craniofacial, audiologic, ocular, oral, dental, skeletal, hand, foot, and skin abnormalities found in these conditions. Management is symptomatic and psychosocial support is often indicated. Recommendations for follow-up and management are reviewed for chondrodysplasias by Horton and Hecht (1993) and for craniosynostosis by Cohen (1986). Further studies of development pathways, animal models, cell biologic aspects, and biochemical signal transduction components involved in the pathogenesis and in the modification of the phenotype are required. Chemical

inhibitors of FGFRs have been developed. As yet, no approaches to the management of these conditions have been devised using techniques of gene therapy.

115 Aarskog-Scott Syndrome

Jerome L. Gorski

INTRODUCTION

Aarskog-Scott syndrome, or Faciogenital dysplasia (FGDY, MIM 305400), is an uncommon X-linked recessive developmental disorder that primarily affects skeletal morphogenesis. The condition was first described by Aarskog and Scott in the early 1970s. Mutations in FGD1, the gene responsible for Aarskog-Scott syndrome, result in a developmental disorder affecting specific skeletal structures that include elements of the face, cervical vertebrae, and distal extremities. Genetic and biochemical analyses show that FGD1 encodes a guanine nucleotide exchange factor (GEF), or activator, for Cdc42, a member of the Rho family of Ras-like GTPases. Rho proteins comprise a family of at least eight distinct proteins that are involved in the control of a wide variety of cellular functions, including the organization of the actin cytoskeleton, the control of cellular division, and the transcriptional regulation of gene expression. Together, members of the Rho protein family and their activators regulate cell shape, adhesion, and migration, properties that are involved in tissue morphogenesis. The identification that FGD1, the gene responsible for Aarskog-Scott syndrome, is a RhoGEF and a component of the Rho signal transduction pathway suggests that other components of this signaling pathway will be found to be responsible for defects in mammalian morphogenesis.

CLINICAL FEATURES OF AARSKOG-SCOTT SYNDROME

PHYSICAL MANIFESTATIONS OF THE DISEASE The Aarskog-Scott syndrome, or Faciogenital dysplasia (FGDY), phenotype consists of a characteristic set of facial and skeletal anomalies, disproportionate short stature, and urogenital malformations. The cardinal features of this disease are summarized in Table 115-1 and illustrated in Fig. 115-1.

Facial Features The face is typically round and the forehead broad with ridging of the metopic suture. Facial features typically consist of widely-spaced eyes (hypertelorism), ptosis, down-slanting palpebral fissures, and a short up-turned (anteverted) nose (Fig. 115-1). The philtrum is commonly long and the maxilla is typically hypoplastic. A variety of external ear anomalies have been described, including low-set ears, posteriorly-rotated auricles, and thickened over-folded helixes.

Musculoskeletal Features Impaired growth is another major manifestation of the disease; growth retardation usually becomes apparent during the first few years of life, and affected males rarely exceed 160 cm in height. Stature is disproportionate and the distal extremities are most severely shortened (Fig. 115-1). Hands and feet are broad and short. Interphalangeal joints are typically hypermobile; however, camptodactyly and contractures of the interphalangeal joints have also been observed. The majority of affected males have a pectus excavatum and inguinal hernias. Typically, relative to affected males, the phenotype of obligate female heterozygotes is mild and limited to relative short stature and a subtler form of the characteristic craniofacial anomalies.

Radiographic Abnormalities Radiographic findings are usually limited to the cervical spine and distal extremities; these abnormalities are summarized in Table 115-1. About half of the affected males have a cervical spine abnormality such as spina bifida occulta, odontoid hypoplasia, fused cervical vertebrae, and ligamentous laxity with subluxation. Radiographic abnormalities of the hands and feet typically consist of shortened digits, hypoplasia of the terminal phalanges, clinodactyly, fusion of the middle and distal phalanges, and retarded bone maturation. Other radiographic abnormalities include maxillary hypoplasia, additional pairs of ribs and other segmentation anomalies, and calcified intervertebral disks.

Urogenital Anomalies The scrotum typically appears bifid. Scrotal folds commonly extend ventrally around the base of the penis to form what resembles a shawl. Cryptorchidism is common; penile hypospadius has also been reported.

Other Features Although mild-to-moderate mental retardation has been described in some affected males, it does not appear to be a consistent feature. Affected males have been observed to have a delayed eruption of teeth; some have congenitally missing teeth. Other anomalies occasionally occur including cleft lip and palate and congenital heart defects. Some males have a single palmar crease or distally placed axial triradii. Affected males and obligate carrier females both appear to have normal fertility.

Epidemiology Population surveys estimate that FGDY occurs with a recognized frequency of approximately 1 per one million in the general population. However, because it is likely that mildly affected individuals would not be detected, it is probable that the disease frequency is actually higher than this estimate.

EMBRYOLOGIC CORRELATIONS Mutations that result in the Aarskog-Scott syndrome alter the size and shape of a limited number of specific cartilaginous and bony elements but leave other skeletal structures unaffected. Similar abnormalities have been observed in the *short-ear* (*se*) and *brachypodism* (*bp*) mouse

Table 115-1
Primary Clinical and Radiographic Features of FGDY

Anatomical region or system	Clinical features
Craniofacial	Broad forehead, abnormally formed ears, hypertelorism, down-slanted palpebral fissures, ptosis, maxillary hypoplasia, anteverted nostrils, hypodontia and malocclusion (cleft lip and palate, enamel hypoplasia)[a]
Musculoskeletal	Disproportionate short stature, distally shortened limbs and brachydactyly, pectus excavatum, soft tissue syndactyly of the digits, interphalangeal joint hypermobility, camptodactyly and clinodactyly, broad feet, inguinal hernias (single palmar crease, abnormal dermatoglyphics)
Urogenital	Shawl and bifid scrotum, crytorchidism (hypospadius, renal hypoplasia)
Miscellaneous	Mild-to-moderate mental retardation, strabismus, growth hormone deficiency (congenital heart defects)
Radiographic Features	Spina bifida occulta, odontoid hypoplasia, cervical vertebral defects and ligamentous laxity, calcified intervertebral disks, additional ribs, hypoplastic phalanges, retarded bone age (osteochondritis dissecans)

[a]Items in parentheses are less commonly observed.

Figure 115-1 Aarskog-Scott syndrome. Facial features are characterized by a broad forehead, a widow's peak, hypertelorism, bilateral ptosis of the upper eyelids, midface hypoplasia, a depressed nasal bridge, anteverted nose, and low-set ears. Stature is short and disproportionate with shortened distal extremities; hands and feet are short and broad. Bilateral inguinal herniorrhaphy scars are present. Consequential to scrotal folds joining ventrally over the base of the penis, an abnormal penoscrotal configuration is present. (Courtesy R Gorlin, University of Minnesota.)

mutants. During development, *se* and *bp* embryos manifest abnormalities in the formation of a characteristic subset of skeletal progenitors. During mammalian embryogenesis, the first observable sign of skeletal morphogenesis is the aggregation of mesenchymal cells into regions of high cell density termed condensations; these condensations represent the initial outlines of future skeletal elements. The mesenchymal cells within these condensations later elaborate extracellular matrix and differentiate into cartilage and bone cells; final skeletal shapes result from a combination of partial cell loss (apoptosis), the fusion of adjacent condensations, and the coordinated resorption and deposition of bone by osteoclasts and osteoblasts. *Se* and *bp* embryos exhibit abnormalities in the size and shape of specific skeletal condensations, anomalies that result in the mutant phenotype. The similarity of these mutations to Aarskog-Scott syndrome suggests that, like *bp* and *se* mice, FGDY males may have an altered pattern of skeletogenesis that affects a limited number of specific skeletal progenitors. Additional analyses will be required to verify this hypothesis.

DIFFERENTIAL DIAGNOSIS   Several other inherited conditions, including Noonan syndrome, Robinow syndrome, and Leopard syndrome, share clinical features with Aarskog-Scott syndrome; shared features include short stature, hypertelorism, and hypogonadism. Pseudohypoparathyroidism and hydantoin embryopathy also share several physical features with FGDY. In combination with the distinctive radiographic abnormalities, the characteristic pattern of craniofacial abnormalities, disproportionate short stature, shortening of the distal extremities, and characteristic urogenital anomalies distinguish Aarskog-Scott syndrome from these other conditions. Unlike these other conditions, FGDY is an X-linked recessive trait; therefore, a demonstrated X-linked pattern of inheritance assists in confirming the diagnosis.

MOLECULAR GENETICS OF AARSKOG-SCOTT SYNDROME

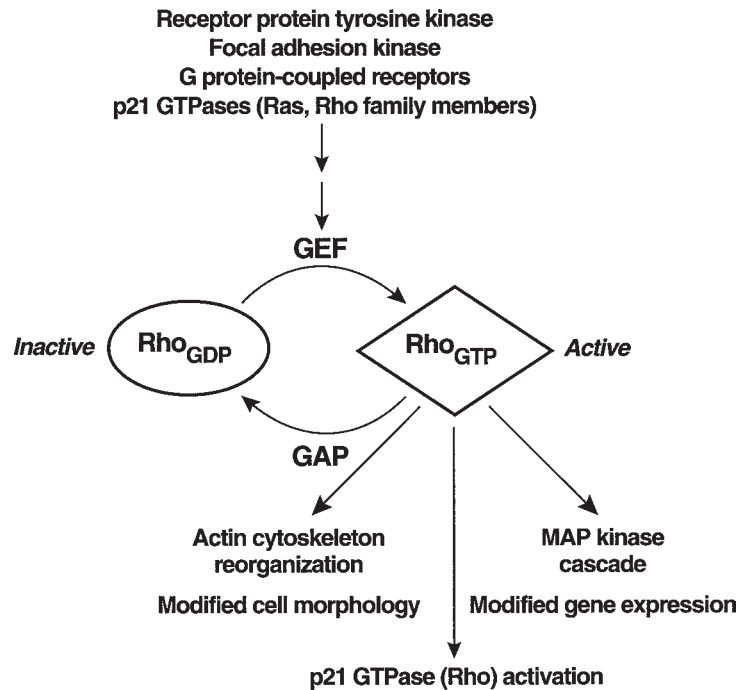
AARSKOG-SCOTT SYNDROME GENE, FGD1, MAPS TO REGION Xp11.21   Gene Localization   Pedigree analyses of families segregating FGDY strongly suggested an X-linked recessive pattern of inheritance; subsequent genetic linkage studies mapped the responsible locus to the pericentric region of the X chromosome. The observation of a mother and son who both displayed all of the major features of FGDY in association with a reciprocal X;8 chromosome translocation tentatively localized the disease gene to the X-chromosomal breakpoint, region Xp11.21. The observation that, in the affected female, the translocated X chromosome was active in the majority of cells examined, suggested that the translocation breakpoint directly interrupted the disease gene. By isolating the rearranged X chromosome in a rodent somatic cell hybrid, mapping experiments sublocalized the FGDY-specific breakpoint to an estimated 350-kb region within distal Xp11.21.


Figure 115-2 RhoGEFs activate Rho proteins by catalyzing the exchange of GDP for GTP. A variety of stimuli lead to the activation of Rho protein family members via RhoGEFs, including the p21 GTPase Ras, receptor protein tyrosine kinases, and G-protein-coupled receptors. Activated Rho leads to modified cell morphology by a reorganization of the actin cytoskeleton, a modulation of gene transcription by the activation of mitogen-activated protein (MAP) kinase cascade, and the sequential activation of other Rho family member proteins. RhoGAP facilitates the hydrolysis of GTP and the Rho protein inactivation.

Positional Cloning The FGDY-specific X;8 breakpoint was used as a molecular signpost to positionally clone the Aarskog-Scott syndrome gene. Using DNA markers flanking the disease-specific breakpoint, a YAC contig of the region was assembled; DNA clones derived from this contig were used to identify regional transcripts and identify a cDNA clone, designated FGD1, that spanned the disease-specific breakpoint. A number of lines of evidence indicated that FGD1 was the gene responsible for Aarskog-Scott syndrome:

1. FGD1 was mapped to Xp11.21, the region known to contain the Aarskog-Scott syndrome gene.
2. The FGD1 gene was directly disrupted by a disease-specific X;8 translocation breakpoint.
3. FGD1 mRNA was expressed in tissues involved in the disease phenotype including fetal craniofacial bones.

The identification of additional FGD1 mutations in affected FGDY males, including an insertional mutation predicted to result in a severely abbreviated and nonfunctional FGD1 protein, confirmed that FGD1 was the gene responsible for the Aarskog-Scott syndrome.

Genomic Organization The complete FGD1 cDNA is 4439 nucleotides in length, a result consistent with the 4.4-kb transcript detected by Northern blot analysis. The FGD1 transcript contains a 2883-nucleotide open reading frame (ORF) that encodes a protein of 961 amino acids with a predicted mass of 107 kDa. Comparative sequence analyses show that the FGD1 gene is composed of 18 exons that span 51 kb of genomic DNA. Exons range from 1210 to 31 bp in size; intron sizes range from 23 kb to 106 bp in size. RNase protection and primer extension analyses show that the FGD1 promoter belongs to a GC-rich, TATA-less class of promoters.

Mutation Analyses Genomic analyses have failed to identify a common structural rearrangement among FGDY patients. These results suggest that FGD1 mutations will be highly heterogeneous. Expression studies indicate that FGD1 is not expressed in readily biopsied tissues such as lymphocytes and fibroblasts; these results suggest that DNA-based analyses will be necessary to identify individual FGD1 mutations. A determination of the genomic structure of the FGD1 gene provides a means for designing DNA-based diagnostic analyses to detect FGD1 mutations. For example, primers designed to polymerase chain reaction amplify each of the FGD1 exons may provide a means of detecting FGD1 mutations by performing single-strand conformational polymorphism (SSCP) analysis.

FGD1 ENCODES A RHOGEF, A REGULATOR OF CDC42 SIGNAL TRANSDUCTION **Comparative Analyses** Comparative sequence analysis indicated that FGD1 encoded a Rho guanine nucleotide exchange factor (RhoGEF). RhoGEFs form a family of cytoplasmic proteins that activate the GTPase Ras-like family of Rho proteins by catalyzing the exchange of bound GDP for free GTP (Fig. 115-2). The p21 GTPase superfamily and the biological roles of the family members are summarized in Table 115-2.

The RhoGEF family consists of at least 16 distinct members. Like FGD1, all members contain a 200-amino acid RhoGEF motif; in a number of RhoGEF family members, this domain has been shown to be necessary and sufficient for catalyzing the GDP/GTP exchange for Rho protein family members. In addition, all RhoGEF domains are paired with pleckstrin homology (PH) domains; PH domains are thought to be essential for the proper cellular localization of RhoGEF proteins to the cytoskeleton. In addition to the RhoGEF and PH domains, most RhoGEF proteins contain other types of functional domains that are commonly found in signaling

Table 115-2
p21 GTPase Superfamily Members

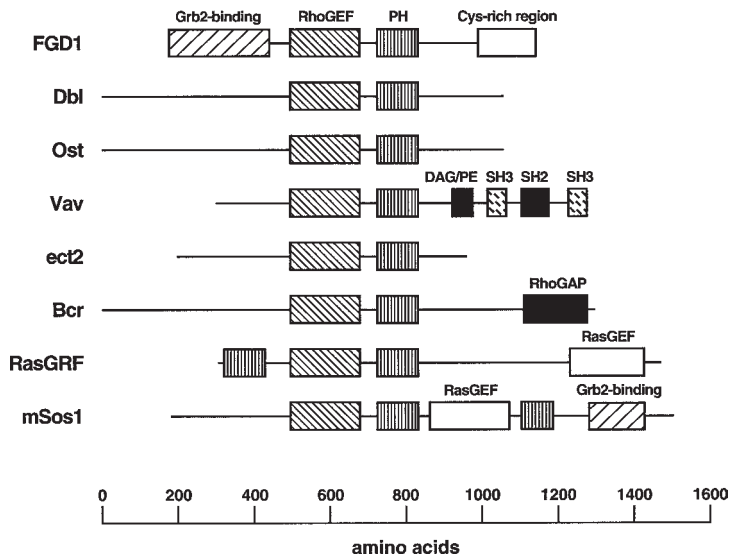
Family	Family members	Biological function
Ras	H-ras, Ki-ras, N-ras, R-ras, rap1A/B, rap2A/B, ralA/B, TC21	Regulation of cell growth Regulation of cell differentiation
Rho	RhoA, RhoB, RhoC, RhoG, Cdc42, Rac1, Rac2, TC10	Actin cytoskeleton organization Regulation of gene expression Regulation of cell growth
Rab/ARF	Rab1,…,Rab26, ARF1,…,ARF6	Vesicle transport
Ran	Ran1	Importation of nuclear proteins


Figure 115-3 Schematic representation of the domain structure of the FGD1 protein compared to other RhoGEF proteins. Domains are drawn approximately to scale. FGD1 contains at least four distinct domains, including a RhoGEF domain and a pleckstrin homology (PH) domain, motifs common to all RhoGEF family members. FGD1 also contains a cysteine-rich zinc finger-like (Cys-rich) motif and a putative Src-homology 3-binding (Grb2-binding) region. Vav contains Src-homology 3 (SH3), Src-homology 2 (SH2), and a putative diacylglycerol/phorbol ester-binding (DAG/PE) zinc butterfly motif; Bcr contains a Rho GTPase activator protein (RhoGAP) domain. RasGRF and mSos1 contain a Ras guanine nucleotide exchange factor (RasGEF) domain.

molecules. For example, although RasGRF and mSos1 both contain RhoGEF domains, they also contain RasGEF motifs (Fig. 115-3), a result suggesting that these proteins may act as two-headed exchange factors by mediating the activation of both the Rho and Ras signaling pathways. Most of the RhoGEFs identified, including Dbl, ect2, and Ost were discovered by virtue of their transforming capability through gene transfer experiments; other RhoGEFs, including Cdc24, Bcr, mSos1, RasGRF, and Vav, were identified by their role in cell growth regulation. As shown in Fig. 115-2, the signaling cascade that couples RhoGEFs to upstream components remains elusive. The specific biological function of many of the RhoGEF family members remains to be determined.

Biochemical Studies   In vivo and in vitro studies indicate that FGD1 is a RhoGEF for Cdc42, a member of the Rho protein family. When microinjected into cultured cells, the FGD1 RhoGEF domain induces fibroblasts to form filopodia, actin-associated membrane complexes generated by activated Cdc42. The FGD1 RhoGEF domain specifically binds to the Cdc42 protein, and FGD1-dependent filopodia formation is blocked by complexing Cdc42 to other Cdc42-binding proteins. In addition, in FGD1 expressing fibroblasts, stress-activated protein kinase (SAPK)/c-Jun N-terminal kinase (JNK) activity is stimulated in a manner similar to that

obtained with constitutively activated Cdc42. Together, these results indicate that FGD1 is a specific RhoGEF for Cdc42.

FGD1 ENCODES ADDITIONAL STRUCTURAL DOMAINS
A Zinc Finger Motif   A comparative analysis of FGD1 showed that it contained two additional conserved structural motifs (Fig. 115-3). Like the proto-oncogene RhoGEF member Vav, the 3' region encoded a 50-amino acid cysteine-rich zinc finger-like motif that was similar to, but distinct from, the diacylglycerol/phorbol ester-binding regulatory domain of protein kinase Cγ. The Vav zinc finger motif is functionally significant; mutations in the conserved cysteine residues abolish transforming activity. Similar putative regulatory domains have been identified in a variety of Ras-associated proteins, including the Raf proto-oncogene, the RhoGAP n-chimerin, and diacylglycerol kinase. The observation that the predicted FGD1 sequence contains a zinc finger-like domain suggests that the FGD1 protein may interact with lipid second messenger molecules. Therefore, it is possible that the FGD1 protein may interact with, or be modified by, the components of multiple signal transduction pathways.

A Putative Grb2-Binding Region   An analysis of the FGD1 protein showed that the 5' region was remarkably proline-rich and that proline constituted 22% of the first 250 amino acid residues.

Table 115-3
Actin-Associated Membrane Complexes

Complex type	Involved Rho family member	Biological function	Proteins[a]
Focal adhesion	Rho	Cellular adhesion	Integrin, vinculin, talin, PTK, FAK, tensin, paxillin, zyxin, ERM, α-actinin
Filopodia	Cdc42	Cellular morphology	Vinculin, fimbrin, talin, PTK, α-actinin, ERM
Lamellipodia	Rac	Cellular movement	Talin, fimbrin, integrin, PTK, α-actinin, ERM
Cortical stress fibers	Rho	Cellular morphology	Fodrin-spectrin, ankyrin, PTK, adhesion molecules
Adherens junction	?	Cellular adhesion	Cadherin, catenin, vinculin, PTK, filamin, α-actinin, ERM

[a]Known to comprise an actin-associated membrane complex; PTK, protein tyrosine kinase; FAK, focal adhesion kinase; ERM, ezrin, radixin, and moesin.

Since proline-rich regions may contain Src-homology 3 (SH3) binding domains, the 5' portion of the derived FGD1 protein sequence was compared to other sequences known to contain SH3 binding sites. An analysis showed that FGD1 contained two putative SH3 binding sites that exhibited strong similarity to the functionally significant regions of several proteins with demonstrated Grb2 binding activity, including the RasGEF, mSos1. Recently, it has been shown that Grb2 selectively binds the proline-rich motifs of the mSos1 protein to form a link in a signal transduction pathway that functionally ties tyrosine kinase receptors to Ras. Among the identified Ras and RhoGEF family members, mSos1 is unique in containing an SH3 (or Grb2)-binding domain. The identification of a putative proline-rich SH3 binding domain in FGD1 implies that, like Sos, the location and/or activity of the FGD1 protein may be modified by Grb2-like proteins.

MOLECULAR PATHOPHYSIOLOGY OF AARSKOG-SCOTT SYNDROME

Identified FGD1 mutations included a frame shift mutation and a chromosomal rearrangement, mutations predicted to result in the total absence of FGD1 protein; therefore, a loss of FGD1 appears to result in the FGDY phenotype. In *S. cerevisiae*, *S. pombe*, *D. melanogaster*, and *C. elegans*, the loss of a RhoGEF activity is functionally equivalent to the loss of the target Rho protein. Although the structural and functional diversity of the RhoGEF protein family indicates that FGD1 is not the only Cdc42 RhoGEF, it is logical to expect that within expressing cells FGD1 mutations will reduce or modify Cdc42 activity. Therefore, it is likely that an examination of the molecular biology of Cdc42 and the other Rho proteins will illuminate the biological role of FGD1.

RHO PROTEINS REGULATE THE ORGANIZATION OF THE ACTIN CYTOSKELETON AND GENE EXPRESSION The mammalian Rho protein family (listed in Table 115-2) consists of at least eight distinct proteins and three subfamilies: Rho, Cdc42, and Rac. Each Rho protein has at least 50–55% homology with any of the others and 30% homology to Ras.

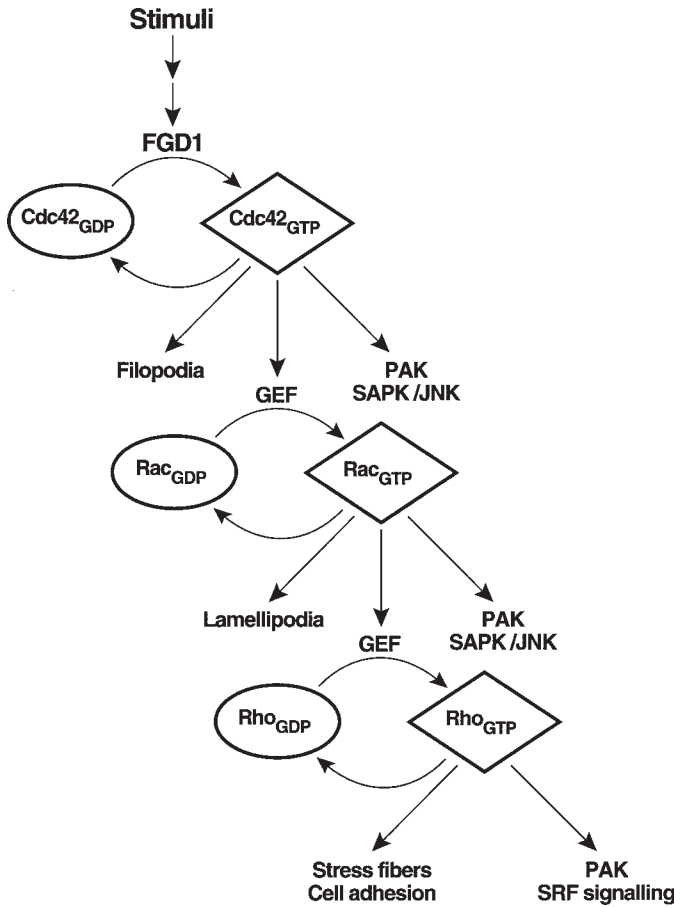
Regulation of the Actin Cytoskeleton Rho proteins are part of a signal transduction pathway that modulates a cell's response to external stimuli by reorganizing the actin cytoskeleton to regulate cellular morphology. Regulated changes in the actin cytoskeleton are required for cytokinesis, cell motility, and cell–cell interactions. Therefore, by regulating the actin cytoskeleton, Rho proteins and their activators regulate cell shape, adhesion, and migration, properties critical to tissue morphogenesis. Expressed in cells, Rho proteins elicit a distinctive actin-associated membrane complex; these complexes, their biological function, and the involved Rho proteins are listed in Table 115-3. In fibroblast cells, microinjection analyses show that activated Cdc42 stimulates the


Figure 115-4 Rho protein family members are activated in a hierarchical cascade. The activation of Cdc42 by FGD1 leads to the sequential activation of Rac and Rho. Activated Cdc42 results in the formation of filopodia, whereas activated Rac leads to the formation of lamellipodia; activated Rho results in the formation of actin stress fibers and focal adhesions. Cdc42 and Rac activate the stress-activated protein kinase (SAPK)/c-Jun N-terminal kinase (JNK) mitogen-activated protein kinase (MAPK) cascade via the Ser/Thr kinase PAK; Rho is required for signaling via PAK to modulate gene transcription through the serum response factor (SRF).

formation of microspikes, or filopodia; in *S. cerevisiae*, Cdc42 is required for polarized cell growth and bud formation. Related studies show that Rac regulates the formation of lamellipodia and cell ruffles, and that Rho stimulates the formation of focal adhesions and cortical stress fibers. These same experiments show that Rho proteins are activated in a hierarchical cascade (Fig. 115-4), and

that activated Cdc42 stimulates the sequential activation of Rac and Rho to sequentially elicit filopodia, lamellipodia, and stress fibers. More recently, use of cell-free assays and intact cell systems show that Rho regulates several enzymes involved in phosphoinositol metabolism, including phosphoinositide 3-kinase, phosphatidylinosital 4-phosphate 5-kinase, and phospholipase D. These results suggest that Rho may regulate the reorganization of the actin cytoskeleton through the metabolism of phospholipid metabolites. However, the exact relationship between Rho, phospholipid metabolism, and the actin cytoskeleton remains to be determined.

Mitogen-Activated Protein Kinase (MAPK) Cascade   Rho proteins are also part of a signal transduction pathway that activates MAPK cascades to modulate gene transcription. Kinases belonging to the MAPK family are used throughout evolution to control cellular responses to external signals, such as growth factors, inductive signals, and nutrient status. MAPKs have received particular attention, because many of these enzymes translocate to the cell nucleus to modulate the action of transcription factors. Recent studies show that Cdc42 and Rac activate the stress-activated protein kinase (SAPK)/c-Jun N-terminal kinase (JNK) MAPK cascade via the Ser/Thr kinase PAK. In contrast, Rho is required for modulating gene transcription through the serum response factor (SRF), results that suggest the existence of a novel signaling pathway (Fig. 115-4).

Implications for Morphogenesis   In addition to the identification of FGD1 as a RhoGEF, several lines of evidence indicate that Rho proteins are critical to development. In *Drosophila*, Cdc42 and Rac1 dominant-negative mutations result in specific developmental defects, including anomalies in the outgrowth of peripheral neurons and abnormal myoblast fusion, defects of cellular polarity that are consistent with the role of Rho proteins in regulating cellular morphology. Cdc42 and Rac1 mutations result in distinct phenotypes, results suggesting that different Rho proteins play specific roles during development. Transgenic mice carrying dominant-negative Rac mutations have similar developmental defects in neurogenesis. In addition, Cdc42 mutations in *S. cerevisiae* and *S. pombe* result in abnormalities in cellular morphology.

FGD1 mutations could alter morphogenesis in at least two ways. Since FGD1 stimulates Cdc42 to activate the SAPK/JNK MAPK cascade, consequential to FGD1 mutations, diminished Cdc42 activity could alter SAPK/JNK activity and critically change patterns of gene transcription. Alternatively, since FGD1 stimulates Cdc42 to form filopodia, as a result of FGD1 mutations, diminished Cdc42 activity could alter cellular morphology. Since the actin cytoskeleton regulates cell shape, adhesion, and migration, altered patterns of cellular morphology are likely to play a critical roles in skeletogenesis. Additional studies will be necessary to determine how FGD1 mutations perturb human morphogenesis.

FUTURE DIRECTIONS

With advances in the molecular understanding of disease processes, it has been appreciated that many diseases, such as the proliferative diseases of cancer, atherosclerosis, and psoriasis, result from a malfunction in signal transduction. This recognition has led to intensive research and the development of therapies based on the modification of cellular signaling in diseased cells. The identification of FGD1 as a RhoGEF and a component of Rho signal transduction suggests that other inherited abnormalities of human morphogenesis may also be the result of defects in embry-onic signal transduction. Recent experiments have shown that cellular signal transduction pathways can be successfully modulated by a variety of reagents, including small molecules, antibodies, DNA encoding dominant-negative proteins, antisense RNA, and target-specific RNA ribozymes. The continued development of these reagents may provide a means for selectively correcting altered patterns of embryonic signal transduction in the future.

Several Ras-associated proteins have been found to be responsible for human genetic diseases. Neurofibromin, the protein defective in von Recklinghausen neurofibromatosis, contains a RasGAP domain homologous to the catalytic domains of p120-GAP. Tuberin, the gene responsible for the form of tuberous sclerosis mapped to chromosome 16 (TSC2), has some homology to the GAP3 protein. The gene responsible for choroderemia (CHM), a retinal degeneration syndrome, was found to be similar to a Rab geranylgeranyl transferase.

Among identified RhoGEF family members, FGD1 is the first to be directly implicated in causing an inherited human disease. However, the involvement of FGD1 in human morphogenesis implies that other components of the Rho signaling cascade may also be critical to embryonic development and responsible for related and/or unrelated inherited birth defects. An analysis of FGD1, in the context of its normal function and regulation, is likely to provide important new information regarding the roles that RhoGEF proteins and, by inference, Rho proteins play in signal transduction and mammalian development.

116 Beckwith-Wiedemann Syndrome

Ellen R. Elias, Michael R. DeBaun, and Andrew P. Feinberg

BACKGROUND

Beckwith-Wiedemann syndrome (BWS) is one of the most common overgrowth syndromes, with an estimated incidence of 1/14,000 births. Independently described by Beckwith in 1963 and Wiedemann in 1964, it was originally called the EMG syndrome for its three main features: exomphalos, macroglossia, and gigantism.

Patients with BWS present with a distinctive craniofacial phenotype and may have multiple congenital anomalies. Macrosomia is present at birth and accelerated growth occurs during early childhood. In addition, asymmetry of the limbs may develop over time. Patients with BWS, particularly those with clinically significant limb asymmetry, have an increased risk of developing intra-abdominal malignancies.

BWS is caused by a gene in chromosomal band 11p15.5. Autosomal-dominant transmission has been documented, though most cases are sporadic. A greater likelihood of maternal vs paternal transmission and increased penetrance when inherited from the mother have been reported, but have not been evaluated systematically in a large number of families.

CLINICAL FEATURES

BWS is a heterogeneous syndrome that can have many different presentations. All or a few of cardinal features of the syndrome can be present at birth. Thus, the diagnosis of BWS can be obvious or difficult in the neonatal period depending on the set of characteristic features observed. BWS can be suspected at birth because of macrosomia, macroglossia, and the presence of abdominal wall defects, which range in spectrum from diastasis recti or umbilical hernia in the milder cases to omphalocele in the most severe case. In addition to these cardinal features, visceromegaly or enlargement of the internal organs (liver, spleen, kidneys, pancreas, and occasionally the heart) may be identified. Adrenal cytomegaly with associated cysts, a rare pathological finding (Table 116-1), is a hallmark of BWS. The classic craniofacial features associated with BWS include facial nevus flammeus, maxillary hypoplasia with a broad nasal bridge, and a prominent occiput (Fig. 116-1). Characteristic ear lobe creases/pits are a distinctive if not pathomnemonic finding in children with other features of BWS. Microcephaly is seen in a small number of cases. Table 116-2 lists the common craniofacial features associated with BWS.

In addition to dysmorphic features, macroglossia, and abdominal wall defects, other congenital anomalies may be present. These include cardiac defects and, occasionally, cardiomegaly and abnormalities of the gastrointestinal tract. Genital anomalies are common, including cryptorchidism and enlargement of the labia and clitoris. Many other anomalies, such as cleft palate, supernumerary nipples, and syndactyly have been reported with variable frequencies in patients with BWS and are listed in Table 116-3.

CLINICAL COURSE

The clinical course during the neonatal period is most remarkable for hypoglycemia, often quite severe. This is felt to be caused by insulin hypersecretion from hypertrophied pancreatic islet cells. Polycythemia may also be problematic. Macrosomia is present at birth, and the growth velocity is greater than normal during the early years of life. The musculoskeletal system in children with BWS can be variably affected. Asymmetry of the musculoskeletal system may manifest as an increase in muscle bulk, bone length, or both. In addition, patients may have scoliosis or chest wall asymmetry independent of asymmetry of the long bones. Bone age is often advanced in early childhood but typically subsides by adolescence. After 4–6 years of age, growth velocity decreases, and puberty is usually achieved at the normal time. Asymmetry, seen in 13–18% of patients, may not be present at birth, but often manifests itself in infancy and early childhood.

Patients with BWS generally have intellectual function in the normal range, although no study of formal cognitive evaluations has been completed. Central nervous system damage and subsequent intellectual impairment may result from severe neonatal hypoglycemia if not adequately managed.

Patients with BWS have an increased risk of cancer. The risk is age-dependent, with most cancers occurring before 5 years of age and virtually all before 10 years. The risk of cancer appears to be higher in children with limb asymmetry, although the magnitude of asymmetry needed to confer a high risk of cancer has not been quantified. Common tumors in patients with BWS include Wilms' tumor, adrenocortical carcinoma, neuroblastoma, and hepatoblastoma. Extraabdominal malignancies are much less common in patients with BWS, but have been reported, including rhabdomyosarcoma, glioblastoma, and cardiac fibrous harmartoma.

DIAGNOSIS

The diagnosis of BWS is suspected on the basis of clinical phenotype. A constellation of abnormalities including macrosomia, macroglossia, abdominal wall defects, mid-face hypoplasia,

 Clinodactyly/polydactyly
 Neural tube defect
 Imperforate anus

and ear pits or creases should prompt the clinician to consider BWS. The diagnosis of BWS within the first days of life is important so that precautionary measures may be taken to prevent hypoglycemia. Hypoglycemia occurs in the majority of newborns within the first days of life and may manifest with seizures. This is in contrast to infants of diabetic mothers who may present with macrosomia but who often are hypoglycemic at birth. Infants of diabetic mothers may also have other congenital anomalies, but do not present with macroglossia, abdominal wall defects, and the typical ear creases seen in an infant with BWS. Macroglossia may also be observed in storage diseases such as Type II glycogen storage disease as well as in neurofibromatosis and hypothyroidism. Neurofibromatosis can be distinguished by its dermatological findings, and congenital hypothyroidism is usually detected on newborn screening. Most patients with storage diseases do not present with impressive macroglossia at birth.

Other rare syndromes that should be considered in the differential diagnosis include Simpson-Golabi-Behmel syndrome, Proteus syndrome, and Perlman syndrome. Simpson-Golabi-Behmel syndrome is an X-linked disorder with a phenotype similar to BWS, including macrosomia, macroglossia, and a predisposition to Wilms' tumor. Patients, in addition, may show cleft lip and/or palate, unusual alveolar grooves, and skeletal anomalies. An abnormality in glypican-3, which binds to IGF2, has recently been reported in Simpson-Golabi-Behmel patients. Proteus syndrome involves gigantism, macrocephaly, hemihypertrophy, enlargement of the limbs, and risk of malignancy, but has distinctive dermatologic manifestations. Perlman syndrome, involving prenatal overgrowth, renal hamartomas and a depressed nasal bridge, may be part of a continuum with BWS, although patients do not usually have macroglossia, midline abdominal defects, or hemihypertrophy.

Other common overgrowth syndromes include Sotos syndrome (cerebral gigantism), Weaver syndrome, and Marshall-Smith syndrome. Sotos syndrome is characterized by early overgrowth and advanced bone age, hypotonia, and mild cognitive impairment in most patients. Facial features are notable for macrocephaly, downslanting palpebral fissures, and a prominent chin. Neoplasms of the kidney and liver have been reported in Sotos syndrome patients, although this is less frequent than in BWS. Weaver syndrome patients also show accelerated growth and advanced bone age. Characteristic facies include a broad forehead, large ears, and a small chin. Patients with Marshall-Smith syndrome show accelerated skeletal growth, but often manifest failure to thrive and severe, life-threatening respiratory problems. Characteristic features include prominent eyes, low-set ears, and choanal narrowing in some individuals. Patients with Sotos syndrome, Weaver syndrome, and Marshall-Smith syndrome can be distinguished from patients with BWS by the marked differences in their physical features and clinical course.

Prenatal diagnosis of BWS is possible, made on the basis of second trimester ultrasound detection of large fetal size, polyhydramnios, and abdominal wall defects. A positive family history

    α fetoprotein every 6–12 weeks of age until age 3[a]

[a]The efficacy for screening for hepatoblastoma with alphafetal protein has not been proven. However, anecdotal reports have indicated that this tumor biomarker may be of potential benefit.

is helpful in those cases of BWS acquired as a dominant trait. Chromosomal analysis in a few cases has revealed a translocation or duplication involving 11p15.5, but most patients with BWS have normal chromosomes.

MANAGEMENT/TREATMENT

The initial management of the newborn with BWS (Table 116-4) must first address the neonatal hypoglycemia, which may be prolonged and quite severe. The macroglossia may cause airway and/or feeding difficulties. Cardiac evaluation, including chest radiographs, electrocardiogram, and echocardiogram are indicated if congenital heart disease is suspected. Surgical intervention may be necessary for the abdominal wall defects and genitourinary abnormalities. Ultrasound of abdominal organs should be performed to rule out the presence of congenital tumors, which may require surgical excision and/or chemotherapy. Polycythemia is another common neonatal problem, which tends to subside without intervention.

Beyond the neonatal period, the most important aspect of management is tumor surveillance. Cancer screening has traditionally consisted of serial abdominal sonography to detect Wilms' tumor, the most common cancer in this group, from birth until 7 or 8 years of age. Other than anecdotal reports, there have been limited data to support cancer screening. Nevertheless, screening for Wilms' tumor in this high-risk cancer population appears prudent. If one plans to do such screening, then screening intervals should be less than 6 months because of the doubling time of Wilms' tumor. Despite the decreasing incidence of Wilms' tumor with age, the doubling time of this cancer does not allow for longer screening intervals. There have been no published prospective studies demonstrating the benefit of screening for the other cancers, such as hepatoblastoma with α fetoprotein or neuroblastoma with urinary catecholamines. However, hepatoblastoma is a very aggressive tumor in which early diagnosis and complete surgical resection markedly improves survival. In contrast, factors predicting survival in children with neuroblastoma are more biological and demographically determined, such as N-myc copy number or age. Thus, preliminary data suggest screening for neuroblastoma is unlikely to be effective.

Other aspects of management may include an early audiology exam to detect hearing loss, orthopedic intervention for leg length discrepancy, urologic management of complex genitourinary anomalies, and speech and language therapy for the consequences of macroglossia.

MODE OF INHERITANCE

BWS is transmitted as an autosomal-dominant trait, with increased penetrance when transmitted from a carrier mother when compared to the father. Discordant monozygotic twins have also been described. These differences in parental origin-specific penetrance are most likely explained by genomic imprinting, a differential modification of the two parental chromosomes in the gamete or zygote, leading to differential function of the two chromosomes in the offspring. Imprinting is by definition reversible, and it usually refers to monoallelic expression of a specific parental allele of a gene. Several genes in mouse and man have been shown to be imprinted. Notably, the insulin-like growth factor-II gene (IGF-2) is expressed exclusively from the paternal allele in most tissues (exceptions are the choroid plexus, leptomeninges, and adult liver). IGF-II is an autocrine growth factor in cancer and has mitogenic effect on cells mediated by signaling at the IGF-I receptor. Approximately 100 kb telomeric to IGF-2 on 11p15 is the gene H19, which acts as an untranslated RNA and is reciprocally imprinted, that is, expressed only from the maternal allele. H19 has shown growth inhibitory effects on cultured tumor cells. IGF2 and H19 are interesting with regard to BWS because of their chromosomal location and potential growth properties.

Based on parental origin-specific differential penetrance data alone, BWS could involve an imprinted gene normally expressed only from the paternal allele, which is somehow activated on the maternal allele in carrier mothers. Alternatively, BWS could represent a gene normally only expressed from the maternal allele, and thus a mutant copy is only phenotypically apparent when transmitted from the mother.

CHROMOSOMAL ALTERATIONS IN BWS

BWS was localized to 11p15 by genetic linkage analysis. While BWS predisposes to Wilms' tumor and other embryonal tumors, it is unlinked to the known Wilms' tumor gene on 11p13 (WT1). Interestingly, a wide variety of embryonal neoplasms, to which BWS patients are susceptible, including rhabdomyosarcoma, hepatoblastoma, and Wilms' tumor, show loss of allelic heterozygosity (LOH) of 11p15 in tumors. Thus, using polymorphic markers, one can demonstrate that one copy of 11p15 is lost in these tumors. Strikingly, almost all cases of LOH involve the maternal allele, again suggesting that an imprinted gene on 11p15 may be involved in the pathogenesis of BWS or cancer.

Rare patients with BWS show cytogenetic abnormalities (Table 116-5) involving chromosome 11p. These include both balanced rearrangements and unbalanced duplications. The balanced germline chromosomal rearrangements (including translocations and inversions) lie near the end of 11p (generally 11p15.4–p15.5), and they involve the maternally inherited chromosome. In contrast, the unbalanced rearrangements are of paternal origin. The unbalanced rearrangement breakpoints are distributed throughout 11p, and what seems to be important is the extra chromosomal material, which always includes 11p15. Furthermore, carriers of the unbalanced rearrangement breakpoints are themselves unaffected, suggesting that the duplications, not the breakpoints themselves, are pathogenic in the chromosome duplication patients.

Table 116-5
Genetic Abnormalities in BWS

Chromosomal rearrangements (~1%)
  Balanced translocations and inversions
    Involve 11p15
    Maternal chromosome affected
  Unbalanced translocations
    Relative trisomy of 11p including 11p15
    Paternal chromosome affected
    Translocation carriers unaffected
    Involves K$_V$LQT1 gene
Uniparental disomy (~10%)
  Region between β globin and H-ras on 11p15
  Paternal duplication with maternal loss
  Occurs postzygotically (mosaic)
Loss of imprinting (~20%)
  Activation of the normally silent maternal IGF-2 gene
Mutation of p57^{KIP2} (~5%)
  Occurs in 70% of embryonal tumors, in both BWS and non-BWS patients

The balanced chromosomal rearrangements in BWS are consistent with either mechanistic hypothesis for an imprinted gene. Thus, the rearrangements could interrupt the coding sequence of a gene normally expressed only from the maternal chromosome, or they could epigenetically activate a gene near the breakpoints on the maternal chromosome that is normally silent on that chromosome. The paternal duplications, however, would suggest that the latter model is correct, that the BWS gene is normally only expressed from the paternal chromosome. Thus, one would be affected by BWS if one had two functional copies of the gene. Normal individuals with one paternal and one maternal chromosome would have only one functional copy. Patients with a paternal duplication would have two, and patients with a balanced rearrangement of the maternal allele would somehow activate their normally silent copy of the BWS gene.

GENOMIC IMPRINTING AND BWS GENES

Strong molecular evidence for genomic imprinting in BWS derives from the observation that 10% of BWS patients have paternal uniparental disomy (UPD) of 11p15. Thus, their maternal chromosome has been replaced with a paternal chromosome over a region extending from the β-globin gene on 11p15 to the H-ras gene. UPD could be pathogenic either by causing loss of the normally expressed maternal gene or duplication of a normally expressed and imprinted paternal gene. UPD in the original reports was suggested to be associated with an increased risk of malignancy. However, other laboratories have not confirmed that finding, and it is unwise to quote a risk of malignancy based on the presence or absence of UPD. Prenatal diagnosis might be done using UPD as a marker, on single cells by PCR, as it has been performed on single circulating cells in BWS patients. The problem with that approach is that the sensitivity of the test is limited to the frequency of UPD, which is 10% or less. Furthermore, in contrast to UPD in Prader-Willi syndrome, UPD in BWS is mosaic in patients, with no more than 90% of peripheral blood lymphocytes or skin fibroblasts showing UPD. Thus, it is likely that UPD cases arise by mitotic recombination in early embryogenesis.

One feature of the BWS germline rearrangements that is inconsistent with a single-gene hypothesis for this disorder is that there are two distinct regions of BWS balanced rearrangement breakpoints, with one located approximately 250 kb centromeric to IGF-2, and a second cluster located 4 Mb centromeric to the first, on the opposite side of the β-globin gene cluster. Because it seems most unlikely that a single gene could span all of these breakpoints, it is conceivable that the breakpoints themselves could influence expression of a BWS gene at some distance, similar to mechanisms observed in both yeast and Drosophila. Furthermore, some human birth defects are caused by spreading inactivation from an X chromosome to a fused autosome in patients with X-autosome translocations.

Genomic imprinting also appears to play an important role in the tumors to which BWS patients are susceptible. Thus, approximately 70% of Wilms' tumors show loss of imprinting (LOI) affecting the IGF-2 and H19 genes. In tumors, the maternal allele of IGF-2 is abnormally activated, and the maternal allele of H19 is abnormally silenced. Other embryonal tumors also show LOI, including rhabdomyosarcoma and hepatoblastoma, and thus LOI appears to be a general feature of embryonal tumors. In addition, a "CpG island," a region rich in CG dinucleotides, appears to distinguish maternal and paternal chromosomes, with the paternal chromosome methylated and maternal chromosome unmethylated. DNA methylation is a covalent modification of cytosine that tends to mark nonexpressed genes but in this case marks the paternal chromosome. In tumors with LOI, the maternal allele is abnormally methylated. Thus, the maternal chromosome appears to undergo an epigenetic switch from a maternal to a paternal epigenotype, with activation of IGF-2, loss of expression of H19, and methylation characteristic of the paternal chromosome. Thus, LOI is the functional equivalent in a tumor of UPD in embryogenesis.

Normal tissues of BWS patients also show LOI of IGF-2; however, this affects only approximately 10% of patients. BWS patients with LOI also show the switch from an unmethylated to a methylated CpG island on the maternal chromosome, again suggesting a shift from a maternal to a paternal epigenotype. However, IGF-2 cannot be the only gene involved in BWS, because it shows abnormal imprinting in only a minority of patients.

Mutations have been described in p57^{KIP2} in patients with BWS. p57^{KIP2} is an inhibitor of several G1 cyclin/Cdk complexes (*see* Chapter 116-6), and it is a negative regulator of cell proliferation. The p57^{KIP2} gene is imprinted and only the maternal allele is expressed. Mice lacking p57^{KIP2} develop some but not all abnormalities that resemble BWS.

A third genetic change in BWS in rearrangement of the K$_V$LQT1 gene, a voltage-gate potassium channel formerly associated only with the cardiac conduction disorder long QT syndrome. All of the balanced germline chromosomal rearrangements in this region involve this gene. Its role in BWS is supported by the discovery that K$_V$LQT1 is also imprinted, with preferential expression from the maternal allele. However, imprinting is relaxed in some postnatal tissues, as well as prenatal and postnatal heart, accounting for the lack of parent of origin effect in long QT syndrome.

A model representing how several different types of genetic alterations could lead to abnormal imprinting in BWS is shown in Fig. 116-2. This model incorporates what is known about LOI of target genes, alterations in DNA methylation, and chromosomal rearrangements in BWS. The model emphasizes the importance of regarding genomic imprinting as a developmental process that may be altered at several different stages in BWS and cancer.
Figure 116-2 A model of genomic imprinting in Beckwith-Wiedemann syndrome. An imprint organizing center (red rectangle) exerts a long-range *cis*-acting influence on IGF-2 and other imprinted genes (blue ellipses) via alterations in chromatin structure (represented as DNA loops). This imprint-organizing center establishes the imprinting mark as maternal or paternal. This effect is propagated outward during development, similar to the organizing center on the X-chromosome. Imprinting is maintained in part by allele-specific methylation of CpG islands as well as interactions with *trans*-acting proteins (green circles). According to this model, loss of imprinting could arise by any of several mechanisms (numbered in the figure): (1) deletion or mutation in the imprint-organizing center itself, which would lead to a failure of parental origin-specific switching in the germline; (2) separation of the imprint organizing center from the imprinted target genes, as seen in BWS germline chromosomal rearrangement cases; (3) abnormal methylation of CpG islands; (4) local mutation of regulatory sequences controlling the target imprinted genes themselves; or (5) loss of or mutations in *trans*-acting proteins that maintain normal imprinting. (Figure modified from Feinberg, et al. 1994, with permission.)

DIAGNOSTIC TESTING

Karyotypic abnormalities are seen in fewer than 1% of BWS patients and generally involve the $K_V LQT1$ gene. LOI of IGF2 is observed in 20–60% of patients, depending on the report, although we believe the more conservative figure is correct. UPD occurs in about 10% of patients. $p57^{KIP2}$ mutations occur in only 5% of patients. Thus, there is no single diagnostic test for BWS, and the sensitivity of any given test is low. At this point, the most useful test for counseling purposes is UPD. That is because, although the frequency of UPD is low, it would indicate a zero recurrence risk when present, because UPD occurs postzygotically. In contrast, diagnosis of an imprinting mutation (LOI), or mutation $p57^{KIP2}$ or $K_V LQT1$ would warrant investigation of other family members for a similar alteration. It is important to emphasize that diagnostic testing for BWS is at the research stage, and that identification of additional target genes should increase the sensitivity and specificity of such testing.

CONCLUSIONS

In summary, BWS involves several 11p15 genes that are imprinted. One of these, IGF2, is normally expresses from the paternal allele and is abnormally activated in patients with LOI. A second gene, $p57^{KIP2}$, is expressed from the maternal allele patients and is mutated in a small fraction of patients. A third gene, $K_V LQT1$, is expressed from the maternal allele and rearranged in most BWS patients with balanced germline chromosomal rear-

rangements. The phenotype may be explained in part by the variable involvement of these specific genes, as well as additional as yet unidentified imprinted genes. Of all BWS patients, 1% or fewer show rearrangements of $K_V LQT1$, approximately 10% show uniparental disomy of 11p15, at least 20% involve LOI of IGF2, but most are sporadically occurring and without a defines genetic abnormality. Currently, the most useful genetic test in evaluating the family of a BWS patient, as with most genetic disorders, is a good family history. It is particularly important to examine infant photographs and to obtain a neonatal history on first-degree relatives of the affected patient. If a family appears to show dominantly transmitted BWS, then the risk to future offspring is 50%.

An interesting and provocative aspect of BWS is that the phenotype appears to abate with age, as does the risk of malignancy. Given that epigenetic factors may play a role in controlling genomic imprinting, it is possible that those factors could be modified epigenetically using novel therapeutic approaches. For example, drugs such as 5-aza-2'-deoxycytidine, which cause hypomethylation of DNA, might eventually present a novel form of gene therapy for disorders of abnormal imprinting such as BWS. Such ideas are at the earliest in vitro experimental stages, but one cannot help but speculate that, because BWS involves, at least in part, epigenetic changes to the chromosome, these changes might be experimentally or therapeutically reversible.

117 Prader-Willi and Angelman Syndromes

ROBERT D. NICHOLLS

BACKGROUND

Congenital disease in a patient usually involves a mutation in a gene that obeys established rules of Mendelian inheritance. This chapter describes two genetically related syndromes that do not conform to these principles and thereby give rise to totally independent clinical disorders. Prader-Willi syndrome (PWS) was first described by three German physicians, Prader, Labhart, and Willi, in 1956, and represents the most common form of syndromic genetic obesity. PWS was originally called the HHHO syndrome for its main features of hyperphagia, hypotonia, hypogonadism, and obesity. Angelman syndrome (AS) was first described by the British pediatrician, Harry Angelman in 1965, in which he coined the term "Happy Puppet syndrome," as it described two of the cardinal features of AS, a happy disposition with unprovoked laughter and severe ataxic movements. PWS and AS each occur at a frequency of about 1/10,000 to 1/20,000 births.

PWS and AS are each caused by genetic abnormalities in chromosome 15q11–q13, which involve imprinted genes. Imprinting refers to a class of non-Mendelian inheritance, in which specific genes or chromosomal regions are "marked" differently in the male and female germline. Following fertilization, this allows a somatic cell to know which parent the "marked" gene came from, and leads to parent-of-origin specific gene expression during development. We do not yet know why imprinting occurs, though much is being learned about the complexities and role of imprinting in AS and PWS, which has important implications for not only diagnosis of these two syndromes, but also as a means of potential therapeutic intervention in the future.

CLINICAL FEATURES AND NATURAL HISTORY OF PRADER-WILLI SYNDROME

DIAGNOSTIC CRITERIA The clinical phenotype of PWS is characterized by neonatal hypotonia and developmental delay, followed by postnatal onset of hyperphagia with subsequent obesity and other features, including short stature, hypogonadism, and mild-to-moderate mental retardation (Fig. 117-1A). These features have been organized into a set of clinical diagnostic scoring criteria for infancy and early childhood or childhood-to-adult periods. However, since most of the clinical features are relatively nonspecific, and non-PWS patients with other disorders can meet the score required to ascertain PWS, these criteria

are meant to suggest a possible diagnosis of PWS and the need for further molecular tests *(see below)*, not that a given patient has the syndrome.

NEONATAL HYPOTONIA AND FAILURE TO THRIVE Decreased fetal activity during the perinatal period has been associated with PWS. This is followed by severe hypotonia in the neonatal period, with feeding difficulties requiring gavage or other feeding methods. There is failure to thrive and developmental delay in the neonatal/infancy period. Physical therapy is important as a therapeutic approach to poor muscle tone and may help prevent scoliosis and improve ability to exercise in later life.

HYPERPHAGIA AND OBESITY The onset of hyperphagia in PWS is between 1 and 6 years of age, with consequent severe obesity. Obesity is perhaps the most significant clinical feature of PWS, since it is life-threatening by the third decade without dietary and behavioral intervention. Hyperphagia in PWS appears to be driven by a failure to reach satiety, thought to be hypothalamic in origin. This results in a high energy intake, which coupled with low activity levels, short stature, and a decreased caloric requirement (for fat-free mass), results in severe obesity that has potentially morbid consequences without intervention, most commonly due to cardiopulmonary failure. However, with dietary and behavior modification, including incorporation of an exercise program, significant weight losses can be achieved, with medical, psychological, and social benefits to the patient. The latter occur because severe obesity in PWS is associated with poor self-image and social acceptance. Early diagnosis and intervention is particularly critical for these aspects.

Hyperphagia is associated with food-seeking behavior, obsession with food, and behavioral problems when food is restricted *(see below)*. PWS patients also have a thick, viscous saliva and inability to vomit. There is a specific pattern of fat distribution which is predominantly truncal and involves the proximal limbs. PWS individuals tend to have 30–40% body fat even when near ideal weight for height. The role of increased adipose tissue lipoprotein lipase is unknown. Diabetes mellitus is present in 10–20% of patients.

HYPOGONADISM PWS patients have hypogonadism, secondary to hypogonadotropism. Hypogonadism is characterized by genital hypoplasia, delayed or incomplete gonadal maturation, delayed puberty, and infertility in males and females.

SHORT STATURE AND SMALL HANDS AND FEET PWS patients have short stature, a consequence of secondary growth hormone (GH) deficiency. The basis for GH deficiency is not known. Therapeutic application of GH has been shown to not only

Figure 117-1 Clinical phenotype of children with **(A)** Prader-Willi syndrome or with **(B)** Angelman syndrome. Note the central obesity, short stature, small hands and feet, and almond-shaped eyes/narrow bifrontal diameter in the PWS child, and the happy disposition, wide-spaced mouth, and teeth, and broad stance of the AS child. (Reprinted with permission from Butler MG. Prader-Willi syndrome: current understanding of cause and diagnosis. Am J Med Genet 1990;35:319–332 [A]; and Williams CA, Zori RT, Stone JW, et al. Maternal origin of 15q11–13 deletions in Angelman syndrome suggests a role for genomic imprinting. Am J Med Genet 1990;35:350-353 [B]).

increase height, but also to increase the muscle mass and decrease fat mass. This results in improved muscle tone, with consequent less problems from effects of hypotonia, and decreased obesity with improvements in behavior, self-image, and social acceptance; these may lead to an increase in measurable IQ. PWS patients have small hands and feet, compared to height, particularly evident after midchildhood, suggesting delay in distal limb maturation, but the basis for this is not known.

MENTAL RETARDATION AND LEARNING AND BEHAVIORAL DISORDERS PWS patients have mild-to-moderate mental retardation (IQ in the 20–100 range, usually 40–80), but they also have learning disabilities, particularly of speech, and reading disabilities. Interestingly, PWS patients also fulfill criteria for obsessive–compulsive disorder. There are many behavioral and emotional problems, such as temper tantrums, stubbornness, rage, violence, and stealing. Many of these abnormal behaviors may be associated with hunger and food-seeking behavior. PWS patients also have other unique behavioral features, such as skill with jigsaw puzzles.

CRANIOFACIAL There is mild craniofacial dysmorphism in most PWS patients, including a narrow bifrontal diameter and almond-shaped palpebral fissures, which may be upslanting, and down-turned mouth, with thin upper lip. At least the down-turned mouth may be a consequence of hypotonia, but it is not clear if the craniofacial features represent a primary embryonic defect or secondary consequence of abnormal brain development.

OTHER FEATURES The hypopigmentation of the hair, skin, and eyes seen in one-half to two-thirds of PWS patients is associated with presence of a cytogenetic deletion and almost certainly results from deletion of the *P* gene. However, since mutations in the *P* gene cause the autosomal-recessive condition, oculocutaneous albinism type 2 (OCA2), in humans and mice, it is unclear why deletions lead to hypopigmentation in PWS (and AS) patients. PWS patients also often display skin picking, perhaps indicating a decreased pain sensitivity, and abnormal temperature control. The somnolence often seen in PWS patients appears not to be a direct consequence of the obesity in the syndrome. Therefore, it is possible that there is a specific sleep (and

possibly circadian rhythm) disturbance in PWS, but this requires further research.

DIFFERENTIAL DIAGNOSIS FOR PWS Many of the syndromes that require differential diagnosis with PWS also display obesity, endocrine abnormalities (e.g., growth, hypogonadism, diabetes), and mental retardation. These include Bardet-Biedl syndrome, Borjeson-Forssman-Lehmann syndrome, Cohen syndrome, Albright hereditary osteodystrophy (including pseudohypoparathyroidism [PHP1a] and pseudo-PHP [PPHP]), Smith-Magenis syndrome, Fragile X syndrome, and other rare conditions. Congenital hypotonia in infancy can have many causes, and molecular diagnostics may be important here for PWS *(see below)*. "Acquired" PWS-like conditions also exist, arising from tumors or other insults to the brain, predominantly in the region of the hypothalamus.

CLINICAL FEATURES AND NATURAL HISTORY OF ANGELMAN SYNDROME

CLINICAL DIAGNOSTIC CRITERIA AS is associated with gait ataxia (jerky, unsteady, stiff with upheld arms), tremulousness, seizures typically beginning after 1–6 years of age, hyperactivity, severe mental retardation, absence of verbal speech, microbrachycephaly, protruding tongue and drooling, widespaced mouth and teeth, and a happy disposition with inappropriate laughter (Fig. 117-1B). AS patients display abnormal electroencephalograms (EEGs), with a characteristic pattern of large amplitude slow-spike wave activity (usually 2–3 Hz), which is facilitated by eye closure. The EEG abnormalities are a useful diagnostic guide for AS, although after the second decade of life, the EEG can appear normal. Mild cerebral atrophy has been seen on CT scan in about 30% of patients.

NEONATAL/INFANCY FEATURES AS children appear normal at birth, but soon suffer severe developmental delay. From early childhood, AS patients have developmental delay, with no development of speech, a smiling, happy disposition, ataxia and limb tremulousness, and microbrachycephaly. Seizures usually begin by 3–6 years of age.

MOVEMENT DISORDER Gross motor milestones are delayed, although hyperkinetic movements of the trunk and limbs may be seen in early infancy. Tremulousness may begin as early as 6 months. Most AS children are ambulatory, but there is a prancing ataxic gait with tendency to lean forward, pronounced in running, with upheld arms flexed at the elbows and wide-spaced legs. More severely affected children are very stiff, shaky, and jerky when walking, and some individuals remain nonambulatory.

SEIZURES Seizures typically begin after 1 year of age but usually before 3 years. They can be severe, episodic, of all types, but mostly major motor type or minor type, requiring anticonvulsant medication. However, no one medication has proven effective for seizures in AS and usually depends on the minor or major motor type. Seizures can be confused with the tremulousness and jerky movements seen in AS. While the abnormal EEG may be associated with seizure behavior, an abnormal EEG can persist even when seizures are controlled. Seizures may decrease in frequency or cease by the teenage years.

INAPPROPRIATE LAUGHTER An apparent happy disposition typifies the AS child. In addition, most reactions to mental or physical stimuli are accompanied by laughter or similar facial expressions. This behavior has an onset early in childhood. It does not appear to be related to the seizure disorder. Sometimes irritability and hyperactivity can also be present.

MENTAL RETARDATION AND SPEECH Developmental milestones are greatly delayed, although formal testing is difficult because of absence of formal speech, hyperactivity, motor difficulties, and attention deficit. Nevertheless, IQ scores are in the severely retarded range, although AS children perform better on receptive social skills, and it is believed that cognitive abilities are higher than thought from developmental testing. Most AS children have one to four words, at most, although a few rare cases with milder presentation *(see below)* have up to 10–20 words. Nevertheless, most AS children are able to follow and understand commands, except for cases with severe seizures and hyperactivity. In higher-functioning individuals, there may be nonverbal language, such as some degree of sign language.

CRANIOFACIAL The microcephaly present in some AS patients may be a secondary result of developmental brain abnormalities, associated with decelerated growth by 1 year of age. Many of these patients also have a flattened occiput, some with a distinct occipital groove. Brachycephaly is a common finding in AS. The mandible is normal in size but can appear large because of a forward and upward orientation, with midface hypoplasia, a thin upper lip, and deep-set eyes. A wide mouth and wide-spaced teeth are often present, and prognathia can result from excessive chewing. Facial dysmorphism is not present at birth.

OTHER FEATURES Virtually all AS individuals display features of hyperactivity, both constant movement (including running), and handling and mouthing of objects in infancy. This may improve in adults. There is attention deficit, which in severe cases prevents facial and social cues, but in others allows sufficient attention for developmental training programs. Sleep abnormalities consisting of short periods of sleep and abnormal sleep/wake cycles are characteristic of AS. The role of abnormal circadian rhythms and other features of sleep and hyperactivity remain to be assessed. The hypopigmentation of the hair, skin, and eyes seen in one-half to two-thirds of AS patients likely results from deletion of the *P* gene, as explained above for PWS. It is present only in PWS and AS patients with deletions of 15q11–q13. AS patients also share intriguing behavioral features, such as love of water, of bright, shiny objects, and of music. About 5% of AS patients show obesity.

DIFFERENTIAL DIAGNOSIS FOR AS Conditions that need to be considered in the differential diagnosis of AS include Rett syndrome, a neurodegenerative syndrome affecting girls only, distinguished by the history of regression and loss of acquired skills, the alpha-thalassemia-mental retardation syndrome, X-linked (ATRX syndrome), ataxic cerebral palsy with less severe mental retardation, and others.

CLINICAL MANAGEMENT OF THE SYNDROMES

For PWS, feeding and behavior management are critical, particularly from an early age. Appetite suppressant agents have not generally been successful in PWS. Growth hormone replacement for height, improved muscle-to-fat mass, and associated behaviors is beneficial during childhood, but is still controversial. Learning disabilities require evaluation and may require speech therapy. Early intervention with physical therapy can significantly help difficulties associated with poor muscle tone. While hormonal treatment can be applied to hypogonadism, the benefits are not clear.

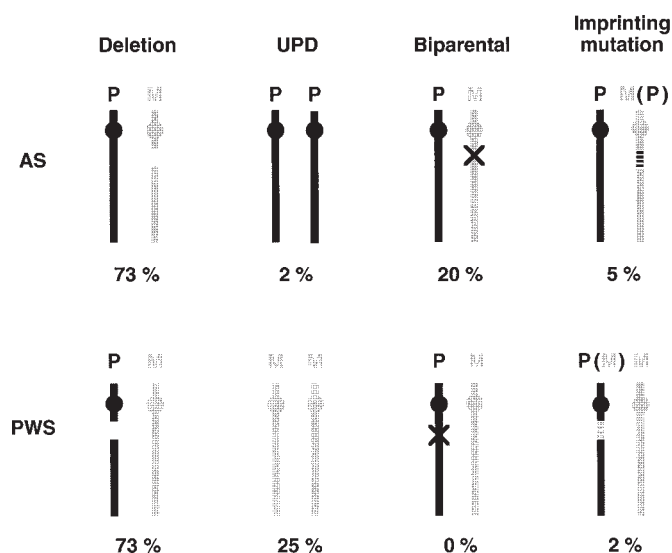
For AS, the principle management issues relate to seizure control (in which no one anticonvulsant has been successful) and to hyperactivity, sleep disturbances, and education. It would also be


Figure 117-2 Molecular classes of Prader-Willi and Angelman syndromes. The chromosome 15 genotypes (and frequency) are shown for the major classes of AS and PWS. (*See text* for details.)

beneficial to treat the ataxia and tremulousness of the limbs in AS, since this may improve the ability to learn sign language, or, potentially, computer skills, both very difficult for AS individuals.

Although the biological basis of AS and PWS are unknown, both syndromes are likely to arise predominantly from failure of an aspect of neural development during embryogenesis (particularly the hypothalamus or associated structure for PWS and the cerebellum or other limbic structure in AS). However, some features of both syndromes clearly have postnatal onset, including in AS of seizures (and their resolution) and coarsening of the facial appearance during the first two decades of life, and in PWS of hyperphagia (hypotonia and poor feeding ability may prevent this in infancy and early childhood), behavioral disturbances, and small hand and foot size. No consistent abnormality has been identified in PWS or AS by biochemical, endocrine, or anatomical studies.

GENETIC BASIS OF PRADER-WILLI AND ANGELMAN SYNDROMES

CHROMOSOME 15 There are multiple molecular genetic mechanisms that can lead to PWS and AS (Fig. 117-2), but despite this complexity, each leads to a common gene deficit. Each molecular mechanism that leads to PWS and AS abolishes imprinted (parent-of-origin)-specific expression, such that paternal gene expression is abrogated in PWS (one or more genes) and maternal gene expression is silenced in AS (probably one gene). Chromosome 15q11–q13 is now known to have three subregions (Fig. 117-3):

1. A proximal region containing genes that are expressed from the paternally inherited chromosome only (hence each of these genes is a candidate to play a role in PWS).
2. A central region containing a gene, or genes, expressed from the maternally inherited chromosome only (and thus this gene is a candidate for AS).

3. A distal region containing genes that are expressed from both alleles and thus show normal Mendelian inheritance, (which includes a cluster of gamma-aminobutyric acid (GABA) class A receptor genes and the *P* gene involved in the autosomal-recessive disorder OCA2).

CYTOGENETIC DELETIONS Cytogenetically visible deletions of 15q11–q13 were first observed in PWS by Ledbetter and colleagues in 1981 and in AS by Latt and Magenis and their colleagues in 1987. Although initially thought that the deletions in PWS and AS would be adjacent, it was first shown in 1989 that the majority of the deletions in PWS and AS are in fact of a very similar size. This conclusion was supported by the cloning of a yeast artificial chromosome (YAC) contig spanning 15q11–q13, which showed that about 4 Mb of DNA was deleted in these PWS and AS patients. It is likely that specific sequences at the proximal and distal breakpoints predispose to recombination, to generate the common deletion. Although the deletion size is generally the same in PWS and AS, from the study of differently sized deletions in rare patients, it was subsequently realized that the PWS and AS genes do in fact map to adjacent chromosome regions (Fig. 117-3).

PARENTAL ORIGIN OF DELETIONS Since the majority of deletions in PWS and AS are the same size, it was initially an enigma as to how two different clinical syndromes arise. However, the use of cytogenetic and molecular polymorphisms led to the findings that all deletions in PWS are paternal in origin, and all deletions in AS are maternal in origin (Fig. 117-2). Therefore, the parental origin determines the clinical nature of the syndrome, and both parental contributions of chromosome 15q11–q13 are required for normal development.

UNIPARENTAL DISOMY (UPD) UPD was first discovered in PWS in 1989, in which studies with molecular polymorphisms showed that two PWS children had inherited two maternal alleles but no paternal allele for chromosome 15 (Fig. 117-2). Subsequent studies showed that maternal UPD is quite common in PWS, occurring in 25% of cases. There is an association of advanced maternal age with UPD in PWS, consistent with maternal nondisjunction and subsequent formation of a trisomic zygote. Since trisomy 15 is lethal during embryogenesis, there is selection for loss of one chromosome 15, which one-third of the time would lead to maternal UPD and hence PWS. UPD also occurs in AS, in which it is paternal in origin (Fig. 117-2) and may be associated with a milder phenotype, but a larger study population is needed to confirm this.

The finding of UPD confirms that the parental origin of 15q11–q13, and hence genomic imprinting, underlies the etiology of PWS and AS. Thus, a second totally normal copy of a maternal chromosome 15 cannot complement the missing paternal chromosome in PWS, indicating that the maternally inherited PWS genes are normally silent, and that the paternally inherited PWS genes are expressed. Likewise, paternal UPD in AS indicates that the paternally inherited AS gene is normally silent, and that it is the maternally inherited allele that is active. Therefore, the absence of expression of the active PWS or AS genes leads to the respective syndrome (by any mechanism in Fig. 117-2).

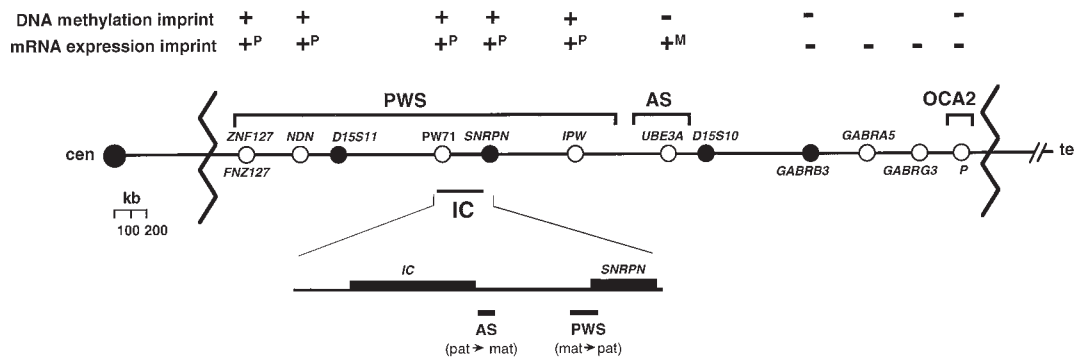
PATERNAL PWS AND MATERNAL AS GENES In AS, there are about 20% of patients who do not have a deletion, UPD, nor imprinting mutation *(see below)*. Some of these cases are familial. These patients inherit a copy of chromosome 15 from each parent (biparental) and likely have a point mutation (or small DNA rear-


Figure 117-3   Human chromosome 15q11–q13 map. Genetic loci are shown as circles and FISH probes as filled circles. Regions containing the AS and PWS structural genes are indicated above the line, and the region affected by microdeletions in AS and PWS imprinting mutation patients in the expanded segment below (the latter define the imprinting center, IC). Two genes are expressed from the IC, the *SNRPN* gene and *IC* transcript. The shortest region of microdeletion overlap in AS and PWS is shown by bars; these correspond to elements critical for paternal (pat) to maternal (mat) imprint switching in the female germline or maternal to paternal imprint switching in the male germline, respectively. At the top, the presence (+) and absence (–) of imprinted features are shown. The zigzag lines reflect the end points of the common cytogenetic deletion in AS and PWS. P, paternal-only expression; M, maternal-only expression in brain; cen, centromere; tel, telomere.

rangement) in a single, maternally expressed gene (Fig. 117-2). Recently, the *UBE3A* gene (formerly *E6AP*), encoding a ubiquitin-protein ligase thought to be involved in protein degradation pathways, was shown to have mutations in AS patients of this class. Recent studies have shown that the *UBE3A* gene undergoes spatially (tissue-specific) regulated imprinted expression in human and mouse.

In contrast, no PWS patients with the classical phenotype appear to come under this class (Fig. 117-2). This may mean that at least two genes are required for classical PWS (all cases of PWS would then represent a contiguous gene syndrome); mutations in a single gene may therefore only result in a PWS-like syndrome that is presently unrecognized. Consistent with this idea, there are multiple paternally expressed genes in the 15q11–q13 region involved in PWS (Fig. 117-3). Nevertheless, a single major gene has not yet been ruled out.

FAMILIAL CASES RESULTING FROM IMPRINTING MUTATIONS   About 5% of AS and PWS patients have been shown to have inherited a copy of chromosome 15 from both the mother and the father, but they have abnormal DNA methylation imprints *(see below)* throughout the imprinted 15q11–q13 region (Fig. 117-2). However, the DNA methylation is typical of the syndrome (uniparental maternal in PWS and uniparental paternal in AS). This suggests that such patients have a mutation in the imprinting process, since the paternally inherited chromosome in PWS patients has maternal DNA methylation, and the maternally inherited chromosome in AS patients has paternal DNA methylation. These AS and PWS patients have the classical clinical phenotype, and about half the cases are familial. The molecular basis of this class of patients is described below.

BALANCED TRANSLOCATIONS IN PWS   Three PWS patients have been described with a balanced translocation of 15q11–q13. One patient with classical PWS has a breakpoint in the 5' part of the *SNRPN* gene, implicating this gene as a major PWS gene. Two patients with a PWS-like syndrome (not fulfilling all major clinical criteria of PWS) are associated with a second cluster of breakpoints about 50–150 kb distal of the *SNRPN* gene, and thus other genes may contribute to the PWS phenotype. However, how the translocations lead to the phenotype in this rare class of patients is presently not understood.

MOLECULAR DIAGNOSTICS OF PRADER-WILLI AND ANGELMAN SYNDROMES

FLUORESCENT *IN SITU* HYBRIDIZATION (FISH)   FISH, with unique probes from 15q11–q13 (Fig. 117-3), and a centromeric control probe, is the method of choice of cytogenetic diagnostic laboratories to identify large deletions or unbalanced translocations in suspected PWS and AS cases. Probes within at least the PWS and AS critical regions (Fig. 117-3) should be utilized.

MICROSATELLITE ANALYSIS FOR UPD   Polymorphic marker analysis, preferably the use of highly informative microsatellites such as $(CA)_n$ markers, using parental and affected-child DNA samples, is commonly used to identify UPD. However, both parental DNA samples are often not available.

DNA METHYLATION ANALYSIS   Several genes and DNA markers in 15q11–q13 (*ZNF127, NDN, PW71, SNRPN* [Fig. 117-3]) have been shown to display differential DNA methylation of the paternal and maternal alleles. These differences arise in the male and female germline or are established in early development. The most reliable methylation probe is at *SNRPN*, in which the maternal allele is completely methylated, and the paternal allele is completely unmethylated (Fig. 117-4), in all tested tissues. Clearly, AS samples with only the unmethylated band and PWS samples with only the methylated band can be easily distinguished from one another and from normal controls (or patients with another diagnosis). Methylation at *SNRPN* represents the best single diagnostic tool for these syndromes, since it identifies all PWS and AS patients with a deletion, unbalanced translocation, UPD, or imprinting mutation (it does not detect the biparental class of AS patients), and does not require parental DNA samples. However, DNA methylation is not reliable to distinguish between different classes of PWS and AS patients. Nevertheless, DNA methylation detects about 98% of classical PWS patients (deletion, UPD, and imprinting mutations) and 80% of AS patients (deletion, UPD, and imprinting mutations).

PWS AND AS IMPRINTING MUTATIONS   Imprinting mutation cases are diagnosed by the absence of a deletion by FISH (with the exception of a *SNRPN* deletion only) and the absence of UPD (tested by polymorphic markers), but with the presence of abnormal DNA methylation using any of the probes that detect differential DNA methylation. About one-half of cases, including
Figure 117-4 Molecular diagnosis by DNA methylation. DNA from peripheral blood leukocytes is digested with *Xba*I/*Not*I and probed with a *SNRPN* 5' probe. *Not*I does not cut if DNA is methylated (maternal band; PWS UPD patient) but does cut if DNA is unmethylated (paternal; AS UPD patient). PWS and AS patients are easily distinguished from each other and from normal individuals, who show a normal "biparental" pattern.

all familial cases, have a microdeletion overlapping the first exon (PWS) or upstream of the first exon of the *SNRPN* gene (AS). This region is termed the imprinting center (IC), and microdeletions or mutations in the IC are detected by molecular techniques in a research laboratory (Fig. 117-3).

STRUCTURAL GENE MUTATION IN AS   Since the *UBE3A* gene has been identified as the AS gene, it is now possible to perform mutation analysis. However, since most cases arise *de novo*, it is likely that most patients will have different mutations in the AS gene. The ease of performing repeated mutation screens on each new case will depend on whether mutations cluster in functional domains of the encoded protein or throughout the fairly large coding region (or in regulatory regions) of the *UBE3A* gene.

GENETIC COUNSELING IN PRADER-WILLI AND ANGELMAN SYNDROMES

DELETIONS AND UPD IN PWS AND AS   Essentially, the recurrence risk of a deletion or UPD in extended families is the population risk (1/10,000 to 1/20,000). Nevertheless, in instances of advanced maternal age, the risk for having a child with UPD is significantly larger, though still small, but prenatal screening is possible where there is concern for the risks. The presence of a familial, phenotypically silent balanced translocation in chromosome 15q11–q13 has a risk of meiotic rearrangement or nondisjunction, leading to a deletion of 15q11–q13 or UPD, respectively, and prenatal diagnosis and genetic counseling are recommended in such cases.

IMPRINTING MUTATIONS IN PWS AND AS   In those families in which a microdeletion in the IC has been identified, or in which multiple sibs of PWS or AS have already occurred, "at risk" or prenatal diagnosis are options, based on detection of the microdeletion. Since imprinting mutations can be transmitted silently for multiple generations *(see below)*, relatives of the same sex as the transmitting parent have up to a 50% risk for transmitting the mutation silently, whereas offspring of the opposite sex have a risk of up to 50% for a child with the syndrome. In such cases, referral for molecular testing and genetic counseling are strongly recommended (*see* Saitoh et al., 1997, for further discussion of recurrence risks). In cases with no detectable microdeletion or IC mutation, no known recurrence has occurred, and such cases may be sporadic (unpublished data).

OTHER FAMILIAL AS   In families with multiple affected AS cases, once an imprinting mutation has been ruled out, it is likely that there is an inherited mutation in the AS gene. Paternal inheritance of this gene will be phenotypically silent, since the paternal AS gene is normally silent, and the AS phenotype will only appear after maternal inheritance. Now that the *UBE3A* gene has been identified as the AS gene, the specific familial mutation can be identified, and "at risk" individuals can be screened. Females carrying the mutation inherited from their father have a 50% recurrence risk. Prenatal testing and counseling are recommended in such cases.

MOLECULAR GENETICS OF PRADER-WILLI AND ANGELMAN SYNDROMES

FEATURES OF IMPRINTING   As is evident from the preceding discussion, imprinted genes are characterized by monoallelic expression (paternal or maternal allele only) and differential DNA methylation imprints, whereby the two alleles differ in methylation status. In addition, imprinted chromosome regions show asynchronous DNA replication, in which the two parental alleles appear to replicate at different times in S phase of the cell cycle, in comparison to nonimprinted chromosome regions in which replication is synchronous for the two alleles. Nevertheless, the basis for replication timing asynchrony is unknown, and it may be a consequence rather than a cause of imprinting. Replication timing has been used to specifically identify PWS and AS UPD patients by cytological techniques. The potential role of other factors in imprinting, such as chromatin structure, histone acetylation, and DNA binding proteins, is presently unknown.

The mechanism of imprinting is complex and not completely understood, but the following picture has emerged. Imprinting is set in the germ line, and must be erased and reset (i.e., is reversible) at each generation, specific for the sex of that individual. The first step in imprint erasure and resetting is controlled by the IC, since mutations in this region block resetting of the imprint *(see below)*. The IC signal is then transferred bidirectionally by an unknown mechanism to each imprinted gene in 15q11–q13 (Fig. 117-3). This allows each imprinted gene to set its own germ line (gametic) imprint, based on DNA methylation specific for the male or female germ line. Subsequent to fertilization, some imprinted genes carry the gametic imprint in the body of the gene and undergo modification of the imprint at the promoter, which then locks in the imprinted state and/or determines the allele-specific expression. It is well-known that the presence of DNA methylation blocks transcription, whereas an unmethylated promoter is capable of transcription, depending on tissue-specific factors.

OCULOCUTANEOUS ALBINISM The only clinical feature known to be shared between PWS and AS, in deletion patients, is hypopigmentation of the skin, hair, and eyes, and is thus a result of a nonimprinted gene (the *P* gene). Therefore, at least in deletion patients, AS and PWS represent contiguous gene syndromes in which the clinical features arise because of more than one gene. Some PWS (and AS) patients have albinism (OCA2), at the frequency expected for carriers of OCA2, which arises from inheritance from one parent of a *P* gene mutation coupled with a large deletion of the other allele.

MOUSE MODELS All the identified genes from human chromosome 15q11–q13, including imprinted genes and nonimprinted genes, have homologs in the same respective genetic order in the central part of mouse chromosome 7. The imprint status of these genes is also conserved between humans and mice. These findings suggest that mouse models should be an excellent model of PWS and AS. Mice with radiation-induced deletions of the nonimprinted genes allow assessment of the contribution of such genes to recessive phenotypes in this chromosomal region. Mice with maternal UPD specifically for the PWS/AS homologous region, or with paternal UPD, albeit for a much larger chromosome region that may contain other imprinted genes, have been generated by clever breeding techniques, and these animals have imprinted phenotypes that may provide models of the imprinted PWS and AS phenotypes. For example, the maternal UPD mice die at birth, probably because of the inability to feed, which may mimic the failure to thrive and gavage feeding necessary for newborn PWS infants. Nevertheless, such animals are difficult and expensive to generate, and models based on targeted mutation of the mouse homologs of the specific PWS and AS genes, or the IC elements, may provide more workable models in the future.

IMPRINTING MUTATIONS Perhaps one of the most remarkable findings to come from the study of PWS and AS is that of patients with mutations in the imprinting process. These patients have microdeletions that define an IC, overlapping and upstream from the *SNRPN* gene (Fig. 117-3), as previously discussed. Familial mutations of the IC can transmit silently through many generations, as long as the transmitting sex does not change (Fig. 117-5). Imprinting is a reversible process in which the germline imprint must be erased and reset at each generation; thus, in the male germline, the maternally inherited imprint must be erased and reset as a male imprint, or epigenotype (referring to information that is heritable and alters the phenotype of offspring but is not encoded specifically in the genetic code of DNA), and in the female germline, the paternally inherited imprint must be erased and reset (switched). IC mutations block this resetting of the imprint in the opposite germline, leading to a failure to reset the imprint specific for the sex of that individual.

Thus, when a maternally derived imprinting mutation [represented by M(M)] is transmitted through a male, the maternal epigenotype cannot be reset in his germline to the normal paternal epigenotype (Fig. 117-5A). He therefore transmits a maternal imprint on his paternal chromosome [P(M)] to 50% of his gametes; resulting offspring inheriting the abnormal gametic epigenotype [P(M)] also inherit a normal maternal epigenotype (M) from their mother, and thus they are homozygous for a maternal epigenotype (Fig. 117-5A). This is equivalent to maternal UPD, and hence PWS develops. Likewise, transmission of a paternally derived imprinting mutation [P(P)] through a female results in failure to switch the imprint and inheritance of the abnormal epigenotype [M(P)], along
Figure 117-5 Inheritance of imprinting mutations. The inherited chromosome 15 imprint (epigenotype) in somatic cells is shown inside the female (circles) and male (squares) symbols, whereas the germline imprint is shown below these symbols. When an imprinting mutation in the IC arises during maternal meiosis (I, left), a maternal epigenotype (i.e., imprint) is fixed into this chromosome. Females transmit the maternal epigenotype silently (I and II, left), but the IC mutation blocks resetting of the imprint in a male (III, left). Thus, he transmits a maternal epigenotype to 50% of his offspring, who have a "uniparental" maternal epigenotype and hence will have PWS. An analogous pattern occurs for origin and transmission through males of an IC mutation generating a fixed paternal epigenotype, but maternal transmission now gives rise to AS at 50% risk (right).

with a normal paternal imprint (P), and thus the resulting offspring are homozygous for a paternal imprint and develop AS (Fig. 117-5B). In such PWS and AS patients, the mutation has no direct effect in the patient; rather, the mutation exerts its effect in the parental germ line, and it is a consequence of this effect that genetic disease arises in the offspring. This clearly represents a new paradigm as a mechanism of inherited genetic disease.

FUTURE STUDIES

IDENTIFICATION OF THE PWS AND AS GENES The most important immediate research is to identify the gene(s) responsible for clinical features in PWS and to explain the clinical pleiotropy (range of features) of AS in terms of the molecular functions of the *UBE3A* gene. Accurate molecular diagnosis can then follow in those cases in which a gene mutation is a possible mechanism for the syndrome. Identification of the etiological gene will allow subsequent studies of:

1. Developmental expression of the gene, which may lead to insight as to the embryological or postnatal stages at which cellular and hence phenotypic abnormalities arise.
2. Characterization of the protein product of the gene.
3. Development of mouse models in which the function of the mouse homolog of the PWS or AS gene is ablated.
4. Ultimately, the derivation and testing of potential therapeutic approaches to clinical features of the two syndromes.

MECHANISM OF IMPRINTING AND RELATIONSHIP TO OTHER DISORDERS INVOLVING IMPRINTED GENES

Imprinting also plays a role in several cancers and other genetic disorders, such as Beckwith-Wiedemann syndrome (BWS; *see* Chapter 116). In particular, many of the same mechanisms, including UPD, specific parental origin chromosome rearrangements and imprinting mutations occur in BWS, suggesting that an understanding of the imprinting and disease mechanisms in PWS and AS may lead to insight in other conditions.

THERAPEUTIC APPROACHES TO PWS AND AS Additional advances may result from clinically based applications (previously discussed), such as melatonin treatment of the sleep disorder in AS and PWS. Recent advances in understanding the genes involved in feeding behavior and obesity, such as the *Ob* gene, may lead to better understanding of the pathway of hyperphagia and obesity in PWS and hence to therapeutic approaches, even though specific mutations in such genes are not present. More important will be the identification of the specific gene products missing in PWS patients, and the protein substrates of the *UBE3A* gene product that are deregulated in AS patients, which may lead to important therapeutic approaches. Finally, an understanding of the mechanism of imprinting, by which genes are silenced or activated as a consequence of their parental origin (set during gametogenesis), may lead to therapeutic approaches based on reactivation of silent imprinted genes or silencing of abnormally expressed imprinted genes in somatic cells.

118 Fragile X Syndrome

DAVID L. NELSON

INTRODUCTION

Fragile X syndrome (MIM 30955) is among the most common of human single-gene disorders and is the leading cause of inherited mental retardation, with an estimated frequency of 1/2000 to 1/4000 individuals. It is inherited as an X-linked dominant disorder with reduced penetrance. Males and females can be affected; however, the degree of mental retardation is usually more severe in males.

Fragile X syndrome derives its name from the observation of a folate-sensitive fragile site at Xq27.3 in chromosomes at metaphase prepared from afflicted individuals (Fig. 118-1). This site was initially identified in 1969, although more complete characterization of the parameters of its appearance was not completed until the mid-to-late 1970s. Fragile X syndrome had previously been recognized clinically as Martin-Bell syndrome, after a report of X-linked mental retardation in an English family in 1943.

The defective gene in fragile X syndrome *(FMR1)* was identified by positional cloning in 1991 following efforts to locate the chromosomal anomaly. Both the fragile site and the gene defect derive from expansion and methylation of a trinucleotide repeat (CGG) located in the 5' untranslated region of the *FMR1* mRNA. This was the first of a large number of unstable trinucleotide repeats found to cause human genetic disorders and remains among the best understood for the mutation's effect on gene function.

CLINICAL FEATURES

The association of the fragile X site with families exhibiting X-linked mental retardation allowed the clinical description of the syndrome to be improved. This description is being refined with the advent of DNA-based diagnosis; however, it remains a highly variable phenotype. The syndrome is difficult to diagnose in newborns and the physical features gradually accumulate with age. However, even in fully affected males, the facies are subtle and generally unremarkable to those unfamiliar with the syndrome, especially those in younger patients (Fig. 118-2).

Adult male patients generally exhibit a long and narrow face with moderately increased head circumference (>50th percentile). Prominence of the jaw and forehead with particularly large and mildly dysmorphic ears are typical. Some of the phenotype is reminiscent of a mild connective-tissue disorder, exhibiting hyperextensible joints, high arched palate, pes planus, pectus excavatum, and mitral valve prolapse. Macroorchidism (enlarged testicular volume) is a common finding in postpubescent affected

males. Almost 90% of such males exhibit testicular volumes in excess of 25 mL as measured by an orchidometer.

Mental retardation and developmental delay are the most significant clinical features of the fragile X syndrome. Prepubescent males have delayed developmental milestones, and some may display avoidance behavior similar to autism, as well as hyperactivity and attention deficit. The latter two are frequent presenting complaints in boys with fragile X syndrome. Development of speech and language is almost always involved but to variable degrees. While absence of speech is rare, milder communication difficulties are common, including a characteristic jocular, litany-like speech. Mental retardation ranges from profound to borderline with an average IQ in the moderately retarded range. It has been estimated that fragile X syndrome accounts for as much as 20% of all boys with IQ levels between 30 and 55.

Females are usually much less involved compared with affected males. Somatic signs may be absent or mild, although the facies of older females may tend to resemble affected males. The mental retardation, in particular, is less severe with most female patients falling in the mild-to-borderline range. A number of studies suggest increased emotional lability in both affected and carrier females. These manifest as both behavioral and psychiatric abnormalities. While these are highly variable, several studies have identified schizotypal features, depression, social avoidance, anxiety, and shyness among girls and women with IQs in both the normal and affected ranges.

DIAGNOSIS

Patients are typically referred for developmental delay, and because of the relatively mild phenotype in young patients, diagnosis is rarely achieved on clinical grounds alone. Any family with an X-linked pattern of mental retardation should be considered for fragile X testing. Cytogenetic testing for the presence of the fragile site was the only diagnostic test available until the discovery of the gene and mutation. Since the CGG repeat expansion mutation is found in virtually all fragile X patients, the use of DNA testing for diagnosis is highly reliable and has largely supplanted the use of cytogenetic testing for the fragile site. However, because of the prevalence of mental retardation from other cytogenetic abnormalities, it is important to consider a routine karyotype in the evaluation of any case of developmental delay.

MOLECULAR GENETICS

MUTATIONS The vast majority (>99.5%) of fragile X patients carry the same mutation, which is a massive expansion of

Figure 118-1   Partial karyotype of Geimsa-stained human chromosomes showing the fragile X site (arrow). (Reprinted with permission from JAMA 1994;271:536–542.)

Figure 118-2   Mentally retarded adolescent male with fragile X syndrome. Note long facies with prominent forehead and ears. Typical of most patients, there is no major dysmorphia associated with this syndrome, confounding the clinical diagnosis. (Reprinted with permission from JAMA 1994;271:536–542.)

a trinucleotide repeat (CGG) located in the 5' untranslated region of the *FMR1* gene. This repeat is polymorphic in the human population and outside of fragile X families ranges in length from 5 to as many as 50 triplets. The most common alleles carry either 29 or 30 repeats. Approximately 70% of females are heterozygous at this locus, and normal-sized alleles are transmitted with high fidelity to the next generation. Affected individuals are found to carry more than 200 repeats and typically exhibit repeats in excess of 500. These can range to as many as 2000 and are often mosaic in length, with many different lengths observed in a single sample from an individual. These large numbers of repeats are termed "full mutations" and are usually found to be methylated at C residues within the repeat sequence as well as in the nearby CpG island that marks the gene's promoter. Methylation has been found to correlate with loss of mRNA production, presumably through diminished transcriptional initiation. This results in loss of the product of the *FMR1* gene (FMRP) and the disease. Thus, the expansion mutation in fragile X syndrome leads to loss of function of the *FMR1* gene. Additional loss of function mutations have been identified in the *FMR1* gene, and these are found to confer the same phenotype, reducing the likelihood that other genes are affected by methylation of the region and play a significant role in the phenotype. Mosaicism in the pattern of methylation is seen in some patients, and it is methylation status that most closely correlates with disease severity, although the extent of variation of the mutation among tissues in a single individual complicates such correlation studies, which typically rely on blood leukocytes for DNA testing. There is evidence that translation of mRNAs carrying long (>200) CGG repeats is also diminished, suggesting that large, unmethylated alleles may also confer the disease.

Alleles of a size intermediate between those found in the general population and those in affected individuals have been termed "premutations." These are found in unaffected carriers (both male and female) of the disorder in fragile X families. No instance of expansion has been identified to arise from a normal allele, and premutations appear to be maintained for many generations in fragile X lineages without selective disadvantage. Premutations can range in length from 44 to ~200 repeats and are typically found to be between 70 and 100 repeats. They are not methylated in males, although they, like normal alleles, are subject to methylation associated with X inactivation in females.

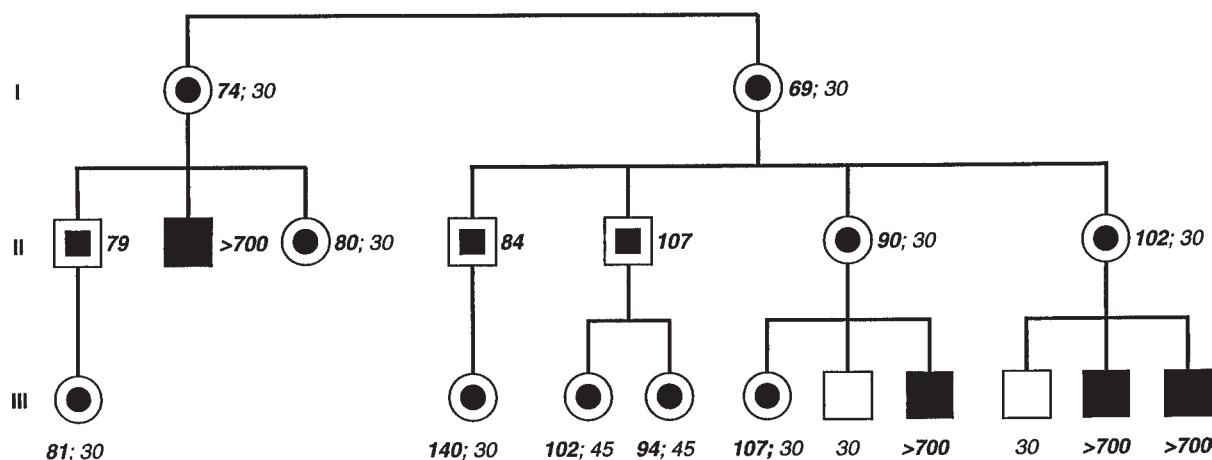
Premutations are found to change in size in nearly all transmissions from parent to offspring, yet are usually somatically stable. Thus they exhibit an extremely high mutation frequency. Mutations can take the form of changes within the premutation size range or they can involve massive expansions (transitions) to the disease, causing full mutation (Fig. 118-3). However, these latter events are found exclusively to occur on transmission from mothers to their children, never from fathers to their daughters. This sex-specificity had been recognized in empiric pedigree studies of fragile X families along, with the tendency for the probability of this event to increase in subsequent generations of a fragile X family. The molecular genetic basis for the female transition specificity is as yet unknown. However, as shown in Table 118-1, the increasing likelihood of the disease in a family can be accounted for by the observation of increasing risk of transition to the full mutation with escalating size of premutation in a female carrier, coupled with the tendency for the repeats to increase in size, while transmitted in the premutation size. This unstable character to the CGG repeat explains most of the peculiar (non-Mendelian) inheritance patterns found in fragile X syndrome. Similar phenomena in other human genetic disorders caused by unstable triplet repeats can also explain the deviations from Mendelian inheritance in those diseases as well.


Figure 118-3 Representative fragile X syndrome pedigree. Partially filled circles (female) and squares (male), nonpenetrant carriers; closed squares, penetrant males; open squares, normal males. Numbers by each symbol indicate the number of *FMR1* trinucleotide repeats (bold numbers signify the abnormal allele). Note that the premutation changes when transmitted as evidenced by siblings having unique premutation sizes. (Reprinted with permission from JAMA 1994;271:536–542.)

Table 118-1
Incomplete Penetrance Based on Repeat Length—Risk[a]
of Full Expansion on Transmission

Repeat number[b]	Maternal carrier, %	Paternal carrier, %
<60	<1	0
61–70	17	0
71–80	71	0
81–90	86	0
>91	>99	0

Table reprinted with permission from JAMA 1994;271:536–542.

[a]Risk of having penetrant offspring for fragile X syndrome based on premutation size.

[b]Parental alleles. Risk of the premutation expanding to a full mutation is indicated for maternal or paternal transmission. Actual risk for a penetrant offspring of a carrier female is half the indicated value to reflect segregation of the normal X chromosome, which half the time will be included in the mature ovum. These data from Fu et al., which illustrate the molecular basis of the Sherman paradox, require further investigation before being used as definitive risk assessments during genetic counseling.

Instability of the *FMR1* CGG repeat has been found to increase as the number of repeats is enlarged; however, interrupting AGG triplets have been found to play an important role in maintaining stability of the repeat, both in human pedigrees and in evolutionary time. A threshold of approximately 35 uninterrupted CGG repeats appears to mark the transition from reasonably stable to completely unstable transmissions and explains the observation of stable alleles with longer repeat tracts than some unstable alleles. The *FMR1* gene has conserved the CGG repeats throughout mammalian evolution, suggesting that these have a specific function in the gene. A report of specific binding proteins suggests one possibility for function.

PREVALENCE OF THE PREMUTATION The high incidence of fragile X syndrome, coupled with the rather unusual inheritance pattern of premutation alleles, suggests a very high prevalence of premutations in the general population. Small-scale studies have suggested allele frequencies of 1/500 to 1/600. A recent large study found a carrier frequency for premutations (defined as >55 repeats) of 1/259 women (approximately 1/500 X chromosomes). This finding underscores the impact of this very common genetic disorder.

GENE AND GENE PRODUCTS The *FMR1* gene has been completely sequenced (GenBank accession L29074), and spans 38 kb divided into 17 exons. To date, no other genes have been described in the immediate vicinity. A variety of alternatively spliced transcripts has been observed in human and mouse. These lead to a number of protein isoforms.

The protein product of the *FMR1* gene, FMRP has been found to be present in many adult and fetal tissues, but is concentrated in neurons, particularly those of the hippocampus and in Purkinje cells of the cerebellum. High levels of FMRP are also found in cells of the testis, primarily spermatogonia. These two sites of high-level expression are consistent with the major phenotypic aspects of the disorder.

Within the cell, FMRP appears predominantly cytoplasmic; however, isoforms lacking exon 14 appear to be limited to the nucleus. In the cytoplasm, the protein appears to interact with ribosomes and may form complexes with two or more recently identified proteins of similar amino acid sequence, *FXR1* and *FXR2*. Homologs of all three members of this gene family have been identified from a variety of vertebrates. Each of these three proteins is found to have features of RNA-binding proteins, and RNA binding has been demonstrated in vitro for each. FMRP appears to have a selectivity for certain mRNAs. These features of FMRP begin to suggest a protein involved in mRNA metabolism, perhaps with a role in the regulation of translation. It remains to be discovered how defects in this function might lead to mental retardation.

NEARBY FRAGILE SITES Two additional rare, folate-sensitive fragile sites are found distal to FRAXA, the site in the *FMR1* gene responsible for fragile X syndrome (Fig. 118-4). These are FRAXE and FRAXF, which were both assumed to be FRAXA by cytogenetic testing, and were only distinguished after the development of DNA probes at FRAXA. Each of these sites also results from expansion and methylation of CGG repeats, and FRAXE is clearly associated with a relatively rare form of mental retardation distinguishable from fragile X syndrome. FRAXF appears to cause no abnormalities in individuals carrying expanded repeats. A gene *(FMR2)* whose expression is reduced by FRAXE expansion has been recently identified. This gene is quite large (approximately 500 kb) and is transcribed from the FRAXE CpG island. The gene
Figure 118-4   Map of the Xq27.3–q28 region. Three fragile sites—FRAXA, FRAXE, and FRAXF—are shown relative to the X chromosome at Xq27.3–q28. The two genes associated with FRAXA and FRAXE are indicated as *FMR1* and *FMR2*, respectively, with their lengths. IDS indicates iduronate sulfatase, the gene defective in Hunter's syndrome. Distances indicated are approximate.

product bears no resemblance to the *FMR1* gene, and its function is not suggested by its sequence, although it shares similarity with transcription factors.

MOLECULAR GENETICS OF CHROMOSOMAL FRAGILE SITES   Two additional autosomal folate-sensitive fragile sites have been characterized at the molecular level. These are FRA16A and FRA11B. Each results from an expansion of a polymorphic CGG repeat sequence, with strong similarity to the expansions seen at FRAXA, FRAXE, and FRAXF. Each shows significant methylation in the fully expanded form, suggesting that methylation of expanded CGGs does not require that the repeat be located on the X chromosome. FRA16A, like FRAXF, is not known to be associated with pathology in the expanded form. FRA11B, however, appears to predispose to the loss of the terminal portion of 11q in the gametes of carriers of the fragile site. The resulting offspring develop 11q- or Jacobsen syndrome, a disorder resulting from haploidy for this region of chromosome 11 (11q23–qter). Jacobsen syndrome patients exhibit severe mental retardation and specific dysmorphic features. FRA11B results from expansion of a CGG repeat found in the 5' untranslated region of the proto-oncogene CBL2. No relationship between this fragile site and elevated risk of oncogenesis has been found.

Each of the five fragile sites identified at the molecular level is characterized by expanded and methylated CGG repeats, and each is rare and folate-sensitive. Fragile sites are classified as either rare or common depending on their frequency in the human population, with common sites being homozygous in nearly every person. Rare fragile sites are typically found in less than 1% of individuals. Fragile sites are visualized in metaphase preparations of chromosomes after "induction" or treatment of the cells with a variety of reagents that elicit the sites. In addition to folate, fragile sites can be induced by distamycin-A, BrdU, aphidicolin, and 5-azacytidine. The folate-sensitive sites are the most numerous of the rare fragile sites, but aphidicolin-inducible sites are plentiful among the common sites. There are 21 known folate-sensitive sites, and these can be elicited by a variety of conditions. A culture medium lacking folic acid and thymidine is the simplest method, although inhibitors of folate metabolism such as methotrexate can also be used. High thymidine can also induce these fragile sites at concentrations below those that result in mitotic arrest. These treatments all impinge on the pyrimidine biosynthetic pathway and result in diminished dTTP pools in the cell. The mechanism by which the depletion of dTTP results in a chromosomal abnormality at a CGG repeat is unknown, as is the precise molecular nature of the fragile site itself. It is likely that all folate-sensitive fragile sites will be found to result from CGG repeat expansion. Recent work has described a common aphidicolin-sensitive site on chro-

mosome 3 (FRA3B) as a broad region without specific repetitive sequence elements. However, a gene associated with renal carcinoma, FHIT, has been found to span the region of fragility. It remains to be seen whether specific sequence elements will be found associated with common fragile sites.

MOLECULAR PATHOPHYSIOLOGY

The emerging evidence that *FMR1* plays a role in cytoplasmic mRNA metabolism, possibly in control of translation, is somewhat at odds with the pathophysiology of fragile X syndrome. The disorder has profound consequences on intellect, yet few structural or pathological abnormalities are found. It might be expected that loss of a protein involved in a fundamental process such as translational control would lead to much more widespread anomalies. It may therefore be the case that for most tissues, sufficient redundancy of function is provided by other similar proteins (*FXR1* and *FXR2*, for example), and that it is only in the neurons that absence of *FMR1* is problematic. A knockout mouse model of fragile X syndrome is similarly mildly affected, with very subtle learning defects and enlarged testes. Thus, the very highly conserved *FMR1* protein can be regarded as dispensable for normal growth and structural development (if not normal intellectual development).

MANAGEMENT/TREATMENT

Currently, a variety of educational interventions are employed to treat fragile X children. These can have significant benefits. Pharmacological treatment has yet to be standardized, with trials ongoing of a variety of psychoactive substances, particularly serotonin reuptake inhibitors. Additional understanding of the normal function of the *FMR1* gene may provide suggestions for effective drug intervention. The potential for treating the disease through gene therapy is tempered by the observation of affected females, which suggests strongly that the gene product acts in a cell-autonomous fashion. In females, the random pattern of X-inactivation found in the critical tissue (presumably neurons) affects the intellectual potential of women carrying full mutations. This has significant bearing on the potential for treatment by gene therapy, since this modality would necessitate targeting of neurons and would require a rather high efficiency (50% or higher) to exceed the average number of expressing neurons found in female patients.

FUTURE DIRECTIONS

Of the large number of human genetic disorders known to be caused by expanding trinucleotide repeats, fragile X syndrome is the best characterized with respect to the effect of the mutation on the gene. The challenges that remain, however, are large. They include development of a better understanding of the natural his-

tory of the fragile X mutation and improved methods for its detection. With improved tests, the potential for population-based screening for this common mutation will be a reality; however, along with such a scheme comes a significant challenge in providing meaningful information to those at risk. The very dynamic nature of this mutation is confusing to professionals, and this can be quite difficult to convey to individuals at risk. Given the high frequency of the disease and its profound cost to families and society, the demand for population-based screening will be high. It will be vital to develop inexpensive and accurate tests in support of such efforts, along with effective vehicles to convey the information to the public.

Clearly, a large focus on the function of the *FMR1* gene product is required for developing rational treatment strategies. What is the role of *FMR1* in the development of neuronal circuits? What are the consequences of its absence, and how can these be modulated? Despite 5 years of attention to this interesting protein, these investigations remain in their infancy. The added benefit of such studies may be an improved understanding of fundamental cell biological processes, possibly ones integral to learning and memory.

119 Down Syndrome

Stylianos E. Antonarakis

BRIEF HISTORICAL NOTE

Down syndrome was first described by Dr. Langdon Down in 1866. The advanced mean maternal age at the time of birth of an individual with Down syndrome was first emphasized in a study by Shuttleworth in 1909. Lejeune, Gautier, and Turpin showed in 1959 that individuals with Down syndrome had a supernumerary small acrocentric chromosome that was subsequently recognized as being chromosome 21. Soon after (1960–1961), cases of trisomy 21 resulting from translocations were described by Polani and Fraccaro. Mosaicism for trisomy 21 was first published by Clarke in 1961. In the same year, some patients were described with partial trisomy 21 and phenotypic characteristics of Down syndrome (Ilbery et al., 1961; Dent et al., 1963; Hall, 1963). The parental and meiotic origin of the extra chromosome 21 was first studied (1970–1980) by cytogenetic heteromorphisms (e.g., de Grouchy 1970) and more recently by DNA polymorphisms (e.g., Antonarakis et al., 1991). The association of recombination rate and abnormal chromosomal segregation was first observed in 1987 (Warren et al.). The human genome project and the identification of genes on chromosome 21 are beginning to provide the tools for understanding the pathophysiology of the diverse phenotypes in Down syndrome. Important landmarks in this process are the descriptions of the first linkage map of chromosome 21 (Warren et al., 1989) and the first physical map using yeast artificial chromosomes (Chumakov et al., 1992).

THE CLINICAL PHENOTYPES OF DOWN SYNDROME

The clinical diagnosis of Down syndrome (DS) (MIM 190685) depends on the presence of a number of different abnormal features that affect many tissues and organs. Table 119-1 contains a partial list of physical characteristics and abnormalities found in DS, and Fig. 119-1 shows an individual with the syndrome. No individual DS patient has all of these features. Furthermore, these features may be present in other syndromes or in otherwise normal individuals. Diagnostic indexes and scoring systems have been developed for accurate diagnosis in patients suspected to have DS. Mental retardation is always present. The mean intelligence quotient (IQ) typically drops from about 80 the first year to approximately 30 the second decade of life. Newborns and infants invariably have hypotonia, which is the most common feature of

the phenotype. The pathological, metabolic, and neurochemical changes of Alzheimer disease are present after the third decade in the brains of almost all individuals with DS, who also show a progressive loss of cognitive functions. Congenital heart disease, mainly atrioventricular (AV) canal and ventricular septal defect (VSD) is present in 30–40% of living individuals with DS, while in affected fetuses the estimated presence of AV canal is about 70%. Duodenal stenosis or atresia, imperforated anus, and Hirschsprung disease are present in 1.0–2.5% of DS individuals, frequencies much higher than in the general population. Furthermore, DS patients have a 10–20 times greater risk of developing acute leukemia. Both acute nonlymphoblastic and acute lymphoblastic leukemia may be observed. The most characteristic leukemia of DS is the acute megakaryocytic leukemia (AMKL); it has been estimated that AMKL is 200–400 times more frequent in DS than in the normal population. Another form of abnormal clonal cellular proliferation of white blood cells that is observed in some newborns with DS is the "transient" acute leukemia or "leukemoid reaction." There is spontaneous, complete remission of this blood abnormality. Additional phenotypic findings in trisomy 21 of note include immunologic defects, hematologic alterations, hyperuricemia, thyroid dysfunction and autoimmunity, growth retardation, and sterility in males. The life expectancy of DS patients is reduced, and the causes of death are the congenital malformations (mainly heart defects), infections, and leukemia.

CHROMOSOMAL ABNORMALITIES IN DOWN SYNDROME

Since the discovery of Lejeune in 1959, the phenotype of DS has been associated with trisomy for chromosome 21. Trisomy 21 is the most common autosomal aneuploidy in live births; it occurs with a frequency of 1.03–1.30 per 1000 live births in all ethnic groups. Table 119-2 shows the frequencies at birth of specific chromosomal disorders, including trisomy 21.

The majority of trisomy 21 cases are because of a free supernumerary chromosome 21. For every 1000 individuals with DS, 925 are because of free trisomy 21, 46 to translocation of the supernumerary, 21 to another acrocentric chromosome, and two to other reciprocal translocations (Fig. 119-2). Recognizable mosaicism for a normal and a trisomic cell line accounts for 27 of 1000 individuals with DS.

MATERNAL AGE AND DOWN SYNDROME

It has long been recognized that maternal age is an important determinant of the incidence of DS in newborns. Figure 119-3 shows the increase of the incidence of trisomy 21 in mothers of

Table 119-1
Phenotypic Features of Down Syndrome[a]

	%
Physical characteristics	
Oblique (upslanting) palpebral fissures	80
Loose skin on nape or neck	80
Narrow palate	75
Brachycephaly	75
Hyperflexibility	75
Flat nasal bridge	70
Large gap between 1st and 2nd toes	70
Short, broad hands	65
Short neck	60
Abnormal teeth	60
Epicanthic folds	60
Short 5th finder	60
Open mouth	60
Brushfield spots	55
Furrowed tongue	55
Transverse palmar crease	55
Folded or dysplastic ear	50
Protruding tongue	45
Abnormal dermatoglyphics	85
Skeletal abnormalities	
Incurved 5th finder	55
Pelvic dysplasia (newborns)	70
Atlantoaxial or atlantoccipital instability	15–20
Mental retardation	100
Hypothyroidism	7–17
Neurological features	
Hypotonia	100
Delayed dissolution of early reflexes	80
Alzheimer-like brain pathology (over 35 years of age)	100
Congenital anomalies	
Congenital heat defects (CHD) (of living patients)	30–40
AV canal (of total CHD)	40
VSD (of total CHD)	31
ASD (of total CHD)	9
Fallot's tetralogy (of total CHD)	6
PDA (of total CHD)	9
Gastrointestinal abnormalities	
Duodenal atresia	2.5
Imperforated anus	1.0
Hirschsprung disease	0.6
Infertility in males	100
Leukemia	1.1
AMKL (acute megakaryocytic)	200–400× normal
AML/ALL	10–20 × normal
Leukemoid reaction (newborn)	0.1

[a]The frequencies of phenotypic features were obtained from numerous sources, and most have been rounded to the nearest 5%. (Majority of data are from Epstein CJ, 1995.)

different ages. The risk remains low, at about 1 in 1500 to 1 in 1000 live births, until age 30 and then increases substantially. For mothers of 35 years of age, the risk is about 1 in 380 live births, at age 40 it is 1 in 110, and at 45 years about 1 in 30. The reason for this strong maternal age effect is presently unknown, and many theories have been formulated to explain this well-documented phenomenon. There is no convincing evidence for a paternal age effect. Molecular analysis has clearly shown that this advanced maternal age effect is associated with errors of maternal meiotic origin and not paternal or mitotic errors; in these latter two categories of errors, the mean maternal age is not different from that of the mean maternal age in Western societies. This finding is against the theory of relaxation of selection in utero that seeks to explain the increased incidence of DS with maternal age by a decrease (in older mothers) in the rate of a spontaneous abortion of aneuploid embryos and fetuses. In addition, there is no maternal age effect in trisomy 21 resulting from translocations. The theory of aging of sperm has not been supported, as no paternal age effect has been shown in paternally derived trisomy 21; however, more data are needed for this category of meiotic errors. Interestingly, more male trisomy 21 individuals than expected have been observed in DS originating from paternal meiotic errors.

Figure 119-1 Facial photograph of a 2-year-old male with trisomy 21 (Down syndrome).

Many conspectuses with trisomy 21 do not survive to birth. Data from amniocentesis without any further intervention during pregnancy revealed that over 20% of the DS fetuses die *in utero*. Furthermore, data from chorionic villus sampling at approximately 9–10 weeks of gestation indicate that about 20% of DS fetuses die between the 9th to 10th and 16th to 18th week of gestation. The estimate of survival of a DS fetus to term is about 30%.

The production-line hypothesis was advanced by Henderson and Edwards in 1968. Based on mouse studies, they proposed that oocytes with greater number of chiasmata in their chromosomes are formed earlier in embryogenesis and are ovulated earlier in adult life than oocytes with fewer chiasmata. Warren et al. in 1987 first provided evidence that there is a reduced number of crossing-over events in chromosomes 21 that undergo nondisjunction. Further studies from our laboratory and that of Sherman/Hassold have shown that, in maternal meiosis I errors, the number of cases with no detectable crossover is excessive, and the total length of the observed linkage maps of these nondisjoined chromosomes 21 is about half of normal. Thus, it is now clear that there is abnormal (reduced) recombination rate in maternal meiosis I nondisjunction; this abnormality in recombination may have some causative effect in nondisjunction. In maternal meiosis II errors, Lamb et al. (1996) observed increased recombination that was largely restricted to the maximal long arm of chromosome 21.

ORIGIN OF THE EXTRA CHROMOSOME IN TRISOMY 21

FREE TRISOMY 21   The availability of highly informative DNA polymorphic markers has allowed the determination of the parental origin of the extra chromosome 21 in free trisomy 21. Furthermore, DNA markers close to the centromeric region can indicate the stage of meiosis in which the segregation error had occurred. Finally, homozygosity for all markers throughout 21q,

including the pericentromeric markers, is interpreted as the result of a mitotic, postzygotic error. Table 119-3 shows the results of two large independent studies of more than 500 families. The conclusions are as follows:

1. Errors in meiosis that result in trisomy 21 were overwhelmingly of maternal origin, as only about 6.5% occurred during spermatogenesis.
2. The majority of errors in maternal meiosis occurred in meiosis I, and the mean maternal age associated with these was 31.2 years. The meiosis I errors accounted for 77.5% of maternal meiotic errors and 68% of all instances of free trisomy 21.
3. Maternal meiosis II errors comprised 22.5% of maternal origin errors and 20% of all cases of free trisomy 21. The mean maternal age in these errors was 32.5 years.
4. In a minority (6.6%) of the total number of families in which there was paternal nondisjunction, there are more meiosis II than meiosis I errors (62% and 38% of paternal meiosis I and II errors, respectively). The mean maternal and paternal ages in this category were similar to the mean reproductive age in Western societies.
5. In about 5.5% of free trisomy 21, the extra chromosome 21 appeared to result from an error in mitosis. In these families, the mean maternal age was around 28 years, which is similar to the mean maternal reproductive age. As expected, there was no preference for which chromosome 21 was duplicated in mitotic errors, and the extra chromosome was equally likely to be derived from either parent.

TRANSLOCATION TRISOMY 21   In all 24 cases examined of *de novo* translocation t(14;21) trisomy 21, the extra chromosome 21 appears to be maternal in origin. In these cases, the mean maternal age was 29.2 years. The most likely mechanism of these events is that the translocation occurs before crossing over in meiosis I and is followed by normal segregation in meiosis I and II.

In the majority (14 of 17 cases) of *de novo* translocation t(21;21) trisomy 21, the abnormal chromosome is an isochromosome (dup21q), rather than the result of a translocation caused by a fusion between two heterologous chromatids. About half of the isochromosomes studied were of paternal and half of maternal origin. The dup21p was probably formed by failure of separation, either of the chromatids in meiosis II or of sister chromatids in early mitosis. Finally, all of the t(21;21) true *de novo* translocations are of maternal origin similar to the t(14;21).

ORIGIN OF THE EXTRA CHROMOSOME IN OTHER TRISOMIES   For comparison with trisomy 21, the parental and meiotic origin of other human trisomies are as follows:

1. In trisomy 18, in which more than 150 families were studied, the origin of the extra chromosome 18 is maternal in about 90%. Postzygotic, mitotic errors probably account for about 8% of the cases. Among the maternal meiotic errors, about 34% occur in meiosis I and 66% in meiosis II. The excess of maternal meiosis II errors is in contrast with the data from all the other aneuploidies studied. Increased maternal age is associated with both maternal meiotic errors.
2. In trisomy 16, the most common trisomy at conception but not at birth, because virtually all such fetuses are spontaneously aborted, the origin of the extra chromosome 16 is always maternal. Furthermore, in all cases the error is found

Table 119-2
Chromosomal Abnormalities in 1000 Live Births[a]

All abnormalities	5.71–6.25
Autosomal trisomies	1.23–1.42
Trisomy 21	1.03–1.30
Trisomy 18	0.09–0.12
Trisomy 13	0.05–0.07
Balanced autosomal rearrangements	1.85–1.93
Unbalanced autosomal abnormalities	0.48–0.59
Sex chromosomal abnormalities in phenotypic males	2.55–2.59
XXY	0.92–1.04
XYY	0.90–0.92
Sex chromosomal abnormalities in phenotypic females	1.33–1.51
45,X	0.09–0.13
XXX	0.86–1.04

[a]Numbers have been derived after karyotyping of more than 70,000 consecutive newborns. (Most of the data are from Hook and Hamerton, 1977.)
Figure 119-2 Histogram of frequencies of the various chromosomal abnormalities found in Down syndrome. The number of abnormalities per 1000 individuals with Down syndrome is shown. The data are averages from various sources.

in maternal meiosis I. There is increased maternal age associated with trisomy 16.

3. In trisomy 13, the data from about 50 families show that the origin of the extra chromosome 13 was maternal in about 90% of cases. Among maternal errors, the great majority (approximately 90%) occur in maternal meiosis I.

4. The data on a limited number of families with spontaneous abortions with trisomies 14, 15, and 22 indicate that, again, the majority of the errors (87%) occur in maternal meiosis.

5. In XXY (Klinefelter) syndrome, about half of the cases result from paternal and half from maternal meiotic errors. Among the paternal errors, all occur in meiosis I; among the maternal errors, 75% occur in meiosis I and 25% in meiosis II. About 5% of the maternal cases can be attributed to mitotic error. In XXX females, only 10% have received two copies of the paternal X, the remaining 90% have inherited two copies of the maternal X chromosome. Among the maternal origin XXX females, 68% are because of meiosis I and 32% to meiosis II errors.

PRENATAL DIAGNOSIS AND COUNSELING

Programs for prenatal detection of trisomy 21 have been introduced by many public and private health care providers. Chromosomal analysis after amniocentesis or chorionic villus sampling have been done in hundreds of thousands of pregnancies. Amniocentesis is usually carried out at approximately 16 weeks, while chorionic villus sampling is performed at 8–10 weeks of pregnancy. In most health systems, both of these procedures are usu-

ally offered to women over 35 years of age because the risk of abortion from the procedure almost equals the risk of trisomy 21. Prenatal detection of trisomy by cytogenetic analysis of the fetus has slightly reduced the number of liveborn with DS, since in the general population only a minority of trisomy 21 individuals are born to mothers older than 35 years of age. Rapid DNA-based methods (either fluorescent *in situ* hybridization [FISH] or DNA polymorphisms or dosage analysis) have been developed to detect trisomy 21 in fetal tissues (after amniocentesis or chorion villus sampling); however, these methods are not in wide use, because they only detect trisomy 21, whereas a karyotype detects all of the other visible chromosomal abnormalities.

Monitoring of all pregnancies using maternal serum alpha fetoprotein (AFP) in combination with chorionic gonadotropin (UCG), inhibin A, and unconjugated estrol (uE3) have provided a way to estimate a woman's risk of having an affected fetus. If the risk exceeds a specified cutoff level (usually 1 in 250), then a karyotypic analysis of fetal cells is indicated. Although this "triple test" is not trisomy 21-specific and has a high false positive rate, it is a valuable tool for the *in utero* detection of trisomy 21. The introduction of this screening test in the United Kingdom and elsewhere had resulted in the in utero detection of more than half of all cases of trisomy 21.

Many efforts are now being directed toward the development of methods to detect aneuploidies in fetal nucleated erythrocytes or other cells in the maternal circulation. No such method has yet been introduced in large-scale clinical trials, because their technology is still in the development stage.
Figure 119-3 Incidence of Down syndrome cases per 1000 live births as a function of maternal age.

Table 119-3
Analysis of the Origin of the Supernumerary Chromosome 21 in 510 Families
with Free Trisomy 21 Using DNA Polymorphisms[a]

Error	N	%	Mean maternal age (years)
Maternal meiosis I	347	68.04	31.2
Maternal meiosis II	101	19.80	32.5
Paternal meiosis I	13	2.55	26.4
Paternal meiosis II	21	4.12	27.9
Mitosis	28	5.49	28.4
Maternal chrom duplication	17		27.2
Paternal chrom duplication	11		28.4

[a]Data are from two major studies: Johns Hopkins University (Antonarakis, et al., Nature Genet 1993) and Emory University (Sherman/Hassold) (Lamb et al., 1996).

The counseling of pregnant couples includes the explanation of the incidence of trisomy 21 in different-age mothers, the phenotypes of DS, and the presentation of risks of available diagnostic and screening procedures. Postdiagnostic counseling (after the discovery of a chromosomal abnormality) is necessary. The risk of a couple with one member being a carrier for a Robertsonian or reciprocal chromosome 21 translocation differs according to the translocations and the sex of the carrier parent. This empirically observed risk differs from the theoretical risk based on the meiotic products. Empirical data show that if the mother is a Robertsonian translocation carrier of chromosome 21 and either 13, 14, 15, or 22, the risk for an unbalanced, trisomy 21-affected offspring is about 15%; if the father is the carrier of such a translocation the risk is about 2%. For reciprocal translocations involving chromosome 21, the empirical risk is about 10% for both translocation carriers. The risk of trisomy 21 among the viable offspring of t(21;21) carriers is the expected 100%. The maternal age-independent risk for recurrent trisomy 21 for a couple who already has one child with free trisomy 21 is slightly higher than that of the general population of the same maternal age. This is probably because of germline and/or somatic mosaicism for a trisomy 21 cell line in one of the parents. In a recent study of 22 families with two free trisomy 21 offspring, parental mosaicism has been detected in five cases. It is not known if a predisposition for nondisjunction (other than mosaicism) exists in some families with two or more affected offspring.

CHROMOSOME 21: GENOME MAPPING

In order to understand the pathophysiology of the different phenotypes of trisomy 21, knowledge of the genes that map in chromosome 21 is necessary. The identification and characteriza-

tion of these genes and the subsequent elucidation of their function may permit the assignment of specific phenotypes to specific gene products. The elucidation of the role of the additional copy of certain genes in specific clinical abnormalities may then open new possibilities for intervention in order to modify the resulting phenotype.

The effort for mapping, cloning, sequencing, and initial characterization of chromosome 21 genes is part of the international human genome project initiative, which is already greatly enhancing the understanding of the molecular pathophysiology of human disorders. Chromosome 21 is the smallest human chromosome. The long arm (21q) is approximately 40 Mb (40 million nucleotides) and makes up about 1.2% of the human genome; the short arm (21p), which is highly homologous to those of the other four acrocentric chromosomes, is around 10–15 Mb. Because complete absence of 21p is not associated with clinical phenotypes, and trisomy 21 resulting from t(21;21), in which 21p is also deleted from the translocated chromosomes, is not different from the free trisomy 21, we do not consider 21p to be as important or contributory to the phenotypes of trisomy 21. The estimated number of genes on 21q is approximately 600–1000. Figure 119-3 shows schematically the different maps that have been developed for chromosome 21. The information from these different maps is integrated in a unifying system, the final goal of which is to decipher the nucleotide sequence of the entire 21q. The different maps are briefly described below.

CHROMOSOMAL BREAKPOINT MAP The breakpoints of naturally occurring chromosomal abnormalities serve as the initial landmarks in the building of maps. A large collection of such abnormal chromosomes has been introduced into rodent-human somatic cell hybrids and used to divide the chromosome in intervals of a few megabases each.

LONG-RANGE RESTRICTION SITE MAP   A relatively accurate estimate of the distance in kilobases between landmark cleavage sites of selected restriction endonucleases is provided after restriction analysis. Infrequent cutting enzymes studies, such as *Not*I, are used for the initial "framework" map that provides information about the size of the chromosome. An approximately 37-Mb-long range map of *Not*I restriction sites has been produced for 21q.

LINKAGE MAP   At present, the linkage map is perhaps the most medically useful of all chromosomal maps. It consists of polymorphic DNA markers ordered, by recombination frequencies to each other, throughout the entire length of the chromosome. The majority of the polymorphic markers used are because of the normal variation of short sequence repeats and can be detected after PCR amplification. The current linkage map of 21q is the most dense map of all human chromosomes. More than 130 DNA markers have been analyzed and placed on the linkage map; the average genetic distance between adjacent markers is less than 1.5% recombination. The linkage map constructed from male meioses is shorter than that made from female meioses, probably because the meiotic process is different in the two sexes. The female map is usually longer in the proximal half of 21q; however, in the most distal region of 21q, there is an excess of male recombination and therefore a longer male linkage map. The total lengths of the male and female maps are about 55 cM, and 85 cM respectively; the sex-averaged map is 67 cM long. The linkage map of chromosome 21 is an outstanding tool for mapping both Mendelian and complex polygenic traits for the identification of specific chromosomes involved in aneuploidies or malignancies, for the determination of the origin of nondisjunction, and for the determination of the extent of partial trisomies 21.

RADIATION HYBRID MAP   When somatic cell hybrids that contain a single chromosome 21 are irradiated and then fused with a rodent cell line, radiation hybrids are produced that carry only small fragments of the human chromosome. By screening a large number of such hybrids for the presence or absence of particular loci, another type of a statistical map can be built up. Neighboring loci are most likely to be present together in these hybrids, while distant loci are separated. The major advantage of radiation hybrid mapping is that there is no need for polymorphic markers; any piece of DNA can be assigned to this map. The radiation hybrid map of chromosome 21 is becoming increasingly important with the addition of expressed sequence tags (ESTs), the short sequences of human cDNA clones.

CLONING OF CHROMOSOME 21 IN OVERLAPPING CLONES   The cloning of chromosomal 21 DNA and the identification of a continuous array of overlapping clones (contigs) is an essential step in the characterization of disease-related genes, sequencing of chromosomal DNA, precise mapping of genes, and study of the importance of partial trisomy 21 to the DS phenotypes. Various vectors have been used to clone large fragments of DNA; the most widely used are cosmids, yeast artificial chromosomes (YACs), P1 bacteriophage, P1 artificial chromosomes (PACs), bacterial artificial chromosomes (BACs). An almost continuous array of chromosome 21 YACs has been produced for 21q and now serves as the backbone for the mapping efforts. This contig was composed of 810 YACs and extends from the 21cen to 21qter. There are several areas of noncoverage, with YACs and regions with erroneous order of the mapping objects; this map is therefore in constant improvement. A cosmid contig of a 4-Mb region in the

so-called DS critical region *(see below)* has been recently made. Additional smaller cosmid contigs for different regions of 21q have been constructed. All of these maps of overlapping clones are necessary for the identification and characterization of chromosome 21 genes that are involved in various disease phenotypes, including those of DS.

DOWN SYNDROME CRITICAL REGION (DSCR)   It has long been recognized that some patients with a clinically recognized DS have only a partial trisomy 21. Many laboratories have therefore collected DNA from patients with (1) phenotypic characteristics of DS and partial trisomy 21, (2) partial trisomy 21 without the phenotypes of DS, and (3) phenotypes of DS without any obvious chromosomal abnormality. The latter group of patients is intriguing, because even after careful and extensive molecular analysis, no chromosome 21 triplication has been found, and yet the phenotypic analysis of these patients fulfills the minimal criteria for the diagnosis of DS. It is possible that these patients have a small triplicated region of chromosome 21 that has yet escaped detection or that abnormalities of few genes on chromosome 21, or elsewhere, result in a phenotype similar to that of DS.

The study of patients with partial trisomy 21 and several phenotypes of DS suggested that there is a region of approximately 4 Mb between DNA markers D21S17 and ETS2 (Fig. 119-4) that, if triplicated, is associated with numerous features of DS, including flat nasal bridge, protruding tongue, high arched or narrow palate, folded ears, short and broad hands, clinodactyly of fifth finger, large gap between first and second toes, joint hyperlaxity, muscular hypotonia, short stature, and mental retardation. This region is termed Down syndrome critical region (DSCR). Extension of the triplication distally to DNA marker BCEI includes additional features of DS, such as oblique eye fissure, epicanthus, Brushfield spots, transverse palmar crease, and several dermatoglyphic signs. In all of these studies, the presence of a phenotypic feature is of importance; its absence is not taken into account, because patients with the full trisomy 21 do not show all of the phenotypic characteristics. The DSCR, which is about 10% of 21q, may contain between 50 and 100 genes (assuming that the gene distribution is the same throughout 21q).

There are, however, three known patients with proximal triplication of chromosome 21 (that does not extend to the DSCR) and several phenotypes of DS, including facial features, microcephaly, short stature, hypotonia, abnormal dermatoglyphics, and mental retardation. This observation argues against a single chromosomal region being responsible for most of the DS characteristics. On the other hand, the conflicting data can be explained by a DSCR as described on distal 21q and an additional partial trisomy 21 syndrome on proximal 21q. More cases are necessary to clarify the contribution of several 21q regions to the phenotypes of DS and the precise mapping of these regions. For the remaining discussion of this chapter, the DSCR definition is for the region between D21S17 to ETS2. The atrioventricular canal, which is a characteristic heart defect in DS, has been mapped to a large 5- to 6-Mb region between D21S267 and MX1.

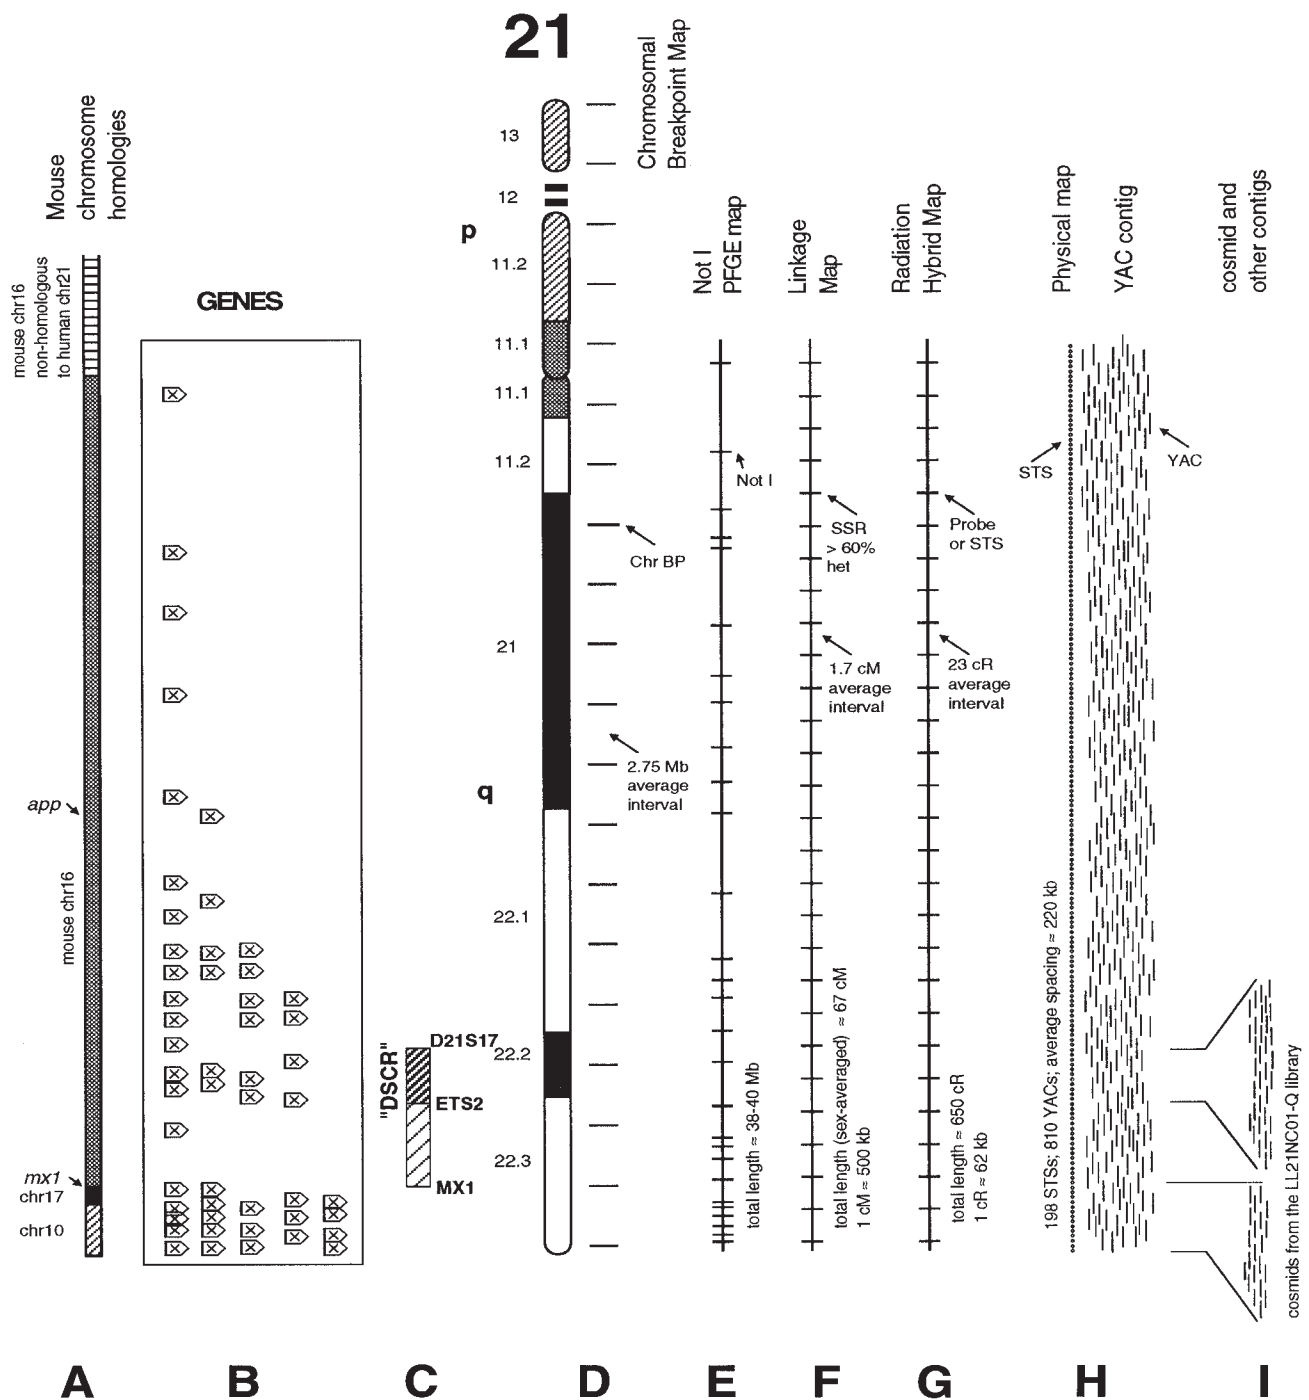
GENES AND DISORDERS   The number of genes on chromosome 21 is estimated to be about 600–1000. The gene density varies according to the chromosomal band. There are, therefore, "gene-rich" and "gene-poor" regions on 21q. Chromosomal bands 21q22.3 and 21q22.1, which do not stain with Giemsa, probably contain the majority of genes of this chromosome. In contrast, the large Giemsa-positive 21q21 band is apparently gene-poor.


Figure 119-4 Schematic representation of chromosome 21 and several of its maps. (**A**) Human chromosome 21 homologous regions of mouse chromosomes. (**B**) Mapping of the known cloned genes on chromosome 21. (**C**) Down syndrome critical region (DSCR). (**D**) Chromosome 21 breakpoint map. (**E**) Pulsed field gel electrophoresis map of *Not*I restriction fragments. (**F**) Linkage map using highly informative, short sequence repeats, polymorphic markers. (**G**) Radiation hybrid map. (**H**) sequence tagged site (STS) map and yeast artificial chromosome (YAC) contig. (**I**) Cosmid contigs of the DSCR and a portion of chromosomal band 21q22.3.

A total of 54 genes thus far have been described that map on 21q. These represent only 5.4–9% of the total number of genes on 21q, and more information on them can be obtained from the pub-

licly available databases (Genome Database, OMIM, Genbank). The function of some of these genes is known; their protein products belong to various categories, such as proteins involved in cell

division, cell signaling and communication, cell structure and motility, metabolism, cell defense, gene/protein expression, and development of the organism. Some genes have been associated with specific disorders such as the APP with a rare form of early onset Alzheimer's disease (MIM 104760), CBS with homocystinuria (MIM 236200), ITGB2 with a leukocyte adhesion deficiency syndrome (MIM 600065), AML1 with translocations involved in acute myeloid leukemia (MIM 151385), PFKL with a form of hemolytic anemia caused by phosphofructokinase deficiency (MIM 171860), SOD1 with one form of amyotrophic lateral sclerosis (MIM 147450), HCS with biotin-responsive multiple carboxylase deficiency (MIM 253270), ENTC with enterokinase deficiency (MIM 226200), and CST6 (cystatin B) with one type of progressive myoclonus epilepsy (MIM 254800). The loci for several monogenic hereditary disorders have been mapped to chromosome 21, such as the autoimmune polyglandular disease syndrome (MIM 240300), one form of manic-depressive illness (MIM 125480), one form of hereditary deafness (MIM 601072), and one form of a platelet disorder. The genes for all of these disorders map outside of the DS critical region, and all but one map in the gene-rich 21q22.3 region.

The following genes map in the so-called DSCR (from D21S17 to ETS2):

1. Carbonyl reductase (CBR) is one of several monomeric, NADPH-dependent oxidoreductases with wide specificity for carbonyl compounds. Lymphoblasts with increased copy number of CBR show increased aldo-, keto-, and quinone reductase activity.

2. SIM2 is homologous to the drosophila single-minded gene. Its protein product is a transcription factor with basic helix-loop-helix motif and two PAS domains. The drosophila sim protein is a master developmental regulator of the fly nervous system midline lineage. The role of three copies of SIM2 in trisomy 21 is under investigation.

3. The gene for the p60 subunit of the human chromatin assembly factor I (CAF1p60) encodes a protein that belongs to the WD-motif family and interacts with other polypeptide subunits to promote assembly of histones to replicating DNA. Its potential role in some phenotypes of DS is also under investigation.

4. The holocarboxylase synthetase (HCS) gene encodes an enzyme that catalyses biotin incorporation in various carboxylases involved in fatty acid synthesis, gluconeogenesis, or amino acid catabolism.

5. The ERG oncogene is related to the ets family of oncogenes. It encodes a nuclear phosphoprotein that binds to purine-rich sequences, and perhaps it is required for maintenance or differentiation of early hematopoietic cells. Translocation of chromosome 21 associated with some forms of myeloid leukemias or Ewing sarcomas show breakpoints within the ERG gene, resulting in abnormal fusion of mRNA transcripts. The role of ERG in some phenotypes of DS is unknown.

6. The gene for G-protein-coupled inwardly rectifying potassium channel (GIRK2) has been also mapped within the DSCR. Its mouse homolog gene is responsible for the weaver mutant mouse. The GIRK2 belongs to a family of proteins that participate in the formation of heteromultimeric channels whose activation is regulated via a G-protein-coupled receptor. The role of GIRK2 in DS is unknown.

7. The gene for the small polypeptide PEP19 that accumulates in the developing cerebellum encodes a cytoplasmic protein containing several motifs common in proteins involved in calcium-dependent signal transduction. It is predominantly expressed in cerebellar Purkinje cells and granule cells of the olfactory bulb.

8. The gene for TPRD that encodes a protein with tetratricopeptide repeat motifs; these domains were found in proteins involved in the regulation of RNA synthesis or mitosis. The involvement of this gene in DS is unknown.

Short sequences of additional genes map in the DSCR and have been obtained as parts of the exon trapping and cDNA selection experiments or the EST collections from various laboratories. The full content of genes in the DSCR and other parts of 21q will soon permit the exploration of the contribution of each gene to the trisomy 21 phenotypes.

THE TRANSCRIPTION/GENE MAP   A medically and biologically important map is being developed, in which the mapping objects are sequences from transcripts of chromosome 21 genes. Two main methods, namely exon trapping and cDNA selection, using the cloned material from the physical maps, are now contributing to the development of such a map. More than 1000 partial sequences from chromosome 21 genes have already been identified; these sequences are probably obtained from at least 50% of the genes of this chromosome. In addition, large international efforts to partially sequence hundreds of thousands of human cDNAs from different tissues (ESTs) will soon result in the mapping of many new transcripts to chromosome 21. Finally, future efforts to determine the sequence of the entire 21q will provide the basis for understanding the contribution of chromosome 21 genes in human disease and DS in particular.

MOUSE MODELS FOR TRISOMY 21

The laboratory mouse has attracted attention as a potential model for trisomy 21. Because three copies of many genes are contributing to DS transgenic mice with three or more copies of the mouse homologs of chromosome 21, genes can serve as models for overexpression of selected genes. Transgenic mice with overexpression of genes such as SOD1 or APP or other genes have been made in order to study the contribution of each gene to the phenotype. Furthermore, breeding of transgenic mice with different transgenes will produce strains with more than one overdosed gene. The use of YACs for microinjected material into mouse oocytes will also permit the study of overexpression of several neighboring genes (perhaps all of the DSCR genes) in one transgenic strain.

Human chromosome 21 is homologous to segments of three mouse chromosomes, namely mouse chromosomes 16, 17, and 10, as shown in Fig. 119-4A. The entire DSCR is included in the mouse chromosome 16. A mouse with trisomy 16 (Ts16) was created that exhibited some characteristics of DS; however, its value was limited because Ts16 mice die *in utero*, and mouse chromosome 16 contains a number of genes found on human chromosomes other than 21. A more recent mouse model has been generated using a reciprocal chromosomal translocation. This model, Ts65Dn, contains a partial trisomy 16 that corresponds to human chromosome 21 from marker APP to MX1, which includes all of the DSCR. However, in addition, the Ts65Dn mouse contains a trisomy for the pericentromeric region of mouse chromosome 17 that is not homologous to human chromosome 21. The Ts65Dn mice display a variety of phenotypic abnormalities, in-

cluding early developmental delay, reduced birth weight, muscular trembling, male sterility, abnormal facies, and impaired performance in the Morris water maze test. The heart defect characteristic of DS has never been observed in liveborn Ts65Dn mice, nor do these mice show the pathology of early-onset Alzheimer's disease. More extensive evaluation of the phenotype of the Ts65Dn mice is needed to further assess the similarity of this mouse model to the human trisomy 21.

TRISOMY: MOLECULAR PATHOPHYSIOLOGY OF INCREASED GENE DOSAGE

Trisomy 21 and all other partial or full trisomies are fascinating disorders in which the phenotypes do not result from abnormal gene products but result from increased (three instead of two) copies of *normal* genes. The different phenotypes of trisomy 21 can therefore be viewed as the result of the increased concentration of gene products of a number of genes that map on chromosome 21. Gene dosage effects for autosomal loci have been described in Drosophila. In addition, overexpression of transgenes in mice cause distinctive phenotypes. For example, mice with an additional copy of the human erythropoietin gene develop polycythemia, a condition of increased number of red blood cells resulting from the stimulatory hematopoietic effect of the increased levels of erythropoietin in mouse.

A duplication of a relatively small region (about 1.5 Mb) on chromosome 17 that includes the PLP22 gene causes Charcot-Marie-Tooth disease type IA, which is a common autosomal-dominant peripheral neuropathy. Overexpression of bmi-1 gene (a member of the polycomb-group gene family) in transgenic mice results in abnormalities of the axial skeleton of the animals. Furthermore, transgenic mice with overexpression or ectopic expression of hox transgenes develop skeletal abnormalities and other malformations. It is therefore conceivable that the increase dose of some chromosome 21 genes trigger directly or indirectly (through products of genes throughout the genome) a pathway that results in a physical abnormality, homeostatic disturbance, altered developmental process, and abnormal cognitive function. It is also conceivable that some but not all genes, when in three copies, result in an abnormal phenotype. There are perhaps hundreds of genes on chromosome 21, a trisomy of which does not have any effect on the phenotype. In contrast, the trisomy 21 of some genes may always be detrimental for the organism and always results in an abnormality (Fig. 119-5A). Furthermore, some phenotypes may be allele-specific (i.e., only the triplication of certain alleles is associated with a phenotype), whereas extra copies of other alleles are compatible with normal development (Fig. 119-5B). Of course, as with many of the Mendelian, monogenic disorders, the phenotype can be modified by the contribution of the protein products of all of the other human genes, as well as by environmental factors.

Gene dosage may be important in a number of gene products. Some illustrative examples from genes in mammals include the following:

1. Receptors and ligands. Increased amounts of ligands or receptors may modify the receptor-mediated cascades. For example, as mentioned above, increased levels of erythropoietin (a ligand for the erythropoietin receptor) lead to increased volume of red blood cells because of stimulation of erythropoiesis. Overexpression of the low-density lipoprotein receptor in transgenic mice prevents diet-induced hypercholesterolemia.
Figure 119-5 **(A)** Schematic representation of the effect of different chromosome 21 genes on the pathophysiology of Down syndrome. Filled squares represent genes, three copies of which contribute to the DS syndrome. Empty squares represent genes that, if trisomic, do not contribute to the DS phenotype. **(B)** Possible effects of trisomy of genes in the pathophysiology of Down syndrome. Examples of allele-independent and allele-dependent dosage effects are shown. In the allele-dependent example, the combination of two stripped and one gray allele contributes to the phenotype; in contrast, the combination of two gray and one stripped allele does not have an effect on the phenotype.

2. Genes important in pattern formation in development. The overexpression or ectopic expression of hox and other development-controlling genes in transgenic mice results in abnormalities of the skeleton and other organs.

3. Enzymes. The overproduction of such proteins involved in key steps of metabolic pathways may result in a recognizable phenotype. A mutant form of alpha$_1$-antitrypsin, which acts as antithrombin III, causes a fatal bleeding disorder from an effective increase of antithrombin III activity by 50%. However, the enzyme levels are usually not tightly regulated, and in general, three copies of genes encoding enzymes are probably not associated with phenotypes of trisomy.

4. Molecules involved in cell–cell interactions. The rate of cellular adhesivity is modified by differences in concentration of the neural cell adhesion molecule (NCAM). A 50% increase in concentration produces a fourfold increase in cell adhesion. This particular alteration may be important for some aspects of morphogenesis and anomalies of trisomy.

5. Subunits of multimeric proteins. Many proteins are composed of a number of subunits, each being a product of a different gene. The number of molecules of each subunit in the multimeric protein is constant and well-regulated. Abnormalities in the function of the multimeric protein can therefore arise by a change in the number of molecules of a particular subunit in the whole complex. This abnormal stoichiometry may result from the extra copy of a certain gene in a trisomy. Imbalance of α- and β-subunits of human hemoglobin leads to different forms of thalassemias (hereditary anemias).

6. Transcription factors. Gene products that regulate the expression of "downstream" genes are perhaps the best candidates for gene-dosage imbalance. Increased concentration of transcriptional regulators may either increase or decrease the expression of genes or alter the temporal or tissue distribution of expression of these genes.

The examples and possibilities listed above are only some alternatives to understanding the relationship of increased gene product and a resulting phenotype. The list can be enriched by other examples of different classes of gene products; furthermore, additional examples come from other model organisms, cellular biology, and transgenic animals.

THE FUTURE

Patients with Down syndrome will greatly benefit from the results of the human genome project, in the identification of all chromosome 21 genes and the elucidation of their function. Products of these genes will be associated with specific phenotypes of the syndrome. Therapeutic interventions based on the molecular pathophysiology of the syndrome will be introduced that may ameliorate or prevent the appearance of certain phenotypes. Better, faster, and more accurate diagnostic methods will be introduced. Further understanding of the molecular and cellular bases of cognitive functions may also lead to prevention or treatment of the mental impairment of this common syndrome.

120 The 22q11 Deletion

DiGeorge and Velocardiofacial Syndrome

DEBORAH A. DRISCOLL AND BEVERLY S. EMANUEL

INTRODUCTION

The association of thymic aplasia with congenital hypoparathyroidism was initially noted by Lobdell in 1959 but was not recognized as a syndrome until 1965, when Dr. Angelo DiGeorge described a group of infants with congenital absence of the thymus and parathyroid glands. Subsequently, facial dysmorphia and cardiac defects, specifically conotruncal malformations, were included in the spectrum of DiGeorge syndrome (DGS) (MIM 188400). Acknowledgment of the phenotypic overlap with velocardiofacial syndrome (VCFS) (MIM 192430) and identification of a common genetic etiology for these disorders has led to further expansion of the phenotype and a better understanding of the physical, cognitive, neurological, and psychiatric disorders that DiGeorge and velocardiofacial patients may develop.

DGS was presumed to be a heterogeneous disorder. However, cytogenetic and molecular studies have shown that deletion of chromosomal region 22q11 is the leading cause of DGS and VCFS. This may result from an unbalanced translocation with monosomy 22pter→q11.2, a cytogenetically visible interstitial deletion of 22q11 [del(22)(q11.21q11.23)] or a submicroscopic deletion. In rare instances, DGS has been associated with other chromosomal abnormalities, in particular, deletions of the short arm of chromosome 10 [del(10)(p13)]. Individual case reports of other chromosomal rearrangements seen in association with DGS include monosomy and trisomy 18q, monosomy 18p, monosomy 12p with trisomy 1q, monosomy 5p, partial trisomy 1q, and duplication 9q. DGS has been associated with exposure to teratogens such as retinoic acid and alcohol, and with maternal diabetes. There have been several reports of cytogenetically normal infants with DGS and renal agenesis born to women with insulin-dependent diabetes. Molecular studies of two of these patients failed to detect a deletion within 22q11.

DGS is believed to arise as a result of abnormal cephalic neural crest cell migration into the third and fourth pharyngeal arches. The neural crest cells populate the pharyngeal pouches that contribute to the development of the bones of the skull, mesenchyme of the face and palate, thymus, and thyroid, and the neuronal constituents of the head and neck. Kirby (1983) demonstrated that removal of the premigratory cardiac neural crest cells in the chick

embryo results in cardiac outflow tract anomalies similar to those seen in DGS. The cardiac neural crest cells have also been shown to be important in supporting the development of the glandular derivatives of the pharyngeal arches, lending further support to the hypothesis that this is a disorder of the neural crest cells (Kirby and Bockman, 1984).

DGS was initially considered a rare disorder. However, recent studies suggest that the 22q11 deletion, seen in approximately 90% of DGS patients, may occur as frequently as 1 in 3000–4000 live births. The majority of 22q11 deletions occur as new mutations in the affected individual. However, a deletion may be transmitted in an autosomal-dominant fashion from parent to offspring. The clinical features are highly variable between individuals and within families with the 22q11 deletion, ranging from classic DGS to individuals with mild facial dysmorphia and a history of learning and speech difficulties. Although previously described as two distinct disorders, DGS and VCFS are manifestations of a single disorder, the 22q11 deletion.

CLINICAL FEATURES

DiGEORGE SYNDROME The three classic features of DGS include congenital cardiac defects, immune deficiencies secondary to aplasia or hypoplasia of the thymus, and hypocalcemia resulting from small or absent parathyroid glands. The cardiovascular malformations involve the conotruncal region and include interrupted aortic arch type B, truncus arteriosus, and tetralogy of Fallot. The immunologic deficits are variable. Although some patients may have a profound immunodeficiency requiring thymic transplantation, many patients can maintain reasonable lymphocyte counts and normal proliferative responses to mitogens. Recent studies suggest that patients are at risk for a spectrum of parathyroid gland abnormalities, including latent hypoparathyroidism which may evolve into hypocalcemic hypoparathyroidism during adolescence or early adulthood. Patients with DGS often have dysmorphic facial features, such as hypertelorism, low-set prominent ears, and micrognathia. Since 1965, the spectrum of clinical features associated with DGS has expanded to include cleft palate, cleft lip, renal agenesis, neural tube defects, and hypospadias. Advances in medical and surgical management of children with complex congenital cardiac disease have led to increased survival of newborns and children with DGS. Recent neuropsychological evaluations indicate that these children are at risk for cognitive impairment and neurological and psychiatric problems.
Figure 120-1   Frontal and side views of two patients with the 22q11 deletion syndrome. **(A)** Note prominent nasal root, bulbous nasal tip, protruberant right ear with underdeveloped superior helix in 9-month-old Hispanic male. **(B)** Note prominent nasal root, bulbous nasal tip, malar hypoplasia, long facies, thick superior helices, and protruberant ears in 11-year-old Caucasian male. (Kindly provided by Dr. EH Zackai and DM McDonald-McGinn, MS.)

VELOCARDIOFACIAL SYNDROME   The major clinical features in VCFS include palatal abnormalities (cleft palate, submucous cleft palate and velo-pharyngeal insufficiency [VPI]), cardiac defects, learning disabilities, and a characteristic facial appearance. Other features seen less frequently include microcephaly, short stature, slender hands and digits, inguinal and umbilical hernias, and scoliosis. Parents may report a history of nasal regurgitation, feeding difficulties, and failure to thrive. In contrast to DGS, ventricular septal defects are the most frequent cardiac defects in VCFS patients. Characteristic facial features have been described that include a long face, a prominent nose with a bulbous nasal tip and narrow alar base, almond-shaped or narrow palpebral fissures, malar flattening, recessed chin, and malformed prominent ears (Fig. 120-1). However, these features are not always apparent during infancy and childhood.

An early study of clinically diagnosed VCFS children reported a history of developmental delay and mean verbal IQ scores in the dull normal intelligence range to mildly retarded range. More recently, an analysis of the psychoeducational and neurodevelopmental status of a cohort of patients, ages 4–20, with the 22q11 deletion, found similar full-scale IQ scores (mean 73.1 ± 10.1). In contrast, there was a striking difference between verbal and performance IQ scores with 9 of 10 patients demonstrating higher verbal IQ scores. These studies suggest that both males and females with the 22q11 deletion are at risk for nonverbal learning disabilities.

In addition to developmental delay and hypotonia, neural tube defects have been described in a small number of patients. Magnetic resonance imaging (MRI) of the brains of VCFS patients has identified several structural brain abnormalities including a small vermis, small posterior fossa, and small cysts adjacent to the anterior horns, suggesting that neurological findings may not be uncommon. However, these findings did not appear to correlate with developmental, cognitive, or personality disorders. In contrast,

Lynch et al. (1995) described a symptomatic 34-year-old man with VCFS and a 22q11 deletion who presented with progressive gait difficulties, muscle stiffness, dysarthria, and dysmetria suggestive of a neurodegenerative disorder. Cerebellar atrophy was diagnosed by MRI. The significance of these findings will require prospective neurological assessments of deletion-positive patients to determine their risk for developing neurological problems.

Recent studies suggest that individuals with VCFS are at a higher risk than the general population to develop schizophrenia during late adolescence and early adulthood. Additional studies that include a larger sample size will be necessary to determine the relative risk for developing schizophrenia in this population of patients. Molecular studies of families with schizophrenia have suggested linkage to the long arm of chromosome 22, and it has been hypothesized that there may be a schizophrenia-susceptibility gene in this region. However, it remains to be proven whether these two findings indicate the presence of a single locus associated with schizophrenia within the DiGeorge chromosomal region (DGCR) on 22q.

PHENOTYPIC VARIABILITY ASSOCIATED WITH THE 22q11 DELETION SYNDROME There is a wide range of intra- and interfamilial phenotypic variability associated with the 22q11 deletion. While some individuals present with classic findings of DGS, others, including the parents of some individuals, have relatively subtle features such as minor dysmorphic facial features and mild cognitive impairment. Furthermore, the observed differences between patients with DGS and VCFS probably reflects an ascertainment bias. For example, the majority of DGS patients are identified in the neonatal period with a major congenital heart defect, whereas many patients with VCFS are diagnosed in a cleft palate or craniofacial center and remain unrecognized until they reach school age when speech and learning difficulties are evident. DGS and VCFS were previously recognized as two distinct disorders. However, there is significant phenotypic overlap and they share a common etiology. Thus, we and others consider deletion-positive DGS and VCFS patients as having the same disorder, the 22q11 deletion syndrome.

OTHER DISORDERS ASSOCIATED WITH THE 22q11 DELETION The DiGeorge anomaly has been observed in several other syndromes, including CHARGE association, asymmetric crying face syndrome, Kallman syndrome, and Noonan syndrome. However, the 22q11 deletion has not been found to be causally related to these disorders in a significant number of cases. In contrast, deletions of 22q11 have been detected in patients with conotruncal cardiac malformations, conotruncal anomaly face syndrome (CTAFS), and Opitz syndrome. Knowledge of the genetic basis for these disorders has also expanded the spectrum of features associated with DGS and, more specifically, with the 22q11 deletion.

CONOTRUNCAL CARDIAC MALFORMATIONS Several studies have detected 22q11 deletions in patients with isolated and familial forms of congenital cardiac defects, suggesting that the genes in this region play a major role in cardiac development. Goldmuntz et al. (1993) demonstrated that 20–30% of newborns and children ascertained through the cardiology clinic with one of the three most common types of cardiac defects seen in DGS (interrupted aortic arch type B, truncus arteriosus, and tetralogy of Fallot) have deletions within 22q11. Although patients with hypocalcemia and immunodeficiencies were excluded from the study, prospective follow-up of these patients has demonstrated

that they eventually manifest subtle dysmorphic facial features and report a history of nasal regurgitation suggestive of velopharyngeal insufficiency or unrecognized palatal problems. Similar findings were noted in the reported familial studies.

CONOTRUNCAL ANOMALY FACE SYNDROME Conotruncal anomaly face syndrome (CTAFS) has striking similarities to DGS and VCFS and is characterized by the presence of conotruncal cardiac defects in association with a characteristic facial appearance. The facial features include ocular hypertelorism, lateral displacement of the inner canthi, flat nasal bridge, small mouth, narrow palpebral fissures, bloated eyelids, and malformed ears. This syndrome has been well characterized in a population of Japanese patients. The finding of 22q11 deletions in CTAFS patients confirmed an earlier suggestion that CTAFS and VCFS are the same entity.

OPITZ/GBBB SYNDROME Recent cytogenetic and molecular studies suggest that Opitz/GBBB syndrome is genetically heterogeneous. However, there appears to be at least one autosomal-dominant locus on chromosome 22q11.2. Opitz/GBBB syndrome is characterized by hypospadias, laryngotracheal anomalies, and hypertelorism. Patients may have other features, including cleft lip and palate, cardiac defects, umbilical and inguinal hernias, cryptorchidism, imperforate anus, and facial dysmorphia such as telecanthus, prominent nasal bridge, or depressed nasal root with anteverted nares. Four patients, including a father and son, with Opitz syndrome with 22q11 deletions have been reported, suggesting that, in some cases, deletions within 22q11 are causally related to Opitz syndrome. Linkage analysis of families with Opitz syndrome provide additional evidence that there is a genetic locus within 22q11 responsible for this disorder as well as a locus on the X chromosome (Xp22). While there are some phenotypic similarities between these disorders, additional studies will be necessary to determine if Opitz syndrome is a genetically distinct disorder from DGS and VCFS.

CYTOGENETIC AND MOLECULAR STUDIES

Cytogenetic studies of patients with DGS provided the initial evidence linking chromosome 22 to DGS. Early reports of DGS patients with unbalanced translocations resulting in the loss of 22pter→q11 and two patients with interstitial deletions of 22q11 suggested that this region of 22 was important in the etiology of DGS. Subsequently, restriction fragment-length polymorphism analysis and DNA dosage studies demonstrated that approximately 90% of cytogenetically normal DGS patients have microdeletions within 22q11. The presence of features common to DGS in patients diagnosed with VCFS prompted investigators to study VCFS patients for evidence of a 22q11 deletion. Cytogenetic studies using high-resolution banding techniques detected interstitial deletions (del[22][q11.21q11.23]) in 20% of VCFS patients. Molecular studies with chromosome 22 probes previously shown to be deleted in patients with DGS demonstrated that the majority of individuals with VCFS have deletions of 22q11. Furthermore, these studies coincided with the increasing utilization of fluorescence *in situ* hybridization (FISH) for the detection of microdeletions and subtle translocations. FISH of metaphase chromosomes using DNA probes from the DiGeorge chromosomal region (DGCR) led to a dramatic increase in the detection of 22q11 deletions in patients with features of DGS, VCFS, CTAFS, and conotruncal cardiac malformations (Fig. 120-2).
Figure 120-2   FISH. Metaphase chromosomes from a patient with 22q11.2 deletion syndrome hybridized with the probe N25 (D22S75) from the DGCR and control probe cos 82 that marks the distal long arm of 22. A hybridization signal for N25 is seen on only one chromosome 22 (arrow). This is consistent with a deletion on the other 22 (arrowhead).

THE DiGEORGE CHROMOSOMAL REGION   The majority of patients have large deletions (1–2Mb) within 22q11; this commonly deleted region is referred to as the DiGeorge chromosomal region (DGCR). Delineation of this region was initially based on the finding of a consistently deleted region within 22q11 in patients with DGS; the minimal region of overlap in the first 14 patients studied spanned the region from D22S75 (N25) through D22S259 (R32). Since then, efforts in several laboratories have been directed toward determining the "minimal critical region" or the smallest region of overlap between patients with unbalanced translocations and interstitial deletions. YAC and cosmid contigs have been constructed across this region to facilitate the identification of candidate genes, and pulsed field gel electrophoresis (PFGE) and translocation breakpoint mapping have been utilized to develop a physical map of the region.

The positioning of DGS/VCFS-associated translocations in this region of 22 has been used to refine the localization of DNA markers within the region and to narrow the "minimal critical region." Many of these translocations serve as landmarks within 22q11 (Fig. 120-3). Initially, the critical region was defined by positioning a balanced 10;22 translocation (GM05878) established from an unaffected father of a child with DGS. Subsequently, an unbalanced 11;22 translocation (GM00980) from a VCFS patient was positioned centromeric to the 10;22 translocation as the distal boundary of the minimal critical region. More recently, we have narrowed the critical region to a 200- to 300-kb segment by positioning the 22q11 breakpoint of an unbalanced 15;22 translocation from a patient with features of DGS and VCFS between locus D22S75(N25) and GM00980. The proximal boundary of the critical region and the commonly deleted region lies between loci D22S427 and D22S36.

Within this "minimal critical region" lies a balanced 2;22 translocation that was initially described by Augusseau in 1986. The patient (ADU) had telecanthus, micrognathia, severe aortic coarctation with a hypoplastic left aortic arch, decreased E rosettes, and mild neonatal hypocalcemia consistent with a diagnosis of partial DGS. Her mother (VDU), who is also a balanced carrier of this translocation, reportedly has features suggestive of VCFS including hypernasal speech, micrognathia, and an inverted T4/T8 ratio. This is the only balanced translocation in the region that is associated with a classical DGS/VCFS phenotype. Budarf et al. (1995) recently cloned this translocation and identified a candidate gene, DGCR3, which is disrupted by the chromosomal rearrangement. Numerous other DGS/VCFS-associated translocations have been localized within the commonly deleted region, distal to the minimal critical region (Fig. 120-3).

PARENTAL ORIGIN OF THE 22q11 DELETION   Sporadic 22q11 deletions may be of either maternal or paternal origin. Several investigators have suggested that there may be an excess of maternally-derived *de novo* 22q11 deletions; however, these studies are limited by their small sample size. Furthermore, both maternally and paternally derived DGS/VCFS-associated translocations occur with approximately equal frequency, suggesting that there is not a preferential parental origin associated with DGS and VCFS. Hence, it is unlikely that parental origin accounts for the phenotypic variability seen in association with the 22q11 deletion. This is in contrast to Prader-Willi and Angelman syndromes, where paternal and maternal deletions of chromosome 15q11–13, respectively, are the rule.

CLINICAL AND PRENATAL DIAGNOSIS

Deletions of 22q11 may be detected using high-resolution banding techniques; however, several studies have clearly shown that FISH of metaphase chromosomes using DNA probes from this region of chromosome 22 is the most efficient method for detecting 22q11 deletions. Routine cytogenetic analysis continues to be important for the detection of other chromosomal rearrangements, such as translocations, which may involve chromosomes other than 22. Hence, it is recommended that FISH be used as an adjunct to routine cytogenetic analysis.

At the present time, many commercial and hospital-based laboratories are utilizing FISH with the probes from the DGCR for the clinical and prenatal detection of the 22q11 deletion (Fig. 120-2).

Antenatal detection of the 22q11 deletion by FISH has been successfully performed on cultured amniocytes and chorionic villi obtained from at-risk pregnancies by FISH. Pregnancies considered at high risk include those of deletion-positive parents and those in which ultrasound or echocardiography demonstrates a fetal conotruncal cardiac malformation. Although the recurrence risk for normal parents with a previously affected child is low, parents often request prenatal testing for the deletion to exclude the small possibility of germline mosaicism. Since the size and extent of the deletion do not correlate with the phenotype, the phenotypic outcome cannot be predicted based solely on the presence of a deletion. Fetal imaging techniques, such as ultrasonography and fetal echocardiography, may be used to evaluate the
Figure 120-3   Diagram of the DGCR demonstrating the relative positions of several loci and translocations, including ADU/VDU and the t(15;22), GM00980, and GM05878, which have been used to define the minimal critical region. The location of the breakpoints associated with the interstitial deletions or microdeletions and the distal translocations are included. The commonly deleted region or DGCR includes the deletion boundaries and the minimal critical region.

fetus for the presence of a cleft palate and/or cardiac malformation. Subtle congenital anomalies, such as a submucous cleft palate and dysmorphic features, cannot be appreciated by sonography. Fetal sonography and echocardiography are the only available prenatal tests that are helpful when evaluating at-risk pregnancies that are not causally related to an abnormality of 22q11.

MANAGEMENT ISSUES   Patients with the 22q11 deletion are ascertained through a variety of medical specialty clinics on the basis of their presenting feature(s). Recognition of which patients are at risk for the deletion is important so that the medical community and the schools can meet their needs. This has been clearly demonstrated in the cardiology clinic where a significant number of deletion-positive patients were ascertained solely by the presence of a conotruncal malformation. Because of the wide range of congenital anomalies, immune, endocrine, speech, neurologic, cognitive, and psychiatric problems that 22q11 deletion

patients may develop, we urge clinicians to consider comprehensive evaluations by a team of medical professionals in genetics, cardiology, immunology, endocrine, plastic surgery, speech and hearing, and developmental pediatrics. Because DGS, VCFS, CTAFS, and (in some instances) Opitz/GBBB syndrome share a common etiology, we should consider deletion-positive patients with these disorders as having the 22q11 deletion syndrome. Prospective studies of 22q11 deletion patients will further delineate the range and severity of physical, cognitive, and neuropsychological problems for which these patients are at risk.

Furthermore, identification of a 22q11 deletion enables the clinician to provide the affected patients and their families with a more accurate assessment of their recurrence risk. Although the majority of the 22q11 deletions occur *de novo* only in the affected individual, a deletion may be transmitted in an autosomal-dominant fashion. Hence, we recommend deletion testing of parents of

deletion-positive individuals. Because the phenotype is so variable, parents with only minor features and mild cognitive impairment are often undiagnosed until the birth of a more severely affected child. Features that are highly suggestive of a 22q11 deletion in one of the parents include mild facial dysmorphia, history of poor school performance, hypernasal speech, and nasal regurgitation. Deletion-positive parents and children have a 50% chance of transmitting the deletion-bearing chromosome in a subsequent pregnancy.

Presently, it remains difficult to counsel families of nondeleted children with DGS and VCFS unless an etiology such as a translocation or maternal diabetes has been identified. It remains a possibility that these individuals may have a smaller deletion that cannot be detected with the probes currently available or a mutation within one of the genes in the DGCR. Alternatively, there may be more than one chromosomal locus associated with DGS and VCFS.

IDENTIFICATION OF GENES IN THE DiGEORGE CHROMOSOMAL REGION (DGCR)

Two genes, catechol-*O*-methyltransferase *(COMT)* and glycoprotein Ibβ *(GpIbb)*, have been mapped to the DGCR, but distal to the minimal critical region. COMT is important in the metabolism of catecholamines, such as noradrenaline, adrenaline, and dopamine. It has been suggested that it may play a role in the development of the psychiatric disorders associated with the 22q11 deletion syndrome. *GpIbb* is a component of the major platelet receptor for von Willebrand factor. Defects in the receptor result in a rare autosomal-recessive bleeding disorder, Bernard-Soulier syndrome (BSS), which is characterized by excessive bleeding, thrombocytopenia, and very large platelets. A single patient with features of BSS and VCFS with a 22q11 deletion has been described. Haploinsufficiency for this region of 22 unmasked a mutation in the remaining *GpIbb* allele, resulting in manifestations of BSS. Although presumably an infrequent occurrence, this mechanism, unmasking a recessive allele, might explain some of the phenotypic variability seen among patients with 22q11 deletions.

Several genes have been isolated from the DGCR that may play a role in the development of some of the phenotypic features observed in association with deletions of 22q11. The most promising candidate genes lie within the minimal critical region. One of the first novel genes described in the region, N25 cDNA clone, was identified by screening fetal liver and brain libraries with a chromosome specific *Not*I linking clone from the commonly deleted region. The N25 cDNA is expressed in adult skeletal muscle, and studies are in progress to determine its function and developmental expression pattern. *DGCR3* was identified using a positional cloning approach. It was hypothesized that the only balanced translocation associated with a DGS/VCFS phenotype in the DGCR, ADU/VDU [t(2;22)], interrupts a locus critical to DGS. The 2;22 translocation disrupts an open reading frame whose predicted protein product is weakly homologous to rat and mouse androgen receptor sequences at the N-terminal transactivation domain. In addition, it contains a leucine zipper motif, suggesting that it might be a DNA binding protein. Another candidate gene, *DGCR2*, maps 10 kb distal to the ADU/VDU breakpoint, within the minimal critical region, and is deleted in known-deletion patients. This gene is expressed in a variety of human adult and fetal tissues and codes for a potential adhesion receptor, which might mediate specific adhesive interactions resulting in abnormal migration of the neural crest cells or interaction with the branchial arches. By sequence analysis, this gene appears to be homologous to the genes *LAN* and *IDD*. Although these genes are not disrupted by the ADU/VDU translocation, the translocation may separate a locus control region from the coding sequence. The human homolog of the rodent citrate transport protein *(CTP)* gene has been cloned and mapped to the minimal critical region in 22q11. *CTP* is located on the mitochondrial inner membrane and functions as an anion transport protein. However, its role in the 22q11 deletion syndrome remains to be determined. Several groups have isolated a gene *(CLTCL/CLTD/CLH-22)* with significant homology to clatharin heavy chain, a major structural component of coated pits and vesicles. *CLTCL* lies within the minimal critical region and is expressed predominantly in adult skeletal muscle. Further studies will be necessary to determine the possible role this gene plays in the 22q11 deletion syndrome.

Several other genes have been identified distal to the minimal critical region, suggesting that they may not be as crucial to the phenotype. Functional and genetic analyses of these genes may determine whether they modify or influence the phenotypic outcome. The novel gene, N41 cDNA, is expressed in human tissue, including heart, liver, brain, and placenta. A zinc finger gene, *ZNF74*, is expressed during mouse embryogenesis as well as in human fetal tissues. A cDNA clone, T10, isolated from a mouse embryo library, encodes a serine and threonine-rich protein with no strong homologs or known function. This gene is expressed during early mouse embryogenesis as well as in human fetal tissue, but is probably not the major gene involved in DGS. Another cDNA, *TUPLE1*, was isolated from a human fetal brain library and a 10.5-day mouse embryo library. *TUPLE1*, also referred to as *HIRA*, encodes a putative transcriptional regulator. Although it has been shown to be deleted in patients with known 22q11 deletions, it does not appear to be deleted nor rearranged in nondeleted patients with DGS, VCFS, or conotruncal cardiac defects. Finally, the gene LZTR-1, was isolated from a fetal brain cDNA library. Sequence analysis demonstrates homology to a leucine-zipper-like transcriptional regulator protein. *LZTR-1* is expressed in fetal brain, heart, liver, kidney, and lung. However, the *LZTR-1* gene is not consistently deleted in DGS patients and does not appear to be rearranged in the nondeleted patients. Thus, it is unlikely to be a good candidate gene for the major features of DGS/VCFS.

Further studies are necessary to understand the role that each of these genes might play in the development of the complex and variable phenotype of the 22q11 deletion syndrome. Additional studies are in progress to determine whether nondeleted patients with DGS/VCFS have mutations within these or other genes in the minimal critical region. To understand the effects of haploinsufficiency of these genes, functional studies and the creation of transgenic or knockout mice will be required. These studies may enable us to determine if these disorders are caused by deficiency of a single gene or loss of several genes within the DGCR.

CONCLUSION

The 22q11 deletion associated with DiGeorge and velocardiofacial syndrome is one example of a microdeletion syndrome. Such syndromes were well-defined clinical entities prior to the identification of a specific chromosomal deletion. The deletion is rarely identified by routine cytogenetic analysis, often requiring high-resolution banding and/or molecular cytogenetic techniques such as FISH. These techniques have led to the detection of dele-

tions in a proportion of patients with the following clinically recognizable syndromes: Prader-Willi and Angelman syndromes (15q), Miller Dieker and Smith Magenis syndromes (17p), Langer-Gideon (8q), WAGR (Wilm's tumor, aniridia, genital abnormalities, and retardation) (11p), Williams syndrome (7q), Alagille syndrome (20p), and Rubenstein-Taybi syndrome (16p). These disorders have been referred to as "contiguous gene deletion syndromes" or, more recently, "microdeletion syndromes." It has been hypothesized that the clinical features result from the deletion of several different genes in close proximity within the same chromosomal segment. The deleted region presumably contains numerous genes, and it is unlikely that all of these genes play a major role in the development of the phenotype associated with these disorders. Some of these disorders may result from haploinsufficiency of a single gene, whereas others may result from the loss of several genes within the deleted segment. As the genes are identified within the segment lost in each of the microdeletion syndromes, additional studies will be necessary to understand their function and role in the pathogenesis of each disorder.

121 Orofacial Clefting

Jacqueline T. Hecht and Susan H. Blanton

INTRODUCTION

Clefts of the orofacial region are a group of common birth defects that may range from those with little clinical consequence, such as a bifid uvula, to those requiring extensive surgical intervention, such as bilateral cleft lip with palatal involvement. While orofacial clefts often occur as isolated defects, they are also part of over 300 recognized genetic syndromes. In most cases, the underlying etiology is unknown, but it is widely accepted that genetic and nongenetic factors are important. The most common orofacial clefts involve the lips and palate. As with the larger group of orofacial clefts, clefts of these structures most often occur as isolated defects. However, McKusick currently lists cleft lip with or without associated cleft palate (CLP) or only cleft palate (CP) in nearly 100 syndromes each. These do not include the nearly 100 recognized chromosome syndromes.

Whereas the causes of clefting are poorly understood, nonsyndromic cleft lip with or without cleft palate (CL/P) and nonsyndromic cleft palate (CPO) are generally regarded to be distinct conditions. This distinction is based on both population and embryologic studies. Epidemiological and observational studies have demonstrated that CL/P and CPO do not usually segregate together in the same families.

Animal studies have shown that neural crest cells migrate into the region that eventually becomes the facial structures, and these cells play an important role in the skeletal, connective, and dental tissues of facial morphogenesis. The anterior neuropore closes at the fourth gestational week, and there is active growth during the fifth and sixth weeks. Maxillary swellings arise and enlarge through ectomesenchymal proliferation, and these swellings become the anterior portion of the first pharyngeal arch. The medial nasal prominences merge with each other and the bilateral maxillary processes. The upper lip is formed laterally by the maxillary prominences and medially by fused nasal prominences by the end of the sixth week. A defect in any of the developmental steps could lead to a cleft lip.

The primary palate consists of two merged medial nasal prominences called the intermaxillary segment. This segment is made up of two portions, the labial component, which becomes the philtrum and the triangular palatal component of bone that includes four maxillary incisor teeth. The secondary palate includes 90% of the hard and soft palate but does not include the anterior portion

that holds the incisor teeth. The palatal shelves originate from swellings on the medial surface of the maxillary prominences that appear during the sixth week and grow downward and lateral to the tongue. Elevation of the palatal processes to a horizontal plane begins during the seventh week, and closure occurs by the ninth week. Closure occurs by fusion and is slightly later in males than females. Clefts of the secondary palate may result from hypoplasia of the shelves, delayed timing of the shelf fusion, interruption of normal fusion, or a problem in programmed cell death.

CL/P and CPO are complex malformations that require a multidisciplinary approach with evaluations by plastic surgery, otolaryngology, genetics, speech pathology, dental, and dietary disciplines. Practitioners representing these disciplines usually comprise the craniofacial teams that provide care for these children. Multiple surgeries are often required for lip and palate repair. Recurrent otitis media is a common complication, often requiring placement of PE tubes, especially when there is palatal involvement. Dental, especially orthodontic, intervention, is required for most of the children, and speech therapy is commonly necessary because of nasal speech patterns. Finally, genetic evaluation and counseling provides information pertaining to correct diagnosis and recurrence risks for future children. The following discussion will focus on some common causes and research pertaining to the etiology of clefting.

NONSYNDROMIC CLEFTING

NONSYNDROMIC CLEFT LIP AND PALATE (CL/P) CL/P occurs in approximately 1/1000 live births, and males are affected approximately twice as frequently as females. CL/P is unilateral in 80% of cases and bilateral in the remaining 20% (Fig. 121-1). The left side is affected in 70% of the unilateral cases; 85% of the bilateral and 70% of the unilateral cases are associated with cleft of the anterior palate.

Etiologic studies of CL/P are complicated by the difficulties in sorting out the inheritance patterns. Familial recurrences are well-documented but do not follow a Mendelian pattern of inheritance. The multifactorial model was developed to explain the familial recurrences, and the recurrence risk estimates used in genetic counseling practice are based on this model. For isolated cases, a recurrence risk of 3–5% for subsequent pregnancies is given, but higher risks of 10% are quoted if there are other affected first-degree relatives. While the multifactorial model has been useful, it has not provided a completely satisfactory explanation for the observed familial cases. Indeed, complex segregation analyses of different populations have suggested a Mendelian contribution with auto-

Figure 121-1   Infant with bilateral CL/P.

somal-dominant and/or recessive genes that are influenced by other genes, sex, and environmental factors (Table 121-1). Other studies suggest that oligogenic inheritance with as many as six to eight major genes may play a role in the development of CL/P. Growth factors are an example of multiple interacting genes that may play a role in orofacial clefting and are discussed below. Thus CL/P appears to be a genetically heterogeneous condition with multiple factors impacting the final developmental outcome. Identification of these genetic factors has proven to be a challenge.

Two approaches, association and linkage studies, using candidates genes and random mapped polymorphic markers, have been undertaken to study the genetic basis of CL/P. These approaches have been successfully used to delineate the molecular causes of other multifactorial conditions such as Hirschsprung disease and diabetes. The two statistical methods of studying clefting, linkage and association studies, each has strengths and weaknesses. Linkage testing requires multiplex families, generally with at least three affected offspring, and some assumptions regarding the mode of inheritance must be made. With these criteria fulfilled, it is possible to perform genome-wide screening to look for linkage. In some cases, a single family may be sufficient to establish linkage, although this has not been the case with clefting, as there are generally only a few affected individuals in a pedigree. Association studies, on the other hand, make no assumptions about the mode of inheritance. They require only a single affected individual from a family, but large numbers are required. A control population is also needed, and special attention must be paid to ensuring that the allele frequencies being used are correct. Association studies are looking for a specific allele of a gene to be associated with the

disease, so that random testing is not practical, but testing of candidate genes is. Finally, association studies are generally better at detecting modifier loci than a linkage study. Given the apparent complex nature of clefting, it is unlikely that a single method will succeed in elucidating the etiologies of clefting.

Candidate genes have been identified in human and/or murine embryology studies. For example, transforming growth factor-α (TGF-α) is expressed in the pharyngeal pouch and activates epidermal growth factor (EGF/TGFA) receptors. It has been suggested that cell–cell contacts during embryogenesis may be discrete, and sequential events are mediated by growth factor receptor transduction. For this reason, all of the growth factors— such as retinoic acid receptor-α (RAR-α), TGFs, EGF, and so on— are excellent candidates and many of these have been tested. The results of both association and linkage studies are summarized in Table 121-2. Association studies from different populations have suggested that TGF-α plays a role in the development of CL/P. However, two linkage studies have demonstrated that TGF-α does not segregate with the disease phenotype in 20 multigenerational families. TGF-α is now considered to have a modifying effect on the development of CL/P.

Two candidate genes for CL/P, RARA-α and MSX1 (Hox 7), have been identified in murine models. MSX1 knockout mice exhibit craniofacial and tooth abnormalities in addition to cleft palate, and a CL/P gene has been mapped to the mouse chromosomal region containing RAR-α. Association of RAR-α with CL/P has been demonstrated in two population studies but not in a third, and linkage was excluded to RAR-α in ten multigenerational CL/P families. These results suggest that RAR-α does not play a major role in CL/P. MSX1 was excluded in a CLP linkage study, but the results of a recent association study suggest this locus may play a role in CPO.

Linkage studies have suggested there may be CL/P loci on chromosomes 6p, 4p, and 19q. A locus on chromosome 6p was first suggested by Eiberg et al. in 1987, when evidence for linkage to Factor 13A (F13A) at 6p23 was found. Additionally, linkage to F13A was demonstrated in 14 of 21 families from Italy, and chromosomal rearrangements involving 6p in individuals with CL/P have been reported. However, linkage to F13A was not found in 20 US and UK CL/P families, and a subsequent study expanded to include 33 Caucasian CL/P families was not able to confirm linkage to the 6p chromosomal area that spans from F13A to D6S89. A LOD (Log odds) score suggestive of linkage to an anonymous marker, D4S192, was reported in a single large family, and an association study provided evidence for linkage disequilibrium with the same marker. These findings could not be substantiated in 33 multigenerational CL/P families. Finally, linkage has recently been reported to BCL3 on chromosome 19q. Seventeen of thirty-nine families were found to have a posteriori probability of greater than 50% of being linked to this chromosomal region. BCL3 is a proto-oncogene, which was the candidate gene in the immediate chromosomal vicinity. Additional studies need to be performed to determine whether mutations can be identified in BCL3 or whether there is another candidate gene in close proximity to BCL3. The families linked to BCL3 have been excluded from the chromosome 4 and 6 markers, providing additional evidence that CL/P is genetically heterogeneous. A great deal of work remains to be done to identify the genetic loci that contribute to human CL/P. This will entail large numbers of families and populations for linkage and

association studies, respectively, in order to have sufficient power to identify the different CL/P loci.

NONSYNDROMIC CLEFT PALATE (CPO) CPO occurs in 0.4/1000 live births, and females are affected more often than males. CPO most commonly occurs sporadically; however, isolated families with multiple affected family members have been reported. A multifactorial model has also been used to describe recurrence of CPO in families. However, segregation analysis has suggested that a major gene explains half the familial recurrence of CPO. It has also been suggested that an oligogenic model with six loci would explain the data. Interestingly, in a large breeding colony of Brittany spaniels, CPO was found to be segregating as an autosomal-recessive disorder.

A chromosomal locus on chromosome 6p has also been implicated in CPO, but has not been confirmed by linkage studies in multigenerational CPO families. Association of TGFA with CPO has been reported in one study. A systematic study of CPO by both association and linkage methods remains to be undertaken.

SYNDROMIC CLEFT LIP AND PALATE (CLP) AND CLEFT PALATE (CP) Some of the several 100 syndromes that feature orofacial clefts have been mapped, and the genes responsible are known in some cases (Table 121-3). Here we discuss a few of the syndromes in which orofacial clefts are a prominent finding.

Van der Woude syndrome (VWS) is a well-described autosomal-dominant condition associated with CLP and/or CP, cleft uvula, hypodontia, and paramedian lower-lip pits. Lip pits are observed in 65–80% of cases, and surgical removal is recommended as these fistulas may communicate with underlying sali-vary glands, which can produce watery discharge. Not all gene carriers exhibit lip pits or CLP/CP, and family studies suggest that the penetrance is 75–80%. One to three percent of CLP cases are estimated to be VWS. VWS was mapped to chromosome 1q in 1990 with tight linkage to the renin gene. The chromosomal region containing the VWS gene has since been refined to a 4.1-cM region between microsatellite markers D1S245 and D1S414. Linkage of nonsyndromic CL/P and CPO to VWS was excluded using tightly linked markers.

Stickler syndrome (Hereditary Arthro-ophthalmopathy) is an autosomal-dominant condition characterized by flat facies, CP, myopia, retinal detachment, deafness, and epiphyseal abnormalities. Pierre Robin sequence (*see* Sporadic Conditions discussion) may be the presenting diagnosis in infancy. Stickler syndrome demonstrates marked variability, and individuals may inadvertently be misdiagnosed as CPO. Retinal detachments, myopia, and sensorineural deafness are common complications, and annual ophthalmologic and hearing evaluations are suggested. Arthritis occurs in adulthood and may be progressive with advancing age. Mutations in COL2A1 (12q14.3) and COL11A2 (6p21.2) have been identified in individuals with Stickler syndrome. The mutations in COL2A1 produce stop codons that lead to truncated proteins, whereas the characterized COL11A2 mutation causes a change in the splice donor site, resulting in an in-frame exon skipping. The associated phenotype appears to be milder than that observed for COL2A1 mutations; however, only one case has been reported. An autosomal-recessive mutation in COL11A2 has been reported, and the associated phenotype appears to be more severe than the autosomal-dominant form. Other type II collagenopathies, Kniest dysplasia and spondyloepiphyseal dysplasia, also have CP.

An X-linked type of CP (CPX) associated with ankyloglossia (tongue-tie) was first described and characterized in an Icelandic native family and later in a Mennonite native family. Males are affected with CP and tongue-tie, and only rarely will carrier females be similarly affected. Submucous CP and bifid or absent uvula are also found in this condition. The CPX gene was mapped to Xq in a large Icelandic family in 1987 and the map location has been further refined to a 5-cM region within the interval of Xq21.1–q21.31.

CHROMOSOMAL CAUSES OF CLEFTING Velocardial facial syndrome (VCF) or Shprintzen syndrome was first described by Shprintzen et al. in 1978 and is characterized by craniofacial,

Table 121-3
Mapped Clefting Syndromes

MIM	Syndrome	Location	Locus
Cleft lip/palate			
109400	Basal cell nevus syndrome	9q22.3–q31	
129900	EEC syndrome	7q11.2–q21.3	
305400	Faciogenital dysplasia	Xp11.21	FGD1
161200	Nail-Patella syndrome	9q34.1	
263520	Polydactyly with neonatal chondrodystrophy	4q13	
312870	Simpson dysmorphia syndrome	Xcen–q21.3	
313850	Thoracoabdominal syndrome	Xq26.1	
119300	Van der Woude syndrome	1q32–q41	
194190	Wolf-Hirschorn syndrome	4p13.7	
193500	Waardenburg syndrome, Type I	2q235	PAX3
Cleft palate			
101400	Acrocephalosyndactyly type III	7p21.3–p21.2	
301590	Anophthalmos	Xq27–q28	
222600	Diastrophic dysplasia	5q31–17q24.2q33	DTD
211970	Camptomelic dwarfism	17q24.2	SOX9
215150	Chondrodystrophy with sensorineural deafness	6p22–p21.3	COL11A2
154500	Mandibulofacial dysostosis	5q31.3–q32	
311300	Otopalatodigital syndrome	Xq28	
182290	Smith-Magenis syndrome	17p11.2

184840	Stickler syndrome, type 2	6p22–	COL11A2
303400	X-linked cleft palate	Xq13–q21	
214100	Zellweger syndrome 1	7q11	
170995	Zellweger syndrome-2	1p22–p21	PXMP1
170993	Zellweger syndrome-3	8q21.1	PAF1

cardiac, and palatal abnormalities. It is estimated to be the most common syndrome featuring CP, having a prevalence of 1/5000 live births. The facies are distinctive with malar hypoplasia, prominent nose with a squared nasal root and narrow alar base and CP. Hypotonia, failure to thrive, and short stature are frequent in infancy and childhood. Cardiac anomalies include ventricular septal defect, right aortic arch, tetralogy of fallot, and aberrant left subclavian artery. Robin sequence is occasionally observed. Learning disabilities and impairment are consistent findings. Speech development is delayed and hypernasality is common. Phenotypic findings can overlap with the DiGeorge syndrome, which also includes thymic aplasia/hypoplasia and hypocalcemia.

Most cases of VCF syndrome are sporadic, although familial cases demonstrating autosomal-dominant inheritance have been reported. Cytogenetic abnormalities involving 22q11 are detected in approximately 20% of VCF syndrome patients. Deletion of molecular markers from this chromosomal region have recently been identified in 82% of VCF patients. No difference in the sex of the parent transmitting the chromosomal deletion was found among the patients with deletions and on whom DNA was available suggesting that imprinting does not play a major role in the etiology of this syndrome. Further discussion of VCF can be found in Chapter 120.

Trisomy 13 is a common chromosomal abnormality, with a prevalence of 1/5000 live births. Microcephaly, secondary to the holoprosencephaly spectrum of brain abnormalities, microphthalmia, retinal dysplasia, and polydactyly of the hands and sometimes in the feet are common. CLP is present in about 60–80% of cases. Cardiac abnormalities are identified in 80% of cases and

include ventricular septal defect, patent ductus arteriosus, and atrial septal defect. The constellation of phenotypic findings is caused by the presence of an extra chromosome 13, either as a free trisomy or, rarely, as a translocation. The risk of recurrence for trisomy 13 is less than 1% except where maternal age is a factor, which elevates the risk. Translocations are associated with an empiric risk of recurrence of 5–10%, depending on the sex of the parent who is the translocation carrier. Trisomy 13 is generally lethal by 1 year of age with only a few long-term survivors reported.

TERATOGENIC CAUSES OF CLEFTING Fetal Hydantoin syndrome is a constellation of phenotypic findings associated with *in utero* exposure to Dilantin or phenytoin. These findings include unusual facies, digit and nail hypoplasia, and growth and mental deficiencies. CLP is found approximately 11 times more frequently in exposed offspring compared with those not exposed.

Deficiency of folic acid during pregnancy may play an etiologic role in some cases of CL/P and CPO. A recent study has demonstrated that supplementation during pregnancy decreased the birth prevalence of orofacial clefting.

SPORADIC CONDITIONS WITH CLEFTING Pierre Robin sequence is characterized by micrognathia, glossoptosis, and a U-shaped CP. Posterior airway obstruction may occur secondary to the small mandible and tongue obstruction. Hypoplasia of the mandibular area prior to 9 weeks' gestation is postulated to be an initiating defect in this condition. The tongue becomes posteriorly displaced and interferes with the normal movement and fusion of the palatal shelves, causing the large U-shaped cleft compared with the V-shaped palate defect observed in CPO. Deformational processes have also been implicated in some cases.

The etiology and natural history depends on whether there are other associated anomalies or whether it is part of a syndrome as observed in the Stickler syndrome *(see above)*.

Facio-auriculo-vertebral spectrum (Goldenhar/Hemifacial microsomia) is a nonrandom association of anomalies involving the first and second branchial arches. The prevalence is estimated to be 1/3000–5000 live births, and males are affected more often than females. The spectrum includes unilateral hypoplasia malar, maxillary and mandibular regions facial musculature, vertebral and ocular abnormalities, with epibulbar dermoid being the most common eye finding. The clefts most often associated with this spectrum are lateral-like extensions from the corner of the mouth, although CLP and CP have been observed. Unilateral microtia with accessory pits and tags are frequent and may be associated with deafness. The soft palate may show poor resilience and lead to speech problems. Hemivertebrae, most commonly in the cervical spine, are often present, and cardiac and renal anomalies may occur. The etiology is unknown, and there is a very low recurrence risk for other family members.

CONCLUSION

As illustrated, CLP and CP are associated with a wide range of syndromes whose underlying etiologies are diverse. Although not all of the known genes for syndromic forms of CLP and CP have been tested for linkage to the nonsyndromic forms, most of them have been excluded from playing a major role in the development of nonsyndromic CL/P and CPO. Given the complex nature of craniofacial embryology, it is not surprising that many different genes may exert an effect.

122 Molecular Genetics of Hearing Disorders

WILLIAM J. KIMBERLING

BACKGROUND

Hearing is the result of a mechanical transduction process that translates sound waves into neural signals, which are then interpreted by our minds as language, music, signals of danger, or just plain noise. Hearing is a critical sense for communication, and whenever hearing is impaired, oral communication suffers, and one's quality of life is considerably diminished. The cochlea is the sensory organ responsible for hearing; it is complex and hundreds of genes must be responsible for its development and normal homeostasis. Thus, it is no surprise that hearing loss occurs in a great many different genetic disorders.

The three major parts of the ear are the outer, middle and inner ear. The inner ear develops from the otic placode, whereas the middle and outer ear develop primarily as a result of differentiation of the first and second branchial arches. The inner ear is divided into two parts: the membranous labyrinth (balance) and osseous labyrinth or cochlea (hearing). While both structures share certain features, they are quite different in function. Consequently, each part of the ear must be controlled by different sets of genes, but their effects must be well coordinated in order to produce a single effective hearing organ. As expected, some genes are expressed in more than one part of the ear, whereas others are specific. For example, some hearing loss disorders have vestibular symptoms and others do not; some disorders involve neurosensory hearing loss in combination with conductive loss resulting from external and/or middle ear abnormalities, and others have only a neurosensory component. The clinician must be cognizant of the fact that the ear comprises a set of embryologically related but distinct structures, and that patterns of involvement of the parts of the hearing organ are often important clues in the differential diagnosis of hearing disorders.

Hearing loss disorders are divided into syndromic and nonsyndromic categories, depending on whether there are any associated nonotologic symptoms accompanying the hearing deficit. While most childhood deafness is nonsyndromic, advances in the molecular genetics of the auditory system have occurred more with syndromic disorders because they can be recognized as distinct groups and are more amenable to positional cloning strategies.

Epidemiological studies to determine the magnitude of hereditary vs nongenetic causes of hearing loss are not common, especially when adult-onset hearing impairment is being considered.

The role of heredity in causing hearing impairment in children is better defined, and most studies indicate that the overall frequency of deafness in children is about 1/1000. Over one-half of all causes of childhood deafness can be identified as genetic in origin. Information about the role of heredity in adult-onset hearing loss is virtually nonexistent, although one would predict that genes play a major role; the fact that several adult-onset progressive hearing loss genes have been localized supports this hypothesis.

DIAGNOSIS OF HEARING IMPAIRMENT

The diagnosis of hearing impairment is aided by the consideration of a variety of symptoms that permit the subcatergorization of hearing loss disorders into several different groups. The list below gives some of the clinical parameters and tests that are frequently helpful in diagnosing the different forms of hearing impairment:

1. Mode of inheritance (dominant, recessive, x-linked, mitochondrial, not inherited).
2. Age of onset (congenital, early childhood, young adult, and so on).
3. Severity (mild to profound).
4. Ears involved (bilateral vs unilateral or symmetric vs asymmetric).
5. Type of hearing loss (sensorineural, conductive, or mixed).
6. Frequencies involved and audiologic profile (e.g., high frequency, low frequency, U-shaped, and so on).
7. Presence and degree of vestibular deficit.
8. Presence of external-, middle-, or inner-ear malformation.
9. Evaluation for common syndromes: electroretinogram (Usher syndrome), thyroid function and perchlorate discharge test (Pendred syndrome), electrocardiogram (Jervell and Lange-Nielsen syndrome), renal function tests (Alport syndrome).

The audiogram defines the severity of the hearing loss and is an indispensable component to the clinical evaluation of patients and families with hereditary types of hearing impairment. Some families have distinct audiometric patterns, whereas other families show considerable variation in hearing acuity. Examples of selected different audiologic profiles are presented in Figure 122-1. In some disorders, such as Usher Type II, the audiologic profile is quite consistent across families, whereas in other disorders, like Branchio-oto-renal syndrome, the audiological phenotype can vary considerably even between ears of the same person. Hearing can also be assessed using auditory brain-stem responses (ABR)
Figure 122-1 This presents examples of different types of audiograms seen in a few hereditary disorders. The circles and triangles indicate the hearing loss observed in right and left ears, respectively. **(A)** Sloping audiogram characteristic of Usher Type II; the hearing loss is mild in the low frequencies and tapers to a severe-to-profound loss in the high frequencies. **(B)** Two audiograms at different ages and illustrates a configuration and progression typical of dominantly inherited high-frequency hearing loss. **(C)** U-shaped audiogram where the loss of hearing acuity is mostly in the middle frequencies. **(D)** Low-frequency type of hearing impairment. Such audiometric configurations are often helpful in diagnosing specific inherited forms of deafness.

and oto-acoustic emissions (OAE). The ABR is useful for separating a central from a peripheral (i.e., cochlear) hearing problem, and the OAE assesses hair cell function. The age at onset and nature of the progression of the hearing loss are also important variables in characterizing a family's phenotype. Some dominant progressive hearing losses involve a specific range of frequencies early in life, and only at older ages are all the frequencies involved. It is frequently necessary to ask for older audiograms to document the type hearing loss at an earlier age. The role of the inner ear for balance is often forgotten by geneticists, and the presence or absence of vestibular symptoms can often be important for the differential diagnosis. For example, Usher syndrome type I has vestibular areflexia, whereas the milder type II does not. Inner-ear malformations are associated with some syndromes and not others. For example, Pendred syndrome often has a Mondini deformity. The audiogram, vestibular studies, and CT of the temporal bone are essential for giving a full description of the hearing loss phenotype.

CLINICAL FEATURES OF DISORDERS WITH HEARING LOSS

NONSYNDROMIC HEARING LOSS   Dominant Nonsyndromic Hearing Loss   The identification of the genes responsible for nonsyndromic hearing loss has been difficult and slow.

The traditional approach to positional cloning for dominantly inherited disorders relies on having large, multigenerational kindreds. When families are large enough, evidence of linkage can be found without having to pool information from several different families, thus avoiding the problem of heterogeneity. Unfortunately, this research strategy is difficult to apply to dominant congenital profound deafness. Congenitally deaf people belong to a separate subculture and will tend to marry other deaf people, thus complicating attempts to follow gene transmission. Because of this phenomenon, the initial focus of localization of nonsyndromic dominant genes has been directed toward dominantly inherited progressive hearing loss. Because of their later age of onset, members of families with progressive hearing loss seldom see themselves as part of the deaf community and do not marry within it. At least 10 dominant hearing loss genes exist. The first gene for nonsyndromic hearing loss, called DFNA1, was localized to chromosome 5q31 (DFNA is used as code for dominant hearing impairment genes and DFNB for recessive genes; the numerals 1, 2, … are assigned in order of discovery). The first linkage was observed in a large Costa Rican kindred whose members had a rapidly progressing hearing loss with adult onset that initially involved the low frequencies. Replication of this linkage in a second family has not been reported, and so it must be presumed that the gene is uncommon. A second gene was localized to chromosome 13q at or near a nonsyndromic recessive deafness gene (DFNA2). This family had a hearing loss that was evident by 4 years of age. Hearing impairment ranged from 15 to 90 dBHL, and the higher frequencies were more involved than the lower frequencies. The HL was not progressive in most gene carriers. Another dominant progressive hearing loss gene was localized to chromosome 1p32 (DFNA3) in two families, one Indonesian and the other American, both of which showed a progressive loss with onset in the high frequencies. A gene for a progressive hearing loss involving all frequencies was localized to chromosome 19, and a family with high-frequency hearing loss has been linked chromosome 7p15, whereas another with a low-frequency loss was localized to 4p16.3. An up-to-date listing of the new localizations of dominant, recessive, X-linked, and mitochondrial hearing loss genes can be found on the Internet by accessing the Hereditary Hearing Loss Homepage at www.uia.ac.be/u/dnalab/hhh.html . This web site also gives the flanking markers for each linkage as well as the appropriate references citing the original linkage observation.

Recessive Nonsyndrome Hearing Loss   Autosomal recessive nonsyndromic hearing impairment is responsible for 80% of all the cases of childhood deafness. Most deaf-by-deaf marriages result in hearing offspring, a phenomenon that underscores the fact that several different loci are involved. The number of genes responsible has been variously estimated as at between 7 and 150. Since the recessive nonsyndromic families cannot be differentiated from each other, few useful pools of families are generated for gene localization research. Despite this problem, significant advances have been made into locating recessive genes responsible for nonsyndromic hearing loss, notably by focusing research efforts on population isolates. Three loci for autosomal-recessive congenital profound nonsyndromic hearing loss have been localized. Two are from consanguineous kindreds from Tunisia: One at 13q13 (DFNB1) and a second at 11q13 (DFNB2) in the region homologous to the mouse shaker-1 gene and close to myosin VIIa, the gene for Usher Type Ib. A third gene (DFNB3) for nonsyndromic recessive congenital deafness has been localized to chro-

Table 122-1
Usher Syndrome Genotype/Phenotype Relationship

	Subtype	*Location*	*Gene*	*Phenotype[a]*
Type I (MIM 276900)	1a	14q		Profound sensory neural hearing loss
	1b	11q	Myosin VIIa	Vestibular areflexia
	1c	11p		
	1d	Unlinked		
Type II (MIM 276901)	2a	1q		Sloping mild-to-profound hearing loss
	2b	Unlinked		Normal vestibular responses
Type III	3	3q		Progressive hearing loss
				Variable vestibular deficit

[a]All have retinitis pigmentosa.

mosome 17p in an Indonesian population. A congenital-recessive severe-to-profound deafness (DFNB4) found in the Druze population has been mapped to 7q13, and consanguineous families from India were used to identify a locus on chromosome 14q.

X-Linked Hearing Loss   X-linked deafness is a special category of deafness because its pattern of inheritance is distinctive. As a specific cause of hearing impairment, X-linkage is not common, accounting for no more that 2% of all cases. The most common form is X-linked deafness with stapes fixation and perilymphatic gusher (DFN3), which has been localized to Xq13–q21.1. The structural defect is an open connection between the cerebrospinal fluid and the perilymph that causes the "gusher" seen in inner-ear surgery. The human gene, Pou3F4, was found to carry mutations that correlate with the gusher phenotype, suggesting that it and DFN3 are the same. Two other X-linked nonsyndromic genes are know to be located at Xq21(15) and Xp21.2.

Mitochondrial Inheritance   Defects in the mitochondria affect the cellular respiratory chain and lead to a wide variety of progressive clinical manifestations, namely ataxia, epilepsy, dementia, myopathy, polyneuropathy, retinal pigment anomalies, and cardiomyopathy with conduction anomalies (*see* Chapter 103). Hearing loss is a regular feature and is often the first clinical symptom of many of the mitochondrial disorders. Some mitochondrial disorders involve a full spectrum of disease, whereas others involve only hearing. For example, one family with sensorineural hearing loss of varying severity but with no other pathological feature had a mutation at nucleotide position 7445, which converted the 3' terminal T residue of tRNA-ser to a C and caused a silent alteration to the stop codon. Another mutation close to the same position was reported in association with Leber's hereditary optic neuropathy, pointing to the fact that the mitochondrial mutations do not yet sort into neat diagnostic categories.

Summary   Progress has been made in the localization of genes involved in nonsyndromic hearing loss. However, studies of associated symptoms are still lacking. Presence or absence of vestibular defect, existence of inner-ear structural abnormality, brain stem responses, and the results of oto-acoustic emission studies are infrequently reported. As a consequence, it is not yet possible to determine if different hearing loss genes produce slightly different phenotypes. Undoubtedly, as research progresses, clinical studies will be found that will aid in the differentiation of one nonsyndromic type from another.

SYNDROMIC HEARING LOSS   There are two syndromes that, because of their high frequency among the congenitally deaf, are especially important to consider when evaluating the deaf patient. These are Usher syndrome and Waardenburg syndrome. Together, these syndromes comprise the largest proportion of identifiable hereditary deafness. It is important to realize that, because of the late diagnosis of the RP for Usher syndrome and the reduced penetrance for Waardenburg syndrome, many patients with either syndrome may initially be considered to have a nonsyndromic hearing loss.

Usher Syndrome   Usher syndrome (US) is defined as hearing impairment with retinitis pigmentosa and is estimated to be responsible for about 5% of all of the cases of childhood deafness. It is both clinically and genetically heterogeneous. There are three phenotypic types (Table 122-1). Type I has a congenital profound hearing loss, vestibular areflexia, and retinitis pigmentosa. It has a frequency of 4.4/100,000 people. Type II is milder, showing a stable sloping audiogram (*see* Fig. 122-1A); patients with US II have reasonably good speech and are often helped by hearing aids. Significantly, they have a normal vestibular response. Type III displays a progressive hearing loss and variable vestibular responses. There are at least five, possibly seven, genes responsible for the different types of Usher syndrome. Table 122-1 outlines the relationship between the five known genes and the three phenotypes as they are currently recognized.

The most common types of US are Usher IIa (on chromosome 1q) and Usher Ib (on chromosome 11q). Usher Type III is linked to markers on chromosome 3q and is more common in Finland. In the United States, it was estimated that 88% of all Usher II result from mutations at the USH2a locus on chromosome 1, and the rest were either type III or unlinked to either 1q or 3q markers. Thus, it is likely that many families failing to show linkage to 1q are actually Type III Usher syndrome. However, a very small proportion, between 4 and 6%, are not linked to either the USH2a locus nor to the USH3 locus and may represent a novel type of Usher syndrome Type II.

Usher type I also shows considerable genetic heterogeneity. The first localization was to chromosome 14q. This gene was subsequently found to constitute approximately 20–30% of Usher I patients in a worldwide series of patients. Two other Usher I linkages were found, one to 11q (USH1b) and one on 11p (USH1c). The Usher Ic variant appears to be limited mostly to the French Acadian population of southern Louisiana and has not yet been observed outside of descendants of that population. Usher Ib accounts for 70–80% of the Usher cases seen in a large series from the United States and Europe. Myosin VIIa on human chromosome 11q has been recently been identified as the gene responsible for Usher Ib. Myosin VIIa is coded by a large gene of over 110 kb

Table 122-2
Locations of Nonsyndromic Hearing Loss Genes

Gene ID[a]	Location	Phenotype
Dominant		
DFNA1	5q31	Low-frequency HL beginning in the second decade progressing to a profound loss involving all frequencies
DFNA2	1p32	Variably late-onset high-frequency HL with variable rates of progression to a severe-to-profound loss
DFNA3	13q	Juvenile-onset high-frequency HL
DFNA4	19q13	Mild HL across all frequencies progressing to a severe-to-profound loss
DFNA5	7p15	Adult-onset high-frequency HL
DFNB6	4p13.6	Adult-onset low-frequency HL
Recessive		
DFNB1	13q	Profound congenital HL
DFNB2	11q	Profound, childhood-onset HL
DFNB3	17p	Profound congenital HL
DFNB4	7q13	Severe-to-profound congenital HL
DFNB5	14q	Profound congenital HL
X-linked		
DFN1	Xq21	Congenital
DFN2	Xp21.2	Profound HL in males; mild-to-moderate HL in female heterozygotes
DFN3	Xq21	Mixed conductive and HL; perilymphatic gusher with stapes fixation

[a]There is not yet a common consensus for locus nomenclature, and the gene ID given here may differ slightly with some reports in the literature.

Table 122-3
Identified Genes Causing Hearing Impairment in Humans

Disorder (MIM no.)	Inheritance	Linkage	Gene
Neural crest/pigmentary			
Waardenburg syndrome Type I (193500)	AD	2q35	PAX3
Waardenburg syndrome Type II (193510)	AD	3p12	MITF
Craniofacial			
Treacher Collins syndrome (154500)	AD	5q13	TCOF1
Crouzon syndrome (123500)	AD	10q25	FGFR2
Collagen disorders			
Alport syndrome (203780)	AR	2q35	COL4A3/4
Alport syndrome (301050)	XL	Xq	COL4A5
Osteogenesis imperfecta (166200)	AD	17q21	COL1A1
Stickler syndrome (108300)	AD	12q12	COL2A1
Stickler syndrome (108300)	AD	6p21.3	COL11A2
Other disorders			
Norries disease (310600)	XL	Xp11.4	NDP
Neurofibromatosis Type II (101000)	AD	22q12.2	NF2
Stapes fixation with gusher (304400)	XL	Xq13	POU3F4

of genomic sequence whose coding region of about 7.5 kb has now been completely sequenced. Forty-nine exons have been identified, and several mutations occurring primarily in the first 14 exons have been observed. The role of Myosin VIIa in the inner ear and the retina has yet to be elucidated.

Waardenburg Syndrome   Waardenburg syndrome (WS) is an autosomal-dominant disorder that is recognized by its characteristic signs of pigmentary abnormality in the form of a white forelock, premature graying, and heterochromia iridis (two different colored eyes). About 2% of all children in schools for the deaf have Waardenburg syndrome. Deafness is variable; sometimes it is bilateral, sometimes unilateral, sometimes there is no hearing impairment at all. The syndrome is divided into two types, WS1 and WS2, based on the presence or absence of the dystopia canthorum. WS1 has been shown to be a result of mutations in the PAX3 gene on chromosome 2. The PAX3 gene is a transcription factor and controls the migration of melanocytes from the neural crest. A second gene for WS2 has been localized to chromosome 3 and

has been shown to be homologous to microphthalmia in the mouse. This gene, MITF, is also a transcription factor (*see* Chapter 112).

COLLAGEN DISORDERS ASSOCIATED WITH HEARING LOSS

ALPORT SYNDROME   Alport syndrome (AS) is glomerular nephritis with high-frequency progressive sensorineural hearing loss (*see* Chapter 68). Most cases of AS are inherited in an X-linked pattern, although both autosomal-dominant and recessive patterns of inheritance have been noted in a few families. Typical of X-linked disorders, males are more severely affected than females. X-linked AS is a result of mutations in the collagen 4α5 gene (COL4A5). Collagen 4α5 is a component of the basement membrane of the glomerulus and the cochlea. Mutations in COL4A5 result in a defective collagen that renders the basement membrane susceptible to lamelation and splitting. Presumably, this process leads to the gradual deterioration of the glomerulus and the cochlea, which accounts for the gradual nature of the disease.

The range and severity of expression of the Alport gene is more variable between families than within, suggesting that different mutations have different clinical effects. For example, some X-linked Alport cases do not have an associated hearing deficit but others do. No correlation between the site of mutation and the presence of hearing deficit has yet been made, but it is tempting to speculate that some parts of the COL4A5 molecule are more critical for hearing impairment than other regions. A recessive form of Alport syndrome with mutations in the COL3A3 and COL3A4 collagen genes has recently been described.

STICKLER SYNDROME   Stickler syndrome is a clinically variable disorder associated with arthropathy, ocular symptoms (vitreoretinal degeneration, severe myopia, retinal detachments, and cataracts), hearing impairment, Pierre-Robin sequence, and midface hypoplasia. There is great phenotypic variation both between and within families. Whereas the hearing loss is variable, it seems to involve the high frequencies more often, and no correlation between the hearing loss and degree of orofacial involvement has been noted. Stickler syndrome was found to result from mutations in the COL2A1 gene. The type of COL2A1 mutation may be related to the severity of the Stickler phenotype. Mutations causing premature termination of transcription of the COL2A1 gene are associated with the "typical" Stickler phenotype, which includes hearing loss and facial hypoplasia, while mutations replace glycine codons with codons for bulkier amino acid appear to produce phenotypes of lethal chondrodysplasia or with only ocular problems. About 50% of Stickler syndrome families fail to show linkage to COL2A1, indicating the existence of a second type of Stickler syndrome from a mutation in another gene that may be located on chromosome 6p22–6p21.3.

OSTEOGENESIS IMPERFECTA   Osteogenesis Imperfecta refers to several different heritable disorders characterized by bone fragility. Deafness is a frequent feature of both Types I and IV. Type I is a result of mutation in the COL1A1 gene on chromosome 17q21, and Type IV is a result of mutations in the COL1A2 gene on chromosome 7. About 50% of all Type I patients have hearing loss. Type IV (COL1A2) is also associated with hearing loss but only in about 30% of the cases.

CRANIOFACIAL DISORDERS

BRANCHIO-OTO-RENAL SYNDROME   Branchio-oto-renal syndrome (BOR) is characterized by renal anomaly, external ear anomaly, and mixed hearing impairment. The hearing impairment can range from none to severe. It may be sensorineural (20%), conductive (30%), or mixed (50%). The hearing loss is quite variable between individuals and even between the ears of the same person. The inner-ear anomalies include malformations of the middle ear, cochlear hypoplasia, a wide internal auditory canal, and malformation of the vestibular system. The gene for BOR has been localized to chromosome 8q, but has not yet been identified.

CROUZON SYNDROME   Crouzon syndrome is one of the most distinctive and frequent forms of dominantly inherited craniosynostosis. Fifty-five percent of Crouzon patients have a conductive hearing loss and 13% have atresia of the external auditory canals. Crouzon syndrome has been mapped to chromosome 10q25–26 and found to result from mutations in the fibroblast growth factor receptor-2 gene (*see* Chapter 114).

TREACHER COLLINS SYNDROME (MANDIBULOFACIAL DYSOSTOSIS)   Treacher Collins syndrome shows significant craniofacial dysmorphology. The phenotype is characterized by down-slanted palpebral fissures with a coloboma on the outer

supraorbital rims, and zygomas give the face a narrow appearance. Cleft palate is seen in about 35% of the cases. The external auricle is often malformed. The ossicles as well as the cochlea and labyrinth have been observed to be absent or hypoplastic. Bilateral hearing loss is seen in over half of the cases. The gene (PTX-2) has been mapped 5q13–5q33.3 near the gene for DFNA1.

OTHER DISORDERS ASSOCIATED WITH HEARING LOSS

PENDRED SYNDROME   Pendred Syndrome is an association between deafness and euthyroid goiter (*see* Chapter 50). The hearing loss may be progressive. The cause of the hearing defect is a congenital bilateral malformation of the cochlea of the Mondini type. A patient with multiple congenital anomalies and Pendred syndrome was observed to have a chromosomal abnormality, dup(10p)del(8q), suggesting that a gene for Pendred was on one or the other of these chromosomes.

NEUROFIBROMATOSIS 2   Neurofibromatosis Type 2 (NF2) is an autosomal-dominant disorder characterized by the development of bilateral schwannomas from the vestibular nerves (*see* Chapter 106). Gene carriers often show eighth nerve dysfunction starting in early childhood and is manifest by tinnitus, bilateral hearing loss, and vestibular dysfunction. NF2 is always important to consider in the differential diagnosis of patients with sudden onset hearing loss, especially when unilateral. Gene linkage analysis has localized the NF2 gene to chromosome band 22q2. The NF2 gene has recently been identified and encodes a protein that has a high degree of homology with moesin, ezrin, and radixin, a family of proteins probably responsible for linking the cell membrane with the cytoskeleton. The mechanism by which mutations of this gene act to cause tumor growth is not known.

NORRIES DISEASE   Norries Disease (ND) is an X-linked disorder characterized by progressive atrophy of the eyes, mental disturbances, and deafness. It has been mapped to chromosome Xp11.4, and its gene spans 28 kb and consists of three exons. Detailed molecular analyses of genomic deletions in Norrie patients shows that they are heterogeneous, both in size of material deleted and in position of the deletions. It has been hypothesized that, because of homology with known proteins, that norin codes for a protein that regulates neural cell differentiation and proliferation.

MANAGEMENT AND TREATMENT OF HEREDITARY HEARING IMPAIRMENTS

From a genetic perspective, diagnosis is the main problem encountered when dealing with hereditary hearing loss disorders and must be solved before other issues of management can be effectively addressed. Advances in molecular diagnostics will undoubtedly prove to be valuable in this area. Even though a limited number of syndromic genes have been identified so far, it is possible to verify diagnosis for Waardenburg syndrome, one type of Usher syndrome, Alport syndrome, X-linked gusher, and Norries disease. Together, these syndromes constitute a large proportion of patients seen for hearing impairments. With regard to nonsyndrome hearing losses, several linkages have been found, but none of the specific genes responsible have been identified. Improved efficiency in diagnostic screening is certainly to be expected as more genes are identified, and it is reasonable to expect that such screening will become increasingly important in other aspects of management. Early diagnosis is critical for the development of communication skills in children with hearing losses. As

more mutations are identified, infants in at-risk families can be diagnosed as early as desired. Early diagnosis may be important with regard to other strategies of intervention. For example, Usher I patients seem to do well with cochlear implants and early diagnosis would be useful in planning patient care that could lead to implant surgery done at a stage of development most effective for enhancing the language skill of Usher patients. Thus, it is expected that, as molecular genetics improves the diagnostic skills for the detection of specific genetic mutations, novel approaches to the treatment of the hearing-impaired will emerge.
