The demonstration that RET/PTC1 rearrangement induces PTC in transgenic mice suggests that this rearrangement is an early event in their development. This is also supported by a high incidence of these rearrangements in occult PTC and the induction of RET/PTC1 rearrangements by irradiation of human fetal thyroid explants.

A second type of chimeric oncogene has been described in PTC. The TRK gene, encoding a receptor for the nerve growth factor, is placed under the control of several unrelated sequences through intrachromosomal rearrangements on chromosome 1q23-24: the TPR (tropomyosin) gene and a gene referred to as the TRK activating gene.

Recent studies have shown that B-RAF mutations are the most prevalent thyroid oncogene in papillary thyroid cancer. B-RAF is an intracellular serine-threonine kinase that is downstream of RAS. It is predominantly expressed in the thyroid, hematopoetic cells, neurons and the testis. Oncogenic mutations lead typically to a structural change that results in a catalytic activation. The B-RAF mutation T1796A is found in 40–70% of all papillary cancers. They are not found in other forms of well-differentiated thyroid carcinoma. Moreover, mutations in B-RAF, RET/PTC rearrangements and RAS mutations appear to be mutually exclusive. Remarkably, these oncogenes result in the activation of the same signaling cascade emphasizing its importance for tumorigenesis. PTC with B-RAF mutations have a more aggressive behavior and present frequently with extrathyroidal metastasis. Both RET and B-RAF are potential targets for kinase inhibitors, which may serve as new therapeutic modalities for well-differentiated thyroid cancer and MTC that are not curable with currently available treatments.

A fusion gene between the *PAX*8 and the *peroxisome proliferators-activated receptor-*γ gene has been identified in a substantial number of follicular carcinomas. In contrast, it is relatively uncommon in follicular adenomas. Ongoing research is clarifying the oncogenic role of this fusion gene and its clinical utility in the distinction of follicular neoplasms.

The tumor suppressor genes that have been studied to some extent in thyroid malignancies are the retinoblastoma susceptibility gene (*Rb*) and the *p53* gene. *Rb* maps to chromosome 13q14 and encodes a 110-kDa protein. Rb is activated by cyclin-dependent kinases (CDK4/cyclinD) in the G1 phase and this induces the expression of genes required for DNA replication. During the cell cycle, Rb regulates the actions of several transcription factors like

E2F and cyclins. The suppressive effect on cell cycle progression and growth can be lost through heterozygous loss in a single Rb allele in the germline, associated with retinoblastomas and sarcomas, or somatic mutations found in several carcinomas. These mutations affect residues that can be phosphorylated or that are involved in protein–protein interactions. When studied at the genomic or protein level, no Rb abnormalities were found in thyroid carcinomas. This contrasts with a report on mRNA abnormalities in 55% of thyroid carcinomas and absent differences between differentiated carcinomas and ATCs. Of these latter tumors, 12% also harbored p53 mutations, a finding that was reported to be more prevalent in advanced disease.

P16, also called MTS1, is an inhibitor of CDK involved in the phosphorylation of Rb. The demonstration of homozygous deletions of P16, localized on chromosome 9p21, in two of three FTC and two of four PTC cell lines suggests that P16 might be an important tumor suppressor gene involved in the pathogenesis of thyroid malignancies. P16 abnormalities (mutations, deletions) occur in high frequency in adenocarcinomas of the pancreas.

The p53 gene plays an important role in the development and progression of several human cancers. It exerts its function as a tumor suppressor by arresting cells in the G_1 phase of the cell cycle, thus enabling repair of DNA damage. The p53 gene is localized on chromosome 17p13. Four monomers oligomerize to a tetramer. Germline mutations of p53 are found in the Li-Fraumeni syndrome, familial breast cancer (Chapter 74) and a wide variety of other human malignancies. As in other malignancies, mutations in p53 are also thought to be involved in the progression of thyroid carcinomas and to play a key element in the process of dedifferentiation. Although they are more frequently found in ATCs, they may even occur in some follicular adenomas and differentiated carcinomas.

MEDULLARY THYROID CANCER AND MULTIPLE ENDOCRINE NEOPLASIA MEN, FMTC and MTC are more thoroughly reviewed in Chapter 40. MEN2A is an autosomal-dominant disease characterized by the association of MTC, parathyroid adenomas and pheochromocytoma. In MEN2B, parathyroid disease is absent, but patients additionally develop mucocutaneous ganglioneuromas, and some patients have a marfanoid habitus. FMTC is a familial cancer syndrome without other manifestations of the MEN complex.

Several mutations in the ret tyrosine kinase receptor have been identified as causes of MEN2A and FMTC. Most of these mutations affect conserved cysteines in the cysteine-rich domain thought to be involved in receptor dimerization and activation. In MEN2B, a mutation at position 918, substituting methionine–threonine, has been found in 95% of the patients.

Although genetic testing for the diagnosis of cancer predisposition remains controversial in many instances, the recognition of mutations in the *RET* gene as the cause of MEN2A and FMTC has profound clinical relevance. Before the availability of genetic testing, families with MEN2A and FMTC were evaluated on a regular basis by measuring calcitonin levels after stimulation with pentagastrin or calcium. This test was however hampered by a low specificity with the possibility of false-positive results and required repeated testing and a high compliance of the mostly asymptomatic family members. The possibility to identify gene carriers by mutational analysis allows identifying gene carriers accurately. Consequently, thyroidectomy can be performed in early childhood to prevent the development of MTC, which occurs in approx 90% of affected patients. This procedure is thus associated with diagnostic accuracy, improved cure and lowered costs.

RECOMBINANT TSH AS A CLINICAL TOOL

After surgical procedures, patients with differentiated carcinomas of the thyroid are routinely evaluated by means of radioiodine scans and measurements of TG. To achieve a high sensitivity, these tests are traditionally performed after withdrawal of the suppressive treatment with T4 for several weeks to achieve an increase in TSH and thus a high uptake of radioiodine in residual tissue. Withdrawal of T4 leads to hypothyroidism and potentially to all the clinical problems associated with it. Moreover, the increase in TSH may lead to proliferation of residual tumor cells. To avoid these problems, exogenous TSH was successfully administered during uninterrupted treatment with T4 before performing radioiodine scans and TG measurements. These procedures have initially been performed with bovine TSH or human TSH from autopsies, sources that are no longer acceptable because of the possibility of anaphylactic reactions and the transmission of infectious disease (Jakob-Creutzfeld). After the cloning of the α- and β-subunits of human TSH, production of pure TSH in large quantities has been possible. Administration of recombinant human TSH is already used routinely in the follow-up of patients with differentiated thyroid cancer and may become a standard procedure. Recombinant TSH has also been applied successfully to stimulate uptake of radioiodine for the treatment of thyroid cancer or multinodular goiters.

GENETICALLY MODIFIED ANIMALS

Important new insights into the pathophysiological mechanisms controlling goiter and thyroid tumor formation have been gained with genetically modified mice, including a large number of transgenic models, knock-out and knock-in strains. These studies have allowed the confirmation of several paradigms in vivo. The characterization of the TG promoter easily achieves tissue-specific expression of transgenes in the thyroid. A first model expressed the chloramphenicol acetyltransferase to the thyroid; chloramphenicol acetyltransferase activity could be detected in thyroid tissue but not in any other tissue and assured that the *cis* regulatory elements present in the first 2000 bp of the promoter are sufficient for thyroid specific expression. Thyroid-specific expression of the large T antigen of SV40, one of the most potent known viral oncogenes, under control of the TG promoter resulted in rapidly growing undifferentiated goiters with progressive dedifferentiation with increasing age and loss of expression of thyroid specific genes. The loss of differentiation was accompanied by marked hypothyroidism. Most of these animals died early, primarily from tracheal compression. By targeted overexpression of the herpes virus thymidine kinase 1 gene using the TG promoter and treatment with the antiviral drug ganciclovir, thyroid follicular cells could be ablated selectively. Predicted by the property of the adenosine A2a receptor to be a constitutive activator of the adenlylyl cyclase pathway, its overexpression under the control of the TG promoter resulted in severe hyperthyroidism, tachyarrhthmias, and premature deaths owing to congestive heart failure. These transgenic animals develop huge goiters that are initially diffuse but later develop nodules; they provide an interesting model for hyperthyroidism and formation of nodular goiters. The E7 oncogene of the human papillomavirus type 16 inactivates the tumor suppressor protein

encoded by Rb. Transgenic mice expressing E7 under control of the TG promoter develop huge hyperplastic goiters with large follicles with well-differentiated follicular cells. The animals are euthyroid but show a higher radioiodine uptake suggesting a lowered hormonogenic activity. Overexpression of the RET/PTC1 oncogene in a transgenic model led to carcinomas comparable to human papillary cancers, indicating that the RET/PTC1 rearrangement can be the primary cause for development of thyroid papillary cancer. Disruption of CREB signaling by overexpression of a dominant negative CREB isoform results in a phenotype characterized by congenital hypothyroidism with a hypoplastic thyroid emphasizing the importance of the cAMP pathway for thyroid follicular cell growth and function.

Many of the knock-out models were mentioned above. Targeted disruption of the *Pax8*, *Ttf1*, and *Ttf2* genes revealed the essential role of these transcription factors in thyroid development. Pax8 –/– mice die shortly after weaning because of severe hypothyroidism. There are no detectable thyroid follicular cells after E12 indicating that Pax8 is required for the expansion of precursor cells. In contrast to humans, the heterozygous mice are normal. Ttf1 knock-out mice are not viable and have a complex phenotype that includes an absent thyroid, severe brain malformations (missing ventral forebrain and pituitary) and sac-like lung structures. Reminiscent of humans with haploinsufficiency for TTF1, heterozygous mice have elevated TSH levels and a neurological phenotype with impaired coordination. Mice homozygous for targeted disruption of Ttf2 have thyroid agenesis or a sublingual thyroid in combination with a cleft palate.

Deletion of transcription factors such as Hex and Eya1, as well as several members of the Hox family, results in complex phenotypes that not only affect the thyroid. Whether naturally occurring mutations in these genes are associated with developmental or functional thyroid defects is unknown.

Multiple mouse models have focused on the two TRs, TRα, and TRβ, and their isoforms. Disruption of these genes individually or in combination revealed the physiological role of the two receptors and their isoforms in various tissues. The combined knock-out for TRα and TRβ illustrated that the silencing of genes by TRs is of physiological importance. Lastly, several knock-in strains have been created in order to model RTH by introducing naturally occurring human mutations into TRβ or by introducing the corresponding mutation into TRα.

ACKNOWLEDGMENTS

I am indebted to Dr. J.L. Jameson, MD, PhD, for his mentoring and his many contributions to the previous version of this chapter. This work has, in part, been supported by grant 1R01DK63024-01 (NIH/NIDDK) and MAF D02FE-14 (Morris foundation) to P.K.

36 Disorders of the Parathyroid Gland

ANDREW ARNOLD AND MICHAEL A. LEVINE

SUMMARY

The parathyroid glands play a crucial role in maintaining normal calcium homeostasis, primarily through their regulated secretion of parathyroid hormone. A variety of congenital and acquired causes of diminished parathyroid function exist, including developmental abnormalities and defective parathyroid hormone synthesis or release, and the genetic basis for many of these is known. Primary disorders of parathyroid hyperfunction, mostly owing to parathyroid gland tumors, can be familial or sporadic. Molecular pathogenetic insights into these disorders are substantial, and have been exploited for clinical management.

Key Words: Calcium receptor; cyclin D1; GCMB; HRPT2; hypoparathyroidism; hyperparathyroidism; MEN1; parathyroid; parathyroid adenoma; parathyroid carcinoma; PTH.

DEVELOPMENT AND GROWTH OF THE PARATHYROID GLANDS

The parathyroid glands first appear during the fifth week of gestation in human fetuses, which corresponds to day E11.5 in the mouse embryo. The inferior parathyroid glands and the thymus form as lateral evaginations of the third branchial pouches. As the thymus and parathyroid complex migrates caudally, the parathyroids become associated with the lower poles of the thyroid gland, thus resting below the superior parathyroid glands, which are derived from the fourth branchial pouch along with the ultimobranchial bodies. Errant migration can lead to considerable variability in the location of the parathyroid glands. Because of their more extensive repositioning during embryogenesis, the inferior parathyroids are more likely to assume an ectopic location than the superior parathyroids. Nearly all (84%) humans have four parathyroid glands, but the number of glands can vary from 1 to 12, and it is not unusual to find three (1–7%) or five (3–13%) parathyroid glands in normal individuals. Expression of the transcription factor encoded by the *GCMB* gene is critical for proper development of the parathyroids, because deletion of this gene results in the absence of the parathyroids in mice, and is associated with hypoparathyroidism in humans (*see* Familial Isolated Hypoparathyroidism).

The parathyroid glands grow to a total parenchymal weight of about 3 μg at a gestational age of 8 wk, to 300 μg by age 18 wk, and to 4 mg at birth. Mineralization of the fetal skeleton is facilitated by active calcium transport from mother to fetus across the placenta, utilizing a calcium pump in the basal membrane of the trophoblast that maintains a 1/1.4 (mother/fetus) calcium gradient throughout gestation. Parathyroid hormone (PTH) and PTH-related protein share in the regulation of the fetus' unique calcium and mineral metabolism, and both hormones are synthesized in the fetal parathyroids, with PTH-related protein also being produced in other fetal tissues (e.g., placenta and liver).

After birth parathyroid growth continues for three decades. Adult parathyroid tissue mass varies with sex, race, and overall nutritional status, and the combined weight of all parathyroid glands is approx 120 mg in normal adult males and 145 mg in females. Individual glands range in weight from 3 to 75 mg, with most glands weighing approx 35–55 mg.

Cell turnover in the adult parathyroid gland is approx 5%/yr, with cycling cells randomly distributed and without evidence for a separate stem cell population. As adult parathyroid cell number remains constant, the very slow rate of cell gain must be balanced by a correspondingly slow rate of cell loss, presumably occurring through apoptosis. How the remaining parathyroid cells are somehow triggered from G_0 to G_1 in order to maintain a stable cell number is unknown. Such a compensatory mitotic response typically occurs in endocrine cells under the control of the hypothalamus or the pituitary, but its occurrence in the parathyroid gland, for which no trophic hormone has been identified, suggests the existence of novel proliferative mechanisms. Under special circumstances, the rate of parathyroid cell proliferation can be increased. The parathyroid glands can enlarge greatly during states of chronic hypocalcemia, particularly during renal failure when hyperphosphatemia and low levels of calcitriol accompany hypocalcemia.

PTH STRUCTURE, BIOSYNTHESIS, AND SECRETION

The *PTH* gene is located on the short arm of chromosome 11. Its three exons encode mature PTH (84 amino acids), as well as its signal (25 amino acids) and "pro" (6 amino acids) peptides. The study of the structure and regulation of the *PTH* gene and the intricacies of PTH biosynthesis, post-translational processing, and intracellular targeting have led to the accrual of a body of information that is as complete as that for any other peptide hormone. In the sections that follow, these areas are briefly reviewed for purposes of introduction.

THE EXTRACELLULAR CALCIUM-SENSING RECEPTOR

Increases in the serum-ionized calcium inhibit the secretion of PTH. Conversely, reductions in serum-ionized calcium stimulate

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

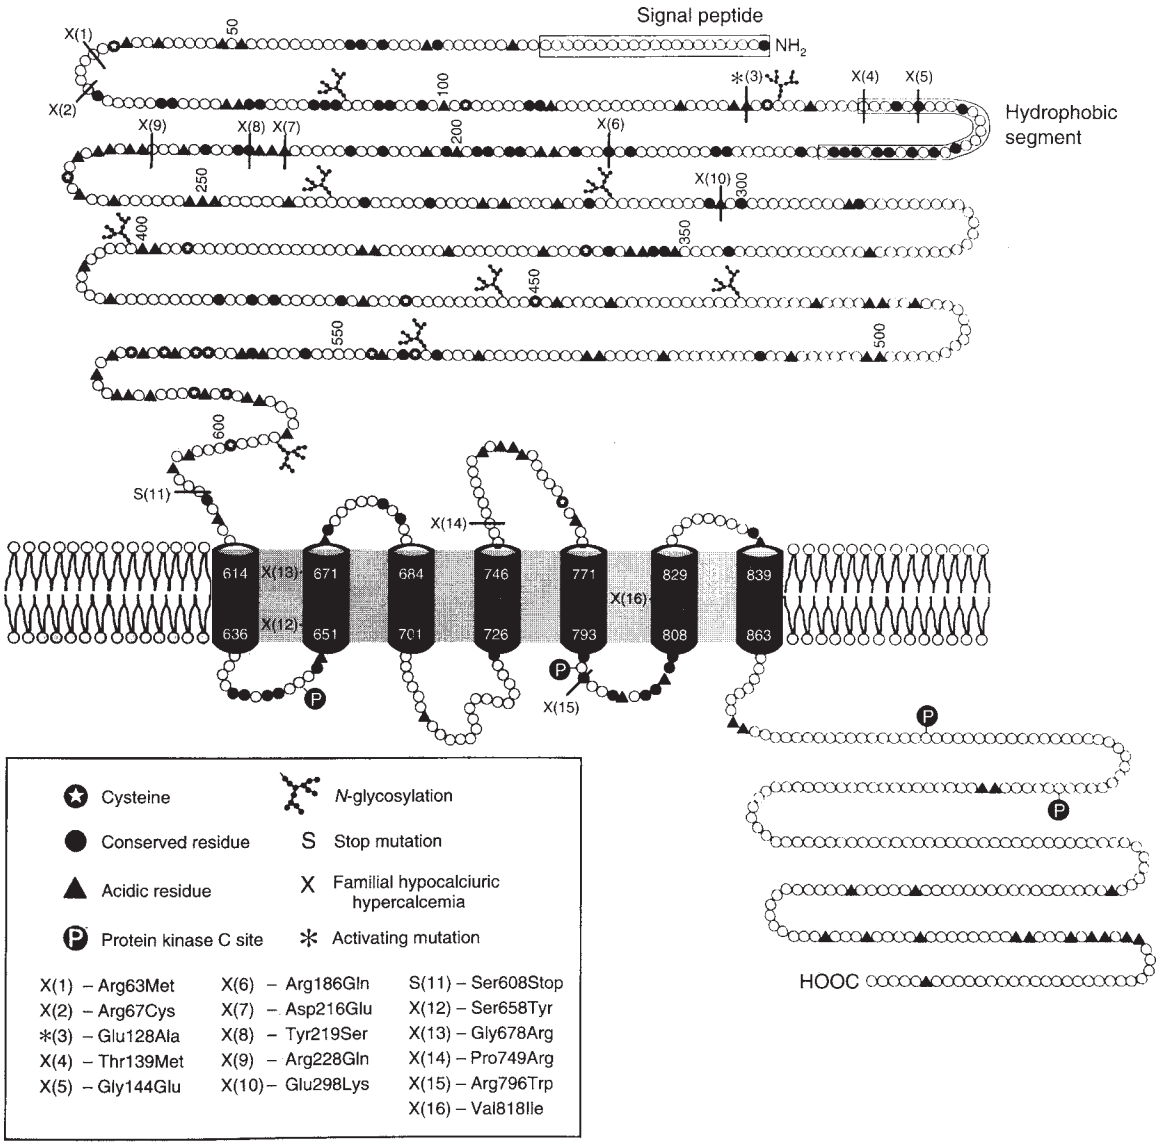

Figure 36-1 The structure of the calcium receptor. This figure shows the structure of the bovine calcium receptor or sensor. The important structural features are the seven putative transmembrane-spanning domains, the extracellular amino-terminal domain, and the cytoplasmic carboxy-terminus. As can be seen from the key within the figure, both activating (causing hypoparathyroidism) and inactivating (causing familial hypocalciuric hypercalcemia) mutations can occur. (Reproduced with permission from Brown EM, Pollak M, Herbert SC. Molecular mechanisms underlying the sensing of extracellular Ca^{2+} by parathyroid and kidney cells. Eur J Endocrinol 1995;132:523–531. Copyright Society for the European Journal of Endocrinology 1995.)

the cascade of events that lead to the secretion of PTH. This inverse sigmoidal relationship between serum calcium and PTH secretion is precisely controlled, is the key physiological feature of the parathyroid gland, and accounts for the tight minute-to-minute regulation of PTH secretion and the strict maintenance of serum calcium. Parathyroid cells express on their surface a G protein coupled, seven transmembrane domain receptors with a large extracellular domain, encoded by the *CASR* gene on chromosome 3q. This receptor recognizes extracellular calcium in physiological concentrations and transduces signals through cytosolic calcium–inositol phosphate–phospholipase C intracellular pathways to regulate PTH release (Fig. 36-1). The calcium receptor is expressed in a restricted number of tissues (including the parathyroid gland, the thyroid C cell, the renal tubule, gastrointestinal tract, and the CNS).

TRANSCRIPTIONAL AND POST-TRANSCRIPTIONAL CONTROL *PTH* gene transcription is subject to both positive and negative regulation primarily through the combined regulatory effects of serum calcium concentration and of $1,25(OH)_2D$, the active form of vitamin D. Reductions in serum calcium and reductions in circulating $1,25(OH)_2D$ lead to activation of *PTH* gene transcription. Conversely, increases in serum calcium and in circulating $1,25(OH)_2D$ inhibit *PTH* gene transcription. These effects occur during a period of hours to days and are viewed as important in the long-term or tonic regulation of PTH secretion.

PTH BIOSYNTHESIS PTH synthesis requires translation of the PTH mRNA on ribosomes, entry of the nascent preproPTH into the cistern of the endoplasmic reticulum (ER), cleavage of the signal peptide cotranslationally by signal peptidase on the lumenal side of the ER, passage of the immature peptide through the lamellae of

the Golgi apparatus, targeting of the peptide into the secretory granules of the regulated secretory pathway, and cleavage of the "pro" segment of the peptide, presumably within the Golgi compartment. In addition, the quantity of stored hormone within secretory granules appears to be subject to regulation through degradation of mature PTH within secretory granules or within phagolysosomes.

SHORT-TERM CONTROL OF SECRETION PTH secretion is regulated by the serum ionized calcium concentration. Changes in serum calcium concentration lead to immediate (minutes) and opposite changes in PTH secretion. The key features of this acute regulation appear to be those observed in other neuroendocrine peptide secretory systems (i.e., storage of preformed, completely processed hormone in dense core secretory granules, with secretory granule fusion to the cell membrane leading to immediate secretion) with one important difference: in most neuroendocrine cell types, fusion of secretory granules with the cell membrane is triggered by an increase in cytosolic calcium. The reverse is true in the parathyroid. The cellular mechanisms governing this inverse secretion-stimulus coupling in the parathyroid gland are incompletely understood.

HEREDITARY FORMS OF HYPOPARATHYROIDISM

The majority of patients with hypoparathyroidism have surgical or acquired autoimmune hypoparathyroidism. In contrast to these acquired forms of hypoparathyroidism, familial forms of congenital and acquired hypoparathyroidism have been described. These can be subdivided into familial syndromes in which hypoparathyroidism is accompanied by abnormalities in multiple other organ systems, and familial forms of hypoparathyroidism that are unaccompanied by other abnormalities.

FAMILIAL VARIETIES OF HYPOPARATHYROIDISM ASSOCIATED WITH MULTIPLE ORGAN SYSTEM ABNORMALITIES

These syndromes represent genetic syndromes associated with hypoparathyroidism, but given their multisystem abnormalities, it is intuitive that the parathyroid gland abnormalities are not intrinsic to defects within the parathyroid gland but are in some fashion secondary to other developmental or regulatory abnormalities.

HYPOPARATHYROIDISM ASSOCIATED WITH THE POLYGLANDULAR FAILURE SYNDROME Autoimmune hypoparathyroidism may occur alone or in association with additional features, including mucocutaneous candidiasis and adrenal insufficiency, as a component of the autoimmune polyglandular syndrome type 1 (APS-1). APS-1 may be sporadic or familial with an autosomal-recessive inheritance pattern. By contrast, the autoimmune polyglandular syndrome type 2 is characterized by adult-onset adrenal insufficiency associated with insulin-dependent diabetes mellitus and thyroid disease, and is thought to be polygenic with apparent autosomal-dominant inheritance. The APS-1 syndrome most commonly consists of the triad of hypoparathyroidism, adrenal insufficiency, and mucocutaneous candidiasis. The clinical onset of these disorders follows a predictable pattern, in which mucocutaneous candidiasis first appears at a mean age of 5 yr, followed by hypoparathyroidism at a mean age of 9 yr and adrenal insufficiency at a mean age of 14 yr. Patients may show only one or two of these features, and less than a year to decades may elapse between the diagnosis of one disease and the second in the same individual.

Some patients with APS-1 develop additional features. Alopecia occurs in approximately one-third of patients with the highest incidence at ages 5–9 yr. It appears as hairless patches, and may proceed to complete baldness and lack of eye and body hair. Other features include keratoconjunctivitis, malabsorption and steatorrhea, gonadal failure, pernicious anemia, chronic active hepatitis, thyroid disease, and insulin-requiring diabetes mellitus. Enamel hypoplasia of teeth is also common, and appears to be unrelated to hypoparathyroidism. The presence of these additional defects in patients with APS-1 has led to the suggestion that a more inclusive term be used to describe the syndrome: "autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy." In cases that have been examined pathologically, complete parathyroid atrophy or destruction has been demonstrated. In some patients, treatment of hypoparathyroidism has been complicated by apparent vitamin D "resistance," possibly related to coexistent hepatic disease, steatorrhea, or both.

The autoimmune basis for the disorder is suggested by the findings of circulating autoantibodies directed against the parathyroid, thyroid, and adrenal glands in many patients, but the presence of organ-specific autoantibodies may not correlate well with the clinical findings. Some reports describe patients who have circulating autoantibodies that are directed against the parathyroid calcium-sensing receptor (CaR). These antibodies apparently behave as receptor activators and thereby decrease secretion of PTH (*see* Familial Isolated Hypoparathyroidism, autosomal-dominant hypocalcemia).

The APS-1 syndrome results from mutations in the *AIRE* (for autoimmune regulator) gene, and different geo-ethnic groups have unique *AIRE* mutations. The *AIRE* gene encodes a predicted 57.7-kDa protein that is expressed in thymus, lymph nodes, and fetal liver, and which contains motifs, including two plant homeodomain zinc fingers, that are suggestive of a role as a transcriptional regulator. Mutations in the *AIRE* gene are predicted to lead to truncated forms of the protein that lack at least one of the plant homeodomain zinc fingers, and which fail to localize to the cell nucleus.

THE DIGEORGE SYNDROME The DiGeorge syndrome (DGS) is the most frequent contiguous gene deletion syndrome in humans, occurring in approx 1 of 5000 live births. DGS is classified as a developmental field defect resulting from a defect in the development of the third and fourth branchial arches, which leads to thymic, parathyroid, and conotruncal cardiac defects. Because of thymic aplasia, T-cell-mediated immunity is impaired, and affected infants have an increased susceptibility to recurrent viral and fungal infections. Despite the emphasis on thymus dysgenesis in these syndromes, clinically significant immune defects occur in very few patients. The basic embryological defect is inadequate development of the facial neural crest tissues that results in maldevelopment of branchial pouch derivatives. Facial features associated with DGS include hypertelorism or telecanthus, short or hypoplastic philtrum, micrognathia, and low-set, posteriorly rotated ears. The most common cardiac defect is truncus arteriosus. The degrees of thymic hypoplasia and immune dysfunction also vary, and there is a tendency toward spontaneous remission. Last, there is variability in the degree of parathyroid hypoplasia and ensuing hypoparathyroidism, and in some cases hypoparathyroidism may be the principal or only feature of DGS. The presence of thymic hypoplasia or aplasia constitutes the "complete" form of DGS. Developmental field defects may have multiple causes and even multiple pathogenetic mechanisms, and DGS can arise in infants who were exposed *in utero* to retinoic acid, alcohol, or maternal diabetes mellitus.

Molecular mapping studies have demonstrated an association between the syndrome and deletions involving 22q11.2 (DGSI) in the great majority of patients with DGS. Many commercial laboratories offer genetic testing services that can identify these microdeletions in 22q11 by fluorescent *in situ* hybridization. Most cases of DGS are sporadic, but familial occurrence with apparent autosomal-dominant inheritance has been described. In these cases a heterozygous deletion of chromosomal region 22q11.2 is inherited from a mildly affected parent.

Analysis of the human DSG1 deleted region on chromosome 22q11.2 has defined a 250-kb minimal critical region that includes a variety of candidate genes, including a human homolog of a yeast gene, referred to as *UDFIL* that encodes a protein involved in the degradation of ubiquinated proteins. Deletion of the homologous region in the mouse (Df[16]1) causes a very similar disorder, and recently, mouse models that closely replicate the DGS have been generated through targeted ablation of genes within the DGS/ Df(16)1. Mice deficient in *Crkol*, a gene expressed in neural crest cells and which encodes an adapter protein implicated in response to growth factors and focal adhesion signaling, exhibit defects in multiple cranial and cardiac neural crest derivatives. A similar phenotype occurs in mice deficient in *Tbx1*, a transcription factor that is expressed in nonneural crest-derived cells of head mesenchyme, pharyngeal arches and pouches, and otic vesicles of the embryo. Haploinsufficiency of *TBX1*, the human homologue, has emerged as the likely explanation for the developmental defects of DGS1, including hypoplasia or aplasia of the parathyroid glands, as this gene is deleted in patients with DGS1. *TBX1* is a member of a family of transcription factors with more than 20 members identified in humans so far, and homologues in many other organisms. The discovery of the developmental role of *Tbx1* in the mouse prompted extensive searches for mutations of the *Tbx1* gene in patients with *del22q11* phenotype but without chromosomal deletion. These mutational analysis efforts culminated with the identification of five patients (three of whom were from the same family) carrying a *TBX1* gene. Most of these patients had a typical *del22q11DS*/DGS phenotype (including heart defects) but did not have learning disabilities. Hence, consistent with mouse genetic results, human *TBX1* mutation (presumably leading to haploinsufficiency, but this is not known yet) is sufficient to cause most of the abnormalities observed in *del22q11DS* or DGS.

The associated embryological defects that characterize the phenotype caused by loss of genes in the 22q11 region have been compiled to create the acronym "CATCH-22," which refers to cardiac anomalies, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia with deletion at 22q. Because hypoparathyroidism in patients with DGS can be transient, with resolution during infancy, all infants with congenital hypoparathyroidism should be thoroughly evaluated for the genetic and physical defects associated with CATCH-22 syndrome, including evaluation of T-cell immunity.

Deletions at a second locus at 10p13, termed DGSII, have been found in some patients, but commercial molecular testing for the 10p13 microdeletion is not widely available. The genomic draft sequence of this region contains only one known gene, *BRUNOL3*, which is strongly expressed in the thymus during different developmental stages. Although *BRUNOL3* appears to be an important factor for thymus development, pathogenic mutations have not been found in DGS-like patients without chromosomal deletions.

HYPOPARATHYROIDISM ASSOCIATED WITH RENAL DYSGENESIS AND SENSORINEURAL HEARING LOSS Hypoparathyroidism is also a variable component of Barakat syndrome, also termed the HDR syndrome because of the association of hypoparathyroidism with deafness and nephrosis. The HDR syndrome is associated with autosomal-dominant mutations in the *GATA3* gene located at 10p14 near the DGSII locus. Hypoparathyroidism also has been described in patients with rare familial syndromes that are associated with collateral developmental defects such as lymphedema, prolapsing mitral valve, brachytelephalangy, and nephropathy or microcephaly, beaked nose, and crognathia.

OTHER COMPLEX SYNDROMES ASSOCIATED WITH HYPOPARATHYROIDISM Hypoparathyroidism occurs in >50% of patients who have the Kenny–Caffey syndrome, an unusual syndrome characterized by short stature, osteosclerosis, basal ganglion calcifications, and ophthalmic defects. Studies indicate that the Kenny–Caffey syndrome is related to the Sanjad–Sakati syndrome, in which congenital hypoparathyroidism is associated with growth and mental retardation. Both of these autosomal-recessive disorders are linked to the same 2.6 cM region on chromosome 1q43-44, are allelic and are associated with defects in the *TBCE* gene, which encodes one of several chaperone proteins required for the proper folding of α-tubulin subunits and the formation of αβ-tubulin heterodimers. Cells from patients with these genetically related disorders show disturbances in subcellular organelles that require microtubules for membrane trafficking, such as the Golgi and late endosomal compartments. These findings provide evidence that the Sanjad–Sakati and Kenny–Caffey syndromes are chaperone diseases caused by a genetic defect in the tubulin assembly pathway, and establish a potential connection between tubulin physiology and the development of the parathyroid. Congenital hypoparathyroidism also occur as a feature of several generalized metabolic defects and in several mitochondrial neuromyopathies.

FAMILIAL ISOLATED HYPOPARATHYROIDISM

Isolated hypoparathyroidism may be sporadic or familial, with inheritance of PTH deficiency by autosomal-dominant, autosomal-recessive, or X-linked modes of transmission. The age at onset covers a broad range (1 mo to 30 yr), but the condition is most commonly diagnosed during childhood.

Isolated hypoparathyroidism has been associated with genetic defects that impair PTH synthesis (i.e., *PTH* gene defects) or secretion (i.e., *CASR* gene defects) as well as parathyroid gland development (e.g., *GCMB* gene defects). Defects in the *PTH* gene are an uncommon cause of hypoparathyroidism, with mutations reported in three families. One form of autosomal-dominant hypoparathyroidism has been attributed to a heterozygous mutation of the *PTH* gene consisting of a single base substitution (T → C) in exon 2. This mutation results in the substitution of arginine (CGT) for cysteine (TGT) in the leader sequence of preproPTH. The substitution of a charged amino acid in the midst of the hydrophobic core of the leader sequence inhibits processing of the mutant preproPTH molecule to proPTH by signal peptidase and is presumed to impair translocation of the mutant hormone and of the wild-type protein across the plasma membrane of the ER. Thus, this heterozygous mutation results in a dominant inhibitor phenotype that also prevents processing of the wild-type preproPTH molecule from the remaining normal *PTH* allele. This preproPTH mutation was the

first signal peptide mutation reported to cause human disease; signal peptide mutations have subsequently been found in other molecules such as preprovasopressin (causing diabetes insipidus) and Factor X (causing a coagulopathy).

Mutations in the *PTH* gene are also the cause of autosomal-recessive hypoparathyroidism in two unrelated families. In one family, affected children were homozygous for a mutation in exon 2 that is predicted to disrupt normal processing of the preproPTH molecule. The mutant allele carries a T → C transition in the first base of codon 23 that results in the replacement of serine (TCG) by proline (CCG) at the –3 position of the signal peptide of preproPTH. This change is hypothesized to inhibit cleavage by signal peptidase at the normal position, and thereby lead to rapid degradation of the preproPTH protein in the rough ER. Affected patients who are homozygous for this allele present with symptomatic hypocalcemia within the first few weeks of life. In a second family, hypoparathyroidism occurred in members who were homozygous for a single base transversion (G → C) at the exon 2-intron 2 boundary. This mutation alters the invariant GT dinucleotide of the 5′ donor splice site that presumably affects annealing of the U1-snRNP recognition component of the nuclear RNA splicing enzyme. The use of a highly sensitive modification of reverse transcriptase-polymerase chain reaction allowed detection of very small amounts of preproPTH mRNA in cultured lymphoblasts from these patients, and revealed a PTH cDNA in affected subjects that was 90 bp shorter than the corresponding wild-type form. Nucleotide sequence analysis of the shortened cDNA revealed that exon 1 had been spliced to exon 3 in the mutant PTH mRNA, a process that resulted in the deletion of exon 2 from the mature transcript (i.e., exon skipping). The loss of exon 2 would eliminate both the initiation codon and the signal peptide sequence from the aberrant preproPTH mRNA, presumably explaining the molecular basis for autosomal-recessive hypoparathyroidism in this family.

Isolated hypoparathyroidism can also arise because of failure of the parathyroid glands to develop properly during embryogenesis. Homozygous mutations in the *GCMB* gene lead to congenital hypoparathyroidism because loss of this transcription factor results in failure of the parathyroid glands to develop (i.e., parathyroid agenesis) during embryogenesis. Mice and humans who are deficient in the transcription factor g*cm2* (glial cell missing, 2) develop hypoparathyroidism but lack defects in other tissues derived from the neural crest or pharyngeal pouches. These data implicate the *GCMB* gene, located at chromosome 6p23-24, as a cause of autosomal-recessive parathyroid aplasia in humans, but the prevalence of *GCMB* gene mutations in IH remains unknown. An X-linked-recessive form of IH (OMIM 307700) has also been reported in two related multigeneration kindreds from Missouri, USA, and a deletion–insertion [del(X)(q27.1) inv ins (X;2)(q27.1;p25.3)] that could result in a position effect on *SOX3* expression has been identified in affected subjects.

Another mechanism underlying familial isolated hypoparathyroidism has been described. Heterozygous mutations in the gene encoding the CaR (*CASR*) that result in a *gain of function* have been identified in many subjects with autosomal-dominant hypocalcemia, a syndrome associated with low serum levels of PTH and relative hypercalciuria. In other cases, linkage of hypocalcemia to the chromosomal locus for the CaR (3q21-24) has provided indirect evidence for the involvement of this gene with familial hypoparathyroidism. Expression of mutant CaRs in oocytes and mammalian cells leads to constitutive activation of the inositol phosphate signal transduction pathway. The host parathyroid cell, therefore, behaves as though it were being exposed to higher than normal concentration of extracellular calcium and appropriately fails to secrete PTH. Subsequent studies have identified similar activating mutations of the CaR gene in many patients with sporadic hypoparathyroidism. In both familial and sporadic cases, each affected propositus has demonstrated a unique mutation, suggesting that new mutations must sustain this disorder in the population. These results suggest that mutation of CaR gene may be the most common cause of genetic hypoparathyroidism.

The CaR is expressed in the parathyroid gland and the kidney, in which it appears to play an important role in regulating calcium reabsorption. Thus, gain-of-function mutations in the CaR are likely to account for the increased calcium clearance and relative hypercalciuria noted in patients with autosomal-dominant hypocalcemia. These patients may therefore be at increased risk of nephrocalcinosis or nephrolithiasis. By contrast, loss of function mutations of the CaR in patients with familial hypocalciuric hypercalcemia (FHH) (*see* FHH and Neonatal Severe Hyperparathyroidism) are associated with decreased calcium clearance and relative hypocalciuria.

FHH AND NEONATAL SEVERE HYPERPARATHYROIDISM

FHH, also called familial benign (hypocalciuric) hypercalcemia, is a disorder typically discovered incidentally on routine serum calcium screening. The hypercalcemia is usually mild (i.e., in the 10.5–12.0 mg/dL range), is lifelong, is generally not associated with the symptoms of hypercalcemia, and is associated with a reduction in the fractional urinary excretion of calcium. Historically, patients with FHH were confused with patients with typical sporadic parathyroid tumors, with the unfortunate consequence that affected patients underwent unnecessary partial parathyroidectomy, which would not alter the serum calcium, or equally unnecessary complete parathyroidectomy with the serious consequence of surgical hypoparathyroidism. Since the initial description of the syndrome in the 1970s, it has become clear that these patients manifest a form of biochemically defined primary hyperparathyroidism with slightly elevated or inappropriately normal serum PTH concentrations, that they have inappropriately efficient renal reabsorption of calcium, that the parathyroid glands have a defective ability to sense the hypercalcemia, and that multiple family members are typically involved, usually in an autosomal-dominant fashion.

Inherited inactivating mutations in the extracellular CaR (encoded by the *CASR* gene) are responsible for the features of FHH in most affected kindreds (*see* Fig. 36-1). The responsible mutations generally involve either the extracellular domain (presumably adversely influencing calcium binding to the receptor) or one of the transmembrane loops (presumably interfering with conformational changes that in turn lead to the activation of signal transduction pathways). In general, affected patients have been heterozygous for the mutant calcium receptor allele. Notably, infants have been described who have a potentially life-threatening syndrome, characterized by severe hypercalcemia (sometimes in the 20 mg/dL range) and, in contrast to typical FHH, prominent parathyroid hypercellularity. This syndrome has been referred to as neonatal severe hyperparathyroidism (NSHPT), and may occur within typical FHH kindreds. NSHPT can result from a germline double dose of a mutant, inactivated calcium receptor gene, often

in the context of consanguineous parentage. Finally, germline heterozygosity for a calcium receptor gene bearing a specific missense mutation in the cytoplasmic tail was reported in familial parathyroid adenoma/hyperplasia with symptomatic hypercalcemia and hypercalciuria, suggesting a spectrum of possible phenotypic consequences of different germline CaR alterations.

In support of the concept that inactive mutant forms of the calcium receptor are responsible for these syndromes, expression in *Xenopus* oocytes of calcium receptors containing the same mutations as those encountered in humans results in impaired ability to sense extracellular calcium. Also, an FHH-like phenotype is found in mice in which a single *casr* allele has been inactivated, and a more severe phenotype similar to NSHPT is seen in mice in which both *casr* alleles have been disrupted. FHH families have been defined whose responsible genetic locus maps to the *CASR*'s 3q locus but no mutations are apparent in the gene's coding region. These findings suggest that mutations in the intronic or regulatory regions of the calcium receptor gene may explain additional kindreds. Mutations in other genes will undoubtedly be demonstrated in the future; for some families with FHH, the disease locus maps to locations distinct from 3q, namely 19p and 19q. It is presumed that the genes at these other loci encode other proteins that play a role in the calcium sensing machinery.

MOLECULAR GENETICS OF SPORADIC PARATHYROID GLAND NEOPLASIA

Primary hyperparathyroidism is caused by excessive secretion of PTH, resulting in hypercalcemia. Patients with primary hyperparathyroidism have both an excessive parathyroid cell mass and a resetting of the set point by which PTH secretion is tightly coupled to the parathyroid cell's ambient calcium level. In most (>80%) patients with primary hyperparathyroidism, a single benign parathyroid tumor (adenoma) is responsible, whereas multiple hypercellular glands are present in approx 15% (primary hyperplasia or "double adenomas"). Parathyroid carcinoma is rare, as is the ectopic secretion of PTH from nonparathyroid tumors. A comprehensive molecular pathophysiological description of parathyroid tumorigenesis will eventually need to fully explain the development of these types of tumors, as well as a variety of other special features such as the increased incidence of parathyroid tumors after exposure to neck irradiation and the disease's epidemiological weighting toward postmenopausal women. Detailed molecular understanding will likely yield information of diagnostic, prognostic, preventative, or therapeutic importance.

CLONALITY IN PARATHYROID TUMORIGENESIS The monoclonality or polyclonality of human tumors is an informative reflection of their underlying pathogenetic mechanism. Early data measuring isoforms of the X-chromosome-encoded protein G6PD in parathyroid adenomas in heterozygous women had indicated that apparently single parathyroid adenomas were polyclonal growths, likely to result solely from a generalized growth stimulus. These results, however, proved to be misleading, because modern molecular methods have now solidly established the monoclonality of typical parathyroid adenomas, both by X-chromosome inactivation analysis and by the direct demonstration of monoclonal genetic alterations in parathyroid adenomas (*see* below). Monoclonality highlights the concept that parathyroid adenomas are true neoplasms, consistent with clinical experience that surgical removal of the enlarged gland is generally curative. Neoplasia is a genetic disease, with most relevant DNA damage occurring somatically.

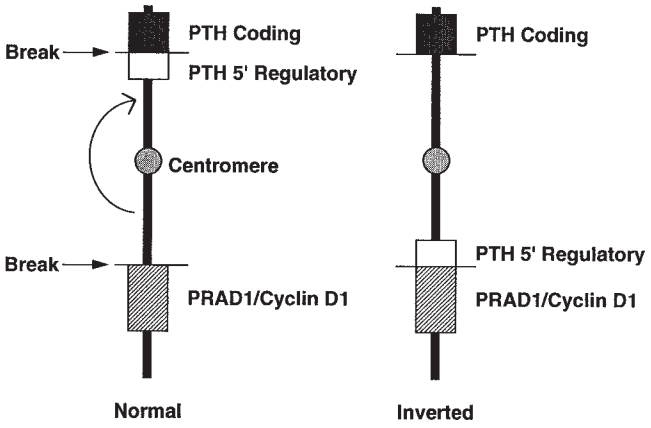

Figure 36-2 Schematic diagram illustrating the pericentromeric inversion of chromosome 11 deduced to have caused the observed rearrangement involving the *PTH* gene and the *PRAD1* gene in a subset of parathyroid adenomas. The tumor's other copy of chromosome 11, which contains an intact *PTH* gene, is not shown. (Reproduced with permission from Arnold A. Genetic basic of endocrine disease 5: molecular genetics of parathyroid gland neoplasia. J Clin Endocrinol Metab 1993;77: 1108–1112. Copyright 1993, The Endocrine Society.)

Monoclonality implies that the necessary accumulation of multiple mutations in a tumor progenitor cell occurs only rarely in a large population of cells within a tissue, conferring a selective growth advantage critical in tumor outgrowth or clonal evolution. The search for the specific oncogenes and tumor suppressor genes that are clonally activated or inactivated, respectively, in common sporadic parathyroid tumors is ongoing. Three notable successes and several important leads, described in the next section have emerged.

The clonal status of parathyroid tumors other than adenomas has also been investigated. As expected, parathyroid carcinomas are monoclonal. More surprisingly, however, a substantial percentage of parathyroid tumors in the setting of primary hyperplasia and severe secondary hyperparathyroidism of uremia are monoclonal, indicating that somatic mutations have given selected cells a growth advantage over their already hyperplastic neighbors. It is conceivable that the "conversion" from polyclonality to monoclonality may be a key factor in the increasing autonomy of PTH secretion that develops in many hemodialysis patients, making them refractory to conventional medical therapy. Future identification of the specific molecular culprits in such clonal outgrowths may lead to rational new therapy or preventive measures for this important clinical problem.

GENETIC DERANGEMENTS IN SPORADIC BENIGN PARATHYROID TUMORS

The Cyclin D1/PRAD1 Oncogene *Cyclin D1/PRAD1*, the only oncogene implicated in sporadic parathyroid neoplasia, was discovered by virtue of its proximity to a clonal chromosomal breakpoint in a subset of parathyroid adenomas. This chromosomal inversion causes overexpression of the *cyclin D1/PRAD1* gene by placing it in proximity to the strong tissue-specific enhancer of the *PTH* gene (Fig. 36-2). Cyclin D1 protein overexpression, resulting from gene rearrangement or other mechanisms, has been found in 20–40% of parathyroid adenomas. That such overexpression indeed causes parathyroid neoplasia has been experimentally validated by the demonstration of primary hyperparathyroidism in transgenic mice with parathyroid-targeted overexpression of cyclin D1. Cyclin D1 activation has also been incriminated in a variety

of other human tumors, including B-cell lymphoma, breast, and esophageal cancers.

Cyclin D1/PRAD1 is recognized to have a crucial role in regulating progression through the G1 phase of the cell division cycle. To do so, the cyclin D1 protein is thought to act as an activating regulatory subunit for its partner cyclin-dependent kinase(s), cdk4 or cdk6. One action of active cdk4 or cdk6 may be phosphorylation of the retinoblastoma gene product pRB, moving the cell toward S phase, but this mechanism has not been established in parathyroid tissue.

TUMOR SUPPRESSOR GENES Inactivation of both alleles of a tumor suppressor gene is typically necessary to adequately eliminate its antioncogenic product, and somatic deletion of a sometimes large stretch of DNA that includes the relevant gene is a common inactivating mechanism. Thus, identification of genomic regions that are clonally and nonrandomly lost in parathyroid adenomas can point to the locations of putative parathyroid tumor suppressor genes.

Of sporadic parathyroid adenomas, approx 25–35% contain allelic losses of chromosome 11 DNA, often (but not always) including the region containing the *MEN1* gene. This gene, responsible for familial multiple endocrine neoplasia type 1 (MEN1), was identified using positional cloning techniques (Chapter 39). Mutations in the affected individuals predict loss of function of the protein, indicating that *MEN1* is a tumor suppressor gene. The gene product, menin, is a 610-amino acid protein located in the nucleus, but the precise molecular mechanisms responsible for its tumor suppressor activity remain uncertain. In sporadic parathyroid tumors, not associated with familial MEN1, biallelic somatic mutations inactivating *MEN1* occur in 12–17%, or about half the tumors with allelic losses on 11q. It is not clear whether the tumor suppressor target in the remaining tumors with 11q loss is *MEN1* or a different gene in its vicinity. Mutation of another tumor suppressor gene, *HRPT2*, was identified as the cause of the rare autosomal-dominant hyperparathyroidism-jaw tumor (HPT-JT) syndrome, and somatic mutations in *HRPT2* have been reported in a few sporadic parathyroid adenomas. However, the rarity of these mutations stands in marked contrast to the high frequency of *HRPT2* mutations in parathyroid carcinoma (*see* Molecular Pathogenesis of Parathyroid Carcinoma). Finally, several other genomic regions of nonrandom clonal allelic loss in parathyroid adenomas highlight the locations of putative parathyroid tumor suppressor genes that remain unidentified, including 1p, 6q, 9p, and 15q. These data emphasize the molecular heterogeneity underlying parathyroid adenomatosis.

OTHER GENETIC ASPECTS Some genes responsible for rare inherited predispositions to certain tumors have also proved important in more common, sporadic forms of the same tumors. The *MEN1* gene, as mentioned, is an example. The discovery of *RET* proto-oncogene germline mutation in MEN2a (Chapter 40) made this gene a candidate for involvement in nonfamilial hyperparathyroidism. However, studies have failed to document somatic *RET* mutations in sporadic parathyroid adenomas. Similarly, inactivating mutations of the extracellular CaR have been sought but not found in sporadic adenomas, although secondary changes in CaR expression may well be important in determining the tumors' altered sensitivity of PTH secretion to serum calcium. Finally, although the syndrome of familial isolated hyperparathyroidism can include phenotypic variants caused by germline mutations in *MEN1*, *CASR*, or *HRPT2*, additional genetic bases are likely to exist and, once identified, will be candidates for involvement in sporadic parathyroid tumors.

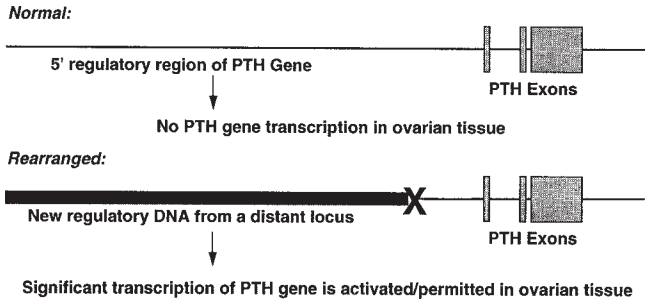

Figure 36-3 Molecular pathology of the ectopic production of PTH by an ovarian cancer. Schematic diagram of the normal *PTH* gene region (top) and the rearranged, amplified *PTH* gene region (bottom) in a PTH-secreting ovarian tumor. The bold "X" represents the breakpoint of the DNA rearrangement. (Reproduced with permission from Arnold A. Genetic basis of endocrine disease 5: molecular genetics of parathyroid gland neoplasia. J Clin Endocrinol Metab 1993;77:1108–1112.)

MOLECULAR PATHOGENESIS OF PARATHYROID CARCINOMA Apart from distant metastasis and extensive local invasion, most histopathological features of parathyroid carcinoma can overlap with parathyroid adenoma. Molecular insights that distinguish between them are thus of potential diagnostic and therapeutic importance. Because parathyroid carcinoma is overrepresented in the rare hereditary HPT-JT syndrome, the *HRPT2* gene identified as responsible for this syndrome was examined as a candidate for involvement in sporadic parathyroid carcinoma. Inactivating mutations of *HRPT2* were found in the majority of parathyroid cancers, and because noncoding mutations would not have been detected in these analyses, *HRPT2* inactivation could be a factor in virtually all parathyroid cancers. Importantly, a subset of patients with apparently sporadic parathyroid carcinoma harbored unsuspected germline mutations of *HRPT2*, indicating that they may have HPT-JT or a phenotypic variant. The possibility of a familial disorder must be considered in any patient presenting with sporadic parathyroid carcinoma, and DNA diagnosis is being used for early diagnosis and treatment to prevent metastatic carcinoma in genetically susceptible family members.

Recurrent clonal alterations have been reported that strongly suggest the involvement and chromosomal locations of other genes important in malignant parathyroid neoplasia. For example, recurrent losses have highlighted a region on chromosome 13 as the site of at least one such tumor suppressor, still to be identified. Several additional locations of frequent clonal DNA losses or gains have been reported as well. Importantly, several genomic regions frequently lost in parathyroid adenomas, including 11q (location of *MEN1*), 6q, and 15q, are rarely if ever lost in carcinomas, suggesting that parathyroid carcinomas arise *de novo* rather than from preexisting adenomas. Cyclin D1 may be overexpressed in many parathyroid cancers but larger sample sizes are needed.

ECTOPIC SECRETION OF PTH

The ectopic secretion of PTH by nonparathyroid tumors is a rare cause of primary hyperparathyroidism. The molecular basis of ectopic PTH production in one such case, an ovarian carcinoma, was found to be a DNA rearrangement in the regulatory region of the tumor's *PTH* gene (Fig. 36-3). Similar detailed molecular pathology has not been described in other examples of human ectopic hormone excess, and might involve analogous DNA

rearrangements or, alternatively, a change in the tumor tissue's characteristic DNA-binding proteins. Preliminary reports indicate that ectopic production of PTH in some neoplasms may be associated with expression of GCMB, which may induce transdifferentiation of neoplastic cells to a parathyroid cell-like phenotype.

37 Congenital Adrenal Hyperplasia

Robert C. Wilson and Maria I. New

SUMMARY

Congenital adrenal hyperplasia is a family of autosomal-recessive disorders caused by mutations that encode for enzymes involved in one of the various steps of adrenal steroid synthesis. This chapter discusses adrenal steroidogenesis, 21-hyroxylase deficiency, 11β-hydroxylase deficiency, 3β-hydroxysteroid dehydrogenase deficiency, 17α hydroxylase/17,20-lyase deficiency, lipoid congenital adrenal hyperplasia, and various treatments.

Key Words: Adrenal steroidogenesis; congenital adrenal hyperplasia (CAH); 3β-hydroxysteroid dehydrogenase deficiency; 11β-hydroxylase deficiency; 17α hydroxylase/17,20-lyase deficiency; 21-hydroxylase deficiency (21-OHD); lipoid congenital adrenal hyperplasia; salt wasting.

INTRODUCTION

Congenital adrenal hyperplasia (CAH) is a family of autosomal-recessive disorders caused by mutations that encode for enzymes involved in one of the various steps of adrenal steroid synthesis (Table 37-1). These defects result in the absence or the decreased synthesis of cortisol from its cholesterol precursor. The anterior pituitary secretes excess adrenocorticotropic hormone (ACTH) via feedback regulation by cortisol, which results in overstimulation of the adrenals and causes hyperplasia.

Symptoms owing to CAH can vary from mild to severe depending on the degree of the enzymatic defect. In the classical forms of CAH, defects in the cytochrome P450s 21-hydroxylase (21-OH) or 11β-hydroxylase (11β-OH) cause varying degrees of genital ambiguity in females owing to shunting of excess cortisol precursors to the androgen synthesis pathway (Fig. 37-1). Prenatal adrenal androgen excess causes virilization of female genitalia and postnatally results in advanced bone age and puberty in both females and males. Defects in androgen synthesis owing to defects in 3β-hydroxysteroid dehydrogenase (3β-HSD)/$\Delta^{5,4}$-isomerase, in 17α-hydroxylase (17α-OH)/17,20-lyase, and in the steroidogenic acute regulatory protein (StAR) result in inadequate prenatal virilization of males and depressed puberty in both sexes. Less severe, nonclassical forms of CAH present postnatally as signs of androgen excess.

ADRENAL STEROIDOGENESIS

Aldosterone, cortisol (compound F) and testosterone are derived from cholesterol and utilize many of the same enzymes for their synthesis in the adrenal cortex (*see* Fig. 37-1). Therefore, defects in any of the enzymes that are common to the synthesis pathway of these hormones can result in the loss of a combination of some or all of their production.

Cortisol and aldosterone are synthesized in distinct zones of the adrenal cortex called the zona fasciculata and zona glomerulosa (ZG), respectively. Synthesis of these hormones is regulated by different mechanisms: cortisol synthesis is regulated by a negative feedback loop in which high serum levels of cortisol inhibit the release of ACTH from the pituitary, whereas low serum levels of cortisol stimulate the release of ACTH. This defines the hypothalamic–pituitary–adrenal axis (Fig. 37-2). Aldosterone, a hormone required for the regulation of sodium reabsorption across the tight epithelium of the renal distal tubule, controls fluid volume and is regulated by the renin-angiotensin system and by serum potassium. Angiotensin II (a potent vasoconstrictor) directly stimulates the secretion of aldosterone by the ZG when there is a reduction in renal perfusion resulting from an increase in plasma renin. Serum potassium also regulates the synthesis of aldosterone, though independently of volume status.

21-HYDROXYLASE DEFICIENCY

Over 90% of cases with classical CAH are because of 21-hydroxylase deficiency (21-OHD). There are three forms of this syndrome: classical salt wasting, classical simple virilizing, and nonclassical.

CLASSICAL SIMPLE VIRILIZING Fetal adrenocortical function begins in the third month of gestation. At this time, reduction or loss of 21-OH activity results in the buildup of 17α-hydroxyprogesterone (17-OHP). Because 17-OHP is a precursor of testosterone, elevated levels of 17-OHP are shunted to the androgen pathway, thus producing excess androgens. This excess adrenal androgen production coincides with the time of sexual development of the fetus and results in varying degrees of genital ambiguity in newborn females. In extreme cases, the urethra extends the full length of the phallus and cannot be distinguished from that of a normal male. In most cases, however, the excess androgens result in an enlarged clitoris with fusion of the labioscrotal folds; it can also result in a urogenital sinus. For these females, the internal genitalia are normal with normal development of ovaries and Müllerian structures.

Males affected with 21-OHD are born with normal genitalia. After birth, both females and males develop signs of androgen excess such as precocious development of pubic and axillary hair,

The Forms of Adrenal Hyperplasia

Deficiency	*Syndrome*	*Ambiguous genitalia*	*Postnatal virilization*	*Salt metabolism*	*Steroids increased*	*Steroids decreased*	*Chromosomal location*
StAR	Lipoid hyperplasia	Males		No salt wasting	None	All	8p11.2
3β-Hydroxysteroid dehydrogenase	Classical	Males	Yes	Salt wasting	DHEA, 17-OH-pregnenolone	Aldo, T, cortisol	1p13.1
	Nonclassical	No	Yes	Normal	DHEA, 17-OH-pregnenolone	–	
17α-Hydroxylase	—-	Males	No	Hypertension	DOC, cortico-sterone	Cortisol, T	10q24-25
21-Hydroxylase	Salt wasting	Females	Yes	Salt wasting	17-OHP, Δ^4-A	Aldo, cortisol	6p21.3
	Simple virilizing	Females	Yes	Normal	17-OHP, Δ^4-A	Cortisol	6p21.3
	Nonclassic	No	Yes	Normal	17-OHP, Δ^4-A	—-	6p21.3
11β-Hydroxylase	Classical	Females	Yes	Hypertension	DOC, 11-deoxycortisol	Cortisol, ± aldo	8q21-22
	Nonclassical	No	Yes	Normal	11-deoxycortisol, ± DOC	—-	8q21-22
Corticosterone methyl oxidase type II	Salt wasting	No	No	Salt wasting	18-OH-corticosterone	Aldo	8q21-22

Aldo, adosterone; T, testosterone; Δ^4-A, Δ^4-androstenedione; DHEA, dehydroepiandrosterone; DOC, 11-deoxycorticosterone; 17-OHP, 17α-hydroxyprogesterone

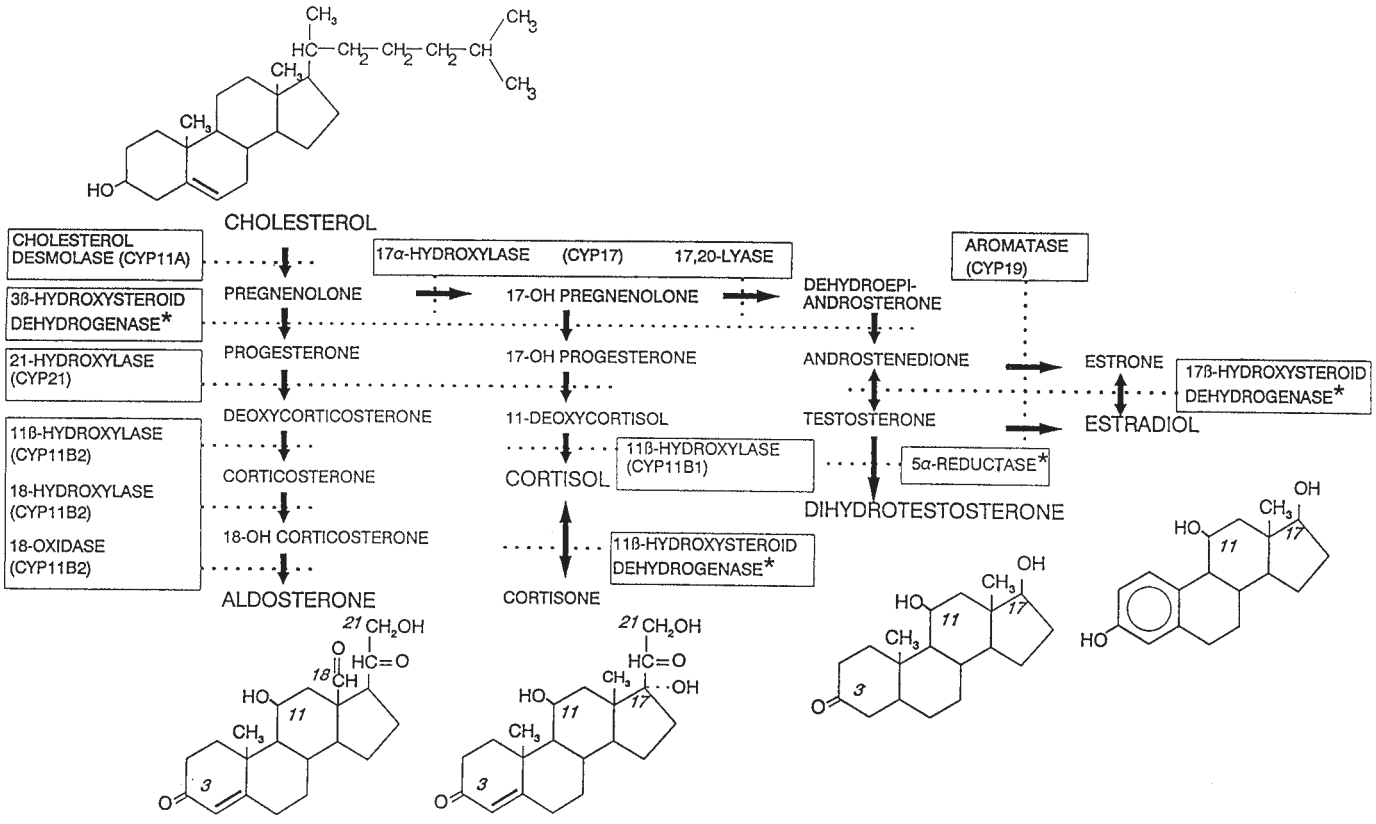

Figure 37-1 Pathways of steroid biosynthesis. Enzymatic activities catalyzing each bioconversion are enclosed in boxes. For activities mediated by specific P450 cytochromes, systematic names of the enzymes ("CYP" followed by number) are listed in parentheses. Other bioconversions (*) are mediated by different enzymes in various tissues. The planar structures of cholesterol, aldosterone, cortisol, dihydrotestosterone, and estradiol are placed near the corresponding labels.

acne, phallic enlargement, rapid growth, and musculoskeletal development. Though initial growth in these patients is rapid, because of premature epiphyseal fusion, potential height is reduced and short adult stature results. Diagnosis may be delayed in males, as the genital ambiguity that leads to diagnosis at birth in females is absent in males. Even if diagnosis is not delayed and adrenal androgen excess is controlled, patients do not generally achieve their target height.

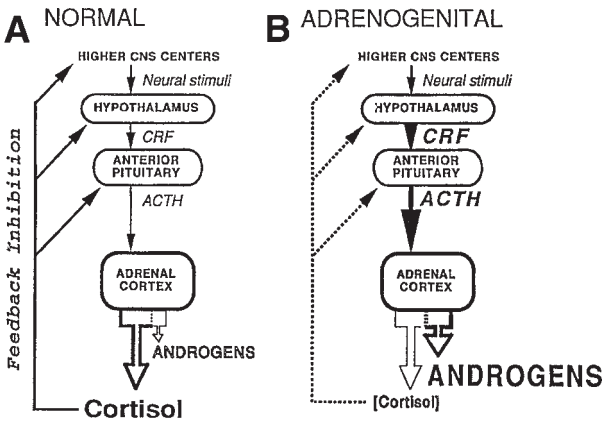

Figure 37-2 Feedback in the hypothalamic–pituitary–axis in **(A)** the normal individual and **(B)** the patient with classical CAH, formerly known as "adrenogenital syndrome."

CLASSICAL SALT WASTING Salt-wasting 21-OHD makes up approx 75% of cases with classical 21-OHD. Depending on the severity of the loss of 21-OH function, adrenal aldosterone secretion may not be sufficient for regulating sodium reabsorption by distal renal tubules. Patients with insufficient aldosterone can suffer from salt-wasting 21-OHD. These patients exhibit the same symptoms as those with simple virilizing 21-OHD but with the potential of adrenal crisis (azotemia, vascular collapse, shock, and death) because of renal salt wasting. Adrenal crisis can occur as early as 1–4 wk of life. Although salt-wasting 21-OHD females may be diagnosed at birth owing to ambiguous genitalia, affected males are at high risk of salt-wasting adrenal crisis because their normal genitalia do not make the condition obvious.

NONCLASSICAL Nonclassical 21-hydroxylase deficiency (NC21-OHD) may present at any time, in childhood, adolescence, or adulthood. Symptoms of NC21-OHD may include acne, premature development of pubic hair, advanced bone age, accelerated linear growth velocity, and as in classical 21-OHD, reduced adult stature owing to premature epiphyseal fusion. Symptoms have been observed to wax and wane.

Females affected with NC21-OHD are born with normal genitalia, though postnatal symptoms may include hirsutism, temporal baldness, severe cystic acne, delayed menarche, menstrual irregularities, and infertility. A subset of female patients with NC21-OHD develops polycystic ovaries.

Boys manifesting NC21-OHD may have early beard growth, acne, early growth spurt, premature pubic hair, and an enlarged phallus. Proportionately small testes as compared with the phallus is a reliable indication of adrenal androgen excess as opposed to testicular androgen excess. Adrenal androgen excess in men is not easily detectable and may only be manifested by short stature or oligozoospermia and diminished fertility.

A limited number of males and females who are affected with NC21-OHD remain asymptomatic, as discovered during family studies. However, biochemically such patients compare to affected individuals.

EPIDEMIOLOGY Newborn screening worldwide of nearly 6.5 million babies has demonstrated an overall incidence of 1:15,000 live births for the classical form of 21-OHD. However, in two isolates the frequency is much higher (Yup'ik Eskimos in Alaska, 1/282, and the inhabitants of La Réunion island in France, 1/2141). The incidence of classical CAH in either homogenous or heterogenous general populations is as high as 1/7500 live births (Brazil).

It has been suggested that NC21-OHD is the most common autosomal-recessive disorder. In some ethnic populations, the frequency of NC21-OHD is so high it is regarded to be the most frequent autosomal-recessive defect. The highest ethnic-specific disease frequency was found among Ashkenazi Jews at 1/27. Other ethnic-specific frequencies were found to be 1/53 for Hispanics, 1/63 for Yugoslavs, 1/100 in a heterogeneous New York City population, and 1/333 for Italians.

MOLECULAR GENETICS In 1977, molecular genetic studies of 21-OHD showed linkage with certain human leukocyte antigens (HLA), the human major histocompatibility complex, on the short arm of chromosome 6. For many years, HLA linkage was used for establishing the affected status in family studies. However, in some cases in which the parents shared the same HLA antigens, or if intra-HLA recombination occurred, HLA typing was not diagnostic.

The gene for 21-OH, cloned in 1984, is termed *CYP21*, following the nomenclature for cytochrome P450. Southern blot analysis determined that the *CYP21* gene was located within the serum complement component *C4*. This region of chromosome was duplicated, resulting in two isoforms of *C4* (*C4A* and *C4B*) and what initially looked like two isoforms of *CYP21*. Sequence analysis of the two *CYP21* genes revealed that one isoform contained a sequence that on translation resulted in a truncated nonfunctional protein, and it was therefore termed *CYP21P* for pseudogene. The nonfunctionality of *CYP21P* was confirmed in families without any hormonal abnormalities in which the CYP21P gene was completely missing.

CYP21 and *CYP21P* are 96–98% homologous (Fig. 37-3) and are arranged in tandem within C4A and C4B, separated by approx 30 kb. The duplication of the locus containing *CYP21* allows for misalignment of chromatids during meiosis, resulting in unequal crossing over. This results in a high frequency of deletions of the *CYP21* and *C4B* genes. Duplications also occur, but without any clinical consequence. Deletions of *CYP21* are found in approx 20% of the patients with classical 21-OHD.

CYP21 and *CYP21P* consist of 10 exons spanning approx 5 kb. Most of the 21-OHD patients carry mutations found in *CYP21P* (Fig. 37-4). The generally accepted mechanism by which these deleterious mutations are transferred to the active *CYP21* gene

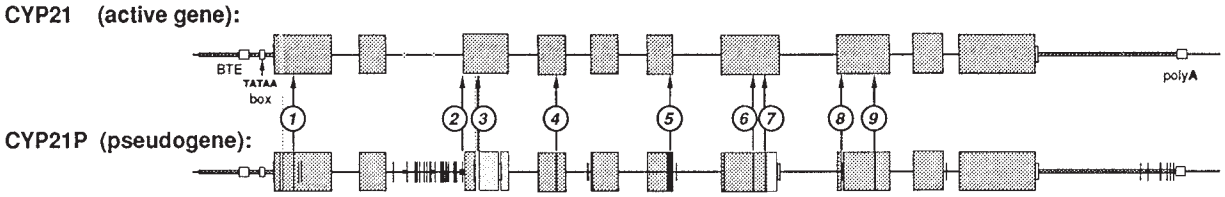

Figure 37-3 The two homologues: *CYP21* (the active gene) and *CYP21P* (the pseudogene). Noncorrespondent bases number less than 90 over a distance of 5.1 kb of DNA. Numbered are the pseudogene base changes frequently identified on mutant *CYP21* genes responsible for 21-OHD through an apparent process termed gene conversion. (1) Missense mutation Pro-30 to Leu. (2) Point mutation in intron 2 causes new acceptor 3´-site to be recognized by intron splicing mechanism. (3) Eight basepair deletion shifts the reading frame. (4) Missense mutation Ile-172 to Asn. (5) Cluster of three nonconservative amino acid substitutions. (6) Conservative amino acid substitution Val-281 to Leu. (7) Single-base T insert shifts reading frame. (8) Nonsense mutation Gln to TAG. (9) Radical amino acid substitution (Arg-356 to Trp). KEY: BTE, basic transcriptional element; large boxes/line spaces, exons/introns (to scale); light shading, out-of-frame coding; half-height open boxes, stop codons; vertical lines not numbered, neutral amino acid polymorphisms; half-height vertical lines, silent mutations.

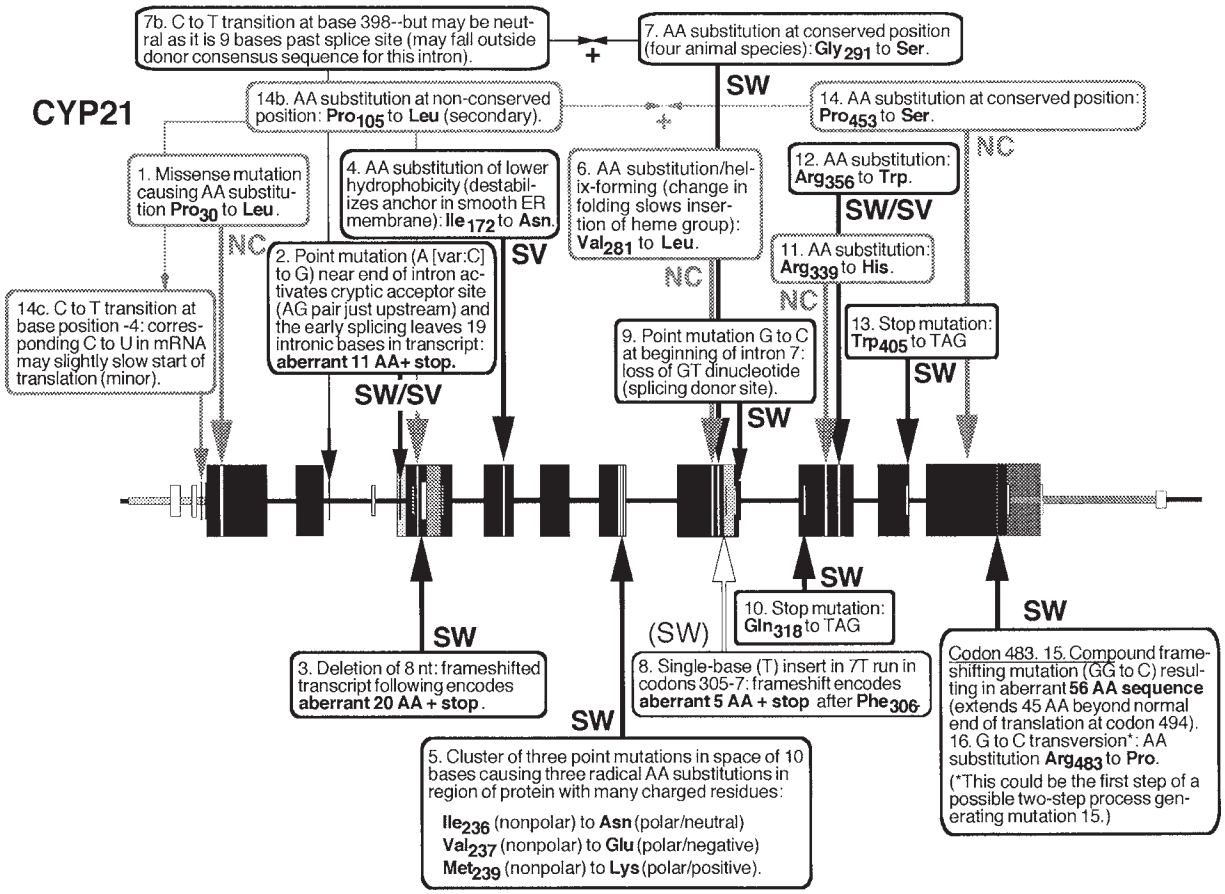

Figure 37-4 Mutations in the 21-hydroxylase gene (CYP21). CAH phenotypes: SW, salt wasting; SV, simple virilizing; NC, nonclassical.

from the homologous position in *CYP21P* is through gene conversion. Nine of these mutations can be transferred to the active *CYP21* gene. Four of these mutations result in truncated proteins owing to premature termination of translation and are associated with the salt-wasting phenotype: (1) a point mutation in the second intron near the 3´ splice site results in aberrant splicing of 13 nucleotides upstream of the normal splice site; (2) in the third exon, an eight base deletion can occur, resulting in nonsense amino acids and the occurrence of a stop codon 20 amino acids toward the carboxyterminus; (3) in exon 7, one T nucleotide can be inserted into a run of seven T nucleotides, resulting in a frameshift that produces five aberrant amino acids and premature termination; and (4) a point mutation in exon 8 in codon 318 changes a glutamine to a stop codon. The five other mutations that can be transferred from *CYP21P* to *CYP21* result in amino acid substitutions.

1. A point mutation in exon 1 causes a substitution of proline by a leucine at codon 30 (P30L). This mutation had 30–60% of the activity of normal 21-OH when expressed in cell culture. The P30L mutation has been found to be associated with the nonclassical phenotype.
2. A point mutation in exon 4 causes a substitution of isoleucine by an asparagine at codon 172 (I172N) and is most often associated with the simple virilizing phenotype.

Table 37-2
Mutations Causing CAH

Exon/Intron	*Mutation*	*NT/Mutation*	*AA*	*Phenotype*
	30-kb deletion			SW
Ex 1	Missense	89 CΔT	P30L	NC
Int 2	Aberrant splicing of intron 2	656 A [or C] ΔG		SW, SV
Ex 3	Frameshift	Δ708–715	G110Δ8nt	SW
Ex 4	Missense	1001 TΔA	I172N	SV
Ex 6	Cluster	1382 TΔA 1385 TΔA 1391 TΔA	I236N, V237E, M239K	SW
Ex 7	Missense	1685 GΔT	V281L	NC
Int 7	Loss of splice donor site	1781 GΔC		SW
Ex 8	Nonsense	1996 CΔT	Q318X	SW
Ex 8	Missense	2060 GΔA	R339H	NC
Ex 8	Missense	2110 CΔT	R356W	SW
Ex 10	Missense	2580 CΔT	P453S	NC
Ex 10	Missense	2672 GΔC	R483P	SW

Ex, exon; Int, intron; Δ, deletion; SW, salt-wasting; SV, simple virilizing; NC, nonclassical; NT, nucleotide.

This mutation results in <2% of normal 21-OH activity in in vitro expression studies.

3. A cluster mutation in exon 6 resulting from the exchange of four nucleotides results in three amino acid substitutions and one polymorphism (the change codes for the original amino acid).
4. A point mutation in codon 281 substitutes a valine with a leucine (V281L). This mutation is associated with the nonclassical phenotype. Expression studies of the V281L mutation show 20-50% of normal 21-OH activity.
5. A point mutation in exon 8 results in the substitution of arginine with tryptophan (R356W). This mutation is associated with the salt-wasting phenotype.

Assignment of a phenotype to each of the individual mutation was done with patients that were either homozygous for the mutation or hemizygous for the mutation (the other allele had undergone a deletion). In addition to the nine mutations found in the pseudogene, several other mutations have been described in patients affected with 21-OHD. The most common mutations of *CYP21* are listed in Table 37-2, over 100 mutations in the CYP21 gene have been identified. A complete list of mutations may be viewed on the World Wide Web.

HORMONAL DIAGNOSIS Baseline serum concentrations of 17-OHP are diagnostic of classical 21-OHD. The best method for hormonal diagnosis of 21-OHD is comparing baseline serum 17-OHP concentration and serum 17-OHP concentrations following adrenal stimulation by administration of synthetic ACTH (Cortrosyn). In NC21-OHD diagnosis is made during the diurnal peak of cortisol production, as serum 17-OHP concentrations are elevated, though random basal serum concentrations may not differ from that of normal. Nomogram plots of baseline vs stimulated 17-OHP concentrations result in three distinguishable groups (Fig. 37-5): Patients with classical 21-OHD have the highest coordinates, followed by patients with NC21-OHD, followed by plots of heterozygotes and genetically unaffected individuals, which overlap and cannot be distinguished.

Newborn diagnostic screening for CAH has been instituted in approx 44 states (http://genes-r-us.uthscsa.edu). On day 2 or 3 of life, blood from a heel prick is spotted onto filter paper and is tested for 17-OHP levels by radioimmunoassay. In adults, NC21-OHD can also be screened by measuring morning salivary 17-OHP, which correlates well with serum concentrations. It should be noted that serum 17-OHP may be elevated in premature infants and infants under stress, which can result in false positives.

PRENATAL DIAGNOSIS AND TREATMENT Prenatal diagnosis of 21-OHD has been performed for several decades. Originally, second trimester amniotic fluid was tested for elevated 17-OHP levels. However, in most cases when the fetus is a nonsalt waster, simple virilizer, or nonclassical, amnionic fluid 17-OHP levels are not elevated.

When HLA was found to be linked to 21-OHD, prenatal diagnoses using HLA serotyping of cultured fetal cells from amniocytes were performed. This procedure resulted in errors because of recombination or haplotype sharing between parents. Once mutations in CYP21 were identified, direct molecular analysis could be performed more accurately, and more effective prenatal diagnosis became possible. This technique requires fetal DNA derived from either cultured amniocytes or from cultured fetal cells obtained via chorionic villus sampling. Southern blot analysis is used to detect large gene deletions whereas allele-specific polymerase chain reaction is performed to detect the nine most common mutations. This technique allows for prenatal diagnosis within several days.

Prenatal treatment (Fig. 37-6) of female fetuses affected with 21-OHD can greatly reduce or prevent virilization of the external genitalia, avoiding the need for genital surgery and possible sex misassignment. To achieve this outcome, prenatal treatment must be initiated before the ninth week of gestation (ideally by the seventh week). Oral dexamethasone (20 μg/kg/d) is conventionally given in daily divided doses to mothers at-risk, without knowing the sex or affected status of the fetus. Dexamethasone is used because it crosses the placenta, crossing from maternal to fetal circulation, and thus suppresses fetal adrenal androgen secretion. Depending on which procedure is available, either chorionic villus sampling (10–12 wk of gestation) or amniocentesis (15–18 wk of gestation) is performed. Fetal cells are cultured for karyotyping and DNA analysis. If the fetus is male or the fetus is an unaffected female, prenatal treatment is terminated. Prenatal treatment is continued to term for affected female fetuses.

Maternal side effects owing to prenatal dexamethasone treatment can include mood changes, weight gain, pedal and leg edema, striae, elevated blood pressure, and general discomfort. However, the majority of these side effects disappear on discontinuation of treatment. Furthermore, owing to the proven benefits

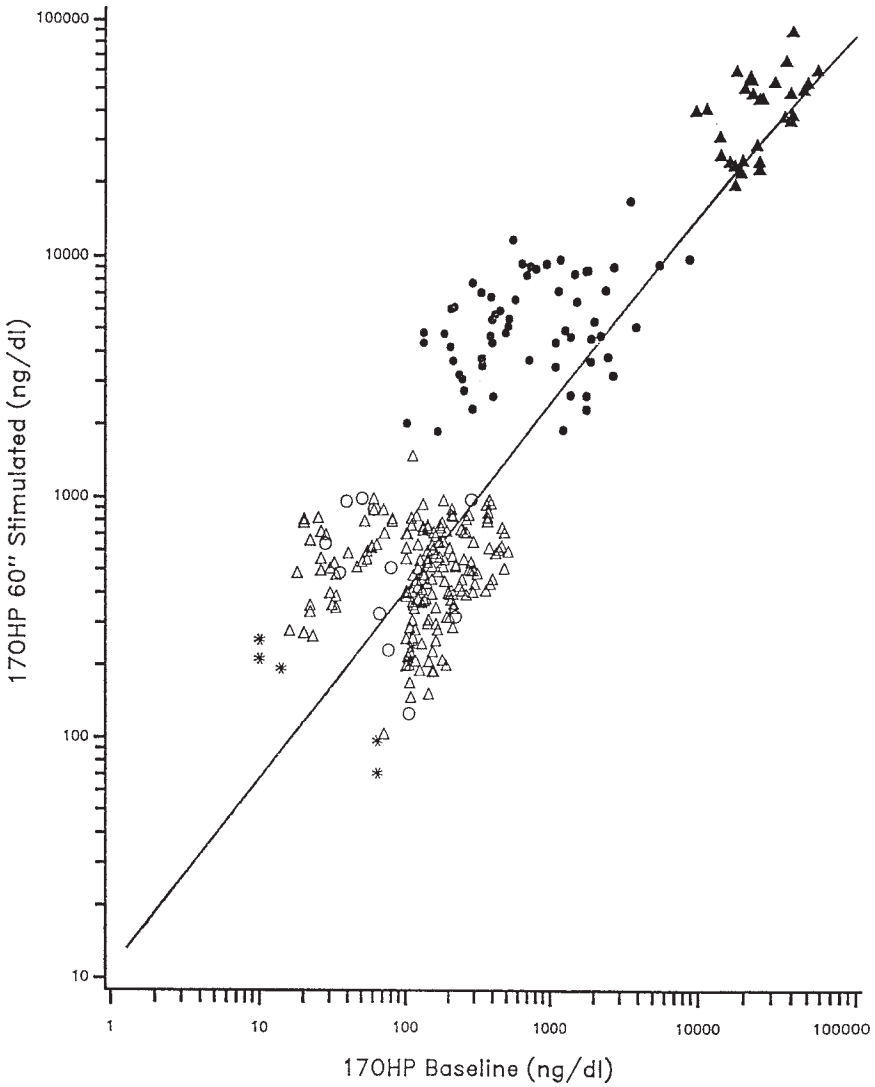

Figure 37-5 Nomogram relating baseline to ACTHstimulated serum concentrations of 17-hydroxyprogesterone. The scales are logarithmic. A regression line for all data points is shown. *, Genetically unaffected. Patients with: ▲, classical CAH; •, nonclassical CAH. Heterozygotes for: Δ, classical CAH; ○, nonclassical CAH. (The data for this nomogram were collected from 1982–1991 at the Department of Pediatrics, The York Hospital, Cornell Medical Center, New York, NY 10021.)

of prenatal therapy, the majority of mothers, including those who developed side effects, reported that they would repeat therapy during a future pregnancy. In an ongoing study of over 600 pregnancies, in which over 300 received dexamethasone therapy, no enduring side effects have been reported in mothers and their offspring as compared to controls. In a different study, some patients have been followed in excess of 20 yr of age without reported side effects.

11B-HYDROXYLASE DEFICIENCY

Patients with 11β-hydroxylase deficiency (11β-OHD) are unable to convert 11-deoxycortisol (compound S) to cortisol. 11β-OHD is the second most common cause of CAH, representing 5–8% of all cases. The frequency of 11β-OHD is in the order of 1 in 100,000 births in Caucasians. As with 21-OHD, cases of mild, late-onset forms of 11β-OHD also have been reported.

As in 21-OHD, 11β-OHD results in shunting of excess 17-OHP to the androgen pathway, causing prenatal virilization of external genitalia in affected females at birth. Also, as in 21-OHD, both males and females undergo premature virilization, resulting in precocious adrenarche and premature epiphyseal closure.

Patients with 11β-OHD also have a defective 17-deoxysteroid pathway. In 11β-OHD, 11-deoxycorticosterone (DOC) cannot be converted to corticosterone, which is eventually converted to aldosterone. In most cases, owing to their mineralocorticoid activity, elevated serum levels of DOC and its metabolites induce hypokalemia with metabolic alkalosis and hypertension. High levels of serum S and DOC, and their corresponding urinary tetrahydrometabolites, are diagnostic of 11β-OHD.

MOLECULAR GENETICS The genes that encode the two known isoforms of 11β-OH in humans are CYP11B1 and CYP11B2, located on chromosome 8, region q21-22, and separated by 30 kb. These isozymes have 93% identity between their amino acid sequences. CYP11B1 is highly expressed in all zones of the adrenal cortex and is regulated by ACTH. CYP11B2 is expressed in the ZG under the control of angiotensin II and potassium ion. Mutations in the CYP11B1 gene are responsible for 11β-OHD (Table 37-3).

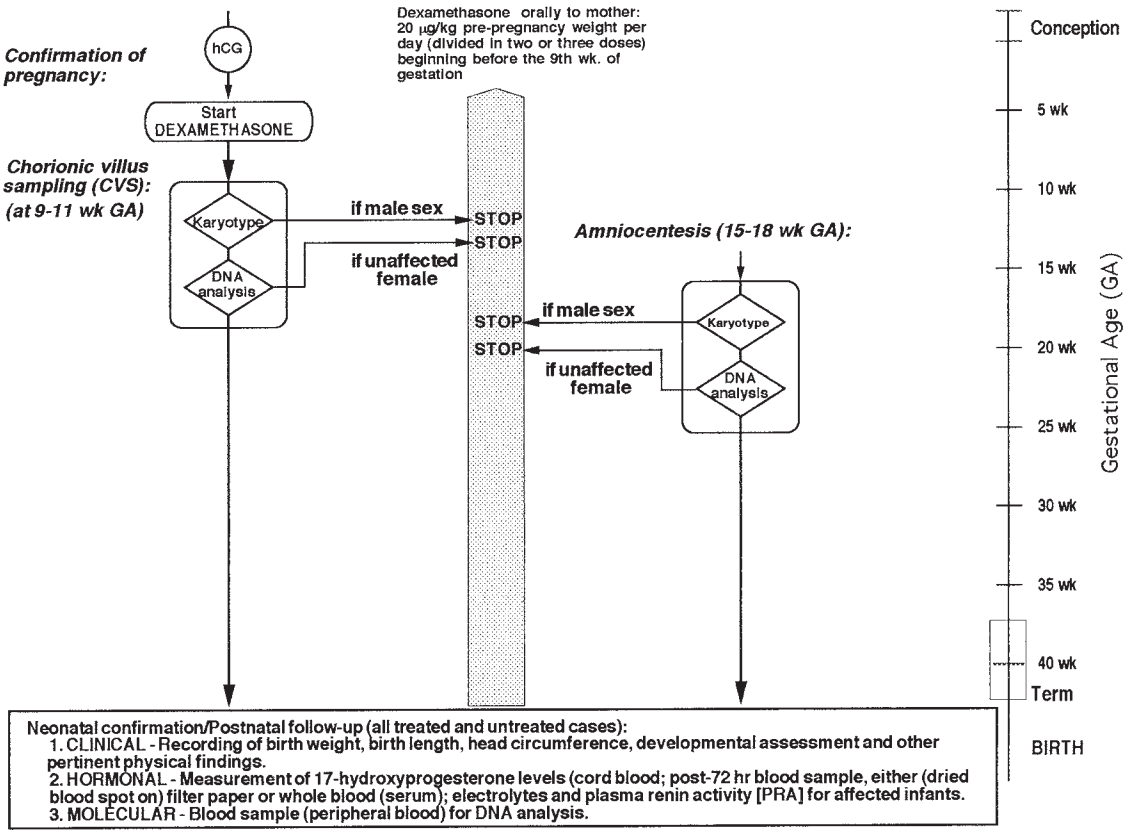

Figure 37-6 Algorithm depicting prenatal management of pregnancy in families at risk for a fetus affected with 21-OHD.

Mutations in the *CYP11B2* gene cause a less frequently inherited disease called aldosterone synthase deficiency or corticosterone methyloxidase (CMO) deficiency II in which aldosterone cannot be synthesized. Aldosterone synthase, in addition to 11β-OH activity, also has 18-hydroxylase and 18-oxidase activities.

CYP11B1 (11β-OH) Approximately 45 mutations have been identified in the CYP11B1 gene. Some of the mutations found in the *CYP11B1* gene causing 11β-OHD are shown in Fig. 37-7. A complete list of mutations may be viewed on the World Wide Web. The first mutation in the *CYP11B1* gene was found in families from Israel. A single point mutation in exon 8 was found in many of these families, resulting in a substitution of arginine at codon 448 with histidine. This mutation in these families was traced back to Moroccan Jewish settlements. A two-base insert in exon 7 resulting in a frameshift was identified in a Turkish Jewish pedigree. This mutation completely altered the heme-binding domain resulting in an inactive enzyme. Within a heterogeneous population, eight other mutations have been identified: four missense mutations, a frameshift mutation (a single base deletion), and three point mutations. A mutation in codon 116 in exon 2, found in a Japanese patient, resulted in a substitution of tryptophan with a stop codon. Finally, a 5-base duplication has been found in exon 2.

***CYP11B2* (ALDOSTERONE SYNTHASE)** Defects in the last two steps of aldosterone synthesis result in salt-wasting syndromes (CMO I, 18-hydroxylation; CMO II, 18-oxidation) during infancy. There are approx 20 mutations identified in the *CYP11B2* gene. Table 37-3 lists some of these mutations. A complete list of mutations may be viewed on the World Wide Web. Two homozygous mutations were identified in patients with CMO II in seven kindreds of Iranian-Jewish origin, a substitution of arginine with tryptophan at codon 181 (R181W), and a substitution of valine with an alanine at codon 386 (V386A). Three other Iranian-Jewish families also had the same mutations. Family members homozygous for either of the mutations alone were asymptomatic. In vitro studies of the individual mutations showed that the R181W mutation was deficient in 18-oxidase activity with reduced 18-hydroxylase activity and intact 11β-OH, whereas the V386A mutation had reduced 18-hydroxylase activity only.

A five-base deletion in exon 1 of *CYP11B2* was identified in a patient who had the biochemical CMO I phenotype. This frameshift mutation results in early termination at the end of exon 1 with complete lack of enzymatic activity in homozygous individuals.

***CYP11B1-CYP11B2* CHIMERA** A form of aldosteronism known as dexamethasone-suppressible or glucocorticoid-remediable hyperaldosteronism (results from the fusion of *CYP11B1* and *CYP11B2* genes in addition to a normal copy of each. The chimeric gene contains the 5′ end of *CYP11B1* and the 3′ end of *CYP11B2*. Therefore, the regulation of this chimeric gene is under the control of ACTH, resulting in high levels of 18-oxocortisol from cortisol and abnormal 17α,18-hydroxysteroids. One copy of this chimeric gene is sufficient to produce the syndrome; hence, this disorder is autosomal-dominant. Dexamethasone treatment results in a prompt and sustained reduction of aldosterone. Patients with glucocorticoid-remediable hyperaldosteronism have abnormal serum and urinary elevations of 18-hydroxy and 18-oxocortisol steroids.

PRENATAL DIAGNOSIS AND TREATMENT In 1996, the first case of prenatal treatment of a female fetus affected with 11β-OHD was reported. As with 21-OHD, treatment of this fetus was initiated before a diagnosis could be completed. The molecular diagnosis revealed a homozygous missense mutation in *CYP11B1*

identical to the mutation of her two affected sisters, who were both severely virilized at birth. However, prenatal dexamethasone treatment of this fetus resulted in normal genitalia at birth.

3β-HYDROXYSTEROID DEHYDROGENASE DEFICIENCY

A rare deficiency in the 3β-HSD/$\Delta^{5,4}$-isomerase enzyme results in high a ratio of Δ^5 to Δ^4 steroids, characterized by elevated serum $\beta\Delta^5$-steroids pregnenolone, 17-hydroxypregnenolone, and dehydroepiandrosterone (DHEA), with increased urinary Δ^5 metabolites pregnenetriol and 16-pregnenetriol. Because 3β-HSD is required for both adrenal and gonadal steroidogenesis, affected males may have incomplete genital development, resulting in sexual ambiguity at birth. Affected females may have very high levels of circulating DHEA with some peripheral conversion to more potent androgens, which leads to limited clitoral enlargement. A complete deficiency of 3β-HSD results in impaired aldosterone synthesis, causing salt wasting.

As with 21-OH and 11β-OH deficiencies, there is a spectrum of the level of 3β-HSD deficiency. The variations include a nonclassical form with postadrenarchal or peripubertal onset.

MOLECULAR GENETICS Two human isoforms of 3β-HSD have been identified by cloning of cDNA (several isoforms have been identified in rodents). Type-I enzyme is expressed in the placenta, skin, and adipose tissue, and type II is expressed in the adrenal gland and the gonads.

The gene *HSD3B1* encodes the type-I isoenzyme, and HSD3B2 encodes the type-II isoenzyme. Classically affected patients have mutations in the *HSD3B2* gene (Fig. 37-8, *see* Table 37-3). A complete list of mutations of which more than 30 have been identified, may be viewed on the World Wide Web. Patients with impaired aldosterone synthesis carry nonsense or frameshift mutations, or missense mutations that were shown to destroy enzymatic activity completely, when mutant cDNA was expressed in cultured cells. No mutations have been found in the gene for type I. It is not known if nonclassical 3βHSD deficiency is because of allelism of type II or if a defect in another 3βHSD is responsible for this phenotype. Cloning and physical mapping has identified five pseudogenes in addition to the two genes described above.

17α-HYDROXYLASE/17,20-LYASE DEFICIENCY

Defects of the CYP17 gene produce CAH owing to 17α-OH deficiency, which manifests as a combined 17α-OH/17,20-lyase deficiency. Patients with 17α-OH deficiency are unable to convert pregnenolone and progesterone to 17α-hydroxypregnenolone and 17-OHP, respectively, and subsequently unable to convert these

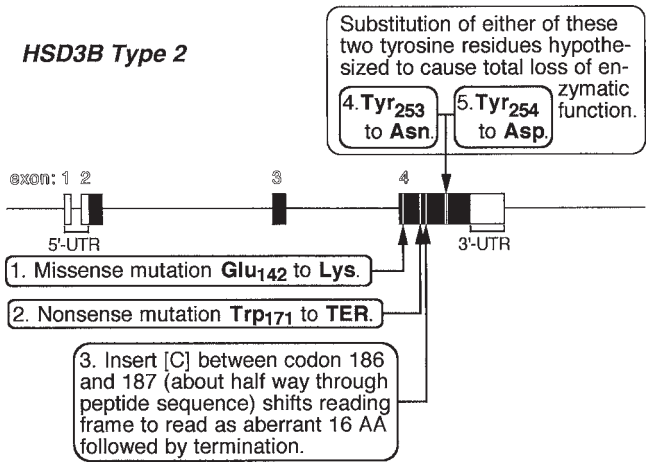

Figure 37-8 Some mutations in the type-II 3β-HSD gene (*HSD3B2*), producing salt-wasting and nonsalt-wasting forms of 3β-HSD deficiency.

hormones to DHEA and Δ^4-androstenedione, respectively, by 17,20-lyase activity. With a decreased ability to synthesize cortisol, elevated ACTH increases serum levels of DOC and especially corticosterone. Both adrenal glucocorticoids and sex steroids are diminished. Isolated 17,20-lyase has also been observed, which results in deficient C19 sex steroids in the adrenals and gonads. Patients with defective 17,20-lyase activity have increased levels of pregnanetriolone, a metabolite of 17OHP.

A deficiency in 17α-OH activity results in low-renin hypertension, hypokalemia, and metabolic alkalosis. Affected females have normal genitalia at birth, but at pubertal age present with primary amenorrhea, lack of axillary and pubic hair, and no pubertal development, leading to hypoplastic breasts in adolescence. Affected males can be born with external female genitalia because of their deficient gonadal testosterone production, though a uterus and fallopian tubes do not develop because anti-Müllerian hormone secretion by Sertoli cells inhibits Müllerian duct development. The Wolffian ducts are incompletely developed as well.

Steroid 17α-OH deficiency is a relatively rare cause of CAH, accounting for approx 1% of cases overall: between 100 and 120 cases of 17α-OH deficiency have been described, and only approx 20 cases of 17,20-lyase deficiency have been reported.

MOLECULAR GENETICS A single gene, *CYP17*, encodes the 17α-hydroxylase enzyme (also a cytochrome P450); it exists in a single active copy and is identically transcribed in both adrenal and testis. *CYP17* is located on chromosome 10, region q24-q25, and approx 50 mutations have been described (Fig. 37-9, *see* Table 37-3). These mutations appear to be random and hence do not appear to be owing to a predisposing mechanism. A complete list of mutations may be viewed on the World Wide Web.

Patients either heterozygous for two mutations or homozygous for a single mutation have both been observed. Although homozygosity for a rare mutation is often taken to suggest consanguinity, an exception to this (an insertion mutation of four nucleotides in codon 480) was found homozygously in several Mennonites, a small Anabaptist sect found in a number of communities across North America. The same mutation was also identified in patients from Friesland, the region in the Netherlands where the Mennonites first formed, suggesting an earlier founder effect.

Partial deficiencies are associated with missense mutations or, in one case, deletion of a single codon (ΔF53 or 54) maintaining the reading frame of translation. Complete deficiency of CYP17 has also been found and is associated with frameshifts and nonsense mutations.

LIPOID CONGENITAL ADRENAL HYPERPLASIA

Lipoid congenital adrenal hyperplasia (LCAH) is extremely rare. The biochemical defect responsible for LCAH resides in the cholesterol side chain cleavage system, causing a deficiency in the conversion of cholesterol to pregnenolone and resulting in profoundly impaired synthesis of all steroids. The term "lipoid" refers to the abnormal appearance of the adrenals at autopsy, now known to be the result of massive accumulations of cholesterol and cholesterol esters. Males are born with female-appearing external genitalia but have undescended testes, and females have a normal genital phenotype at birth but remain sexually infantile without treatment.

If not detected and treated, LCAH is fatal in newborn infants and death can occur within days to weeks of birth. Severe fluid and electrolyte disturbances, low levels of all steroids in plasma and urine and addisonian pigmentation are present. Very poor stress response and great susceptibility to infection are also seen.

MOLECULAR GENETICS In most patients with LCAH, mutations in the StAR protein have been identified (Fig. 37-10, *see* Table 37-3). This enzyme, essential for steroidogenesis, is involved in the transfer of cholesterol from the outer to the inner mitochondrial membrane, in which it is then converted to pregnenolone. The gene encoding *StAR* is on chromosome 8, region p11.2, and a *StAR* pseudogene is located on chromosome 13. In three patients, a C to T transition in this gene resulted in premature termination. This was confirmed by Western analysis and in vitro studies, showing that these mutations produced completely inactive enzymes. In another report, a patient had a splice site mutation because of a T to A transversion in intron 4, resulting in the elimination of 185 nucleotides from the StAR mRNA. Six other mutations in the gene encoding StAR were reported from four patients in 1996. A complete list of mutations in the STAR gene may be viewed on the World Wide Web.

It was originally thought that a defect in the cholesterol side-chain cleavage enzyme, cytochrome $P450_{scc}$, was responsible for this disease, as $P450_{scc}$ produces pregnenolone from cholesterol. However, previously this enzyme was shown to be normal in patients with LCAH and no mutations were identified in the *CYP11A* gene, which encodes for the $P450_{scc}$ enzyme. In 2001, a mutation (a heterozygous in-frame insertion of Gly and Asp between Asp271 and Val272) was identified in the *CYP11A* gene in a patient with LCAH. Later, two novel compound heterozygous mutations in *CYP11A* were reported in a patient with congenital adrenal insufficiency with a maternally inherited R353W mutation and a *de novo* A189V mutation in the paternal allele. These findings suggest that genetic analysis should include both of these genes in patients with LCAH.

TREATMENT

Treatment of CAH owing to 21-OHD has been ongoing since 1950. Glucocorticoid replacement therapy replaces the deficient hormone and reduces the overstimulation of the adrenal cortex by reducing the release of ACTH, thereby suppressing the overproduction of

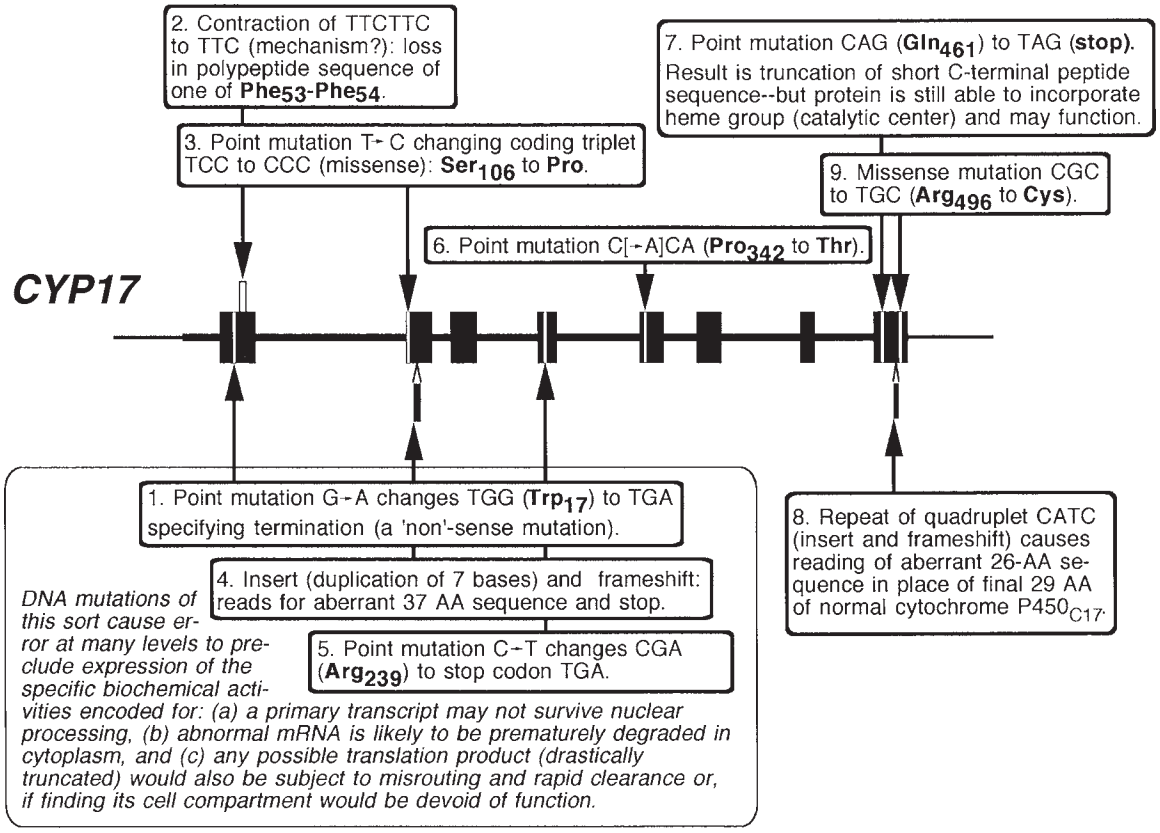

Figure 37-9 Mutations in the 17α-hydroxylase/17,20-lyase deficiency gene (*CYP17*).

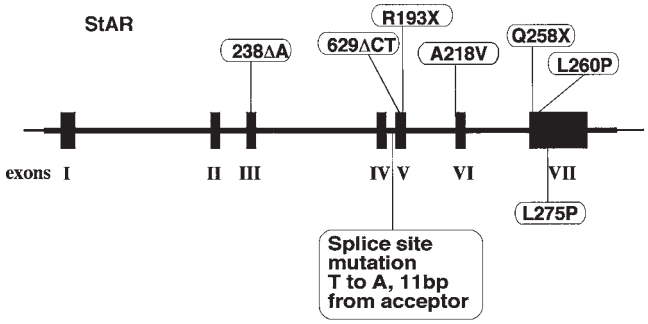

Figure 37-10 Mutations in the StAR gene.

adrenal androgens. Hydrocortisone (cortisol) is the most often used compound for replacement therapy in 21-OH, 11β-OH and 17α-OH deficiencies. Proper replacement therapy in 21-OHD and 11β-OHD ameliorates the effects of oversecretion of adrenal androgens, thus preventing further virilization, slowing accelerated growth and bone age advancement to a more normal rate, and allowing a normal onset of puberty. In 11β-OHD and 17α-OH deficiency, glucocorticoid treatment suppresses the oversecretion of DOC, leading to the remission of hypertension. Excessive glucocorticoid administration can cause cushingoid facies, growth retardation, and inhibition of epiphyseal maturation.

Hydrocortisone is the physiological hormone and therefore minimizes complications. Oral administration is the usual mode of treatment, conventionally given daily in divided doses. It is believed that divided doses better suppress the production of adrenal androgens.

Hydrocortisone given in two equally divided doses of 10–20 mg/m^2 daily is adequate for the otherwise healthy child. The dosage may have to be increased for a few days to two to three times that of the normal daily dosage during times of non-life-threatening illness or stress. Families are given injection kits of hydrocortisone (50 mg for young children; 100 mg for older patients) for times of emergency. Up to 5–10 times the daily dosage may be required during surgical procedures.

Patients who show a poor response to the standard dosage of hydrocortisone may have their dosage increased to 20–30 mg/m^2/d or their regimen may have to be changed to a synthetic hormone analog such as prednisone or dexamethasone. The use of these analogs requires critical dosage adjustment because they are more potent and longer acting.

Patients with salt-wasting CAH may also require mineralocorticoid replacement. A cortisol analog, 21-acetyloxy-9α-fluorohydrocortisone (Florinef: 9α-FF), is used for its potent mineralocorticoid activity. A combination of hydrocortisone and Florinef has proven effective in treatment of patients with salt-wasting 21-OHD.

In simple virilizing patients, it is common to find elevated PRA resulting from the interaction of the renin–angiotensin–aldosterone system and the hypothalamopituitary–adrenal axis. Florinef given in these cases reduces the plasma renin activity (PRA) which in turn further lowers ACTH levels and results in better control of androgens without increasing the glucocorticoid dose.

Patients with NC21-OHD and nonclassical 3β-HSD deficiency are treated with low doses of dexamethasone. Excess ovarian androgen production may have to be suppressed by the use of progestational and estrogenic agents, by suppression of the release of

gonadotrophin. Other anti-androgen agents that may help include spironolactone and cyproterone acetate, and the androgen receptor blocker, flutamide. The aim of treatment in these patients is to minimize symptoms without giving rise to glucocorticoid side effects.

In LCAH, as all steroidogenic enzymes are normal, a substrate for steroidogenesis can be used for effective treatment of patients. Freely diffusable 20α-hydroxycholesterol is recommended, which must be implemented as a lifelong treatment plan. Successful continuing management of a patient for 18 yr was reported in 1985 using replacement glucocorticoids and mineralocorticoids in physiological doses, and estrogen replacement induced a pubertal growth spurt.

FUTURE DIRECTIONS

For many diseases reasonably well defined clinically, genetically, and molecularly, there remain a number of cases that demonstrate genotype–phenotype nonconcordance. In these cases, patients present with clinical signs that are not predicted by the genotype. Specifically, steroid 21-OH is being studied to elucidate the extent and reasons for discordance. As the mechanism for this phenomenon remains elusive, future studies should investigate the promoter and regulatory areas of the 21-OH gene. The surrounding genes may play a role in altering gene expression, though the different phenotypes of mutation-identical sibs casts doubt on this explanation. Activity of transcription factors, transport proteins, and other modifiers must also be studied.

ACKNOWLEDGMENT

We wish to express our appreciation to Brian Betensky for his editorial assistance in preparing this manuscript.

38 Adrenal Diseases

Richard J. Auchus, William E. Rainey, and Keith L. Parker

SUMMARY

The adrenal cortex play key roles in regulating intermediary metabolism, fluid and electrolyte balance, and the response to stress. Molecular analyses of specific disorders resulting from either the diminished or enhanced production/action of corticosteroids have led to the identification of a number of genes that play key roles in adrenal function and corticosteroid action. These genes provide potential targets for novel therapies that may revolutionize our approaches to these rare adrenal diseases. In addition, understanding the molecular causes of these diseases has provided important insights into basic adrenal functions that may translate into improved therapy of more common disorders such as hypertension and obesity.

Key Words: ACTH receptor; adrenocorticotrophic hormone (ACTH); adrenal cortex; glucocorticoids; glucocorticoid receptor; hypertension; mineralocorticoids; hypothalamic-pituitary-adrenal axis; mineralocorticoid receptor; stress; zonation.

INTRODUCTION

Thomas Addison first described the essential role of the adrenal glands for human survival in 1855, and Brown-Séquard confirmed this essential role in adrenalectomized experimental animals 1 yr later. Subsequent studies led to the concept that the basic function of the adrenal glands is to protect the organism against acute and chronic stress, popularized as the "fight-or-flight" response for the medulla and the "alarm" reaction for the cortex. Although the adrenal gland includes two functionally distinct compartments—the outer cortex that makes steroid hormones and the inner medulla that makes catecholamines—it is the cortical steroids that are essential for life. In contrast, disorders of both the adrenal cortex and the medulla cause disease states because of excess hormone production. This chapter reviews advances in understanding the molecular pathogenesis of genetic diseases associated with impaired production or action of adrenocortical steroids.

GENERALIZED GLUCOCORTICOID RESISTANCE

Generalized glucocorticoid resistance (GGR) is a rare disorder characterized by elevated circulating cortisol levels and the absence of most stigmata of glucocorticoid excess. Because glucocorticoids are crucial regulators of the central nervous system, intermediary metabolism, cardiovascular function, inflammation, and immunity, a complete abrogation of glucocorticoid action in human beings presumably is incompatible with life, as is supported by the early postnatal death of knockout mice lacking the glucocorticoid receptor (GR) that mediates most actions of glucocorticoids. Thus, the described syndromes of GGR encompass partial glucocorticoid resistance resulting from GR defects.

CLINICAL FEATURES AND DIAGNOSIS Glucocorticoid production is tightly regulated by complex, reciprocal interactions among the hypothalamus, anterior pituitary, and adrenal cortex, collectively termed the hypothalamic–anterior pituitary–adrenal (HPA) axis (Fig. 38-1). A critical component of HPA function is negative feedback inhibition. Normally, glucocorticoids act via GR to diminish both the hypothalamic secretion of corticotropin-releasing hormone and the pituitary secretion of corticotropin (adrenocorticotropic hormone [ACTH]). The resulting decrease in ACTH secretion removes the major stimulus to glucocorticoid synthesis by the adrenal cortex, thereby permitting precise regulation of cortisol levels.

In the setting of partial loss of GR function, levels of cortisol that normally mediate feedback inhibition fail to suppress completely the HPA axis, which resets to a higher level because of compensatory increases in ACTH and cortisol secretion. Because the GR defect is partial, adequate compensation for the end-organ insensitivity apparently is achieved by the elevated concentration of cortisol in circulation; however, the excess ACTH secretion also stimulates the production of adrenal steroids with salt-retaining (e.g., corticosterone, deoxycorticosterone, cortisol) or androgenic (e.g., androstenedione and dehydroepiandrosterone) activities (*see* Fig. 38-1). Because the mineralocorticoid and androgen receptors are intact, GGR presents with symptoms and signs of mineralocorticoid excess (hypertension and hypokalemic alkalosis) and/or of hyperandrogenism (acne, hirsutism, male pattern baldness, menstrual irregularities, anovulation, and infertility). In children, the excessive secretion of adrenal androgens can cause sexual precocity. Finally, abnormal spermatogenesis and male infertility can result from effects of excess adrenal androgens on the regulation of pituitary gonadotropin secretion or from ACTH-induced growth of adrenal rests in the testes. These clinical manifestations are not observed in all patients with GGR, and the presentation may vary even within families.

The diagnosis of GGR is made by demonstrating a high cortisol production rate (high plasma total and free cortisol or elevated 24-h urinary free cortisol), resistance to dexamethasone suppression,

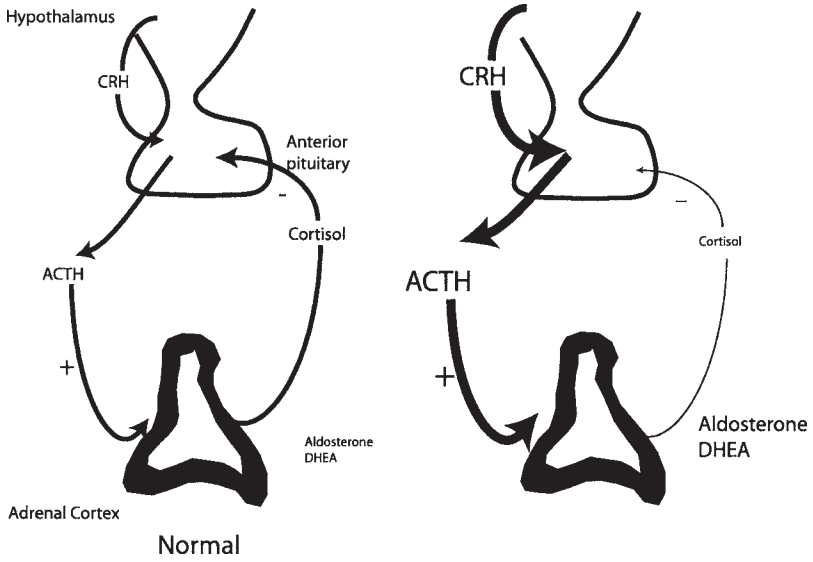

Figure 38-1 Dysregulation of corticosteroid production in glucocorticoid resistance syndromes. At left, normal feedback mechanisms allow precise regulation of corticotropin-releasing hormone, corticotropin (ACTH), and cortisol synthesis. In glucocorticoid resistance (right), partial insensitivity to cortisol feedback elevates the set-point for the hypothalamus, anterior pituitary, and adrenal cortex axis, reaching steady state at higher hormone production. As a consequence, mineralocorticoids (cortisol intermediates) and androgens (metabolites of adrenal DHEA-S) also accumulate. CRH, corticotropin-releasing hormone.

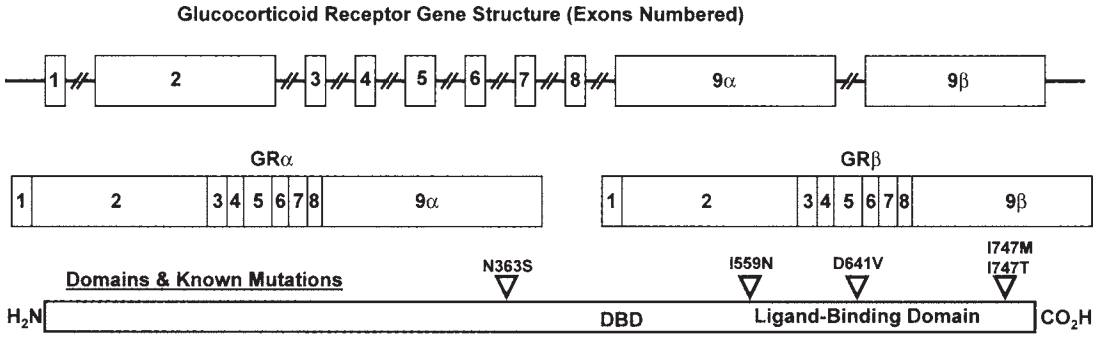

Figure 38-2 Structures of the gene, cDNA, and protein of the GRs are shown. The α- and β-isoforms are derived from alternative splicing of the last two exons. The ligand-binding domain and DNA-binding domain (DBD) of the GR-α protein are shown in protein structure, along with the location of four known mutations causing glucocorticoid resistance (arrowheads).

and preservation of the circadian and stress-induced patterns of glucocorticoid secretion, albeit at higher levels, without the stigmata of Cushing's syndrome.

GENETIC BASIS The cloning of the GR cDNA and gene permitted studies on the molecular mechanisms of glucocorticoid resistance (Fig. 38-2). The *GR* gene (officially designated *NR3C1*) is located on chromosome 5q31-32. Like most nuclear receptor proteins, GR has three main functional domains: an amino-terminal domain that includes residues important for transcriptional activation, the zinc-finger DNA-binding domain, and the carboxyl-terminal ligand-binding domain. Mutations that impair any of these functions may manifest clinically as GGR, and the molecular mechanism(s) by which these mutations impair receptor function may be complex and multifactorial.

Mutations within the ligand-binding domain (R477H, V571A, D641V, G679S, V729I, and I747M) decrease both affinity for glucocorticoids and agonist-induced transcriptional activation. A 4 bp deletion in a splice donor site of intron 6 reduces receptor number by 50%, presumably by decreasing the efficiency of RNA splicing, whereas other missense mutations reduce receptor number or function by effects exerted on the GR protein. Mutation I559N reduces receptor number by more than 50%, but this substitution also interferes with subcellular trafficking, perhaps because it is immediately adjacent to a nuclear localization motif. When tagged as a fusion with green-fluorescent protein, mutation I559N translocates to the nucleus more slowly than wild-type GR and only at high concentrations of agonist. Mutation I559N also interferes with agonist-induced nuclear translocation and transactivation by wild-type GR. These studies illustrate how a single GR mutation can impair its activity in multiple ways, including dominant negative effects on the function of the wild-type GR protein that yield clinical manifestations in heterozygotes. Of note, there is considerable heterogeneity in the phenotypes associated with various GR mutations and some family members with the identical mutation are clinically asymptomatic; these findings argue that genetic variations in other proteins may modulate GR function. Finally, no mutations in the gene for GR have been identified in some GGR subjects, again supporting the idea that proteins other

than GR are critical for glucocorticoid action and may form the basis for GGR in these subjects.

CLINICAL MANAGEMENT Patients with GGR are treated with carefully titrated doses of synthetic glucocorticoids such as dexamethasone that have no intrinsic mineralocorticoid activity. It is essential to monitor clinical (e.g., linear growth rate) and biochemical parameters to avoid glucocorticoid excess, especially in children.

FUTURE DIRECTIONS Glucocorticoid resistance may be more prevalent than previously believed and, thus, may have even broader implications for human disease. As noted, the variety of phenotypes and receptor abnormalities described, as well as the complexity of the GR structure and its multitude of interactions within the cell, suggest that additional genetic defects will be shown to cause glucocorticoid resistance. GR associates with a number of proteins in its cytoplasmic state, including the heat shock proteins hsp-90 and hsp-70 and the immunophilins. Specific mutations that affect these components of the GR complex may similarly affect function. Moreover, several transcription factors (e.g., c-*jun*, c-*fos*, and NF-κB) and coactivator and corepressor molecules interact physically and functionally with GR, and mutations in these transcription factors and coregulators may modulate its activity. The spectrum of GGR may also include tissue-specific unresponsiveness to glucocorticoids, as observed in lymphoid and corticotrope neoplasia, autoimmune and allergic diseases, and probably, psychiatric disorders. The *GR* gene also encodes a β-isoform (GRβ) that does not bind glucocorticoids but can inhibit the activity of the classic α-isoform. GRβ is expressed differentially in various glucocorticoid target tissues, and alterations in GRβ thus may cause a tissue-specific effect on glucocorticoid responses. Finally, although the molecular basis has not been defined, GR polymorphisms are associated with metabolic syndromes such as obesity.

ISOLATED GLUCOCORTICOID DEFICIENCY

Isolated glucocorticoid deficiency (IGD, also called familial glucocorticoid deficiency type 1) is a rare, autosomal-recessive disorder characterized by primary adrenal insufficiency without mineralocorticoid deficiency. Affected children typically have recurrent hypoglycemia, convulsions, or coma, which—unless recognized—may result in death within the first 2 yr of life or may subsequently cause cachexia and failure to thrive.

CLINICAL FEATURES AND DIAGNOSIS Patients with IGD have adrenocortical resistance to ACTH and present in early infancy with hypoglycemia, hyperpigmentation, low or undetectable plasma cortisol, and failure to respond to ACTH stimulation with increased steroidogenesis. In contrast, their zona glomerulosa increases aldosterone production in response to activation of the renin–angiotensin axis by salt restriction, orthostasis, or furosemide-induced diuresis. Consistent with these steroidogenic profiles, the zonae fasciculata/reticularis in these patients are reduced to a narrow band of fibrous tissue, whereas the zona glomerulosa is relatively well preserved.

GENETIC BASIS The adrenocortical unresponsiveness to ACTH in patients with IGD suggested an underlying defect somewhere within the signaling cascade from the ACTH receptor to $G\alpha_s$ to the kinase(s) that stimulate steroidogenesis. The human gene encoding the ACTH receptor, designated the melanocortin 2 receptor (MC2R), encodes a 297-amino acid protein that belongs to the family of G protein-coupled, seven transmembrane domain receptors. Mutations of the *MC2R* gene on chromosome 18p11.2 have been described in a number of families with hereditary IGD. Defining how these mutations impair receptor function has been problematic, because many standard cell lines express endogenous MC2R or other members of the melanocortin receptor family. The Y-6 and OS-3 cell lines are derived from the mouse adrenal Y-1 cell line and retain functional pathways downstream of cAMP generation but lack endogenous MC2R expression. Studies in Y-6 cells showed that mutation D103N, positioned at the C-terminus of the first extracellular loop, partially impairs both ACTH binding and cAMP generation; in contrast, mutation S74I, which is predicted to lie at the junction of transmembrane helix 2 and the same extracellular loop, shows complete ablation of both activities. Using a cAMP-responsive reporter assay in OS-3 cells, mutation Y254C was devoid of activity, whereas mutation R137W showed a shifted dose–response curve and a lower maximal response than wild-type MC2R. In general, it has been difficult to correlate specific mutations of MC2R with impairment of either ACTH binding or cAMP generation, and genotypes generally cannot be used to predict severity of disease. Consequently, although the identification of MC2R mutations in IGD has advanced the knowledge of melanocortin receptor biology, structure-function aspects of MC2R remain poorly understood.

Although mutations of *MC2R* clearly are one cause of IGD, the genetic defects in other kindreds remain obscure. Using linkage analysis, genetic heterogeneity has been demonstrated by the exclusion of *MC2R* gene in three families with IGD. In two additional families, the *MC2R* gene was sequenced and no mutations were found. In one of these, peripheral blood lymphocytes from the two affected siblings failed to respond to ACTH with an increase in cAMP. In aggregate, it appears that only half of the cases of IGD are caused by mutations of the *MC2R* coding region. Consistent with this model, recent studies identified a gene, designated MC2R associated protein, that is mutated in some kindreds with IGD. This protein associates with the MC2R in adrenocortical cells and may have a role in the trafficking of the receptor from the endoplasmic reticulum to the plasma membrane.

CLINICAL MANAGEMENT Patients with IGD are treated with replacement doses of hydrocortisone or equivalent doses of other glucocorticoids. They achieve normal growth and intellectual development if diagnosed early and treated appropriately. Unlike patients with primary adrenal insufficiency, they do not require mineralocorticoid supplementation, as their zona glomerulosa is normal.

TRIPLE-A SYNDROME

Some patients with manifestations of IGD have a complex, autosomal-recessive syndrome in which adrenocortical insufficiency coexists with alacrima and achalasia of the esophagus (termed "triple A" for adrenal insufficiency, alacrima, achalasia); many of these patients also have neurological dysfunction. Unlike patients with IGD, the neurological manifestations in patients with the triple-A syndrome progress independence of the time of onset of glucocorticoid replacement or the number of hypoglycemic episodes, suggesting that they have primary CNS defects. Histologically, the adrenal gland exhibits marked impairment of the zonae fasciculata and reticularis, but has relatively preserved zona glomerulosa and adrenal medulla. Patients with the triple-A syndrome do not have any genetic changes of the *MC2R* gene. Positional cloning resulted in the identification of a gene designated *ALADIN* on chromosome 12q13. ALADIN, a member of the WD-repeat family, is a component of the nuclear pore complex (NPC) that mediates nucleocytoplasmic transport. Although the mechanism by which loss-of-function mutations of *ALADIN*

impair adrenocortical and neurological function is unknown, mutations H106R, S263P, and V313A, all found in the WD-repeat domain, result in mislocalization of the protein to the cytoplasm rather than the NPC. The ultrastructure of the NPC from cells expressing these mutations is normal, yet their function apparently is impaired. In contrast, mutation Q15K retains its targeting to the NPC and causes a less severe form of triple-A syndrome. Therefore, it appears that the triple-A syndrome results from either defective NPC targeting, because of disruption of the propeller structure in the WD-repeat domain, or the loss of other, yet-to-be-defined functions of ALADIN. Ongoing studies may define further the pathogenesis of the triple-A syndrome.

ADRENAL HYPOPLASIA CONGENITA

Adrenal hypoplasia congenita (AHC) is a developmental disorder of the adrenal gland that—if untreated—results in severe adrenal insufficiency and death in early infancy. Two distinct forms of AHC have been described: an autosomal-recessive form associated with miniature adrenal glands and an X-linked form associated with a cytomegalic histopathology. AHC encompasses a complex endocrine disorder that includes primary adrenal insufficiency, hypogonadotropic hypogonadism because of combined hypothalamic and pituitary defects, and impaired spermatogenesis. In addition, some AHC kindreds have a contiguous gene deletion syndrome that results in glycerol kinase deficiency, hearing loss, and Duchenne's muscular dystrophy (DMD).

CLINICAL FEATURES Both the miniature and the X-linked forms of AHC usually present in infancy as failure to thrive, vomiting, feeding difficulties, neonatal cyanosis and apnea, and seizures. Hypoglycemia, hyponatremia, and hyperkalemia are caused by the extremely low cortisol and aldosterone levels that fail to respond to endogenous or exogenous ACTH. Ambiguous genitalia or cryptorchidism also may be present in both the autosomal-recessive and X-linked forms, whereas impaired response of gonadotropins to gonadotropin-releasing hormone (i.e., hypogonadotropic hypogonadism) is limited to the X-linked form. However, association of the autosomal-recessive form of AHC with anencephaly or isolated pituitary abnormalities also has been reported. The adrenal histology differs in the X-linked and autosomal-recessive forms of AHC. The postnatal adrenal gland from subjects with X-linked AHC has a poorly developed cortex, with poor zonal differentiation and residual clumps of eosinophilic, cytomegalic cells thought to be residual cells from the fetal zone. In contrast, both the fetal cortex and the permanent cortex are markedly affected in the miniature adult type.

GENETIC BASIS The description of patients with the X-linked variant of AHC associated with glycerol kinase deficiency, hearing loss, and DMD suggested a contiguous gene deletion syndrome (Fig. 38-3). Indeed, the identification of several patients with deletions of Xp21 mapped an AHC locus to Xp21, adjacent to the DMD locus. The same region of Xp21 also encompassed the critical region for a phenomenon called dosage-sensitive sex reversal, in which microscopic duplications of the X chromosome caused male-to-female sex reversal of 46, XY subjects. The *DAX-1* (dosage-sensitive sex reversal, AHC critical region on the X chromosome) gene was then cloned from contiguous phage clones encompassing the region. *DAX-1* (officially designated *NR0B1*) encodes an atypical member of the nuclear hormone receptor superfamily that has the conserved ligand-binding domain but lacks the zinc finger DNA-binding domain typically found in the nuclear receptors. Instead, DAX-1 has 3.5 copies of a conserved motif that has alternately been reported to bind DNA or RNA or to mediate protein–protein interactions.

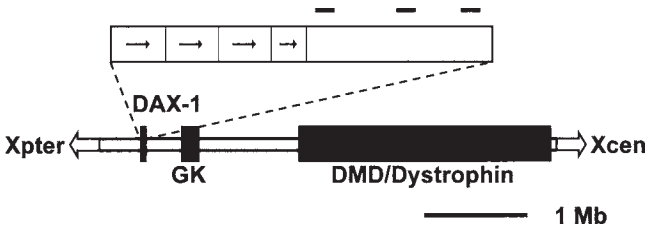

Figure 38-3 Locations of genes involved in contiguous deletion syndromes on the short arm of the X-chromosome. Bottom, The short arm of X-chromosome (Xp21) contains loci for DAX-1, glycerol kinase, and dystrophin, which is mutated in DMD. The scale bar indicates 1 Mb. Top, A schematic diagram of DAX-1 protein. DAX-1 contains 3.5 repeats containing LXXLL motifs in the amino-terminus (arrows) and a C-terminal domain that is essential for function (shaded). Regions in which mutations in DAX-1 were identified in patients with adrenal hypoplasia congenita cluster are indicated by the lines above the diagram.

Mutations of the *DAX-1* gene (nonsense, missense, and frameshift mutations and a single amino acid deletion) were found in patients with both X-linked AHC and hypogonadotropic hypogonadism who had no other genetic abnormality of the chromosome Xp critical region. These missense mutations cluster at the carboxyl-terminal region of the DAX-1 protein, including one mutation that deletes only the last 18 amino acids from the protein. Thus, the carboxyl-terminal, ligand-binding domain of DAX-1 is essential for its function.

The isolation of the *DAX-1* gene has expanded the understanding of the phenotypic spectrum resulting from DAX-1 mutations. In addition to the phenotypes described above, female carriers in some kindred have presented with delayed puberty or even hypogonadotropic hypogonadism. Similarly, a 28-yr-old man presented with late-onset adrenal insufficiency, partial hypogonadotropic hypogonadism, and impaired spermatogenesis; this milder phenotype is proposed to result from use of an alternate translation initiation site to produce a DAX-1 protein that retains some functional activity. Thus, different DAX-1 mutations can lead to a variety of phenotypes. It should be noted, however, that DAX-1 mutations appear to be an infrequent cause of either sporadic delayed puberty or hypogonadotropic hypogonadism.

DAX-1 is expressed in steroidogenic tissues (testes, ovaries, adrenals), as well as in pituitary gonadotropes and the ventromedial nucleus of the hypothalamus. This expression profile closely parallels that of the orphan nuclear receptor steroidogenic factor 1 (SF-1 or NR5A1), an orphan nuclear receptor that regulates many key components of steroidogenesis and reproduction, and studies suggest that SF-1 regulates DAX-1 expression. The best-established function of DAX-1 is to inhibit the transcriptional activity of SF-1, presumably by recruiting corepressors to the regulatory regions of SF-1 target genes. How and why adrenal function is impaired by the deficiency of DAX-1, which inhibits a transcription factor that is essential for adrenal development, is not immediately apparent, and this is an area of ongoing investigation.

As noted, duplication of *DAX-1* is associated with impaired testis development in dosage-sensitive sex reversal. The ability of DAX-1 to interfere with SF-1 induction of target genes provides a

plausible explanation for the sex reversal in these patients, and studies in transgenic mice have supported the model that excess DAX-1 expression can interfere with testis development.

CLINICAL MANAGEMENT Patients with AHC are treated with replacement doses of glucocorticoids and the synthetic mineralocorticoid fludrocortisone, and also receive salt supplementation in infancy and early childhood. Serum testosterone levels and a gonadotropin-releasing hormone stimulation test are indicated in patients with AHC, even with normal testicular descent, because the absence of cryptorchidism does not preclude hypogonadotropic hypogonadism. Owing to a direct role of DAX-1 in testis function, it is likely that DAX-1 mutations in males will impair spermatogenesis even if gonadotropin levels are restored.

FUTURE DIRECTIONS A number of patients with AHC, including one with classic cytomegalic histopathology of the adrenal glands, do not have mutations in *DAX-1*. This genetic heterogeneity suggests that other genes play similar roles in adrenal development and steroidogenesis. A clinical presentation similar to that of AHC is seen in patients with mutations in SF-1. Based on studies in knockout mice, the predicted phenotype for human beings with SF-1 mutations encompassed gonadal dysgenesis and adrenal insufficiency. The human gene encoding SF-1 maps to chromosome 9q33, and mutations in SF-1 have been identified in several patients who presented initially with adrenocortical insufficiency. The first two subjects had heterozygous mutations that abrogated function, whereas another subject was homozygous for a mutation that impaired but did not eliminate activity. Thus, like DAX-1, the dosage of SF-1 in humans appears to be critical for its normal function in endocrine development. Interestingly, other subjects with heterozygous mutations of SF-1 presented with gonadal dysgenesis and sexual ambiguity but had apparently normal adrenal function. Because isolated gonadal dysgenesis is considerably more common than the combined presentation of gonadal dysgenesis and adrenal insufficiency, additional subjects with SF-1 mutations may be identified in this group of patients.

ADRENOLEUKODYSTROPHY AND ADRENOMYELONEUROPATHY

Adrenoleukodystrophy (ALD) was first reported as an X-linked syndrome of primary adrenal insufficiency and cerebral sclerosis in the 1960s. A decade later, it was found that cholesterol esters in the brain and adrenal tissue of these patients contained an excess amount of fatty acids with a chain length of 24–30 carbon atoms. The clinical phenotype varied considerably, leading to the description of four different forms based on the age of onset and clinical severity. A defective peroxisomal β-oxidation system was found in skin fibroblasts from the patients in the early 1980s, and genetic studies in patients with ALD ultimately led to the identification of the gene that is mutated in ALD.

CLINICAL FEATURES ALD is a progressive, degenerative neurological disorder with spastic paraplegia, peripheral neuropathy, limb and truncal ataxia, slurred speech, blindness, hearing loss, and cognitive dysfunction associated with primary adrenal insufficiency and primary hypogonadism. Four distinct phenotypes have been recognized:

1. A neonatal form manifested by severe neurological deficits in infancy that leads to death in early childhood.
2. Classic ALD, which affects young children and usually leads to death during childhood.
3. Adrenomyeloneuropathy, which usually is first manifested by adrenal insufficiency during the second and third decade of life, primarily affects the spinal cord, and gradually leads to severe neurological deficits.
4. Adult ALD, which presents with progressive spinal cord disease and ataxia in female heterozygote carriers.

Patients with adrenal insufficiency only, or a form limited to the cerebrum, have also been described. As in the nervous system, the adrenal cortex in subjects with ALD contains marked lipid inclusions. Similar lipid inclusions are seen in Leydig cells, presumably accounting for the primary hypogonadism. Plasma levels of very long-chain fatty acids (VLCFA, C26:0) are elevated, a hallmark that can be used to diagnose ALD, to detect the disease prenatally, and to identify female carriers. An ACTH stimulation test is essential to assess the extent of adrenal impairment in every patient with ALD, so that replacement therapy can be instituted promptly if needed.

GENETIC BASIS The sex-linked inheritance of ALD was confirmed when the responsible gene was linked to glucose-6-phosphate dehydrogenase. Thereafter, positional cloning led to the identification of a gene on Xp, originally designated *ALD* and now called *ABCD1* that was mutated in a number of subjects with classic ALD or adrenomyeloneuropathy. Comparison with the amino acid sequences of known genes suggests that ABCD1 is a member of the ATP-binding cassette transmembrane transporter protein superfamily. Thus, ALD is proposed to encode a peroxisomal membrane transporter that facilitates the ATP-driven import of VLCFAs and/or the action of the peroxisomal enzyme lignoceroyl-CoA synthetase (VLCFA CoA synthetase), the enzyme whose activity is reduced in subjects with ALD. In a study of 28 unrelated kindreds, mutations of *ABCD1* (mostly missense or nonsense) were found in all of the patients; large deletions in *ABCD1* also have been reported. The missense mutations are found throughout the coding region of ABCD1, and nearly two-thirds of these substitutions result from methylcytosine deamination at CpG dinucleotides. Several mutations are located in the ATP-binding domain (Walker A and B motifs, plus a conserved LSGGEKQRIGMA sequence) encoded by exons 6, 8, and 9. The specific structural and functional consequences of most other mutations are not known, but immunocytochemistry studies demonstrate that many missense and C-terminal truncation mutations are not sorted to peroxisomes in normal amounts. This finding is consistent with the existence of a peroxisomal targeting sequence at the carboxyl-terminus of ABCD1, although this region lacks the canonical peroxisome targeting tripeptide SKL. Correlation of genotype and phenotype in ALD is poor, perhaps because mutant ABCD1 proteins in some patients can heterodimerize with other ATP-binding cassette transporters to partially rescue its function.

CLINICAL MANAGEMENT Patients with ALD have multiple neurological problems that are treated with supportive care. If adrenal insufficiency is present, replacement with hydrocortisone and fludrocortisone is given, and treatment with gonadal steroids may also be needed if hypogonadism is present. A substantial decrease of serum VLCFA levels results from dietary modification with glycerol trierucate—so-called Lorenzo's oil—and recent studies suggest some degree of decreased deterioration of neurological function with dietary modification. Bone marrow transplantation has emerged as the treatment of choice for ALD when an appropriate donor is available.

PSEUDOHYPOALDOSTERONISM

The condition called pseudohypoaldosteronism (PHA) was first described in an infant with a severe salt-wasting syndrome in 1958, and approx 100 cases have since been reported. Some of these cases have been familial, with either autosomal-recessive or autosomal-dominant inheritance. When all actions of aldosterone are impaired, the disorder is referred to as PHA type I. In contrast, Gordon syndrome or hyporeninemic hypoaldosteronism (PHA type II), is characterized by renal tubular unresponsiveness to the kaliuretic—but not the antinatriuretic—effect of aldosterone. The latter is inherited in an autosomal-dominant manner, and most patients have mutations in the serine/threonine kinases WNK1 and WNK4.

CLINICAL FEATURES Type-I PHA is manifested early in infancy with salt wasting, vomiting, and feeding difficulties that can lead to severe dehydration and death if untreated. Hyponatremia, hyperkalemia, and acidosis are present despite markedly elevated renin and aldosterone levels. All infants are dependent on aldosterone action because their diet is relatively low in sodium and their kidneys are relatively unresponsive to aldosterone. Consequently, PHA-I patients are most symptomatic shortly after birth. Thereafter, the symptoms often improve with age and older patients with PHA I require smaller doses of salt supplements and salt-retaining steroids.

GENETIC BASIS The absent or decreased aldosterone binding to circulating leukocytes from patients with PHA suggested that the disorder was caused by quantitative or qualitative defects of the mineralocorticoid receptor (MR) (officially designated *NR3C2*) on chromosome 4q31.1-2. In fact, heterozygous inactivating mutations in MR were demonstrated in some kindreds that exhibited autosomal-dominant inheritance, showing that the full complement of MR is essential for fluid and electrolyte balance immediately after birth. These patients exhibit a milder phenotype than do most patients with type-I PHA, who instead have loss-of-function mutations in the subunits of the amiloride-sensitive epithelial sodium channel (ENaC). ENaC contains α-, β-, and γ-subunits encoded by the *SCNN1A*, *SCNN1B*, and *SCNN1G* genes, and the heterotrimer mediates Na^+ resorption in the distal nephron. Most of these mutations cause frameshifts, deletions, or premature truncation of the proteins early in the coding sequence, yielding inactive protein fragments. In contrast, activating mutations in *SCNN1B* and *SCNN1G* cause Liddle's Syndrome (or pseudohyperaldosteronism), an autosomal-dominant condition characterized by hypertension, hypokalemia, and suppressed aldosterone production that is the mirror image of PHA I. Most mutations that cause Liddle's syndrome are truncations that leave the conducting portion of the channel subunits intact but delete a PPXY domain at the C-terminus. The phosphorylation of this domain is the signal for channel recycling, and loss of this motif allows the channels to remain on the cell membrane.

CLINICAL MANAGEMENT Patients with type-I PHA are treated in early infancy with salt supplementation. Close monitoring of sodium balance is needed, especially during infancy when plasma renin activity is not useful because of the large variation of this parameter in the first year of life. After 2 yr of age, gradual improvement of the symptoms and decrease in the frequency of the dehydration crises often are noted, permitting a reduction of sodium supplement. Carbenoxolone, an inhibitor of 11β-hydroxysteroid dehydrogenase (11β-HSD, *see* Syndrome of Apparent Mineralocorticoid Excess), also has been used successfully in the treatment of type-I PHA.

FUTURE DIRECTIONS Gain-of-function mutations of MR or ENaC could be envisioned to cause the opposite manifestations, presenting with hypertension and hypokalemia. Subjects in one kindred with autosomal-dominant segregation of early-onset hypertension were shown to have a heterozygous serine to leucine substitution at residue 810 of the MR. This missense mutation caused constitutive MR activation and altered ligand binding in cell expression studies such that progesterone, which normally is an MR-antagonist, became an agonist. Consistent with this model, severe pregnancy-induced hypertension was seen in two women with this MR mutation, likely related to the elevated progesterone levels seen during pregnancy.

SYNDROME OF APPARENT MINERALOCORTICOID EXCESS

The syndrome of apparent mineralocorticoid excess (AME) was described initially as a syndrome of hypertension, hypokalemia, and low plasma renin activity associated with normal cortisol but suppressed aldosterone levels. Subsequent investigations failed to identify elevated levels of any known mineralocorticoids, but rather revealed an abnormal cortisol-to-cortisone ratio. The oxidation of cortisol to its inactive metabolite cortisone is mediated by the enzyme 11β-HSD. 11β-HSD is inhibited by licorice (glycyrrhetinic acid) and carbenoxolone, and chronic licorice ingestion induces a clinical and biochemical syndrome that mimics that of AME. These observations led to the suggestion that AME results from a deficiency of 11β-HSD. Indeed, mutations of the type-2 isozyme of 11β-HSD have been identified in most of the approx 50 patients with congenital AME. A normal cortisol-to-cortisone ratio has been identified in a few patients, who do not appear to have a defect in 11β-HSD (AME type II).

CLINICAL FEATURES AME typically presents in early childhood (1–5 yr of age) with failure to thrive, severe hypertension, hypokalemic alkalosis, low plasma renin activity, and low-to-normal aldosterone levels. If untreated, the hypertension may lead to left ventricular hypertrophy, strokes, and retinopathy before the teenage years, although adult patients with milder manifestations of the syndrome also have been described. Type-I AME is diagnosed by measuring the urinary tetrahydrocortisol-to-tetrahydrocortisone or serum cortisol-to-cortisone ratios.

GENETIC BASIS The 11β-HSD isozymes interconvert cortisol, which can activate both GR and MR, and cortisone, which is biologically inactive (Fig. 38-4). The type-1 isozyme—expressed in bone, liver, and adipocytes—converts cortisone to cortisol, whereas the type-2 isozyme—expressed predominantly in classic mineralocorticoid target tissues—catalyzes the reverse reaction to convert cortisol into cortisone. The action of the type-2 isozyme is crucial to protect the MR, which has an equal affinity for both cortisol and aldosterone, from the vast excess of circulating cortisol. Thus, mutations in the *HSD11B2* gene on chromosome 16q22 expose the MR in the distal nephron to unabated stimulation by cortisol. Most patients are homozygous for mutations in exons 3–5, which encode residues that surround the active site, although some mutations have been found in the cofactor-binding region. A partial correlation between phenotype and genotype is evident, because patients whose mutations are associated with complete loss of enzymatic activity, such as L250P and L251S, have the highest tetrahydrocortisol/tetrahydrocortisone ratio. Deletion and nonsense mutations that eliminate critical residues also correlate with severe clinical phenotypes. In contrast, mutations R213C and R208C show a trace of activity, mutation R186C has 17% of wild-type activity, and mutation R337C, depending on assay conditions,

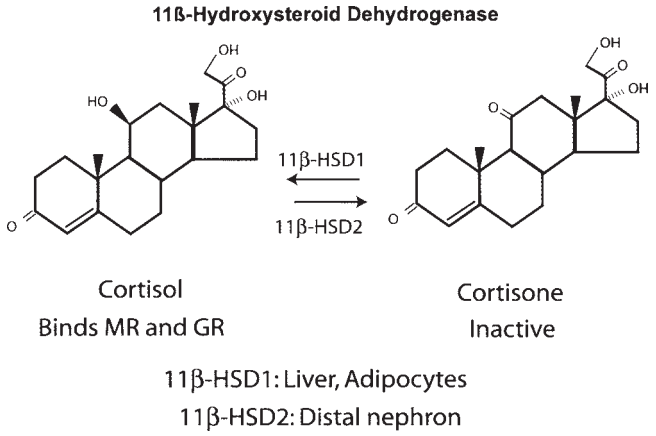

Figure 38-4 Role of the type-2 isozyme of 11β-hydroxysteroid dehydrogenase to protect the mineralocorticoid receptor. The structures of cortisol and cortisone are shown, as are the reactions catalyzed by the type-1 and -2 isozymes of 11β-hydroxysteroid dehydrogenase.

shows up to 53% of wild-type activity. These arginine substitutions are associated with progressively milder clinical phenotypes, although the correlation of activity with disease severity is not perfect. Interestingly, intrauterine growth retardation, a previously unrecognized manifestation of AME, is seen in most of the patients. Because 11β-HSD2 is highly expressed in the placenta, intrauterine growth retardation in AME patients has been attributed to the placental deficiency of the enzyme. One of the investigated kindreds did not harbor mutations of the *HSD11B2* gene, suggesting genetic heterogeneity for the disease.

CLINICAL MANAGEMENT Patients with congenital AME respond to treatment with spironolactone (50–200 mg/d) and low-sodium diet. Treatment with the potent glucocorticoid dexamethasone may suppress cortisol levels sufficiently to control the hypertension, but care must be taken to avoid overreplacement. The hypokalemia also may respond to amiloride or triamterene. Early diagnosis and treatment are essential to avoid complications of hypertension.

FUTURE DIRECTIONS The finding that patients with AME and mutations of the *HSD11B2* gene have intrauterine growth retardation correlates with the observation that low-birth weight infants are at increased risk for developing essential hypertension in later life. It is possible that genetic variations of 11β-HSD2 enzymatic activity have significant effects on fetal growth and on subsequent risk of hypertension. The *HSD11B2* gene thus may be one of the multiple genes that cause essential hypertension. However, an emerging link between 11β-HSD1 and obesity suggests that dysregulation of the cortisol-cortisone shuttle may cause other disease states. Fat contains 11β-HSD1 and targeted overexpression of this enzyme in adipocytes of transgenic mice is associated with increased adiposity, presumably because of increased local conversion of cortisone to active cortisol. Ongoing studies are examining whether alterations in *HSD11B1* are associated with conditions such as obesity and the metabolic syndrome in human beings.

GLUCOCORTICOID-REMEDIABLE ALDOSTERONISM

Glucocorticoid-remediable aldosteronism (GRA) was initially described as a familial syndrome of hypertension and hypokalemia that responded clinically to treatment with glucocorticoids. Subsequent studies indicated that this autosomal-dominant disorder includes patients who do not have spontaneous hypokalemia and may occur in up to 1–3% of patients with primary aldosteronism.

CLINICAL FEATURES Patients with GRA typically present with early-onset, moderate-to-severe hypertension. Although aldosterone production is increased, it is the 18-oxygenated cortisol derivatives in the urine and circulation that are characteristically elevated in patients with GRA. Earlier reports described patients with unprovoked hypokalemia, but subsequent studies have indicated that serum K^+ can often be in the normal range unless patients receive potassium-wasting diuretics. It also is appreciated that GRA is associated with a significant incidence of hemorrhagic strokes in affected family members, partly because of the early onset of hypertension, but also possibly related to direct effects of aldosterone on cerebral vasculature. Although the hypertension is often difficult to control with conventional agents, there is a distinct salutary response to glucocorticoids, hence the name GRA.

GENETIC BASIS A critical component of normal adrenocortical function is the zone-specific expression of the two isozymes of steroid 11β-hydroxylase. CYP11B1 and CYP11B2 are encoded by highly homologous, tandemly duplicated genes on the long arm of chromosome 8 (8 q21-q22). GRA results from an unequal crossover that fuses the 5′-end of *CYP11B1*, including zone-specific regulatory sequences, with the 3′-end of *CYP11B2*, which encodes critical regions of the protein that determine the ability to catalyze the three separate reactions that convert 11-deoxycorticosterone to aldosterone. This chimeric gene causes the ectopic expression in the zona fasciculata of a protein that produces mineralocorticoids under ACTH stimulation, ultimately leading to mineralocorticoid excess and its attendant hypokalemia and hypertension. Furthermore, the ectopic fusion protein in the zona fasciculata also acts on cortisol to form the characteristic 18-oxygenated steroids. Site-directed mutagenesis studies show that amino acid substitutions V320A and/or N335D, the corresponding residues of CYP11B2, are sufficient to confer 18-oxygenase activity onto CYP11B1. Further studies also show that the location of the crossover is critical to determining the activity of the chimeric protein, which must contain most of the I-helix of CYP11B2 that starts near residue 295, to have aldosterone synthase activity.

CLINICAL MANAGEMENT Because ACTH regulates steroid production by the zona fasciculata, administration of glucocorticoids will suppress ACTH and ameliorate the process. Traditionally, the potent glucocorticoid dexamethasone has been used in treatment. However, this logical therapy does not always normalize blood pressure, as the long-standing hypertension may induce secondary changes that do not respond to suppression of the synthesis of mineralocorticoids. Particularly in children, it is important to minimize the potential deleterious effects of glucocorticoid therapy. Thus, shorter-acting steroids such as cortisol and prednisone are sometimes preferred over dexamethasone, and careful titration of dose and monitoring for consequences of glucocorticoid excess (e.g., impaired linear growth) are essential.

As with AME, patients with GRA also can be treated with drugs that impair aldosterone action in the distal nephron, such as spironolactone, amiloride, and triamterene. Combination therapy with low doses of dexamethasone and moderate doses of spironolactone often allows good blood pressure control while minimizing glucocorticoid-related side effects.

FUTURE DIRECTIONS With the definition of the molecular basis of GRA, it is recognized that hypertension and hypokalemia are not always severe in this disorder. Further studies may identify modifier loci that affect the clinical severity of GRA, as well as other genes mutated in the rare GRA kindreds that do not harbor a chimeric *CYP11B1/CYP11B2* gene. The manifestations of GRA strikingly illustrate the essential role of zone-specific expression of the steroidogenic enzymes in normal adrenal function. However, little is understood about the mechanisms that determine zone-specific function. Subcapsular cells are capable of regenerating all three cortical zones, and one theory of zonation proposes that the subcapsular region contains adrenocortical progenitor cells that modulate their phenotype as they migrate centripetally from the zona glomerulosa to the zona fasciculata to the zona reticularis. There are no cell culture systems that accurately mimic the differential function of the zona glomerulosa vs the zona fasciculata, and the specific regulatory elements that confer zone-specific expression remain to be defined. Of note, advances in the use of relatively large DNA segments such as bacterial artificial chromosomes in transgenesis hold considerable promise for mapping the regulatory elements that specify zone-specific expression of *CYP11B1* and *CYP11B2* within the adrenal cortex.

CARNEY COMPLEX

Carney complex is a familial syndrome of multiple neoplasias (endocrine tumors and myxomas) and lentiginosis that is inherited in an autosomal-dominant manner. Although the existence of the complex was first suggested in 1985, combinations of several components of the syndrome and their familial occurrence had been reported earlier. Thus, the characteristic pathological findings of the adrenal glands (primary pigmented nodular adrenocortical disease [PPNAD])—multiple, small, pigmented, adrenocortical nodules, and internodular cortical atrophy—and a pituitary-independent, primary adrenal form of hypercortisolism were described in children and young adults with Cushing's syndrome as early as 1949. In the late 1970s, several familial cases of cutaneous and cardiac myxomas associated with lentigines (lentigo simplex) or ephelides and blue nevi of the skin and mucosae had been described under the acronyms, NAME (for nevi, atrial myxoma, myxoid neurofibromata, and ephelides) and LAMB (for lentigines, atrial myxoma, mucocutaneous myxoma, blue nevi) syndromes.

CLINICAL FEATURES Carney complex is manifested in children and young adults with at least two of the following: (1) PPNAD that can lead to Cushing's syndrome; (2) lentigines, ephelides, and blue nevi of the skin and mucosae; and (3) a variety of nonendocrine and endocrine tumors. The latter include myxomas of the skin, heart, breast, and other sites, psammomatous melanotic schwannomas, growth hormone-producing pituitary adenomas, testicular Sertoli cell tumors, and possibly other benign and malignant neoplasms, including tumors of the thyroid gland and ductal adenomas of the breast.

GENETIC BASIS Genes causing Carney complex were mapped by linkage analysis to chromosomes 2p16 and 17q22-24. The variant mapping to chromosome 17 apparently results from loss-of-function mutations of the type-1 regulatory subunit of cAMP-dependent protein kinase A (PKA, PPKAR1A). Mutations in *PPKAR1A* have been detected in approximately half of the patients with Carney complex, and also have been described in some sporadic endocrine tumors. Most mutations from Carney complex kindreds introduce premature stop codons into the PPKAR1A mRNA, resulting in nonsense-mediated mRNA decay of the altered transcripts. Although the molecular basis for tumorigenesis in patients with PPKAR1A mutations has not been defined, most tumors show loss of heterozygosity at 17q22-24 owing to somatic loss of the wild-type *PPKAR1A* allele. Consequently, cells bearing only the inactive copy of the *PPKAR1A* gene have no functional regulatory subunit to downregulate the catalytic activity of cAMP-dependent PKA. Because PKA activity in adrenocortical cells increases steroidogenesis and cell growth, the formation of functional adrenal tumors when PPKAR1A is mutated and/or deleted is consistent with an important regulatory role for PPKAR1A to limit PKA stimulation. Furthermore, increased PKA activity can be demonstrated in tumors from Carney complex subjects bearing PPKAR1A mutations. The gene(s) responsible for the variant mapping to chromosome 2, as well as other genes potentially associated with Carney complex, remain to be defined.

CLINICAL MANAGEMENT Patients with the diagnosis of Carney complex require extensive and frequent monitoring for the detection and early treatment of the multiple tumors that are associated with this condition. Cardiac myxomas, if undiagnosed, can lead to sudden death, strokes, or peripheral embolization; thus, annual screening by echocardiography is recommended in patients with the complex and their families. If PPNAD is diagnosed, then bilateral adrenalectomy and lifelong replacement with glucocorticoid and mineralocorticoid is recommended.

FUTURE DIRECTIONS The lesions associated with Carney complex originate from cells of mesenchymal (myxomas) or neural crest origin (spotty skin pigmentation, endocrine tumors). These features suggest that the genetic defects leading to Carney complex are involved in early development, growth, and proliferation of the affected cells. Thus, candidate genes for cases not caused by PPKAR1A mutations include those involved in tumor suppression and the control of the cell cycle, as well as those with specific effects on the function and growth of mesenchymal cells, zona fasciculata cells, and melanocytes. Because there is considerable overlap between Carney complex and the familial lentiginosis syndromes (Peutz–Jeghers syndrome and others), it is expected that the Carney complex genes will contribute to the identification of the unknown genetic defects responsible for the various lentiginoses.

CONCLUSION

In addition to the diseases discussed here, the genes for a number of genetic conditions that affect adrenal function have been cloned. These include the genes for multiple endocrine neoplasia 2A and 2B (*RET* proto-oncogene) and Von Hippel–Lindau disease, which are associated with pheochromocytoma; the genes for other phakomatoses, such as neurofibromatosis -I and -II and tuberous sclerosis, which are associated with tumors of the adrenal medulla and sympathetic ganglia; and the gene for multiple endocrine neoplasia 1, which is associated with benign adrenal nodules. The gene responsible for the type-1 variant of polyglandular autoimmune endocrinopathy, which is characterized by the triad of autoimmune Addison's disease, hypoparathyroidism, and mucocutaneous candidiasis and also may include other endocrine defects, has been cloned and designated the autoimmune regulator. Although their roles in human adrenal disease have not yet been defined, additional genes that play important roles in adrenal development and physiology have been identified in transgenic and knockout mice. These genes include the transcriptional coregulator CITED2, Wnt4, and

Wilms' tumor-related 1. Because the era of molecular medicine continues, many exciting discoveries are expected in the understanding of normal physiology of the adrenal glands and the perturbations in various diseases.

39 Multiple Endocrine Neoplasia Type 1

RAJESH V. THAKKER

SUMMARY

Multiple endocrine neoplasia type 1 (MEN1) is characterized by the combined occurrence of tumors of the parathyroids, pancreatic islets, and anterior pituitary. In addition, some patients may also develop adrenal cortical, carcinoid, facial angiofibromas, collagenomas, and lipomatons tumors. MEN1 is inherited as an autosomal-dominant disorder and the gene causing MEN1 is located on chromosome 11q13. The MEN1 gene consists of 10 exons that encode a 610 amino acid protein, menin, which has a role in transcriptional regulation and genome stability. The mutations causing MEN1 are of diverse types and are scattered throughout the coding region. Mice deleted for a MEN1 allele develop endocrine tumors similar to those found in MEN1 patients. The availability of these mouse models for MEN1 will help to further elucidate the role of menin in regulating cell proliferation.

Key Words: Adrenal; carcinoid; lipoma; pancreatic islets; parathyroid; pituitary; tumors; tumor suppressor gene; Wermer's syndrome.

INTRODUCTION

Multiple endocrine neoplasia (MEN) is characterized by the occurrence of tumors involving two or more endocrine glands within a single patient. The disorder has previously been called multiple endocrine adenopathy or the pluriglandular syndrome. However, glandular hyperplasia and malignancy may also occur in some patients and the term "multiple endocrine neoplasia" is now preferred. There are two major forms of MEN referred to as type 1 and type 2, and each form is characterized by the development of tumors within specific endocrine glands (Table 39-1). Thus, the combined occurrence of tumors of the parathyroid glands, the pancreatic islet cells, and the anterior pituitary is characteristic of MEN1, which is also referred to as Wermer's syndrome. However, in MEN2, also called Sipple's syndrome, medullary thyroid carcinoma occurs in association with pheochromocytoma, and three clinical variants referred to as MEN2a, MEN2b, and medullary thyroid carcinoma only are recognized (*see* Table 39-1). Although MEN1 and MEN2 usually occur as distinct and separate syndromes as previously outlined, some patients occasionally develop tumors that are associated with both MEN1 and MEN. For example, patients suffering from islet cell tumors of the pancreas and pheochromocytomas, or from acromegaly and pheochromocytoma, have been described and these patients may represent "overlap" syndromes. All these forms of MEN may either be inherited as autosomal-dominant syndromes, or they may occur sporadically, i.e., without a family history. However, the distinction between sporadic and familial cases may sometimes be difficult as in some sporadic cases the family history may be absent because the parent with the disease may have died before developing symptoms. This chapter discusses the main clinical features and molecular genetics of MEN1; MEN2 is reviewed in Chapter 40.

CLINICAL FEATURES

Parathyroid, pancreatic, and pituitary tumors constitute the major components of MEN1. In addition to these tumors, adrenocortical, carcinoid, facial angiofibromas, collagenomas, and lipomatous tumors may also occur in some patients.

PARATHYROID TUMORS Primary hyperparathyroidism is the most common feature of MEN1 and occurs in more than 95% of all MEN1 patients (Fig. 39-1). Patients may present with asymptomatic hypercalcemia, or nephrolithiasis, or osteitis fibrosa cystica, or vague symptoms associated with hypercalcemia, for example, polyuria, polydipsia, constipation, malaise, or occasionally with peptic ulcers. Biochemical investigations reveal hypercalcemia usually in association with raised circulating parathyroid hormone concentrations. The hypercalcemia is usually mild, and severe hypercalcemia resulting in crisis or parathyroid carcinoma are rare occurrences. Additional differences in the primary hyperparathyroidism of MEN1 patients from that in non-MEN1 patients include an earlier age of onset (20–25 yr vs 55 yr), and an equal male:female ratio (1/1 vs 1/3). Primary hyperparathyroidism in MEN1 patients is unusual before the age of 15 yr, and the age of conversion from being unaffected to affected has been observed to be between 20 and 21 yr in some individuals. No effective medical treatment for primary hyperparathyroidism is generally available and surgical removal of the abnormally overactive parathyroids is the definitive treatment. However, all four parathyroid glands are usually affected with multiple adenomas or hyperplasia, although this histological distinction may be difficult, and total parathyroidectomy has been proposed as a definitive treatment for primary hyperparathyroidism in MEN1, with the resultant lifelong hypocalcemia being treated with oral calcitriol (1,25 dihydroxy vitamin D_3). It is recommended that such total parathyroidectomy should be reserved for the symptomatic hypercalcemic patient with MEN1, and that the asymptomatic hypercalcemic MEN1 patient should not have parathyroid surgery

Table 39-1
The Multiple Endocrine Neoplasia (MEN) Syndromes

Type	*Tumors*	*Biochemical features*
MEN1	Parathyroids	Hypercalcemia and ↑PTH
	Pancreatic islets	
	Gastrinoma	↑Gastrin and ↑basal gastric acid output
	Insulinoma	Hypoglycemia and ↑insulin
	Glucagonoma	Glucose intolerance and ↑glucagon
	VIPoma	↑VIP and WDHA
	Ppoma	↑PP
	Pituitary (anterior)	
	Prolactinoma	Hyperprolactinemia
	GH-secreting	↑GH
	ACTH-secreting	Hypercortisolemia and ↑ATCH
	Nonfunctioning	Nil or α-subunit
	Associated tumors	
	Adrenocortical	Hypercortisolemia or primary hyperaldosteronism
	Carcinoid	↑5-HIAA
	Lipoma	Nil
MEN2a	Medullary thyroid carcinoma	Hypercalcitoninemia[a]
	Pheochromocytoma	↑Catecholamines
	Parathyroid	Hypercalcemia and ↑PTH
MEN2b	Medullary thyroid carcinoma	Hypercalcitoninemia
	Pheochromocytoma	↑Catecholamines
	Associated abnormalities	
	Mucosal neuromas	
	Marfanoid habitus	
	Medullated corneal nerve fibres	
	Megacolon	

[a]In some patients, basal serum calcitonin concentrations may be normal, but may show an abnormal rise at 1 and 5 min after stimulation with pentagastrin, 0.5 μg/kg.

Autosomal-dominant inheritance of the MEN syndromes has been established.

↑, increased; PTH, parathyroid hormone; VIP, vasoactive intestinal peptide; WDHA, watery diarrhea, hypokalemia, and achlorhydria; PP, pancreatic polypeptide; GH, growth hormone; ACTH, adrenocorticotrophin; 5-HIAA, 5-hydroxyindoleacetic acid; CgA, chromogranin A.

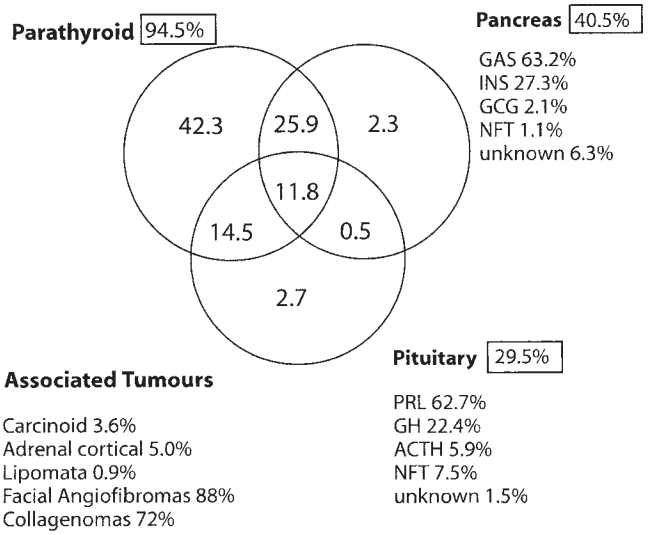

Figure 39-1 Schematic representation of the distribution of 384 multiple endocrine neoplasia type 1 tumors in 220 MEN1 patients. The proportions of patients in whom parathyroid, pancreatic, or pituitary tumors occurred are shown in the respective boxes; for example, 94.5% of patients had a parathyroid tumor. The Venn diagram indicates the proportions of patients with each combination of tumors, for example, 37.7% (25.9 + 11.8%) of patients had both a parathyroid and pancreatic tumor, whereas 2.3% of patients had a pancreatic tumor only. In addition to these tumors observed in one series, multiple facial angiofibromas were observed in 88% of 32 patients, and collagenomas in 72% of patients. The hormones secreted by each of these tumors are indicated: GAS, gastrin; INS, insulin; GCG, glucagon; NFT, nonfunctioning tumors; PRL, prolactin; GH, growth hormone; ACTH, adrenocorticotrophic hormone. Parathyroid tumors represent the most common form of MEN1 tumors and occur in approx 95% of patients, with pancreatic islet cell tumors occurring in approx 40% of patients, and anterior pituitary tumors occurring in approx 30% of patients. (Reproduced from Trump D, Farren B, Wooding C, et al. Clinical studies of multiple endocrine neoplasia type 1 [MEN1] in 220 patients. Q J Med 1996;89: 653–669, by permission of Oxford University Press.)

but have regular assessments for the onset of symptoms and complications, when total parathyroidectomy may be undertaken. However, all of these options should be discussed with the patient and an optimal course of management planned.

PANCREATIC TUMORS The incidence of pancreatic islet cell tumors in MEN1 patients varies from 30 to 80% in different series. The majority of these tumors produce excessive amounts of hormone, for example gastrin, insulin, glucagons, or vasoactive intestinal polypeptide (VIP), and are associated with distinct clinical syndromes.

Gastrinomas Gastrinomas, gastrin-secreting tumors, represent more than 50% of all pancreatic islet cell tumors (*see* Fig. 39-1) in MEN1 and approx 20% of patients with gastrinomas will have MEN1. Gastrinomas are the major cause of morbidity and mortality in MEN1 patients because of the recurrent severe multiple peptic ulcers that may perforate. The association of recurrent peptic ulceration, marked gastric acid production, and non-β-islet cell tumors of the pancreas is referred to as the Zollinger–Ellison syndrome. Additional prominent clinical features of this syndrome include diarrhea and steatorrhea. The diagnosis is established by demonstration of a raised fasting serum gastrin concentration in association with an increased basal gastric acid secretion. Medical treatment of MEN1 patients with the Zollinger–Ellison syndrome is directed to reducing basal acid output to less than 10 mmol/L, and this may be achieved by the parietal cell H+, K+-ATPase inhibitor, omeprazole. The ideal treatment for a nonmetastatic gastrinoma is surgical excision of the gastrinoma. However, in patients with MEN1 the gastrinomas are frequently multiple or extrapancreatic and the role of surgery has been controversial. For example, in one study, only 16% of MEN1 patients were free of disease immediately after surgery, and at 5 yr this had declined to 6%; the respective outcomes in non-MEN1 patients were better at 45 and 40%. The treatment of disseminated gastrinomas is difficult and hormonal therapy with octreotide, which is a human somatostatin analog, chemotherapy with streptozotocin and 5-fluoroaracil, hepatic artery embolization, and removal of all resectable tumor have all occasionally been successful.

Insulinoma Insulinomas are β-islet cell tumors that secrete insulin. They represent one-third of all pancreatic tumors in MEN1

patients (*see* Fig. 39-1). Insulinomas also occur in association with gastrinomas in 10% of MEN1 patients, and the two tumors may arise at different times. Insulinomas occur more often in MEN1 patients who are less than 40 yr, and many of these arise in individuals before the age of 20 yr, whereas in non-MEN1 patients insulinomas generally occur in those greater than 40 yr. Insulinomas may be the first manifestation of MEN1 in 10% of patients, and approx 4% of patients presenting with insulinoma have MEN1. Patients with an insulinoma present with hypoglycemic symptoms, which develop after a fast or exertion, and improve after glucose intake. Biochemical investigations reveal raised plasma insulin concentrations in association with hypoglycemia. Circulating concentrations of C-peptide and proinsulin, which are also raised, may be useful in establishing the diagnosis, as may an insulin suppression test. Medical treatment, consisting of frequent carbohydrate feeds and diazoxide, is not always successful and surgery is often required. Most insulinomas are multiple and small, preoperative localization with CT, celiac axis angiography and pre- or perioperative percutaneous transhepatic portal venous sampling is difficult, and success rates have varied. Surgical treatment, ranging from enucleation of a single tumor to a distal pancreatectomy or partial pancreatectomy, has been curative in some patients. Chemotherapy, which consists of streptozotocin or octreotide, is used for metastatic disease.

Glucagonoma Glucagonomas, which are α-islet cell, glucagon-secreting pancreatic tumors, occur in less than 3% of MEN1 patients (*see* Fig. 39-1). The characteristic clinical manifestations of a skin rash (necrolytic migratory erythyema), weight loss, anemia, and stomatitis may be absent and the presence of the tumor is indicated only by glucose intolerance and hyperglucagonemia. The tail of the pancreas is the most frequent site for glucagonomas; surgical removal is the treatment of choice. However, treatment may be difficult as 50% of patients have metastases at diagnosis. Medical treatment with octreotide or streptozotocin has been successful in some patients.

VIPoma Patients with VIPomas, VIP-secreting pancreatic tumors, develop watery diarrhea, hypokalemia, and achlorhydria, referred to as the WDHA syndrome. This clinical syndrome has also been called the Verner–Morrison syndrome or the VIPoma syndrome. VIPomas have been reported in only a few MEN1 patients and the diagnosis is established by documenting a markedly raised plasma VIP concentration. Surgical management of VIPomas, which are mostly located in the tail of the pancreas, has been curative. However, in patients with unresectable tumor, treatment with streptozotocin, octreotide, corticosteroids, indomethicin, metoclopramide, and lithium carbonate has proved beneficial.

Ppoma Ppomas, tumors that secrete pancreatic polypeptide (PP), are found in a large number of patients with MEN1. No pathological sequelae of excessive PP secretion are apparent and the clinical significance of PP is unknown, although the use of serum PP measurements has been suggested for the detection of pancreatic tumors in MEN1 patients.

PITUITARY TUMORS The incidence of pituitary tumors in MEN1 patients varies from 15 to 90% in different series. Approximately 60% of MEN1 associated pituitary tumors secrete prolactin, less than 25% secrete growth hormone, 5% secrete adenocorticotrophin, and the remainder appear to be nonfunctioning (*see* Fig. 39-1). Prolactinomas may be the first manifestation of MEN1 in less than 10% of patients, and somatotrophinomas occur more often in patients greater than 40 yr of age. Of patients with anterior pituitary tumors, less than 3% have MEN1. The clinical manifestations depend on the size of the pituitary tumor and its product of secretion. Enlarging pituitary tumors may compress adjacent structures such as the optic chiasm or normal pituitary tissue and cause bitemporal hemianopia or hypopituitarism, respectively. The tumor size and extension are radiologically assessed by CT and nuclear MRI. Treatment of pituitary tumors in MEN1 patients is similar to that in non-MEN1 patients and consists of medical therapy or selective hypophysectomy by the transphenoidal approach if feasible, with radiotherapy being reserved for residual unresectable tumor.

ASSOCIATED TUMORS Patients with MEN1 may have tumors involving glands other than the parathyroids, pancreas, and pituitary. Thus carcinoid, adrenocortical, facial angiofibromas, collagenomas, thyroid, and lipomatous tumors have been described in association with MEN1 (*see* Fig. 39-1).

Carcinoid Tumors Carcinoid tumors, which occur in more than 3% of patients with MEN1 may be inherited as an autosomal-dominant trait in association with MEN1. The carcinoid tumor may be located in the bronchi, gastrointestinal tract, pancreas, or thymus. Bronchial carcinoids in MEN1 patients predominantly occur in women (M/F = 1/4), whereas thymic carcinoids predominantly occur in men, with cigarette smokers having a higher risk of developing tumors. Most patients are asymptomatic and do not suffer from the flushing attacks and dyspnea associated with the carcinoid syndrome, which usually develops after the tumor has metastasized to the liver. Octreotide has been successfully used to treat symptoms and may result in regression of gastric carcinoids.

Adrenocortical Tumors The incidence of asymptomatic adrenocortical tumors in MEN1 patients has been reported to be as high as 40%. The majority of these tumors are nonfunctioning. However, functioning adrenocortical tumors in MEN1 patients have been documented to cause hypercortisolemia and Cushing's syndrome, and primary hyperaldosteronism, as in Conn's syndrome.

Lipomas Lipomas may occur in more than 33% of patients, and are frequently multiple. In addition, pleural or retroperitoneal lipomas may also occur in patients with MEN1.

Thyroid Tumors Thyroid tumors consisting of adenomas, colloid goiters, and carcinomas have been reported in more than 25% of MEN1 patients. However, the prevalence of thyroid disorders in the general population is high and it has been suggested that the association of thyroid abnormalities in MEN1 patients may be incidental and not significant.

Facial Angiofibromas and Collagenomas Multiple facial angiofibromas, which are identical to those observed in patients with tuberous sclerosis, have been observed in 88% of MEN1 patients, and collagenomas have been reported in more than 70% of MEN1 patients.

GENETICS AND MEN1 MUTATIONS

The gene causing MEN1 was localized to chromosome 11q13 by genetic mapping studies that investigated MEN1 associated tumors for loss of heterozygosity (LOH) and by segregation studies in MEN1 families. The results of these studies, which were consistent with Knudson's model for tumor development, indicated that the MEN1 gene represented a putative tumor suppressor gene. Further genetic mapping studies defined a less than 300 kb region as the minimal critical segment that contained the MEN1 gene. Characterization of genes from this region led to the identification, in 1997, of the MEN1 gene, which consists of 10 exons with a 1830 bp coding region (Fig. 39-2) that encodes a novel 610 amino acid protein, referred to as "menin." Over 600 germline

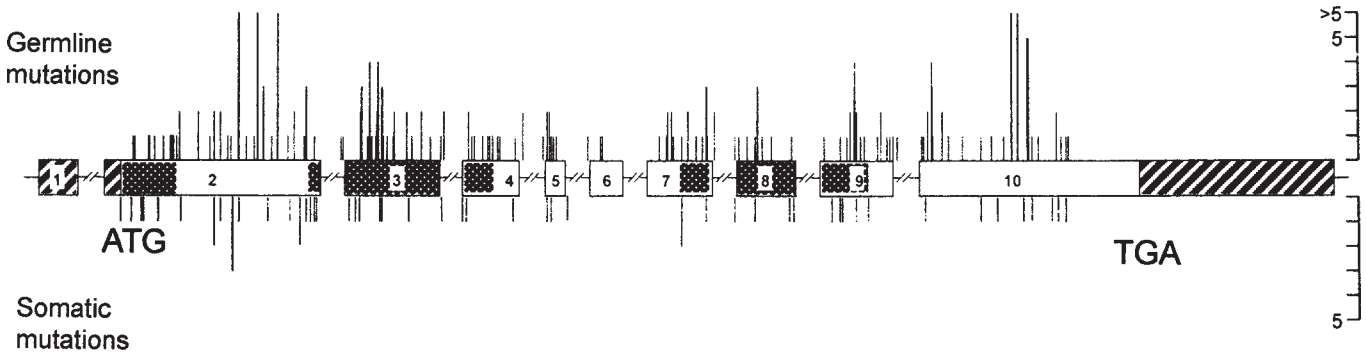

Figure 39-2 Schematic representation of the genomic organization of the multiple endocrine neoplasia type-1 gene illustrating germline and somatic mutations. The human MEN1 gene, located on chromosome 11q13, consists of 10 exons that span >9 kb of genomic DNA and encodes a 610 amino acid protein. The 1.83-kb coding region is organized into nine exons (exons 2–10) and eight introns (indicated by a line but not to scale). The sizes of the exons (boxes) range from 88 to 1312 bp and those of the introns range from 41 to 1564 bp. The start (ATG) and stop (TGA) sites in exons 2 and 10, respectively, are indicated. Exon 1, the 5′ part of exon 2 and 3′ part of exon 10 are untranslated (indicated by the hatched boxes). The locations of the three domains, which are formed by codons 1–40 (exon 2), 139–242 (exons 3 and 4), and 323–428 (exons 7–9), that interact with JunD are indicated by the stippled black boxes. The sites of the 623 germline mutations are indicated by the vertical lines above the gene and the sites of the 164 somatic mutations are represented below the gene. Mutations that have occurred more than four times (scale shown on the right) are indicated. (Reproduced by permission of the Society for Endocrinology. Pannet AAJ, Thakker RVT. Multiple endocrine neoplasia type1 [MEN1] gene. Endocr Relat Cancer 1996;6:449–473.)

mutations of the MEN1 gene have been identified, and most (>80%) of these are inactivating and consistent with its role as a tumor suppressor gene. These mutations are diverse in their types: approx 25% are nonsense mutations, approx 45% are frameshift deletions or insertions, approx 5% are in frame deletions or insertions, approx 5% are splice site mutations, and approx 15% are missense mutations (Fig. 39-3). More than 10% of the MEN1 mutations arise *de novo* and may be transmitted to subsequent generations. It is also important to note that 5–10% of MEN1 patients may not harbor mutations in the coding region of the MEN1 gene, and that these individuals may have mutations in the promoter or untranslated regions, which remain to be investigated. The mutations are not only diverse in their types but are also scattered throughout the 1830-bp coding region of the MEN1 gene (*see* Fig. 39-2) with no evidence for clustering as observed in MEN2 (*see* Chapter 40). Correlations between MEN1 mutations and the clinical manifestations of the disorder appear to be absent. This apparent lack of genotype–phenotype correlations, which contrasts with the situation in MEN2 (*see* Chapter 40), together with the wide diversity of mutations in the 1830 bp coding region of the MEN1 gene has made mutational analysis for diagnostic purposes in MEN1 time-consuming and expensive.

Tumors from MEN1 patients and non-MEN1 patients have been observed to harbor the germline mutation together with a somatic mutation or LOH involving chromosome 11q13, as expected from Knudson's model and the proposed role of the MEN1 gene as a tumor suppressor. The somatic mutations in tumors are scattered throughout the coding region (*see* Fig. 39-2) in a manner similar to that observed for the germline mutations. The 164 reported somatic mutations are also diverse in their types: approx 20% are nonsense mutations, approx 40% are frameshift deletions or insertions, approx 5% are inframe deletions or insertions, approx 5% are splice-site mutations, and approx 30% are missense mutations. Interestingly, somatic missense mutations have a significantly ($p < 0.001$) higher occurrence than germline missense mutations (*see* Fig. 39-3), although the reasons underlying this observation remain to be elucidated. Somatic MEN1 mutations also occur in sporadic (i.e., nonfamilial) tumors in patients who do not have MEN1, and this is consistent with the Knudson hypothesis that predicts that mutations of a gene causing a hereditary cancer syndrome will also be involved in causing some nonhereditary forms of the cancer. Thus, MEN1 mutations have been reported in sporadic tumors of the parathyroids, pancreatic islet cells, anterior pituitary, and adrenal cortex (Fig. 39-4). Such MEN1 somatic mutations have also been observed in carcinoid tumors, lipomas, angiofibromas, and melanomas.

OTHER HEREDITARY ENDOCRINE TUMOR SYNDROMES AND GERMLINE MEN1 MUTATIONS

The role of the MEN1 gene in the etiology of other endocrine disorders in which either parathyroid or pituitary tumors occur as an isolated endocrinopathy has been investigated by mutational analysis. Germline MEN1 mutations have been reported in 16 families with isolated primary hyperparathyroidism. The sole occurrence of parathyroid tumors in these families is remarkable and the mechanisms that determine the altered phenotypic expressions of these mutations remain to be elucidated. Mutational analysis studies in another inherited isolated endocrine tumor syndrome, that of familial isolated acromegaly, have not detected abnormalities of the MEN1 gene, even though segregation analysis in one family indicated that the gene was likely to be located on chromosome 11q13. However, nonsense mutations have been detected in MEN1 families with the Burin or prolactinoma variant, which is characterized by a high occurrence of prolactinomas and a low occurrence of gastrinomas.

FUNCTION OF MEN1 PROTEIN (MENIN)

Initial analysis of the predicted amino acid sequence encoded by the MEN1 gene did not reveal homologies to any other proteins, sequence motifs, signal peptides, or consensus nuclear localization signal, and, thus, the putative function of the protein (menin) could not be deduced. However, studies based on immunofluorescence, Western blotting of subcellular fractions, and epitope tagging with enhanced green fluorescent protein, revealed that menin was located primarily in the nucleus. Furthermore, enhanced green

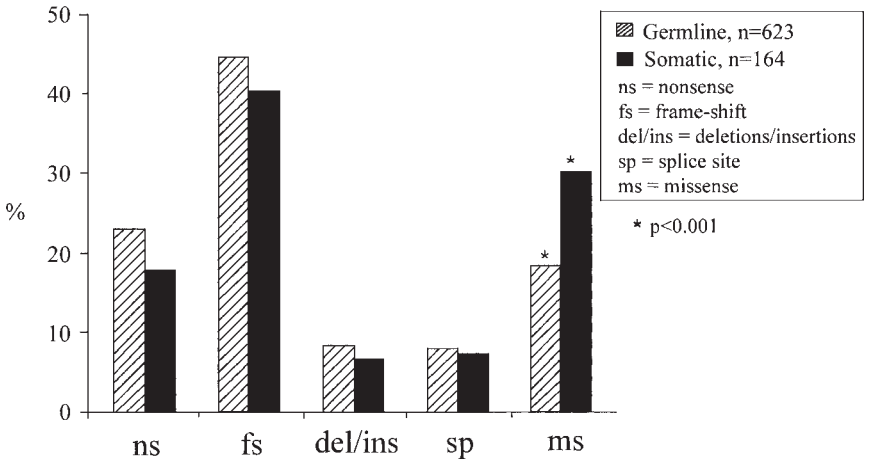

Figure 39-3 Frequency of germline and somatic multiple endocrine neoplasia type 1 mutations. A total of 623 germline mutations and 164 somatic mutations have been reported, and these are of diverse types, for example, nonsense, frameshifts, deletions, insertions, splice site, and missense mutations. The frequencies of each type of mutation in the germline and somatic group are similar with the exception of the missense mutations, which are found more frequently in tumors, i.e., the somatic group.

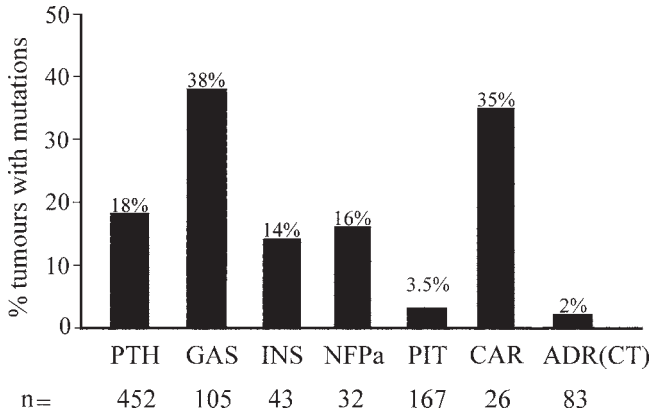

Figure 39-4 Frequencies of multiple endocrine neoplasia type-1 somatic mutations in nonfamilial (i.e., sporadic) tumors from non-MEN1 patients. The numbers (*n)* of tumors studied is indicated below for each group. Thus, MEN1 somatic mutations were observed in 18% of sporadic parathyroid tumors, 38% of gastrinomas (GAS), 14% of insulinomas (INS), 16% of nonfunctioning pancreatic islet cell tumors (NFPa), 3.5% of anterior pituitary (PIT) tumors, 35% of carcinoid tumors, and 2% of adrenocortical tumors (ADR[CT]). In addition, MEN1 somatic mutations have been observed in 57% of VIPomas (n = 7), 60% of glucagonomas (n = 5), 28% of lipomas (n = 7), 10% of angiofibromas (n = 19), and 2.5% of melanomas (n = 40) (data not shown).

fluorescent protein-tagged menin deletional constructs identified at least two independent nuclear localization signals (codons 479–497 and 588–608) that were located in the C-terminal quarter of the protein. Interestingly, the truncated MEN1 proteins that would result from the nonsense and frameshift mutations, if expressed, would lack at least one of these nuclear localization signals (*see* Fig. 39-2). Indeed menin is predominantly a nuclear protein in nondividing cells, but in dividing cells it is found in the cytoplasm. The function of menin remains to be elucidated but it does interact with a number of proteins involved in transcriptional regulation cell division, and genome stability. Thus, in transcriptional regulation, menin interacts with the activating protein-1, transcription factors JunD and C-jun, to suppress Jun mediated transcriptional activation; members, for example, p50, p52, and p65, of the nuclear factor κB family of transcriptional regulators to repress nuclear factor κB mediated transcriptional activation; members of the Smad family, Smad3 and the Smad 1/5 complex, to inhibit the transforming growth factor-β and the bone morphogenetic protein-2 signaling pathways, respectively; and the mouse placental embryonic expression gene that encodes a homeobox containing protein. An interaction between menin and the nonmuscle myosin II-A heavy chain (NMHC II-A) indicates a role in cell division, as NMCH II-A may mediate alterations in cytokinesis and cell shape during cell division. A role for menin in controlling genome stability has been proposed because of its interactions with a subunit of replication protein (RPA2), which is a heterotrimeric protein required for DNA application, recombination, and repair; the tumor metastases suppressor NM23H1/nucleoside diphosphate kinase that induces GTPase activity; and the glial fibrillary acidic protein and vimentin, which are involved in the intermediate filament network. Thus, menin appears to have a large number of potential functions through interactions with proteins; whether these alter cell proliferation mechanisms independently or act via a single pathway remains to be elucidated.

MOUSE MODEL FOR MEN1

Mouse models for MEN1 have been generated through homologous recombination (i.e., knockout) of the mouse MEN1 gene. The mouse MEN1 gene consists of a 1833-bp open-reading frame that encodes a 611 amino acid protein. The mouse menin protein contains one more amino acid residue than the human menin, a glycine at 528. However, the mouse and human coding regions have 89 and 96% identities of the nucleotide and amino acid sequences, respectively, indicating a high degree of evolutionary conservation. One mouse knockout model for MEN1 was generated by introducing a floxed PGK-neomycin cassette into intron 2 and a third loxP site into intron 8, with the aim of deleting exons 3–8 in one allele. Heterozygous mice (+/–) developed parathyroid dysplasia and adenomas by 9 mo of age, pancreatic islet cell tumors that contained insulin by 9 mo of age, anterior pituitary tumors that contained prolactin by 16 mo of age, and adrenocortical carcinomas. The tumors, which had LOH at the MEN1 locus,

were not associated with any serum biochemical abnormalities, such as hypercalcemia, or hypoglycemia, but those +/– mice developing pancreatic islet cell tumors or hyperplasia had elevated serum insulin concentrations. Thus, these heterozygous (+/–) mice provide a model for the human MEN1 disease. However, in another study, heterozygous mice (+/–) surprisingly died as embryos in late gestation, with some embryos developing omphaloceles. Two studies have reported that homozygous (–/–) mice die in utero at embryonic d 11.5–13.5. In one study these –/– mice were developmentally delayed and significantly smaller, and 20% of them developed craniofacial abnormalities. The craniofacial abnormalities were because of dysplasia of the membranous skull bones, and this developmental pathway involves the bone morphogenetic protein-2 signaling pathway. In another study, –/– mice were smaller in size, and developed extensive hemorrhage and edema. In addition, many of these –/– mice also had abnormalities of the neural tube, heart, and liver. Thus, many –/– mice had a failure of the closure of the neural tube, myocardial hypotrophy with a thin intraventricular septum, and decreased hepatic cellularity, which was associated with an altered organization and enhanced apoptosis. These results from the –/– mice reveal an important role for the MEN1 gene in the embryonic development of multiple organs.

FUTURE DIRECTIONS

Combined clinical and laboratory investigations of MEN1 patients will improve patient management and treatment, and also facilitate institution of a screening protocol. In addition, these advances will provide a better understanding of the role of these mutations in causing the endocrine tumors. One of the challenges remaining is the remarkable tissue specificity of the MEN1 tumors. The MEN1 gene is ubiquitously expressed from an early embryonic stage, and yet the tumors form principally in three endocrine glands. The availability of the mouse model may help to answer this question, and the availability of cellular models will help elucidate the role of menin in regulating cell proliferation via transcriptional regulation and genome stability.

40 Multiple Endocrine Neoplasia Type 2

Robert F. Gagel, Sarah Shefelbine, Hironori Hayashi, and Gilbert Cote

SUMMARY

Multiple endocrine neoplasia is a genetic endocrine tumor syndrome characterized by the presence of medullary thyroid carcinoma (MTC), pheochromocytoma, and hyperparathyroidism. There are two major variants. Multiple endocrine neoplasia (MEN) type 2A or Sipple syndrome has three clinical features: MTC, pheochromocytoma, and hyperparathyroidism; MEN2B has a different phenotype: MTC, pheochromocytoma, mucosal neuromas distributed throughout the mouth and gastrointestinal tract, and Marfanoid features including long thin arms and legs, an altered upper/lower body ratio, and pectus abnormalities. These clinical syndromes are caused by specific activating mutations of the RET tyrosine kinase receptor, important in neurological development of the gastrointestinal tract. MEN2 is one of a handful of genetic syndromes where the identification of a mutation leads to a specific action. Children with germline activating mutations of RET are treated in early childhood with a total thyroidectomy to prevent the development of metastatic MTC.

Key Words: Activating mutation; C cell; chromaffin cell; genetic testing; hereditary cancer; hyperparathyroidism; marfanoid features; medullary thyroid carcinoma; MEN2A; MEN2B; mucosal neuromas; multiple endocrine neoplasia type 2; parathyroid cell; pheochromocytoma; RET proto-oncogene; thyroid cancer; tyrosine kinase receptor.

INTRODUCTION

John Sipple first described components of the clinical syndrome that bears his name. Recognizing the association of thyroid cancer and bilateral pheochromocytomas in a patient at autopsy he reported this case with several others in a 1961 article. The type of thyroid carcinoma was more clearly defined and the clinical features of this syndrome, defined as multiple endocrine neoplasia (MEN) type 2, were separated from MEN1 (Table 40-1).

CLINICAL FEATURES

MEN2 consists of medullary thyroid carcinoma (MTC), pheochromocytoma, and hyperparathyroidism inherited as an autosomal-dominant trait. The nomenclature for this disease syndrome has evolved since its initial description; a classification system that reflects the clinical features and molecular causes is shown in Table 40-1. The syndrome originally described by Sipple has been classified as MEN2A. MTC is found in nearly all gene carriers, pheochromocytoma in one-half, and hyperparathyroidism in 10–20%. Characteristics of all neoplastic components associated with MEN2 are bilaterality and multicentricity. This is especially important for MTC in which surgical cure is possible only by removal of all thyroid tissue.

There are three variants of MEN2A: familial medullary thyroid carcinoma (FMTC); MEN2A with cutaneous lichen amyloidosis (MEN2A/CLA); and MEN2A with Hirschsprung disease. MTC in FMTC is inherited as an autosomal-dominant trait without other features of MEN2A. The MTC associated with FMTC tends to be less aggressive and is most likely to be confused with sporadic MTC because other manifestations of MEN2A are not present, and many affected family members may be asymptomatic. A diagnosis of FMTC should be made only in large, multigenerational families because of the incomplete penetrance (50% or less) for other manifestations of MEN2A. The MEN2A/CLA variant, found in approx 18 kindreds worldwide, is the association of MEN2A with a characteristic pruritic skin lesion located over the central upper back. The clinical features, other than the skin lesion, are identical to classic MEN2A, although hyperparathyroidism may be less common. Finally, a handful of families have been described with MEN2A and Hirschsprung disease. The penetrance of the Hirschsprung phenotype is variable, ranging from complete penetration to a single affected member.

MEN2B is characterized by MTC and pheochromocytoma as well as a unique phenotype of marfanoid habitus and mucosal, oral and intestinal ganglioneuromatosis (*see* Table 40-1). This disorder is transmitted as an autosomal-dominant trait, although the majority of cases represent *de novo* mutations; the mutant allele is generally inherited from the father and the mutation is thought to occur during spermatogenesis. MTC associated with MEN2B is more aggressive than observed in MEN2A. Development of carcinoma during the first year of life is common and early death from metastatic MTC occurs in 30–40% of patients. The prognosis, however, is not universally poor. A number of multigeneration families suggest considerable variability in the outcome.

DIAGNOSIS

MEN2 is a clinical syndrome that affects multiple endocrine organs. MTC and pheochromocytoma are the most common causes of morbidity and death. Hyperparathyroidism and its associated

No parathyroid disease
Marfanoid habitus (nearly 100%)
Intestinal ganglioneuromatosis and mucosal neuromas (nearly 100%)

findings of hypercalcemia, nephrolithiasis, and bone loss are less commonly a clinical problem.

The C cell, the cell type comprising MTC, produces a small peptide hormone, calcitonin. In patients with MTC, serum calcitonin values are characteristically elevated and secretion may be stimulated 3- to 20-fold higher by intravenous pentagastrin, calcium, or by a combination of the two. Prospective studies utilizing provocative testing with pentagastrin or the combination of calcium and pentagastrin have been used successfully to identify MTC early in the course of the disease. Prospective pentagastrin screening and thyroidectomy has improved survival and quality of life in these kindreds, although not all children or young adults are cured utilizing this approach. As many as 10–15% of these patients have evidence of recurrent disease or elevated calcitonin values in long-term follow-up studies.

Pheochromocytoma occurs in approx 50% of family members with MEN2. These tumors cause palpitations, headaches, and attacks of nervousness early in the course of tumor development; hypertension is infrequently found in patients with small tumors or hyperplasia of the adrenal. In patients with large or bilateral tumors, hypertension and cardiac arrhythmias may occur. Before the recognition of this syndrome in 1961 it is estimated that one-half of the deaths in MEN2 kindreds occurred suddenly and were attributed to cardiac disease; many were likely related to pheochromocytoma. The goal of screening for pheochromocytoma in kindreds with MEN2 is to identify an adrenal tumor before it causes significant or life-threatening manifestations of catecholamine excess. One successful approach is the annual measurement of plasma or 12 or 24 h urine for catecholamines or metanephrines. Symptomatic patients frequently have an elevation of either plasma or urine catecholamines or metanephrines. MEN2-related pheochromocytomas are unique in that they preferentially produce disproportionate amounts of epinephrine and its metabolite metanephrine when compared with sporadic pheochromocytomas or those associated with von Hippel Lindau syndrome that produce predominately norepinephrine or normetanephrine. Patients with abnormal values should have imaging studies. CT provides better definition of the adrenal medulla and is less expensive. MRI provides greater specificity if the adrenal medulla lights up on T2-weighted images.

The major diagnostic problems occur at the transition between normal and abnormal. Patients may have symptoms suggestive of pheochromocytoma with normal catecholamine measurements and imaging studies. In this situation the differentiation between intermittent abnormal catecholamine secretion and an anxiety disorder can be difficult. A trial of adrenergic blockade or inhibition of catecholamine synthesis with α-methyl tyrosine may help separate these two possibilities. If the patient is improved by pharmacological intervention and surgery is contemplated, the choice of which adrenal to remove may be difficult. Higher resolution CT scans using fine cuts through the adrenal glands permits localization in most cases; in others octreotide or met-iodobenzyl guanidine scanning may provide insight. Another alternative would be to continue the patient on adrenergic blockade or catecholamine synthesis inhibition until a pheochromocytoma can be clearly identified. Successful experience with long-term management of malignant pheochromocytoma, a much more challenging situation, suggests that this approach could be used safely in a compliant patient.

Earlier detection and improved surgical techniques have reduced the morbidity and mortality associated with pheochromocytoma to negligible levels. In fact, there is growing evidence that death from adrenal insufficiency may be a greater risk than death from pheochromocytoma; these concerns have led to a renewed interest and use of cortical sparing adrenalectomy, a technique in which the adrenal medulla is removed, leaving the cortex with intact vascularity.

GENETIC BASIS OF MEN2

MAPPING THE CAUSATIVE GENE The MEN2 gene was mapped to centromeric chromosome 10 in independent efforts in 1987. Subsequent work narrowed the region containing the MEN2 gene, leading to the identification of mutations of the *RET* proto-oncogene in 1993 (Fig. 40-1).

The *RET* proto-oncogene was first discovered in 1985 when a rearranged form of this gene was shown to cause transformation. The *RET* proto-oncogene encodes a tyrosine kinase receptor. A naturally occurring rearrangement was subsequently identified in 10–35% of papillary thyroid carcinomas (PTC) and named the PTC oncogene. Multiple different PTC variants exist, each resulting from a chromosome 10 rearrangement that places the tyrosine kinase domain of the *RET* proto-oncogene under the transcriptional control of another constitutively expressed gene. There is compelling evidence that the *RET* rearrangement causes transformation of the thyroid follicular cell in animal models of PTC.

The Glial Cell-Derived Neurotrophic FACTOR/RET/GFRA Receptor System A remarkable series of studies have defined a tyrosine kinase receptor signaling system important for the development of several components of the nervous system and normal kidney development. Individual components of this system include RET and a small protein ligand, glial cell-derived neurotrophic factor (GDNF), identified as a neuronal survival factor. The recognition that GDNF is a ligand for the RET tyrosine kinase receptor was not suspected until the mid-1990s when mice with *RET* or GDNF genes deleted were found to have nearly identical phenotypes, characterized by gastrointestinal neuronal features analogous to Hirschsprung disease, severe renal abnormalities, and developmental abnormalities of components of the

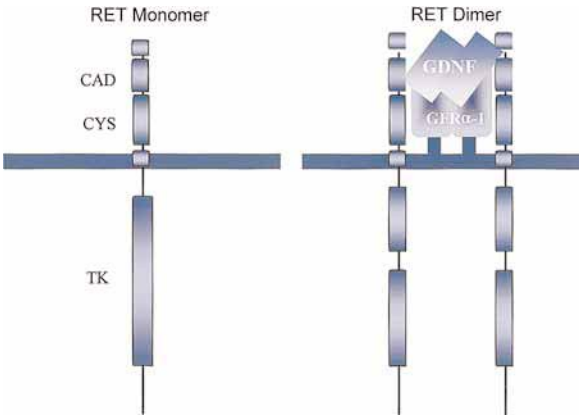

Figure 40-1 The RET tyrosine kinase receptor is a transmembrane receptor with a cadherin (CAD), cysteine-rich (CYS), and tyrosine kinase domain (TK). Interaction of GDNF, one of four ligands for RET, with the glial cell-derived neurotrophic factor receptor (GFRα-1) leads to dimerization of the receptor, autophosphorylation, and phosphorylation of downstream signaling substrates.

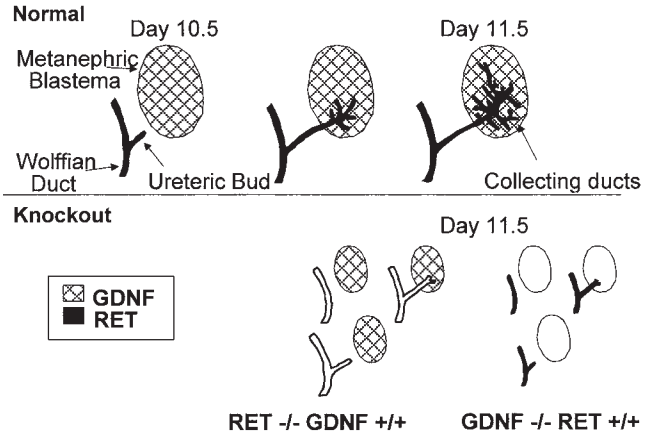

Figure 40-2 Schematic view showing mouse embryonic kidney development. The ureteric bud, derived from the Wolffian duct, normally migrates into the developing metanephric blastema to form the collecting system. In either *RET* (RET –/–) or *GDNF* (GDNF –/–) knockouts there is a defect in migration of the ureteric bud into the metanephric blastema resulting in a failure of normal kidney development. (Derived from information contained in work published by several authors: Schilling T, Burck J, Sinn HP, et al., 2001; Pichel JG, Shen L, Sheng HZ, et al., 1996; Moore MW, Klein RD, Farinas I, et al., 1996.)

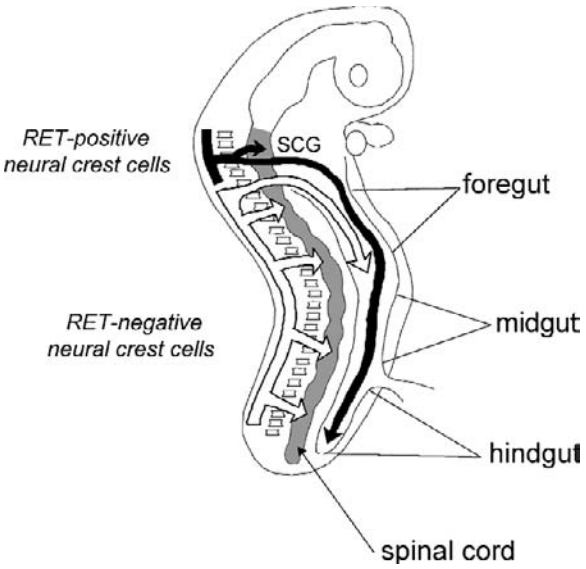

Figure 40-3 Migration of neural crest cells expressing the RET tyrosine kinase into the developing spinal cord and gastrointestinal tract. RET expressing cells form the superior cervical ganglion, parts of the dorsal root of the spinal cord, and the enteric neuronal plexus of the gastrointestinal tract.

sympathetic nervous system. Detailed studies in these animals showed gastrointestinal neuronal features analogous to those found in Hirschsprung disease with incomplete development of the enteric nervous system. There was also a complete lack of renal development in these animals. Components of the sympathetic nervous system, including the superior cervical ganglion, were also underdeveloped.

In an independent series of experiments, researchers discovered a receptor for GDNF, termed GDNF family receptor (GFR)-α and showed it to interact with the RET tyrosine kinase receptor. RET and GFRα-1, an extracellular protein tethered to the cell membrane by a glycosyl phosphatidylinositol linkage, together form a receptor for GDNF (*see* Fig. 40-1). Subsequent studies showed that targeted disruption of the mouse GFRα-1 gene causes a phenotype nearly indistinguishable from that observed for the mice in which GDNF and RET were deleted.

Additional work has defined a complex receptor system. The RET tyrosine kinase receptor forms the transmembrane backbone for each of these variants. The four ligands (GDNF, artemin [ARTN], persephin [PSPN], and neurturin [NRTN]) belong to the transforming growth factor-β superfamily and are collectively known as GDNF family ligands (GFL). The presence of seven cysteine residues characterize them as members of the cystine knot protein family. These ligands interact with RET and one of four GFRα proteins (GFRα-1, GFRα-2, GFRα-3, GFRα-4).

Perhaps more important than the components of the receptor system is the nature of the interaction between ligand and receptor system and how this interaction serves a developmental role. In a familiar theme of developmental biology, the ligand–receptor interaction serves to bring one tissue expressing the ligand into proximity with another expressing the receptor system. This interaction is perhaps best shown in the interactions between the ureteric bud and the metanephric blastema in kidney development. The ureteric bud (the developing renal ureteral collecting system) normally penetrates the metanephric blastema and branches to form the collecting system (Fig. 40-2). The peptide GDNF is expressed in the developing metanephric blastema and interacts with the RET receptor in the ureteric bud to promote branching of the ureteric bud into the developing kidney. In the absence of either GDNF or RET there is a failure of this interaction, leading to an undeveloped, shrunken kidney.

Available facts suggest a similar pattern of interaction between RET and GDNF in the developing enteric neuronal system. Clearly, RET is expressed in neural crest cells associated with somites 1–5. These RET positive cells migrate into the spinal cord and into the developing gastrointestinal tract during embryonic life (Fig. 40-3). The finding of incomplete intestinal neuronal development in RET, GDNF, and GFRα-1 knockout mice, provides compelling evidence for an interaction between the ligand/receptor systems of importance in neuronal innervation of the intestine.

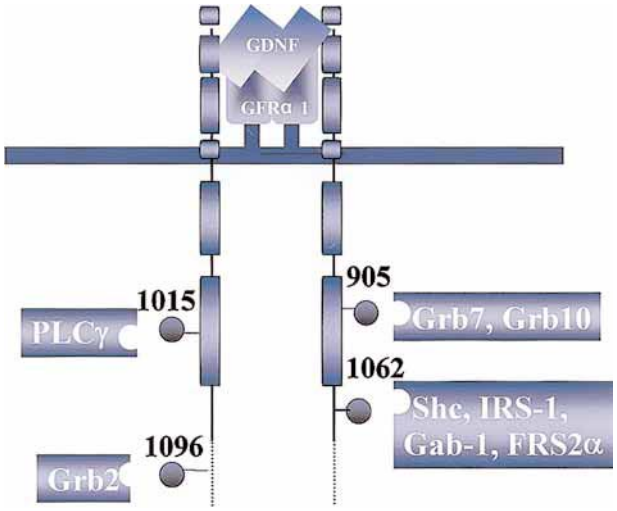

Figure 40-4 Diagram of the glial cell-derived neurotrophic factor/RET/GDNF family receptor-α1 receptor system showing intracellular tyrosine phosphorylation sites at codons 905, 1015, 1062, and 1096 with known interacting signaling linkage proteins.

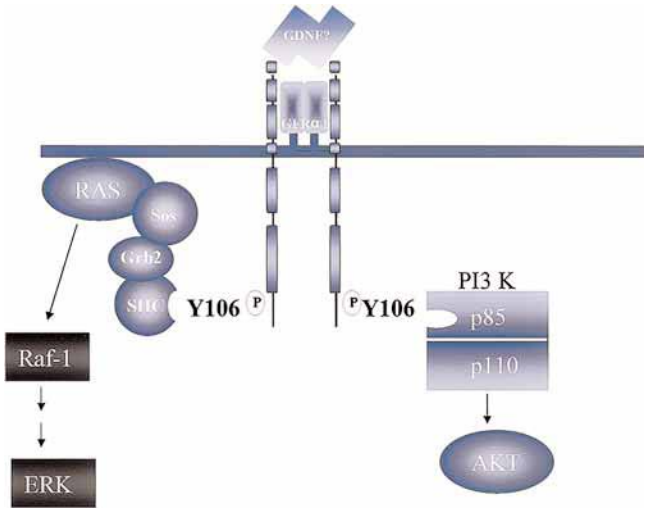

Figure 40-5 Transformation of the C cell by the mutant RET receptor requires phosphorylation of tyrosine 1062 and involves activation of at least two signaling pathways, PI 3 kinase and MAP kinase. There is evidence that glial cell-derived neurotrophic factor interaction with the RET/GDNF family receptor-α1 receptor system is not required for transformation caused by mutation of extracellular cysteine residues, but may be involved for mutations involving the tyrosine kinase domains.

In the broader perspective these studies provide insight into an important neural crest development pathway. Studies of RET expression in developing embryos have shown RET expression in neural crest derived from somites one to five. Between day 9 and 10.5 there is migration of RET positive cells from the neural crest into the developing spinal cord and gastrointestinal tract (*see* Fig. 40-3). It is possible to envision a tropic effect of GDNF interaction with the RET/GFRα-1 receptor system to entice neural crest cells into their normal developmental location.

There is an evolving body of literature that GDNF, NRTN, ARTN, and PSPN function as survival factors. Indeed, GDNF was originally identified as a neurotrophic factor whose presence in a culture system prevented neuronal death. A substantial amount of data indicates that this receptor system functions in neurons and neuroendocrine cells to prevent apoptotic cell death. This is certainly evident in mice in which the GFL (GDNF, ATRN, PSPN, or NTRN), RET, or one of the four GFRα receptors have been deleted. In most of these single-gene deletion mice there are features that indicate a developmental loss of neurons at various developmental stages, arguing that this receptor system promotes neuronal survival. Postnatally, however, the receptor system appears to have a different set of functions that relate both to neuronal survival and specific neuronal function.

The interaction of one of the four GFLs with the RET/GFRα family receptor activates a complex cascade of signaling systems. There are at least four different tyrosine phosphorylation sites on RET that could mediate downstream signaling (Fig. 40-4). There is a general agreement that Tyr 1062 of RET activates both mitogen-activated protein kinase and phosphatidyl inositol-3-kinase pathways (Fig. 40-5). There is considerable evidence that tyrosine 1062 is necessary for the neoplastic transformation events found in MEN2. Substitution of another amino acid at codon diminishes the transformation efficiency of mutant RET.

MUTATIONS OF THE *RET* PROTO-ONCOGENE ASSOCIATED WITH MTC The mutations of *RET* in MEN2 predominantly affect two domains within the RET tyrosine kinase receptor. Mutations of a cysteine-rich region of the extracellular domain are the most common mutations found in MEN2 and its variants (Fig. 40-6). Each of these mutations converts a conserved cysteine at codons 609, 611, 618, 620, 630, or 634 to another amino acid. Of all *RET* mutations, 75% affect codon 634 and a single mutation, cys634arg, accounts for >50% of all mutations

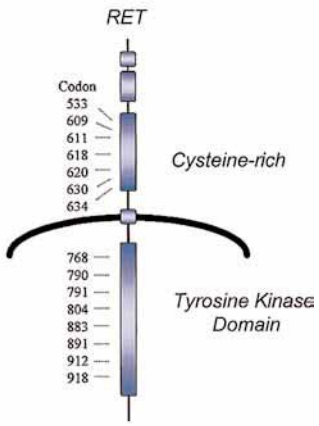

Figure 40-6 Mutations of the *RET* proto-oncogene associated with hereditary medullary thyroid carcinoma. The most common mutations affect two regions of the RET tyrosine kinase. Mutations of an extracellular cysteine domain (codons 609, 611, 618, 620, 630, and 634), important for dimerization of the receptor, cause MEN2A and its variants. Mutations of the tyrosine kinase domain are found in MEN2B (codons 883 and 918) and a few families with FMTC (768, 804, 891, 912). Abbreviations: multiple endocrine neoplasia type 2A, MEN2A; familial medullary thyroid carcinoma, FMTC; MEN2A/cutaneous lichen amyloidosis, MEN2A/CLA; MEN2A/Hirschsprung disease variant, MEN2A/Hirschsprung; and multiple endocrine neoplasia type 2B, MEN2B.

associated with hereditary MTC. Genotype–phenotype correlation shows that a codon 634 mutation is most commonly associated with classic MEN2A or Sipple's syndrome. Mutations of the codons found in exon 10 (609, 611, 618, 620) are most commonly found in FMTC. Despite these correlative efforts, any of the extracellular cysteine mutations can be associated with MEN2A or FMTC, a point of importance in the clinical management of kindreds with these mutations. A clinician should not conclude that an individual with an exon 10 mutation will not develop a pheochromocytoma unless there are multiple generations within a family that have not developed pheochromocytoma. All patients with the MEN2A/CLA syndrome have codon 634 mutations. MEN2 can also be associated with mutations of codon 790, 791, V804L, and 891.

Germline mutations of the tyrosine kinase domain are found in MEN2B (codons 883 and 918) and FMTC (codons 768, V804M, and 912) (*see* Fig. 40-6). Of patients with MEN2B, 98% have the M918T substitution; a handful of MEN2B patients with the codon 883 mutation have been identified. The mutation in the remaining 1–2% has not been identified. In the handful of kindreds with the codon 533, 768, V804M, and 912 mutations the only clinical phenotype is familial MTC.

Additional evidence for the oncogenicity of these mutations came from studies in which expression of mutant *RET* proto-oncogene in NIH 3T3 cells caused transformation. These studies showed that codon 634 mutation resulted in dimerization of the RET tyrosine kinase receptor in the absence of its ligand, leading to autophosphorylation and phosphorylation of downstream proteins. Transfection of the *RET* cDNA containing the met918thr mutation also causes transformation, although dimerization of the receptor does not occur and a different set of substrate proteins are phosphorylated.

MUTATIONS OF THE *RET* PROTO-ONCOGENE ASSOCIATED WITH HIRSCHSPRUNG DISEASE Two independent lines of analysis led to the identification of mutations of the *RET* proto-oncogene in patients with Hirschsprung disease. The identification of a chromosome 10 deletion in a child with Hirschsprung disease led to mapping studies in familial Hirschsprung disease that localized the causative gene to proximal chromosome 10q. Subsequent investigations identified inactivating and presumed activating mutations of the RET tyrosine kinase in Hirschsprung disease. Analysis of kindreds in which MEN2A and Hirschsprung disease cosegregate (*see* Table 40-1) have identified codon 609, 618, or 620 mutations of the *RET* proto-oncogene. Mutations of the endothelin-β receptor gene and its ligand, endothelin-3, have also been identified in Hirschsprung disease.

Mutation analysis is readily available from several commercial sources (www.genetests.org). Several techniques have been applied to detection of mutations including direct DNA sequencing and restriction analysis for specific mutations and denaturing gradient gel electrophoresis. Direct DNA sequencing has become the detection procedure of choice because it permits rapid sequencing of the seven exons known to be involved in MEN2. There are a few caveats. Genetic testing like most other forms of laboratory analysis will be associated with a small error rate caused by sample mix-up, contamination of the PCR reaction, failure of specific primers to amplify the mutant allele, or technician copying errors, collectively estimated in the range of 5%.

MUTATIONS OF THE *RET* PROTO-ONCOGENE IN SPORADIC MTC Somatic met918thr mutations of the *RET* proto-oncogene have been identified in approx 25% of sporadic MTCs. Evidence indicates that tumors with this particular mutation may pursue a more aggressive clinical course. It is important to consider *RET* proto-oncogene analysis in patients with apparent sporadic MTC because a compilation of available information indicates that 5–7% of patients with apparent sporadic MTC have germline mutations of the *RET* proto-oncogene.

MANAGEMENT/TREATMENT

MANAGEMENT OF MTC

Negative Genetic Test Results The availability of reliable genetic testing makes it possible to identify gene carriers with near certainty. Children with negative test results can be excluded from further screening studies. It is important to *repeat* the analysis on more than one blood sample to be certain of the test results. This is especially true of individuals who have a normal *RET* analysis and will receive no further screening.

Positive Genetic Test Results Clinical decision making based on *RET* proto-oncogene testing has evolved over the past several years. In an international conference focused on MEN there was consensus that genetic testing should form the basis for a decision for thyroidectomy. There was a general agreement that children with the highest risk mutations (codon 883, 918 associated with MEN2B) should have thyroidectomy performed shortly after birth. Those with high-risk codons (611, 618, 620, 630, 634, and 891) should be considered for thyroidectomy around the age of 5 yr, the earliest age at which metastasis has been identified in a child with one of these mutations. Others have argued for earlier thyroidectomy based on the finding of microscopic MTC (without evidence of metastasis) in younger children. In children with low-risk *RET* mutations (codons 790, 791, 768, 804, and 912), there are large kindreds in which there has never been a death caused by MTC. In these kindreds physicians are unwilling to recommend and parents are unwilling to accept a recommendation for early thyroidectomy. In patients with these mutations, thyroidectomy should be performed at some later age, perhaps between 10 and 15 yr of age. Some continue to perform pentagastrin or calcium testing for calcitonin and perform a thyroidectomy at the time of a positive test result. It is unclear whether earlier thyroidectomy would prevent the recurrences found in 15–20% of children thyroidectomized based on calcitonin testing in earlier series. A report of the European experience suggests that earlier thyroidectomy would be beneficial; in this large series metastasis to local lymph nodes was not observed until the mid-teenage years (although it is not clear how many lymph nodes were examined in each patient), suggesting earlier thyroidectomy may improve outcomes. At this point clinicians participating in the decision to perform early thyroidectomy should balance the risks and benefits of the procedure in each age group.

The completeness of thyroidectomy may be important. It is difficult to perform a total thyroidectomy without damage to blood vessels associated with the posterior capsule of the thyroid gland. Such damage can cause a higher incidence of hypoparathyroidism, a situation most surgeons choose to avoid. A few normal C cells in residual thyroid tissue attached to the posterior capsule may be of little concern in a 40- to 50-yr-old patient, but there is the real possibility that a few normal cells expressing a mutant RET kinase in a 5-yr-old child may transform over a several-decade period of follow-up. This concern has led some clinicians to recommend a total thyroidectomy including the posterior capsule, central lymph node dissection, and transplantation of

parathyroid tissue to the nondominant arm. Whether this approach will improve the already excellent long-term cure rate for this disease is unclear, but seems worthy of investigation.

MANAGEMENT OF PHEOCHROMOCYTOMA The advent of genetic testing will have little impact on the management of pheochromocytoma in MEN2 other than to exclude 50% of family members with normal genetic tests from further screening. Patients with pheochromocytomas should have unilateral or bilateral adrenalectomy or a cortical sparing adrenalectomy, dependent on the specific clinical situation. Issues related to unilateral or bilateral adrenalectomy in this disease have been discussed in Chapter 38 and are not reviewed in this chapter. Patients with abnormal catecholamine secretion should have adrenal surgery performed prior to consideration of thyroidectomy.

MANAGEMENT OF HYPERPARATHYROIDISM Hyperparathyroidism occurs infrequently in children who have received prophylactic thyroidectomy for MTC. In one series there have been no cases of hyperparathyroidism in children who received thyroidectomy at a mean age of 13 yr with a mean follow-up period in excess of 20 yr. There is debate about the appropriate management of parathyroid neoplasia in older patients. Either subtotal parathyroidectomy or total parathyroidectomy with transplantation of parathyroid tissue to the nondominant forearm has been advocated.

FUTURE DIRECTIONS

Hereditary MTC is a rare disorder, but the specific molecular defect that causes this neoplastic syndrome provides a useful model in which to study strategies for inactivation of mutant RET tyrosine kinase activity. The fact that a single gene defect causes three different neoplastic manifestations makes it an interesting model for study. There are several small organic molecule tyrosine kinase inhibitors with activity against the RET kinase domain in phase I trials. The prolonged period during which transformation occurs makes MEN2 and hereditary MTC excellent models in which to assess the impact that prophylactic treatment with a drug designed to prevent RET activation would have on the natural history of the disease.

41 Disorders of Sex Determination and Differentiation

CHARMIAN A. QUIGLEY

SUMMARY

Abnormalities of sex determination and differentiation comprise two major clinical groups: disorders of gonadal development (i.e., disorders of sex determination: sex reversal, true hermaphroditism), with secondary effects on genital development, and defects of genital development in the presence of normal gonads (disorders of sex differentiation: male and female "pseudohermaphroditism"). This chapter will review the embryology of normal sex determination and differentiation, the genetic basis of normal and abnormal sex determination and differentiation, and the approaches to diagnosis of disorders of sex determination and differentiation.

Key Words: Adrenogenital primordium; androgen insensitivity syndrome; congenital adrenal hyperplasia; gonadoblastoma; granulosa cell; hermaphroditism; labioscrotal fold; Leydig cell; Leydig cell hypoplasia; mosaicism; ovary determination; persistent Müllerian duct syndrome; primordial gonad; pseudohermaphroditism; Sertoli cell; sex differentiation; sex reversal; testis determination; theca cell; urogenital sinus.

INTRODUCTION

Sex determination and differentiation are distinct, consecutive processes that follow the establishment of chromosomal sex at the time of gamete fertilization, subsequently requiring the coordinated expression of a specific set (or sets) of genes in a strict spatiotemporal manner. The term *sex determination* (alternatively called *primary sex differentiation*) refers to the development of gonadal sex—a process that occurs at approx 6–7 wk gestation in the human male fetus, and approx 10–11 wk gestation in the female fetus. As generally used, the term *sex differentiation* refers to the processes downstream of gonadal development—those regulated by gonadal secretions or lack thereof (also called *secondary sex differentiation*). In essence, the genetic complement endowed at fertilization determines gonad type and the latter determines the pattern of differentiation of the internal genital ducts and external genitalia.

GENERAL CLINICAL FEATURES Abnormalities of sex determination and differentiation consists of two major clinical groups: disorders of gonadal development (i.e., disorders of sex determination: sex reversal, true hermaphroditism), with secondary effects on genital development, and defects of genital development in the presence of normal gonads (disorders of sex differentiation: male and female pseudohermaphroditism). The disorders of sex determination and differentiation are summarized in Table 41-1. Approaches to diagnosis and management are discussed at the conclusion of the chapter.

Sex Reversal and True Hermaphroditism The terminology is sometimes confusing: sex reversal refers to the condition in which the individual's genetic sex opposes the gonadal (and therefore generally the phenotypic) sex. These are individuals with 46,XY karyotype who have no testes (in their place usually are streak gonads) and have a female (or ambiguous) phenotype, and those with 46,XX karyotype who have testes and varying degrees of genital masculinization. The archetypal and most common form of sex reversal is 46,XX maleness (approx 1 in 20,000 men has 46,XX karyotype). The phenotype of most 46,XX males is similar to that seen in Klinefelter syndrome (47,XXY): structurally normal (sometimes cryptorchid) testes are present and the internal and external genitalia are male. Testicular size and histology are normal in infancy. Pubertal virilization occurs to a greater or lesser degree, but like those with Klinefelter syndrome, affected postpubertal individuals have small testes and are azoospermic. Up to 20% of 46,XX males have subnormal masculinization, manifest by cryptorchidism, hypospadias or frank genital ambiguity. The testes have atrophic, hyalinized, seminiferous tubules and Leydig cell hyperplasia. The absence of spermatogenesis in 46,XX males may relate two factors, the presence of the extra X-chromosome, and the absence of Y-chromosomal genes involved in spermatogenesis. 46,XX males are taller than average for females, but shorter than 46,XY males, presumably because of absence of stature-determining genes located on Yq.

There are two main subtypes of 46,XX maleness (and 46,XX true hermaphroditism, described later)—XX^{Y+} and XX^{Y-}. The majority of patients with complete 46,XX maleness are XX^{Y+}, resulting from translocation of all or part of the distal end of the Y-chromosome (Yp), containing the sex-determining region of the Y-chromosome *(SRY)*, to the short arm of an X-chromosome (Xp) during paternal gamete meiosis. In contrast, the majority of patients with 46,XX true hermaphroditism are XX^{Y-}. The molecular/ phenotypic inference from these findings is that the greater the amount of Y-chromosome material, the more complete the masculinization. Two specific hot spots for Yp-Xp recombination within areas of high X-Y sequence homology

Table 41-1
Genetic Disorders of Sex Determination and Differentiation

Disorders of sex determination (development of gonad discordant from karyotype)
46,XX sex reversal/true hermaphroditism (46,XX karyotype with testes or ovotestes)
XX^{Y+} (SRY translocation to terminal Xp)
XX^{Y-} (probable mutation of downstream regulator of testis development)
46,XY sex reversal/true hermaphroditism (46,XY karyotype with ovaries, ovotestes or streak gonads)
SF1 deletion/mutation (homozygous, heterozygous)
WT1 deletion/mutation (heterozygous)
SRY deletion/mutation (Y-linked)
SOX9 mutation (heterozygous)
ATRX mutation (X-linked)
DHH mutation (homozygous)
Monosomy 9p (possible haploinsufficiency of DMRT1/2)
DSS (duplication)
WNT4 (duplication)
Disorders of sex differentiation (development of phenotype discordant from gonad)
46,XY pseudohermaphroditism (46,XY karyotype with testes and female or ambiguous internal or external genitalia)
Impaired testosterone production
LHCGR mutation (homozygous, compound heterozygous)
Defects of testosterone biosynthesis
StAR mutation/deletion (homozygous, compound heterozygous)
POR mutation (homozygous, heterozygous, compound heterozygous)
CYP11A mutation (heterozygous, compound heterozygous)
HSD3B2 mutation (homozygous, compound heterozygous)
CYP17 mutation (homozygous, compound heterozygous)
HSD17B3 mutation (homozygous, compound heterozygous)
Impaired androgen response
SRD5A2 deletion/mutation (homozygous, compound heterozygous)
AR gene deletion/mutation (hemizygous)
Impaired anti-Müllerian hormone production or action
AMH mutation (homozygous, compound heterozygous)
AMHR2 mutation (homozygous, compound heterozygous)
46,XX pseudohermaphroditism (46,XX karyotype with ovaries male or ambiguous internal or external genitalia)
Fetal androgen excess
Congenital adrenal hyperplasia
POR mutation (heterozygous, compound heterozygous, homozygous)
HSD3B2 mutation (homozygous, compound heterozygous)
CYP21 mutation (homozygous, compound heterozygous)
CYP11B1 mutation (homozygous, compound heterozygous)
Aromatase deficiency
CYP19 mutation (homozygous, compound heterozygous)
Disorders affecting Müllerian structures
HOXA13 mutation (heterozygous)
Mayer-Rokitansky-Kuster-Hauser syndrome (unknown etiology)

AMH, anti-Müllerian hormone; AMHR, anti-Müllerian hormone receptor; AR, androgen receptor; ATRX, α-thalassemia/mental retardation, X-linked gene; CG, chorionic gonadotropin; DHH, desert hedgehog; DSS, dosage-sensitive sex reversal; HOXA13, homeobox A 13; LH, luteinizing hormone; LHCGR, luteinizing hormone/chorionic gonadotropin receptor; POR, P450 oxidoreductase; SF1, steroidogenic factor 1; SOX, Sry-related homeobox gene; SRY, sec-determining region of the Y-chromosome; StAR, steroidogenic acute regulatory; WNT, wingless-type MMTV integration site family member; WT1, Wilms tumor 1.

have been reported to account for >50% of such recombination events. However, many 46,XX males have no definable genetic change and because approx 10% of 46,XX males with testes are completely negative for all Y-encoded sequences, it is likely that non Y sequences are responsible for testis determination in these cases. For example, female-to-male sex reversal has been found in association with duplication of the region of chromosome 17 containing the *SRY-related homeobox gene (SOX) 9*.

The converse of 46,XX maleness is complete gonadal dysgenesis in a 46,XY female (Swyer syndrome; XY gonadal dysgenesis), however, it is much less common, occurring in only 1/100,000 females. Affected individuals have streak gonads with female internal and external genitalia, although significant phenotypic variation is found within affected families. Partial testicular dysgenesis is associated with genital development that essentially reflects the functional state of the gonads at the critical period of sex differentiation. Because of deficient estrogen production, breast development is poor and 46,XY females often present with delayed puberty or primary amenorrhea, accompanied by gonadotropin concentrations in the castrate range. Pubic hair is

usually present. There is a high incidence of gonadal neoplasia (gonadoblastomas and germinomas). Probably because of the presence of Y-chromosomal stature-determining genes, affected women are of normal to tall stature compared with 46,XX females. Individuals with deletion of Yp (including the *SRY* gene) in addition to the general features described earlier, may have certain features of Turner syndrome such as lymphedema, likely because of haploinsufficiency of a gene or genes on Xp.

Male-to-female sex reversal has been reported in association with mutations of genes described in the following sections, including Wilms tumor 1 *(WT1), steroidogenic factor (SF) 1,* α*-thalassemia/mental retardation, X-linked gene (ATRX), SRY* and SRY homeobox-like gene 9 *(SOX9)* and also occurs in association with deletions of the region of chromosome 9 in which doublesex/mab-related transcription factors *(DMRT1 and DMRT2)* reside, and with duplication of the chromosomal regions in which *dosage-sensitive sex reversal adrenal hypoplasia congenita locus on the X chromosome, gene 1 (DAX1;* X chromosome) and wingless-type MMTV integration site family *(WNT4;* chromosome 1*)* reside.

True hermaphroditism defines the condition in which, regardless of karyotype, there is coexistence of ovarian and testicular tissue in the same individual, either an ovary on one side and a testis on the other (~20% of patients), bilateral ovotestes (~30%) or one ovotestis and one testis or ovary (~50%). The testicular portions of the gonads are dysgenetic, with interstitial fibrosis and rare or absent spermatogonia, whereas the ovarian portions are histologically normal. Malignant degeneration of the gonad is reported in approx 5% of cases. Most affected invididuals have ambiguous genitalia, however, the phenotypic spectrum is broad: for example, a fully masculinized boy with bilaterally descended ovotestes has been reported. A hallmark, although not universal feature, is asymmetric genital development—Müllerian structures (that may include a full or hemiuterus) on one side, and Wolffian structures on the other; a gonad-containing hemiscrotum on one side (more often the right) with a flat, empty labium majorum on the other. In general the pattern of development reflects the predominant functional nature of the gonad on the ipsilateral side. In association with an ovotestis, the internal genitalia may show elements of both Müllerian and Wolffian origin on the same side. The pattern of pubertal development reflects the function of the gonads and fertility is not uncommon.

Of affected individuals with true hermaphroditism, approx 70% have a 46,XX karyotype and some cases may represent a variant form of 46,XX maleness. Without thorough histological evaluation of the gonads it may be impossible to distinguish an undervirilized 46,XX male from a 46,XX true hermaphrodite. In addition, true hermaphroditism and complete sex reversal can coexist within the same family, so these disorders may be phenotypic variations of a certain genotype. The majority of patients with 46,XX true hermaphroditism are negative for any detectable Y-chromosomal sequences. About 20% of affected individuals have chromosomal mosaicism for 46,XX/46,XY or less commonly 46,XX/47,XXY; a small number of cases have a pure 46,XY karyotype and a few with 47,XXY karyotype have been reported. Although the molecular basis of this condition is unknown, genetic causes are implicated by the finding of familial cases of the disorder.

Pseudohermaphroditism Pseudohermaphroditism (either male [46,XY] or female [46,XX]) refers to conditions in which the karyotype and gonad are congruous, however, there is a discrepancy between the gonadal sex and the phenotypic sex: individuals with 46,XY karyotype and testes whose phenotype is female or ambiguous (e.g., disorders of androgen production or action) and those with 46,XX karyotype and ovaries whose phenotype is male or masculinized (e.g., disorders resulting in excess androgen production, such as congenital adrenal hyperplasia [CAH]). Individuals of either karyotypic sex with these disorders have phallic development that ranges from a diminutive clitoris in a 46,XY individual to a completely formed penis in a 46,XX individual; the labioscrotal region may be fully fused and rugose, or bifid and smooth; the internal structures may be mainly female-type (Müllerian, in the absence of anti-Müllerian hormone [AMH] action), mainly male-type (Wolffian, in the presence of local androgen action), or a combination of the two. The internal and external genital morphology essentially reflects fetal production of, and response to, androgens and AMH during the critical period of gestation.

OVERVIEW OF MOLECULAR PATHOPHYSIOLOGY

Because of the multiplicity of enzymes, hormones, receptors, and transcription factors involved, there are numerous opportunities for the usually well-coordinated processes of sex determination and differentiation to go awry. Some general principles are worth elucidating before delving into the specific disorders:

1. Hormones have no intrinsic action and must act through specific receptors. Thus hormone deficiencies are typically manifest by lack of function of the corresponding receptor. In general, steroid hormone deficiencies, resulting from defects of genes encoding the biosynthetic enzymes responsible for generation of the respective hormones, typically manifest only in the presence of two defective gene alleles and are inherited as autosomal-recessive traits.
2. Receptors that mediate hormone action comprise two broad categories. (1) Membrane-associated receptors act as transducers of the hormone signal. Binding of the hormone (typically a peptide) to the extracellular domain of such a receptor sets off an intracellular signal cascade in which a downstream factor or second messenger eventually influences gene transcription. (2) Intracellular receptors, such as those for the steroid and thyroid hormones, function as nuclear transcription factors themselves by entering the nucleus and binding directly with target genes to modify their transcription, usually in a ligand-dependent fashion. A subclass of the nuclear transcription factor family referred to as *orphan receptors* (e.g., DAX1) function in the absence of known ligand. In addition, other nonreceptor transcription factors of different classes and families also function in a ligand-independent manner (e.g., SRY, SOX9, WT1).
3. Defects of membrane-associated transducer-type receptors that mediate peptide hormone action, such as the luteinizing hormone/chorionic gonadotropin receptor (LHCGR), cause an increase or a decrease in the activity of the system, depending on whether the mutation is an activating or an inhibitory one. This is illustrated by the contrasting effects of mutations in the LHCGR: inhibitory mutations cause the syndrome of leydig cell hypoplasia (LCH, *see* LHCG Receptor), whereas activating mutations are associated with the syndrome of familial male precocious puberty (*see* Chapter 43). Defects of these receptors are expressed only in the presence of two defective gene alleles.
4. In the intracellular receptor system, absence of ligand or defective binding of ligand to the receptor translates to

absent or reduced activity of the ligand-dependent transcription factor; complete absence of a transcription factor (e.g., when the encoding gene is deleted) results complete loss of target gene transcription. Mutations of the DNA-binding regions of these receptors alter protein-DNA interactions between transcription factors and their target genes, potentially resulting in decreased, increased or sometimes promiscuous transcriptional activation, the latter resulting from loss of DNA-binding specificity. In the case of a heterozygous mutation, the abnormal protein produced from the mutant allele may interfere with the action of the normal protein produced from the wild-type allele of the gene—a "dominant negative" effect. In this situation, the mutant protein may block access of the normal factor to its target DNA, by forming inactive dimers that are unable to bind the target DNA sequence, or sequester other critical transcription factors because of disturbed protein–protein interactions. Defects in genes encoding nuclear transcription factors may manifest as dominant conditions, with dysfunction occurring in the presence of a single mutant allele (e.g., thyroid hormone receptor), or as recessive conditions in which both alleles must be mutated to cause disease (e.g., vitamin D receptor). Defects of this receptor class manifest clinically as hormone resistance syndromes, because hormone action is diminished in the presence of increased hormone levels.

EMBRYOLOGY OF NORMAL SEX DETERMINATION AND DIFFERENTIATION

Normal development of the gonads and genitalia has three major phases. First, in the earliest stages of gestation, the fetus develops a bipotential gonad, two sets of embryonic internal genitalia, and undifferentiated female-like external genitalia. The next step is the differentiation of the bipotential gonads into either ovaries or testes and the final phase is the differentiation and development of the internal and external genital primordia along male or female lines, depending on the nature of the hormonal products of the gonads (or lack thereof).

PHASE 1: DEVELOPMENT OF THE PRIMORDIAL STRUCTURES

GONADS At approx 5 wk of human gestation, the intermediate mesoderm in the area that will become the kidney, adrenal, and gonad condenses into distinct regions. As development progresses, the urogenital ridges form on the dorsal wall of the body cavity. The urogenital ridge consists of the mesonephros (the forebear of the primitive kidney) located laterally, and the genital ridge, which will become the primitive gonad, located medially. Development of the genital ridge is accompanied by thickening and proliferation of the coelomic epithelium, which penetrates the underlying mesenchyme to form the primitive sex cords. Blood vessels grow into the developing gonad from the mesonephros, subsequently developing in a sexually dimorphic manner. The primitive genital or gonadal ridges initially contain no germ cells. Between weeks 5 and 6 of gestation, primordial germ cells migrate from the endoderm of the yolk sac along the dorsal mesentery of the hindgut into the indifferent gonad, invading the developing primary sex cords. At this stage the gonad consists of an outer cortex and inner medulla, and no morphological difference between the gonads of male and female fetuses can be detected until approx 7 wk gestation, at which time testicular development begins in the male fetus.

INTERNAL GENITALIA Both the urinary and genital components of the urogenital system are derived, to a large extent, from the intermediate mesoderm, which becomes segmented into units termed nephrotomes. The lateral portions of the nephrotomes unite, forming a longitudinal duct on each side of the embryo, the mesonephric duct (later to become the Wolffian duct), by about week 4 of gestation. At approx 6 wk, the paramesonephric duct (to become the Müllerian duct) forms from the epithelium on the surface of the urogenital ridge, such that by 6 wk, both male and female fetuses are endowed with two sets of internal duct structures.

EXTERNAL GENITALIA Just as the gonads and internal genitalia are indistinguishable between the sexes for the first few weeks of life, so it is for the external genital primordia (Fig. 41-1). In the fourth week of gestation the external genitalia of both sexes are represented simply by a midline protuberance—the genital tubercle. By week 6 (still indifferent), two medial folds, the urethral folds, flank the urogenital groove and two larger folds, the labioscrotal folds, are present laterally.

PHASE 2: SEX DETERMINATION (DEVELOPMENT OF TESTIS OR OVARY)

TESTIS DEVELOPMENT Soon after the germ cells arrive, the gonad in the 46,XY fetus begins to differentiate; the first histologically discernible event in testis development is the appearance of primordial Sertoli cells, which differentiate from somatic cells of the coelomic epithelium at approx 7 wk gestation. The Sertoli cells proliferate, aggregate around the primitive germ cells and align into cord-like structures (medullary sex cords) that subsequently become the seminiferous tubules. The seclusion of germ cells within the tubules prevents meiosis and commits the germ cells to spermatogenic development. The prevention of meiosis may be the key event that directs gonadal development away from the ovarian pathway. This organizational process appears to be regulated by the Sertoli cells themselves. Germ cells are not required for this process, because morphological testis development occurs in their absence. About 1 wk later (approx 8 wk), steroidogenic Leydig cells differentiate from primitive interstitial cells of mesonephric origin, likely controlled by paracrine influences from Sertoli cells, possibly AMH. Another key event is the differentiation of peritubular myoid cells, thought to derive from the same interstitial cell lineage as Leydig cells. These myoepithelial cells are required for the development of the testis cords—the defining event in testicular organogenesis. Timing is critical as there is only a limited window during which these events can occur.

OVARY DEVELOPMENT In contrast with testis development, normal ovarian differentiation specifically requires the presence of germ cells. Without the germ cell seeding of the 46,XX gonadal primordium, the tissue degenerates into a nonfunctional, mainly fibrous "streak." Prior to week 10 of gestation the only histological feature that distinguishes an ovary is the absence of testicular features. Thereafter, ovarian structure becomes distinguishable, with the regression of the primary medullary sex cords, which are replaced by a vascular stroma. Secondary cortical sex cords that provide the supporting structure for the germ cells develop close to the surface of the gonad under the influence of the germ cell lineage. Within the sex cords the primary germ cells undergo vigorous mitotic replication to become oogonia; then the sex cords break up

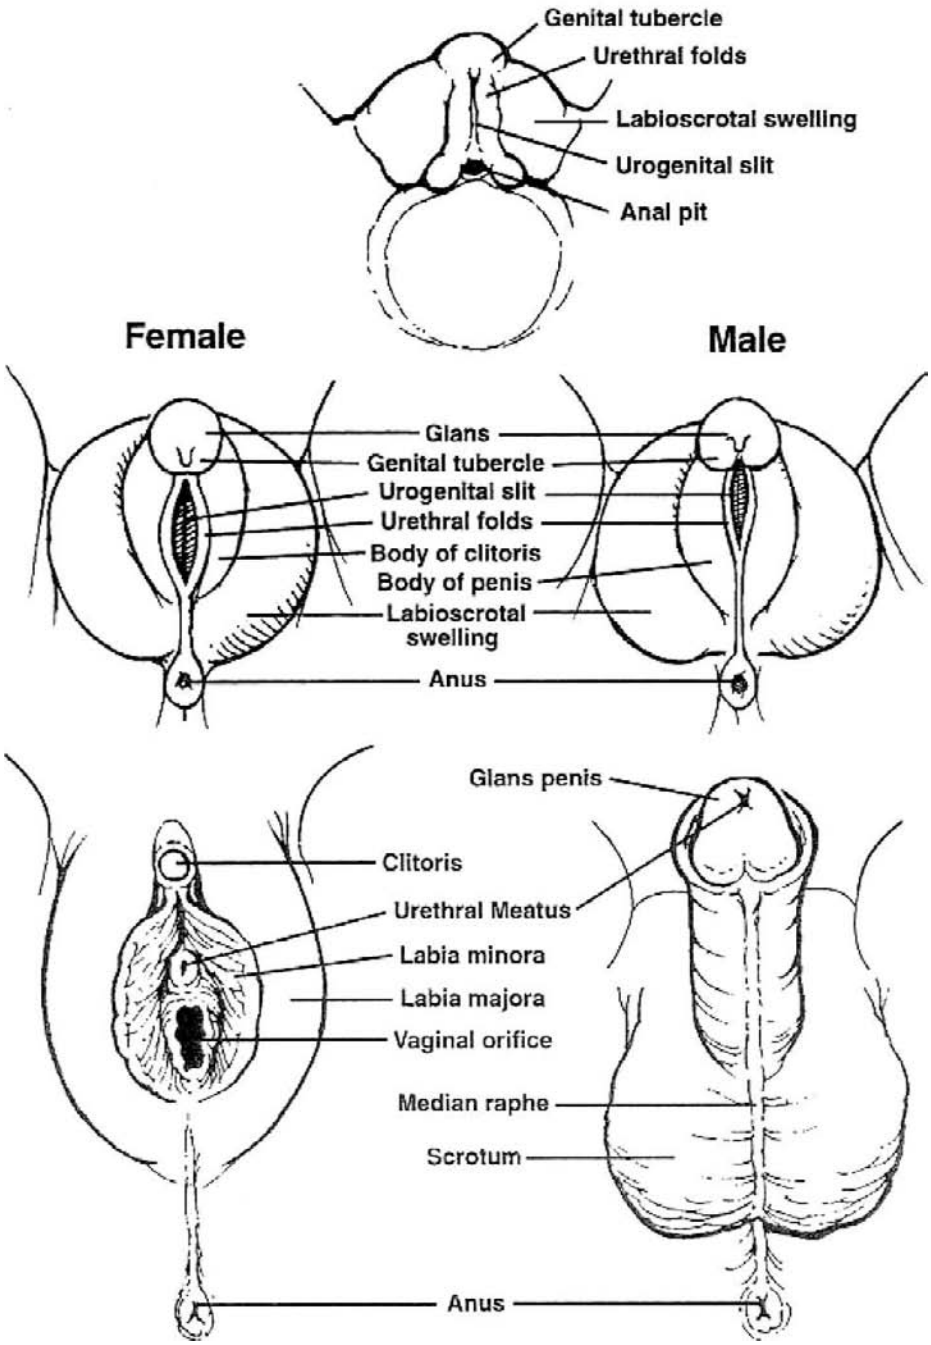

Figure 41-1 Differentiation of the external genitalia. (**Top**) At week 6 of gestation the external genitalia are undifferentiated, consisting of the midline genital tubercle, two medial urethral folds flanking the urogenital slit, and two larger labioscrotal swellings laterally. (**Left**) In the absence of androgen action the genital tubercle becomes the clitoris and the urogenital sinus remains patent. The vesicovaginal septum forms to separate the urethra from the vagina, located posteriorly. The urethral folds develop as the labia minora, whereas the labioscrotal folds enlarge slightly, remaining unfused, as the labia majora. (**Right**) In the male fetus in the presence of androgens (mainly DHT), the genital tubercle elongates to become the body of the penis, and the urethral folds fuse in the midline to form the penile urethra. The labioscrotal swellings fuse and enlarge to become the scrotum. These processes are completed approximately between weeks 8 and 12 of gestation.

into clusters, becoming the primordial follicles at about week 16. The primordial follicles contain the diploid (i.e., 46 chromosomes) primary oocytes, which after entering into the first stage of meiosis (reduction division) remain quiescent until puberty. Follicular (granulosa) cells arise from the same somatic cell lineage as Sertoli cells. Theca cells represent the ovarian counterpart of Leydig cells.

There is a notable difference in the chronology of testicular vs ovarian development, the process of testis formation being completed by 8 wk gestation, at which time the process of ovarian development has not yet begun. In fact, ovarian development is not completed until after most of the processes of phenotypic sex differentiation, described below, have occurred. This, and the fact that phenotypic development is normal even in complete absence

of the ovary, highlights the lack of involvement of the ovary in the processes of normal female genital development.

PHASE 3: SEX DIFFERENTIATION (DEVELOPMENT OF MALE OR FEMALE GENITALIA)

INTERNAL GENITALIA: MALE The primitive internal genital tracts are indistinguishable between the sexes until 7 wk gestation. From week 8 of gestation, hormonal secretions from the fetal testes induce masculinization of the internal genital structures in the 46,XY fetus. Initially the Wolffian ducts are stabilized (prevented from undergoing resorption) by the action (mainly local) of testosterone; between 9 and 13 wk gestation they undergo differentiation into the epididymides, vasa deferentia and seminal vesicles. Dihydrotestosterone (DHT) does not appear to mediate these processes, because the enzyme required for its production (5-α reductase 2) is not expressed in Wolffian tissues at the time of their differentiation. In parallel to the masculinization of the internal genitalia represented by Wolffian development, a process of "defeminization" of the redundant set of genital ducts occurs as the Müllerian ducts regress under the influence of locally acting AMH secreted by Sertoli cells. The Müllerian ducts are obliterated by week 11 of gestation, the only remnant of their existence in the male being the prostatic utricle. Absence of one testis results in retention of Müllerian structures and only limited Wolffian development on the ipsilateral side, indicating that the effects of AMH and testosterone are largely mediated in a paracrine fashion.

INTERNAL GENITALIA: FEMALE In the absence of testicular secretions, as in the normal 46,XX fetus, the inverse set of genital tract developmental processes occurs. Without local androgen action, the Wolffian ducts regress. Meanwhile, absence of AMH allows the Müllerian ducts to develop. Their upper portions form the fallopian tubes; the lower sections fuse and differentiate as the uterus and upper part of the vagina. The lower portion of the vagina derives from the urogenital sinus (the ventral part of the embryonic mammalian cloaca formed by the growth of a fold dividing the cloaca where the gut and allantois meet), which remains patent in the absence of androgen action.

EXTERNAL GENITALIA: MALE Under the influence of androgen action (primarily DHT), the genital tubercle elongates to form the body of the penis, and the urethral folds fuse ventrally from behind forward, to form the penile urethra. The labioscrotal folds grow toward each other, fusing in the midline to form the scrotum. DHT also induces the urogenital sinus to differentiate as the prostate, and inhibits the formation of the vesico-vaginal septum. These processes are completed by week 12 of gestation (Fig. 41-1). Between 12 and 24 wk gestation the testes migrate from their original lumbar location to the level of the internal inguinal ring above the scrotum. Descent of the testes through the inguinal ring and into the scrotum begins around week 28, and in most infants is completed by term.

EXTERNAL GENITALIA: FEMALE In the absence of significant androgen action, such as in the normal female fetus, the genital tubercle elongates only slightly to form the clitoris (Fig. 41-1). The urogenital sinus remains open and the vesico-vaginal septum (a fold of tissue that separates the posterior wall of the bladder from the anterior wall of the vagina) forms, so that the urethra opens anteriorly and the vagina posteriorly. The vestibule of the urogenital sinus is bordered laterally by the urethral folds, which do not fuse and instead develop as the labia minora. Further lateral, the labioscrotal swellings enlarge somewhat but also remain unfused, forming the labia majora. There is minor fusion posteriorly, forming the posterior commissure, and anteriorly, producing the mons pubis. These events occur from about week 7–12 of gestation.

GENETIC BASIS OF NORMAL AND ABNORMAL SEX DETERMINATION AND DIFFERENTIATION

A complex interplay of genes, transcription factors, hormones, and receptors is required for normal sex determination and differentiation (Table 41-2). The primary event governing the path of morphological sex differentiation is the development of the gonad. In 1947 the elegant experiments of Jost determined that "maleness" was a state imposed on the fetus that would otherwise develop as a phenotypic female, leading to the theory that development of the ovary and female phenotype occur when the fetus is not exposed to the influences of specific "maleness-determining" genes. However, newer information, indicates that rather than being a passive, "default" process, female development likely also requires activation of specific, perhaps opposing, gene pathways. From these findings the concept has developed that sex determination represents the primordial "Battle of the Sexes"*—the dominance of one set of gonad-specific genes over another. The key event determining the winner of the battle appears to be whether the primordial germ cells that colonize the indifferent gonad enter meiosis. Testis cord development, under the influence of a number of *SOX* genes during a narrow developmental window, arrests the primordial germ cells in mitosis; in the absence of testis cord development, germ cells enter meiosis and ovarian development ensues. The genes involved in the regulation of sex determination and sex differentiation reside on both the sex chromosome and the autosomes. Based on studies of sex determination in other species it has been hypothesized that the mammalian sex chromosomes evolved from a homologous autosome pair.

The initial event in sex determination—the development of the primordial, bipotential gonad—depends on a network of interacting factors encoded by at least a dozen, and possibly scores of genes. Subsequent development of the testis or the ovary is exquisitely regulated by a team of cooperative transcriptional activators and repressors that selectively up- or downregulate the genes required for sex-specific gonadal differentiation.

BIPOTENTIAL GONAD AND PRIMORDIAL INTERNAL GENITAL DUCTS There is a relationship between renal, adrenal, and gonadal cellular precursors that underlies both normal and abnormal development, because these tissues all arise from the same regions of the primitive mesoderm and coelomic epithelium known as *adrenogenital primordium*. The adrenal cortex derives from mesenchymal cells attached to the coelomic cavity lining adjacent to the urogenital ridge within the intermediate mesoderm; similarly, the steroid-producing cells of the gonads (Leydig and theca cells) differentiate from mesenchymal stem cells. The specific ontogeny of steroidogenic tissues has particular relevance for the understanding of the genetic regulation of gonadal development. Because these tissues have common cellular ancestors, it is not surprising that they share aspects of their genetic makeup. Thus the roles and responsibilities of a number of transcription factors involved in the early stages of renal, adrenal

*This term was coined by Blanche Capel and colleagues in "The Battle of the Sexes: Opposing Pathways in Sex Determination" in The Genetics and Biology of Sex Determination, Novartis Foundation Symposium 2002;244: pp. 187–202.

Table 41-2
Factors Involved in Sex Determination and Differentiation

Gene name or pseudonyms	*Human gene locus*	*Human protein name*	*Protein type*	*Genetic or cellular targets*	*Action*	*Effects of over- or under-expression*
Factors involved in primordial gonad/reproductive tract formation						
SF1[a] *Ftzf1 Ad4BP NR5A1*	9q33	SF1	Orphan nuclear receptor/ zinc finger transcription factor	*WT1, SRY, SOX9, DAX1, GnRHR, LHb, ACTHR, AMH, AMHR, StAR, P450scc, 21-OH'lase, 11b-OH'lase, oxytocin, SF1, others*	Activates transcription of many genes in development of gonads, adrenals; regulates steroidogenesis. Synergizes with WT1; antagonizes DAX1. Dose dependent activity.	KO mice: no gonads or adrenals; retained Müllerian structures; abnormal hypothalamus. Haploinusfficient mice: reduced but not absent adrenal function. Homozygous human mutation: 46,XY sex reversal and adrenal hypoplasia. Heterozygous human mutation: 46,XX normal ovary, partial adrenal insufficiency.
WT1[a]	11p13	WT1	Zinc finger transcription factor; tumor repressor	*DAX1, IGF-II, type 1 IGF receptor, PDGF-A, Pax2, WT1, SRY*	Represses transcription; activates transcription of Sry. Dose dependent effects	XY homozygous deletion of WT1+KTS isoform: male-to-female sex reversal; XY homozygous deletion of WT1-KTS isoform: streak gonads in XX and XY. Human Denys-Drash syndrome: gonadal dysgenesis, congenital nephropathy, Wilms tumor.
Lim1 Lhx1	11p12-13	LIM1	Homeodomain transcription factor with 2 LIM domains (4 zinc fingers)	Not reported	Expressed at stage of primitive streak. Organizes development of anterior neural tissues	KO mice lack heads, kidneys and genital ridges.
Emx2[a]	10q26.1	EMX2	Homeodomain transcription factor	Wnt4, possibly Lim1	Similar to Lim1. Probably functions downstream of WT1	KO mice (XX or XY) lack kidneys, ureters, gonads and genital tracts and have brain defects. Human mutation causes schizencephaly; no urogenital phenotype reported.
Lhx9	1q31-32	LHX9	LIM homeodomain transcription factor, similar to LIM1	Binds *SF1* promoter. May have additive effect with -KTS isoform of WT1 in activating *SF1* expression	Drives formation of sex cords	XX and XY KO mice have gonadal agenesis.
CBX2 M33	17q25, near Sox9	M33	Transcription repressor	Possibly SRY	Mediates changes in chromatin structure	KO mice (XX or XY) have retarded development of gonadal ridges; XY mice have male-to-female sex reversal.
Wnt4[a]	1p35	WNT4	Cysteine-rich signaling molecule/secreted growth factor	Mesonephric mesenchyme	Directs Müllerian duct formation	XX and XY null mice have Müllerian agenesis (*see* "ovary" for details of human mutation).

c-Kit	4q12	Kit	Transmembrane tyrosine kinase receptor; protooncogene	Germ cell, hemopoetic and melanocyte precursors	Suppresses apoptosis, directs migration/ proliferation of stem cell populations	Mouse mutations: white coat color, sterility, anemia. Human mutation: piebaldism, mast cell luekemia.
Steel	12q22	Slf/KL	Ligand or c-Kit	Unknown	As for c-Kit	Mouse mutations: white coat color, sterility, anemia.
Factors involved in testis/male sex determination/differentiation[b]						
SRY[a]	Yp11.3	SRY	HMG box-containing transcription factor	*SF1, SOX9, CYP19, AMH*	Bends DNA; may antagonize SOX3	XX mice expressing transgenic *Sry* female-to-male sex reversal. Human *SRY* mutations: 46,XY sex reversal. Translocation of *SRY* to X-chromosome: 46,XX female-to-male sex reversal or true hermaphroditism.
SOX9[a]	17q24-25	SOX9	HMG box-containing transcription factor of SRY family	Supporting cells of gonadal primordium	Stimulates differentiation of Sertoli cells	*Odsex* mice (deletion of regulatory locus upstream of *Sox9*): derepression of *Sox9* expression in XX gonads → testis development.
ATRX[a] *XH2 XNP*	Xq13.3	ATRX	Helicase; transcription factor	Widespread expression early in mouse embryogenesis, more restricted expression later	Gene regulation at interphase and chromosomal segregation at mitosis	Human mutations cause α–thalassemia, mental retardation and genital anomalies → male-to-female sex reversal.
Dhh	12q13.1	DHH	Signaling molecule	Expressed only in testis	Involved in interactions between Sertoli cells and germ cells. May regulate mitosis and meiosis in male germ cells	Strain-specific effects: XY null mice have defective Leydig cell development and are feminized.
LHCGR[a]	2p21	LH/CG Receptor	G protein-coupled, 7-transmembrane peptide hormone receptor	Not applicable	Transduces LH signal to activate Gsα → cAMP. Required for Leydig cell testosterone production	Human mutation: Leydig cell hypoplasia → male pseudohermaphroditism. Mouse: normal sex differentaition. Males and females infertile.
StAR[a]	8p11.2	StAR	Mitochondrial transport protein	Not applicable	Transports cholesterol to inner mitochondrial membrane	Human mutation: congenital lipoid adrenal hyperplasia and male pseudohermpahroditism.
SRD5A1[a]	5p15	5α-reductase2	Mitochondrial enzyme	Not applicable	Converts testosterone → DHT	Male pseudohermaphroditism.
AR[a]	Xq11-12	AR	Ligand-dependent nuclear receptor/transcription factor	*AMHR, ?CYP19*	Regulates transcription	Mouse, rat: testicular feminization (Tfm). Human mutations: androgen insensitivity syndromes.
AMH[a]	19p13.2-13.3	AMH	Glycoprotein homodimer of TGFβ family	Not reported	Ligand for AMH-R	Persistent Müllerian duct syndrome.
AMHR[a]	12q13	Type II AMH receptor	Transmembrane serine/ threonine kinase receptor	Mesenchymal and epithelial cells of müllerian ducts	Mediates apoptosis of Mullerian duct	Persistent Müllerian duct syndrome.

Table 41-2 ***(Continued)***

Gene name or pseudonyms	*Human gene locus*	*Human protein name*	*Protein type*	*Genetic or cellular targets*	*Action*	*Effects of over- or under-expression*
Factors involved in ovary/female sex determination/differentiation						
Wnt4[a]	1p35	WNT4	Cysteine-rich signaling molecule/secreted growth factor	Mesonephric mesenchyme	Directs initial Müllerian duct formation in both sexes; possible "anti-testis" factor in ovarian development	XX and XY null mice: Müllerian duct agenesis. Overexpression in XY: male-to-female sex reversal. Human: duplication of *WNT4* associated with 46,XY male-to-female sex reversal. Mutation in 46,XX: Müllerian regression, androgen excess.
FoxL2[a]	3q23	FOXL2	Transcription factor	Not reported	Expressed predominantly in ovary; earliest known marker of ovarian differentiation in mammals	Goat: deletion associated with XX sex reversal. Human mutation: 46,XX ovarian dysgenesis.
Fst	5q11.2	Follistatin	Glycosylated protein related to TGFβ family	Granulosa cells	Antagonizes action of activins and BMP15 in steroidogenesis; involved in Wnt4 signaling	Overexpression in XX mice: small ovaries with block in folliculogenesis; *Fst*-null XX mice: development of testis-like vasculature
Gdf9	Unknown	GDF9	Secreted growth factor member of TGFβ family	Ovarian somatic cells	Secreted by oocytes as paracrine factor required for ovarian somatic cell function	*Gdf9* null XX mice: block in oocyte differentiation
Bmp15 *Gdf9b*	Xp11.2	BMP15	Secreted growth factor member of TGFβ family	Granulosa cells	Paracrine stimulation of ovarian granulosa cell growth and proliferation; downregulates FSH receptor expression; antagonized by FST	XX KO mice: subfertile; homozygous mutation in XX sheep: premature ovarian failure; XX human heterozygous mutation: ovarian dysgenesis
Hoxa13[a]	7p15-p14.2	HOXA13	Homeodomain transcription factor	*Fgf8, Bmp7*	Involved in epithelial-mesenchymal interactions required for morphogenesis of terminal gut and urogenital tract, including Müllerian structures	Mouse: XX null have hypoplasia of cervix and vagina. Human mutation: hand-foot-genital syndrome with uterine malformation in 46,XX
Factors with possible roles in either sex						
DAX1[a] *Ahch* *NR0B1*	Xp21	DAX1	Orphan nuclear receptor transcription factor	*Retinoic acid receptor, retinoid X receptor, StAR, P450scc, 3β-HSD, CYP17*	Antagonizes SF1; regulates testis cord organization. Dose-dependent effects.	Strain-specific defects in XY mice: overexpression → testis maldevelopment and sex reversal; homozygous deletion → adrenal hypoplasia, normal testes. Human mutations: adrenal hypoplasia congenital, hypothalamic hypogonadism

DMRT1/2	9p24.3	DMRT1 and DMRT2	Doublesex-MAB domain transcription factors	Not reported	Expressed only in genital ridge Dose-dependent effects on postnatal testis development	XY null mice have normal prenatal testis development, but abnormal postnatal testis differentiation. Human monosomy 9p: 46,XY testis maldevelopment; 46,XX primary hypogonadism
GATA4[a]	8p23.1-p22	GATA4	Zinc finger transcription factor	"*GATA*" motif on target genes; *AMH*; genes for steroidogenic enzymes	Expressed early in both ovary and testis	KO in mouse–embryonic lethal, no gonadal phenotype reported. Human mutation–cardiac defects; no gonadal phenotype reported
WNT7a	3p25	WNT7a	Signaling molecule	Mesenchymal and epithelial cells of Müllerian ducts	XY: involved in Müllerian duct regression; XX: stimulates development of Müllerian duct	XY null mice: retained Müllerian ducts; female *Wnt7a* deficient mice: defective, though not absent, development of oviducts and uterus

[a]Genes in which human mutations have been reported.

[b]Note: *see* Table 4 for enzymes of steroidogenesis.

A number of the genes listed have been implicated in gonadal/genital development only by studies in mice and defects have not been reported in humans.

ACTHR, adrenocorticotropic hormone receptor; AMH, anti-Müllerian hormone; AMHR, anti-Müllerian hormone receptor; AR, androgen receptor; ATRX, α-thalassemia/mental retardation, X-linked gene; BMP15, bone morphogenetic protein 15; CG, chorionic gonadotropin; DAX1, dosage-sensitive sex reversal-adrenal hypoplasia congenita locus on the X-chromosome, gene 1; DHH, desert hedgehog; DHT, dihydrotestosterone; DMRT1/2, Doublesex and MAB-3-Related Transcription Factors 1 and 2; FSH, follicle stimulating hormone; FST, follistatin; FOXL2, forkhead transcription factor 2; GDF, growth differentiation factor; GnRH-R, gonadotropin-releasing hormone receptor; HMG, high-mobility group; HOXA13, homeobox A 13; HSD, hydroxysteroid dehydrogenase; IGF, insulin-like growth factor; KO, knockout; KTS, lysine/threonine/serine; LH, luteinizing hormone; LHCGR, luteinizing hormone/chorionic gonadotropin receptor; LHX9, LIM homeobox gene 9; LIM, Lin-11, Islet-1 and Mec-3; LIM1, LIM homeobox gene 1; PDGF, platelet-derived growth factor; SF1, steroidogenic factor 1; SOX, Sry-related homeobox gene; SRY, sex-determining region of the Y chromosome; StAR, steroidogenic acute regulatory protein; TGF-β, transforming growth factor-β; WNT, wingless-type MMTV integration site family member; WT1, Wilms tumor 1.

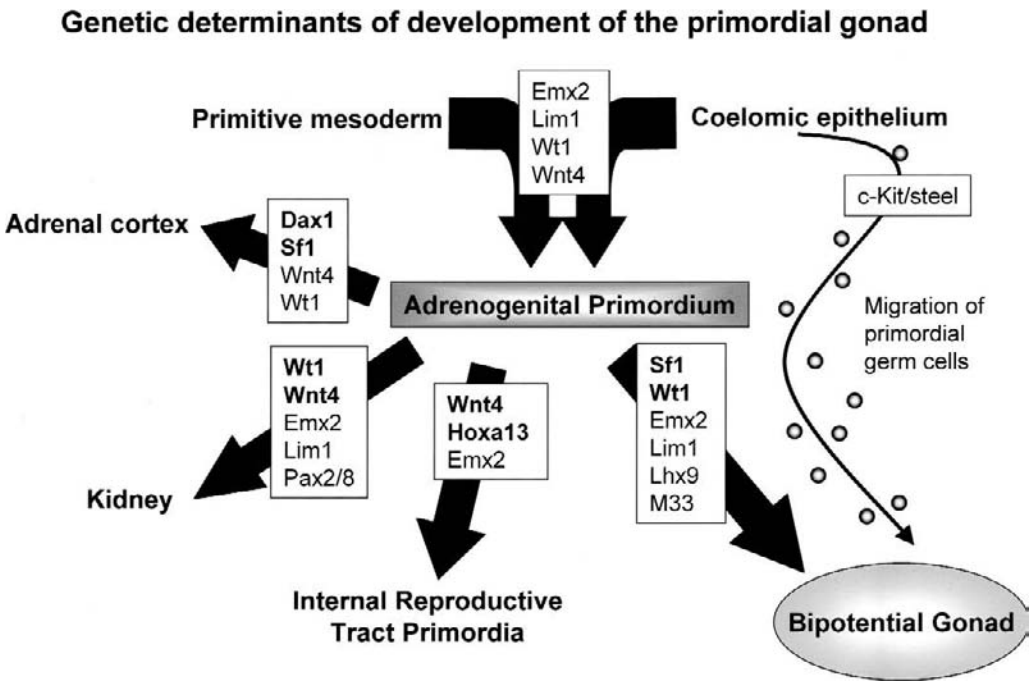

Figure 41-2 Genetic determinants of development of the primordial gonad. Transcription factors Emx2, Lim1, Wt1, and Wnt4 are required for development of the adrenogenital primordium, which forms following condensation of primitive mesoderm and coelomic epithelium. Thereafter, various combinations of transcription factors direct the fate of the undifferentiated primordial cells down one of a number of pathways to form the adrenal cortex, kidney, bipotential gonad and internal reproductive tract primordia. Factors highlighted in bold have been established to be involved in human development. Dax1, dosage-sensitive sex reversal-adrenal hypoplasia congenita locus on the X-chromosome, gene 1; Emx2, empty spiracles 2; Hoxa1, homeobox A1; Lhx9, LIM homeobox gene 9; Lim1, Lin-11, Islet-1, and Mec-3 homeobox gene 1; Sf1, steroidogenic factor 1; Wt1, Wilms tumor 1; Wnt4, wingless-type MMTV integration site family member 4.

and gonadal development overlap, when tissues are undifferentiated and the major developmental need of the organism is to increase cell mass. As development progresses, and populations of cells begin to differentiate along specific, irreversible paths, there is a requirement for a much more focused program of transcription factor action. This concept may help in the understanding of the diverse roles served by transcription factors such as SF1, WT1, and LIM (the acronym stands for Lin-11, Islet-1 and Mec-3—the three original members of the family) homeobox* gene 1 (LIM1), compared with the much more limited roles, expression, timing and cellular specificity of factors such as SRY and AMH.

Factors implicated in the early development of the bipotential gonadal and reproductive tract primordia on the basis of defects observed in humans include SF1, WT1, and WNT4. In addition, LIM1, empty spiracles 2 (EMX2), and LIM homeobox gene 9 (LHX9) are implicated in these processes on the basis of murine studies. Furthermore the ligand/receptor pair Steel/c-Kit is vital, at least in mice, to the process of germ cell migration from the yolk sac to the gonadal primordium in both sexes. Exact relationships between these factors and the precise timing and order of their expression remain to be determined; a hypothetical scheme for their potential roles in regulating the processes of early development of the reproductive tract is shown in Fig. 41-2. In the next section, descriptions of the molecular biology of individual factors and their molecular defects in humans, are provided. Additional genes postulated to be involved in these processes based on studies in nonhuman species are described briefly at the end of this section.

*The homeobox is the approx 180 bp sequence in the gene that encodes the approx 60 AA homeodomain of the respective protein.

Steroidogenic Factor 1 (SF1)

Normal Function The orphan nuclear receptor transcription factor, SF1 (also referred to as adrenal 4-binding protein and officially termed nuclear receptor subfamily 5, group A, member 1) appears to be one of the earliest-acting and most critical factors in the primitive development of the reproductive tract. SF1 affects reproductive function at all three levels of the hypothalamic-pituitary-gonadal axis, as well as the adrenal gland, and subsequently regulates factors acting further down the pathway of gonadal/genital development in a male-specific fashion. Importantly, SF1 appears to act in a dose-dependent manner in both mice and humans.

The human *SF1* gene is located at chromosome 9q33, spans 30 kb of genomic DNA and contains seven exons including an initial noncoding exon. SF1 is a 461-amino acid (AA), 53-kDa protein containing two central DNA-binding zinc fingers (ZFs) typical of nuclear receptors, an activation domain and a C-terminal ligand-binding domain (for which no ligand has yet been identified, hence its designation as an "orphan" receptor). SF1 differs structurally from most nuclear receptors by lacking an N-terminal domain and differs functionally by binding as a monomer, rather than as the more usual dimer, to a nonpalindromic DNA sequence. Based on studies of human mutations, two regions of the protein appear particularly critical for function: the so-called P-box, located in the proximal portion of the first ZF, is responsible for interaction with the major groove of DNA; the A-box region downstream of the ZFs modulates monomeric binding to DNA.

In the mouse *Sf1* (also known as *FtzF1*, based on its similarity to the drosophila gene, fushi tarazu factor 1) is expressed in male

and female urogenital ridge at embryonic day (E)9-9.5, the earliest stage of organogenesis of the indifferent gonads. Consistent with its role in regulation of steroidogenesis, *Sf1* is expressed prior to expression of the first enzyme of steroidogenesis, P450 side chain cleavage enzyme (p450scc). Because both *Sf1* and *Wt1* (discussed later) are expressed in the gonadal primordium at a similar time, before gonadal differentiation occurs, Sf1 interaction with Wt1 may play a role in proper development of the gonadal precursor. After a sex-specific gonad can be discerned, *Sf1* expression becomes sexually dimorphic, presumably under the regulation of other sex-specific factors: in the fetal testis (specifically Sertoli and Leydig cells) *Sf1* expression continues at a high level; in XX gonads *Sf1* is expressed in somatic cells until E13 and disappears altogether between E13.5 and 16.5, in keeping with the lack of ovarian steroidogenic activity at that time. In adult mice *Sf1* is expressed in all primary steroidogenic tissues, including all zones of the adrenal cortex, testicular Leydig and Sertoli cells, ovarian theca and granulosa cells and corpus luteum. Not only does Sf1 regulate gonadal and adrenal development, it also appears to control development of an important hypothalamic nucleus, and of pituitary gonadotropes. *Sf1* mRNA is detectable in the developing mouse pituitary at E13.5-14.5 specifically in the gonadotropes.

The expression of *Sf1* and *Dax1*, another orphan nuclear receptor described later, overlap in their tissue distribution. Dax1 appears to repress or antagonize Sf1 activity, particularly the synergy between Sf1 and Wt1, probably via a protein–protein interaction with Sf1. On the basis of this finding it has been proposed that Sf1 and Dax1 functionally oppose each other. These interactions may be key for the differential expression of genes involved in female vs male development.

SF1 is implicated in the regulation of numerous genes, as binding sites for this transcription factor have been located within the promoter regions of at least 20 target genes, including those encoding a number of other transcription factors, hormones, receptors, proteins, and enzymes of steroidogenesis, and the signaling molecule, Wnt4. SF1 binds to the *AMH* gene promoter and upregulates *AMH* expression in association with WT1. Notably, SF1 is unable to regulate *AMH* expression in a heterologous cell line unless its ligand-binding domain is deleted. This finding suggests existence of a possible ligand for SF1, perhaps a Sertoli cell-specific factor.

Studies in transgenic null mice highlight the requirement for Sf1 in both sexes for development of the organs that derive from the adrenogenital primordium—primordial gonads and adrenal cortex—as well as the hypothalamus and pituitary. Male and female mice homozygous for deletion of *Ftzf1* failed to develop steroidogenic tissues, having neither gonads nor adrenal glands. The mice had phenotypically female internal and external genitalia and died in the neonatal period of adrenal insufficiency. These mice did display mesenchymal thickening in the gonadal ridge area at the earliest stages of gonadal development (E10.5), but thereafter the cells of this region underwent apoptosis, suggesting that the role of Sf1 may be in maintaining rather than initiating gonadal development. The mice also had abnormal development of the ventromedial hypothalamic nucleus, important in control of pituitary gonadotropin secretion. Expression of proteins specific to gonadotropes, leutenizing hormone (LH), follicle stimulating hormone (FSH) and gonadotropin-releasing hormone (GnRH) receptor (GnRH-R) was absent, implicating Sf1 in gonadotrope development and LH/FSH expression.

The presence of female internal genitalia in the null animals of both sexes indicates that the Müllerian ducts did not regress as would normally occur in the males. Because Sf1 upregulates expression of *Amh*, deficiency of Sf1 in males would result in lack of Amh and therefore retention of Müllerian structures. Therefore, Sf1 is likely active earlier than Amh in the ontogeny of mouse sexual differentiation. Müllerian ducts develop normally in null female mice because Sf1 expression in the normal developing ovary is low, so the female is unaffected by its absence.

In contrast to the complete absence of gonadal development in the null mice, *Sf1* haploinsufficiency resulting from heterozygous *Sf1* deletion is associated with gonads that apart from being slightly small, are essentially normal, indicating that a single active gene is adequate for this function. In addition, although significant defects in adrenal development and organization were observed, the mice were able to maintain adequate basal adrenal function by compensation via cellular hypertrophy and increased expression of steroidogenic acute regulatory protein (*Star*).

Clinical Features and Molecular Defects The infrequent mutations identified in the human *SF1* gene are instructive regarding the roles of SF1 in human, as compared to murine, development. In one report, a 46,XY phenotypically female infant presented with adrenal failure soon after birth. She had retained Müllerian structures, including a uterus, and small, intra-abdominal streak-like gonads containing poorly differentiated tubules. Gonadotropin responses to GnRH were normal but she had no testosterone response to human chorionic gonadotropin (hCG). A heterozygous mutation encoding a glycine to glutamic acid substitution in the first ZF of the SF1 DNA-binding domain was found, resulting in loss of DNA-binding activity of the receptor and therefore loss of transcription activating capacity. Because no dominant-negative activity was detected, it is unclear why this mutation caused gonadal dysgenesis in the heterozygous state.

A second case involved a less severe missense mutation of *SF1* manifest only in the homozygous state. Male-to-female sex reversal and adrenal hypoplasia were present in the homozygous 46,XY infant, but the heterozygous sister and consanguineous parents were clinically normal. A uterus was present on MRI scan. Histology of the gonads was not reported. The infant had massively elevated adrenocorticotropic hormone (ACTH), with extremely low cortisol and aldosterone. This mutation caused an arginine to glutamine substitution in the A-box region of the protein, associated with reduction but not complete loss of DNA binding and transcriptional activity.

In the third case a 46,XX female presented at 14 mo of age with adrenal insufficiency. She had no apparent defect in ovary development. A heterozygous *de novo* mutation causing an arginine to leucine substitution in the SF1 hinge region was found, resulting in a transcriptionally inactive protein. This latter case in which a heterozygous mutation resulted in impaired, but not absent, adrenal development is similar to the phenotype of *Sf1* haploinsufficiency in mice. Comparison of these clinical cases suggests the importance of gene dosage in humans. Double-copy expression of *SF1* appears to be required for testis development in males, but not for ovarian development in females. Normal adrenal development occurred in the presence of a heterozygous *SF1* mutation in one case and failed to occur in the other, suggesting that *SF1* mutations may have varying effects on adrenal development depending on the location and type of mutation, the functional effects on the SF1 protein and perhaps the genetic background of the individual.

Wilms Tumor 1 (WT1)

Normal Function Like SF1, the transcription factor WT1, plays a pivotal role in early development of the primordial gonad and the bipotential internal genital duct systems prior to sex

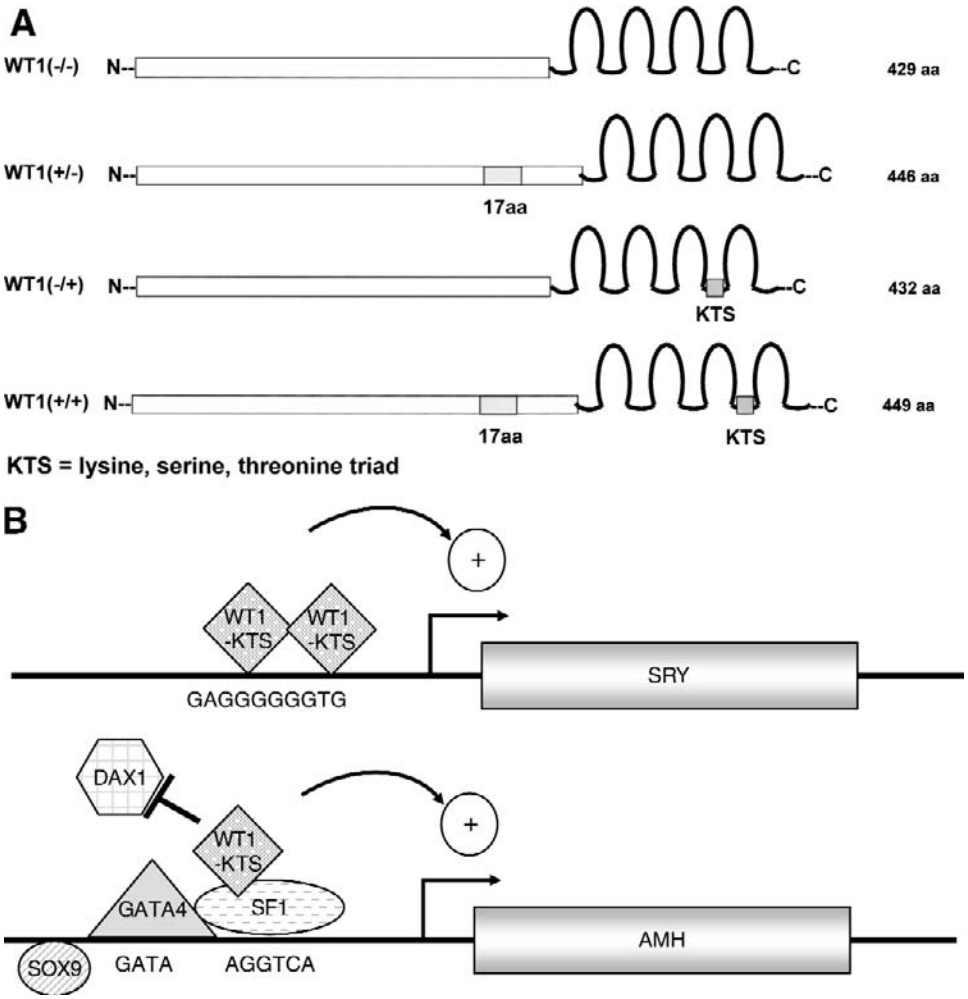

Figure 41-3 Structure and function of transcription factor WT1. **(A)** Major isoforms of WT1. WT1 is a potent transcriptional activator or repressor, depending on the specific cellular and genetic context. There are four major isoforms of WT1, formed by differential splicing of exons 5 and 9 that either include or exclude a 17 amino acid sequence in the central region of the protein (encoded by exon 5) and a lysine, threonine, serine (KTS) triad between the third and fourth zinc fingers (encoded by exon 9) that alters the DNA-binding specificity of the protein. The –/– isoform, lacking both inserts, has greater transcriptional activation potential than the major isoform (+/+) that contains both inserts. (**B**) Wt1 binding at target genes. WT1 regulates transcription of numerous target genes involved in various aspects of sex determination and differentiation, including *SRY*, *DAX1* and *AMH*. WT1 (–KTS) binds as a homodimer to the promoter of the *SRY* gene to upregulate its transcription. In contrast, at the AMH gene, WT1-KTS binds as a heterodimer with SF1, antagonizing binding of DAX1 to the promoter. AMH, anti-Müllerian hormone; DAX1, dosage-sensitive sex reversal-adrenal hypoplasia congenita locus on the X-chromosome, gene 1; KTS, lysine/threonine/serine; SF1, steroidogenic factor 1; SOX, Sry-related homeobox gene; SRY, sex-determining region of the Y-chromosome; WT1, Wilms tumor 1.

determination, and in addition, a specific isoform appears to be required for subsequent development of the testis. WT1 is a member of the early growth response (EGR) family of transcription factors (proteins expressed early in the cell cycle, at G0–G1 transition) and acts as a transcriptional activator or repressor depending on the cellular or chromosomal context. There appears to be a general requirement for WT1 in the formation of organs derived from the intermediate mesoderm, particularly the differentiation of glomerular epithelial cells and gonadal primordium. In renal tissue WT1 acts as a tumor suppressor.

The human *WT1* gene is a complex locus at 11p13 that in fact consists of two genes, *WT1* and *WIT-1*, expressed from opposite DNA strands. The function of the WIT-1 transcript is unknown, but a role as an antisense regulator of *WT1* has been postulated. The highly conserved 50-kb *WT1* gene itself contains 10 exons that can be alternatively spliced to yield four distinct mRNA species of approx 3–3.5 kb each. The primary WT1 protein is a 429-AA (~50 kDa) transcription factor with 4 contiguous Cys2-His2 ZF domains (encoded by exons 7–10) and an amino terminus rich in proline and glutamine, typical of certain transcription factors. Separate domains subserve transcriptional repression and activation: residues 85–124 encompass the repressor domain, and 181–250 the activator domain. These regions are distinct from the DNA-binding domain and their activities are probably mediated by protein–protein interaction. The four mRNA species encode four major proteins, designated WT1 (A–D), and perhaps as many as 32 different isoforms, differing mainly on the basis of the presence or absence of an additional 17 AA in the middle of the protein, and of a lysine/threonine/serine (KTS) triad between ZFs 3 and 4 that alters their spacing, thereby changing the DNA-binding specificity (Fig 41-3A). The –KTS and +KTS isoforms also have differential expression patterns within cell nuclei and appear to have distinct but

somewhat overlapping roles. The fact that all transcripts are expressed at similar levels suggests that each encoded protein makes a significant contribution to overall WT1 action, and interactions between the proteins, each of which may have distinct targets and functions, may be important in the control of cellular proliferation and differentiation exerted by WT1.

Various forms of WT1 regulate *SRY*, *DAX1*, and *AMH* expression (Fig. 41-3B). WT1 can homodimerize and also binds several other proteins; WT1-KTS isoforms associate and synergize with SF1 to promote *AMH* expression and can activate the *DAX1* promoter. However, DAX1 antagonizes the synergy between SF1 and WT1, most likely through a direct protein–protein interaction with SF1, suggesting that WT1 and DAX1 functionally oppose each other in testis development by modulating SF1-mediated transactivation. The fact that WT1 can upregulate expression of *DAX1*, which in turn antagonizes WT1/SF1-mediated stimulation of *AMH* expression suggests that the relative dosages of WT1-KTS and DAX1 and the timing of their expression during embyrogenesis are critical in the delicate balance of transcription factor activity required for gonadal/genital development.

Wt1 expression in mouse embryogenesis also supports a role for Wt1 in development of urogenital tissues: *Wt1* is expressed very early in fetal life, at about the same time as *Sf1* and before *Dax1*. *Wt1* is faintly detectable as early as day 9 and readily detectable in pronephric and mesonephric tissues on E10.5, at which time *Sry* expression is detectable in pre-Sertoli cells. By E11.5 the nephrogenic cord, condensing metanephric tissue and urogenital ridge display high levels of *Wt1* message. In the developing gonad *Wt1* expression localizes to the sex cords. Although the role for Wt1 in primordial gonad development is fairly clear, its roles in specific testis or ovary development are less well understood, and it seems likely that the various isoforms of Wt1 may function differentially in the different genetic contexts of testicular vs ovarian development. Consistent with this concept, *Wt1* expression is differentially regulated during development depending on the sexual differentiation of the gonad. In mature gonads *Wt1* expression is confined to the Sertoli cells and tunica albuginea of the testis and the granulosa and epithelial cells of the ovary.

WT1 expression in human development between weeks 7–10 of gestation is similar to that seen in the mouse at the equivalent time. *WT1* is expressed mainly in mesodermally derived tissues—kidneys, gonads and mesothelium—but is also expressed in spinal cord and brain, tissues of ectodermal origin. Midtrimester human embryos show strong expression in kidneys and gonads. *WT1* expression is limited to Sertoli cells in adult testes.

Transgenic mice homozygous for a knockout mutation of the entire *Wt1* gene had failure of renal and gonadal development. At day 11 of gestation, cells of the metanephric blastema underwent apoptosis, the ureteric bud failed to grow out from the Wolffian duct, and the metanephric kidney did not form. A later study also demonstrated a requirement for *Wt1* in the development of epicardium and adrenal gland (the reason for the difference in phenotype between studies is not clear).

Different gonadal phenotypes are seen when the knockout targets a specific isoform of Wt1. Mice completely lacking the –KTS Wt1 isoforms had reduced *Dax1* expression, tiny streak gonads (both males and females) and abnormal development of the internal genital ducts. Homozygous deletion of the +KTS isoforms in male mice caused complete XY sex reversal, the embryonic gonads having the morphological appearance of ovaries, associated with a dramatic reduction of gonadal *Sry* and *Sox9* expression and female-type *Dax1* expression. These findings imply a key role for the +KTS isoforms in regulation of the critical testis-determining *Sox* genes in male gonadal development. As female mice lacking the +KTS isoforms had normal ovaries, this isoform appears to be unnecessary for ovarian development. Mice with reduced (but not absent) Wt1 +KTS levels had normal fetal urogenital development but developed glomerulosclerosis after 2–3 mo, representing a model for the human disease, Frasier syndrome (described later). This result indicates that Wt1+KTS dosage is important for normal postnatal renal function, but not for prenatal development, because the level of Wt1 (either isoform) expressed from a single normal *Wt1* allele was adequate for normal urogenital development. These data demonstrate distinct functions for the Wt1 +/–KTS isoforms. It appears from these different transgenic experiments that some level of *Wt1* expression is absolutely required for primordial gonad development, but that the subsequent development of the testis specifically requires the +KTS isoform.

Clinical Features and Molecular Defects Three clinical syndromes are associated with allelic defects of *WT1* (Table 41-3). The Denys-Drash syndrome comprises a triad of gonadal dysgenesis, congenital nephropathy and subsequent development of Wilms tumor. Gonadal and genital development is heterogeneous in these patients, ranging from streak gonads or ovotestes in either 46,XX or 46,XY individuals, to rudimentary or dysgenetic testes in 46,XY patients, or normal ovaries in a 46,XX patient. Perhaps because of an ascertainment bias, approx 90% of patients have 46,XY karyotype. Their external genitalia are usually ambiguous, sometimes female, occasionally male. The internal genitalia are often incongruous with respect to the external genitalia: Wolffian structures may be present in phenotypic females, Müllerian structures in phenotypic males. Even in 46,XX females, there may be anomalous internal genital development, and one 46,XY patient with dysgenetic testes had neither Müllerian nor Wolffian structures, compatible with a primary role of WT1 in early development of the bipotential internal duct systems. Gonadoblastomas and granulosa cell tumors have been reported. The severe congenital nephropathy (diffuse or focal mesangial sclerosis) generally leads to death by age 2. Wilms tumor is reported in over 50% of cases, most presenting with an abdominal mass in the second year of life. The prevalence of Wilms tumor would probably be higher if the patients survived longer, and most are found at autopsy to have persistent intralobar renal blastema, which may be the precursor of Wilms tumor. Notably, in patients with isolated bilateral Wilms tumor (distinct from the Denys-Drash syndrome) the occurrence of hypospadias and cryptorchidism is 10-fold higher in than in the general population.

The Denys-Drash syndrome is associated with heterozygous *WT1* mutations in >90% of cases. The disorder is genetically dominant, as no patient has been reported with mutations in both alleles of the gene. Mutations cluster within or near the ZF coding region (exons 7–10, particularly exon 9), most producing AA substitutions in ZF2 and ZF3. One mutation, encoding an arginine to tryptophan substitution at position 394 in ZF3, has occurred recurrently, being present in at least a dozen reported cases. Mutations in a nearby AA, aspartic acid 396 (either to asparagine or glycine), have been reported in other cases, suggesting an important role for these two AAs in ZF function. Another mutation that is reported in several instances is conversion of arginine 362 to a stop codon, resulting in a truncated protein lacking three of the four ZFs. Notably, there is significant phenotypic variation even among individuals with

Table 41-3
Clinical Syndromes Associated With Mutations in WT1

Syndrome	*Mode of dysfunction*	*Mutation*	*Phenotype*
Denys-Drash	Dominant negative. Possible reduced expression of *SRY* and *AMH*	Heterozygous amino acid substitutions in zinc fingers	Kidney: diffuse mesangial sclerosis → glomerular nephropathy; Wilms tumor common. Gonads/genitalia: 46,XY–heterogeneous effects, from streak gonads with complete sex reversal to dysgenetic testes with partial or normal masculinization. Ovotestes have also been reported. 46,XX–streak gonads, ovotestes or ovaries. Internal genitalia may be discordant from external genitalia in both sexes.
Frasier (atypical subtype of Denys–Drash)	Hapolinsufficiency of +KTS isoform → imbalance in ratio of –KTS/+KTS forms	Heterozygous point mutation in intron 9 splice donor site.	Kidney: focal and segmental glomerular sclerosis; later onset of renal failure than Denys–Drash Syndrome. Wilms tumor rare. Gonads/genitalia: 46,XY sex reversal, gonadoblastoma common; 46, XX–no reported phenotype.
WAGR (Wilms tumor, Aniridia, Genitourinary abnormalities, mental Retardation)	Hapolinsufficiency	Heterozygous gene deletion	Kidney: Wilms tumor common. Gonads/genitalia: 46,XY–cryptorchidism, hypospadias; 46,XX–no reported phenotype.

Note: Homozygous deletion of WT1 in approx 10% of Wilms tumors.
AMH, anti-Müllerian hormone; KTS, lysine/threonine/serine; SRY, sex-determining region of the Y-chromosome; WT1, Wilms tumor 1.

this severe truncation mutation. Other defects include a variety of nonsense, frameshift, splice-junction, and missense mutations, most of which appear *de novo*, as parental *WT1* genes are normal. In one case, however, the normal father of an affected child was found to be heterozygous for the mutant allele, suggesting either mosaicism or reduced penetrance of the mutant gene.

The primary molecular pathophysiology of *WT1* mutations appears to be lack of normal DNA binding by the WT1 protein; mutant WT1 proteins containing nonconservative AA substitutions within the ZF region do not bind to the EGR1 consensus binding sequence bound by wild type WT1. Complete *WT1* deletion produces milder genital abnormalities (cryptorchidism and/or hypospadias), than does a mutation that encodes expression of an abnormal WT1 protein, suggesting a dominant negative effect of mutant WT1 proteins by formation of inactive dimers with wild-type WT1. Mutations that affect zinc-coordinating cysteine or histidine residues likely prohibit DNA binding by disrupting proper spatial organization of the ZF. Although *WT1* mutations are heterozygous at the germ cell level, tissue from the Wilms tumors of these patients generally demonstrates loss of heterozygosity for *WT1*, indicating that two mutant *WT1* alleles may be required for loss of tumor suppressor function of WT1 ("two-hit" hypothesis).

In a second WT1-related disease, Frasier syndrome (which in fact may be a variant of Denys-Drash), 46,XY patients have streak gonads, female external genitalia and frequently develop gonadoblastoma but not Wilms tumor. The renal failure is milder and of later onset than in the Denys–Drash syndrome, progressing to end-stage renal failure in adolescence or early adulthood. Frasier syndrome is caused by mutations in the donor splice site in intron 9 of WT1, with predicted loss of the +KTS WT1 isoform, resulting in a reduction of the normal +KTS/–KTS isoform ratio.

The third WT1-related condition, the WAGR syndrome, includes Wilms tumor, aniridia, genitourinary abnormalities/gonadoblastoma and mental retardation. This syndrome likely results from heterozygous loss of genes contiguous with *WT1* in the 11p13 region, accounting for the aniridia and mental retardation that accompany the Wilms tumor and genitourinary abnormalities. In patients in which it has been examined, the mutant allele appears to have arisen in the paternally derived chromosome 11.

GENES WITH PUTATIVE ROLES IN BIPOTENTIAL GONAD DEVELOPMENT The following genes are discussed briefly on the basis of significant evidence in nonhuman species for roles in development of the primordial gonad.

Lim Homeobox Gene 1 (LIM1) LIM transcription factors constitute a large family (at least 40 members) of proteins that carry 2 tandem copies of the LIM domain, a unique cysteine-rich zinc-binding domain involved in protein–protein interactions, followed downstream by a homeodomain that mediates DNA binding. LIM domains can interact with other proteins to form complexes that regulate transcription. *Lim homeobox gene* 1 (*Lim1*), encodes an early member of the family that appears to be a transcriptional activator. Lim1 plays a major role in organizing the development of the head in mice and is implicated in gonadal and renal development. *Lim1* expression in mice occurs extremely early in the intermediate mesoderm and nephrogenic cord. Consequently, the action of Lim1 in gonad formation is likely at the level of the primordial gonad. *Lim1* is also expressed later in development in several urogenital tissues such as mesonephros, Wolffian ducts, ureteric buds and definitive kidney. Mice homozygous for a null mutation of *Lim1* or for mutations that alter conserved AAs required for structure of the LIM domains had no heads, kidneys, or gonads.

Empty Spiracles 2 (EMX2) Another homeodomain transcription factor, empty spiracles 2 **(**Emx2), appears in mice to have similar functions to Lim1, being essential for the development of the dorsal telencephalon and components of the developing urogenital system. *Emx2* is intensely expressed in the bipotential gonads and ovaries and in epithelial components of the developing urogenital system, specifically the pronephros and mesonephros, Wolffian and Müllerian ducts, ureteric buds and in early epithelial structures derived from metanephrogenic mesenchyme. *Emx2* is also detected in brain, kidney, and uterus. Notably, expression of *Lim1* in *Emx2*-null mice was reduced and that of *Wnt4* was absent, suggesting that

Emx2 may modulate their expression. In addition to developmental defects of the brain, *Emx2*-null mice lacked kidneys, ureters, gonads, and genital tracts. Degeneration of the Wolffian duct and mesonephric tubules was abnormally accelerated and Müllerian ducts did not form. These abnormalities imply a role for Emx2 in very early development of the renal, gonadal and internal genital primordia, probably at the stage of development of the mesonephros.

Lim Homeobox Gene 9 (LHX9) *Lhx9*, encodes another member of the LIM family of transcription factors. Like Lim 1, Lhx9 also plays a role in primordial gonad development, evidenced by the finding of complete gonadal agenesis in *Lhx9*-null mice of both sexes, without apparent extra-gonadal defects (in contrast with the headless *Lim1*-null mutants). Gonadal agenesis appeared to result from failure of gonadal cell proliferation at about E12, rather than exaggeration of apoptosis. Lhx9 appears to be necessary for proliferation and invasion of the epithelial (somatic) cells of the genital ridge into the underlying mesenchyme and subsequent formation of sex cords—an essential step in formation of the gonads.

Lhx9 expression is detectable at E9.5 in epithelial and subjacent mesenchymal cells of the early gonadal ridge. Expression localizes to the interstitial region of the developing testis as morphological differentiation occurs, then disappears as epithelial cells differentiate into Sertoli cells and begin to express *Amh*. In the fetal ovary *Lhx9* is highly expressed in epithelial cords, then is downregulated as ovarian epithelial cells differentiate into granulosa cells. Thus it appears that *Lhx9* expression is inversely correlated with the degree of differentiation of mesenchymal cells of the gonad. In human embryos *LHX9* is expressed in the abdominal region of both sexes at the time of gonad formation. Human LHX9 mutations have not been reported, despite a careful search in at least one study in 27 patients with 46,XY gonadal agenesis or dysgenesis.

All *Lxh9*-null mice were phenotypically female. They had atrophic uteri, vagina, and oviducts indicating that Lhx9 is not required for development of the internal genital primordia. As would be expected in the situation of gonadal agenesis, the mice had high FSH concentrations and no detectable testosterone or estradiol.

A key role of Lhx9 may be in regulation of *Sf1* expression. Lhx9 binds directly to the *Sf1* promoter and may act synergistically with the –KTS isoform of Wt1 in activating *Sf1* expression. This regulatory interaction appears to be specific to the gonad, evidenced in *Lhx9*-null mice by the finding of normal adrenal *Sf1* expression despite absent expression in genital ridges.

NORMAL AND ABNORMAL TESTIS DETERMINATION

Male sex determination is synonymous with testis determination. Once development of the primordial gonadal and genital structures has occurred, the next steps diverge between the sexes. The process of testis development in the karyotypic male appears to be controlled by a switch-like mechanism that involves the crucial Y-chromosome-encoded transcription factor SRY, a related homodomain transcription factor, SOX9, and no doubt other genes and proteins that either regulate or are regulated by these factors. One of the earliest effects of *SRY* expression is the induction of somatic cell migration from the mesonephros into the XY gonad—a critical first step in preparation for development of testis cords. Subsequently, SOX9 directs the process of seminiferous tubule organization by Sertoli cells and regulates expression of the Sertoli cell glycoprotein AMH. AMH may in turn play a role in directing undifferentiated interstitial cells to develop as Leydig cells. Once testicular differentiation is established, other Y-encoded factors are required to maintain spermatogenesis. A number of other molecules have been identified as having involvement in testis development; however, their exact positions in this pathway, their functions and the factors they regulate or by which they are regulated, remain to be elucidated. These include the +KTS isoform of WT1, the helicase enzyme ATRX, perhaps the intracellular signaling molecule, desert hedgehog (DHH) and gene(s) on chromosome 10q. Additional X-chromosomal sequences likely affect testis development, perhaps negatively, because the presence of one or more extra X-chromosomes (as found in Klinefelter syndrome and its variants) is associated with reduced testicular size.

There are many hypothetical schemes for the interactions of the ever-expanding coterie of transcription factors involved in testis determination, and no definitive model for this process exists. Analyses of humans with gonadal dysgenesis, mouse models and in vitro assays have revealed that testis determination results from a complex network of interacting transcription factors and target genes in a nonlinear web of upregulation or activation and downregulation or repression steps. A hypothetical model, based primarily on work in mice, is as follows:

1. Establishment of the gonadal primordium (multiple factors, described earlier).
2. Activation of Sry by Wt1 and Gata4.
3. Sry repression of Wnt4 and perhaps forkhead transcription factor 2 (Foxl2) thus.
4. Allowing Sf1 to.
5. Stimulate expression of Sox9 (possibly by interfering with binding of a repressor factor to the *Odsex* locus upstream of the *Sox9* gene) and perhaps Atrx, leading to.
6. Development of Sertoli cells followed by.
7. Wt1/Sf1/Sox9/Gata4-mediated induction of Amh expression.
8. Action of Amh via the Amh receptor(s) causing Müllerian duct regression.
9. Sf1-mediated stimulation of steroidogenic activity by fetal Leydig cells (Fig. 41-4).

There may be significant species differences in the processes of testis development, so although the mouse is generally a convenient model, differences between mice and humans must not be overlooked and the details of sex determination and differentiation that have been elucidated in rodents cannot necessarily be extrapolated to human development.

SRY-Related Homeobox (SOX) Genes There is an ever-expanding family of DNA-binding, atypical transcription-regulating proteins related to each other by the presence of a central high mobility group (HMG) domain,* homologous (>60% AA identity) to the HMG domain of the founding member of the family, SRY. At least 20 *SOX* genes have been described, and a number of these appear to be involved in sex determination or have testis-specific expression, including *SRY* itself, *SOX9, SOX3, SOX30*, and perhaps *SOX8*. Only the most well characterized genes—*SRY* and *SOX9*—are discussed.

Sex-Determining Region Of The Y (SRY) Gene

Normal Function The existence of a Y-chromosomal "maleness-determining" gene was postulated in the 1930s, and in the 1960s was designated the "testis-determining factor." Many candidates were proposed and rejected over the years, until 1990,

*The HMG domain is a 70–80 AA DNA-binding motif comprised mainly of hydrophobic and charged AAs, shared by a group of architectural proteins involved in DNA transcription, replication, recombination, and repair.

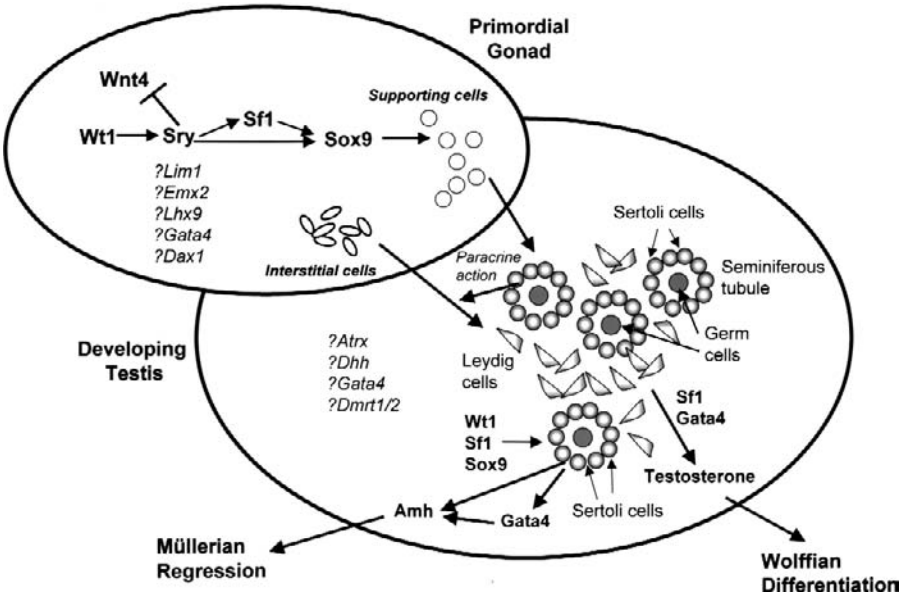

Figure 41-4 Hypothetical model of testis determination. The bipotential gonad of an XY fetus expresses the key testis-determining gene *Sry*, which is upregulated by Wt1 and Gata4. Sry represses the "anti-testis" gene, *Wnt4*, and perhaps *Foxl2* thus allowing Sf1 to stimulate *Sox9* expression leading to differentiation of supporting cells into Sertoli cells, the primary organizers of the seminiferous tubule. The seclusion of germ cells within the tubules prevents germ cell meiosis and commits them to spermatogenic development. Wt1, Sf1, Sox9, and Gata4 induce Sertoli cell expression of Amh, which, acting via its type 2 receptor, causes Müllerian duct regression. Under the influence of Sertoli cells, interstitial cells differentiate as Leydig cells, subsequently secreting testosterone under the drive of Sf1 and Gata4 inducing development of Wolffian structures. Other factors that have less well-defined roles include Lim1, Emx2, Lhx9, Dax1, Dhh, Atrx, and Dmrt1/2. AMH, anti-Müllerian hormone; ATRX, α-thalassemia/mental retardation, X-linked gene; DAX1, dosage-sensitive sex reversal-adrenal hypoplasia congenita locus on the X-chromosome, gene 1; DHH, desert hedgehog; DMRT1/2, Doublesex and MAB-3-Related Transcription factors 1 and 2; EMX2, empty spiracles 2; LHX9, LIM homeobox gene 9; LIM1, LIM homeobox gene 1; SF1, steroidogenic factor 1; SOX, Sry-related homeobox gene; SRY, sec-determining region of the Y-chromosome; WNT, wingless-type; MMTV integration site family member; WT1, Wilms tumor 1.

when the existence of such a gene was confirmed, with the discovery of *SRY*. Insertion of the mouse *Sry* gene into fertilized XX mouse eggs resulted in development of testes and male genitalia (female-to-male sex reversal). These seminal studies demonstrated that *Sry* was the key Y-chomosomal gene sufficient to induce maleness. However, replacement of the homeobox of *Sry* with that of *Sox3* or *Sox9* also results in sex reversal in XX mice, indicating that *Sox3* or *Sox9* can functionally replace *Sry* and elicit development of testis cords, male patterns of gene expression, and male genital development.

Human *SRY* is a 3.8-kb single-exon gene located just centromeric to the pseudoautosomal region of Yp (Yp11.3) that encodes a 204-AA (24 kDa) protein. Approximately the middle one-third of the protein (79 AAs) represents the HMG domain that endows SRY with its sequence specific DNA binding to a target nucleotide sequence. This region is the most critical to protein function and almost all human mutations are located here. Outside the HMG domain the remainder of the protein is poorly conserved among mammals.

The target genes of SRY are largely unknown, but may include those encoding AMH, SOX9, and the steroidogenic enzyme CYP11. Similarly, the exact mechanism of action and whether SRY has any direct transcriptional activating capacity, remain to be determined. Human SRY lacks a transcription activation domain (present in mouse), so it has been suggested that SRY function depends solely on the HMG domain and that it acts as an "architectural" transcription factor, by creating the spatial arrangement needed for the transcription "machinery" to work.

Expression of *Sry* occurs in fetal mouse gonad at the earliest stage of specific testis formation, being first detected at E10.5 in pre-Sertoli cells in the developing gonadal ridge, to which its expression is limited, about 1 d before testicular morphology can be discerned. This finding suggests that these pre-Sertoli cells are integral to the process of testis development. Indeed, one of the primary events in testis development is induction of Sertoli cell differentiation. *Sry* expression peaks at E11.5 and declines once testicular development is established, at E12.5. *Sry* expression and Sertoli cell differentiation are followed by testis differentiation, manifest by Sertoli cell-regulated organization of seminiferous tubules and Leydig cell differentiation. In human testes *SRY* expression begins at approx 6 wk gestation, just prior to specific testis development. The fundamental role of SRY appears to be the upregulation of *SOX9* expression, which in turn stimulates development of the prime organizers of testicular architecture—the Sertoli cells. SRY may continue to act as a splicing factor in Sertoli cells and germ cells in the adult testis.

Despite its preeminent role in testis determination, other transcription factors appear to regulate *SRY* expression, including WT1. Furthermore other upstream and downstream factors must be activated or repressed to allow testis development to occur. Evidence for this conclusion includes the following:

1. *Sry* expression during mouse gonadogenesis; occurs during a very brief time window.
2. The majority of 46,XY females with gonadal dysgenesis have an intact *SRY* gene.
3. Some 46,XX males with testes are completely Y negative, indicating that non-Y sequences must be responsible for testis determination in these cases.

Clinical Features and Molecular Defects The study of individuals with the syndromes of 46,XX maleness and 46,XY gonadal

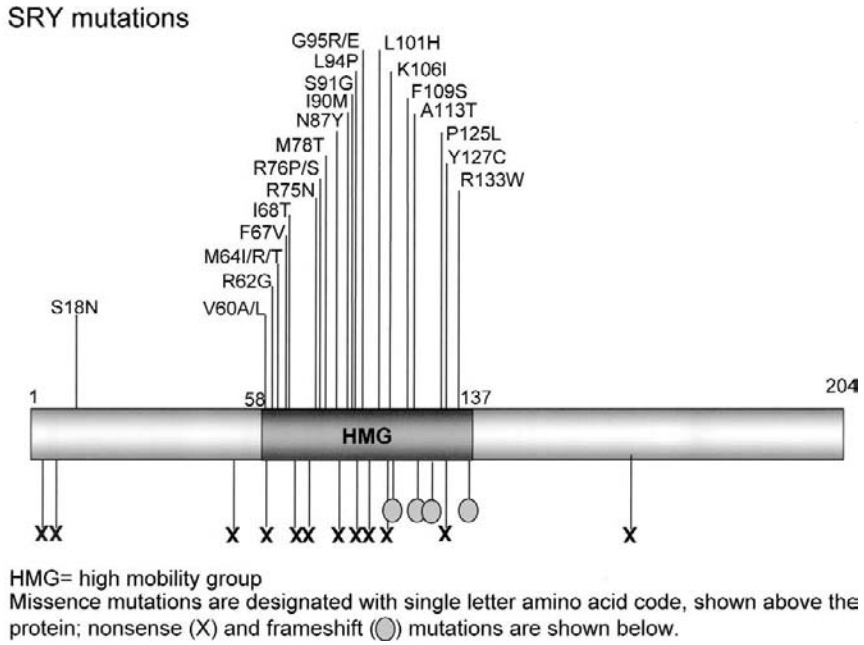

Figure 41-5 Mutations in human SRY.

dysgenesis was the catalyst for the eventual localization and characterization of the *SRY* gene. Of 46,XX males with unambiguous masculinization, >90% are *SRY* positive (this can be confirmed by PCR or fluorescent *in situ* hybridization analysis), whereas the converse holds for 46,XX males with genital ambiguity and 46,XX true hermaphrodites, of whom only a small number are *SRY* positive. Nonrandom inactivation of the X-chromosome carrying the translocated *SRY* is the postulated explanation for the presence of ovarian and testicular tissue in the same gonad in individuals with *SRY*-positive hermaphroditism. The coexistence of 46,XX complete maleness and 46,XX true hermaphroditism in a number of families may reflect variations in the pattern of inactivation of the *SRY*-bearing X-chromosome between affected individuals.

In parallel to the finding of *SRY* sequences in the majority of 46,XX males, it would be predicted that most sex-reversed 46,XY females would have *SRY* defects. However, in general this has not proven to be the case as mutations in *SRY* have been detected in only 15–20% of 46,XY sex-reversed individuals with complete or partial gonadal dysgenesis (more common in complete dysgenesis). Suggested explanations for this finding include the theoretical presence of mutations outside the HMG box, perhaps in sequences important for regulation of *SRY* expression, inactivating mutations in upstream regulators of *SRY*, mutations that induce constitutive activity in genes usually negatively regulated by SRY, or activating mutations in factors that suppress or interfere with SRY.

A variety of cytogenetic and molecular abnormalities have been reported in individuals with 46,XY sex reversal, including deletion of Yp, isolated deletion of *SRY*, nonsense mutations resulting in protein truncations, and at least 25 missense mutations within the *SRY* HMG box (Fig. 41-5). Only one missense mutation has been reported outside the HMG box, a serine to asparagine change in the N-terminal region. Most *SRY* mutations in 46,XY sex reversal produce nonconservative AA substitutions at highly conserved sites within the HMG domain. In vitro analysis of mutant SRY proteins reveals abnormal DNA binding and bending: some mutants bind DNA normally but less avidly, whereas others bind with near-normal affinity but bend the DNA to a different angle. Less dramatic missense mutations cause partial, rather than complete, gonadal dysgenesis, as the mutant SRY protein likely retains some function. *SRY* mutations also have been reported in a few cases of 46,XY true hermaphroditism. One example was a postzygotic somatic mutation evidenced by the finding of both wild-type and mutant *SRY* alleles in gonadal DNA but only the wild-type *SRY* sequence in leukocyte DNA. There may be phenotypic variation between 46,XY individuals harboring the same *SRY* mutation, ranging from sex-reversed to unaffected, both within and between kindreds, perhaps because of variable penetrance or influences of the genetic background. The most severe *SRY* defects appear to arise *de novo*, whereas the milder defects are compatible with fertility and thereby transmission to offspring. Germline mosaicism for the *SRY* mutation may be associated with fertility in the fathers of affected individuals.

SRY Homeobox-Like Gene 9 (SOX9)

Normal Function *Sox9*, like *Sry*, can induce testis formation when inserted into XX mouse embryos and appears to be equally as important as its brother *Sry*, in the process of testis development. The human *SRY* gene is located at 17q24-25, in a region termed sex reversal autosomal 1 and encodes a 509-AA protein with features of a transcription regulator—a DNA-binding HMG domain and two transcriptional activation domains, including a proline and glutamine-rich domain in its C-terminal region. In vitro deletion of this latter region destroys the transactivating function of the protein. Unlike *SRY*, *SOX9* displays strong sequence conservation throughout mammalian evolution. Furthermore, the sequence similarity between *SOX9* and *SRY* suggests a relationship between the two that may represent evolution from a dosage-dependent autosomal sex determination system to a dominant Y-chromosomal system.

Sox9 is initially expressed in the genital ridges of both sexes in mice at low levels and is subsequently downregulated in female genital ridges and upregulated in male genital ridges, its expression paralleling Sertoli cell differentiation, consistent with a role in testis determination. Based on the timing of expression and the

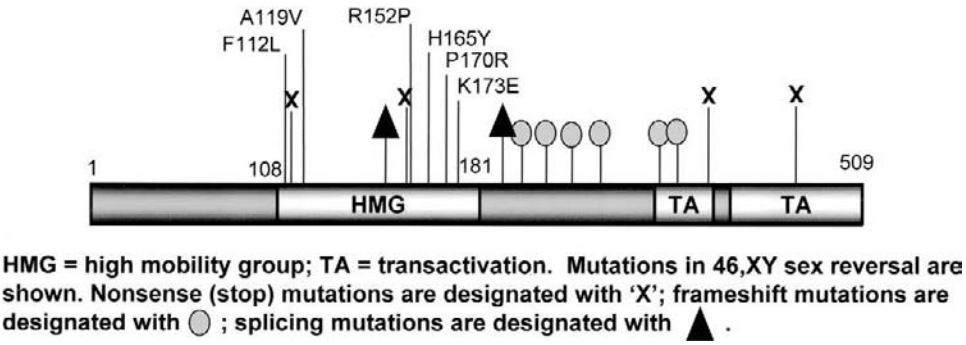

Figure 41-6 Mutations in human SOX9.

presence of a potential binding site for Sry within its promoter, Sox9 appears to be acting just downstream of Sry and is likely a target gene for Sry. However, there is probably not an absolute requirement for Sry regulation of *Sox9*, because Sox9 can induce testis development in the absence of Sry. *Sox9* expression precedes that of *Amh* and Sox9 appears to play the pivotal role (in conjunction with Sf1, Wt1, and Gata4; Fig. 41-3B) in activating *Amh* expression, a role befitting a key maleness-determining factor. Sox9 may represent another "switch"-like mechanism, as it appears to act in a dominant fashion, similar to Sry. Indeed, Sox9 may be the pivotal maleness-determining factor, potentially displacing Sry in this role—a battle whose outcome is awaited.

Human *SOX9* expression is detectable in the testis at week 18 of gestation in the area of the rete testis and seminiferous tubules. In the adult, *SOX9* is expressed most strongly in the testis, pancreas, prostate, kidney, brain, and the skeleton and at low level in most other adult tissues.

Mice with heterozygous *Sox9* deletion had skeletal malformations equivalent to those seen in the human disease, campomelic dysplasia, and died soon after birth. However, the testes were normal in the male mutant mice in contrast to many human *SOX9* mutations, well known for causing male-to-female sex reversal in the heterozygous state, suggesting differences in SOX9/Sox9 function between mice and humans. Overexpression of *Sox9* in XX gonads is associated with testis development in *Odsex* mice, providing additional evidence for the importance of Sox9 in testis determination.

Clinical Features and Molecular Defects *SOX9* was identified by cloning of a chromosomal translocation breakpoint from a sex-reversed patient with campomelic dysplasia, a rare syndrome featuring a distinctive form of skeletal malformation that causes severe limb bowing (campomelia), accompanied in approx 75% of affected 46,XY individuals by sex reversal (ovaries or streak gonads, and female internal and external genitalia). Affected 46,XX individuals have normal ovarian development, reflecting lack of involvement of SOX9 in this process. Death typically occurs in early childhood from respiratory compromise related to the skeletal dysplasia. A milder form of the condition, in which the limbs are not bowed is referred to as "acampomelic" campomelic dysplasia.

Heterozygous mutations in *SOX9* have been identified in 46,XY individuals with campomelic dysplasia and sex reversal (Fig. 41-6). In general *SOX9* mutations occur *de novo* and affect only one *SOX9* allele, although one case of compound heterozygosity has been reported. Most disease-causing mutations severely disrupt the protein (e.g., premature termination and frameshift mutations) and the phenotype appears to result from loss of function of the transcription factor (haploinsufficiency). Affected sibling pairs with normal parents have been reported, as a consequence of gonadal mosaicism for the mutant gene. As with *SRY* mutations, variation in phenotype has been reported within the same family. For example, in one family with three children bearing a framsehift mutation, one 46,XY child had true hermaphroditism with ambiguous external genitalia, whereas a 46,XY sibling had sex reversal with bilateral ovaries and female genitalia. In patients with the milder "acampomelic" form, missense mutations resulting in AA substitutions within the HMG domain have been reported. The genital abnormalities are also milder than in those with complete *SOX9* inactivation, manifest in one such patient by a bifid scrotum, perineal hypospadias, and undescended right testis.

A number of patients with 46,XY autosomal-dominant sex reversal and campomelic dysplasia have chromosome 17 breakpoints at least 50–130 kb from the *SOX9* locus, suggesting the presence of other genes responsible for the same phenotype, or perhaps a disturbance of *SOX9* expression resulting from mutation of an upstream regulator. Positional cloning of the chromosome 17q breakpoint in one patient with sex reversal and "acampomelic" dysplasia identified a 3.5-kb complementary DNA that is expressed in testis but appears not to be translated. In addition, cases with chromosomal rearrangements involving 17q have been described most likely affecting regulatory elements upstream of *SOX9*.

Partial 46,XX female-to-male sex reversal has been reported in an infant with mosaicism for a chromosomal rearrangement resulting in duplication of *SOX9*. The child had severe penile/scrotal hypospadias, a small penis with descended palpable gonads in a bifid scrotum and absence of uterus on ultrasound. This finding suggests that an extra dose of *SOX9* is sufficient to initiate testis differentiation in the absence of *SRY* in humans as well as mice.

α-*Thalassemia/Mental Retardation, X-Linked (ATRX)*

Normal Function α-Thalassemia/mental retardation, X-Linked (ATRX) (also known as X-linked helicase-2) is a helicase—an enzyme that catalyzes the unwinding of double-stranded nucleic acids—and is a member of a family of proteins involved in DNA recombination and repair, chromatin remodeling, chromosome segregation and regulation of transcription.

The large (>200 kb, 35 exon) *ATRX* gene is located at Xq13.3 (and is also on mouse X chromosome) and is subject to alternate splicing in different tissues. There is a homologous gene on the Y chromosome of marsupial mammals (not present in mouse or human) that is expressed specifically in the testis, giving additional weight to its role in male sex determination. The protein contains a nuclear localization signal and three ZFs in the N-terminal region; the C-terminal region contains six helicase domains and a glutamine

rich sequence common in transcription factors. ATRX is thought to function by binding to DNA via the ZF region then opening the double helix with the helicase region in an ATPase-dependent manner. The protein is associated with pericentromeric chromatin during interphase and mitosis, suggesting that ATRX may act as part of a protein complex that modulates chromatin structure.

ATRX is expressed in a wide range of embryonic and adult human tissues, including developing brain and testis. Because of its X-chromosomal location, the gene undergoes X-inactivation in females to retain dosage equivalence with males. As a single active copy in normal females is not associated with testis development, although a single copy is adequate for testis development in males, ATRX likely functions downstream of a male-specific transcription factor such as SRY or SOX9, requiring activation by such a factor. Apart from the fact that human mutations are associated with sex reversal, little is known about the function of this protein in sex determination and differentiation, as comprehensive studies in mice are lacking.

Clinical Features and Molecular Defects The ATRX syndrome is an X-linked disorder characterized in 46,XY individuals by variable severity of α-thalassemia, psychomotor retardation, dysmorphic features, gonadal dysgenesis and undermasculinization. In sex-reversed patients the gonads are streaks, however, Müllerian ducts are absent, indicating that *AMH* expression, and therefore Sertoli cell development were retained during the critical period. Consequently, the critical period for *ATRX* expression appears to be after Sertoli cell development. Diverse mutations in the *ATRX* gene have been reported in individuals with the ATRX syndrome and several clinical variants of the syndrome reflect different mutations in the gene, including Smith-Fineman-Myers, α-thalassemia myelodysplasia and Juberg-Marsidi syndromes. There appear to be some genotype–phenotype correlations: mutations associated with sex reversal have mainly been those causing truncation of the protein with loss of the C-terminal region including the "P-element" (a 15-AA region homologous to that found in other transcriptionally active proteins) and the polyglutamine tract; mutations within a helicase domain are associated with severe mental retardation without thalassemia; and mutations that alter residues in carboxyl terminus outside the helicase domains result in the classic ATRX syndrome. As with other sex reversal disorders, phenotype may vary within a given family, likely reflecting influence of genetic background.

Desert Hedgehog (DHH)

Normal Function Desert hedgehog (Dhh) is a signaling molecule involved in interactions between Sertoli cells and germ cells whose primary role appears to be regulation of spermatogenesis. The 3-exon human *DHH* gene located at chromosome 12q13.1 encodes a 396-AA polypeptide.

In mice *Dhh* is expressed only in the testis and not in the ovary. Expression is initiated in Sertoli cell precursors shortly after activation of *Sry* expression, and persists to adulthood. This system appears to regulate mitosis and meiosis in male germ cells, its role varying at different stages of development. In the embryonic testis Dhh regulates germ cell proliferation and Leydig cell development, whereas in the postnatal testis it directs germ cell maturation. The receptor for Dhh, Patched2, is expressed on Leydig cells and peritubular cells, and one of the key roles of Dhh appears to be in the proper development of peritubular tissue. Consequently, the mechanism by which Dhh regulates germ cell development may be indirect, via other cell types, and may be secondary to the more general effects on organization of testicular structure.

In the initial murine studies, homozygous null male mice had small testes and were infertile because of lack of mature sperm. However, apart from the deficiency of germ cells, the testes were structurally and microscopically normal—including the Dhh-producing Sertoli cells themselves. In a subsequent study in mice from a different genetic background, more than 90% of null male mice were feminized. They had small, undescended, ectopically located testes and poor Leydig cell development with low serum testosterone, female external genitalia and a blind vagina. The latter study demonstrated requirement for Dhh for normal development of peritubular myoid cells and the basal lamina and subsequent well-organized development of seminiferous tubules. Thus *Dhh* may or may not be required for testicular organogenesis depending on genetic background (contrast the effect of a human *DHH* mutation described below) and there is phenotypic heterogeneity of the null mutation even within a single genetic background.

Clinical Features and Molecular Defects DHH is included within the section on testis determination primarily on the basis of a single 46,XY patient who had partial gonadal dysgenesis as a result of a homozygous mutation at the initiation codon in exon 1 of *DHH*, with predicted a failure of protein translation. The young woman, whose parents were first cousins, presented for evaluation of primary amenorrhea and had poor breast development, immature female external genitalia, a blind vagina, and a form of polyneuropathy. Laparoscopy revealed a testis on one side and a streak gonad on the other. Serum testosterone was low and FSH was elevated.

NORMAL AND ABNORMAL OVARY DETERMINATION

The factors directing ovarian development are less well characterized than those governing testis development. However, there is presumably an equally complex network of controls guiding this process, which likely requires action on two fronts: repression of autosomal testis-inducing genes such as *SOX9* (but not *SRY*, as this is absent from the normal XX embryo), and either derepression (removal of an inhibitory influence) or activation (direct stimulation) of ovary-inducing genes. Importantly, any factor that functions as a "testis inhibitor" must be expressed and active prior to the time that expression of autosomal testis-determining factors would otherwise occur. One such testis inhibitor likely resides on the X chromosome and is probably a dosage sensitive locus, expressed from both X chromosomes in females. A former candidate for this role was *DAX1*, based on the finding of streak ovaries in place of testes in individuals with duplication of the X-chromosomal region containing the gene. However, *DAX1* became less convincing as the "antitestis" gene when a female with homozygous *DAX1* deletion was reported. Current prime candidates for roles as testis inhibitors are Wnt4, follistatin and "*Odsex*," a locus on chromosome 17 upstream of *Sox9* that may contain a gonad-specific *Sox9* regulatory sequence. No candidate for the role of a positive "ovary-determining factor" has been proposed; however, such a gene is probably also a dosage sensitive locus (therefore likely X chromosomal) required for germ cell survival in the ovarian milieu. This is suggested by the findings in individuals with Turner syndrome, who, in the absence of two functional copies of the X chromosome have ovarian regression because of early fetal demise of germ cells. It is therefore reasonable to speculate that initial ovarian differentiation occurs under the influence of a factor (or factors) expressed in the absence of the Y chromosome, and that subsequently, dosage-sensitive X chromosomal genes (required in double copy) are responsible for ovarian maintenance.

No clearly defined sequence of steps in the pathway of ovarian development has been established and this is likely a complex,

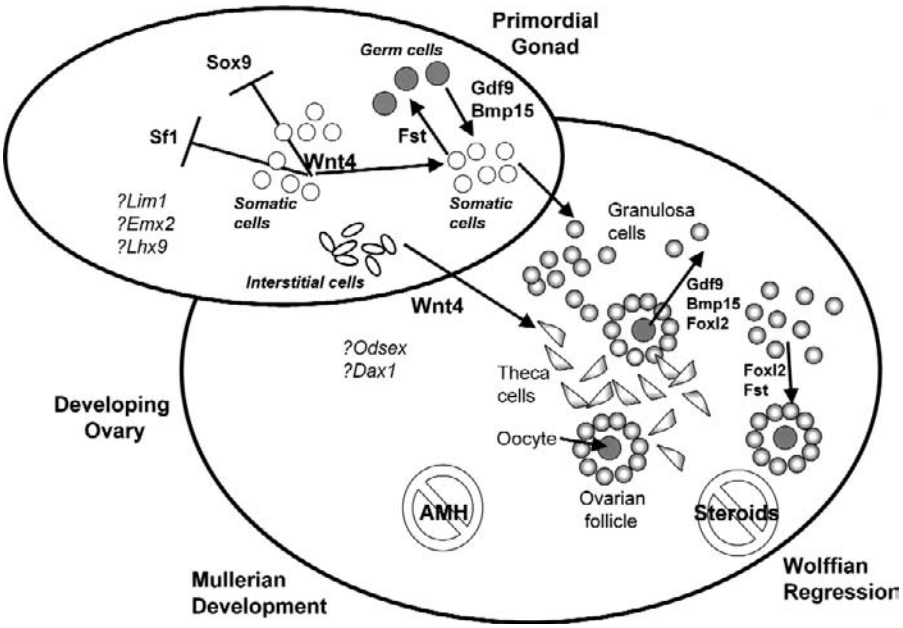

Figure 41-7 Hypothetical model of ovary determination. Wnt4 secreted by somatic cells increases expression of Fst, Dax1 and/or other factor(s) that antagonize Sf1 and repress Sox9 (perhaps by binding to the *Odsex* locus upstream of *Sox9*). Thus bipotential supporting cells do not differentiate as Sertoli cells, but instead as granulosa cells. Paracrine interactions between granulosa cells, secreting Foxl2 and Fst, and germ cells secreting Gdf9 and Bmp15, promote development of ovarian follicles. Wnt4 and Fst together inhibit activin-driven development of testicular (coelomic) vasculature, and Wnt4 inhibits differentiation of bipotential interstitial cells to Leydig cells. Because the XX fetal gonad does not produce sex steroids, the Wolffian ducts regress and external genitalia develop as female. Sertoli cells do not develop, therefore Amh is not produced, so Müllerian structures are maintained and subsequently differentiate under the influence of Hoxa13 and other factors. AMH, anti-Müllerian hormone; BMP15, bone morphogenetic protein 15; DAX1, dosage-sensitive sex reversal-adrenal hypoplasia congenita locus on the X-chromosome, gene 1; EMX2, empty spiracles 2; FOXL2, forkhead transcription factor 2; FST, follistatin; GDF, growth differentiation factor; Hoxa13, hoemobox A 13; LHX9, LIM homeobox gene 9; LIM1, LIM homeobox gene 1; SF1, steroidogenic factor 1; SOX, Sry-related homeobox gene; WNT, wingless-type MMTV integration site family member.

nonlinear, set of interconnected up- and downregulatory events. A speculative model, based on some of the known and hypothetical genetic events, mainly in mice, is as follows:

1. An unknown factor induces expression of Wnt4 by somatic cells.
2. Wnt4 increases expression of Dax1, Fst and/or other factor(s) that antagonize Sf1 and repress Sox9 (perhaps by binding to the *Odsex* locus).
3. Bipotential supporting cells do not differentiate as Sertoli cells, but instead as granulosa cells.
4. Paracrine interactions between granulosa cells, secreting Foxl2 and Fst, and germ cells secreting Gdf9 and bone morphogenetic protein 15 (Bmp15), promote development of ovarian follicles.
5. Wnt4 and Fst together inhibit activin-driven development of testicular (coelomic) vasculature.
6. Wnt4 inhibits differentiation of bipotential interstitial cells to Leydig cells.
7. The fetal gonad does not produce sex steroids, therefore the Wolffian ducts regress and external genitalia develop as female.
8. Because Sertoli cells do not develop, Amh is not produced.
9. Müllerian structures are maintained and subsequently differentiate under the influence of homeobox A 13 (Hoxa13) and other factors (Fig. 41-7).

Wingless-Type MMTV Integration Site Family Gene 4 (WNT4)

Normal Function *Wnt* genes belong to a family of protooncogenes with at least 16 known mammalian members expressed in species ranging from Drosophila to man. These genes encode 38- to 43-kDa cysteine-rich glycoproteins with features typical of secreted growth factors (extracellular signaling molecules): a hydrophobic signal sequence and 21 conserved cysteines whose relative spacing is maintained. Transcription of *Wnt* genes appears to be developmentally regulated in a precise temporospatial manner. Interaction of Wnt factors with Frizzled receptors (members of the seven-transmembrane domain family) results in an intracellular signal cascade that in turn leads to transcriptional activation of target genes. By these interactions the Wnts regulate cell proliferation, morphology and fate. Members of this family are involved in sex determination and differentiation at various levels, including wingless-type MMTV integration site family gene 4 (WNT4) (ovary), WNT5A (external genitalia) and WNT7A (Müllerian duct regression, described later).

Wnt4 is required for the initial stages of Müllerian duct formation in both sexes in mice and appears to be required for normal ovarian development in females, making it a prime candidate for an "anti-testis" gene, interacting with Fst and perhaps Dax1 in this role (Wnt4 regulates expression of both factors). *Wnt4* expression is first detected in the mesonephric mesenchyme, which later forms the bipotential gonad, and is subsequently expressed in the indifferent gonads of both sexes. At the onset of sex-specific gonadal differentiation, *Wnt4* expression is downregulated in the male (probably by Sry/Sox9), but in the female is maintained within somatic cell lineages throughout fetal life. *Wnt4* is also strongly expressed in the mesenchyme underlying the Müllerian ducts, and in the adrenal cortex of both sexes, consistent with a role in regulation of steroidogenesis.

Homozygous *Wnt4*-null mice of both sexes had failure of differentiation of kidney mesenchyme and absence of Müllerian ducts in early gestation. Most striking were the specific effects in female mice, which had masculinization of the gonad and development of Wolffian ducts (the latter because of activation of gonadal steroidogenesis by Leydig cell precursors). Thus, Wnt4 acts in ovarian development by suppressing the differentiation of primordial interstitial cells into Leydig cells, thereby inhibiting testosterone synthesis and allowing female development to occur. Of note, the mice had no masculinization of the external genitalia, probably because testosterone was produced in insufficient quantities from the mutant gonads. Wnt4 further acts by stimulating *Fst* expression and these two factors act in concert to suppress/inhibit activin B, which would otherwise stimulate development of the testicular coelomic vasculature. The ovaries of the XX *Wnt4*-null mice had accelerated loss of oocytes to <10% of the number present in wild-type littermates, suggesting a role for Wnt4 in maintenance of the female germ cell line and oocyte development. The mice also had reduced gonadal *Dax1* expression, reflecting the role of Wnt4 as a regulator of *Dax1*. In complementary experiments overexpression of *Wnt4* in XY mice leads to reduction of testicular steroidogenesis secondary to reduction of Star, which in turn results from repression of Sf1 action by excess Wnt4.

Another member of this family, Wnt5a, is expressed in the genital tubercle and in the genital tract mesenchyme during embryogenesis and postnatally. Wnt5a mutant mice have a stunted genital tubercle and do not develop external genitalia.

Clinical Features and Molecular Defects Mirroring the findings in mice, the phenotypic features of a 46,XX woman with a *WNT4* mutation included the absence of Müllerian structures (uterus and vagina) and signs of mild androgen excess, with a small vaginal introitus (no clitoromegaly) and acne. However, the extent of similarity between the mouse model and the naturally occurring human mutation is unknown, as no information was available regarding ovarian morphology. Additional evidence for the role of WNT4 in human sex determination comes from 46,XY patients with duplication of the region of 1p containing *WNT4* (1p35) who have varying degrees of undermasculinization ranging from cryptorchidism to sex reversal. One such patient who had fibrous gonads with rudimentary tubules, remnants of both Müllerian and Wolffian ducts, and ambiguous external genitalia was specifically demonstrated to have duplication of the *WNT4* gene, with overexpression of the protein.

Winged Helix/Forkhead Transcription Factor 2 (FOXL2)

Normal Function Winged helix/forkhead transcription factor 2 (FOXL2) is implicated in the process of ovarian development by the finding of gonadal dysgenesis in some individuals with mutations of the gene and by the XX sex-reversed goat, which has a deletion in the chromosomal region containing the gene. The single-exon gene is located at human chromosome 3q23 and encodes a member of the winged helix/forkhead transcription factor family (there are at least 20 known human forkhead genes). These proteins contain a characteristic 100-AA DNA-binding domain and are involved in the development of tissues from all three germ layers. FOXL2 appears to be required for maintenance of ovarian follicles, which in turn is required for completion of ovarian development. In the absence of ovarian follicles the gonad regresses to become a fibrous streak; when follicles develop but undergo early atresia, premature ovarian failure ensues.

Foxl2 is highly conserved during evolution and abundantly expressed in the developing ovary of several species with different mechanisms of sex determination (mouse, chicken, and turtle); expression occurs around the time of sex determination and is sexually dimorphic, consistent with a conserved role of this factor in ovarian differentiation. *Foxl2* expression in developing mouse ovary begins at approximately E12.5 and continues into postnatal life; *Foxl2* is detectable in both somatic and germ cell populations in the developing ovary, and in granulosa cells and some oocytes in the adult ovary. Some *Foxl2* expression is also detectable in the developing oviducts. Inhibition of *Foxl2* expression by Sry has been proposed as one of the switch mechanisms that promotes testis development. Further understanding of the role of Foxl2 in ovarian determination awaits a knockout mouse model.

Clinical Features and Molecular Defects Various mutations have been reported in *FOXL2* genes of a number of individuals with the blepharophimosis ptosis epicanthus inversus syndrome and premature ovarian failure. The mutations include frameshifts, premature termination, splicing defects, missence mutations and polyalanine expansion, and result in a form of gonadal dysgenesis that causes early ovarian regression.

Follistatin (FST) Follistatin is a glycosylated single-chain protein functionally (but not structurally) linked to the transforming growth factor-β (TGF-β) superfamily of proteins. Secreted by granulosa cells, follistatin is an important regulator of cellular differentiation and secretion through its potent ability to bind and bioneutralize activin (a stimulator of FSH secretion with which it is colocalized in many tissue systems), and other members of the TGF-β superfamily.

The human *FST* gene is located at chromosome 5q11.2 and includes six exons that encode a 344-AA cysteine-rich protein. Exon 1 encodes a 29-AA signal peptide, whose cleavage results in isoforms of 288 and 215 AAs. The 288-AA protein is made up of a 63-AA N-terminal segment containing hydrophobic residues essential for activin binding, followed by 3 repeating 10-cysteine follistatin domains. Various 31- to 39-kDa follistatin isoforms are generated by alternative splicing, glycosylation, and proteolytic cleavage. Follistatin is highly conserved among species, with 97% AA homology between human and mouse.

Follistatin functions as a downstream component of signaling by WNT4, a key factor involved in repressing testis development. Because the presence of oogonia is critical for survival and maturation of the ovary, follistatin, which promotes survival of oocytes and maintenance of oogenesis, appears to be an important factor in normal ovarian development. Follistatin also antagonizes the action of activins and BMP15 on steroidogenesis in granulosa cells, probably via autocrine/paracrine mechanisms.

FST expression is tightly regulated during development and its promoter contains binding sites for several transcription factors. In the mouse, *Fst* mRNA can be detected in somatic cells of fetal ovaries from E11.5, declining after E14.5. *Fst* is not expressed in *Wnt4*-null mice, indicating that Wnt4 likely regulates its expression. *Fst*-null XX mice have aberrant development of the coelomic blood vessel, a hallmark of testicular organogenesis, as well as prenatal loss of germ cells in the ovarian cortex. Thus the coordinated actions of Wnt4 and Fst appear to be key to suppression of testis development via inhibition of activin-driven coelomic vessel development.

Human *FST* mRNA expression is detectable by Northern blot in nearly all tissues examined, with the highest expression in adult ovary, and in undifferentiated and partially differentiated granulosa cells, the pituitary, kidney, and fetal heart and liver. *FST* is not detectable in the human fetal testis. Human *FST* mutations have not yet been reported.

Transforming Growth Factor-β Family Members: Growth And Differentiation Factor 9 and Bone Morphogenetic Protein 15 The importance of the oocyte in directing the development and function of the ovary is illustrated by the oocyte-secreted factors, growth and differentiation factor 9 (GDF9) and bone morphogenetic protein 15 (BMP15), also referred to as growth differentiation factor 9b (GDF9b), two closely related members of the TGF-β superfamily. The development of an ovarian follicle requires a complex set of reciprocal interactions between the oocyte and granulosa cells for proper development of both cell types; granulosa cell function is not only crucial for oocyte growth but also to maintain follicular quiescence in vivo. The regulatory interactions between the oocyte and granulosa cell are largely orchestrated by the oocyte itself via paracrine factors such as GDF9 and BMP15/GDF9B, which may interact directly as heterodimers. These factors appear to play synergistic roles in development, survival, and function of oocytes and have key roles in granulosa cell development and folliculogenesis via paracrine oocyte-somatic cell interactions. In addition to interacting with one another, these factors also interact with other intra- and extraovarian factors, and both ligands use components of the same signaling pathway via transmembrane serine/threonine kinase receptors. Because fetal ovary differentiation is dependent on the presence of germ cells and their subsequent development as ovarian follicles, and GDF9 and BMP15 are required for these processes, it appears likely that both of these factors are involved in the normal development of the ovary, although their relative roles may differ among species.

Growth Differentiation Factor 9 (GDF9) GDF9 is the first oocyte-derived growth factor required for ovarian somatic cell function in vivo. *Gdf9* mRNA is expressed exclusively in oocytes in all species examined, but there appear to be important species differences in the timing of expression and roles of *Gdf9/GDF9* between mice and other mammals. In the mouse ovary, *Gdf9* is not expressed in primordial follicles but is expressed at all stages of follicular development thereafter in both neonatal and adult ovaries. Expression of *Gdf9* mRNA begins slightly earlier than that of *Bmp15/Gdf9b* (discussed later), but Gdf9 does not appear to regulate *Bmp15* because *Gdf9*-deficient mice continue to express *Bmp15*. *Gdf9*-deficient mice are infertile because of a block in oocyte differentiation and follicular development at the primary follicle stage. In human ovary, *GDF9* mRNA and protein were not detected in primordial follicles but were abundantly expressed in oocytes (and were restricted to this cell type) of primary follicles. Understanding of the role of GDF9 in human ovarian development is hampered by lack of information regarding the human chromosomal locus of the gene, its expression during human fetal ovarian development, or naturally occurring mutations.

Bone Morphogenetic Protein 15 (BMP15)/Growth Differentiation Factor (GDF9b) BMP15/GDF9b, another member of the TGF-β superfamily of extracellular signaling proteins, is the second oocyte-derived growth factor (after GDF9) that may be essential for ovarian function. The human *BMP15* gene is located at Xp11.2 in a region of the X-chromosome conserved in human and mouse. However, there is relatively low AA sequence identity (76%) between the human and mouse proteins. BMP15 binds and activates two types of transmembrane serine/threonine kinase receptors, resulting in potent paracrine stimulation of ovarian granulosa cell growth and proliferation, accompanied by negative regulation of granulosa cell FSH receptor expression, resulting in downregulation of many FSH-responsive genes such as *StAR* and *P450SCC*. Follistatin inhibits the biological activity of BMP15 (and other TGF-β members).

Mouse *Bmp15* is expressed in oocytes at the one-layer primary follicle stage. Expression is similar to that of mouse *Gdf9*, to which *Bmp15* is most closely related (52% identity at the AA level). *Gdf9* expression is unaltered in *Bmp15*-null mice, implying lack of direct regulation of *Gdf9* by Bmp15. Homozygous *Bmp15* knockout female mice were subfertile, although not infertile, and their ovaries were often morphologically and histologically normal, suggesting that Bmp15 is less critical than Gdf9 for ovarian function because the *Gdf9* knockout, being infertile, is more significantly impaired. In contrast, a homozygous naturally occurring *Bmp15* missense mutation in sheep results in an early block in folliculogenesis and primary ovarian failure, highlighting species differences in the relative importance of these two related growth factors. In the human ovary, *BMP15* is expressed after *GDF9* in the oocytes of developing follicles; it is also detectable in pituitary gonadotropes.

Odsex The *Odsex* locus is a region approx 1 mB upstream of the *Sox9* gene on chromosome 17. Deletion of this region in XX mice resulted in male-pattern *Sox9* expression and development of testes—female-to-male sex reversal. No specific gene has been identified within the region and it is hypothesized that instead the region may contain a gonad-specific regulatory sequence. It is proposed that when bound by a repressor factor, this sequence turns off *Sox9* expression in the normal XX gonad. Absence of the sequence therefore results in aberrant *Sox9* expression and testis development. One function of Sry in male development may be to inhibit the repressor of Sox9—a "double-repressor" mechanism of action.

OTHER FACTORS WITH PUTATIVE ROLES IN TESTIS AND/OR OVARY DETERMINATION

Dosage-Sensitive Sex Reversal-Adrenal Hypoplasia Congenita Locus on the X Chromosome, Gene 1 (DAX1)

Normal Function DAX1 (officially termed nuclear receptor subfamily 0, group B, member 1) is an orphan nuclear hormone receptor transcription factor that appears to function primarily as a transcriptional repressor. For some time DAX1 bore the title of main contender for the role of "antitestis" factor, until a role in testis development was demonstrated in a certain mouse strain and it was then touted as a "pro-testis" factor. Currently, the roles of DAX1 in the physiology of sex determination (as opposed to its roles in experimental mice) are unclear, as data regarding the impact of DAX1/Dax1 in testis and ovary development in mice vs humans are conflicting. Indeed, DAX1 may be the key example of a factor whose human physiological roles may not be deducible from murine experiments. Nevertheless, as reflected by its name, a role in sex determination and differentiation has long been postulated for DAX1 based on involvement of its chromosomal locus in human disease. In fact, *DAX1* was initially discovered by cloning the region in Xp21 duplicated in a number of patients with 46,XY sex reversal, and deleted in patients with adrenal hypoplasia congenita (AHC).

The 5.0-kb, 2-exon *DAX1* gene is located at Xp21.3-21.2 and encodes a 470-AA protein. The N-terminal region contains an unusual DNA-binding domain, comprising three repeats of a novel AA sequence (LxxLL), that has little homology with that of other nuclear receptors; the protein does not contain the typical central two-ZF DNA-binding domain. However, the ligand-binding domain has homology with another orphan nuclear receptor and with the retinoic acid and retinoid X receptors. The gene demonstrates a degree of evolutionary conservation,

homologous sequences being detected in an X-linked pattern of distribution in many mammalian species, including mice. However, *Dax1* is autosomal rather than X-chromosomal in the tammar wallaby and the chicken, and does not have a sex-determining function in these species, suggesting that any sex determining role in placental mammals arose fairly recently in evolution. Furthermore, comparisons between mouse and human DAX1 show that specific domains of this transcription factor are evolving rapidly, perhaps explaining its different functions in mice vs humans and differing effects of DAX1 excess or deficiency in the different species.

There is strong expression of the homologous gene in the mouse (*Ahch*) in the first stages of gonadal and adrenal differentiation and in the developing hypothalamus and pituitary gonadotropes. Expression is downregulated at the time of overt differentiation of the testis, but persists in the developing ovary, suggestive of a role in ovarian development (although such a role remains hypothetical). There is significant overlap in the distribution of expression of *Dax1* and *Sf1* in numerous tissues, supporting the concept of linkage between these two transcription factors in regulation of development of steroidogenic tissues. The *Dax1* promoter contains binding sites for Sf1, and Sf1 regulates *Dax1* expression in vitro. Furthermore *Sf1*-disrupted mice lacked *Dax1* expression in the developing genital ridge in one study, although not in another. Wnt4 also may regulate *Dax1* expression, potentially explaining its increased expression in ovary vs testis. The physiology of Dax1 is complicated, because although Sf1 regulates *Dax1* expression, Dax1 inhibits Sf1-mediated transcription of other genes, suggesting a regulatory loop. Indeed, the fact that Dax1 blocks Sf1-mediated steroidogenesis seems to be inconsistent with its role as an important mediator of normal development of steroidogenic tissues. Hence, many aspects of Dax1 remain to be unraveled.

In human studies *DAX1* is expressed in Sertoli cells of the fetal testis by 16 wk gestation, in the adult testis and adrenal cortex, in the hypothalamus and pituitary gland, and at low level in adult ovary and liver. The expression of *DAX1* at all levels of the hypothalamic-pituitary-adrenal/gonadal axis supports its role in the coordinated development and regulation of the adrenal and reproductive systems. Because human *DAX1* is located in a region of Xp that normally undergoes X inactivation, single copy expression would be predicted for both males and females. However, differential regulation by sexually dimorphic factors such as WNT4 could help to explain differences in expression and function of DAX1 in male and female development.

Dax1 binds to target genes as a homodimer, likely acting as a competitive inhibitor of transcription at these sites. Indeed Dax1 has been demonstrated to repress *StAR* and *Cyp17* expression, to inhibit Sf1-mediated transactivation, thereby blocking steroidogenesis, and to antagonize the synergy between Sf1 and Wt1 in their upregulation of *Amh* expression; however, the latter appears to be via protein/protein interaction with Sf1, rather than an effect at the target gene. Sequences responsible for the suppressive function reside in the ligand-binding domain and in the N-terminal leucine repeat region of the protein. Although not yet described, a transcription activating function for Dax1 at other target sites is conceivable, much as has been described for Wt1, which has target-specific activation and repression activities.

Analysis of targeted disruption or transgenic overexpression of *Dax1* in mice highlights the importance of gene dosage and the genetic background on which such experimental changes are expressed. XY mice with *Dax1* deletion have normal testis development and masculinization (but have small testes and spermatogenetic defects) when the deletion is introduced into a normal mouse strain; in contrast, complete XY sex reversal (ovarian and phenotypic female development) occurs when the deletion is introduced into a strain of mice that carries a "weak" *Sry* gene (*M. domesticus poschiavinus*). Thus, depending on the genetic background in which it is acting, Dax1 could be interpreted as unnecessary for testis formation but required for postnatal spermatogenesis on one hand, or required for normal testis determination on the other. Findings are equally enigmatic in mice overexpressing *Dax1*: *w*hen these experiments were performed in the *poschiavinus* (weak *Sry*) strain, overexpression of *Dax1* resulted in XY sex reversal (just as deletion of the gene did), postulated to be because of antagonism of Sry. However, when the excess *Dax1* was expressed on the background of a normal *Sry* gene (*M. musculus*), only a transient delay in testis development was observed. Effects of mutation, homozygous deletion, or overexpression of *Dax1* in XX mice appear to be negligible, as such mice are fertile, giving no indication of a dosage effect on ovarian differentiation and challenging earlier speculation regarding the role of Dax1 as an ovary determinant.

Clinical Features and Molecular Defects *DAX1* has been implicated in two X-linked syndromes: dosage-sensitive sex (DSS) reversal and AHC/hypogonadotropic hypogonadism (HHG). The occurrence of sex reversal in the presence of two copies of sequences in the Xp21 region containing the *DAX1* gene led to the designation of this locus as the reversal region. Karyotypic males with this duplication have typical features of 46,XY sex reversal, with ovaries/streak gonads and a female phenotype. Individuals with deletion of this region have normal testes and male genitalia, although cryptorchidism and postnatal testicular dysfunction have been reported. These males have congenital hypoplasia of the adrenal glands and many die unexpectedly in early childhood of undiagnosed adrenal failure. Those who survive childhood also commonly have HHG resulting in failure of pubertal virilization. Deletion of *DAX1* has been reported in a number of patients with isolated AHC, whereas frameshift, premature termination, codon deletion and missense mutations have been found in *DAX1* genes of individuals with combined AHC/HHG, suggesting a possible dominant negative effect of a retained but structurally abnormal protein. Female carriers of AHC/HHG have no clear abnormality of either adrenal gland development or gonadotropin secretion; however, there have been some reports of menstrual irregularity and early menopause.

Doublesex and Mab-3-Related Transcription Factors 1 and 2 (DMRT1/2)

Normal Function Transcription factors related to the sexual regulatory factors Doublesex (in drosophila) and Mab3 (in earthworm) contain a conserved DNA-binding motif referred to as the "DM" (doublsex/mab) domain. Seven genes encoding such transcription factors, referred to as "*DM*" genes, have been discovered to date in humans and mice. DMRT1 and DMRT2 may have roles similar to SF1 and WT1, with functions as early regulators of primordial gonad formation, and later functions as testis-specific factors. The human genes encoding DMRT1 and 2 are both located at 9p24.3, <30 kb from the critical region for sex reversal on chromosome 9. The genes encode 226-AA peptides that share 80% identity in the 29-AA core region of the DM domain.

Gonad-specific expression is present in a number of species (mice, humans, chickens, amphibians, alligators, lizards, turtles, and fish). Given the different sex-determining switches in these groups, DMRT1 and DMRT2 are thought to represent an ancient, conserved component of the vertebrate sex-determining pathway, upstream of SRY. *Dmrt1* is expressed exclusively in the genital ridge of both XX and XY mouse embryos, before gonadal sex determination. In the early testis differentiation period *Dmrt1* then is upregulated in testes compared to ovaries. As testicular organogenesis proceeds, *Dmrt1* expression becomes restricted to the seminiferous tubules, in which it is expressed by both Sertoli cells and germ cells. Expression in Sertoli cells appears to be regulated by the transcription factors Sp1 and Sp3 and by the cell cycle regulator, Egr1. Expression is regulated by FSH in postnatal Sertoli cells and is testis-specific in human adults.

Male mice with homozygous deletion of *Dmrt1* had normal fetal testis development, but had severe defects in postnatal testis differentiation, resembling those associated with human deletions. Prior to postnatal day 7 the testes of the null mice appeared grossly normal. Thereafter, the testes were hypoplastic with disorganized seminiferous tubules, absent germ cells and fatty degeneration of Leydig cells. Notably, the gonadal tissue was not ovarian and there were no Müllerian duct-derived structures. Thus, the murine *Dmrt1* null phenotype is a postnatal failure of testis development, accompanied by germ cell death, rather than a prenatal failure of testis determination. No effect on gonadal development is seen in female mice.

Clinical Features and Molecular Defects 46,XY patients with monosomy for chromosome 9p have varying degrees of testicular maldevelopment (agonadism, streak gonad, hypoplasia) and ambiguous or female genitalia. In one patient with asymmetric gonadal development, a fallopian tube was present on the side of the absent gonad, as would be expected because of lack of ipsilateral *AMH* expression. One 46,XX patient also had primary hypogonadism, implicating the 9p region in ovarian as well as testicular development. This implies that genes in the 9p region (hypothesized, but not proven, to be *DMRT1 and DMRT2*) are necessary for formation of the bipotential gonad. However, there may be some functional compensation for lack of *Dmrt1* because XY null mice do not have sex reversal. Some patients have associated mental retardation and other congenital anomalies. Gonadoblastoma has been reported in one patient.

GATA4 GATA4 is a member of a group of structurally related DNA-binding transcription factors critical to the development of diverse tissues that control gene expression and differentiation in a variety of cell types. Members of this family contain one or two ZFs that recognize a consensus DNA sequence known as the "GATA" motif (i.e., the four nucleotides G, A, T, and A in this sequence) an important element in the promoters of many genes. With respect to sex determination, GATA4 may, like WT1 and SF1, have dual roles, being involved both in early development of the primordial gonad, and later in male-specific development.

Genes encoding many steroidogenic enzymes may be targets of GATA proteins as they contain the consensus GATA element within their 5′ regulatory regions, suggesting a role for GATA4 in regulation of steroidogenesis. For example, GATA4 has been demonstrated to regulate the *StAR* promoter in the ovary. GATA4 may act synergistically with SF1 through protein/protein interaction mediated by the GATA4 ZF region to regulate *Amh* expression, as there are binding sites for both factors adjacent to each other on the *Amh* promoter (Fig. 41-3B). The affinities of various GATA factors for specific promoters probably depend on interactions with cofactors and other more restricted transcription factors. For example, Leydig cells express factors known as "Friends of GATA" (FOG), which may play a role in tissue-specific effects.

In mice, *Gata4* is expressed from early stages of gonadal development (E11.5) in both sexes in the somatic cell population (later to become the Sertoli and granulosa cells), but not in the primordial germ cells. Abundant *Gata4* expression continues in Sertoli cells throughout embryonic testis development. During early ovarian development, *Gata4* mRNA and protein localize to the granulosa cells and are markedly downregulated shortly after the histological differentiation of the ovary on E13.5. This results in a sexually dimorphic pattern of greater *Gata4* expression in developing testes than ovaries. Reduced *Gata4* expression in the latter stages of ovary development coincides with the necessity for absence of Amh to allow normal Müllerian duct development in the female.

In the human testis, *GATA4* is expressed from early fetal life to adulthood. Like AMH, GATA4 represents an early marker of Sertoli cells, its expression peaking at 19–22 wk gestation (FSH and testosterone are also high during this period). Consistent with a role in regulation of steroidogenesis *GATA4* is also expressed in a number of human steroidogenic tissues such as Leydig cells during the fetal period and after puberty, the periods of most active androgen synthesis. Other tissues in which *GATA4* is expressed include fetal and postnatal granulosa cells, adult theca cells, fetal adrenal cortex, fetal germ cells and prepubertal spermatogonia (it is downregulated in these cells after puberty).

Targeted disruption of *Gata4* or *Fog2* in mice resulted in reduced *Sry* expression, failure of Sertoli cell differentiation and early failure of testis differentiation. Human GATA2 mutations are associated with cardiac defects but no gonadal phenotype has been reported.

NORMAL AND ABNORMAL MALE SEX DIFFERENTIATION

Once function of the testis is established, at approx 8 wk gestation, development of the male sexual phenotype is under the control of testicular secretions and the receptors that mediate their action. These include fetal LH, the LHCGR, steroidogenic enzymes involved in testosterone biosynthesis, steroid 5α-reductase 2 required for conversion of testosterone to DHT, the androgen receptor (AR), AMH and the type 2 anti-Müllerian hormone receptor (AMHR2).

Development of Wolffian structures requires testosterone, produced by steroidogenesis in testicular Leydig cells following activation of the cell surface LHCGR. During the first trimester of gestation the ligand for this receptor is probably chorionic gonadotropin (CG), produced in large quantity by the placenta. Subsequently, endogenous fetal LH is the primary ligand. The lack of dependence on fetal LH during male genital morphogenesis is evidenced by the normal penile structure of males with hypopituitarism; however, the subnormal penile size of these infants highlights the role of fetal LH/testosterone action in the penile growth that occurs in the third trimester. Sertoli cells may also help regulate Leydig cell steroidogenesis in a paracrine fashion. The outcome of this multistep process is a high local, and to a lesser extent systemic, concentration of testosterone.

Testosterone action is mediated by the AR, a nuclear receptor/transcription factor found in high concentration in the tissues of the Wolffian ducts (in which testosterone itself is the ligand) and external genitalia (in which the ligand is DHT). In the absence of high androgen concentration, as in the female or androgen-deficient fetus, there is insufficient activated AR to

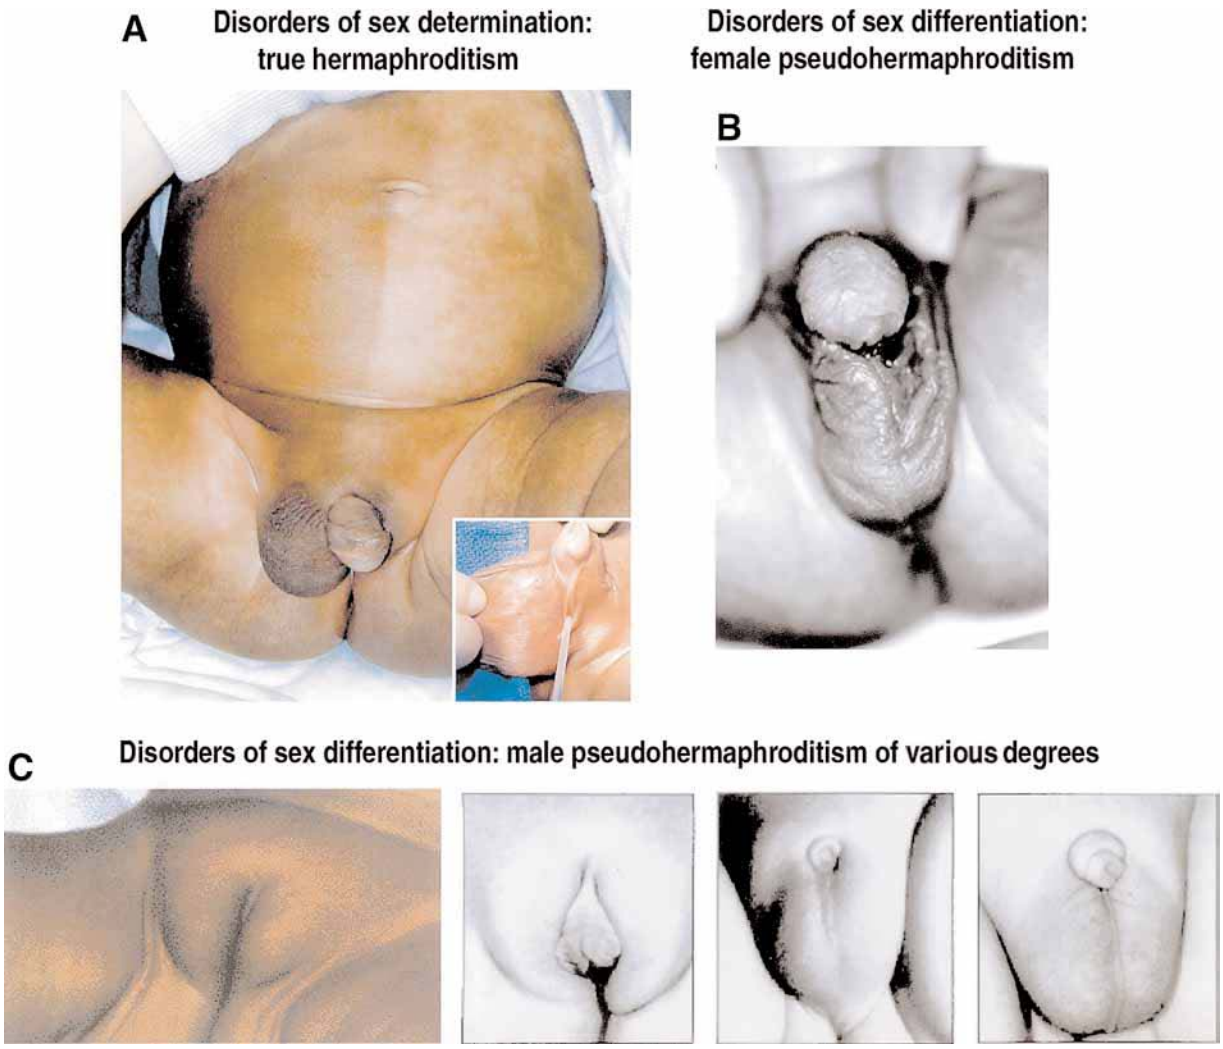

Figure 41-8 Clinical examples of disorders of sex determination and differentiation. **(A)** Disorders of sex determination: true hermaphroditism. This infant had 46,XX/46,XY mosaicism and normal male testosterone levels. Note the asymmetry of the labioscrotal folds and urethral orifice in a perineal location (inset). Internal genitalia mirrored the external asymmetry, with an ovary, Fallopian tube and hemiuterus on the left. The right scrotal fold contained an ovotestis. (Reproduced with permission from Karam JA, Baker LA. Images in clinical medicine. True hermaphroditism. N Engl J Med 2004;350[4]:394.). **(B)** Disorders of sex differentiation: female pseudohermaphroditism. This 46,XX child has significant virilization due to androgen excess resulting from 21-hydroxylase deficiency. Marked clitoromegaly and labioscrotal fusion are present. (Reproduced with permission from Pinhas-Hamiel O, Zalel Y, SmithE, Mazkereth R, Aviram A, Lipitz S Achiron R: Prenatal diagnosis of sex differentiation disorders: the role of fetal ultrasound. J Clin Endocrinol Metab 2002;87[10]:4547–4553. Copyright 2002 The Endocrine Society.) **(C)** Disorders of sex differentiation: male pseudohermaphroditism Left: 46,XY infant with androgen receptor mutation who subsequently showed significant penile enlargement in response to treatment with topical dihydrotestosterone gel. (Reproduced with permission from: Ong YC, Wong HB, Adaikan G, Yong EL. Directed pharmacological therapy of ambiguous genitalia due to an androgen receptor gene mutation. Lancet 1999; 354[9188]: 1444, 1445.) Right: These three individuals are 46,XY siblings with the same androgen receptor gene mutation who show significant phenotypic variability within a family. (Reproduced with permission from Holterhus PM, Sinnecker GH, Hiort O. Phenotypic diversity and testosterone-induced normalization of mutant L712F androgen receptor function in a kindred with androgen insensitivity. J Clin Endocrinol Metab 2000;85[9]:3245–3250.)

induce transcription of target genes required for stabilization and development of the Wolffian system and for masculinization of the external genitalia.

Müllerian duct regression is induced by the Sertoli cell glycoprotein hormone, AMH, mediated by AMHR2, a member of the serine/threonine kinase group of transmembrane proteins, localized in the mesenchyme surrounding the Müllerian ducts. AMH/AMHR2 action causes involution of Müllerian structures by apoptosis. What can be considered as perhaps the final phase of masculinization—testicular descent—is controlled in part by a Leydig cell secreted protein, insulin-like protein 3.

Male (46,XY) pseudohermaphroditism describes conditions in which an individual with male karyotype and normally formed testes has abnormal masculinization of the internal and/or external genitalia. In essence there are two major classes: defects of production or response to testosterone, and defects of production or response to AMH. The causes of male pseudohermaphroditism are summarized in Table 41-1. Clinical examples are provided in Fig. 41-8.

The genital phenotype in disorders of production and action of testosterone generally reflects the severity of the defect during fetal life. 46,XY individuals with profound deficiency of androgen

production or action have fully female external genitalia. Those in whom some degree of androgen production and action is retained have a wide spectrum of genital phenotypes, ranging from minor degrees of posterior labial fusion and a clitoris-like phallus to ambiguous genitalia characterized by incomplete labioscrotal and urethral fusion to more significant masculinization with reasonable penile size accompanied by urethral hypospadias, penile chordee, and cryptorchidism. The testes may be located anywhere from the abdomen to the inguinal canals or the labioscrotal region. Internal genital structures range from feminized lower genital tracts with separate vaginal and urethral structures in cases in which there is minimal androgen action, to more masculinized structures such as a urogenital sinus with ectopic vaginal orifice, in milder cases in which a moderate degree of androgen action has occurred. The development of Wolffian duct structures (epididymis and vas deferens) is also variable, depending on the degree of local testosterone secretion/action in early gestation. The vaginal pouch is blind and Müllerian duct structures (uterus and fallopian tubes) are absent or diminutive because of the action of AMH secreted normally by the Sertoli cells.

An uncommon form of male pseudohermaphroditism occurs in conditions caused by failure of secretion or action of AMH. These males have normal testes and normal male external genitalia, but retain the Müllerian structures to varying degrees, sometimes including development of a complete uterus and fallopian tubes.

LHCG Receptor (LHCGR)

Normal Function The LHCGR is a seven-transmembrane domain G protein-coupled receptor responsible for transducing the hormonal effects of LH and CG. It is required for male sex differentiation by its role in the early development of Leydig cells and in mediating Leydig cell steroidogenesis. The 60-kb, 11-exon *LHCGR* gene located at 2p21 is transcribed into a number of mRNA splice variants whose function is unclear. Exons 1–10 encode the major portion of the N-terminal extracellular domain, containing a leucine-rich repeat; exon 11 codes for a small part of the extracellular domain, as well as all seven transmembrane loops and the C-terminal intracellular region. The 85-95-kDa LHCGR has significant homology with the FSH and TSH receptors. Ligand binding induces increased intracellular production of cyclic AMP, the principal mediator of hormone action in this system.

Fetal Leydig cells in mice constitutively express *LHCGR* in the absence of hormone. In contrast, in mouse ovary *LHCGR* mRNA can be detected only on day 5 postnatally, after the onset of postnatal LH stimulation of gonadal function (detectable in granulosa, theca, interstitial, and luteal cells). No mouse model for LHCGR defects has been described.

Clinical Features and Molecular Defects LCH is a rare (approx 1/1,000,000) autosomal-recessive cause of male pseudohermaphroditism in which Leydig cell differentiation and testosterone production are impaired because of absence or defective function of LHCGR on Leydig cell progenitors. In its severe form, patients present with female external genitalia and cryptorchid testes. Müllerian derivatives are absent, because Sertoli cells and therefore AMH production are normal. Although the genital phenotype is generally female, posterior labial fusion or a urogenital sinus may be present, and occasional patients with a small penis are reported, suggesting significant testosterone production in the first trimester. Because the testes remain quiescent, negligible development of either male or female secondary sexual characteristics occurs at puberty, a feature that distinguishes this condition from the androgen insensitivity syndromes (AISs), in which high estrogen production at puberty typically produces ample breast development. Postpubertal individuals with LCH have slightly small testes due to hyalinization of the seminiferous tubules, interrupted spermatogenesis and absent or diminished Leydig cells, reflecting the requirement of LH for their development and survival.

The diagnosis of LCH should be suspected in a 46,XY infant with female or slightly masculinized external genitalia in the presence of low testosterone and high LH levels (Table 41-5). Unlike individuals with a testosterone biosynthetic defect, who also have low testosterone and high LH, there is no elevation of testosterone precursors and no increase in testosterone or its precursors in response to exogenous hCG administration. Failure of pubertal development in a phenotypic female with high LH and no measurable sex steroids would also suggest this diagnosis.

Diverse mutations in the *LHCGR* gene have been reported in patients with varying phenotypes of LCH. The mutations are not localized in any particular region of the gene and cause variable reductions of receptor activity. Most mutations are present in the homozygous or compound heterozygous state (i.e., both copies of the gene carry a mutation). Three phenotypically female 46,XY siblings with typical clinical findings of LCH and their 46,XX sister were homozygous for a nonsense mutation that predicts protein termination in the third cytosolic loop of the receptor. If the protein gets to the cell membrane (which it may not, if severely disturbed), it would be predicted to lack the sixth and seventh transmembrane domains and the intracellular domain, regions important for G protein-coupled signaling. The patient's 46,XX sister had late menarche at 20 yr of age, thereafter developed secondary amenorrhea, and had increased serum LH, suggesting that hapolinsufficiency for ovarian LHCGR may have impaired ovarian function. A similar mutation present in the compound heterozygous state in another pair of phenotypically female 46,XY siblings resulted in truncation within the 5th transmembrane domain. In this case not only was cAMP production impaired, but cell surface receptor expression was reduced, providing two reasons for lack of LH/CG action. A pair of affected 46,XY siblings born to consanguineous parents had a homozygous missense mutation resulting in an AA change in the 6th transmembrane domain of the receptor. Because the extracellular domain was intact the receptor had normal CG binding affinity, however, the ligand-bound state did not induce cAMP production, required for induction of steroidogenic enzyme activity.

Variability of the phenotype associated with *LHCGR* mutations is underscored by the report of a phenotypically male child with small penis whose testes were normally descended and whose serum LH was at the upper limit of normal. A missense mutation converted serine to tyrosine at position 616 in the seventh transmembrane domain. Surprisingly, in view of the normal masculinization, in vitro studies of the mutant receptor revealed absent LH binding and cAMP production. One possible explanation is that the receptor function *in utero* under the drive of maternal CG was adequate for normal first trimester Leydig cell function and testosterone secretion, but was inadequate in the presence of LH.

Proteins and Enzymes of Testosterone Biosynthesis

Leydig cell testosterone production during the critical period from weeks 8 to 12 of male gestation is required for normal internal and external genital masculinization. Following LH/CG stimulation of Leydig cells, testosterone production requires the well-regulated

action of numerous proteins and enzymes of steroidogenesis. A defect in any of these steps can cause male pseudohermaphroditism with ambiguous or female external genitalia and varying degrees of Wolffian hypoplasia as a result of insufficient testosterone production during fetal sex differentiation. Depending on the location of the enzymatic defect in the steroidogenic pathway, these disorders may also affect adrenal glucocorticoid and mineralocorticoid biosynthesis (Table 41-4, Fig. 41-9). Because all of the genes encoding these enzymes are located on autosomes, these disorders are inherited as autosomal-recessive traits, requiring two defective alleles to cause disease in most, but not all cases. Defects of testosterone biosynthesis are relatively uncommon causes of male pseudohermaphroditism. The molecular and biochemical heterogeneity within each defect and the consequent variability of the testosterone biosynthetic defect makes it impossible to distinguish these enzyme disorders on clinical grounds alone, and careful analysis of gonadal and adrenal steroids and their precursors is required (Table 41-5, Fig. 41-9.).

Steroidogenic Acute Regulatory Protein (StAR)

Normal Function The first and rate-limiting step in gonadal and adrenal steroidogenesis is the StAR-mediated transfer of cholesterol from the outer mitochondrial membrane to the inner membrane resulting in a rapid increase in pregnenolone synthesis. StAR is not required for basal steroidogenesis, but is essential for the increased rate of steroid production required for the acute response of steroidogenic cells to tropic hormone stimulation (e.g., LH, ACTH), because the first enzyme of steroidogenesis (cholesterol side-chain cleavage) is located on the inner mitochondrial membrane. The mechanism of action of StAR in this process appears to be the formation of contact sites between the inner and outer mitochondrial membranes, mediated by the protein's C-terminal steroidogenic acute regulatory-related lipid transfer (START) domain. The N-terminal domain contains a mitochondrial targeting sequence and the central region of the protein is thought to slow the protein's transit into the mitochondria, permitting the biologically active carboxyl terminus to have more interactions with the outer mitochondrial membrane.

StAR is an 8-kb, 7-exon gene located at 8p11.2 that contains an 855-bp open reading frame. The 285-AA StAR protein is produced as a 37-kDa cytosolic precursor that is imported to the mitochondria, in which it is processed to four mature 30-kDa forms. Human *StAR* expression is seen in the ovary, testis, adrenal cortex and kidney—tissues that perform mitochondrial sterol oxidations subject to acute regulation by cAMP, but not in placenta (despite is abundant steroidogenic capacity) because placenta does not exhibit acute regulation of steroidogenesis. *StAR* expression is stimulated by LH and ACTH via their receptors. In addition, the *StAR* promoter contains binding sites for SF1 and the estrogen receptor, implicating these transcription factors in regulation of *StAR* expression.

Homozygous *Star* deletion in mice resulted in adrenal cortical abnormalities highly reminiscent of the human disease congenital lipoid adrenal hyperplasia (CLAH) discussed later. Defects included florid lipid deposition in steroidogenic cells, very low levels of adrenal steroids, high ACTH and corticotrophin-releasing hormone; the mice died in the early postnatal period. The testes of the male (phenotypically female) mice, although grossly normal, showed similar cytological changes with lipid deposits in steroidogenic cells. The internal genitalia were normally masculinized indicating that the testes had retained at least a modest degree of steroidogenic capability during fetal development. The ovaries of the female mice were normal. The sex-specific differences in gonadal involvement reflect a "two-hit" mode of pathogenesis of Star deficiency: trophic hormone stimulation (present prenatally in males but not females) induces progressive accumulation of lipids within the steroidogenic cells and the lipid accumulation eventually causes cell death.

Clinical Features and Molecular Defects *STAR* mutations are one cause of CLAH, the rarest and most severe form of CAH. In this autosomal-recessive condition, basal steroidogenesis proceeds normally, but neither the adrenals nor the testes are capable of tropically stimulated steroidogenesis. CLAH is relatively more common among Japanese, Korean, and Palestinian Arab populations. Indeed CLAH is thought to be the second most common form of CAH in Japan and the majority of reported cases worldwide are of Japanese/Korean heritage. There is a 3/1 preponderance of affected males vs females (unusual in an autosomal-recessive condition, in which a 1/1 male/female ratio is expected), perhaps because of an ascertainment bias on the basis of genital anomalies in males, or early postnatal death in females before a diagnosis can be made.

Infants with severe CLAH usually present in the first few weeks of life with hyponatremia, hypovolemia, hyperkalemia, and metabolic acidosis reflecting severe salt-wasting adrenal insufficiency, often resulting in neonatal death. Affected 46,XY infants usually have completely female genitalia although mild degrees of external masculinization and normal Wolffian duct development have been reported. Affected 46,XX infants have normal female internal and external genital development. ACTH concentrations are markedly increased (causing a generalized increase in skin pigmentation as a result of the concomitant excess of melanocyte-stimulating hormone produced from the ACTH precursor, proopiomelanocortin), as is plasma renin activity; serum and urinary concentrations of all adrenal and gonadal steroids and their metabolites, even after ACTH or hCG stimulation, are profoundly reduced. Some patients with milder forms of the condition, especially those with delayed onset of mineralocorticoid deficiency, have presented as late as the teenage years, and patients can survive to adulthood with appropriate mineralocorticoid- and glucocorticoid-replacement therapy. Spontaneous pubertal development has been reported in 46,XX patients because of the milder effects of StAR deficiency on the ovaries vs the testes.

Because cholesterol can not be actively converted to pregnenolone patients with StAR deficiency have large, lipid-laden adrenal glands due to hyperstimulation by ACTH leading to accumulation of cholesterol and cholesterol esters. The testes in infancy and childhood contain normal to increased numbers of lipid-laden Leydig cells. Adrenal and gonadal tissues from these patients are unable to convert cholesterol to pregnenolone in vitro. As in the mouse model, the cellular pathophysiology of StAR defects involves a "two-hit" mechanism: adrenal and testicular cells, initially capable of StAR-independent steroidogenesis, are unable to increase steroidogenesis in response to ACTH and LH, respectively, which are chronically elevated. This leads to intracellular accumulation of cholesterol esters and their byproducts, causing cellular damage and eventual loss of basal steroid production. This two-hit model explains the finding of normal ovarian steroidogenesis and pubertal development in 46,XX patients, because the ovaries are unstimulated during fetal life and do not sustain the damage suffered by fetal testes. However, they later

CYP11B2	8q21	P450XIB2 P450cmo P450AS CMOI CMOII	18 hydroxylase 18 hydroxysteroid dehydrogenase Aldosterone synthase	18-hydroxylation of corticosterone; 18-oxidation of 18-OH-corticosterone to aldosterone	Isolated aldosterone deficiency → hyponatremia, hyperkalemia, failure to thrive No effect on sex differentiation
CYP19A1	15q21.1	P450arom	Aromatase Estrogen synthetase	Converts androstenedione to estrone and testosterone to estradiol by addition of two double bonds to steroid A ring	Virilization of pregnant woman in latter part of pregnancy and: 46,XY: normal male 46,XX: virilization of external genitalia
SRD5A2	2p23	5α-reductase 2	5α-reductase	5α-reduction of testosterone to dihydrotestosterone	46,XY: defective external genital masculinization with normal Wolffian duct development 46,XX: normal female

DHEA, dehydroepiandrosterone; P450arom, p450 aromatase; StAR, steroidogenic acute regulatory protein.

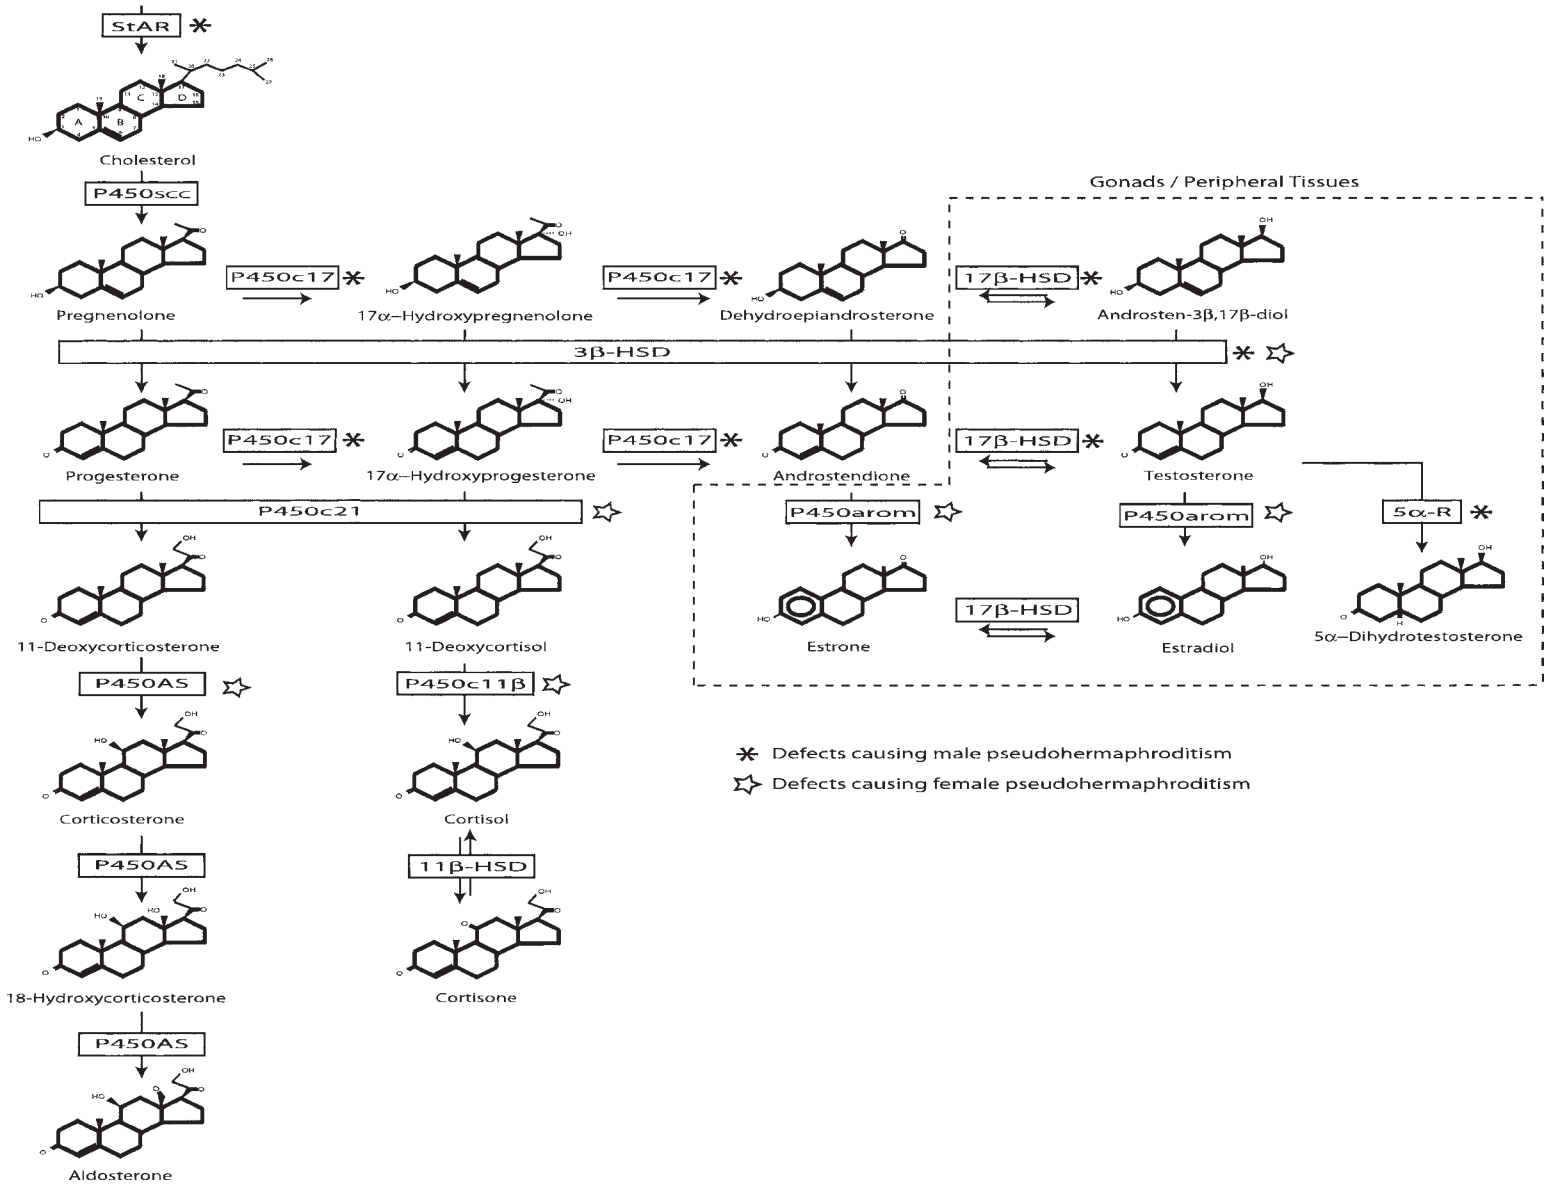

Figure 41-9 Pathway of steroid biosynthesis and defects in steroidogenesis. The first step in steroidogenesis is the transport of cholesterol across the mitochondrial membrane, mediated by the transport protein StAR. The remaining steps in adrenal and gonadal steroidogenesis are accomplished by a number of enzymes. Most are of the P450 cytochrome family. However, 3β-hydroxysteroid dehydrogenase (HSD) and 17β HSD are of the short-chain alcohol dehydrogenase family. Molecular defects that cause male pseudohermaphroditism are designated by asterisks. Defects that cause female pseudohermaphroditism are designated by stars. 3β-HSD deficiency can cause either male or female pseudohermaphroditism. p450arom, p450aromatase; p450AS, p450 aldosterone-synthase; StAR, steroidogenic acute regulatory.

[a]There is evidence for an alternate androgen production pathway during fetal life, resulting in prenatal virilization of affected females.
[b]Testosterone is likely low prenatally, increasing postnatally because of peripheral conversion by nontesticular 3β -HSD isozymes.
AIS, androgen insensitivity syndrome; CG, chorionic gonadotropin; CLAH, congenital lipoid adrenal hyperplasia; DHEA, dehydroepiandrosterone; DHT, dihydrotestosterone; DOC, 11-deoxycorticosterone; LCH, Leydig cell hypoplasia; LH, luteinizing hormone; LHCGR, luteinizing hormonechronic gonadotropin receptor; N, normal.

develop polycystic changes and premature ovarian failure, accompanied by hypergonadotropic hypogonadism.

More than 30 distinct *StAR* mutations, present in the homozygous or compound heterozygous state, have been reported in over 50 patients with CLAH. Most *StAR* mutations are severe at the molecular level (e.g., frameshift mutations caused by small insertions or deletions, nonsense mutations leading to premature termination and splice site mutations), resulting in loss of translation or a severe protein truncation. One mutation common in Japanese and Korean patients (Q258X; 80% of affected alleles) that deletes the final 28 AAs of the StAR protein demonstrates the crucial biological role of the carboxyl terminus, as do missense mutations causing AA substitutions that cluster in exons 5–7 of the gene encoding AAs 169-275 in the carboxyl terminus. A specific mutation that converts arginine 182 to leucine is common in Palestinian Arabs (>70% of affected alleles). This mutation results in disordered protein folding that destroys protein function. Unlike other forms of CAH, heterozygotes have normal steroid responses to ACTH stimulation.

P450 Oxidoreductase (POR)

Normal Function P450 oxidoreductase (POR) is a flavoprotein (a protein containing the coenzyme flavin) that donates electrons to all P450 enzymes, including the steroidogenic enzymes cytochrome $P450_{17\alpha}$ (P450c17), mitochondrial cytochrome P450 steroid 21-hydroxylase (P450c21), and P450aromatase (P450arom) as well as those responsible for the metabolism of retinoic acid, drugs, fatty acids, and prostaglandins. POR may in fact be the sole electron donor for the whole P450 system, which plays an essential role in many developmental processes.

POR is located in the endoplasmic reticulum of steroidogenic cells bound in complex with its coenzymes flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN), and the cytochrome P450 proteins. POR binds nicotinamide adenine dinucleotide phosphate (NADPH), accepts a pair of hydrogens through its FAD moiety, then transfers them to its FMN moiety, finally passing them on one at a time from FMN to one of the cytochrome P450 enzymes, which then uses them in hydroxylation of its substrate(s). The human *POR* gene is located at 7q12 and encodes a 670-AA protein. The N-terminal region is required for anchoring the protein to the endoplasmic reticulum, ensuring proper spatial orientation with the P450 cytochromes and for binding the FMN molecule; the midportion of the protein contains two FAD-binding domains; and the carboxyl terminus contains the NADPH-binding domain. POR proteins from various species show high AA sequence homology, reflecting the importance of the enzyme throughout evolution.

Por is expressed extremely early in mice, at the two-cell stage of development, and knockout of the gene was embryonically lethal from approx E10 onward. No gonadal phenotype was reported, probably because the animals died before gonadogenesis could occur. Detailed ontogeny of human *POR* expression has not yet been reported.

Clinical Features and Molecular Defects Human *POR* gene mutations have been reported in a number of unrelated patients with ambiguous genitalia with or without a skeletal malformation disorder known as Antley-Bixler syndrome. Based on the patterns of disordered steroidogenesis, these cases were formerly thought to have an uncommon form of CAH with apparent combined deficiencies of 17α-hydroxlyase and 21-hydroxylase. Reported genital abnormalities include in females vaginal atresia, clitoromegaly, fusion of labia minora, and hypoplasia of labia majora, and in males ambiguous external genitalia. Some patients die early, reportedly because of respiratory complications. *POR* mutations have generally been reported in the compound heterozygous state, most encoding single AA substitutions in the FAD-binding and NADPH-binding domains. Homozygous mutations associated with consanguinity and simple heterozygous missence mutations have also been reported. However, no human patient has been reported with two null alleles of the *POR* gene suggesting that complete POR deficiency is probably lethal. The mutant POR proteins containing AA substitutions had reduced capacity to oxidize NADPH and reduced catalytic efficiency in vitro. Proteins containing mutations detected in patients with the Antley-Bixler syndrome phenotype had disruption of both the 17α-hydroxylase and 17,20-lyase activities of $P450_{17\alpha}$. In contrast, the mutations detected in a female patient who presented with isolated amenorrhea in the presence of normal genitalia encoded milder AA substitutions that allowed the protein to retain some activity. Overall, the electron transfer properties of the mutant proteins correlated with phenotypes: the severely impaired enzyme was associated with genital and skeletal anomalies, whereas the more mildly dysfunctional enzyme resulted in disordered steroidogenesis without skeletal anomalies.

One striking aspect of the phenotype of affected 46,XX individuals is the combination of prenatal virilization with postnatal androgen deficiency. This is postulated to result from activation of an alternate androgen synthesis pathway in fetal life that does not function after birth, explaining why female virilization does not progress postnatally. Genitalia may be normal in males despite *POR* deficiency, suggesting adequate androgen production via either the typical or the alternate pathway. Transient maternal virilization has been reported during pregnancy in one case, presumably because of failure to aromatize fetal androgens resulting from reduced activity of P450 aromatase, which like other cytochromes P450, requires *POR* for full function.

Beyond the Antley–Bixler clinical syndrome, mild disorders of steroid synthesis are common, and could result from milder mutations in *POR*, which may be more common than is suggested by the low prevalence of Antley-Bixler syndrome. Although the relationship between *POR* mutations and the skeletal anomalies of patients with Antley-Bixler syndrome is unclear, it is of interest that developmental defects of the limb buds were also seen in *Por* knockout mice.

P450 Side-Chain Cleavage Enzyme (P450SCC)

Normal Function P450 side-chain cleavage enzyme (P450scc) is a mixed function oxidase located on the inner mitochondrial membrane in complex with adrenodoxin and adrenodoxin reductase. It is the first enzyme of steroidogenesis, catalyzing the conversion of cholesterol to pregnenolone in 3 distinct biochemical reactions: 20α-hydroxylation, 22-hydroxylation, and side-chain cleavage of the C20-C22 bond. Electrons are transferred from NADPH to adrenodoxin reductase, a membrane-bound flavoprotein cofactor, then to adrenodoxin, a soluble iron/sulfur protein, and finally to P450scc itself.

P450scc is encoded by the 20-kb, 9-exon *CYP11A* gene located at 15 q23-q24. *CYP11A* is expressed in steroidogenic tissues such as adrenal cortex, ovarian granulosa cells, testicular Leydig cells and placenta, and is also expressed in skin, heart and brain. Expression is enhanced by ACTH, gonadotropins, cAMP and SF1 (for which binding sites are located in the *CYP11A* promoter). There is also evidence for insulin-like growth factor (IGF-1)-mediated

stimulation of *Cyp11a* expression in mouse Leydig cells. Expression patterns appear to be tissue- and species-specific, involving the use of alternate promoter sequences.

Mice with targeted disruption of the *Cyp11a1* gene were unable to make steroids, had markedly elevated ACTH and died shortly after birth. Male mice had small testes, epididymi and vas deferens, no prostate or seminal vesicles and feminized external genitalia. Similar to the findings reported in mice with *Star* deletions, the *Cyp11a1*-deleted mice had abnormal lipid deposits in the adrenals and testes, whereas the ovaries of the females were normal.

Clinical Features and Molecular Defects Mutations of *CYP11A* appear to be a much less frequent cause of CLAH than *StAR* defects, probably because total deficiency of this enzyme would completely abolish steroidogenesis, including placental steroidogenesis, causing fetal demise. The clinical phenotype of the 2 reported patients, both Japanese, represents a later-onset version of the clinical effects of *StAR* defects. A 46,XY phenotypic female with mild clitoromegaly presented with life-threatening adrenal insufficiency at 4 yr of age. She had low serum cortisol, with elevated ACTH and plasma renin activity. Her *CYP11A* gene had a heterozygous *de novo* in-frame 6-bp insertion in exon 4, resulting in insertion of two additional AAs into the protein, completely inactivating its enzymatic activity.

The second case involved a 9 mo-old 46,XX girl who presented primarily because of hyperpigmentation. Like the first patient her ACTH and plasma renin activity were markedly elevated, but adrenal steroid levels were normal. She had compound heterozygous mutations of *CYP11A:* a maternally inherited arginine 353 to tryptophan substitution caused marked reduction of P450scc activity, indicating that arginine 353 is crucial for P450scc activity; the second mutation created an alternative splice donor site that resulted in deletion of 61 nucleotides causing a frameshift and partial inactivation of the enzyme. The heterozygous nature of the patients' mutations was consistent with the partial preservation of adrenal steroidogenesis. As in the case of *StAR* mutations, the pathophysiology of the adrenal insufficiency in these cases appears to be progressive cellular damage caused by ACTH-stimulated accumulation of intracellular cholesterol. Thus, although homozygous absence of *CYP11A* is likely incompatible with term gestation, haploinsufficiency of *CYP11A* causes a late-presenting form of CLAH that can be explained by the same two-hit model of CLAH caused by STAR deficiency.

3β-Hydroxysteroid Dehydrogenase (3βHSD)

Normal Function The 3β-hydroxysteroid dehydrogenase (HSD)/Δ^5-Δ^4 isomerases (3β-HSD1 and 3β-HSD2) are two highly homologous, membrane-bound, noncytochrome, nicotinamide adenine dinucleotide (NAD)+-dependent, short chain alcohol dehydrogenase isozymes located in the endocplasmic reticulum and mitochondria. Both have two separate, sequential enzymatic activities—dehydrogenase activity and isomerase activity (conversion of Δ^5-steroids to Δ^4-steroids)—the net result of which is the conversion of 3β-hydroxy-Δ^5-steroids (pregnenolone, 17-hydroxypregnenolone, dehydroepiandrosterone [DHEA] and androstenediol) to the 3-keto-Δ^4-steroids (progesterone, 17α-hydroxyproges terone [17-OHP], Δ^4-androstenedione and testosterone, respectively; Fig. 41-9). NAD phosphate, the product of the rate-limiting dehydrogenase reaction, induces a conformational change around the bound 3-oxo-Δ^5-steroid (the substrate for the second enzymatic step), to activate the isomerase reaction. This bifunctional dimeric enzyme is therefore required for the biosynthesis of all classes of steroid hormones. Deficiency of 3β-HSD activity in steroidogenic tissues impairs both adrenal and gonadal (testicular and ovarian) steroidogenesis and is reported to be the second most common cause of CAH.

There are two highly homologous human genes encoding isoenzymes responsible for 3β-HSD activity—*HSD3B1* and *HSD3B2*, encoding 3β-HSD1 and 3β-HSD2, respectively. There is tight linkage between these genes, located at 1p13.1. *HSD3B1* is the predominant form expressed in placenta, liver, kidney, skin, mammary gland, and prostate. *HSD3B2* encodes the 371-AA 3β-HSD2 isoform expressed almost exclusively in the steroidogenic cells of the adrenals and gonads. The isozymes have 93.5% AA identity and have the same enzymatic activities but 3β-HSD2 has a somewhat lower affinity for its substrates. Specific AA residues are critical for the separate enzymatic activities: His261 for the dehydrogenase activity and Tyr263/264 for the isomerase activity. In bovine adrenocortical cells the enzyme colocalizes with P450scc at the inner mitochodrial membrane, suggesting a possible functional association between the two enzymes. 3β-HSD is detectable in human testicular interstitial cells from 8 wk gestation, consistent with the requirement for Leydig cell testosterone production critical for masculinization. In contrast, as might be expected because fetal ovarian steroid production is not required for female sex differentiation, 3β-HSD expression in ovary is not observed until 28 wk, at which time it is detected in theca and interstitial cells. Expression in the adrenal can be detected from approx 11 wk gestation, declining at midgestation and rising again in the third trimester. In cultured human adrenal cells 3β-HSD mRNA and protein levels are regulated by ACTH and angiotensin II. In mouse Leydig cells 3β-HSD expression is regulated by LH/CG. A putative SF1 binding site is present in the *HSD3B2* promoter, and promoter activity is enhanced by SF1.

Clinical Features and Molecular Defects Deficiency of human 3β-HSD2 impairs adrenal and gonadal steroidogenesis, resulting in variable deficiencies of all classes of steroids—glucorticoids, mineralocorticoids and gonadal steroids—causing CAH and disturbances of external genital development in both males (undermasculinization) and females (virilization).

Affected 46,XY individuals have impairment of internal and external genital masculinization resulting from inadequate fetal testosterone biosynthesis. Individuals with 46,XX karyotype may have mild virilization of the external genitalia presumed to result from ACTH-driven DHEA excess. In severe cases there is also salt-wasting adrenal insufficiency because of reduced synthesis of aldosterone and cortisol. Less severe "late-onset" cases present with more complete masculinization and without salt wasting, reflecting genetic heterogeneity.

Deficiency of 3β-HSD2 in karyotypic females is a less common form of 46,XX pseudohermaphroditism than 21-hydroxylase deficiency (described below), and may be associated with normal or mildly virilized genitalia (mild clitoromegaly with minor posterior labial fusion), not of sufficient severity to suggest genital ambiguity. Androgenization resulting in premature development of pubic and axillary hair and further clitoral enlargement may occur during childhood in response to exaggerated levels of the relatively weak androgen DHEA. Because of low estrogen production, there is no breast enlargement at puberty, either in 46,XX or 46,XY individuals.

The classic hormonal profile in 3β-HSD2 deficiency is markedly increased concentrations of the Δ^5-steroids (pregnenolone, 17-hydroxypregnenolone, and dehydroepiadrosterone) and their metabolites in the serum and urine. However, somewhat confusingly, Δ^4-steroids may also be increased, because of peripheral conversion of Δ^5-steroids to Δ^4-steroids resulting from 3β-HSD1 activity in peripheral tissues. Nevertheless, despite peripheral conversion, the ratio of Δ^5- to Δ^4-steroids and their metabolites is generally elevated. The peripheral Δ^5- to Δ^4-steroid conversion explains the paradoxic finding of ambiguous genitalia in conjunction with apparently normal δ^4-steroid levels in some of these patients. Although postnatal Δ^4-steroid concentrations may be normal, it is probable that testosterone was inadequate in the developing genitalia, and that specific activity of the testicular isozyme, 3β-HSD2, is required to generate adequately high androgen levels during embryogenesis.

More than 30 *HSD3B2* mutations have been identified in families with classic 3β-HSD deficiency. In contrast to mutations affecting StAR and P450scc, the majority have been homozygous missense mutations (associated with consanguinity), however, frameshift, nonsense, deletion and splicing mutations have also been reported. Compound heterozygosity has been reported in a number of classically affected patients, and minor manifestations of simple heterozygosity have been described, including mild overproduction of Δ^5-steroids and mild ovarian dysfunction. One affected female without genital ambiguity was homozygous for a nonsense mutation that produced a truncated protein of 169 AAs, compared with the usual 371 AAs. Compound heterozygosity for a missense mutation and an intronic mutation likely causing a splicing defect was found in another female with normal genitalia, whose affected brother had ambiguous genitalia.

In vitro studies reveal significantly reduced enzyme affinity and specific activity for its steroid substrates, and in some cases for the cofactor NAD+. The finding of a specific abnormality of NAD+ binding associated with substitution of aspartic acid for glycine at position 15 raises the speculation that this region may contribute to the NAD-binding domain of the enzyme. Although absence of salt losing in some undermasculinized males and some virilized females suggests that impairment of enzyme activity may differ between gonads and adrenals, the enzyme is similarly dysfunctional for either of its two main substrates, pregnenolone (adrenal) and DHEA (gonad) in vitro. Thus the absence of salt wasting in some individuals likely results from weak residual enzyme activity sufficient to prevent salt loss, but insufficient to produce the testosterone levels required for male sex differentiation. The clinical heterogeneity (i.e., salt-losing vs nonsalt losing; varying degrees of masculinization) is in part explained by the genetic heterogeneity. Not surprisingly, mutations that completely destroy enzyme activity are associated with a more severe syndrome than are those that allow retention of some enzyme function. No functional 3β-HSD2 is expressed in the adrenals or gonads of patients with the salt-wasting form. In general patients with nonsalt-wasting disease have up to 10% retained enzyme activity, typically associated with missense mutations. However, there is no clear correlation between the molecular defect, enzyme activity and clinical phenotype. Certain mutations appear to destabilize the protein, contributing further to the enzyme deficiency.

17α-Hydroxylase and 17,20-Lyase

Normal Function A single enzyme, P450c17, catalyzes two consecutive oxidation reactions, the 17α-hydroxylase and 17,20-lyase (17,20-desmolase) reactions required for cortisol, androgen and estrogen synthesis. $P450_{17\alpha}$ is encoded by *CYP17*, a 6.6-kb, 8-exon gene located on chromosome 10q24.3. The *CYP17* gene is similar to *CYP21* (encoding the 21-hydroxylase enzyme, described below), and the two may have originated from a common ancestral gene. The two genes have approx 30% homology, with some regions of higher and others of lower homology. The main difference is that *CYP17* has lost two exons present in *CYP21*.

The $P450_{17\alpha}$ complex anchored to the smooth endoplasmic reticulum of steroidogenic cells includes the cytochrome $P450_{17\alpha}$ enzyme itself, and a flavoprotein, POR (described above). $P450_{17\alpha}$ consists of an N-terminal membrane-attachment domain, a steroid-binding domain, a redox-interaction domain, and a heme-binding domain. $P450_{17\alpha}$ accepts electrons from NADPH via POR to catalyze its reactions. The 17α-hydroxylase reaction converts pregnenolone to 17-hydroxypregnenolone and progesterone to 17-hydroxyprogesterone (17-OHP), respectively (Fig. 41-9), the rate-limiting step in androgen biosynthesis. The 17,20-lyase reaction cleaves the C17,20 bond to convert the C21 steroid 17-hydroxypregnenolone to the C19 steroid DHEA and catalyzes the equivalent conversion of 17-OHP to Δ^4-androstenedione, although this latter reaction occurs much more slowly. DHEA and androstenedione are the major precursors of testosterone and estradiol respectively, although because of the enzyme's preference for Δ^5-steroids, most human sex steroids derive from DHEA. Specific AA residues are critical for either the 17α-hydroxylase or the 17,20-lyase activity. Serine phosphorylation of the enzyme increases lyase activity; dephosphorylation eliminates this activity. Other regulatory features may include variation in the ratio of POR to $P450_{17\alpha}$ itself, resulting in alteration of electron transfer to the enzyme.

$P450_{17\alpha}$ is present in human adrenal, testis and ovarian theca cells, but not in granulosa cells or placenta. *CYP17* expression begins between 41 and 44 d after conception in the human fetus, limited to the fetal adrenal zone. *CYP17* is upregulated by ACTH via cAMP and markedly by SF1 for which binding sites are located in the 5′-flanking region of the gene. SF1 regulation may be inhibited by DAX1. Expression is also regulated by the inhibin/activin system in the ovary. The ratio of 17α-hydroxylase to 17,20-lyase activity differs between adrenal and testis and is developmentally regulated at adrenarche, with an increase in the ratio of lyase to hydroxylase activity. The basis for the time- and tissue-specific differential regulation of the enzyme's two main activities is not fully understood.

Clinical Features and Molecular Defects Deficiency of this enzyme is another fairly uncommon cause of male pseudohermaphroditism (but does not cause female pseudohermaphroditism), characterized by deficiency of either or both of this enzyme's 17α-hydroxylase and 17,20-lyase activities. Both enzymatic activities depend on correct steroid binding, but isolated lyase deficiency can occur in association with disturbances of the C-terminal region that normally interacts with POR. Because of fetal androgen deficiency, 46,XY individuals with 17α-hydroxylase deficiency in the adrenals and gonads have female or minimally masculinized external genitalia. In 46,XX individuals the external genitalia are normal; however, there is failure of breast, pubic and axillary hair development at puberty, because of deficiency of both adrenal androgens and ovarian estrogen (*see* Chapter 43). Deficiency of 17α-hydroxylase activity also impairs adrenal cortisol production, and the resultant compensatory ACTH hypersecretion stimulates synthesis of progesterone, 11-deoxycorticosterone (DOC), corticosterone, and 18-hydroxycorticosterone.

The excess of the latter 3 compounds causes salt and water retention, hypertension, and hypokalemia because of their mineralocorticoid activity. Renin activity is therefore suppressed and aldosterone production reduced. Despite impaired cortisol production, evidence of glucocorticoid deficiency is unusual, perhaps because corticosterone has weak glucocorticoid activity.

Isolated deficiency of gonadal 17,20-lyase activity prohibits synthesis of DHEA, Δ^4-androstenedione, testosterone and estradiol. Glucocorticoid and mineralocorticoid production are retained because the enzymatic defect is distal to these pathways. ACTH hyperstimulation in patients with 17α-hydroxylase deficiency results in elevated progesterone; those with isolated deficiency of 17,20-lyase activity of have elevated 17-OHP. hCG stimulation produces an increased ratio of 17-hydroxy-C_{21}-steroids (17-OHP and 17-hydroxypregnenolone) to C_{19}-steroids (DHEA and Δ^4-androstenedione).

A variety of *CYP17* defects have been described, either in a homozygous or compound heterozygous state. These include large deletions/insertions, small deletions and duplications, and single base mutations causing frame shifts, premature termination or AA substitutions. The approx 20 missense mutations are scattered throughout the gene, affecting residues in the membrane-attachment, steroid-binding, POR-interaction, and the heme-binding domains. Mutations in the steroid-binding domain cause combined complete or partial 17α-hydroxylase and 17,20-lyase deficiencies, whereas mutations in the POR-interaction domain cause less severe 17α-hydroxylase deficiency, but complete 17,20-lyase deficiency. A recreated mutant $P450_{17}\alpha$, in which histidine at position 373 was replaced by leucine, failed to bind the heme moiety critical for catalytic activity. Other mutations are located distant from the critical heme-binding region or the active site, suggesting that the enzyme is sensitive to structural change.

Correlation between in vitro enxyme activity and clinical findings indicates that retention of approx 20% of normal 17,20-lyase activity is adequate for some degree of masculinization. One specific mutation, a 4-bp duplication that alters the reading frame of *CYP17*, was found in six Dutch families and six families of Canadian Mennonites, likely because of a founder mutation in the Dutch antecedents of the Mennonites. Individuals heterozygous for a *CYP17* mutation are clinically normal. However, ACTH stimulation may produce increased concentrations of 11-deoxycorticosterone, corticosterone, and 18-hydroxycorticosterone.

17β-Hydroxysteroid Dehydrogenases (17β-HSD)

Normal Function The 17β-hydroxysteroid dehydrogenases (17β-HSDs) (also known as 17β-ketosteroid reductases and as estradiol 17β-dehydrogenases) are NAD+/NADPH-dependent, membrane-bound noncytochrome enzymes. There are at least 11 17β-HSDs encoded by separate genes; only those related to gonadal steroidogenesis are discussed here. These enzymes catalyze the only reversible steps in the steroid biosynthetic pathway—interconversion of Δ^4-androstenedione↔testosterone, DHEA↔Δ^5-androstenediol and estrone↔estradiol by oxidation or reduction of C-18 and C-19 steroids (Fig. 41-9).

The nomenclature of this group of genes and enzymes is daunting: the type 1 enzyme, 17β-HSD I (estradiol-17β dehydrogenase II) is encoded by the *HSD17B1 (*or *EDH17B2)* gene located at 17q 11-12. This locus contains two genes: the active gene is *h17β-HSDII; h17β-HSDI* (*EDH17BP1*), is a pseudogene 89% homologous to the active gene. 17β-HSD I is the isozyme responsible for ovarian 17β-HSD activity. The type 2 isozyme, 17β-HSDII(2), encoded by *HSD17B2*, is responsible for 17β-HSD activity in placenta and endometrium. The testicular (type 3) isozyme, 17β-HSDIII(3), responsible for the final step in testosterone synthesis, reduction of androstenedione to testosterone, is encoded by *HSD17B3 (EDH17B3)*, which shares only 23% sequence homology with the *HSD17B1* and two genes. The finding of small amounts of testosterone in patients with deficiency of the type 3 isozyme suggests that one of the other isozymes can also convert androstenedione to testosterone.

The 17β-HSDs are expressed in a tissue-specific fashion, some being expressed predominantly in estrogenic or androgenic tissues and others more widely, but are not expressed in the adrenals. In addition to ovary, testis and placenta, significant levels of *HSD17B* mRNAs are found in peripheral sites such as uterus, breast, prostate, and adipose tissue. The tissue-specific isozymes have differing specificity for either the oxidative or the reductive reaction. In peripheral locations, 17β-HSDs may play a role in regulating the levels of active androgens and estrogens, by utilizing either their oxidative or reductive functions. The testicular isozyme preferentially utilizes NADPH as its cofactor in reduction of androstendione to testosterone.

Clinical Features and Molecular Defects Deficiency of testicular17β-HSD 3 is the most common defect of androgen production, resulting in impaired testicular conversion of androstenedione to testosterone. 17β-HSD deficiency is inherited in an autosomal-recessive fashion and a number of extensive inbred Arab kindreds with numerous affected individuals have been reported. Although affected 46,XY individuals have female (or partially masculinized) external genitalia, their internal genitalia are well masculinized, with development of epididymis, vas deferens and seminal vesicles. This finding may be because of activity of 17β-HSD isozymes other than 17β-HSD3 converting testis-derived androstenedione to testosterone in the proximity of the Wolffian ducts. In contrast there is insufficient testosterone at the level of the external genital primordia to act as substrate for 5α-reductase conversion to DHT. Ratios of androstenedione to testosterone and estrone to estradiol are elevated in spermatic venous samples and there is impaired conversion of labeled Δ^4-androstenedione to testosterone by testicular tissue in vitro. This defect is restricted to the gonads - the site of expression of 17β-HSD3.

A striking feature of this disorder is the marked virilization that occurs at puberty. Affected 46,XY individuals develop a male body habitus with abundant body and facial hair, enlargement of the testes and penis to normal adult size, and pigmentation and rugation of the labioscrotal folds. Gynecomastia is variably present. Despite having been reared as females during childhood many affected individuals spontaneously adopt the male gender role, with apparently adequate sexual function, but with infertility. These clinical observations correlate with normalization of peripheral and spermatic vein testosterone levels. Part of this effect appears likely to be related to increased LH secretion and Leydig cell hyperplasia, because Δ^4-androstenedione levels remain markedly elevated, indicating persistent enzyme dysfunction. Peripheral testosterone production as a result of extragonadal 17β-HSD activity may also contribute. The phenotype and clinical course of individuals with 17β-HSD deficiency is similar to that of individuals with 5α-reductase deficiency (described below).

Although testosterone and androstenedione levels may vary among patients, the diagnosis of 17β-HSD3 deficiency is suggested by a 10- to 15-fold elevation of the ratios of Δ^4-androstenedione to

testosterone and of estrone to estradiol in the perinatal period, following hCG stimulation in childhood, or after puberty. Because of a secondary increase in 3β-HSD activity, DHEA may be normal or mildly elevated. Glucocorticoid and mineralocorticoid synthesis remain normal because the enzymatic defect is confined to the gonads.

Homozygous or compound heterozygous *HSD17B3* mutations have been identified in >40 patients with 17β-HSD deficiency. The majority are missense mutations resulting in AA substitutions in various regions of the protein; splice site mutations are also common. Phenotypic variability among individuals with the same mutation is well described. Identical mutations have been found within kindreds from widely distant regions of the world, suggesting genetic founder effects. Specific mutations tend to segregate with certain ethnicities, so knowledge of the patient's ethnic background may be helpful in predicting the expected mutation. Like other autosomal-recessive disorders, rates of 17β-HSD deficiency are higher in populations with consanguinity. Compared with a rate of approx 1/140,000 in the Netherlands, Arabs in Gaza have a prevalence of 1/200–300. Homozygosity for a mutation that converts arginine 80 to glutamine was reported in 24 individuals from 9 such extended Arab families. This substitution impairs enzyme activity by increasing the NADPH cofactor binding constant 60-fold. One 46,XY phenotypic female had compound heterozygosity for two distinct AA substitutions and another had compound heterozygosity for a splice acceptor mutation and a missense mutation. When expressed in cultured mammalian cells in vitro the mutant enzymes displayed impaired enzyme activity.

Proteins and Enzymes of Androgen Action*

5α-Reductase

Normal Function The 5α-reductases are microsomal enzymes that catalyze the 5α-reduction of many C19 and C21 steroids, utilizing NADPH as a cofactor. There are two isozymes of 5α-reductase (they share approx 50% AA identity) encoded by separate genes, 5α-reductase 1 by *SRD5A1* at 5p15, and the enzyme important in the context of sexual differentiation, 5α-reductase 2, a 254-AA protein encoded by *SRD5A2* located at 2p23. The genes are structurally similar, with five coding exons each. 5α-reductase 2 mediates the conversion of testosterone to more potent androgen, DHT in androgenic target tissues.

The 5α-reductase isozymes have differential expression patterns: the type 1 isozyme is not detectable in the fetus, but is transiently expressed in newborn scalp and skin and postpubertal skin and is permanently expressed in the liver; the type 2 isozyme is expressed in the liver and in androgen target tissues, including the external genitalia, accessory sex organs, and prostate. It is expressed in the primordia of the prostate and external genitalia before their differentiation, but is not expressed in the Wolffian ducts untill after their differentiation, supporting the contention that testosterone rather than DHT is the critical androgen in this process. Expression is upregulated by androgens, as demonstrated by the marked increase in *SRD5A2* mRNA level in the prostate of castrate animals following testosterone administration. Expression appears to be regulated in the opposite fashion in the liver.

Clinical Features and Molecular Defects Deficiency of 5α-reductase 2 results in an autosomal-recessive form of male pseudohermaphroditism previously referred to as pseudovaginal perineoscrotal hypospadias. Clusters of affected patients have been reported in consanguineous populations in the Dominican Republic, Pakistan, Lebanon and New Guinea. Deficiency of 5α-reductase 2 in the tissues of the fetal external genitalia and urogenital sinus results in inadequate local DHT concentrations. As in other forms of defective androgen production or action, there is subnormal masculinization of these structures. The genital phenotype varies widely among and even within affected kindreds, the most consistent findings being underdevelopment of the penis and prostate. Most patients have ambiguous external genitalia, with testes located in the inguinal region or a bifid scrotum, accompanied by a blind vaginal pouch or urogenital sinus. Because Sertoli cell AMH secretion is normal, Müllerian structures are absent. It is on the basis of these clinical findings, that the requirement for DHT in external genital masculinization was initially inferred. Because differentiation of the gonads and Wolffian ducts depends on high local concentrations of testosterone rather than DHT, the testes, epididymides, vasa deferentia, and seminal vesicles develop normally.

Reduced conversion of testosterone to DHT in target tissues results in a marked increase in testosterone: DHT ratio diagnostic of 5α-reductase 2 deficiency. In normal infants (2 wk–6 mo of age), the testosterone:DHT ratio is 4.8 ± 2.2 (mean ± standard deviation) following stimulation with hCG. Affected infants have markedly increased testosterone:DHT ratios, in the 20–60 range or higher. Serum LH may be mildly increased. 5α-reductase 2 deficiency can be differentiated endocrinologically from 17β-HSD deficiency (with which it shares phenotypic similarity) by the characteristically increased serum androstenedione in the latter condition.

One of the most intriguing and well-documented features of this disorder is the striking virilization, including increased muscularity and deepening of the voice, that occurs at puberty in many affected individuals. In addition, the testes often enlarge, descend and develop Leydig cell hyperplasia, although spermatogenesis is absent or severely impaired. LH is normal or elevated, and testosterone levels increase into the adult male range, whereas DHT remains disproportionately low, but measurable. The testosterone to DHT ratio may be in the range of 30–80 (compared with the normal ratio of approx 9–15 at this age). The pubertal virilization is thought to result from both the high testosterone concentrations and from increased conversion of testosterone to DHT by 5α-reductase 1 in liver and skin. Acne, facial hair, temporal hair recession, and prostatic enlargement do not develop, presumably because these events require higher concentrations of DHT. Gynecomastia does not develop because there is no increase in testicular estrogen production. Many affected individuals initially raised as females, change their gender role to male around the time of puberty.

At least 30 different mutations have been identified throughout the *SRD5A2* gene in affected families from >20 different ethnic groups, ranging from complete *SRD5A2* deletion in a New Guinea kindred, to single base mutations resulting in gene splicing defects, premature termination or AA substitutions (the majority). Deletions, premature termination codons and splice junction defects prevent expression of a functional enzyme. AA substitutions may produce an unstable enzyme or impair binding of testosterone and/or NADPH. Substitutions at the N- or C-terminal ends of the molecule are associated with defective testosterone binding, whereas reduced NADPH binding affinity occurs only with

*These proteins and their associated disorders are discussed in detail in Chapter 44.

C-terminal substitutions. Differences in enzyme stability and affinity for testosterone and NADPH among kindreds reflect the genetic heterogeneity of the enzyme defects, but there is little relationship between the severity of the mutation and phenotype.

Androgen Receptor (AR)

Normal Function The AR is a ligand-activated nuclear transcription factor that mediates the effects of androgens in induction of target gene transcription in androgen-dependent tissues. The 8-exon *AR* gene at Xq11-12 encodes a 110-kDa, 910–919 AA protein consisting of three major functional domains: N-terminal (transcription-regulating), DNA-binding (ZF) and steroid-binding. The AR is expressed in a wide array of genital and nongenital tissues, reflecting its role as a widespread transcription factor. Activation of AR by androgen binding results in interaction of the receptor/ligand complex as a homodimer with androgen response element DNA sequences in the promoter regions of target genes, to regulate their transcription. The exact targets of the AR in genital development remain to be determined, although the AMH receptor appears to be one of them. In external genital tissues, testosterone is converted by 5α-reductase 2 to DHT, which has greater affinity for the AR. Nevertheless, the same molecular events occur following interaction of either testosterone or DHT with AR. The female fetus bears the same AR as the male, thus it is primarily the available concentration of androgens that is the major determinant of genital masculinization. Because Chapter 44 is devoted exclusively to the molecular biology and physiology of the AR, discussion of this important factor in this chapter is limited.

Clinical Features and Molecular Defects Absence or defective function of the AR results in resistance to the effects of androgens, manifest clinically as AIS (previously referred to as testicular feminization), a heterogeneous condition thought to represent the single most common identifiable cause of male pseudohermaphroditism. Affected individuals have normal testicular function, but have variable defects of internal and external genital masculinization, associated with partial retention of Müllerian structures in some cases. In complete AIS (CAIS), which has a prevalence of approx 1/20,000 46,XY births, not only is the phenotype unequivocally female, the labia minora and majora and clitoris may be underdeveloped, suggesting involvement of low levels of androgen action in normal genital development in females.

Infants with CAIS fail to demonstrate the postnatal surge of LH and testosterone seen in normal male infants (and retained in those with partial AIS) and have blunted LH responses to exogenous gonadotropin-releasing hormone. This failure of the normal infantile "mini-puberty" may reflect lack of prenatal "priming" of the hypothalamus due to absence of hypothalamic AR. At puberty, LH, testosterone and DHT increase to supranormal levels and serum estrogen concentrations are also enhanced, as a result of LH-driven testicular estrogen secretion and peripheral aromatization of testosterone. AMH levels are also supranormal during the first year of life and at puberty, a finding that may help to differentiate AIS from intersex conditions caused by testicular dysgenesis, in which AMH is low. Pubertal development in CAIS is entirely female, accompanied by absence of pubic and axillary hair.

Infants with partial forms of AIS (PAIS) have widely varying degrees of genital masculinization and the clinical diagnosis is notoriously difficult, as hormonal profiles are often inconclusive. The diagnosis of PAIS, should be suspected in a 46,XY infant with ambiguous genitalia if the classic elevations of LH and testosterone are present and if the responses of testosterone precursors, testosterone and DHT to exogenous hCG are normal or elevated. In contrast to those with CAIS, infants with PAIS have a vigorous "mini puberty" at approx 6–12 wk of age, as seen in normal male infants, with normal or supranormal LH and testosterone concentrations. Depending on the severity of the androgen resistance, varying degrees of virilization and/or feminization occur at puberty. The prevalence of PAIS is unknown. Demonstration of abnormal androgen binding in cultured genital skin fibroblasts or identification of a mutation in the AR gene of affected individuals confirms the diagnosis, but is generally impractical outside of research institutions. Furthermore, receptor levels in genital skin fibroblasts and androgen binding affinity often correlate poorly with the degree of masculinization and may be falsely negative if the defect falls outside the steroid-binding domain. In addition, in many cases of PAIS complete sequencing of the AR gene fails to reveal a mutation.

Over 300 distinct mutations have been reported in the *AR* genes of hundreds of unrelated individuals with various forms of AIS*. Like the clinical spectrum, the molecular defects are highly heterogeneous. Protein-disrupting defects such as complete and partial gene deletions (rare), small insertions and deletions of a few base pairs, splice junction mutations and premature termination codons, are found in patients with CAIS. Missense mutations causing AA substitutions, the most common mutational type, are found in both CAIS and PAIS. The majority of missense mutations are located in the exons encoding the steroid-binding domain, with all but a few of the remainder reported in the exons encoding the DNA-binding domain. Mutations within the steroid-binding domain cause variable defects of androgen binding—absent, reduced (affinity or capacity or both), or qualitatively abnormal (increased thermolability of binding, ligand dissociation or altered binding specificity). Mutations within the DNA-binding domain typically alter the affinity, capacity or specificity of AR binding to androgen response element DNA sequences, without significant effect on androgen binding. Whether the mutation affects DNA or androgen binding, the final common pathway of AR defects is reduction/loss of ability of the mutant receptor to regulate transcription of androgen-dependent target genes. The *AR* gene appears to be particularly mutation-prone, and approx 25% of mutations arise *de novo.* A few individuals have been identified as having more than one *AR* gene mutation.

Altlhough *AR* mutations can be demonstrated in almost all patients with CAIS, the same is not true for individuals with the clinical diagnosis of PAIS, of whom only approx 1/3 have a detectable alteration of the AR coding sequence. This may in part reflect inaccurate clinical differentiation between PAIS and other causes of male pseudohermaphroditism (e.g., 17α-hydroxylase deficiency) or may represent defects within noncoding regions of the *AR* gene or in cofactors required for normal AR action. Unfortunately, no genotype/phenotype correlation exists for *AR* mutations, and phenotype may differ widely among individuals with the same mutation, even within the same family (Fig. 41-8). Somatic mosaicism for both a mutant and a normal AR may account

* *see* www.mcgill.ca/androgendb.

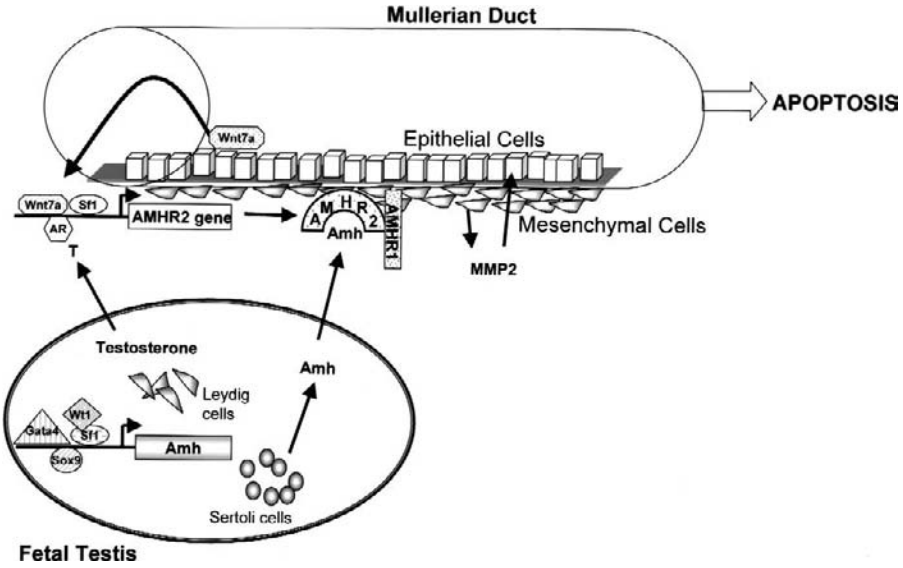

Figure 41-10 Interactions between Amh, its receptor and other transcription factors in induction of Müllerian regression during male embryogenesis. Within the fetal testis, a synergistic combination of transcription factors including Wt1, Sf1, Sox9, and GATA4, stimulates Sertoli cell production of Amh. Meanwhile, Leydig cells produce testosterone, under the stimulatory influence of Sf1 and other factors. The primitive Müllerian ducts consist of epithelial and mesenchmal elements. Epithelial cells secrete Wnt7a—an extracellular signaling molecule. Wnt7a interacts with Sf1 and the androgen receptor (activated by testosterone secreted by Legdig cells) to stimulate transcription of the Amh receptor (Amhr) gene and its expression by the mesenchymal cells surrounding the duct. Binding of Sertoli cell-derived amh to the amhr stimulates apoptosis of the Müllerian epithelium leading to obliteration of the duct lumen, progressing in a cranio-caudal direction down the duct, mediated by a paracrine "death factor" that may be a product of the activated Amhr. This process occurs during weeks 9–11 of human male gestation. Amh, anti-Müllerian hormone; Amhr, anti-Müllerian hormone receptor; AR, androgen receptor; MMP2, matrix metalloprotease 2; Sf1, steroidogenic factor 1; Sox9, Sry-related homeobox gene 9; Wnt7a, wingless-type MMTV integration site family member 7a; Wt1, Wilms tumor 1.

for phenotypic variability in some cases, and may have clinical relevance, because there may be a significant response to exogenous androgens in the cell populations carrying the normal AR. More complete analysis of AR mutations is provided in Chapter 44.

Mediators of Müllerian Duct Regression

Anti-Müllerian Hormone (AMH)

Normal Function Anti-Müllerian hormone (AMH or Müllerian inhibiting substance), produced by testicular Sertoli cells, is a member of the TGF-β family of growth factors that mediates regression of the Müllerian duct structures during normal male embryogenesis. The 5-exon, 2.75-kb *AMH* gene is located on human chromosome 19p13.3-13.2 and encodes a 560-AA glycoprotein that forms a 140-kDa homodimer.

AMH is the first molecular marker after SRY specific for testis (Sertoli cell) differentiation, its expression in developing mouse testis beginning approx 2 d later than that of *Sry*, at approximately E13.5. *Amh* transcription appears to be initiated by Sox9 and subsequently upregulated by coordinated interactions at the *Amh* promoter between Sf1 and Sox9, Wt1, Gata4, and perhaps Dmrt1 (Fig. 41-3B). There is also some evidence suggesting upregulation of *Amh* expression by FSH and downregulation by androgens.

The primary effect of AMH is to induce regression of Müllerian ducts during male sex differentiation (9–11 wk human gestation). These events occur in a paracrine fashion, with AMH secretion from one testis mediating only the regression of the ipsilateral Müllerian duct. Duct regression proceeds in a cranial-to-caudal direction associated with a cranial-to-caudal gradient of AMHR2 (discussed later). This is followed by a wave of apoptosis and accumulation of β-catenin, an adherens junction protein (a factor that mediates cell–cell adhesion) within peri-Müllerian mesenchymal cells. Müllerian epithelial apoptosis seems to be mediated by an extracellular proteinase—matrix metalloproteinase 2—a downstream product of AMH/AMHR2 signalling that functions as a paracrine "death factor" (Fig. 41-10).

AMH is produced by Sertoli cells not only during the critical period of sex differentiation, but also in late gestation, after birth, and even, albeit at a much reduced rate, in adulthood, suggesting that AMH may have physiological roles other than its control of Müllerian duct regression. After puberty, AMH production is downregulated by androgens (this feature is absent in individuals with androgen insensitivity). *AMH* is not expressed prenatally in the ovary. However, low amounts are released into the follicular fluid by mature granulosa cells postnatally and one postulated role of ovarian AMH is to inhibit recruitment of primordial follicles into the pool of growing follicles, via effects on granulosa and theca cells, not on the oocytes themselves. The net effect is to allow for enhanced oocyte maturation prior to selection for ovulation.

As expected from the known function of this protein, male mice with homozygous deletion of *Amh* had normal male reproductive tracts, but also had uteri and oviducts. However, mice with mutations in the *Amh* promoter that affect the regulation of *Amh* transcription had variable phenotypes. Mutation at the Sf1 binding site was associated with reduced *Amh* expression, but expression that was nevertheless adequate to induce Müllerian regression. In contrast, male mice homozygous for a mutant Sox9 binding site did not initiate *Amh* transcription, resulting in complete retention of Müllerian ducts.

Female mice overexpressing human *AMH* had no uteri or fallopian tubes and blind-ending vaginas. The ovaries were devoid of germ cells and underwent reorganization into seminiferous tubule-like structures after birth. Males were also abnormal, with undervirilized external genitalia and impaired Wolffian duct development

associated with undescended testes notable for Leydig cell hypoplasia due to effects of excess AMH on Leydig cell development.

Clinical Features and Molecular Defects Deficiency of AMH or abnormality of its receptor (described below) results in the persistent Müllerian duct syndromes (PMDS type 1 [AMH] and PMDS type 2 [AMHR2]), which are inherited in an autosomal-recessive, male-limited, pattern. Affected karyotypic males have normal male external genitalia, normal testicular histology and normal Wolffian duct differentiation, but have retained and differentiated Müllerian ducts and abnormalities of testicular descent. The typical case is that of a phenotypically normal male infant with unilateral ectopic testis and an inguinal hernia on the contralateral side. One testis descends into the scrotum and the ipsilateral fallopian tube and uterus follow it into the inguinal canal (*hernia uteri inguinalis*), bringing the contralateral testis along (transverse testicular ectopia). The Müllerian structures usually are detected only at the time of surgery for hernia repair. A less common clinical presentation is with bilateral cryptorchidism and inguinal hernias. In this situation the uterus is fixed in the pelvis and the testes are embedded in the broad ligament. These two clinical variants can occur within the same family. Serum testosterone is normal but AMH, which is readily measurable in the serum of normal males until puberty, is reduced. Because of the increased mobility of the testes, they are prone to torsion. In addition, there may be associated aplasia of the epididymis and upper part of the vas deferens. These problems, along with the often difficult task of attempting to relocate the testes, combine to impair fertility in most patients with PMDS.

Because the testes are invariably undescended in PMDS it has been proposed that AMH is involved in the process of human testicular descent. However, this speculation is tempered by the finding of variable AMH levels in boys with simple cryptorchidism and of normal gubernacular development in *Amh*-null mice. Testicular tumors have occasionally been reported.

Diverse *AMH* mutations have been identified in many patients with PMDS with low or undetectable serum AMH. Mutations tend to cluster in the exons encoding the N- and C-terminal regions of the protein (the carboxyl terminus is considered the biologically active region of the molecule) and are of various types including splicing mutations, nonsense mutations and missense mutations, which represent the majority. The fact that AMH molecules containing an AA substitution cannot be detected by standard enzyme-linked immunosorbent assay (ELISA) suggests that even a single AA substitution alters the structure of the protein enough to interfere with binding to the ELISA antibody. In the largest single study of 21 families, most patients were homozygous for *AMH* gene mutations, as the patients derived from consanguineous Arab or Mediterranean communities. About 40% of mutations have been reported in more than one family, but whether these represent a founder effect, or a mutational "hot spot" is not clear.

Anti-Müllerian Hormone Receptor Type 2 (AMHR2)

Normal Function Anti-Müllerian hormone receptor, type 2 (AMHR2) is a membrane-bound serine/threonine kinase similar to those for TGF-β and activin. The 11-exon, 8-kb gene encoding human the 573-AA AMHR2 protein is located at 12q13. Exons 1–3 encode a short signal sequence and the extracellular domain of the receptor, exon 4 encodes most of the transmembrane domain, and exons 5–11 encode the intracellular serine/threonine kinase domains. AMH binding to AMHR2 in target tissues leads to phosphorylation of a TGF-β type I receptor and the resulting intracellular signal cascade that leads to target gene activation and eventually to apoptosis of Müllerian cells. Candidates for the role of the specific type I receptor with which the type 2 receptor interacts include activin receptor-like kinase 2 (ALK2) and the bone morphogenetic protein receptor 1a, also known as ALK3.

Amhr2 is expressed in mesenchymal cells adjacent to the Müllerian ducts during mouse embryogenesis, consistent with the fact that the effects of Amh appear to be via changes in the mesenchyme surrounding the Müllerian ducts which in turn induces apoptosis of the Müllerian epithelium and duct regression. Amh causes regression of the cranial part of the Müllerian duct while it continues to grow caudally, associated with a cranial-to-caudal gradient of Amhr2 protein, followed by a wave of apoptosis spreading caudally along the Müllerian duct. *Amhr2* expression can also be detected in fetal Sertoli and Leydig cells and in fetal and adult granulosa cells. There is evidence that AMH action on Leydig cells causes downregulation of testosterone production. Like AMH itself, the receptor is also expressed postpubertally. Expression of both ligand and receptor in the same cells suggests an autocrine action. AMHR2 expression is enhanced by SF1 (which also regulates expression of AMH itself) and WNT7a and appears to be downregulated by the AR. The receptor may also be regulated by its ligand. Expression of the receptor in female Müllerian mesenchyme does not result in duct regression, because Amh is absent in females prenatally.

Male mice with homozygous deletion of *Amhr2* had a similar internal genital phenotype to those with *Amh* deletion: a complete set of male and female internal ducts. The phenotype of *Amh/Amhr2* double-knockout mutant males was indistinguishable from that of either single mutant.

Clinical Features and Molecular Defects Apart from the fact that serum AMH concentrations are normal or high, the clinical phenotype of patients with *AMHR2* mutations (PMDS type 2) is indistinguishable from that of patients with AMH deficiency (PMDS type 1). Indeed, approx 1/2 of patients with the clinical findings of PMDS have mutations in the ligand and half in the receptor. The single most common mutation in the *AMHR2* gene is a 27-bp deletion in exon 10. Of the more than 20 different reported defects, others include nonsense mutations causing truncation of the receptor to varying degrees, and a variety of missense mutations causing AA substitutions in the extracellular or intracellular domain. As with *AMH* mutations, most *AMHR2* gene mutations are found in the homozygous state and about 1/3 are recurrent, having been reported in more than one family. In a minority of patients, no mutation of either the hormone or its receptor can be detected, and these cases may represent good candidates for analysis of the type 1 AMH receptor required for effective AMHR2 signaling.

Wingless-Type MMTV Integration Site Family Member 7a (WNT7a)

WNT7a is another member of the WNT glycoprotein growth factor/signaling molecule family (page 420) involved in regulation of cell fate and patterning. *Wnt7a* is expressed along the length of the Müllerian epithelium in mice of both sexes but appears to have differing roles in male vs female development. *Wnt7a* is expressed in Müllerian epithelial cells from E12.5-14.5, whereas *Amhr2* is expressed in the mesenchymal cells surrounding the Müllerian ducts at day 14.5. It is hypothesized that the Wnt7a signal from the epithelial cells regulates *Amhr2* expression in the adjacent mesenchyme (Fig. 41-10). *Wnt7a* expression declines following Müllerian duct regression in the male.

Male mice with homozygous deficiency of *Wnt7a* have retained Müllerian ducts, and do not express *Amhr2* in the mesenchyme of the Müllerian ducts. Thus, *Wnt7a* deficiency results in

failure of *Amhr2* expression and therefore failure of Müllerian duct regression in males. In contrast, female *Wnt7a*-deficient mice have defective, though not absent, development of the oviducts and uterus. The human gene is expressed in placenta, kidney, testis, uterus, fetal lung, and fetal and adult brain but no human disease has been reported in association with this gene.

NORMAL AND ABNORMAL FEMALE SEX DIFFERENTIATION Beyond the fact that normal female external genital development requires no estrogen and minimal androgen, little is known about factors directly involved in female sex differentiation. Normal internal reproductive duct development requires persistence and differentiation of the Müllerian ducts into the uterus, upper vagina and fallopian tubes, and regression of the Wolffian ducts. Thus, AMH and testosterone action must be absent. The finding of familial disorders of reproductive tract development in females implies that genetic factors must indeed play a role in either stimulating Müllerian development, or inhibiting its repression. A small amount of information from murine and human studies of *HOX* genes has emerged.

Individuals with 46,XX pseudohermaphroditism develop ovaries but have varying degrees of masculinization of internal and external genital structures. There are far fewer known causes of virilization of a female fetus than there are of undermasculinization of a male fetus. Essentially, disorders of female sex differentiation represent the converse of male pseudohermaphroditism, in general resulting from prenatal exposure to excessive androgen concentrations. In addition to abnormal fetal androgen secretion, maternal androgen excess caused by androgen secreting tumors, drugs or medications with androgenic activity can result in masculinization of the female fetus. These latter problems are not discussed. Abnormalities of Müllerian or vaginal development, such as the Mayer-Rokitansky-Küster-Hauser (MRKH) syndrome, vaginal atresia and Müllerian agenesis, although technically not forms of pseudohermaphroditism because there is no masculinization, are nevertheless significant disorders of female sex differentiation and are also discussed briefly.

Disorders of Female Sex Differentiation Due to Excess Androgen Production The most common cause of excessive fetal androgen production in females is CAH due to deficiency of 21-hydroxylase, 11-hydroxylase, POR (discussed earlier), or 3β-HSD (discussed earlier). A much rarer cause of female pseudohermaphroditism is P450arom deficiency in which fetal virilization results from high levels of testosterone and androstenedione because of the inability of the placenta to convert these precursors to estrogens.

***21-Hydroxylase* (see *Chapter 37 for additional details*)**

Normal Function P450c21 catalyzes the hydroxylation of progesterone to DOC and 17-OHP to 11-deoxycortisol, using POR as a cofactor (Fig. 41-9). P450c21 is a 55-kDa protein encoded by the10-exon *CYP21* gene (*CYP21B or CYP21A2*) located at chromosome 6 p21.3 within approx 2 centimorgans of the human leukocyte antigen complex, with which it has tight linkage. There is a homologous pseudogene, designated *CYP21P* (or *CYP21A*), located nearby, that contains three deleterious mutations: an 8-basepair deletion in exon 3, a T insertion in exon 7, and a stop codon in exon 8.

Clinical Features and Molecular Defects Deficiency of P450c21 is the most common cause of CAH in both males and females. Inheritance is autosomal-recessive and the prevalence of the disorder ranges from 1/15,000 (some white populations) to 1/700 (Yupik Eskimo tribe). Hydroxylation is impaired in the zona fasciculata of the adrenal glands, so that 17-OHP is not converted to 11-deoxycortisol, the immediate precursor of cortisol. Cortisol deficiency leads to a compensatory increase in ACTH secretion that in turn drives the adrenal gland, resulting in overproduction of cortisol precursors, particularly 17-OHP. These steroids are "shunted" down the remaining functional steroidogenic pathway, producing a surfeit of androgens (mainly testosterone) that result in virilization of 46,XX fetuses but have no untoward effect on the male fetus. In more than half of cases, 21-hydroxylase is also deficient in the zona glomerulosa and there is failure of conversion of progesterone to 11-DOC, resulting in deficiency of aldosterone. Shock or death may result from severe salt wasting and accompanying hypovolemia.

There are four major clinical forms of 21-hydroxylase deficiency: salt-wasting (approx 75% of cases), simple virilizing, nonclassic late onset (also called attenuated or acquired), and cryptic (asymptomatic). Only the two most severe forms, those that produce genital ambiguity, are discussed. Female infants with the classic virilizing form of 21-hydroxylase deficiency have masculinization of the genitalia, ranging from limited clitoromegaly and posterior labial fusion in the milder cases, to intermediate phenotypes with labioscrotal fusion, a urogenital sinus and significant clitoral enlargement, to severely virilized genitalia that are indistinguishable from those of a cryptorchid male infant. The gonads are normal ovaries, and Müllerian duct derivatives develop normally, reflecting absence of AMH. Even in the most virilized infants, Wolffian development does not occur, perhaps because of differences in timing of adrenal vs gonadal androgen secretion. Untreated children have penile or clitoral enlargement, premature adrenarche, rapid linear growth and advanced skeletal maturation, ultimately leading to early epiphyseal closure and short stature.

The virilizing form of 21-hydroxylase deficiency is the most likely diagnosis in an infant with genital ambiguity in the presence of 46,XX karyotype and should be suspected in any partially virilized infant in whom gonads cannot be located, either by palpation or by ultrasonography. The presence of a uterus enhances the likelihood of this diagnosis. Increased serum concentrations of 17-OHP are invariably present in infants with enzyme deficiency severe enough to cause virilization; this is accompanied by hyponatremia and hyperkalemia in those with the salt-wasting form. An ACTH stimulation test is not necessary to make this diagnosis in a virilized female infant.

Molecular defects in *CYP21B* have been elucidated in a large number of patients with 21-hydroxylase deficiency. Many appear to have arisen as a result of recombination events between *CYP21B* and its homologous pseudogene, *CYP21P*, and cause either deletion of *CYP21* (approx 20% of salt-wasting cases), or transfer of mutations from the pseudogene to the functional gene. This process, termed "gene conversion," is suggested to account for the predominance of 21-hydroxylase deficiency over other forms of CAH. Single base mutations are also common. In a comprehensive study of 88 families the most common mutation was an A-G change in the second intron affecting mRNA splicing (26%); large deletions occurred in approx 21%; substitution of isoleucine 172 by asparagine was found in 16% and replacement of valine 281 by leucine in 11%. Homozygosity for severe mutations is present in approx 50% of those with classic salt-wasting disease and compound heterozygosity is also common. The clinical and enzymatic findings of such patients reflect the combined effect of mutations in each allele.

In vitro analysis of mutant 21-hydroxylase enzymes has been performed in a number of cases. A mutant containing threonine at

position 428 in place of cysteine has complete loss of enzymatic activity and heme binding. Of note, cysteine 428 is invariant among all P450 enzymes and is thought to be the heme-binding site. Other AA substitutions depress enzyme activity to varying degrees. Weak correlations exist between enzyme activity (phenotype) and mutation (genotype).

11β-Hydroxylase

Normal Function There are two cytochrome P450 isozymes with 11β-hydroxylase activity involved in the latter steps of cortisol and aldosterone production. Regulated by ACTH, P450C11 (P450XIB1) catalyzes the final step in cortisol synthesis, 11β-hydroxylation of 11-deoxycortisol to cortisol in the zona fasciculata of the adrenal gland. The aldosterone synthase isozyme (P450AS, P450aldo, P450cmo, P450XIB2), regulated by the renin-angiotensin system, catalyzes the three-step conversion of 11-DOC to aldosterone (11-hydroxylation, 18-hydroxylation, 18-oxidation) in the zona glomerulosa. Both enzymes use POR as a cofactor. Two genes encode 93% homologous 479- to 503-AA enzymes: the 6.5-kb, 9-exon *CYP11B1* gene localized to 8q22 encodes P450C11; a contiguous gene, *CYP11B2*, located approx 40 kb away within the same chromosomal locus, encodes P450AS. *CYP11B1* and *CYP11B2* are structurally homologous to *CYP11A*, which encodes P450scc (discussed earlier), and the trio represent a subfamily within the P450 superfamily.

Clinical Features and Molecular Defects Deficiency of 11β-hydroxylase results in the second most common form of CAH, accounting for 5–8% of cases, depending on ethnic background. The condition occurs with relatively high frequency in consanguineous families in Saudi Arabia, and in Moroccan and Iranian Jews. Affected 46,XX infants present with variable genital virilization, similar to those with 21-hydroxylase deficiency, in the presence of normal ovaries and female internal genital structures. Some affected females have been so extremely virilized that they have been reared as males, the diagnosis delayed until puberty, when breast development and menses occurred. Driven by increased ACTH levels, 11-deoxycortisol is massively elevated and serum concentrations of 11-DOC, adrenal androgens and testosterone (by conversion from androstenedione) are also increased. The key clinical feature that distinguishes this condition from 21-hydoxylase deficiency is the presence of hypertension, induced by high concentrations of 11-DOC, whose mineralocorticoid activity causes sodium retention, variable hypokalemia and suppression of plasma renin activity. There is minimal correlation between the severity of the virilization and the hypertension. Precocious pseudopuberty and advanced skeletal maturation occur in untreated cases in both sexes.

Mutations in *CYP11B1* include frameshift mutations that delete the enzyme's heme-binding domain and a number of missense mutations. The majority of molecular defects are *de novo* point mutations clustered in exons 6–8 of the gene, suggesting that this region encodes residues critical for enzymatic activity. The relatively high frequency of mutations in this gene is suggested to result from its high number of CpG dinucleotides, a well-recognized mutational "hot spot" in the human genome, rather than from recombination between *CYP11B1* and *CYP11B2*, (as occurs between CYP21 and its adjacent pseudogene). Substitution of arginine by histidine at position 448 is the predominant defect in P450C11 in Moroccan Jews, suggesting a founder effect. This AA is highly conserved and thought to be required for heme binding, which is critical for enzymatic activity.

Aromatase

Normal Function P450arom is a cytochrome P450 enzyme located in the endoplasmic reticulum of estrogen-producing cells. Using POR (described above) as a cofactor, it catalyzes conversion of C19 steroids (androstenedione and testosterone) to C18 estrogens (estradiol, estrone, estriol). Androgens produced by the fetal adrenal gland, then desulfated and aromatized by the placenta are the major source of circulating estrogens during pregnancy. P450arom is encoded by *CYP19*, a 9-exon, 70-kb gene located at chromosome 15q21.1. P450arom is expressed in a wide variety of human tissues, ranging from the preimplantation blastocyst to the placenta, ovarian granulosa and luteal cells, testicular Sertoli and Leydig cells, adipose tissue, brain, muscle, and liver. Expression is regulated in part by the use of tissue-specific alternative promoters; however, the same protein is expressed in all tissues.

Clinical Features and Molecular Defects An apparently rare cause of female pseudohermaphroditism is the inability to convert fetal androgens to estrogens because of lack of placental P450arom activity as a result of mutations in the fetus. In two cases, the mothers developed progressive virilization in the latter part of pregnancy, associated with high androgen and low estrogen concentrations. Despite this, growth of the fetuses and placentas throughout gestation were normal. Following delivery maternal virilization resolved and in vitro assay of the placenta revealed negligible P450arom activity. Absence of maternal virilization in a third case suggested that some P450arom activity was retained.

The affected 46,XX infants had male-appearing or ambiguous external genitalia with marked clitoral enlargement, rugation and fusion of labioscrotal folds, and a single meatus at the base of the phallic structure. The virilization results from placental inability to aromatize DHEA, which is therefore converted to androstenedione and testosterone, leading to massive elevations of the latter. An affected 46,XY infant had normal masculinization.

The two affected 46,XX patients developed features of androgen excess at puberty, associated with ovarian cysts. Clitoral enlargement and facial acne were noted, the result of high adrenal androgens. In addition, the affected individuals had absence of breast development, attributed to deficiency of ovarian P450arom (and therefore low estrogens). Gonadotropins were modestly elevated, accompanied by high testosterone and low estradiol concentrations, which also resulted in delayed skeletal maturation and tall stature. There was also significant osteoporosis in the affected adult male.

The defects in these cases were inherited in an autosomal-recessive manner and there was known parental consanguinity in one case. In the first case, the affected girl was homozygous for a splice junction point mutation that resulted in translation of an abnormal peptide containing an extra 29 AAs. The mutant enzyme retained only a minimal level of activity in vitro. In the second case, the affected individual had compound heterozygosity for two single base mutations that introduced two separate AA substitutions into the enzyme: arginine 435 to cysteine and two residues downstream, cysteine 437 to tyrosine. The mutant enzymes had extremely low activity in the presence of the R435C substitution, and complete absence of activity with the C437Y defect. Cysteine 437 is very highly conserved, and is apparently involved in heme binding, hence the destructive effect of the mutation on enzyme function. In the final case, the mutation introduced a cysteine in place of the highly conserved residue arginine 375, located in a region of the protein that may be involved in anchoring the

enzyme to the cell membrane. The mutant protein expressed in vitro had only 0.2% of the activity of wild-type P450arom. These cases, as well as the single reported case of an estrogen receptor mutation, and the evidence from estrogen receptor -deleted transgenic mice, indicate that contrary to longstanding belief, estrogens are not required for fetal survival.

Disorders of Female Sex Differentiation Affecting Müllerian Structures

Homeobox A 13 (HOXA13) and Related Genes

Normal Function A member of the homeobox family of genes that encode the developmentally important homeodomain proteins, *homeobox A 13* **(***HOXA13*) and related genes, play important roles in the morphogenesis of the terminal part of the gut and urogenital tract and are involved in Müllerian development. *HOXA13* is specifically discussed because in addition to urogenital abnormalities in *Hoxa13*-deficient mice, mutations affecting uterine development have been reported in humans. The human *HOXA13* gene is located within a cluster of at least 8 homeobox genes on chromosome 7, at 7p15-p14.2. Within the protein certain residues and AA motifs are strongly conserved in fish, amphibian, reptile, chicken, and marsupial and placental mammals.

In mice, *Hoxa13* is expressed early in the epithelial cells of tissues of the developing hindgut in a manner that suggests a fundamental role in the epithelial-mesenchymal interaction necessary for tail growth and posterior gut/genitourinary patterning. In the development of the embryonic mouse Müllerian tract *Hoxa9, Hoxa10, Hoxa11, and Hoxa13* are all expressed along the length of the paramesonephric duct. Later in development, expression of *Hoxa13* is localized to the cervical and vaginal tissues. After birth, a spatial *Hox* axis is established, corresponding to the postnatal differentiation of this organ system: *Hoxa9* is expressed in the fallopian tubes, *Hoxa10* in the uterus, *Hoxa11* in the uterus and cervix, and *Hoxa13* in the upper vagina. In the developing mouse genital tubercle, *Hoxa13* is essential for normal expression of *Fgf8* and *Bmp7* in the urethral plate epithelium.

Mice with the semidominant mutation "hypodactyly" (Hd) have a 90-bp deletion within the first exon of *Hoxa13*. Homozygous (Hd/Hd) female mice have profound hypoplasia of the cervix and vaginal cavity, in addition to absence of digits. In male mutant mice, hypospadias occurs as a result of the combined loss of *Fgf8* and *Bmp7* expression in the urethral plate epithelium, as well as the ectopic expression of *noggin* in the flanking mesenchyme. Complete deletion of *Hoxa13* causes more profound defects: *Hoxa13*(–/–) mutant fetuses have agenesis of the caudal portion of the Müllerian ducts, lack development of the presumptive urinary bladder and have premature stenosis of the umbilical arteries, which could account for the lethality of this mutation at midgestation.

Clinical Features and Molecular Defects The hand-foot-uterus or hand-foot-genital syndrome is an autosomal-dominant disorder whose features include limb anomalies (short first metacarpals, small thumbs and great toes, short fifth fingers and fusion or delayed ossification of wrist bones) and disturbances of Müllerian fusion including a partially divided (bicornuate) or completely divided (didelphic) uterus; affected males have hypospadias of variable severity. Heterozygous mutations in *HOXA13* have been found in a number of families with this condition. Such mutations have generally been severe, causing protein truncation that likely eliminates the DNA-binding capacity of the protein. It is of interest that mutations in *HOXA13* have somewhat similar effects to those of another, better characterized, homeobox gene – *SOX9* – which also causes defects in both skeletal and sexual development.

Mayer-Rokitansky-Kuster-Hauser Syndrome (MRKH) Although individuals with the Mayer-Rokitansky-Kuster-Hauser (MRKH) clearly are phenotypic females, there is nevertheless a failure of female sex differentiation of the internal genitalia. Affected girls usually present in their teens with primary amenorrhea despite otherwise normal secondary sexual development. Examination reveals absence or severe hypoplasia of the vagina; uterine agenesis is usual, however, some uterine development (uni- or bicornuate uterus) or occasionally a normal uterus, may be present. The ovaries are normal. There appear to be 2 subtypes of the disorder—the typical (isolated) and atypical forms, frequency being approximately equal. The typical form is characterized by presence of symmetric muscular buds (Müllerian remnants) and normal fallopian tubes. The atypical form has asymmetric aplasia of one or both buds, with or without dysplasia of the fallopian tubes. The atypical form may have associated anomalies including renal defects (agenesis or ectopia in approx 30–50% of patients) and skeletal abnormalities (vertebral malformations; Klippel-Feil anomaly) of variable severity. Laparoscopy is required to distinguish the typical from the atypical form. The most severe form of the disorder, MURCS, includes Müllerian duct aplasia, renal agenesis/ectopia, and **c**ervical **s**omite dysplasia (Klippel-Feil anomaly). Because of these associated anomalies, all girls and women with vaginal atresia should undergo skeletal radiographs and renal/ pelvic ultrasound.

The MRKH syndrome is thought to result from failure of fusion of the lower Müllerian ducts during early embryogenesis. Cases in which there is associated skeletal dysplasia may represent a mesodermal malformation spectrum. The MRKH syndrome occurs in 1 in 4000–5000 females and represents the cause of primary amenorrhea in 15% of cases. Most cases are sporadic, however, a genetic defect likely underlies familial cases (~5%), which have been reported in patterns consistent with sex-limited autosomal-dominant or autosomal-recessive inheritance. Although one study suggested a potential relationship between a heterozygous mutation in the gene encoding galactose-1-phosphate uridyl transferase and vaginal agenesis in about half of patients studied, the data were inconclusive and have not been formally confirmed.

APPROACHES TO DIAGNOSIS

Abnormalities of sex determination and differentiation in infancy require evaluation by an experienced team, including a pediatric endocrinologist, urologist, and geneticist. The principal aims of the diagnostic evaluation are to determine: (1) presence of potentially life-threatening adrenal steroid deficiencies and electrolyte derangements; (2) chromosomal sex; (3) type and functional status of the gonads; and (4) internal genital anatomy.

The history should determine the presence of similarly affected siblings and of consanguinity between parents or of ethnic background in which inbreeding is common (suggestive of autosomal-recessive conditions such steroidogenic enzyme defects and 5α-reductase 2 deficiency). A family history of sudden death in infancy, ambiguous genitalia, lack of pubertal development, amenorrhea or infertility may be found in some cases of CAH. A history in maternal relatives, of genital abnormalities, severe, persistent gynecomastia or infertility suggests an X-linked condition such as androgen insensitivity. Maternal virilization during pregnancy could suggest P450arom deficiency. Clinical examination,

aided by ultrasound and radiographic contrast studies, should examine the following:

1. Location of gonads. Gonads in the inguinal region are highly likely to be testes (ovarian herniation occurs exceptionally rarely), indicating that the infant is probably a genotypic male (or much less likely, another karyotype with presence of *SRY*). If the gonads are impalpable in a partially masculinized infant, ultrasound examination is required to locate the gonads, which may be anywhere from the abdomen to the inguinal ring, and to examine for associated developmental abnormalities of the renal tract.
2. External genital anatomy. Specifically, the size of the phallic structure (stretched penile length, excluding foreskin, and diameter at midshaft) and presence of chordee, location of the urethral meatus, presence of a separate vaginal orifice, size, fusion and rugation of labioscrotal folds, should be carefully documented and the genitalia photographed. Hyperpigmentation of the genitalia is evidence of ACTH excess, due to some form of CAH.
3. Internal genital anatomy. Cystoscopy or voiding cystourethrogram may be required to define the anatomy of the lower urogenital structures, including type of urethra (long, male-type vs short, female-type), presence of a vagina or more rudimentary structure such as a prostatic utricle, and presence/location of vaginal orifice (perineal vs urethral). The longer the urethra, smaller the vaginal structure, and higher its entry to the urethra, the greater the degree of androgenization that occurred *in utero*.
4. Presence or absence of a uterus. Because of exposure to maternal estrogens, the uterus is enlarged and readily detectable by rectal examination or ultrasonography in newborn females. Presence of a uterus reflects absence of AMH effect during gestation, indicating that either the gonads are not testes, or that if testes are present, AMH action was absent at the critical period during gestation (e.g., because of gonadal dysgenesis).
5. Presence of other dysmorphic features or intrauterine growth retardation. These findings may suggest a generalized disturbance of morphogenesis.

Despite careful examination, it is almost impossible to differentiate between many of the disorders of sex determination and differentiation on clinical grounds alone. Detailed laboratory evaluation is important if dealing with an infant with ambiguous genitalia in whom the sex of rearing needs to be determined. Hormone secretion in the immediate postnatal period is dynamic, hormone concentrations changing rapidly over the first few days of life. Therefore, optimally, blood should be drawn within the first 36 h of life for hormone analysis. Primary care institutions should be instructed that for any infant with a concern regarding genital development, 10–15 mL of blood should be drawn immediately and the serum frozen for possible later assay. The following studies should be undertaken without hesitation:

1. Karyotype. In all cases a formal karyotype is required. When specifically requested to do so many laboratories can provide a rapid preliminary karyotype within 48 h.
2. Electrolytes and adrenal steroids. 17-OHP (for 21-hydroxylase deficiency); 11-deoxycortisol (for 11β-hydroxylase deficiency); 17-hydroxypregnenolone and DHEA (for 3β-HSD deficiency), pregnenolone, progesterone, 17-hydroxypregnenolone and 17-OHP (for 17α-hydroxylase deficiency) and in most cases, plasma renin activity, should be measured on the initial blood sample. Other more discriminating steroids can be measured on stored, frozen serum once the karyotype and initial critical values are obtained. Normal electrolyte results in the immediate postnatal period do not exclude CAH, and until definitive results are obtained, the infant should be monitored for development of hyponatremia and hyperkalemia.
3. Testosterone, DHT and testosterone precursors to look for evidence of a defect of testosterone biosynthesis or 5α-reductase 2 deficiency. Serum testosterone is normally high (>200 ng/dl) in cord blood, but plummets to become almost undetectable at the end of the first week of life, rising again from approx 2–3 wk, to peak at approx 8–12 wk of age. It falls again from 12 to 16 wk, finally becoming essentially unmeasurable by 6 mo of age. Steroid analysis should therefore be performed during periods of maximal testicular activity, or, if this is not possible, following testicular stimulation with hCG (gonadal steroids and DHT are measured before, and 24 h after, administration of 1500 IU hCG every other day for three doses). Normal male infants respond with testosterone values >200 ng/dl, often much higher. An increased ratio of testosterone to DHT (>20/1) during periods of active testicular steroidogenesis or following hCG is found in 5α-reductase 2 deficiency. Hormonal profiles found in defects of testosterone biosynthesis and other disorders of sex differentiation are summarized in Table 41-5. Testosterone, DHT, and testosterone precursors are normal or elevated in infants with partial AIS. Infants with CAIS fail to demonstrate the normal postnatal LH/testosterone surge (although this is somewhat moot, because these infants typically do not have ambiguous genitalia).
4. AMH measurement. Serum AMH is low in intersex states associated with defective testis development and is elevated in situations of defective testosterone synthesis or androgen insensitivity, in which Sertoli cells are normal.
5. LH and FSH. LH concentration is increased in LCH and in most infants with PAIS; FSH is increased in those with gonadal dysgenesis.
6. ACTH stimulation test. This is required to evaluate steroidogenic defects that affect the adrenals as well as the gonads (e.g., CLAH, 3β-HSD deficiency, 17α-hydroxylase deficiency). In virilized karyotypic females, an ACTH stimulation test is not required for diagnosis of 21-hydroxylase deficiency, but may aid diagnosis of other forms of CAH by exaggerating precursor steroid levels.
7. Molecular genetic analysis. Analysis of genes such as those encoding the AR, 5α-reductase or 17α-hydroxylase may be helpful particularly in cases in which there is clinical ambiguity. Although expensive, genetic assays are becoming more readily available through specialized laboratories.
8. Gonadal biopsy may be required in cases of suspected gonadal dysgenesis.

Despite a comprehensive work-up many patients with disorders of sexual development remain undiagnosed, reflecting a large number of remaining gaps in understanding the genetics and molecular biology of normal human sex determination and differentiation.

42 Sex Chromosome Disorders

ANDREW R. ZINN

SUMMARY

Sex chromosome disorders have held a special fascination for geneticists and endocrinologists because of the intimate association between the sex chromosomes, germ cells, and sex determination. Molecular studies are beginning to yield explanations for phenotypes associated with sex chromosome abnormalities, such as sex reversal with Yp deletions or Xp duplications, azoospermia with Yq deletions, and short stature in Turner syndrome. Even with completion of the human genome sequence, sex chromosome disorders remain a fertile topic for research in molecular medicine.

Key Words: Azoospermia; gonadal dysgenesis; Klinefelter syndrome; sex chromosome disorders; Turner syndrome; Xp duplications; Yp deletions.

INTRODUCTION

The clinical consequences of sex chromosome abnormalities are best understood by considering four principles. First, sex chromosomes have unique biological functions during gametogenesis and thus infertility is a frequent manifestation of sex chromosome abnormalities. Second, by virtue of their different sex chromosome constitutions, men and women have different copy numbers, or dosage, of X-linked genes. Because a twofold difference in expression of individual genes is sufficient in many cases to perturb mammalian growth and development, special mechanisms have evolved to balance the expression of X-linked genes between the sexes. Third, the Y chromosome has relatively few genes, most of which serve male-specific functions. Thus impaired male sexual development or reproductive capacity is a frequent sequela of various Y chromosome disorders. Last, sex chromosome disorders show extensive genetic and clinical variability, and the common diagnostic entities actually encompass a range of abnormalities. Table 42-1 summarizes the karyotypes, genotypes, and phenotypes associated with the disorders in this chapter.

STRUCTURE AND FUNCTION OF HUMAN SEX CHROMOSOMES

Fig. 42-1 depicts an overview of the human sex chromosomes. The X chromosome is approx 160 million basepairs (Mb) in length. It is estimated to contain approx 1000 genes, encoding a variety of catalytic, structural, and regulatory proteins. Although the Y chromosome is about one-third as large, it contains remarkably fewer genes, numbering only 34 in the Online Mendelian Inheritance in Man database. The Y chromosome is divided into two parts. The approx 30 Mb euchromatic portion encodes all known Y-linked genes. By contrast, the approx 20 Mb heterochromatic portion is made up of just simple repetitive sequences, and it can vary substantially in size among normal men. Because normal females do not have a Y chromosome or any Y-specific gene products, the Y chromosome is often thought to function only in male-specific processes, such as testis formation or spermatogenesis. Indeed, many Y-linked genes are expressed specifically in testis. However, a number of Y-linked genes are expressed in nontesticular tissues and are known to be important in processes that are not male-specific, including viability, growth, and morphogenesis.

Normally the X and Y chromosomes do not recombine except at the tips, where the chromosomes pair during male meiosis. This pairing and recombination may be required for proper chromosome segregation. Genetic markers in these recombining regions do not show sex-linked inheritance; hence the regions are termed "pseudoautosomal". The short arm (p) pseudoautosomal region spans approx 2.6 Mb, within which there are 13 known genes. The long arm (q) pseudoautosomal region is only 0.4 Mb in length and contains only four known genes. As might be expected because males and females both have two copies of the pseudoautosomal regions, genes within these regions do not show any predilection for sex-specific functions.

X INACTIVATION AND DOSAGE COMPENSATION

The X and Y chromosomes began diverging from an ancestral autosome 240–320 $\times 10^6$ yr ago, and over time, most Y-linked genes were lost. As a consequence, males as a rule have only one copy of X-linked genes, whereas females have two. However, this copy number difference is balanced in mammals by transcriptional inactivation of one X chromosome in females, a process termed dosage compensation or X inactivation. X inactivation occurs during early embryogenesis and is irreversible except in oogonia, where the inactive X is reactivated at or before the onset of meiosis. The inactive X chromosome becomes hypermethylated and late-replicating, and in most tissues it condenses into the Barr body, or sex chromatin. The choice of which X undergoes inactivation in each cell of the embryo is normally stochastic, but the inactive state is stably propagated to daughter cells through mitosis. Thus most women are mosaic with respect to which X is inactive in individual cells.

Table 42-1
Summary of Sex Chromosome Disorders[a]

Disorder	*Karyotype*	*Molecular cytogenetics*	*Sexual phenotype*	*Gonads*	*Extragonadal features*	*Molecular defect*
Gene deficiency						
Turner syndrome	45,X and variants		Female	Streak	Short stature, webbed neck, lymphedema, aortic coarctation, cubitus valgus, nonverbal learning disability	Haploinsufficiency of *SHOX* and other X-linked genes
XY gonadal dysgenesis (Swyer syndrome)	46,XY	*SRY* negative in some cases	Female	Streak; risk of gonadoblastoma	Tall stature	*SRY* mutation or deletion in some cases
Azoospermia	46,XY or $^{-}$ 46,XYq^{-}	Yq11.23 deletion	Male	Azoospermia or oligospermia with variable histology	Sometimes short stature	Deletion of *DAZ1*, *USP9Y*, or other spermatogenesis genes
Gene excess						
Klinefelter syndrome	47,XXY		Male	Hyalinized testis; azoospermia	Poor to normal virilization, gynecomastia, long limbs, verbal deficits	Overexpression of *SHOX* and other X-linked genes
Ring X mosaicism	45,X/46,X,r(X)	Ring is *XIST* negative in many severe cases	Female	Streak	Mental retardation, multiple congenital anomalies	Functional disomy of pericentromeric X-linked genes
Dosage sensitive sex reversal	Normal or Xp21.2 duplication		Female	Streak	None	Overexpression of *NROB1* gene
Aberrant gene expression						
XX male	46,XX	*SRY* translocated to X in most cases	Male or hermaphrodite	Testes with azoospermia or ovotestis	Klinefelter-like	Presence of *SRY*, expression modified by X inactivation
Gonadoblastoma	Various	Presence of pericentromeric Y material (*GBY* locus)	Female	Streak + tumor	—	Not known
Nongenic						
Premature ovarian failure associated with X-autosome translocations	46,X,t (Xq;autosome) with breakpoint between Xq13-q26		Female	Ovaries with diminished follicles	None	Failure of meiotic sex chromosome pairing or abnormal X inactivation?

[a]Disorders discussed in this chapter.
DAZ1, deleted in azoospermia; *SRY*, sex-determining region Y gene.

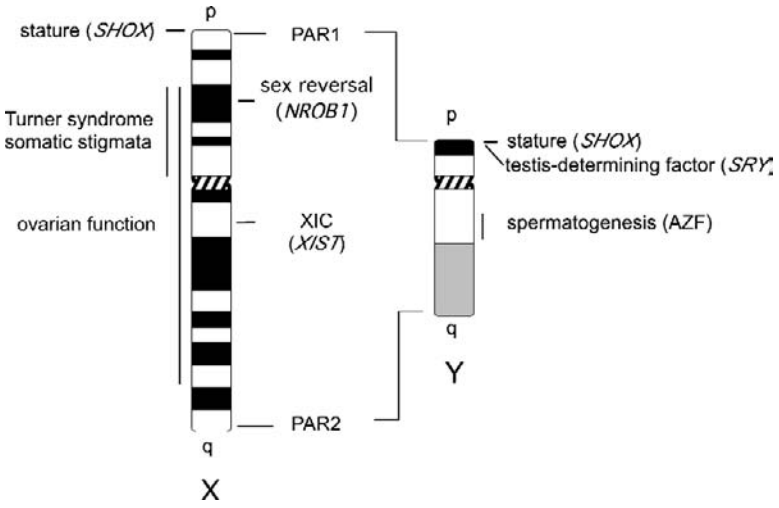

Figure 42-1 Schematic depiction of human sex chromosomes and approximate location of key genetic loci discussed in the text. Symbols for cloned genes in parentheses. p, short arm; q, long arm.

Cytogenetic studies of aberrant X chromosomes pinpointed a *cis*-acting region of the proximal long arm, the X inactivation center (XIC), that is necessary and sufficient for X inactivation. Within the XIC, the X-inactive specific transcript (*XIST*) gene plays a key role in the initiation of X inactivation. *XIST* has a unique pattern of expression; it is transcribed only from the inactive X chromosome. Expression of *XIST* precedes chromatin condensation and transcriptional inactivation of other X-linked genes. The gene is transcribed as a large (>15 kb) polyadenylated, alternatively spliced RNA that does not encode a protein. The *XIST* RNA localizes within the nucleus to the inactive X chromosome, in which it recruits proteins that silence transcription. Once *XIST* is expressed and X inactivation has occurred, the inactive state of the chromosome is maintained by chromatin condensation, histone deacetylation, and DNA methylation.

Although X inactivation occurs on a chromosome-wide scale, some specific genes escape X inactivation, i.e., they are transcribed from both the active and inactive X chromosomes. For some of these genes, Y-linked copies serve instead of X inactivation to equalize their dosage in males and females. For example, all short arm pseudoautosomal genes escape X inactivation and are present on both the X and Y chromosomes. By one estimate, as many as 1/4 of all X-linked genes are expressed from the inactive X in at least some tissue. However, the vast majority of these genes have no functional Y homolog, and the significance of their expression from the inactive X is unclear. The signals that determine whether a gene is subject to X inactivation are unknown, but some genes that escape X inactivation are clustered, suggesting that local chromatin structure is likely to be important.

DISORDERS RESULTING FROM GENE DEFICIENCY

45,X TURNER SYNDROME The loss of one sex chromosome (either an X or Y) results in monosomy X, or Turner syndrome, which occurs once in every 5000 births. The prenatal incidence of monosomy X is much greater: it is estimated that 2% of all human conceptuses are 45,X, but less than 1% of these survive to term. Paradoxically, the life expectancy of 45,X girls is only modestly reduced. Thus persons with Turner syndrome have the mildest manifestations of the underlying genetic disorder, complicating efforts to understand the molecular basis of the phenotype. An adult woman with Turner syndrome is shown in Fig. 42-2. Characteristic features include growth retardation, ovarian failure, and anatomic abnormalities such as webbed neck, aortic coarctation, increased carrying angle of the elbows (cubitus valgus), short 4th metacarpals, lymphedema, and renal anomalies. Other metabolic and endocrine abnormalities associated with Turner syndrome include hypertension, glucose intolerance, and autoimmune thyroid disease. Girls with Turner syndrome are not usually mentally retarded, although they frequently have selective cognitive deficits, notably nonverbal learning disabilities such as impaired mathematical and visual-spatial skills.

The pathophysiology of Turner syndrome is poorly understood. Growth failure is not because of growth hormone deficiency, although administration of pharmacological doses of recombinant human growth hormone during childhood accelerates growth and increases final stature. Ovarian failure is the result of accelerated oocyte atresia, beginning around 6 mo of gestation. By early infancy there are usually few or no remaining germ cells, and infertility is the rule, with rare exceptions. As in postmenopausal women, the loss of germ cells causes fibrosis of the ovaries and subsequent lack of sex steroid production. Most girls with Turner syndrome require hormone replacement therapy to induce puberty and to maintain cyclic menses. Extragonadal abnormalities, including webbed neck, lymphedema of the extremities, and perhaps aortic coarctation, might be caused by defective lymphatic vessel development. Alternatively, coarctation might result from a neural crest cell migratory defect.

The mechanism of chromosome loss in Turner syndrome is not known. Meiotic nondisjunction accounts for only a minority of cases. For this reason, the risk of Turner syndrome is not associated with advanced maternal age, unlike Down syndrome. Most losses occur during mitosis in the early multicellular embryo, resulting in a high incidence of mosaicism, the presence of cells with different chromosomal constitutions within one individual. The additional cell line(s) in Turner syndrome mosaics may contain two or more X chromosomes or a structurally aberrant X chromosome. Embryos mosaic for cells with two or more copies of Xq have greater viability than nonmosaic 45,X embryos.

Mosaicism for a Y-bearing cell line, most often 45,X/46,XY, deserves particular mention. The clinical phenotype depends on the proportion and tissue distribution of XY cells. Bilateral testes

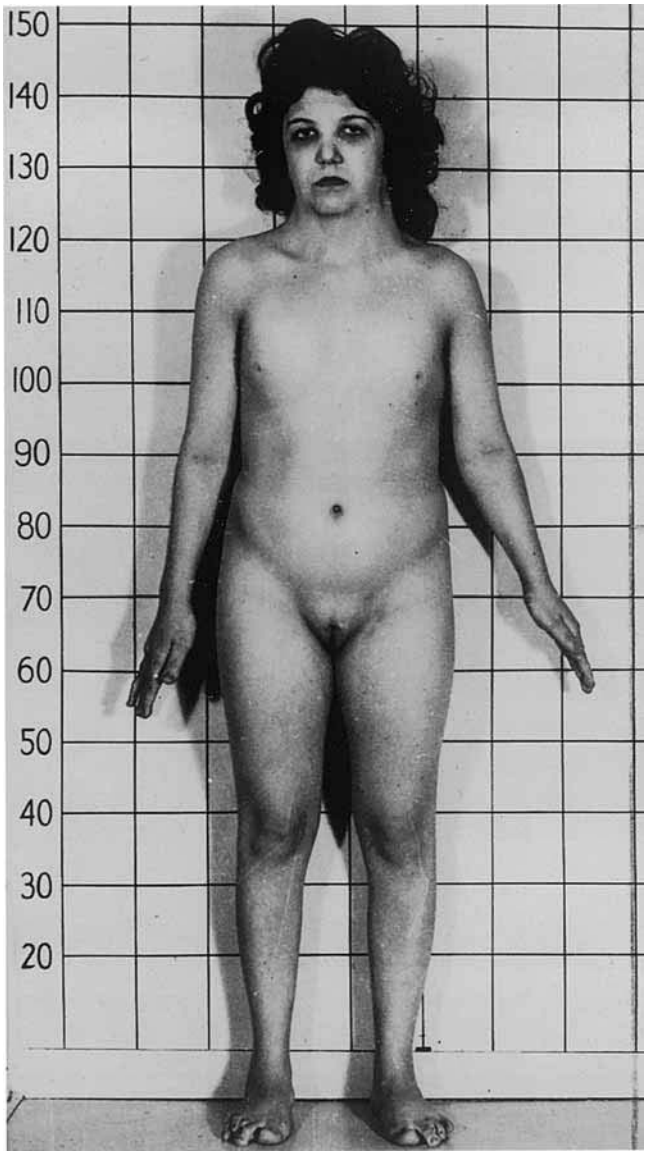

Figure 42-2 Turner syndrome. (Used with permission from Connor JM, Ferguson-Smith MA, Essential Medical Genetics, 4th ed. Blackwell Science.)

may be present, or there may be unilateral testicular tissue with a contralateral streak gonad, a condition termed mixed gonadal dysgenesis (*see* Chapter 41). The presence of Y material in cells of a dysgenetic gonad confers a risk of gonadoblastoma, a malignant tumor. Prophylactic removal of streak gonads or histologically abnormal testes is recommended in any Turner syndrome patient whose karyotype includes Y material. The Y-linked gene predisposing to gonadoblastoma (*GBY*) is distinct from the sex-determining region Y gene (*SRY*), because XY females with deletion or mutation of *SRY* are still at risk. Available evidence suggests that GBY is near the Y centromere, although its precise identity is not known. Some studies using sensitive PCR assays have reported an alarmingly high prevalence of cryptic Y sequences in Turner syndrome. However, in the absence of testes or virilization, the clinical significance of Y material detected only by PCR is uncertain.

The single X chromosome is maternal in approximately three-fourths and paternal in approximately one-fourth of 45,X Turner syndrome patients. The parental origin of the single X does not influence the physical phenotype, i.e., there is no imprinting. One study found that girls with a maternal X had poorer social and behavioral skills than those whose X was paternal; this finding has not been independently replicated.

Several molecular mechanisms contribute to the phenotype of Turner syndrome. The unpaired X chromosome may trigger a meiotic checkpoint to cause oocyte apoptosis. Additionally, two copies of certain X-linked genes may be required for normal oocyte function. Anatomic abnormalities are evidence that proper dosage of genes that escape X-inactivation is also important for extragonadal development. In males, the Y chromosome presumably supplies the second copy of these genes.

The molecular basis of Turner syndrome growth failure is beginning to be understood. Positional cloning identified a single pseudoautosomal gene, *SHOX* (*see* Fig. 42-1), the dosage of which is the major factor in Turner syndrome short stature. The lack of one copy of *SHOX* accounts for approximately two-thirds of the final height deficit in Turner syndrome; the remainder is presumably because of deficiency of other X-linked genes. As predicted, *SHOX* is expressed from both sex chromosomes in males and females. The gene encodes a member of the paired family of homeodomain transcription factors and is expressed in osteogenic cells during limb development. Its transcriptional targets are not yet known.

Point mutations or deletions of *SHOX* are also implicated in three other growth disorders: idiopathic short stature, Leri-Weill dyschondrosteosis, and Langer mesomelic dysplasia, the homozygous form of dyschondrosteosis. Both dyschondrosteosis and Langer mesomelic dysplasia are characterized by disproportionate shortening of the forelimbs and Madelung deformity of the wrist, especially in females. This deformity usually develops around puberty and is rare in normal women but occurs in 2–7% of women with Turner syndrome. Madelung deformity may be because of premature closure of a portion of the radial epiphysis, suggesting that *SHOX* promotes normal bone growth and development by inhibiting epiphyseal closure. Estrogen induces epiphyseal closure, and estrogen deficiency may be the reason that most girls with Turner syndrome do not develop Madelung deformity. Fortunately, hormonal induction of puberty in girls with Turner syndrome does not increase the incidence of Madelung deformity, suggesting that there may be a window of vulnerability during prepubertal skeletal development. *SHOX* deficiency may also cause other Turner syndrome skeletal abnormalities such as cubitus valgus and short 4th metacarpal, which are also seen in some patients with dyschondrosteosis.

46,XY GONADAL DYSGENESIS Classic genetic studies in the fruit fly *Drosophila melanogaster* indicated that phenotypic sex is determined by the numerical ratio of X chromosomes to autosomes; the *Drosophila* Y chromosome is inert regarding sex determination. The same mechanism of sex determination was once thought to occur in mammals. However, with the advent of accurate karyotyping in the late 1950s it became clear that XO and XX humans are female, whereas XY and XXY persons are male. These findings established that the presence or absence of the Y chromosome determines human sex. Studies of rare exceptions, "sex reversed" XX males and XY females, were instrumental in elucidating the molecular basis of sex determination. These studies culminated in 1990 with the discovery of a single Y-linked gene, *SRY*, that directs the differentiation of the bipotential gonad into testes. *SRY* is situated near the pseudoautosomal region of the Y chromosome

short arm. The gene encodes a protein of 204 amino acids belonging to the high-mobility group family of DNA-binding proteins. The *SRY* gene is expressed transiently in the gonadal ridge during embryogenesis and then later in adult testis. *SRY* sits atop a cascade of genes involved in male sex determination and differentiation, such as *AMH*, the gene that encodes anti-Mullerian hormone (*see* Chapter 41).

The discovery of *SRY* clarified the etiology of most XX males and some XY females. The *SRY* gene and adjacent Y chromosome sequences can be detected in most XX males, in whom it is generally translocated to the short arm of the X chromosome. The translocation results from aberrant recombination involving the nearby pseudoautosomal region. The translocated *SRY* gene may become subject to X inactivation, and mosaic *SRY* expression is hypothesized to explain some cases of incomplete sex reversal, for example, XX true hermaphroditism (presence of both testicular and ovarian tissue). Mutations that impair *SRY*'s function are detected in approx 10% of XY females. The approx 90% that remain unexplained are presumably caused by other genetic or environmental factors (*see* Chapter 41).

AZOOSPERMIA Because *SRY* is on the short arm of the Y chromosome, large deletions of the long arm are still compatible with normal male sexual differentiation. However, defects in spermatogenesis are frequently associated with long arm deletions. The most severe defect is azoospermia, the complete absence of sperm in semen, and the Yq locus for this phenotype is denoted azoospermia factor (AZF) (*see* Fig. 42-1). Deletions large enough to detect by karyotype are rare, but molecular analysis reveals microdeletions of Yq in up to 10% of men with otherwise unexplained azoospermia. These deletions arise in many cases by recombination between repeated DNA sequences.

Fifteen genes have been identified in the AZF region, many of these are expressed only in testis. Two AZF genes have been particularly well characterized. Each is present in multiple copies. The RNA binding motif (*RBM*) genes are members of a larger family of RNA-binding proteins. The Y chromosome has at least three functional *RBM* genes and numerous pseudogenes. Most *RBM* sequences are clustered near the AZF region on distal Yq, but related sequences are also present near the centromere on both arms of the Y chromosome. The *RBM* genes are expressed specifically in germ cells and may play a role in RNA splicing or packaging during spermatogenesis. The presence of multiple *RBM* genes makes it difficult to deduce their importance from studying patients with naturally occurring deletions, which typically affect only some of the copies or also affect other genes. For example, one functional *RBM* gene is absent in most normal Japanese men.

The other well-characterized AZF gene is *DAZ1* (deleted in azoospermia). Like *RBM*, *DAZ1* is actually a family of genes that encode a protein with an RNA recognition motif expressed specifically in testis. *DAZ1* is deleted in approx 10% of men with nonobstructive azoospermia or severe oligospermia. Interestingly, the testicular pathology associated with *DAZ1* deletions ranges from the complete absence of germ cells (Sertoli-cell-only syndrome) to meiotic arrest with occasional mature condensed spermatids. In some cases even adjacent seminiferous tubules within the same man show different histological defects.

DISORDERS OWING TO GENE EXCESS

47, XXY KLINEFELTER SYNDROME The most common sex chromosome aneuploidy is Klinefelter syndrome (47,XXY; 46,XY/47,XXY; and variants), with an incidence of approx 1 in 500 male births. The extra X chromosome is usually the result of nondisjunction during paternal or maternal meiosis. The Klinefelter phenotype is variable but characterized by small, firm testes, azoospermia, tall stature, eunuchoid habitus, gynecomastia, and elevated gonadotropin levels (Fig. 42-3). Interestingly, patients with Klinefelter syndrome often have verbal learning disabilities, in contrast to the nonverbal cognitive deficits associated with Turner syndrome. Tall stature in Klinefelter syndrome is at least partially attributable to increased *SHOX* gene dosage and delayed epiphyseal closure. Azoospermia is caused by loss of spermatogenic cells, due either to abnormal gene dosage or to the presence of the unpaired X chromosome at the pachytene stage of meiosis. Hyalinization of seminiferous tubules and impaired Leydig cell testosterone

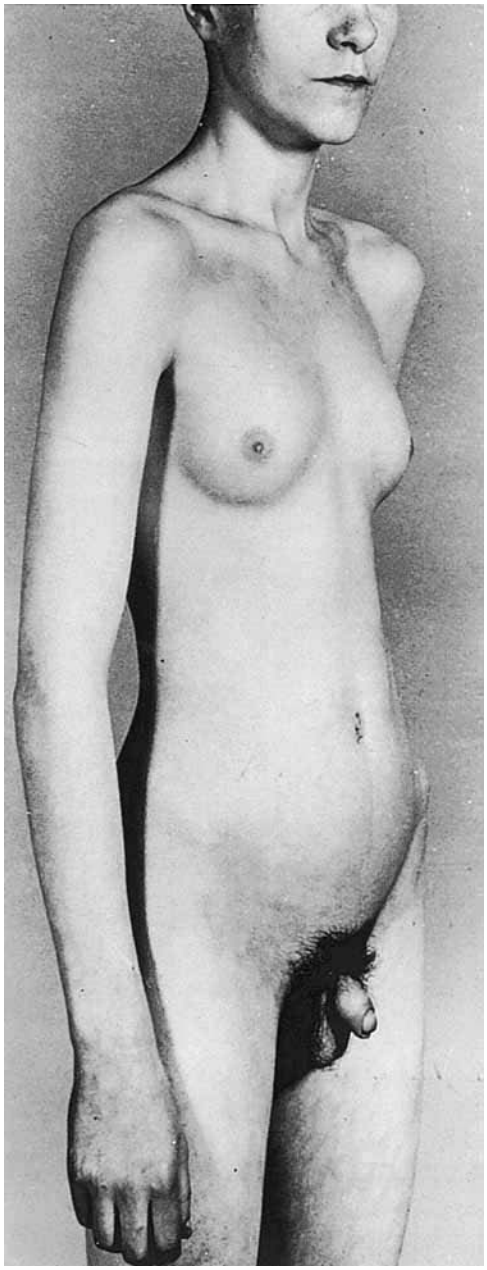

Figure 42-3 Klinefelter syndrome. (Used with permission from Connor JM, Ferguson-Smith MA, Essential Medical Genetics, 4th ed. Essential Medical Genetics, Blackwell Science.)

production follows loss of germ cells. Androgen replacement is the treatment of choice for testosterone deficiency, whereas treatment of severe gynecomastia is surgical.

The phenotype of Klinefelter syndrome is mild compared to disorders involving an extra autosome, for example, trisomy 21 (Down syndrome). The reason is that the additional X chromosome in Klinefelter syndrome is inactivated, whereas the extra chromosome in Down syndrome or other autosomal aneuploidy syndromes remains active. Hence relatively few genes, namely those escaping X inactivation, have an increased functional dosage in Klinefelter syndrome. For this same reason, XXX females are usually normal. Individuals with greater numbers of X chromosomes, for example, 48,XXXY; 48,XXXX; 49,XXXXY; or 49, XXXXX karyotypes, often show more severe abnormalities such as mental retardation or skeletal malformations, even though all but one X chromosome is inactivated. The abnormalities are presumably caused by further increase in the dosage of genes that escape X inactivation. Similar phenotypes have been noted in men with severe Y aneuploidy, for example, 48,XYYY or 49,XYYYY karyotypes, suggesting that the culprit genes are present on both the X and Y chromosomes, for example, *SHOX*.

RING X MOSAICISM Turner syndrome variants involving mosaicism for a ring X chromosome, or 45,X/46,X,r(X) karyotype, are sometimes associated with severe abnormalities such as mental retardation and multiple congenital anomalies. In general, the severity of the phenotype inversely correlates with the size of the ring; larger rings tend to be associated with a milder phenotype. The explanation for the severe phenotypes associated with small rings might lie with X inactivation and dosage compensation. Some small ring X chromosomes either lack the XIC region or fail to express the XIST gene; these rings express some genes that are normally X inactivated. The severe phenotype is probably caused by functional disomy, or expression of both copies, of one or more X-linked genes.

DOSAGE-SENSITIVE SEX REVERSAL A few XY females have been reported with partial duplications of the short arm of the X chromosome that include band Xp21.1 (*see* Fig. 42-1). Because the duplicated X is not inactivated in the absence of a second complete X chromosome, sex reversal is caused by a twofold increase in expression of a gene or genes within the duplication. This locus has been designated dosage-sensitive sex reversal (DSS). Detailed mapping of partially overlapping duplications narrowed the DSS region to a small interval containing *NROB1*, which encodes a member of the nuclear hormone receptor superfamily. Loss-of-function mutations in *NROB1* cause congenital adrenal hypoplasia and hypogonadotropic hypogonadism. Overexpression of *NROB1* in transgenic mice causes XY sex reversal, confirming that *NROB1* is DSS.

EFFECTS OTHER THAN GENE DOSAGE

As mentioned, gonadal failure associated with Turner and Klinefelter syndrome may involve abnormal dosage of X-linked genes that escape inactivation. However, animal studies suggest that the presence of an unpaired X chromosome may cause germ cell apoptosis through a meiotic pachytene checkpoint mechanism. The effect is clearest for spermatogenesis, and explains the observation that men with balanced X-autosome translocations are almost invariably infertile. The presence of an analogous meiotic checkpoint during oogenesis is less certain. For example, gonadal function is usually normal in 47,XXX women. On the other hand, a meiotic checkpoint could explain why some X-autosome translocations are associated with premature ovarian failure. In particular, women whose translocations break within a "critical region" of the X chromosome long arm, Xq13 to Xq26, often have primary or secondary amenorrhea. A number of these translocation breakpoints have been characterized in detail, and most do not appear to disrupt X-linked genes. Although not definitive, these data suggest that the ovarian failure associated with balanced X-autosome translocations is resulting from "nongenic" chromosomal effects such as interference with meiotic pairing or long-range perturbation of X inactivation.

43 Disorders of Pubertal Development

TOMONOBU HASEGAWA

SUMMARY

Puberty is the continuous maturation of growth and development to attain full sexual development and fertility by the hypothalamic–pituitary–gonadal axis and other complex endocrine systems. Although the physiology and molecular mechanism of normal puberty are not completely understood, we have made great progress in the management and treatment of disorders of pubertal development such as precocious puberty and delayed puberty. Moreover, the gene abnormalities of disorders of pubertal disorders have been elucidated one after another. This chapter mainly focuses clinical issues and single gene disorders of disorders of pubertal development.

Key Words: Congenital adrenal hyperplasia; constitutional delay of puberty; delayed puberty; familial male limited precocious puberty; hypergonadotropic hypogonadism; hypogonadotropic hypogonadism; Kallmann syndrome; Klinefelter syndrome; McCune–Albright syndrome; precocious puberty; premature pubarche; premature; puberty; thelarche; Turner syndrome.

INTRODUCTION

Puberty is the continuous maturation of growth and development to attain the full sexual development and fertility by the hypothalamic–pituitary–gonadal axis and other complex endocrine systems. It begins in late childhood and ends in early adulthood. At term, adolescence usually includes psychosocial changes during puberty. This chapter reviews the physiology of normal puberty and the pathophysiology of the disorders of pubertal development.

PHYSIOLOGY OF NORMAL PUBERTY

PHYSICAL CHANGES The physical changes of puberty span a continuum (Tabel 43-1). In girls, the first physical change of puberty is usually breast development (thelarche), although pubic hair growth (pubarche) may be first in a minority of instances. Breast development is followed by pubic hair, then axillary hair growth within 1–2 yr. On an average, menarche occurs 2 yr from the onset of breast development. In boys, the first physical change of puberty is always testicular enlargement. The formal measurement of testicular volume is possible using Prader orchidometer. Testicular volume of 4 mL represents the onset of puberty. Testicular enlargement is followed by penile enlargement and development of pubic hair. The development of axillary and facial hair, acne, and voice change occur in the later half of puberty. Adult testicular volumes and penile dimensions are generally achieved between the ages 14 and 18 yr.

The pubertal growth spurt shows other sexually dimorphic features. Prepubertal growth is similar in both genders; the growth velocity is highest during infancy and decreases to a nadir before the pubertal growth spurt. With respect to the pubertal growth spurt, the later onset of the pubertal growth spurt in boys leads to approx 2 yr difference in peak height velocity, and boys have greater magnitude of peak height velocity.

HORMONAL CHANGES Many dramatic hormonal changes occur during puberty. Two kinds of maturation play central roles. The first involves hypothalamic (gonadotropin releasing hormone; GnRH)–pituitary (gonadotropin)–gonadal axis and the second is the growth hormone (GH)-insulin-like growth factor (IGF)-1 axis. However, it should be emphasized that complex hormonal interactions characterize puberty.

Hypothalamic (GnRH)–Pituitary (Gonadotropin)–Gonadal Axis In the prepubertal stage, the hypothalamic-pituitary-gonadal axis is dormant. Hypothalamus and pituitary activity are thought to be suppressed by neuronal restraint pathways and negative feedback by minute amounts of gonadal steroid hormones. Such neuronal restraint pathways are poorly understood. The signals that control the onset of puberty are also poorly characterized. It appears that the mechanisms responsible for the onset of puberty are extremely complex and likely involve the integration of numerous different signals.

The onset of puberty is heralded by striking increases in luteinizing hormone (LH) secretion at night, manifested by an increase in amplitude and frequency of LH pulses. At least 1 yr before the clinical evidence of the onset of puberty, low serum concentrations of LH during sleep can be measured in serial serum samples obtained every 10–20 min. This sleep-entrained LH secretion is episodic owing to the pulsatile secretion of GnRH (GnRH pulse generator). By contrast, it is difficult to demonstrate the episodic secretion of follicle-stimulating hormone (FSH), as FSH clearance is slower than LH because of its higher sialic acid content. Gonadotropins are responsible for the maturation of the gonads. As pubertal maturation progresses, the amplitude and frequency of gonadotropin pulses increase during the day, in a pattern similar to that seen at night, until the final stage of sexual maturation is reached. In girls, the GnRH pulse generator ultimately establishes the regular cyclic variations of gonadotropins,

Table 43-1
"Tanner Stage" of Development in Secondary Sexual Characteristics

Boys: genital (penis) development
Stage 1 Prepubertal: testes, scrotum, and penis of about same size and proportion as in early childhood
Stage 2 Enlargement of scrotum and testes. Skin of scrotum reddens and changes in texture
Stage 3 Enlargement of penis, at first mainly in length. Further growth of testes and scrotum
Stage 4 Increased size of penis with growth in breadth and development of glans. Testes and scrotum larger; scrotal skin darkened
Stage 5 Genitalia adult in size and shape
Girls: breast development
Stage 1 Prepubertal: elevation of papilla only
Stage 2 Breast bud stage: elevation of breast and papilla as small mound. Enlargement of areola diameter
Stage 3 Further enlargement and elevation of breast and areola, with no separation of their contours
Stage 4 Projection of areola and papilla to form a secondary mound above level of breast
Stage 5 Mature stage: projection of papilla only, related to recession of areola to general contour of breast
Both sexes: pubic hair
Stage 1 Prepubertal: vellus over pubes is not further developed than over abdominal wall
Stage 2 Sparse growth of long, slightly pigmented, downy hair, straight or slightly curled, chiefly at base of penis or along labia
Stage 3 Considerably darker, coarser, and more curled hair. Hair spreads sparsely over junction of pubes
Stage 4 Hair now adult in type, but area covered is still considerably smaller than in adult. No spread to medial surface of thighs
Stage 5 Adult in quantity and type with distribution of horizontal (or classically "feminine" pattern)
Stage 6 Spread up linea alba (male-type pattern)

estrogen, and progesterone of the menstrual cycle. In boys, the same GnRH pulse generator establishes a pattern characterized by relatively constant levels of gonadotropins and testosterone, with minimal diurnal variation.

Undoubtedly, androgen is the principal effector of the physical changes of sexual maturation during puberty in boys, whereas estrogen drives the development of secondary sexual characteristics in girls. Several clinical observations support that estrogen is the main contributor to the process of skeletal maturation, growth spurt, and skeletal mineralization in both genders. First, effective suppression of the rapid skeletal maturation in boys with GnRH-independent precocious puberty requires inhibition of aromatase activity to reduce serum estradiol concentrations, in addition to the use of antiandrogens to interfere with androgen action. Second, patients with aromatase deficiency of both genders exhibit delayed skeletal maturation and have no pubertal growth spurts. Third, patients with complete androgen insensitivity (46,XY) exhibit pubertal growth spurts, suggesting that the growth spurt in boys is not mediated via the androgen receptor, but is instead controlled indirectly via the estrogen receptor, after the conversion of testosterone to estrogen.

GH-IGF-1 Axis The secretion of GH increases two- to three-fold during puberty. GH is produced by the somatotrophs of the anterior pituitary gland and its secretion is regulated mainly by the effects of GH-releasing hormone and somatostatin. Treatment of late pubertal boys with an estrogen receptor antagonist diminished GH secretion, suggesting the critical role of estrogen to increase GH secretion during puberty, even in boys. The mechanism by which estrogen enhances GH secretion is not completely understood.

The effect of GH is primarily through hepatic synthesis of IGF-1. During puberty, increased GH secretion leads to increased serum IGF-1 concentrations, which correlate better with pubertal Tanner stages than chronological age.

Adrenal Androgens Before puberty, the increased secretion of adrenal androgens (dehydroepiandrosterone [DHEA] and dehydroepiandrosterone-sulfate [DHEA-S]) by the zona reticularis ("adrenarche") occurs. Although an adrenal androgen-stimulating factor has been postulated to induce adrenarche, no such factor has been identified. The physiological role of adrenarche has not been elucidated, although adrenal androgen may be functioning in development of scrotal and labial hair. Importantly, the timing of adrenarche and puberty are independent.

Leptin Leptin produced by adipose tissue has a key role in regulating the onset of puberty and/or pubertal development. In boys, serum leptin concentrations increase just before the onset of puberty and decrease after the initiation of puberty. In girls, serum leptin concentrations increase after the onset of puberty, remain stable in midpuberty, and further increase in late puberty. Judging from animal studies, leptin alone is insufficient to induce or promote puberty. However, individuals with congenital leptin deficiency or congenital leptin resistance resulting from mutations of the leptin (*LEP*) or leptin receptor (*LEPR*) genes exhibit hypogonadotropic hypogonadism. Leptin treatment to a 9-yr-old girl with congenital leptin deficiency induced an early pubertal pattern of LH response in GnRH stimulation tests.

THE PATHOPHYSIOLOGY OF DISORDERS OF PUBERTAL DEVELOPMENT

PRECOCIOUS PUBERTY Precocious puberty has been generally defined as the onset of pubertal development before the age of 8 yr in girls and before the age of 9 yr in boys. This definition is arbitrary; however, because of the variation in the age at which puberty begins among different ethnic groups (*see* Table 43-2). In 1999, the Lawson Wilkins Pediatric Endocrine Society proposed new guidelines not to evaluate girls with either breast or pubic hair development after the age of 7 yr in Caucasians and after the age of 6 yr in African Americans. This has not been universally accepted, as some authors believe that the definition of precocious puberty being pubertal development before the age of 8 yr in girls may identify girls with onset of puberty between 6 and 8 yr who may benefit from treatment.

Incomplete (or partial) precocious puberty is isolated manifestations of pubertal development without other signs of puberty such as premature thelarche and premature pubarche (described in Incomplete [or Partial] Precocious Puberty [Variation of Normal Puberty]).

Table 43-2
Mean Age (Years) at the Onset of Development of Breast, Pubic Hair, and Menarche in Different Ethnic Groups

	Breast	*Pubic hair*	*Menarche*
Caucasian	10.3	10.5	12.7
African-American	9.5	9.5	12.1
Mexican-American	9.8	10.3	12.2

Classification Precocious puberty is classified as GnRH-dependent or GnRH-independent. GnRH-dependent precocious puberty is because of the early activation of the normal pubertal hypothalamic–pituitary–gonadal axis. GnRH-gonadotropin activates the gonads leading to increasing gonadal steroid hormone secretion and progressive sexual maturation. Conversely, GnRH-independent precocious puberty is not because of the early activation of normal puberty.

GnRH-dependent precocious puberty is sometimes called gonadotropin-dependent, central, or true precocious puberty. GnRH-independent precocious puberty is also called gonadotropin-independent, peripheral, or pseudoprecocious puberty. The terms "GnRH-dependent" and "GnRH-independent" are employed in this chapter. This terminology is preferred as GnRH is essential for the activation of the gonadotropin–gonadal axis in normal puberty. Furthermore, precocious puberty because of an intracranial human chorionic gonadotropin (hCG)-secreting tumor is definitely GnRH-independent, but gonadotropin dependent and central precocious puberty.

The second classification of precocious puberty is isosexual or heterosexual (contrasexual). "Heterosexual" refers to feminization in boys or virilization in girls. GnRH-dependent precocious puberty is always isosexual by definition, whereas GnRH-independent precocious can be either isosexual or heterosexual.

General Evaluation Evaluation of patients with early pubertal development should always begin with a detailed clinical history. The sequence of sexual developmental changes is most important in differentiating GnRH-dependent and GnRH-independent forms. History should focus on central nervous system (CNS) abnormalities (trauma, infection, neoplasia, irradiation, and so on). Growth charts are indispensable to discern a pattern of rapid linear growth. On physical examination in girls, determining whether maturation is isosexual or heterosexual is critical. In boys, testicular volume should be measured. Any pubertal development without testicular enlargement (less than 3 mL) suggests GnRH-independent precocious puberty. In both sexes, neurological abnormality that suggests CNS disorders should be assessed.

Diagnostic evaluation starts with the assessment of bone age and the measurements of serum gonadotropins, particularly LH. Advanced bone age indicates gonadal steroid hormone action. Sensitive immunometric assays for serum LH such as the immunochemiluminometric assay are widely available. Using such assays, serum LH concentrations are detectable in more than half of children with GnRH-dependent precocious puberty. A random LH more than 0.3 mIU/mL by immunochemiluminometric assay is highly suggestive of GnRH-dependence. By contrast, gonadotropins are undetectable in prepubertal children and children with GnRH-independent precocious puberty. Measurements of estradiol and testosterone should be obtained. Undetectable estradiol, however, does not exclude the absence of precocious puberty, as the detection limits of the current assays are not sufficiently sensitive. Serial measurements of serum LH concentration, usually every 10–20 min, during nocturnal sleep have greater diagnostic power than single random waking measurements. Pulsatile secretion of LH during nocturnal sleep is well illustrated in GnRH-dependent precocious puberty.

Table 43-3
Causes of GnRH-Dependent Precocious Puberty

Idiopathic
CNS disorders
CNS tumors
Hypothalamic hamartoma, astrocytoma, ependymoma, craniopharyngioma, optic glioma, and others
Other CNS lesions
Static encephalopathy (a result of infection, neonatal asphyxia, hypoxia, severe head trauma, and others)
Low-dose cranial radiation
Hydrocephalus
Arachnoid cyst
Maternal uniparental disomy for chromosome 14
Combined GnRH-dependent and GnRH-independent
Treated congenital adrenal hyperplasia
McCune–Albright syndrome, late
Familial male limited precocious puberty, late
Functional ovarian cyst, late

Measurement of both LH and FSH concentrations following a GnRH stimulation test is the standard to differentiate GnRH-dependent from GnRH-independent precocious puberty. LH predominance or a peak LH to FSH ratio >1.0 in the GnRH stimulation test is diagnostic for GnRH dependence in any assays. FSH predominance, however, can be present in the early phase of GnRH-dependent precocious puberty.

Once GnRH-dependent precocious puberty is confirmed, cranial CT and/or MRI is warranted for the CNS disorders (Table 43-3). Additional useful imaging studies are pelvic ultrasonography and MRI. Bilateral ovarian volume more than 2 mL together with large bilateral cysts (>9 mm) suggests GnRH-dependence. A uterine length more than 3.5 cm and a fundus to cervix ratio more than 1.0 indicate estrogen activity.

GnRH-Dependent Precocious Puberty GnRH-dependent precocious puberty is more than 10-fold more frequent in girls than boys, although the reason for this skewed sex ratio is not clear. GnRH-dependent precocious puberty is most often idiopathic in girls, whereas a CNS disorder is demonstrated in 25–75% of boys.

Clinically the sequence of sexual development is preserved. In girls, the first sign is breast development, followed by the appearance of pubic hair, axillary hair, and withdrawal bleeding. In boys, enlargement of testes is the first, although most children do not notice this change. This is followed by enlargement of the penis, the appearance of pubic hair, and facial acne. Erections and nocturnal emissions are not uncommon.

Causes Of cases of GnRH-dependent precocious puberty in girls, two-thirds are idiopathic (Table 43-3). The mechanism of the early activation of GnRH activity in this category is largely unknown.

CNS disorders are well-recognized causes of GnRH-dependent precocious puberty. Precocious puberty with any neurological signs and symptoms, including developmental delay, suggests GnRH-dependence.

Although less common, CNS tumors are important causes of precocious puberty, particularly in girls younger than 6 yr of age

and boys of any age. CNS tumors causing GnRH-dependent precocious puberty are rarely malignant, and can be viewed as causing precocious puberty by one of two distinct mechanisms. First, tumors may act as ectopic GnRH pulse generators that have escaped the normal inhibitory influences exerted in the prepubertal period. Hypothalamic hamartoma is representative of this type of disorder and is the most common CNS lesion associated with precocious puberty. It is more frequently found in boys and the onset is usually before 3 yr of age in girls. The association of gelastic (laughing) episodes or seizures is classic, but rare. Hypothalamic hamartomas are visualized as iso-intense masses on MRI. Histologically, such hamartomas are benign congenital CNS malformations made up of disorganized but otherwise normal neuronal and glial elements. In other instances, tumors may interrupt the normal inhibitory pathways exerted in the prepubertal period. Astrocytomas, ependymomas, craniopharyngiomas, and optic gliomas have all been identified in such cases. The possibility, however, cannot be excluded that focal derangements of the cellular environment in the vicinity of GnRH neurons may be causally related to premature activation of the GnRH pulse generator.

Other CNS lesions are relatively common. Static encephalopathy is a result of infection, neonatal asphyxia, hypoxia, severe head trauma, and other causes during the neonatal period, infancy, or early childhood. These lesions can interrupt the normal tonic inhibitory pathways exerted in the prepubertal period. Cranial radiation has dose-dependent dual effects on hypothalamic–pituitary–gonadal axis. Low doses of cranial radiation (18–24 Gy) may cause precocious puberty. Low-dose cranial radiation has been widely used in the CNS prophylactic treatment of acute lymphoblastic leukemia and has been associated with a downward shift in the distribution of ages at pubertal onset and menarche in girls who have received such treatment. Precocious puberty in girls owing to prior low-dose cranial radiation is increasing in frequency. By contrast, precocious puberty is rare in boys treated in this manner. High doses of cranial radiation (more than 50 Gy to the hypothalamic-pituitary area) may cause gonadotropin deficiency.

The chance of finding CNS disorders in both sexes may be inversely proportional to the age of the child, with the greatest yield in children younger than 4-yr old. Routine MRI is less likely to have positive findings in girls whose pubertal development began after 6 yr of age. In contrast, in a series of 4000 children referred to the National Institutes of Health (NIH), one-third of the girls and more than 90% of the boys had identifiable CNS disorders visible on CT or MRI. This high prevalence of CNS disorders may be biased by the composition of the referral population.

Maternal uniparental disomy for chromosome 14 (UPD14) may cause GnRH-dependent precocious puberty and intrauterine growth retardation. GnRH-dependent precocious puberty in maternal UPD14 results from the loss of the functionally active paternally derived allele. Evidence for a maternal imprinting (paternal expressive) gene(s) on chromosome 14 includes the presence of GnRH-dependent precocious puberty and intrauterine growth retardation in cases with either maternal heterodisomy or isodisomy, and that paternal UPD14 results in a very different phenotype.

Treatment The most important but difficult issue is to determine when treatment is indicated. Treatment goals are to improve adult height and to prevent psychosocial problems, including age-inappropriate treatment. Natural history of GnRH-dependent precocious puberty is the early completion of physical growth and sexual maturation. Despite early acceleration ahead of peers, early epiphyseal fusion usually leads to compromised adult height compared with genetic height potential. Major psychosocial problems are the disruption of familial, educational, and peer relationships, because adults may relate to these children in response to their sexual maturity rather than their chronological age. Some "adolescent" behavior may be exhibited, although sexual behavior such as increased fondling and masturbation are infrequent. Advanced sexual maturity may place these children at increased risk of being sexually abused. Thus, when compromised adult height is highly likely or any psychosocial problems occur, treatment is absolutely required. On the contrary, when compromised adult height is less likely and psychosocial problems do not occur, treatment should be postponed and the child closely observed. Not all children with GnRH-dependent precocious puberty require treatment. Very slowly progressing sexual precocity is possible and may not require treatment. This group can be characterized by the following: the onset age is near 8 yr in girls and 9 yr in boys, and the bone age is less than 2 yr advanced in comparison to chronological age.

The first choice of treatment is long-acting synthetic agonist analogues of GnRH (GnRHa). GnRHa induces "hypogonadism" by the continuous nonpulsatile GnRH action on the pituitary gonadotrophs. The first demonstrable endocrinological change effected by this treatment is reduction in basal and GnRH-stimulated LH and FSH. GnRHa treatment results in suppression of pubertal physical changes, a decrease in growth velocity, and the disappearance of psychosocial problems. The majority of treated girls experience no increase in breast development, and one-third show regression to an earlier Tanner stage. Effects on pubic hair are less predictable, although most children show either no progression or a minor degree of regression. When treated appropriately to prepubertal endocrinological status, the slowing of growth velocity is accompanied by slowing of bone age maturation. Preservation of or increase in adult height can be achieved. The length of time that treatment is continued depends on bone age and estimates of adult height in individual cases. The adult height by GnRHa treatment is higher than predicted height at the start of treatment, but lower than target height and predicted height at the end of treatment. Most studies suggest that the prognosis of adult height is better if bone ages are relatively young at the start of treatment, indicating the importance of early diagnosis and intervention. The combination of GH and GnRHa treatment may improve the prognosis of adult height more than GnRHa treatment alone. Clinical trials addressing this issue are ongoing.

Two major concerns have been raised regarding potential side effects of GnRHa treatment. First, GnRHa treatment may suppress the increase of bone mineral density (BMD), an important feature of normal puberty. Despite this, it has been reported that bone mineral density was not compromised in girls treated with GnRHa for GnRH-dependent precocious puberty who had completed treatment and had subsequently attained a bone age of greater than 14 yr. Second, some have questioned the reversibility of the suppression of pituitary–gonadal axis ("hypogonadism") following cessation of GnRHa treatment. The available data show that pubertal development resumed after withdrawal of treatment. Theoretically, fertility should not be hampered by such treatments, but longitudinal follow-up is necessary.

GnRH-Independent Precocious Puberty GnRH-independent precocious puberty is about one-fifth as common as

Table 43-4
Causes of GnRH-Independent Precocious Puberty

Boys and girls
Late onset congenital adrenal hyperplasia[a]
McCune–Albright syndrome
Peutz–Jeghers syndrome
Adrenal carcinoma associated with Cushing syndrome[a]
Primary hypothyroidism, prolonged and untreated
Iatrogenic
Boys
Testicular disorders
Familial male limited precocious puberty
Leydig cell adenoma
Human chorionic gonadotropin-secreting tumors
Androgen-secreting tumors
Girls
Ovarian disorders
Granulosa cell tumors
Functional ovarian cysts
Other estrogen-secreting tumors

[a]Isosexual in boys but heterosexual in girls.

Table 43-5
Prevalence of Clinical Features of MAS

Clinical findings	*Prevalence (%)*
Fibrous dysplasia	99
Café au lait spots	82
Gonadal abnormalities (boys and girls)	82
Boys: precocious puberty and/or abnormal testes on US or Leydig cell hyperplasia	77
Girls: precocious puberty	78
Thyroid abnormalities (total)	69
Hyperthyroidism	34
Abnormal gland on US only	34
Renal phosphate wasting	49
Growth hormone excess	18
Cushing's syndrome	7
Primary hyperparathyroidism	4
Idiopathic pancreatitis	4

GnRH-dependent forms. This form of precocious puberty is clinically characterized by sexual development of unusual sequence, no history of CNS abnormality, and no rapid linear growth. From an endocrine standpoint, GnRH-independent forms are characterized by increased production of gonadal steroid hormones in the absence of activation of the hypothalamic–pituitary axis (Table 43-4). GnRH-independent precocious puberty includes conditions that mimic the effect of pituitary gonadotropins on gonadal function, such as hCG from germ cell tumor.

Molecular mechanisms underlying two forms of GnRH-independent precocious puberty, McCune–Albright syndrome (MAS) and familial male limited precocious puberty (FMPP), are discussed later.

McCune–Albright Syndrome MAS originally was defined by the clinical triad of precocious puberty, polyostotic fibrous dysplasia of bone, and café au lait spots of skin. It was advocated that MAS' definition should be broader than the triad; fibrous dysplasia plus at least one of the typical hyperfunctioning endocrinopathies and/or café au lait spots. Reasons why a broadening of the definition has been proposed include that although MAS is rare, clinical manifestations vary individually and almost any combination of the clinical features (Table 43-5) is possible. Second, other hyperfunctioning endocrinopathies can be found in association with precocious puberty, including hyperthyroidism, GH excess, Cushing's syndrome, and so on. Third, clinical manifestations other than those within the triad are possible, such as liver dysfunction, idiopathic pancreatitis, and sudden death. Fourth, fibrous dysplasia is not rare and is the most common component of MAS. Fibrous dysplasia can involve a single skeletal site or multiple sites. Fifth, the clinical features of MAS may develop over time. Prevalence of the different clinical features of MAS in the NIH series is summarized in Table 43-5.

Precocious puberty in MAS is GnRH-independent, although the coexistence of GnRH-dependent and GnRH-independent forms is possible in longstanding cases. The prevalence of precocious puberty is less in boys, although that of gonadal abnormalities between boys and girls is similar. In affected girls, the first sign of sexual development is usually vaginal bleeding or spotting. A waxing and waning course of precocious puberty is not uncommon. Ultrasonography and/or MRI scan may reveal ovarian cysts.

The peculiar bone lesion of MAS is fibrous dysplasia. Fibrous dysplasia can occur in any bone, with the common locations being the skull base and proximal femurs. The clinical manifestations can be pain, limp, or pathological fractures. Alternatively, fibrous dysplasia in craniofacial bones can cause a painless lump or facial asymmetry. Radiographs show expansile lesions. Sarcomatous degeneration occurs rarely.

Café au lait spots are usually present at birth or shortly thereafter. These are large and irregular and have serrated outlines, called "coast-of-Maine." Common sites of café au lait spots are the forehead, the neck or upper back, the shoulder and upper arm, the lumbosacral region, and the buttocks, and often limited to half of the body.

Constitutive active mutations of the *GNAS1* gene have been identified in mosaic fashion (somatic mosaicism) in MAS (Fig. 43-1A,B). *GNAS1* encodes the α-subunit of the stimulatory G protein (Gsα), which regulates adenylate cyclase activity. G protein has a key role in intracellular signal transduction of G protein-coupled receptors (GPCR). In these membrane receptors, ligands bind GPCR, activating the adenylate cyclase system, the membrane-bound enzyme that catalyzes the formation of the intracellular second messenger, cAMP.

A heterozygous substitution was identified in exon 8 of the *GNAS1* gene, predicting the replacement of arginine by histidine or cysteine at position 201 of the mature Gsα protein. This substitution causes a marked decrease in the intrinsic GTPase activity of Gsα, prolonging the survival of the active conformation of GTP and resulting in constitutive activation of adenylate cyclase activity. The consequent increased production of cAMP explains the hyperfunctioning of multiple endocrine organs where GPCRs are expressed. Moreover, more mutant allele was expressed than wild type in tissues histologically most affected. This mutation was detected in bone as well as skin lesions.

This somatic mutation may occur very early in gestation leading to prenatal lethality, relatively early in gestation leading to typical MAS because of abnormal monoclonal cell population, or later in life leading to hyperfunction in single endocrine organ. Because these mutations arise somatically, MAS is not inherited.

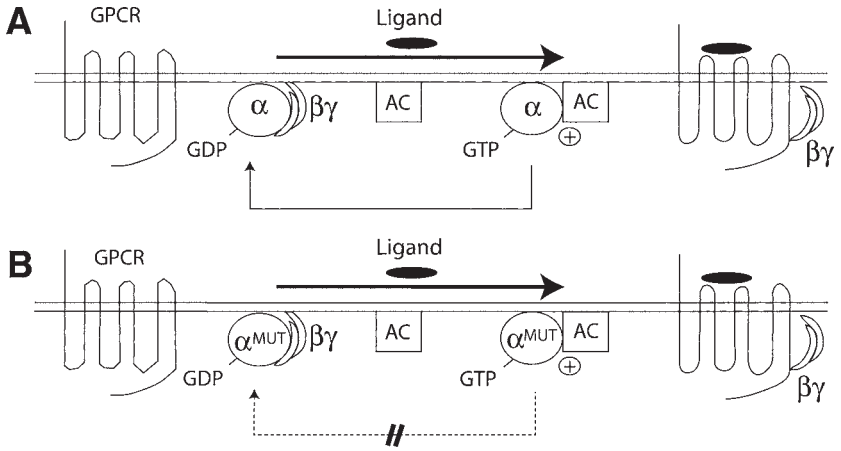

Figure 43-1 In each panel, the parallel horizontal lines are the plasma membrane with the extracellular space above and the intracellular space below. GPCR is G protein-coupled receptor and AC is adenylate cyclase. **(A)** GPCR in normal state. In the basal state, the G protein is a heterotrimer (α-, β-, and γ-subunits) with guanosine diphosphate (GDP) tightly bound to the α-subunit (Gsα). When ligand binds to the G protein-coupled receptor, the interaction with the G proteins leads to the dissociation of guanosine diphosphate, the binding of GTP, and the dissociation of the Gsα and the βγ-subunits. GTP-bound Gsα activates AC activity, inducing signal transduction. Under physiological conditions, the regulation of AC activity is transient and is terminated by the hydrolysis of the bound GTP by the intrinsic GTPase activity of Gsα. The Gsα-subunit with bound GDP reassociates to form the αβγ–heterotrimer. **(B)** GPCR in McCune–Albright syndrome (MAS). In MAS, constitutive active mutations of the *GNAS1* gene encoding Gsα have been identified in mosaic fashion. The mutated Gsα (α^{MUT}) has a markedly reduced intrinsic GTPase activity. When ligand binds GPCR, activated GPCR induces the release of GDP, the binding of GTP, the activation of Gsα, its dissociation from the βγ-dimer, and the regulation of AC activity. Owing to the decreased intrinsic GTPase activity of the Gsα, activated Gsα is not inactivated efficiently, leading to constitutive induction of signal transduction.

For GnRH-independent precocious puberty in MAS, the use of an aromatase inhibitor is recommended. In boys, an aromatase inhibitor is frequently combined with an antiandrogen agent. Surgery is the mainstay for treatment of fibrous dysplasia. Bisphosphonate has been used to reduce pain, although no evidence is available to indicate whether such treatments can alter the natural history of fibrous dysplasia. Effective treatment for café au lait spots has not been described.

Familial Male-Limited Precocious Puberty FMPP or familial testotoxicosis is an autosomal-dominant, male-limited form of GnRH-independent precocious puberty. Histologically, Leydig cell hyperplasia is evident. FMPP is caused by a heterozygous constitutive active mutation of the gene encoding luteinizing hormone/chorionic gonadotropin (CG) receptor (LHCGR).

FMPP is characterized by

1. GnRH-independent precocious puberty.
2. Male-limited autosomal-dominant inheritance.
3. The onset of puberty before 4 yr of age.

A family history of precocious puberty and/or short adult height in males is usually obtained. Sporadic cases have also been reported. Affected males present with progressive virilization by age 4 yr. The clinical hallmark is the relatively mild enlargement of the testes for the degree of virilization. Testosterone production in testes can occur autonomously with increased serum testosterone concentration. Typically, affected subjects have advanced bone maturation, leading to short adult height. Females carrying the same heterozygous mutation are not affected, because activation of both LH and FSH receptors is required for estrogen production in the ovarian follicle.

The molecular pathogenesis of FMPP has been traced to heterozygous constitutively active mutations within specific segments of the LHCGR gene. The LH/CG receptor is a member of the GPCR family. In vitro studies of such mutant receptors have demonstrated marked increase in cAMP production in the absence of ligand, consistent with GnRH-independent precocious puberty. Treatment aims to reduce testosterone production (in the testes) and androgen action (peripherally). Androgen receptor antagonists, aromatase inhibitors, inhibitors of 17, 20 lyase, or the combination of these agents have been employed.

Late-Onset Congenital Adrenal Hyperplasia Congenital adrenal hyperplasia (CAH) is an autosomal-recessive disorder characterized by deficiencies of one of the enzymes critical to normal adrenal steroidogenesis (Chapter 37). In CAH, compensatory hypersecretion of adrenocorticotropic hormone (ACTH) stimulates the increased adrenal androgen. GnRH-independent precocious puberty can be induced by this increased adrenal androgen. Late onset (or nonclassic) CAH should be considered in any child with premature pubarche, especially in association with enlarged penis without testicular enlargement in boys (isosexual precocious puberty) and in association with clitoromegaly in girls (heterosexual precocious puberty). When untreated, rapid linear growth and advanced bone age are likely. Deficiency of 21-hydroxylase accounts for more than 90% of CAH, which is caused by homozygous or compound heterozygous CYP21A2 mutations. Deficiency of 11β-hydroxylase owing to homozygous or compound heterozygous CYP11B1 mutations is less frequent.

hCG-Secreting Tumor hCG-secreting tumors, such as germinoma, hepatoblastoma, or pinealomas, may lead to GnRH-independent isosexual precocious puberty exclusively in boys. Girls with hCG-secreting tumors do not develop precocious puberty, just as girls with LHCGR mutation of FMPP do not. The intracranial pineal region is the common site for germinoma. Mediastinal germinoma producing hCG have been reported in Klinefelter syndrome (described in Klinefelter Syndrome). Precocious puberty caused by hCG secreting tumors is definitely GnRH-independent, as no hypothalamus-pituitary activation is evident. Because of the extensive structural homology of the β-subunits of hCG and LH, at

high levels, hCG can stimulate the production of testosterone via activation of the LH/CG receptor in Leydig cells.

Hormone Production From Tumors in Ovary, Testis, or Adrenal Glands The most common clinical presentation of granulosa cell tumors of the ovary is GnRH-independent precocious puberty, as most can produce estrogen. Granulosa cell tumors are the most common type of ovarian tumors in children, although the etiology is unknown. Tumors are often associated with a large cyst or solid mass, which are easily visible on pelvic ultrasound. They are benign and noninvasive. Surgical resection is the treatment of choice.

Peutz–Jeghers syndrome is an autosomal-dominant disorder characterized by

1. Melanocytic macules of the lips, buccal mucosa, and digits.
2. Multiple gastrointestinal hamartomatous polyps.
3. An increased risk of various neoplasms.

Ovarian theca cell tumors in girls with this syndrome can cause GnRH-independent precocious puberty. Gynecomastia (GnRH-independent heterosexual precocious puberty) has been reported in boys with Peutz–Jeghers syndrome having a testicular sex-cord tumor with increased aromatase activity. The occurrence of ovarian tumors in girls, however, far exceeds that of testicular tumors in boys. A deletion of exons 4 and 5 and an inversion of exons 6 and 7 in an STK11 encoding a widely expressed serine/threonine kinase was found in a large family with Peutz–Jeghers syndrome. Other heterozygous mutations in STK11 have been identified in this disorder. The germline mutations in STK11 in conjunction with somatic mutations in a second allele have been proposed to cause neoplasms in this syndrome.

Leydig cell adenomas are associated with GnRH-independent precocious puberty in boys. In boys with Leydig cell adenomas, signs of isosexual precocious puberty typically appear between the ages of 5 and 9 yr, later than FMPP. The somatic mutation of LHCGR gene in these tumors has been reported. This mutation was proven to be constitutively active, analogous to those seen in FMPP, leading to GnRH-independent precocious puberty. Surgical resection of the tumor results in arrest of pubertal development.

Adrenal carcinoma associated with Cushing syndrome sometimes causes GnRH-independent precocious puberty, whereas adrenal adenoma rarely does. Adrenal carcinoma can produce adrenal androgen, leading to isosexual precocious puberty in boys, and heterosexual precocious puberty in girls. Serum concentrations of DHEA-S, DHEA, and androstenedione are usually elevated. Small adrenal carcinoma is curative by surgery, but larger ones may require additional treatments such as chemotherapy.

Incomplete (or Partial) Precocious Puberty (Variation of Normal Puberty)

PREMATURE THELARCHE Premature thelarche is an isolated breast development without other signs of puberty in girls that commonly occurs in the first 2 yr. Rapid linear growth and advanced bone age are absent. The natural course is spontaneous regression often within 18 mo or no additional change in breast size. Premature thelarche is typically associated with a degree of FSH secretion. If performed, a GnRH stimulation test usually reveals an FSH predominance response. Serum estradiol is undetectable. The prevalence of ovarian microcysts detected by ultrasonography is increased. The etiology of premature thelarche has not been elucidated, although it has been attributed to an increased sensitivity of the breast tissue to estrogen. Careful follow-up for the appearance of other pubertal signs and linear growth is indicated. Premature thelarche can develop to GnRH-dependent precocious puberty in approx 10–15% of cases.

PREMATURE PUBARCHE Premature pubarche is the isolated development of pubic hair, which is usually a benign condition resulting from early adrenarche. A report of the characteristics of 171 subjects with premature pubarche included abnormalities of steroidogenesis (late-onset 21-hydroxylase deficiency, and so on) in 12% of patients as diagnosed by ACTH stimulation tests. Late-onset CAH should, therefore, be considered in any child with premature pubarche. Premature pubarche must be followed closely to monitor for developing GnRH-dependent precocious puberty. Some girls with premature pubarche may develop functional hyperandrogenism in the midteenage years associated with polycystic ovarian syndrome.

DELAYED PUBERTY Delayed puberty is defined as the failure to mature sexually at an appropriate age. Both delayed onset of puberty and failure to complete pubertal development are considered as delayed puberty. In the United States, the ages of 12 or 13 yr in girls and 14 yr in boys serve as practical guidelines to determine the need for evaluation for delayed onset of puberty. In girls, if more than 5 yr have elapsed between the beginning of breast development and menarche, failure of complete pubertal development is considered. In boys, 3–4 yr are normal to complete pubertal development.

Classification Delayed puberty is classified as hypogonadotropic (or secondary) hypogonadism, hypergonadotropic (or primary) hypogonadism, and constitutional delay of puberty. Hypogonadotropic hypogonadism is failure of maturation of hypothalamic-pituitary axis, which is the stimulation signal for the gonads. Hypergonadotropic hypogonadism is the failure of gonads to respond to hypothalamic-pituitary stimulation. Constitutional delay of puberty is delayed maturation of hypothalamic-pituitary–gonadal axis (variation of normal puberty).

General Evaluation Evaluation of patients with delayed pubertal development begins with a detailed clinical history of the onset and pattern of puberty. Recording growth charts (heights and weights) throughout childhood is mandatory. Consistent growth delay (short stature) suggests constitutional delay of puberty. A history of CNS tumors and their treatment, ability to smell, hypopituitarisim, any medication causing hyperprolactinemia as well as general medical history is relevant in both genders. Past history should be focused on cryptorchidism, hypospadias, or micropenis in boys and coarctation of the aorta in girls. Family history is important such as growth, onset and patterns of puberty, infertility, and ability to smell. A family history of delayed onset of puberty suggests constitutional delay of puberty. Physical examination starts with measurements of height, weight, upper–lower segment ratio, and arm span. The evaluation of Tanner stage as well as pubertal development should be performed. In boys, testicular size must be measured. Careful general examination is important to determine whether any major or minor anomalies are present. Neurological examination including the ability to smell should be done routinely.

The initial diagnostic evaluation usually involves the assessment of bone age and measurements of basal serum LH, FSH, and gonadal steroid hormones (testosterone in boys and estradiol in girls). A bone age more than 13.5 yr in boys or 11.5 yr in girls

suggests an active hypothalamic-pituitary axis. Very high concentrations of serum LH and FSH with low gonadal steroid hormones indicate hypergonadotropic hypogonadism. In such cases, a GnRH stimulation test is unnecessary as the hyper response in hypergonadotropic hypogonadism can be predicted by high basal gonadotropins. The difficult task is the differentiation between hypogonadotropic hypogonadism and constitutional delay of puberty. In prepubertal ages, neither basal gonadotropins nor gonadal steroid hormones can differentiate between the two. It should be noted that gonadotropin responses following GnRH stimulation are seldom helpful. GnRH stimulation tests yield overlapping responses that do not permit the differentiation of hypogonadotropic hypogonadism and constitutional delay of puberty. In boys, a hCG stimulation test may provoke a similar response in both hypogonadotropic hypogonadism and constitutional delay of puberty. Serial measurements of serum LH during nocturnal sleep may reveal pulsatile patterns suggestive of puberty, but this is not useful to differentiate hypogonadotropic hypogonadism from constitutional delay of puberty at prepubertal ages.

Once hypogonadotropic hypogonadism is confirmed, cranial CT and/or MRI is warranted for exclusion of CNS disorders (Table 43-6). MRI readily visualizes olfactory bulbs in healthy children even in neonates. Olfactometry or an intravenous olfactory stimulation test may be required to reveal hyposmia.

Hypogonadotropic Hypogonadism Hypogonadotropic hypogonadism refers to the deficiency of pulsatile release of gonadotropins, which may result from a variety of hypothalamic and pituitary disorders. In the presence of a hypothalamic defect, or absence of GnRH-secreting neurons, failure of GnRH secretion results in a lack of stimulation of pituitary gonadotrophs. In contrast, pituitary disorders, such as tumors or hypophysitis, cause direct failure of pituitary gonadotropin secretion. In practice, it is not uncommon to encounter difficulty in determining whether the origin of hypogonadotropic hypogonadism is hypothalamic or pituitary.

Causes No human GnRH deficiency owing to GNRH mutation has been reported, although a mouse *Gnrh* mutation (hpg mouse) exists (Table 43-6). Molecular analysis of the hpg mouse revealed a deletion in the hpg genome of at least 33.5 kb removing the two exons of the *Gnrh* gene. This deletion resulted in a transcriptionally active gene that leads to the synthesis of a truncated GnRH protein and a hypogonadotropic hypogonadism in homozygous state.

GnRH resistance owing to homozygous or compound heterozygous mutations in the GnRH receptor gene has been described in up to 20% of patients with "idiopathic" hypogonadotropic hypogonadism. The clinical features of GnRH receptor gene mutations are variable. Male patients may have prepubertal-sized or adult-sized testes. All female patients had primary amenorrhea, but showed no or Tanner stage III breast development. In one female patient, pulsatile administration of GnRH induced ovulation and allowed pregnancy. Kallmann's syndrome is discussed later.

One human LHβ deficiency resulting from LHB gene mutation has been reported. The affected individual had delayed puberty and arrested spermatogenesis. Laboratory data showed a high serum concentration of immunoreactive LH with low serum testosterone. A homozygous loss of function missense mutation Q54R was identified in the LHB gene. This mutation alters an amino acid that is conserved in all β-subunits of the glycoprotein hormones. CHO cells were transfected with cDNAs encoding α-glycoprotein subunit (GSU) and either the wild or mutant LHB to assess the biological effects of the mutation. When LH concentrations were measured in culture medium by radioimmunoassay and radioreceptor assay, LH concentrations in the medium by radioimmunoassay were higher in cells transfected with αGSU and mutant LHB cDNAs compared with those transfected with αGSU and wild LHB cDNAs. However, the mutant LH was undetectable by radioreceptor assay, indicating that the absence of biological activity of mutant LH was because of its inability to bind its receptor.

[a]No human mutations have been reported so far.
[b]The level of abnormality, hypothalamus or pituitary, is not fully understood.

A small number of women have been reported to have FSHβ deficiency resulting from homozygous or compound heterozygous FSHB gene mutations, V61X/V61X and V61X/C51G. These women presented with delayed puberty and primary amenorrhea. Laboratory data showed an undetectable serum concentration of FSH and high LH. Exogenous FSH treatment resulted in follicular maturation, ovulation, and fertility. V61X caused a deletion of the C-terminus, including residues 90-110, that was essential for heterodimer formation. The C51G substitution mutates a residue that is part of a motif thought to be essential to the organization of the core of the protein. The functional effects of V61X and C51G were studied by coexpressing αGSU and mutant FSHB genes. Immunoradiometric assay of culture media showed undetectable concentrations of mutant FSH, consistent with patients's laboratory data. Two men have been reported to have a homozygous FSHB gene mutation, V61X/V61X or C82R/C82R, presenting with azoospermia. Other patients have been reported to have isolated gonadotropin deficiency. However, in most instances the LHB and FSHB gene analyses have not been reported.

Homozygous or compound heterozygous loss of function mutation of the GPR54 gene causes hypogonadotropic hypogonadism. GPR54 is a GPCR whose ligand is a 54 amino acid peptide derived from the KiSS1 protein. Affected subjects carried a homozygous deletion of 155 nucleotides encompassing the splicing acceptor site of intron 4-exon 5 junction and part of exon 5, homozygous L102P, homozygous L148S, or compound heterozygous R331X/X339R. The transfection of COS-7 cells with L148S, R331X, or X339R plus introduced stop codon after polyA tail showed decreased accumulation of inositol phosphate by ligand stimulation. The patient with R331X/X339R had attenuated secretion of endogenous GnRH. The Gpr54 knockout mice had isolated hypogonadotropic hypogonadism, but they showed responsiveness to both exogenous gonadotropins and GnRH and had normal levels of GnRH in hypothalamus. These studies established the central role for GPR54 in GnRH secretion.

Hypogonadotropic hypogonadism with other endocrine abnormalities resulting from single gene disorder has been reported, consistent with the complex interactions within the hypothalamic-pituitary–gonadal axis and other endocrine systems being absolutely required for normal puberty. For example, prohormone convertase (PC)-1 deficiency because of a PC1 gene mutation causes hypogonadotropic hypogonadism, obesity, and hypocortisolemia. Although PC1 regulates posttranslational modification of prohormones and neuropeptides, it has not been elucidated why PC1 deficiency causes hypogonadotropic hypogonadism. Individuals with congenital leptin deficiency or congenital leptin resistance because of LEP or LEPR gene mutation show hypogonadotropic hypogonadism associated with obesity. Male patients with X-linked adrenal hypoplasia congenita because of hemizygous DAX1 mutation exhibit primary adrenal insufficiency in infancy or early childhood and hypogonadotropic hypogonadism. Some studies have revealed that hypogonadotropic hypogonadism in DAX1 mutation represents defects at the pituitary gonadotrophs as well as the hypothalamus, consistent with the expression of DAX1 at both sites. No fertile male patient with hemizygous DAX1 mutation has been described following GnRH or gonadotropin treatment, suggesting critical roles of DAX1 for the process of spermatogenesis. Interestingly, delayed puberty has been described in one female with a heterozygous DAX1 mutation in one family, and hypogonadotropic hypogonadism without adrenal insufficiency has been described in one female with a homozygous DAX1 mutation. Analysis of DAX1 gene in more than 100 patients with "idiopathic" hypogonadotropic hypogonadism failed to identify any mutations.

Patients with congenital combined pituitary hormone deficiency can have hypogonadotropic hypogonadism when the mutated genes regulate gonadotroph differentiation. Two children with homozygous HESX1 mutation with septo-optic dysplasia and congenital combined pituitary hormone deficiency have impaired gonadotropin secretion, although these children are prepubertal. Homozygous LHX3 mutations have been reported in patients with congenital combined pituitary hormone deficiency including hypogonadotropic hypogonadism. These patients have normal ACTH secretion and limited head rotation because of cervical spine rigidity. Heterozygous LHX4 mutation has been reported in familial combined pituitary hormone deficiency including hypogonadotropic hypogonadism. Patients with PROP1 mutation may develop hypogonadotropic hypogonadism, although the onset of hypogonadism varies. These patients have GH and thyroid-stimulating hormone deficiency in childhood and may develop progressive ACTH deficiency.

Panhypopituitarism with an invisible or thin pituitary stalk can produce hypogonadotropic hypogonadism. These patients usually have a history of complicated delivery as breech presentation or neonatal asphyxia. The invisible or thin pituitary stalk reflects its injury (transection) at birth or the primary abnormality of the stalk. Hypogonadotropic hypogonadism as well as GH, thyroid-stimulating hormone, and ACTH deficiency may gradually develop.

CNS disorders may cause hypogonadotropic hypogonadism by impairing hypothalamic or pituitary function. Sellar or suprasellar tumors (e.g., craniopharyngioma) commonly disturb the processes of pubertal development, causing either precocious puberty (as described earlier) or delayed puberty. Such tumors are often associated with other kinds of pituitary defects, of which GH deficiency is by far the most common.

Anorexia nervosa is notorious for causing functional gonadotropin deficiency in adolescent females. The prevalence of anorexia nervosa is definitely increasing in the United States and other industrialized countries. Anorexia nervosa is characterized by severe weight loss, a distorted body image, obsessive fear of obesity, and multiple endocrine abnormalities including functional gonadotropin deficiency. The recovery of most of endocrine abnormalities after weight gain suggests that endocrine abnormalities are secondary to weight loss. However, amenorrhea or infertility may persist for months to years after weight gain. Higher brain dysfunction in anorexia nervosa may hamper the complete recovery of functional gonadotropin deficiency.

Increasing evidence shows the link between excessive exercise and functional gonadotropin deficiency, especially in adolescent females. Long-distance runners, swimmers, ballet dancers, figure skaters, and gymnasts are well-known athletes who may develop amenorrhea. Excessive exercise itself or strict weight control can cause functional gonadotropin deficiency.

Hyperprolactinemia may cause functional gonadotropin deficiency. Hyperprolactinemia is because of pituitary prolactinoma, hypothyroidism, or drugs such as neuroleptics, antihypertensives, dopamine receptor antagonists, and antidepressants. Galactorrhea may or may not be present. The mechanism by which hyperprolactinemia causes functional gonadotropin deficiency is most likely multifactorial. Increased prolactin may inhibit GnRH secretion and/or decrease responsiveness of gonadotrophs to GnRH.

Treatment The goals of treatment of hypogonadotropic hypogonadism are to induce and maintain puberty and establish fertility. Gonadal steroid hormone replacement can induce and maintain puberty, testosterone in boys and estrogen in girls, when patients are at pubertal ages (about 13 yr in boys and 12–13 yr in girls). Gonadal steroid hormones should be gradually increased to an adult dosage to mimic normal pubertal development. In girls, cyclic therapy using estrogen and progesterone is necessary to establish regular withdrawal bleeding. Pulsatile GnRH treatment or the combination of gonadotropins is effective both to induce and maintain puberty and to establish fertility. It is uncertain whether prolonged gonadal steroid hormone replacement in male hypogonadotropic hypogonadism causes irreversible damage to spermatogenesis before the induction of the treatment to establish fertility. Treatment of underlying diseases should focus on CNS disorders and functional gonadotropin deficiency.

Kallmann's Syndrome Kallmann's syndrome is characterized by the association of hypogonadotropic hypogonadism and anosmia (or hyposmia). Hypogonadotropic hypogonadism is hypothalamic in origin, and anosmia (or hyposmia) results from agenesis or hypoplasia of the olfactory bulbs and tracts (*see* Etiology). Three modes of transmission have been described: X-linked (KAL1), autosomal-dominant (KAL2), and autosomal-recessive (KAL3). The prevalence of Kallmann's syndrome in boys is four times that in girls.

Clinical Features Typical clinical features of Kallmann's syndrome are delayed puberty and no or reduced sense of smell (often unrecognized by the patient). Boys with Kallmann's syndrome may have micropenis and/or bilateral or unilateral cryptorchidism in infancy. Both genders fail to develop puberty. Patients may have other clinical features depending on the mode of transmission. Renal agenesis is observed in up to 40% of KAL1, but not in KAL2. Synkinesia (mirror image movements) is associated principally with KAL1, but has also been observed in KAL2. Cleft lip/palate is present mostly in association with KAL2, but may also be seen in KAL1. MRI can clearly demonstrate the absence of olfactory bulbs and hypoplasia of the olfactory sulci, even in newborn infants. Olfactometry or the intravenous olfactory stimulation test is helpful to identify or confirm anosmia or hyposmia. In contrast to the delayed puberty caused by CNS tumors or constitutional delay of puberty, patients with Kallmann's syndrome usually have appropriate or tall stature for their age. Untreated adults and individuals of pubertal age commonly have eunuchoid proportions. Some subjects with KAL1 or fibroblast growth factor receptor (FGFR)-1 (*see* below) mutations manifest varying combinations of these features or do not have any of the clinical features. In the reported KAL2 families with FGFR-1 mutation, the prognosis of fertility was not compromised without treatment or by the combination of gonadotropins.

Etiology During embryogenesis, olfactory neurons and GnRH-secreting neurons originate in the olfactory placode in the nose and migrate into the CNS. The olfactory nerves associate with the terminal nerve and vomeronasal nerve to produce a bridge between the olfactory epithelium and the forebrain. The cells that will become GnRH-secreting neurons arise within the region of the olfactory placodes and migrate from the nasal epithelium, through the cribriform plate of the nose and then along the olfactory tract–forebrain axis to reach the preoptic and hypothalamic areas, where they differentiate to become the GnRH-secreting neurons. Given the developmental connection between GnRH-secreting and olfactory neurons, abnormalities in this developmental stage can cause Kallmann's syndrome.

An X-linked form of Kallmann's syndrome, KAL1, is caused by the deletion of or mutation of KAL1, which is located at Xp22.3. Examination of the expression of the KAL1 gene during embryogenesis demonstrates that it can be detected in various neuronal populations of the CNS, including cells of the olfactory bulbs. This gene partially escapes X inactivation and encodes a 680 amino acid protein, anosmin-1, an extracellular matrix component. An inactive homologous pseudogene, KALP, is located on the Y chromosome at Yq11. The derived amino acid sequence of KAL1 predicts a protein that contains a leader peptide with protease inhibitor domain that is followed by 4 fibronectin type III repeats; no transmembrane or anchoring regions are present. The protein, anosmin-1, is *N*-glycosylated, secreted in the cell culture medium, and localized at the cell surface. Several lines of evidence indicated that heparan-sulfate chains of proteoglycans are involved in the anosmin-1 to the cell surface. Anosmin-1 is thought to have a dual branch-promoting and guidance activity and is involved in the patterning of mitral and tufted cell axon collaterals to the olfactory cortex. Anosmin-1 may bind by means of a heparan sulfate proteoglycan to its cognate receptor or by other extracellular cues to induce axonal branching and axon misrouting. The role of KAL1 in events such as kidney formation and migration is obscure, although the expressed KAL1 in the Wolffian duct might be involved in renal development by interaction with the metanephric mesenchyme.

Heterozygous loss of function mutations in FGFR-1 have been identified in an autosomal dominant form of Kallmann's syndrome (KAL2). FGFR-1 is located at 8p11.2-p12 and encodes the FGFR-1; and its gain of function has been shown to cause craniosynostosis. Several lines of evidence suggest that KAL1 and FGFR-1 interact functionally to effect the normal migration of GnRH-secreting and olfactory neurons. Anomsin-1 may directly participate in FGF signaling through interactions with the FGFR-1. Notably, nonpenetrance of the disease in some mutation carriers can simulate autosomal-recessive transmission.

An autosomal-recessive form of Kallmann's syndrome (KAL3) also exists. The responsible gene for KAL3 has not been identified.

Constitutional Delay of Puberty (Variation of Normal Puberty) Constitutional delay of puberty is a common, benign condition that represents a variant of normal puberty. The time of onset of puberty is delayed compared with the general population, although the pattern of pubertal development is normal. Boys are referred for evaluation of this condition significantly more often than girls. Together with their delayed pubertal development, these children often have short stature, approximately two to three standard deviations below the mean, called constitutional delay of growth and puberty. The bone age is usually delayed 2–4 yr behind chronological age. These children demonstrate pubertal development that is more commensurate with their bone age than their chronological ages. Adult height and complete pubertal maturation are achieved significantly later, some young men reporting continued linear growth in their late teens or early twenties. Adult height is generally appropriate for the genetic background, but is commonly in the low normal range. The family history often reveals other individuals with suspected constitutional delay of puberty, most often in males. Constitutional delay of puberty usually does not require treatment.

Hypergonadotropic Hypogonadism Hypergonadotropic (or primary) hypogonadism is failure of the gonads to respond to hypothalamic–pituitary stimulation. Hypergonadotropic hypogonadism is associated with elevated serum concentration of

gonadotropins owing to the absence of the negative feedback effects of gonadal steroid hormones.

Causes The most common causes of hypergonadotropic hypogonadism are chromosome abnormalities such as Klinefelter syndrome, Turner syndrome and Down syndrome (Table 43-7). Why hypergonadotropic hypogonadism is common in chromosomal abnormalities is not completely understood, although pairing failure of homologous chromosomes in meiocytes is proposed to cause germ cell loss. Klinefelter syndrome and Turner syndrome are discussed later.

An uncommon form of hypergonadotropic hypogonadism is isolated gonadal dysgenesis. This condition appears to be genetically heterogeneous and both sporadic and familial cases have been reported. Affected patients having female external genitalia, either with 46,XX or 46,XY, typically present with no pubertal development. They do not have any other abnormalities such as short stature and minor anomalies.

One familial variant of isolated gonadal dysgenesis is Perrault syndrome, gonadal dysgenesis in 46,XX with sensorineural hearing loss. This syndrome is autosomal recessive with obligatory ovarian dysgenesis in 46,XX homozygotes and facultative sensorineural hearing loss in 46,XX and 46,XY homozygotes. The molecular defect has not been identified.

The receptors for the gonadotropins LH/CG and FSH are both members of the GPCR family. Selective defects in the gonadal response to gonadotropins have been traced in several pedigrees to mutations of the genes encoding the LH/CG and FSH receptors.

LH/CG resistance is resulting from loss of function mutations in the LHCGR gene. Male patients are classically associated with a form of male pseudohermaphroditism termed Leydig-cell hypoplasia, rather than being associated with delayed puberty. This disorder is characterized by female phenotype in the presence of a 46,XY karyotype, low serum concentration of testosterone, increased LH, and lack of testosterone secretion in response to a hCG stimulation test. Homozygous or compound heterozygous loss of function mutations in the LHCGR gene has been identified. The identification of a missense mutation of the LHCGR gene in a phenotypic male infant evaluated for a small but normally formed penis suggests that the range of altered phenotypes associated with LH/CG resistance because of loss of function mutations in the LHCGR gene may be broader than initially identified. A 46,XX subject with homozygous K354E was a phenotypically normal adult female with primary amenorrhea and cystic ovaries, suggesting that female patients with LH/CG resistance had some pubertal development, but impairment in the normal ovarian cycle.

Follicle-stimulating hormone resistance is caused by a loss of function mutation in the FSHR gene. A homozygous loss of function missense mutation in FSHR gene was found in Finnish female patients associated with 46,XX hypergonadotropic ovarian dysgenesis, which was originally classified as isolated gonadal dysgenesis. The disorder is common in this population (1:8300 females) and is inherited in an autosomal-recessive manner. Males homozygous for this mutation had a normal phenotype with variable degrees of spermatogenetic failure, but surprisingly, did not show azoospermia or absolute infertility.

LH and FSH resistance can be because of GNAS1 mutations (pseudohypoparathyroidism, type 1A [PHP1A]). GNAS1 encodes Gsα and displays imprinting (*see* precocious puberty, MAS in this chapter). Maternally inherited loss of function heterozygous mutation in GNAS1 causes PHP1A. PHP1A can be associated with resistance to multiple hormones, including hypergonadotropic hypogonadism. Patients with pseudohypoparathyroidism, type 1B (PHP1B) exhibit parathyroid hormone resistance, typically without other endocrine abnormalities. PHP1B is most likely caused by mutations in regulatory regions of the GNAS1 gene inherited from the mother that are predicted to interfere with the parent-specific methylation of GNAS1.

Other causes include enzymatic defects in gonadal steroid hormone biosynthesis, syndromes associated with hypergonadotropic hypogonadism, gonadal destruction, and unknown etiologies (*see* Table 43-7).

Treatment The goal of treatment of hypergonadotropic hypogonadism is to induce and maintain puberty. Gonadal steroid hormone replacement (*see* Treatment of Hypogonadotropic Hypogonadism) can induce and maintain puberty. Gonadal steroid hormone replacement therapy in Turner syndrome is more complex, requiring coordination of timing with respect to GH therapy to optimize adult height.

Unfortunately, other than sperm or egg donation, treatment to establish fertility in any hypergonadotropic hypogonadism is unsatisfactory. Some successful pregnancies have been reported, however, by testicular sperm extraction/microsurgical epididymal sperm aspiration combined with in vitro fertilization/intracytoplasmic sperm injection.

Klinefelter Syndrome The most common form of male hypergonadotropic hypogonadism is Klinefelter syndrome

(47,XXY karyotype), which occurs with a prevalence of 1:2500 adult males. Patients with Klinefelter syndrome may demonstrate a slowing or arrest of pubertal development as gonadal function declines after the age of puberty, although gonadal function remains relatively normal until that age. The hallmark of physical findings is small testes, and infertility is the rule. Subjects are relatively tall owing to the additional copy of the X-linked SHOX gene. Mean full-scale I.Q. is between 85 and 90. When a patient with Klinefelter syndrome develops precocious puberty, germinoma of the mediastinum is highly likely.

Turner Syndrome The most common form of female hypergonadotropic hypogonadism is Turner syndrome (45,X karyotype, typically), which occurs with an incidence of 1 in 2000 live-born females. Turner syndrome is a well-defined X chromosome abnormality characterized by short stature, Turner somatic stigmata, and hypergonadotropic hypogonadism. With respect to hypergonadotropic hypogonadism, adult patients usually have "streak" gonads consisting of fibrous tissue without germ cells. However, germ cells may be present in gonads in fetal life and infancy. Short stature is primarily ascribed to SHOX haploinsufficiency in addition to nonspecific growth disadvantage caused by chromosome imbalance. Turner somatic stigmata, either surface (webbed neck, high arched palate, ptosis, and so on) or visceral (coarctation of the aorta, horseshoe kidney, and so on), may be because of haploinsufficiency of postulated "lymphogenic gene(s)" on the short arm of X chromosome and nonspecific developmental disadvantage caused by chromosome imbalance.

GH treatment improves growth rates as well as adult height. Recommendations for diagnosis, treatment, and management of Turner syndrome have been published by the fifth international symposium on Turner syndrome.

44 Defects of Androgen Action

MICHAEL J. MCPHAUL

SUMMARY

The development of the male phenotype is a complex process that involves the active participation of genes involved at many levels, from those specifying gonadal differentiation to the androgen receptor (AR) itself. Defective virilization can be caused by defects anywhere along the pathway. Considering the clinical syndromes caused by known defects of genes such as steroid 5α-reductase II and the AR, the pathogenesis of a large proportion of defects in virilization remains unexplained. It is conceivable that some might represent defects in genes required for normal AR function or at steps beyond the site of action of the AR itself (e.g., coactivators, or defects in genes activated by the AR).

Key Words: Amino; androgen receptor (AR); 5α-dihydrotestosterone; 5α-reductase; Reifenstein's syndrome; sex-determining region Y; testosterone.

INTRODUCTION

Since 1935 it has been recognized that the principal androgen secreted by the testes is testosterone. Although testosterone is the most abundant circulating androgen, 5α-dihydrotestosterone is the predominant hormone found complexed to the androgen receptor (AR) in the nuclei of target cells, such as the prostate. This finding opened a new perspective on androgen physiology and focused attention on the 5α-reductase enzyme(s) that catalyze this conversion as potential modulators of androgen action in selected tissues. As described later, this inference has been confirmed by the recognition that some abnormalities of male sexual development can be traced to defects in the conversion of testosterone to 5α-dihydrotestosterone.

STRUCTURE AND FUNCTION OF THE AR

Abundant biochemical and genetic data demonstrated that the actions of androgen were mediated by a single receptor that was encoded on the X-chromosome, and that defects in this receptor protein, the AR, could result in a range of abnormalities of male phenotypic sexual development. The isolation of cDNAs encoding the AR revealed it to be a member of a large group of related transcription factors, the nuclear receptor family. This family includes members that are ligand responsive, such as the steroid, thyroid hormone, and retinoid receptors, and others that are thought to be constitutively active or modulated by other influences, such as phosphorylation. All exhibit a modular structure (displayed for the AR in Fig. 44-1) consisting of a highly conserved DNA-binding domain, a less highly conserved carboxyl-terminal ligand-binding domain, and an amino-terminal segment that is poorly conserved between individual family members, both in terms of primary amino acid sequence, and length.

The DNA-binding domain is made up of two elements (termed "zinc fingers") that mediate the sequence-specific DNA binding of the AR. This segment is the most highly conserved region between members of this gene family. The carboxy-terminus is approx 250 amino acids long and encodes the portion of the protein that binds androgens with high affinity. The amino-terminus of the AR is somewhat atypical in that it contains three segments made up of repeated amino acids (one of repeated glutamine residues, one of repeated proline residues, and one of repeated glycine residues). Polymorphisms of these regions appear to have little effect on AR function in normal individuals, but expansions of the glutamine repeat have been implicated in the pathogenesis of spinal and bulbar muscular atrophy (SBMA, Kennedy's syndrome, *see* AR Mutations: Special Cases).

The nonligand-bound AR is thought to exist in the cell in association with a number of ancillary proteins, particularly members of the heat shock protein family. After the binding of hormone, the receptor dissociates from these proteins and binds to specific DNA sequences within or adjacent to androgen-responsive genes. This ligand-activated receptor interacts with components of the transcriptional apparatus to stimulate and stabilize active transcription complexes. In some models, the AR appears to modulate genes in a negative fashion or to alter mRNA stability, but these phenomena have been less well characterized.

AR DEFECTS

CLINICAL FEATURES A spectrum of phenotypes can result from defects of AR function (Table 44-1). Patients completely unresponsive to the actions of androgen (referred to as complete testicular feminization or complete androgen insensitivity) have a 46,XY karyotype, but an external phenotype that is completely female in appearance, despite normal or elevated levels of circulating androgens. Owing to the secretion and action of Müllerian inhibitory substance by the functional testes present in these patients, the uterus and fallopian tubes are absent. Such individuals are usually raised as females and might first seek attention for evaluation of primary amenorrhea. Gonadectomy is often performed, because the intraabdominal testes show an increased rate

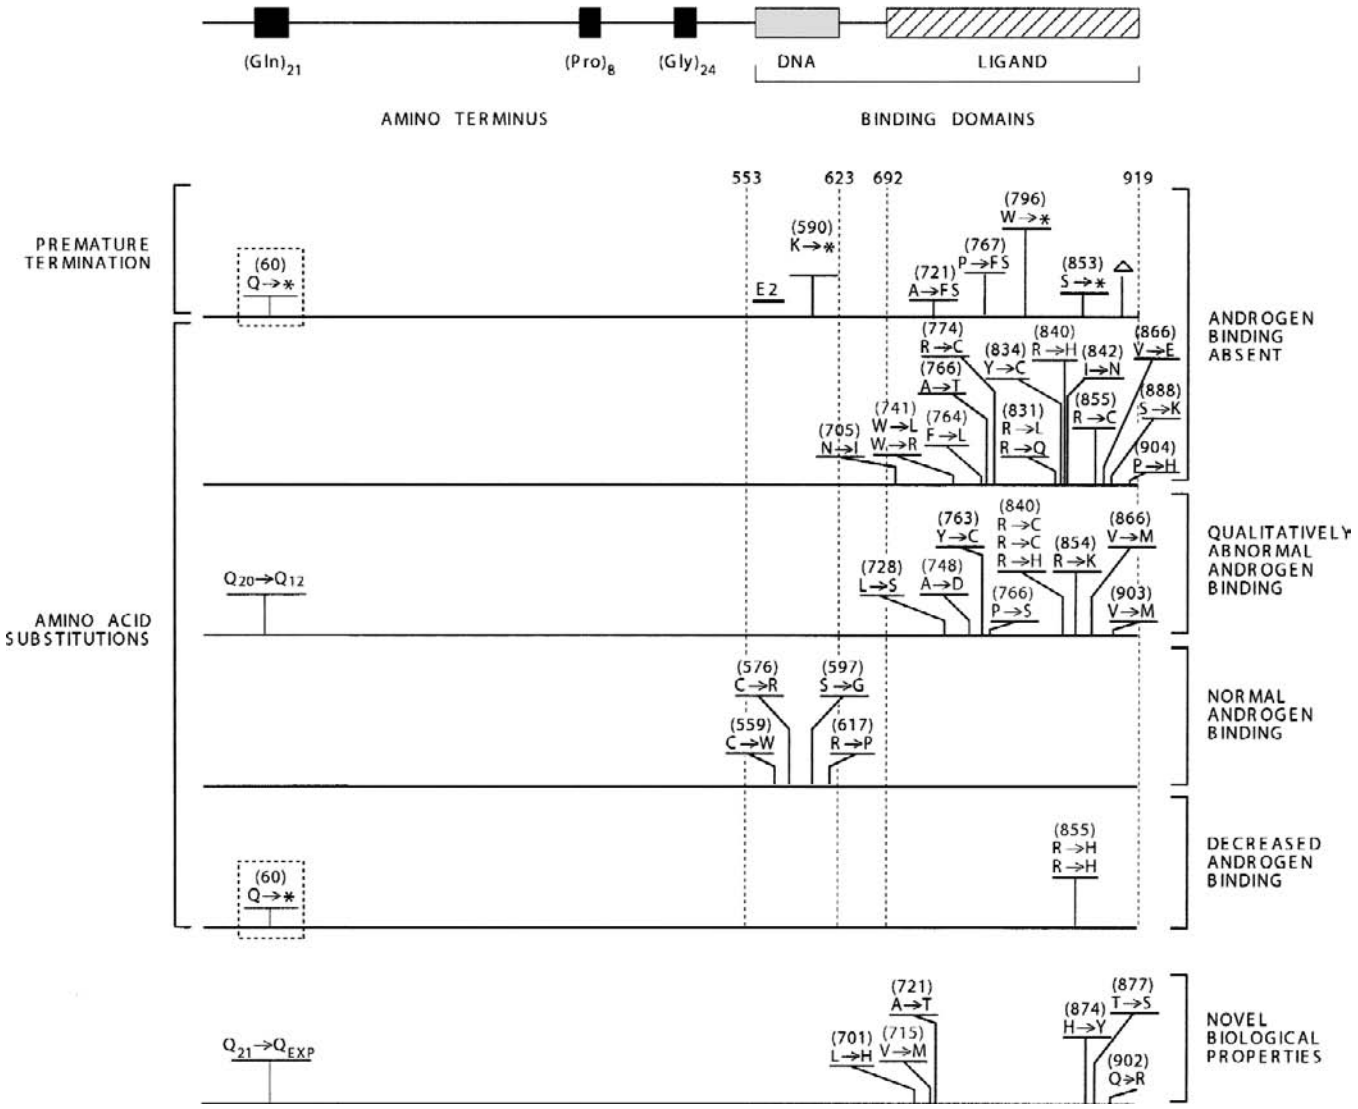

Figure 44-1 Mutations of the human AR that cause abnormalities of AR function (above). A schematic representation of the human AR is shown. The approximate boundaries of the DNA and LBDs are indicated, as are the locations of the repeated stretches of glutamine, proline, and glycine residues within the amino terminus (below). A selected grouping of mutations causing androgen resistance are grouped according to the type of genetic lesion (amino acid substitution or premature termination codon, left margin) or the effect that the mutation has receptor function (right margin). Also comprised in this figure are a selected number of mutations reported in literature that have been detected in prostate cancer specimens that appear to alter the binding characteristics and activities of the AR. The expansion of the glutamine repeat that causes spinal bulbar muscular atrophy is also represented. (Adapted from McPhaul MJ, Marcelli M, Zoppi S, Griffin JE, Wilson JD. Genetic basis of endocrine disease. J Clin Endocrinol Metab 1993;76[1]:17–23.)

Table 44-1
Phenotypes Associated With Defects in the Genes Encoding the Androgen Receptor and 5α-Reductase II

Gene	*Syndrome*	*External genitalia*	*Wolffian duct derivatives*	*Müllerian duct derivatives*
AR	Complete female feminization Complete androgen insensitivity	Completely female	Not virilized	Absent
	Incomplete testicular feminization	Predominantly female; some clitoromegaly, closure of the posterior fourchette	Usually partially virilized	Absent
	Reifenstein syndrome	Substantial phallic development, but with severe forms of hypospadias	Variable defects	Absent
	Under-virilized, fertile male	Male phenotype with small phallus	Male	Absent
	Infertile male	Male phenotype	Male	Absent
5α-Reductase II	5α-Reductase deficiency	Can be variable: ranging from female external genitalia at birth to a predominantly male phenotype with hypospadias	Normal male	Absent

of malignant tumor development. With estrogen replacement, these individuals often lead completely normal lives as women, although they are infertile. Partial androgen insensitivity encompasses a wide range of abnormalities of male phenotypic development. Affected individuals have phenotypes ranging from predominately female to minor defects of male development.

The term incomplete testicular feminization has been applied to individuals with nearly complete forms of androgen resistance who demonstrate only slight evidence of virilization (such as clitoromegaly). These patients are usually managed in a fashion similar to that of patients with complete testicular feminization.

Reifenstein's syndrome is a constellation of features that includes severe defects of male urogenital development (perineal or penoscrotal hypospadias) and gynecomastia. Reifenstein's syndrome represents a far more difficult challenge. As noted clinically, the developmental abnormalities are substantial and surgical correction of these defects often requires multiple separate surgical procedures. Such efforts are further hampered by the small size of the genitalia of affected children. After surgical correction, most individuals with this phenotype are raised as males, although many exhibit difficulty with gender identity.

At the mildly affected end of the spectrum, a small number of individuals have been described in which normal development of the external genitalia has occurred, but in which some degree of undervirilization is clinically evident. In some, this phenotype has been associated with azoospermia and infertility without undervirilization. In others, normal sperm density and fertility is identified in men with varying degrees of virilization. Patients with these phenotypes have been identified as having AR defects on the basis of a family history and abnormalities of in vitro ligand-binding assays of the AR. Although specific AR defects have been reported in association with these syndromes, it is not clear how frequently such phenotypes are caused by AR defects in the general population. Information derived from the analysis of groups of individuals with infertility would suggest that AR mutations can be identified in only a small subset of such patients.

An unusual variation of the undervirilized phenotype is that presented by patients with spinal and bulbar muscular atrophy (SBMA) (*see* Chapter 116). Patients with this syndrome have normal male development and normal male secondary sexual characteristics throughout much of their lives but develop signs of clinical androgen resistance beginning in middle age. Although these signs of androgen resistance are unmistakable (usually gynecomastia), the difficulties presented by the symptoms of anterior motor neuron degeneration pose a far more serious threat to the health of such patients and represent the usual cause of death in affected individuals. Interestingly, expansions of this same element have been identified in a subset of patients with infertility.

AR MUTATIONS AND DEFECTIVE AR FUNCTION

Molecular defects of the AR that cause the syndromes of androgen resistance have been studied by a number of groups. The causative mutations have been identified in more than 100 pedigrees and include all of the major clinical syndromes. A database listing the mutations causing androgen resistance is accessible through the internet.

Deletions or insertions of the AR gene occur with a frequency of approx 5–10% of patients with androgen resistance and range in size from single or multiple nucleotides to deletions of the entire gene. Because such mutations disturb the open reading frame of the AR, patients with this type of mutation do not express an intact receptor protein and, with few exceptions, lack detectable androgen binding in their cells, and tissues. In addition, because the intact AR is not present in the tissues of such patients, AR function is absent and affected individuals always demonstrate the phenotype of complete androgen insensitivity (complete testicular feminization).

In contrast to the frequency of deletions and insertions in the AR gene, single nucleotide substitutions are much more frequent and account for the bulk of patients with androgen resistance as a result of AR mutations. In some cases, such substitutions result in large-scale alterations of receptor structure, as when they result in alterations of AR mRNA splicing or introduction of premature termination codons within the AR open reading frame. These instances, as with gene deletion or insertion mutations that interrupt the primary sequence of intact AR protein, are usually associated with a lack of detectable androgen binding in tissues and a phenotype of complete androgen insensitivity.

Single nucleotide substitutions that result in single amino acid changes within the AR protein are the most frequent type of mutation in the AR. These defects fall into two general categories: those within the DNA-binding domain and those that have been localized to the ligand-binding domain of the receptor. Unlike the other mutation categories previously described (deletions, insertions, premature termination), the effect of these substitutions on AR function can vary, and the entire spectrum of androgen-resistant phenotypes has been traced to single amino acid substitutions within the AR protein. In most instances, the principal effect of the amino acid substitution is on AR function and major effects on the level of AR abundance, as measured in patient fibroblasts, are uncommon.

Amino acid substitutions in the DNA-binding domain have little effect on the binding of ligand by the mutant receptor. Despite the capacity of these mutant ARs to bind ligand normally, receptor function is reduced after ligand stimulation, compared with the activity of the normal AR. This reduced function is caused by a decreased capacity of the mutant AR to bind to target sequences within responsive genes. In this category of mutation, the degree of impairment of receptor binding to DNA appears to have a direct relationship to the degree that receptor function is reduced. Similar conclusions hold true for larger alterations of receptor structure occurring within the DNA-binding domain that maintain the reading frame of the receptor (e.g., deletions of single amino acid residues within the DNA-binding domain or the single reported instance caused by in-frame deletion of exon 3).

Amino acid substitutions in the ligand-binding domain (LBD) can result in a variety of changes in the capacity of the AR to bind its ligand. In a surprisingly small proportion of cases, the amino acid replacement renders the receptor completely unable to bind ligand. Under these circumstances, it is presumed that as a result the alteration of the LBD structure the binding pocket is radically distorted. This conformational change blocks the capacity of the AR to bind its ligand and the mutant receptor is thus "locked" into an inactive conformation. This type of mutant AR is functionally equivalent to mutations that result in the synthesis of truncated forms of the AR, as even pharmacological doses of potent synthetic androgens are unable to restore receptor function in vivo or in functional assays performed in vitro.

Far more frequently, however, amino acid substitutions in the LBD lead to the synthesis of mutant ARs that exhibit the capacity to bind hormone, but with properties that are abnormal compared to the normal AR (e.g., bind ligand with a reduced affinity or stability). Although the exact type of ligand-binding abnormality differs depending on the nature and location of the amino acid substitution within the ligand-binding domain, it appears that the formation and

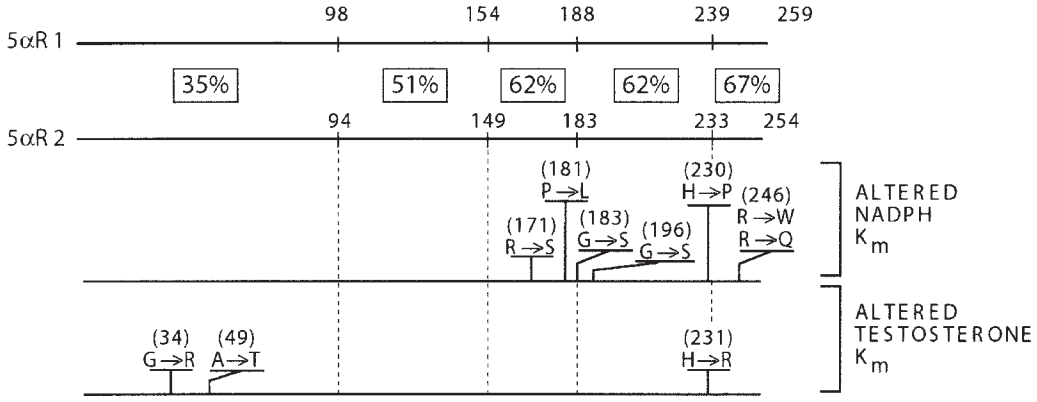

Figure 44-2 Comparison of the structure of human steroid 5α reductases I and II and mutations that alter the binding of testosterone and nicotinamide adenine dinucleotide phosphate (above). Alignment of the predicted protein sequences of steroid 5α-reductase I (259 amino acids) and steroid 5α-reductase II (254 amino acids). The degree of sequence identity is shown for each of the five coding exons (boxed percentages) (below). Mutations identified within the coding sequence of the steroid 5α-reductase II gene in patients with 5α-reductase deficiency. Although more than 50 mutations been identified that cause 5α-reductase deficiency, a much smaller proportion have been analyzed biochemically. In this figure, only the mutations that cause alterations in the binding of testosterone or NADPH are indicated. Comprised in this figure is an amino acid substitution A49T that has been suggested to be associated with an increased risk of prostate cancer. (Drawn after Russell DW, Wilson JD. Steroid 5α-reductase: two genes/two enzymes. Annu Rev Biochem 1994;63:25–61.)

stability of the hormone-receptor complex is the final determinant of the degree of impairment of mutant AR function. In vitro studies of such mutant receptors demonstrate that the use of multiple high doses of physiological ligands (testosterone or dihydrotestosterone) or the use of potent nonmetabolizable androgen agonists can overcome the defective function of many mutant ARs of this type. In addition to its mechanistic implications, this finding might have substantial clinical implications as well, because it suggests that the pharmacological manipulation of many mutant ARs might be possible.

Studies have investigated the levels of expression and the function of normal and mutant ARs. In most circumstances the major effect of most mutations in the AR is not at the level of AR abundance, but at the level of AR function. This is not true in all cases, however, with the most obvious exceptions being mutations that result in truncation of the receptor protein (e.g., termination codons or alterations of mRNA splicing).

GENOTYPE–PHENOTYPE CORRELATIONS AND PHENOTYPIC MODIFIERS

The breadth of mutations that has been identified has permitted the recognition that the effect of an AR mutation depends on the extent to which AR expression and function are altered.

In considering the large number of identified mutations, there is generally good agreement in terms of the phenotype observed when the same mutation is identified in different pedigrees. This agreement is clearest in patients with complete forms of androgen insensitivity and a greater degree of variation is observed in patients with partial forms of androgen insensitivity. This is likely because at the time of sexual development, relatively small variations in AR levels or activity can have discernible effects on the degree of observed virilization. Two different mechanisms have been reported as potential modifiers of the phenotype in different individuals with the same genotype. The first, differences in the level of 5α-reductase activity, contributes to differences between patients with distinctive partial phenotypes of androgen insensitivity. The second mechanism, somatic mosaicism, could account for even larger variations in observed phenotype.

AR MUTATIONS—SPECIAL CASES

The androgen-resistance syndromes described are caused by mutations that impair receptor function to varying degrees. Two additional types of AR mutation have been identified that result in an alteration of AR responsiveness or an apparent "gain" of function.

The first example of a "gain of function" mutation in the AR is the genetic defect causing Kennedy's syndrome. This disease, also known as SBMA, is characterized by signs and symptoms caused by a progressive degeneration of spinal and bulbar motor muscles. These features are associated with clinical signs compatible with mild androgen insensitivity, which also appear in middle age. The pathogenesis of this extraordinary disease was traced to the expansion of a triplet nucleotide repeat (CAG) encoding a repeated sequence of glutamine residues within the amino-terminus of the receptor (*see* Fig. 44-1). The expansion of this glutamine repeat, the first of an increasing number of similar diseases that have also been traced to the expansion of trinucleotide repeats (Chapter 116), is thought to have two different effects on AR function. First, it is clear that the expansion of this segment of the AR diminishes the capacity of the AR to activate responsive genes after androgen stimulation. This diminished AR function can be demonstrated using a variety of functional assays and is presumably the cause of the subtle signs of androgen resistance observed in affected individuals. It is clear from the study of rare patients with complete deletions of the AR that the SBMA phenotype (progressive death of motor neurons in bulbar nuclei and in the spinal cord) is not caused by a simple lack of functional AR. Instead, this disease appears to be caused by a type of toxic "gain of function" that is caused by the expression of ARs containing the expanded glutamine repeats in specific cell types. Analogy to results obtained from the study of the Huntington disease gene (also caused by a glutamine repeat expansion) would suggest that the glutamine expansion might permit interaction of the mutant AR with intracellular targets in spinal motor neurons that somehow mediate the observed cell-type-specific toxicity. Alterations of axonal transport have been identified as one neuron-specific function that might contribute to the pathogenesis of this disorder.

Table 44-2
Distribution of 5α-Reductases I and II Expression in Rat and Human Tissues

	Rat		*Human*	
	Type I	*Type II*	*Type I*	*Type II*
Skin	—	—	+*	+[a†]
Testes	D*	1+*	ND[†]

[a]Histochemical studies indicate that the expression of 5α-reductase II is localized to the cells of the dermal papilla.

[b]Staining localized to epithelial cells in histochemical studies.

[c]Staining localized to basal epithelial and stroma cells.

[d]Type I is detected in basal epithelial cells and type II in stroma cells in *in situ* hybridization studies of the regenerating rat central prostate.

[e]Types I and II are localized to the epithelial cells using *in situ* hybridization.

Summary of studies measuring 5α-reductases I and II expression using measurements of the corresponding RNA (*) or protein ([†]) are derived from published studies of Russell and coworkers. The rating scales (1+ least, 5+ highest) used in summary are designed to convey a sense of the relative abundance of the 5α-reductase isozymes in the two species—rat and human—that have been studied most carefully. Because the rat and human have been conducted separately, they can only be compared with one another in a qualitative fashion. D is detectable (i.e., at the limits of detection). ND, is not detected; —, values not reported. In addition to the results tabulated here, the studies of Thigpen et al. clearly indicate that in the human substantial changes in abundance can be demonstrated in the expression of the types I and II isoenzymes in a tissue at different times in development.

The second type of AR mutation that causes a gain or alteration of receptor function is the mutations identified in human prostate cancer specimens. First recognized in the AR gene of a prostate tumor cell line, LNCaP, amino acid substitutions have been detected in a number of clinical prostate cancer specimens. Although a number of these mutations have been found, fewer have been completely studied concerning their effect on the ligand responsiveness of the mutated AR. In instances in which detailed studies have been performed, tests of receptor function using androgen-responsive reporter genes demonstrate that the mutant ARs can be stimulated by ligands that cannot ordinarily activate the normal AR. Such ligands include adrenal androgens and even compounds (such as hydroxyflutamide) that act to antagonize the function of the normal AR. Although it is not possible to conclude how important these mutant receptors are in the progression of prostate cancers toward the androgen-independent phenotype, the preponderance of analyses suggest that such mutations are found most frequently in advanced stage tumors, particularly in patients treated with AR antagonists, such as hydroxyflutamide.

5α-REDUCTASE DEFICIENCY

PHYSIOLOGICAL AND CLINICAL STUDIES The observation that 5α-dihydrotestosterone was the principal hormone bound to the AR in the nuclei of target cells suggested the potential importance of 5α-reductase in androgen physiology. The subsequent identification of rare patients with specific defects of virilization that formed reduced quantities of 5α-reduced androgen metabolites emphasized the importance of this metabolic step. The normal virilization of other tissues, such as the epididymis in patients with clinical 5α-reductase deficiency, led to the concept that the action of testosterone was sufficient to effect the actions of androgen in selected tissues, but that the formation of 5α-dihydrotestosterone was crucial in others, such as the prostate. This dichotomy has not yet been completely explained at a mechanistic level.

CLINICAL PHENOTYPE The clinical features of many infants with deficiencies of 5α-reductase are consistent with marked defects of androgen action (*see* Table 44-1). The external genitalia are characterized by a microphallus, severe hypospadias, and a bifid scrotum. A blind vaginal pouch is present and opens either directly onto the perineum or onto a urogenital sinus. Owing to the production of Müllerian inhibitory substance by the functional testes, no Müllerian structures are present. It is of interest that in association with the pubertal rise in testosterone levels, several changes may take place in the phenotype of affected individuals. The phallus enlarges and some male secondary sexual characteristics appear, such as changes in voice and muscle mass. Notably, this increase in testosterone has not been reported to result in acne, prostate growth, or male pattern baldness. It has also been reported that in some individuals, raised initially as females, gender identity may change after the pubertal rise in androgen levels. The ability to identify individuals with 5α-reductase II deficiency at the molecular level has permitted the recognition that this syndrome also includes individuals with less severely affected phenotypes.

5α-REDUCTASE STRUCTURE AND MECHANISM OF ACTION

Attempts to purify 5α-reductase using classic techniques of protein purification failed and its structure remained elusive until expression cloning in Xenopus oocytes was employed to isolate a cDNA encoding a steroid 5α-reductase from the rat prostate. This advance permitted a number of studies and resulted in the isolation of cDNAs encoding two related isozymes (Fig. 44-2) encoded by two distinct, related genes from humans and from all vertebrate species examined to date. Inspection of the structures of the cDNAs indicates substantial sequence divergence between the two isozymes, both within and between different species. Both enzymes are extremely hydrophobic and are thought to be imbedded in the nuclear membrane of cells, accounting for the failure of extensive efforts to purify the enzyme in an active form. Structural variations between the two isozymes confer substantial differences in their physical properties that have been exploited to develop compounds that inhibit one or the other isozyme preferentially.

Studies of the distribution of the two isozymes (Table 44-2) have demonstrated that the patterns of expression of these two proteins

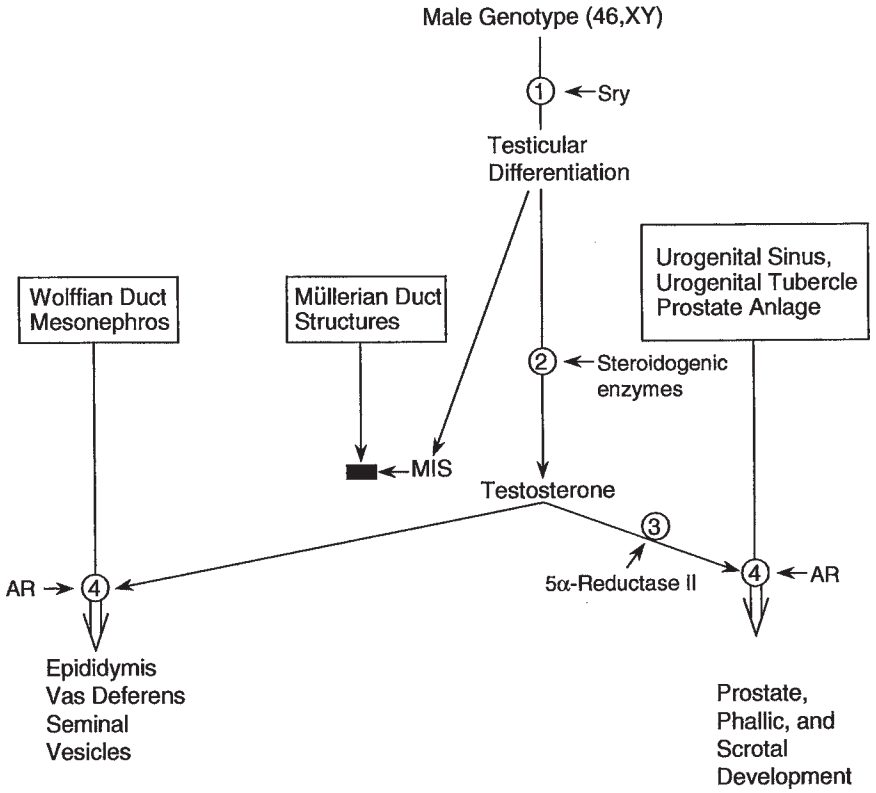

Figure 44-3 Schematic of the pathways controlling the development of the normal male phenotype. Male sexual development is a complex cascade of events that can be affected by lesions in a number of genes. Some, such as lesions in the AR or the sex-determining region Y gene, can cause disturbances of virilization of all androgen-responsive tissues. The effects of defects in other genes, however, (such as mutation of 5α-reductase II), are manifest only in selected tissues. It is likely that defects in other genes can contribute to defects of virilization, as a large proportion of subjects with abnormalities of male phenotypic development cannot be accounted for by defects in the genes most carefully studied to date, such as the AR and steroid 5α-reductase 2 genes.

differ, both in terms of tissue, cell type, and developmental stage. These disparities suggest substantially different physiological roles for the two enzymes.

GENETIC DEFECTS OF STEROID 5α-REDUCTASE II The genetic lesions causing clinical 5α-reductase deficiency have been identified in pedigrees from around the world. In all instances, when a genetic defect has been detected, it has been localized to the 5α-reductase II gene. Unlike the AR, the gene encoding 5α-reductase II is autosomal and each individual possesses two copies. For this reason, mutations causing clinical 5α-reductase deficiency are recessive and the inheritance of two defective 5α-reductase II gene alleles is required for the defects to be manifest. 5α-reductase II deficiency is infrequently caused by deletions or insertions in the gene. More often, defects in the gene are caused by mutations that result in premature termination of the protein or single amino acid substitutions within the open reading frame. Identification of the locations of these substitutions and determination of the physical properties of the mutant enzymes have permitted the identification of amino acid residues important for binding of steroid substrates and for the binding of nicotinamide adenine dinucleotide phosphate, a cofactor required for the reduction reaction. These studies have also identified sites that have been mutated repeated in apparently unrelated pedigrees. These regions are apparently more susceptible to mutation.

As a consequence of the recessive nature of clinical 5α-reductase II deficiency, it would be expected that the genetic basis of this rare trait would be traced most frequently to homozygosity for a single defective allele (e.g., consanguinity). Surprisingly, a high proportion of patients (approx 30%) have been found to be compound heterozygotes, suggesting either an unexpectedly high mutation rate of the 5α-reductase II gene or a high frequency of individuals in the general population that carry single defective alleles. This apparent paradox has not been resolved.

GENETIC DEFECTS OF STEROID 5α-REDUCTASE I An abnormal phenotype caused by a deficiency of 5α-reductase I in humans has not been described. The differential expression of steroid 5α-reductase I in selected tissues (*see* Table 44-2) suggests that specific phenotypes in humans that result from lesions in this gene or abnormalities of its expression might be identified in the future.

Because of the lack of mutations in the human population, the first insights into the nature of defects that might be expected in humans have come from experiments in mice in which steroid 5α-reductase I gene has been disrupted by homologous recombination. Male mice homozygous for this targeted null allele develop normally, both prenatally and postnatally. Unexpectedly, although female mice homozygous for this same null allele develop normally into adulthood, when pregnant, such mice fail to initiate parturition normally. Experiments in which different steroids were administered to these steroid 5α-reductase I-deficient mice suggested that the synthesis and action of 5α-reduced androgens were important elements of the normal parturition process in mice. Although the mechanisms and generality of these findings remain to be determined, such results suggest that

5α-reductase I might play important—and even unexpected—roles in human physiology as well.

ADDITIONAL LESSONS FROM MURINE MODELS Based on the phenotypes of human patients with defects of 5α-reductase II, it was anticipated that defects of virilization would be observed in animals in which the 5α-reductase II gene had been disrupted. Surprisingly, male mice in which both 5α-reductase II genes had been inactivated showed no defects of external genitalia development and only modest reductions in the size of fully formed seminal vesicles and prostates. These findings have been attributed to the observation that in animals with disruptions of either the 5α-reductase II or both the 5-reductase I and II genes, testosterone levels in target tissues are dramatically elevated. These results support the concept that 5α-reductase serves to amplify weak androgenic signals in tissues in which androgen concentrations are limiting (Fig. 44-3).

45 Molecular Endocrinology of the Testis

Marco Marcelli, Glenn R. Cunningham, José M. Garcia, Kirk C. Lo, and Dolores J. Lamb

SUMMARY

This chapter reviews genetically influenced causes of male hypogonadism. Acquired cases of hypergonadotropic hypogonadism and acquired forms of gonadotropin deficiency from functional causes or systemic diseases have not been included because they do not have a genetic etiology.

Key Words: Alström syndrome; Dystrophia myotonica 1 (DM1); hypergonadotropic; Kallmann syndrome (KS); Klinefelter syndrome; 46,XX; 46,XY; reproductive system; Smith–Lemli–Opitz syndrome (SLOS); testis.

INTRODUCTION

Two distinct functions of the male reproductive system are essential for the survival of human species. First is the continuous production, nourishment, and storage of male gametes (spermatozoa). The second function is synthesis and secretion of the androgenic hormones necessary for male sexual differentiation and function. The testis is controlled by signals from the hypothalamus-pituitary–gonadal (HPG) axis, in addition to local paracrine and autocrine signals to fulfil these functions.

MALE HYPOGONADISM

Disorders of testicular function result from abnormalities involving the endocrine (Leydig cells) and/or reproductive (germ cell maturation) compartments of the testis. Low testosterone (T) production in adult males is usually accompanied by decreased libido, abnormal secondary sexual characteristics, and infertility, as normal spermatogenesis requires normal production of testicular androgens (hypogonadism with undervirilization and infertility). However, there are situations in which hypogonadism is restricted to the germinal compartment (hypogonadism with infertility and normal virilization).

The serum level of gonadotropins indicates at what site within the HPG axis the defect is localized. In instances in which gonadal function is abnormal and the hypothalamic-pituitary (HP) structures are normal (hypergonadotropic or primary hypogonadism), gonadotropin levels are elevated. When the primary defect lies at the level of the HP structures (hypogonadotropic or secondary hypogonadism), gonadotropin levels are inappropriately normal or low. Depending on the serum level of gonadotropins, hypogonadism can be classified as hypergonadotropic or hypogonadotropic (if resulting from testicular or HP disorders, respectively) (Table 45-1) and eugonadotropic (if the abnormality lies only in the germinal cells and serum T levels are normal).

Both congenital and acquired forms of Leydig cell dysfunction have been described, and the clinical picture that results when T synthesis is impaired is different depending on whether androgen deficiency developed prenatally, before puberty, or after puberty (Table 45-2). If the developing fetus was not exposed to an adequate level of androgen because of testicular failure during fetal development, the infant manifests pseudohermaphroditisms, characterized by a large spectrum of potential abnormalities, including ambiguous genitalia, micropenism, and rudimentary testes. If reduced T production developed before puberty, but testicular function was normal during embryogenesis, androgen-related somatic changes normally observed at puberty are absent or incomplete and the patient develops an eunuchoid habitus because of failure of the epiphyses to close, and poor development of skeletal muscles and body hair. If reduced T production developed after puberty, the first symptom of the patient is impotence, whereas loss of secondary sexual characteristics may take several years to become complete.

Hypogonadism manifested by abnormal sperm production can be associated with normal virilization, because many infertile men produce a normal or only a minimally abnormal amount of T. However, in other cases infertility is associated with a reduced production of T and clinical signs of androgen deficiency (infertility from hypergonadotropic or hypogonadotropic disorders [*see* Table 45-1]). In such cases, infertility may be a direct consequence of the reduced T production.

HYPERGONADOTROPIC DISORDERS

Hypergonadotropic abnormalities of the testes are owing to primary testicular failure (*see* Table 45-1). They can be classified in two main groups: congenital or acquired disorders. Some genetic syndromes lead to primary hypogonadism as a result of chromosomal abnormalities, enzymatic defects, or receptor defects. Others are congenital multiorgan diseases with associated hypogonadism, and it is not always clear why patients affected by some

Table 45-1
Hypogonadotropic and Hypergonadotropic Disorders

(A) HYPERGONADOTROPIC DISORDERS	(B) HYPOGONADOTROPIC DISORDERS
Genetically inherited	**Genetically inherited**
Chromosomal abnormalities	**Associated with gonadotropin deficiency**
Klinefelter	GPR54 deficiency
	Kallmann syndrome
46,XX males	Fertile eunuch syndrome
46,XY pure gonadal dysgenesis	Hypogonadotropic hypogonadism from biologically inactive molecules of the hypothalamic–pituitary axis
Multi-organ diseases	
Alström syndrome	Hypogonadotropic hypogonadism from mutations of genes causing combined pituitary hormone deficiencies
Dysptrophia myotonica 1	
Dystrophia myotonica 2	Hypogonadotropic hypogonadism from mutations of genes associated with obesity
Cardiomyopathy with hypogonadotropic hypogonadism	Leptin and leptin receptor
Alopecia-mental retardation syndrome with convulsions and hypergonadotropic hypogonadism	Prohormone convertase-1
Insulin-resistant diabetes with acanthosis nigricans, hypogonadism, pigmentary retinopathy, deafness, and mental retardation	
Testicular regression syndrome (bilateral anorchia)	
Hypergonadotropic hypogonadism in autoimmune polyglandular syndromes I and II	
Receptor defects	**Associated with central nervous system disorders**
LH resistant testis	Prader–Lahart–Willi
Syndromes of androgen resistance	Laurence–Moon–Biedl
	Möbius
	Borjeson–Forssman–Lehman syndrome
	Leopard syndrome
	Rud's syndrome
	Loewe's syndrome
	Carpenter syndrome
Defects of steroidogenesis	**Associated with adrenal insufficiency**
7-dehydrocholesterol reductase deficiency (7-DHCR-D) or Smith–Lemli–Opitz syndrome	Adrenal hypoplasia congenita
Lipoid CAH	
3β-hydroxysteroid dehydrogenase 2 deficiency	
17α-hydroxylase 17,20-lyase (CYP17) deficiency	
17β-hydroxy steroid dehydrogenase deficiency	
Acquired	**Acquired**
Viral	**Associated with anatomic disorders**
Medications	Pituitary apoplexy
Trauma	Primary or metastatic tumors of pituitary or adjacent structures
Environmental	Infection
Autoimmunity	Infiltrative disorders (Hemochromatosis, sarcoidosis, histiocytosis, lymphocytic hypophysitis)
Ionizing radiations	Empty sella
	Functional
	Secondary to Cushing's syndrome
	to ethanol
	to exercise
	to empty sella
	to hyperprolactinemia
	Associated with systemic diseases
	AIDS
	Liver diseases
	Renal diseases
	Hemochromatosis
	Neurological diseases

7-DHCR-D, 7-dehydrocholesterol reductase deficiency; CAH, congenital adrenal hyperplasia; LH, luteinizing hormone.

Table 45-2
Manifestations of Leydig Cell Dysfunction

Prenatal leydig cell dysfunction:
External genitalia: female, ambiguous; male, hypoplastic
Wolffian ducts derivatives: absent—rudimentary
Müllerian ducts derivatives: absent
Gonads: Small—rudimentary testes, which can be located within the abdomen, inside the inguinal canal or in the scrotum
Prepubertal Leydig cells dysfunction:
External genitalia: small penis <3–4 cm, small testis <5 mL, lack of rugal folds and pigmentation sin the scrotum
Accessory sex organs: small prostate and seminal vesicles
Hair growth: no development of terminal facial hair, no recession of scalp line, decreased body hair, female escutcheon
Linear growth: eunuchoid skeletal proportions
Bone development: delayed bone age, predisposition to osteoporosis
Voice: voice remains high pitched
Muscle mass: absent-reduced development of muscle mass
Psyche: decreased libido
Postpubertal Leydig cell dysfunction:
External genitalia: softening and decreased volume of the testes
Psyche: decreased libido, sexual potency, and aggressivity
Bone: predisposition to osteoporosis
Hair growth: decreased growth and amount of facial, pubic, and axillary hair
Spermatogenesis: impaired spermatogenesis
Muscles: decreased muscle mass

of these disorders develop hypogonadism. Acquired diseases causing primary hypogonadism result from the direct exposure of the testis to a variety of exogenous toxic agents. Typical endocrine abnormalities in these patients consist of decreased to undetectable serum levels of T. Gonadotropins are elevated owing to the absence of negative feedback inhibition exerted by T.

HYPERGONADOTROPIC HYPOGONADISM CAUSED BY CHROMOSOMAL ABNORMALITIES

KLINEFELTER SYNDROME Klinefelter syndrome initially was described in 1942, when techniques to study serum hormone levels and chromosomal abnormalities were not available. Its frequency is approx 1/600 male newborn and approx 1/300 spontaneous abortions. Of males with this syndrome, 85% have a 47,XXY chromosomal pattern; however, 46,XY-47,XXY mosaicism is detected in approx 10% of the patients. Less frequently it is found in 46,XX males, or in individuals with Xq trisomy, X-autosome translocations, or poly-X's (48XXXY, 49XXXXY).

Prepubertal diagnosis is possible in the cases when microphallus or cryptorchidism is part of the prepubertal phenotype, when the testes are recognized to be unusually firm or when a karyotype is requested for other reasons. The onset of puberty usually occurs at a normal age, so features of undervirilization, gynecomastia, small testes, azoospermia, decreased muscular mass, and abnormal skeletal proportions resulting in an eunuchoid habitus are most often detected in the postpubertal patient. Small testicular size resulting from the loss of germ cells is a consistent clinical abnormality. In addition, progressive hyalinization and fibrosis of the seminiferous tubules result in an increased testicular consistency.

Mild mental retardation and personality disorders are identified more frequently in patients with Klinefelter syndrome than in the general population, and these abnormalities usually are more evident in the group of patients with polysomic-X conditions. Other conditions that have been detected with increased frequency in patients with Klinefelter syndrome include thyroid abnormalities, diabetes mellitus (DM), breast, and other types of cancer.

From a clinical standpoint, Klinefelter patients affected by 47XXY/46XY mosaicism manifest less serious phenotypic abnormalities, and these individuals can be fertile. However, other variants of this disease, including 48,XXXY, 48,XXYY, and 49,XXXXY individuals, are associated more frequently with cryptorchidism, growth retardation, mental deficiency, antisocial behavior, facial dysmorphism, and skeletal abnormalities.

The endocrine features of these patients show a typical evolution that becomes evident over a period of years. Usually, basal follicle-stimulating hormone (FSH), luteinizing hormone (LH), and T are normal before age 12; however, by age 14 LH and FSH are elevated. At these early states, serum T levels usually are within the normal range. When the patient has reached his middle 20s, however, primary gonadal failure becomes more evident, and T levels are low or low normal, despite elevated gonadotropins. If untreated, most patients become T deficient. Final diagnostic confirmation of this syndrome is obtained by analyzing the karyotype, and by detecting one of the many chromosomal abnormalities described earlier.

Genetic Basis The most common cause of Klinefelter syndrome is nondisjunction during the first or second meiotic division. The extra X chromosome can be of paternal or maternal origin with approximately the same frequency. Most maternal cases are associated with impaired disjunction during the first meiotic division, and maternal age is a factor in these cases. The percentage of XY sperm increases with increasing paternal age. A second possible mechanism, occurring in 3% of the cases, is nondisjunction after the first postzygotic mitosis. A third potential mechanism was described in an Italian family, in which the mother had a 46,XX/47,XXX mosaicism, possibly because of a nondisjunction event during her zygotic development, and three of her children were affected by the classic Klinefelter karyotype 47,XXY. The etiology of the 46XY/47,XXY mosaicism derives from nondisjunction events in mitosis during zygotic development. Patients with mosaicism have lesser degrees of gynecomastia and androgen deficiency. Normal testicular size has been described in some of these patients, especially when the normal stem cell line 46,XY is present in the testis. The additional sex chromosomes in patients with 48,XXYY karyotype derives from successive nondisjunction events in the first and second meiotic division in the father. In contrast, the additional X chromosomes in 49,XXXXY patients are maternally derived, and originate from sequential nondisjunction events in both the first and second meiotic divisions. These individuals usually have radioulnar synostosis, hypogonadism, and mental retardation, and they are at increased risk for congenital heart defects. Whether the Klinefelter phenotype requires the entire extra X chromosome to develop remains a question. One study of phenotype–karyotype correlations has associated the development of the Klinefelter phenotype with genes mapping to region Xq11–Xq22, but this observation was not confirmed by other investigators in a patient with a 47,X,del(X)(pter-p11),Y karyotype.

Treatment These patients' main complaints are the symptoms of hypogonadism, particularly gynecomastia, infertility and reduced libido, learning difficulties, and several psychosocial problems. Standard treatment is replacement with T, which should be started at puberty or when T deficiency is recognized.

Gynecomastia usually is unresponsive to treatment with T, and many patients require surgical reduction mammoplasty. Infertility is not improved by treatment with T. Most patients are azoospermic when they present with infertility. However, individuals with mosaic Klinefelter syndrome usually do have sperm in their ejaculate. Intracytoplasmic sperm injection (ICSI) has made fertilization of an egg with a single sperm possible. Many centers that offer assisted reproductive techniques can retrieve spermatids or spermatozoa from needle aspiration of the testes or from open testicular biopsies. Available data indicate that patients with nonobstructive azoospermia, obstructive azoospermia, or Klinefelter syndrome are at some increased risk of having sex chromosome aneuploidy. Nonetheless, the majority of spermatozoa or spermatids have a normal number of chromosomes. The testes of these individuals must have a few spermatogonia with a mosaic chromosomal pattern. Although reports have only a limited number of patients, fertilization rates are approx 50%, pregnancy rates approx 25%, and live births/couples are approx 10%. Because this disorder is associated with an increased risk of developing breast cancer (approx 20 times that for normal men), some authors have advocated yearly screening mammography, but it is not clear whether it would be useful. These individuals are at increased risk for having osteopenia or osteoporosis even when they have been treated with T replacement therapy. Therefore, it may be necessary to add calcium, vitamin D, and possibly a bisphosphonate to the treatment regimen if their bone mineral density indicates significant risk of fractures.

46,XX MALES A variant of the Klinefelter syndrome, the reported incidence of 46,XX varies from 1/9000–20,000 male newborns. Most cases are sporadic. The phenotype resembles that of Klinefelter patients. The major difference is short stature, because of the absence of Y sequences that are important for normal somatic growth, normal intellectual development, and normal skeletal proportions. The testes are small and firm, androgen production is compromised, and gynecomastia is common in adolescent patients. Germ cells are absent, and serum levels of gonadotropins are elevated. Affected individuals have male psychosexual identification.

These patients usually are referred to a physician to investigate typical phenotypic abnormalities that become evident after puberty. Some patients are referred at an earlier stage of their life, because at times this entity is associated with hypospadias, particularly in the subgroup of patients in which no Y sequences are detected. The identification of a 46,XX karyotype associated with a male phenotype and endocrine studies showing hypergonadotropic hypogonadism and infertility permit successful diagnosis.

Genetic Basis The presence of Y material containing *Sry* can be demonstrated in the X chromosome of approx 80% of these patients. This event is because of X–Y recombination occurring outside the pseudoautosomal segments in which X–Y pairing normally occurs, resulting in the transfer of *Sry* from the Y to the X chromosome. The consensus is that *Sry* translocated to the X chromosome is sufficient to trigger testicular differentiation and the development of a male phenotype. The remainder of these patients (approx 20%) does not carry any identifiable Y sequence and have larger incidence of ambiguous genitalia. No mechanism has been identified to account for the male phenotypic development observed in these patients. Possibilities include an activating mutation in an autosomal or X chromosomal gene normally induced by *Sry* in the cascade of events leading to the differentiation of the male gonad, and undetected mosaicism with a Y-bearing cell line.

The pathogenesis of infertility in these patients is probably due, as in Klinefelter syndrome, to the presence of two X chromosomes in the germ cells and to the lack of the long arm of the Y chromosome that contains the azoospermia factor (AZF) gene necessary for normal spermatogenesis. These individuals require regular follow up for possible long-term androgen replacement and counseling through a cooperative interdisciplinary approach.

46,XY PURE GONADAL DYSGENESIS 46,XY gonadal dysgenesis, of which complete and an incomplete forms have been described, occurs in sporadic and familial forms. At birth, patients with the complete form appear to have normal external female genitalia. At puberty they do not develop secondary sexual characteristics, do not menstruate, and have streak gonads. Laparotomy reveals bilateral streak gonads, atrophic fallopian tubes, and a rudimentary uterus with a narrow lumen. They are chromatin negative and have a 46,XY karyotype.

In the incomplete form of the disease, virilization of the phenotype depends on the degree of differentiation achieved by the gonads, which varies from streak gonads to dysgenetic testes, and on their residual capacity to produce T and anti-Müllerian hormone (AMH). In the incomplete form of the disease, virilization is never normal. Therefore, the characteristics of the internal and external genitalia of these patients are more ambiguous than in the complete form. The presence of spontaneous gynecomastia is associated with an estrogen secreting neoplasm, which in these patients is frequently the gonadoblastoma type. Unlikely 46,XX males, this entity is associated with normal stature resulting from the presence of most of the Y chromosome.

Diagnosis A form of primary hypogonadism, 46,XY pure gonadal dysgenesis is typically associated with increased level of gonadotropins. T levels are almost undetectable in patients with the complete form and decreased but detectable in patients with the incomplete form. The diagnosis should be suspected in individuals presenting with primary hypogonadism, a 46,XY karyotype, and with the phenotype and pattern of inheritance discussed.

Genetic Basis This disease is associated with a remarkable degree of genetic heterogeneity. It has been associated with abnormalities occurring in the Y-linked *Sry* gene, with an X-linked pattern of inheritance, and with a sex-limited autosomal-dominant inheritance. Defects of *Sry* (deletions of the *Sry* gene or point mutations), have been detected in approx 10–15% of the sporadic cases and in kindreds with the familial form. Other X-linked and autosomal genes that could be involved, most of which may play a role in the cascade of events leading to testicular differentiation, include DAX1, WT1, AMH, SF-1, WNT4, DMRT1, XH2, DSS and SOX-9 Defects occurring in these genes are discussed later. The association of this disease with alterations in the sequence of *Sry* and other autosomal or X-linked genes is leading to more sophisticated understanding of the complex cascade of events required for normal testicular differentiation. The eventsequence and precise mechanism of interaction among these factors are not completely clear and being investigated.

Treatment The sex of rearing should be based on the degree of genital ambiguity. When this critical dilemma has been properly addressed and skeletal growth is complete, the rudimentary gonads should be removed prophylactically, because they may undergo malignant degeneration. At this point T or estrogen replacement should be started to ensure the development of the secondary sexual characteristics, and the prevention of osteopenia.

HYPERGONADOTROPIC HYPOGONADISM FROM MULTI-ORGAN DISEASES

ALSTRÖM SYNDROME This rare entity, described in 1959 by Alström, is characterized by autosomal-recessive inheritance, and multifactorial disorders including cone-rod retinal dystrophy, obesity, type-2 DM, acanthosis nigricans, sensorineural deafness, chronic nephropathy, and a late-onset cardiomyopathy. Phenotypic expression varies considerably, even within sibships. Although hypogonadism was not considered a feature of this disease in the initial description of Alström, subsequent articles have described its presence, which typically is reported in affected men, but not women. It is a primary form of hypogonadism, associated with low T and high gonadotropin levels. Alström syndrome usually is associated with normal secondary sexual characteristics, but the testes are small and demonstrate hyalinized tubules and thickening of the lamina propria. A few members of Alström kindreds have been fertile and produced normal offspring. Other metabolic and endocrine abnormalities described include hypothyroidism, growth hormone (GH) deficiency, hyperuricemia, and hyperlipidemia. The most frequent causes of death are hepatic dysfunction and congestive heart failure secondary to dilated cardiomyopathy. Unlike other multiorgan diseases, Alström is not associated with mental retardation.

Genetic Basis The syndrome has been mapped to chromosome 2p13 as a result of linkage studies in French Acadian and Algerian families. The identification of the gene responsible for Alström syndrome was reported in 2002. This transcript, named *ALMS1*, was mutated in six of eight families studied by one group, and in all six families studied by another group. The function of the *AMLS1* gene is uncertain. It shares analogy with mucin genes and contains a large tandem-repeat domain comprising 34 imperfect repetitions of 47 amino acids that contain no cysteine residues; but unlike mucins, *AMLS1* does not have high serine and threonine content. *AMLS1* is ubiquitously expressed, and this could explain the disease's syndromic nature, as concomitant defective ALMS1 function in multiple tissues may cause the many phenotypes observed.

DYSTROPHIA MYOTONICA 1 Dystrophia myotonica 1 (DM1) is an autosomal-dominant disorder that expresses remarkable variability in its clinical manifestations. Although usually apparent in adulthood, a congenital form of DM1 characterized by neonatal hypotonia, motor, and mental retardation has also been described in a few cases. The muscular abnormalities consist of progressive weakness and atrophy of the facial, neck, and distal muscles of the extremities and by prolonged contraction with inability to relax. Other features include cataracts, cardiac arrhythmias, baldness, primary hypothyroidism, mental retardation, type-2 DM with insulin resistance, and primary testicular failure in up to 80% of these patients.

Hypogonadism in DM1 is a primary testicular disease as suggested by the presence of T levels ranging from modestly decreased to low normal and slightly elevated gonadotropins that "hyperrespond" in gonadotropin-releasing hormone (GnRH) stimulation tests. The disease duration and the degree of testicular atrophy correlate with T and free T levels, suggesting that hypogonadism tends to worsen with age. There is good correlation between the circulating levels of T and the clinical signs of androgen deficiency, which usually are mild. Patients may maintain normal facial and body hair growth, and normal libido. Testicular histology varies from normal to marked tubular atrophy, and/or peritubular hyalinization, with or without loss of the interstitial cells. Testicular size is frequently decreased in association with complete germinal cell destruction. Infertility is reported in as many as 44% of the cases.

Genetic Basis DM1 is an autosomal-dominant disorder in which the primary genetic defect consists of an amplified trinucleotide (CTG) repeat in the three prime untranslated region of the dystrophia myotonica protein kinase (*DMPK*) gene, which has been mapped on chromosome 19q13.2-13.3. In the normal population, the CTG repeat length ranges from 5 to 30. Severity varies with the number of repeats; mild forms are associated with 50–80 repeats, whereas severe forms have up to 2000 or more copies. Amplification is because of parent-to-child transmission. Extreme amplifications occur almost exclusively in the offspring of affected women. This explains anticipation (increase in severity in successive generations) and that amplification is usually not transmitted through the male line. Myotonia has been reproduced in transgenic mice expressing a human actin gene containing 250 CTG repeats, demonstrating that the expression of CUG-repeat RNA has a deleterious gain-of-function independent of *DMPK*. Developments support a model in which nuclear accumulation of RNA from the expanded allele results in a transdominant effect on RNA processing by altering the function of CUG-binding proteins. A known CUG-binding protein with abnormal phosphorylation and nuclear/cytoplasmic distribution in DM1 cells is CUG-BP, a member of the CELF family of RNA-processing factors that regulates alternative splicing. Increased steady-state level of the splicing regulator, CUG-BP, is present in DM1 skeletal muscle, and this has been associated with abnormal splicing of proteins such as the insulin receptor (IR), resulting in predominant expression of the lower signaling nonmuscle isoform (IR-A). A similar mechanism was detected for abnormal splicing of CLC1, the main chloride channel in muscle, which results in a chloride channelopathy associated with membrane hyperexcitability in DM. Although these findings explain only two of the clinical manifestations of DM1 (i.e., insulin resistance and electrical myotonia), it is likely that the other clinical manifestations will be explained similarly. The mechanism causing hypergonadotropic hypogonadism/infertility in DM1 has not been elucidated, but likely consists in the abnormal splicing of one of the downstream effectors of gonadotropin signaling in the testes.

Treatment Replacement therapy with T has been advocated for patient with low T to correct the hypogonadism, and to increase and maintain muscular size and strength.

DYSTROPHIA MYOTONICA 2 Molecular analysis of a subgroup of patients with clinical features similar to those of DM1 did not yield mutations in the three-prime untranslated region of *DMPK*. This finding was instrumental in the identification of a parallel disorder, called dystrophia myotonica 2 (DM2/proximal myotonic myopathy), characterized by expansion of a CCTG repeat located in intron 1 of the zinc finger protein 9, ZNF9. DM2 is a dominantly inherited disorder in which clinical features similar to those of DM1 include progressive weakness, myotonia, disease-specific muscle histology, cardiac arrhythmias, iridescent cataracts, male hypogonadism, insulin insensitivity, and hypogammaglobulinemia. Hypergonadotropic hypogonadism was present in most (17 of 26) of the men serologically tested for testicular function and was characterized by elevated FSH, low or low-normal T levels, and oligospermia. By analogy with the mechanism causing DM1, it is thought that intranuclear accumulation of RNA with the microsatellite CCUG may be responsible for the DM2's clinical manifestation by causing

accumulation of a CUG-BP-like factor (possibly CUG-BP itself) followed by the abnormal splicing of a variety of proteins.

TESTICULAR REGRESSION SYNDROME (BILATERAL ANORCHIA) This syndrome is also known as congenital anorchia, testicular agenesis, or vanishing testicular syndrome. It is found in approx 1% of boys receiving surgery for bilateral cryptorchidism.

The phenotype detected in these patients correlates with the time of embryological development reached when testicular function became deficient. Individuals in which testicular function became abnormal before 8 wk of gestation develop female internal and external genitalia. Individuals developing abnormal testicular function between 8 and 10 wk of gestation develop an intermediate phenotype, with ambiguous genitalia and variable masculinization of the internal structures. Loss of testicular function after 10 wk of gestation is associated with the development of a normal male phenotype. In each instance, no histological or hormonal evidence for the presence of a functioning testis is available. Hormonal studies are compatible with primary gonadal failure, with high gonadotropin and low T level.

Diagnosis of this disorder should be suspected in patients with anorchia, in whom intra-abdominal gonads cannot be demonstrated by provocative testing or during explorative surgery.

The pathogenesis for the degeneration/disappearance of the testes is controversial as it could result from trauma, vascular insufficiency, or infection. Several sibships with multiple affected individuals have been reported. In one pedigree there was parental consanguinity, suggesting a possible autosomal-recessive transmission.

CARDIOMYOPATHY WITH HYPERGONADOTROPIC HYPOGONADISM Bilateral anorchia was originally reported by Malouf in 1985 in two sisters with congestive cardiomyopathy and ovarian dysgenesis. The association of cardiomyopathy and primary hypogonadism has also been described in male patients. In one case, it was described with mental retardation and cataracts, in another case with a distinctive type of collagenoma in the male members of the family. In the latter kindred, the authors described an autosomal-dominant mode of inheritance.

ALOPECIA-MENTAL RETARDATION SYNDROME WITH CONVULSIONS AND HYPERGONADOTROPIC HYPOGONADISM The initial report of this syndrome was of two brothers who had total alopecia and no scalp hair, eyelashes, or eyebrows at birth. During their first month, they developed tonic-clonic convulsions, which disappeared after age 4. Later in life, they still had alopecia of the scalp but normal eyebrows, and slight mental retardation. Their serum FSH levels were elevated, consistent with hypergonadotropic hypogonadism. Because it is difficult to identify hypergonadotropic hypogonadism before puberty, other similar cases described in prepubescent children may represent the same entity. The genetic basis is not known and may represent a new autosomal-recessive condition.

INSULIN-RESISTANT DIABETES WITH ACANTHOSIS NIGRICANS, HYPOGONADISM, PIGMENTARY RETINOPATHY, DEAFNESS, AND MENTAL RETARDATION This syndrome was initially described by Edwards et al. in 1976 in three males who had small testes, subvirilization, and gynecomastia in association with mental retardation, deafness, retinitis pigmentosa, acanthosis nigricans, and disturbance of glucose metabolism and hyperinsulinism. Siblings with a similar syndrome were subsequently described by Boor et al. in 1993. This syndrome has some general similarities with Alström syndrome, from which it is differentiated by the presence of mental retardation and the absence of renal insufficiency.

HYPERGONADOTROPIC HYPOGONADISM IN AUTOIMMUNE POLYGLANDULAR SYNDROMES I AND II Male hypergonadotropic hypogonadism is a minor manifestation of autoimmune polyglandular syndromes I and II. The main manifestations of autoimmune polyglandular syndrome I, which usually emerge with high penetrance during the initial 15 yr of life, comprise mucocutaneous candidiasis, hypoparathyrodism, and Addison's disease. The type-II form of the disease appears with lower penetrance in the ensuing years, up to the fifth decade. Hypogonadism has been described in up to 60 and 14% of affected females and males, respectively. Patients affected by the disease show an autosomal-recessive pattern of inheritance. The disorder has a high prevalence in Finland, Sardinia, and consanguineous Iranian Jewish families. The gene responsible for this disease was localized to the short arm of chromosome 21 and identified as *AIRE*. It encodes a DNA-binding protein expressed predominantly in the thymus and in lymphoid tissues. The mechanism through which *AIRE* causes disease is unknown. Main and minor manifestations become evident over a spectrum of several years. Therefore, it is recommended to screen these patients for the development of organ-specific antibodies, abnormal calcium and phosphorus levels, thyroid and liver function tests, and plasma vitamin B12 levels to allow the early detection of new disorders before overt symptoms and signs develop. Steroid producing cell autoantibodies have been positive in all patients with hypogonadism in which they were investigated.

Hypogonadism is associated with autoimmune polyglandular syndrome II in approx 4% of the cases. Although this syndrome aggregates in families, there is no clearly discernible pattern of inheritance. Multiple genetic loci, with human leukocyte antigen having the strongest effect, and environmental factors determine susceptibility.

HYPERGONADOTROPIC HYPOGONADISM FROM RECEPTOR DEFECTS

LH-RESISTANT TESTIS (LEYDIG CELL HYPOPLASIA) It is intuitive that mutations in gonadotropin or gonadotropin receptor genes are rare conditions because they severely affect fertility. However, sporadic mutations have been detected in all gonadotropin subunit genes and their related receptor genes, because heterozygous mutations do not affect fertility. Rarely, homozygous or compound heterozygous mutations have been identified, and the phenotypes of these patients have significantly contributed to the understanding of reproductive biology. Leydig cell hypoplasia is a rare condition associated with homozygous or compound heterozygous inactivating mutations of the LH receptor gene. In 46,XY individuals it is associated with primary testicular failure and a spectrum of phenotypic abnormalities of the internal and external genitalia. It is inherited as an autosomal-recessive disorder. In male patients the main clinical features of this syndrome are ambiguous external genitalia, ranging from extreme forms that present as 46,XY females, usually associated with complete inactivation of the LH receptor gene, to milder forms, usually associated with residual function of the LH receptor, in which phallic development is observed. The internal genitalia consist of a blind ending, rudimentary vagina, owing to the absence of Müllerian derivatives, because of normal production of AMH, and the presence of Wolffian duct-derived structures. The overall

phenotype of the complete form is similar to that of complete androgen insensitivity, but no feminization occurs at puberty because there is no production of testicular androgen, which serves as substrate for peripheral aromatization. Complete receptor inactivation is associated with male pseudohermaphroditism but, with incomplete inactivation, the phenotype is that of poor genital masculinization, ranging from micropenis to hypospadias. The histological features of the testis are drastic reduction in the number of Leydig cells and limited germ cell maturation.

Although virilization of the external genitalia is limited in these patients, Wolffian duct-derived structures, such as the vas deferens and the epididymis, have undergone normal embryological development in some cases. This implies that during fetal development these patients' Leydig cells are able to produce androgens despite the inactivating mutations of the LH receptor, suggesting that during early fetal development Leydig cell maturation and androgen production may be independent of LH/human chorionic gonadotropin (hCG) stimulation. Mice with a targeted disruption of the LH receptor have been characterized. Interestingly their phenotype at birth is indistinguishable from wild type of heterozygous littermates, providing conclusive evidence of a phenomenon previously described; rodent fetal testes are able to produce sufficient amounts of T for male differentiation in the absence of gonadotropin stimulation.

Inactivating mutations of the LH receptor have been also described in females, in which the syndrome has a more benign phenotype: primary amenorrhea in the background of normally developed primary and secondary sexual characteristics, a small uterus, normal-sized vagina with hyposecretory function and thin walls and decreased bone mass, indicating osteoporosis resulting from hypoestrogenism. Ovarian histology shows all stages of follicular development, indicating normal FSH function, but, in agreement with lack of LH activity, no preovulatory follicles, or corpora lutea.

Diagnosis These patients manifest a resistance to LH, shown by the elevated level of LH and low level of T. FSH is normal in most cases, and abnormally elevated in a minority of patients. T precursors such as dehydroepiandrosterone (DHEA), 17α-progesterone, progesterone, and androstenedione are low compared to normal males. The GnRH challenge test is associated with an LH "hyperresponse" and with only marginal FSH increase. T is usually completely unresponsive to hCG stimulation.

A clinical picture of abnormal virilization associated with low T and T precursors in the presence of high LH is virtually diagnostic of this syndrome. Alternatives to consider in the differential diagnosis are androgen resistance because of defects in the androgen receptor, type-2 5α-reductase deficiency, and defects of T biosynthesis. Each defect should be differentiated based on the clinical phenotype and hormonal data.

Genetic Basis The association of Leydig cell hypoplasia with an abnormal binding activity of the LH receptor and with the endocrine features described led to the identification of LH receptor mutations in affected patients. Several inactivating mutations of the LH receptor have been identified. Usually mutations associated with major structural abnormalities (i.e., truncation, missense mutations, or insertions causing premature truncation of the sequence) are associated with complete inactivation of receptor function. However, missense mutations are found in patients affected by partial and complete phenotypes.

Molecular Pathophysiology Mutations in the coding sequence of the LH receptor can affect any of the functions of this molecule, including LH binding, G protein activation with subsequent production of cAMP, posttranslational modifications, or postsynthesis transport. Because many mutations have been identified, a comparison is possible between the phenotype of these patients and the residual activity of their LH receptor established by in vitro functional analysis. Mutations associated with complete obliteration of receptor activity, such as Cys343Ser (in the extracellular domain), Cys543Arg (in the fifth transmembrane domain), Ala593Pro (in the sixth transmembrane domain), and those causing premature truncation, are associated with pseudohermaphroditism. In contrast mutations with minimal residual activity, such as Cys131Arg (in the extracellular domain), are associated with micropenis and hypospadias, whereas those with an even more subtle abnormality, such as Ser616Tyr and Ile625Lys (both in the seventh transmembrane domain), are associated with micropenis, the more subtle phenotypic abnormality detected in these patients. Analysis of this mutant receptor showed a low number of hCG-binding sites with normal high affinity, but lack of cAMP production.

Treatment Androgen or estrogen replacement therapy is indicated depending on gender selection. The final choice of how these patients should be raised depends on the same criteria established for patients with other forms of male pseudohermaphroditism. The intra-abdominal gonads should be surgically removed at diagnosis to prevent neoplastic degeneration. It is usually recommended that pediatric patients affected by micropenis should receive a course of T treatment to normalize the size of the phallus.

Inactivating Mutations of the FSH Receptor Gene Few mutations have so far been identified in the FSH receptor gene, which may indicate that the resulting phenotype is subtle and escapes identification, or that a selection mechanism prevents inheritance of FSH receptor mutations based on a strong dominant negative effect on fertility. A population-based study on ovarian dysgenesis has identified the only known inactivating mutation of the FSH receptor. In women, this mutation is associated with ovarian dysgenesis and primary or early-onset secondary amenorrhea with high levels of serum gonadotropins. In contrast, men with the same mutation have normal virilization, normal circulating T, normal or modestly elevated LH, elevated FSH, low inhibin B, and low testicular volume. Although none of these individuals had azoospermia, all of them had some abnormality of their semen analysis, ranging from severe or moderate oligospermia to normal sperm concentration with low volume. Of the five individuals identified two had two children each. Functional analysis of the FSH receptor resulting from this mutation showed near normal binding affinity, but reduced plasma membrane expression, and no activity at the postreceptor level. Hence FSH signaling contributes to testicular size and to the quality of the ejaculate, but it is not essential to male puberty, or to the onset of spermatogenesis. Male FSH receptor null mice produced in the laboratory essentially represent a phenocopy of the patients described earlier.

SYNDROMES OF ANDROGEN RESISTANCE Hypogonadism because of androgen receptor defects is associated with a spectrum of clinical phenotypes, from 46,XY women with the syndrome of complete testicular feminization to phenotypically normal men affected by infertility. The clinical features, endocrinology, biochemistry, and molecular biology of these syndromes are discussed in Chapter 44.

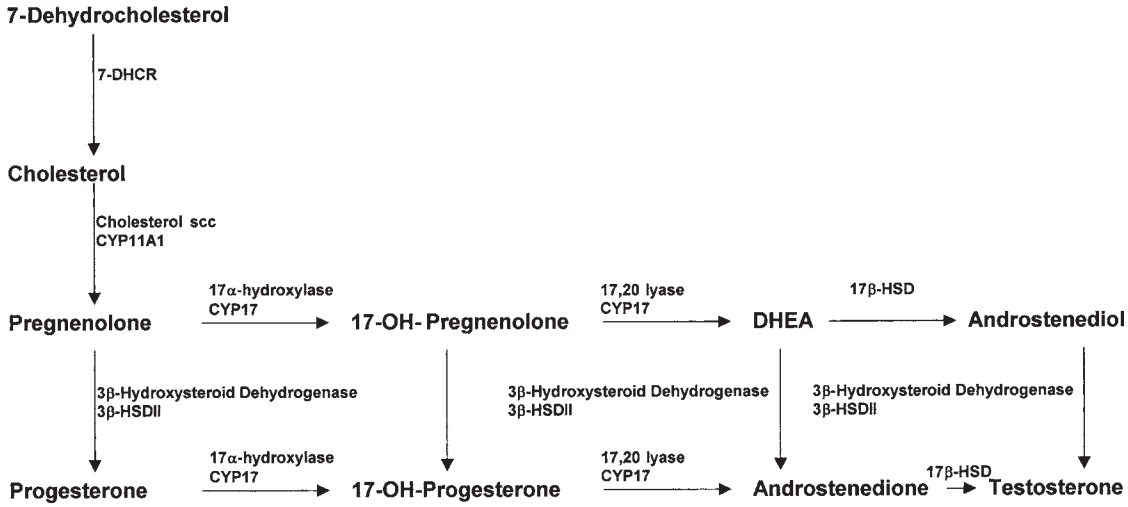

Figure 45-1 Pathway of testosterone synthesis.

HYPERGONADOTROPIC HYPOGONADISM FROM DEFECTS IN T SYNTHESIS IN 46,XY INDIVIDUALS

Several enzymatic steps are necessary for the formation of cholesterol, the common precursor of all steroid hormones. After cholesterol is formed, the StAR (steroidogenic acute regulatory protein) and five well-characterized additional enzymatic steps lead to its conversion to T (Fig. 45-1). A syndrome associated with hypergonadotropic hypogonadism has been described in patients affected by 7-dehydrocholesterol reductase deficiency (7-DHCR-D), the enzyme responsible for the final step leading to cholesterol biosynthesis. Genetic diseases associated with impaired activity of each of the five remaining enzymes and of the StAR also have been described. Because normal production of T by the developing testis is critical for development of the normal male sexual phenotype, abnormalities of these proteins are associated, in 46,XY individuals, with different degrees of male pseudohermaphroditism. Four of these proteins (P450scc, 3β-hydroxy-steroid-dehydrogenase, 17α-hydroxylase, and the StAR) are involved in both cortisol and T biosynthesis. Hence their abnormalities cause a combination of male pseudohermaphroditism and hypoadrenalism. Some of these abnormalities are partial, some become clinically evident only at puberty.

7-DEHYDROCHOLESTEROL REDUCTASE DEFICIENCY OR SMITH–LEMLI–OPITZ SYNDROME Smith–Lemli–Opitz syndrome (SLOS) is an autosomal-recessive malformation syndrome characterized by mental and growth retardation, ambiguous genitalia, and congenital anomalies like microcephaly, cleft palate, and cutaneous second and third toe syndactyly. From biochemical testing, the disease incidence was estimated at 1 in 40,000–60,000. SLOS is caused by a defect in 7-dehydrocholesterol reductase (7-DHCR), the final enzyme in the pathway leading to cholesterol biosynthesis. Affected individuals usually have low plasma cholesterol levels, and invariably have elevated levels of cholesterol precursors including 7-DHCR. Mildly affected individuals may have only subtle dysmorphic features and learning and behavioral disabilities. Cholesterol is important in cell membranes, serves as the precursor for steroid hormones and bile acids, and is a major component of myelin. Cholesterol is covalently bound to the embryonic signaling protein sonic hedgehog (Shh) in a step necessary for the autoprocessing of the precursor to its active form; this critical maturation step occurs at about gestational d 0–7 in humans. Thus, defective signaling of Shh early during development may be a reason why these patients present with several congenital abnormalities. Urogenital anomalies are frequent and are most easily recognized in males. Because of easily recognizable genital abnormalities, males are more likely than females to be evaluated for the diagnosis of SLOS. Many 46,XY individuals with severe manifestations of SLOS have undermasculinization of the external genitalia. This results in female external genitalia in up to 20–25% of 46,XY patients with SLOS described. Because the enzymatic abnormality leading to this disease causes inadequate synthesis of the main precursor to all steroid hormones, a major impairment in the level of C21 and C19 steroids would be expected. Although case reports of adrenal insufficiency with biochemical stigmata of impaired aldosterone production have been reported, this type of presentation is unusual. Further, despite the documented inability to synthesize adequate T in some cases, other patients had normal gonadal function. The HP function seems to be normal in most of these patients. A global mechanism explaining the impaired masculinization of these patients has not been identified and additional hypotheses not completely verified include the presence of concomitant androgen receptor insensitivity, or of 5α reductase 2 deficiency.

CONGENITAL LIPOID ADRENAL HYPERPLASIA The first step in steroidogenesis is the conversion of cholesterol to pregnenolone by the mitochondrial enzyme, P450scc (CYP11A). Pituitary hormones such as adrenocorticotrophic hormone (ACTH) and gonadotropins induce steroidogenesis by interacting with their receptors and changing intracellular cAMP concentrations in the target cells, which induces p450scc activity in two ways. The acute phase, which occurs within seconds to minutes, involves enhanced mobilization and delivery of cholesterol from the outer mitochondrial membrane into the inner mitochondrial membrane to the steroidogenic complex through phosphorylation of pre-existing and rapid synthesis of new StAR. The chronic phase, which requires hours to days, involves increased transcription of the genes implicated in steroidogenesis, including CYP11A. In the absence of StAR, up to 14% of maximal StAR-induced steroidogenesis can persist as StAR-independent steroidogenesis.

Lipoid congenital adrenal hyperplasia (CAH) is a rare autosomal-recessive defect associated with genetic abnormalities of the StAR, in which synthesis of all steroid hormones (estrogens,

glucocorticoids, mineralocorticoids, and androgens) is impaired. The responsible gene is located on chromosome 8q24.3. The disease is more prevalent in the far east, where it is the second most common form of CAH.

Many newborn patients with this disease are hyperpigmented, have female external genitalia irrespective of karyotype, suffer a severe form of salt-losing CAH, and accumulate lipids in the gonads and adrenals, causing gross enlargement of these organs. Interestingly, the time of presentation of these abnormalities is not uniform. For instance, adrenal insufficiency may not present until years after birth, whereas hypogonadism usually is severe at birth in males but does not manifest until after puberty in some females. The most likely explanation for this phenomenon is that the disease has a dual mechanism of presentation. The first, which takes place beginning at the time of embryological development, is related to loss of StAR-dependent steroidogenesis. The second, which requires time to develop, consists in progressive engorgement of steroid-producing cells with lipid droplets that ultimately cause cytopathic changes and deterioration of StAR-independent steroidogenic capacity. Male infants with this syndrome present with male pseudohermaphroditism, characterized by female external genitalia with a blind ending hypoplastic vagina, absent uterus and fallopian tubes, hypoplastic Wolffian derivatives, and cryptorchid testes. No virilization is observed at puberty. Heterozygous parents of affected siblings develop normally. The condition is fatal in infancy in two-thirds of the cases.

This disease should be suspected at birth in patients with a salt-losing crisis and the phenotype discussed earlier. Typical enlargement of the adrenals and testes, visible with MRI or CT aids diagnosis. Usually serum cortisol, aldosterone, and T are undetectable; ACTH, FSH, and LH are elevated; and no response is evident following stimulation with ACTH or β-hCG. At puberty a minimal degree of virilization can occur in 46,XY individuals.

Genetic Basis This disease had previously been ascribed to defects of the $P450_{scc}$ system (CYP11A1), which consists of the cholesterol side-chain cleavage enzyme, and of two electron transfer proteins, termed adrenodoxin reductase and adrenodoxin. This conclusion was based on hormonal studies of affected patients who were unable to produce adrenal and gonadal steroids, and on the inability of mitochondria from affected tissues to convert cholesterol to pregnenelone. A role for $P450_{scc}$ has been excluded in molecular studies of affected individuals, in which abnormalities in the coding sequence of this gene have never been detected. In addition, $P450_{scc}$, adrenodoxin reductase and adrenodoxin genes are normally transcribed and translated in the steroidogenic tissue of affected individuals, suggesting that the lesion responsible for lipoid CAH was located elsewhere. When the role of the StAR became clear, this factor appeared immediately to be the candidate gene responsible for lipoid CAH. Molecular analysis of the StAR confirmed that this factor has a central role in the etiology of lipoid CAH. Mutations affecting both alleles of the StAR gene have been detected in 95% of affected patients. Most families have homozygous mutations; fewer subjects are compound heterozygotes. Interestingly, individuals of Caucasian descent have a large array of different genetic abnormalities, consisting of missense, nonsense, and splice-site mutations, whereas predominant mutations have been detected in patients of Japanese or Arab descent. There is an association between residual StAR activity and time of presentation of certain symptoms. For instance, a compound heterozygous patient presenting with mutations A218V and L275P, each of which maintains approx 20% of StAR activity, survived 4 mo without hormonal replacement. Another compound heterozygous subject carrying mutations M225P (with 43% of activity) and Q258X (totally inactive), survived for 10 mo without therapy. The importance of these mutations in the etiology of lipoid CAH has been demonstrated by showing that StAR cDNAs carrying these mutations lack the ability to promote pregnenolone synthesis in transfected cells and by the presence of a phenotype similar to the human disease in mice with targeted inactivation of the StAR.

Therapy Glucocorticoid and mineralocorticoid replacement is the first therapeutic step for these patients. Given the sexual phenotype, most patients are raised as females. Prophylactic orchidectomy followed by estrogen replacement should be performed to prevent the neoplastic degeneration of the retained gonads and to avoid any possible virilization at puberty.

Late-Onset Congenital Lipoid Adrenal Hyperplasia From Heterozygous Mutations in the Cholesterol Side-Chain Cleavage Enzyme (P450scc) Because P450scc is needed for placental biosynthesis of progesterone, required to maintain pregnancy, it is assumed that inactivating mutations of this enzyme are not compatible with survival. In agreement with this idea, the only identified mutations of P450scc are heterozygous in-frame insertions of Gly and Asp between Asp271 and Val272. The patient was a 4-yr-old 46,XY individual, with atypical features of classic congenital lipoid adrenal hyperplasia consisting in a 4-yr survival without hormonal replacement, before experiencing life-threatening adrenal insufficiency, lack of hypertrophy of the adrenal glands on CT, and some degree of genital virilization, consisting in clitoromegaly. The mutation was found in multiple cell types, but neither parent carried it, suggesting that it arose *de novo* during meiosis. In vitro analysis of the resulting cDNA was associated with total inhibition of enzymatic activity, whereas cotransfection of wild type and mutant cDNAs showed that the mutation did not exert a dominant negative effect. The authors proposed that P450scc haploinsufficiency results in subnormal responses to ACTH, so that continuous ACTH stimulation leads to slow accumulation of adrenal cholesterol, eventually causing cellular damage and a late-onset form of congenital lipoid adrenal hyperplasia explainable with the same two-hit model that has been postulated for congenital lipoid adrenal hyperplasia caused by StAR deficiency, as described earlier.

3β-HYDROXYSTEROID DEHYDROGENASE 2 DEFICIENCY

3β-hydroxysteroid dehydrogenase (HSD) regulates the conversion of Δ^5-3β-hydroxysteroids (pregnenolone, 17-OH pregnenolone, DHEA, and androstenediol) into the corresponding Δ^4-3-ketosteroids (progesterone, 17-OH-progesterone, androstenedione, and T, respectively). Absent or reduced activity of this enzyme is potentially associated with impaired formation of all steroid hormone classes including progesterone, mineralocorticoids, glucocorticoids, androgens, and estrogens. Two isoenzymes with 3β-HSD activity have been cloned, and have been designated type-I and type-II 3β-HSD. Their structural organization consists of four exons and three introns, which are included in a genomic DNA fragment of approx 7.8 kb. The type-I 3β-HSD mRNA is transcribed in the breast, placenta, skin, and, to a much lower degree, in the gonads. The type-II isoenzyme is transcribed exclusively in the adrenals, testis, and ovary. Inactivating mutations of type-II 3β-HSD are responsible for the syndrome.

There is heterogeneity in the clinical presentation of 46,XY individuals affected by this disease. The two major clinical features are incomplete virilization and salt wasting. The degree of salt wasting ranges from life threatening to inapparent. Similarly,

virilization defects can range from the development of genital ambiguities (including hypospadias, micropenis, and presence of a blind ending vagina), to, rarely, the development of normal external genitalia. In most instances, the Wolffian ducts derivatives develop normally, suggesting that although the prenatal testes were capable of some androgen production, even though the quantities were insufficient to permit normal development of the sexual phenotype. The Müllerian duct derivatives involute normally, indicating normal production of AMH by the Sertoli cells. At puberty these patients have typical hypergonadotropic hypogonadism with high gonadotropin and low T. The endocrine abnormalities are associated with spermatogenic arrest and phenotypic features of undervirilization. No correlation has been made between the degree of salt wasting and impairment of male sexual differentiation, suggesting that 3β-HSD mutations can affect the different steroidogenenic pathways differentially.

The diagnosis of this disorder should be suspected in patients presenting with adrenal and gonadal insufficiency. An elevated ratio of Δ^5- to Δ^4-steroids and significant increase in plasma ACTH levels are characteristic of this disorder; however, the interpretation of the endocrine data can be complicated by the increased level of some Δ^4 steroids, including serum 17-OH-progesterone and Δ^4-androstenedione, and urinary pregnanetriol. This is because of the presence of two 3β-HSD enzymes, of which only type II is mutated.

Genetic Basis This disease is transmitted as an autosomal-recessive character, and the gene is located in the region p11-p13 of chromosome 1. The identification of two isoenzymes with the same activity and with a different pattern of expression may explain the normal to elevated serum level of some Δ^4-3-ketosteroids in the patient population with 3β-HSD deficiency. Because the disease causes salt wasting and ambiguous genitalia, it would be expected that the type-II isoenzyme (exclusively transcribed in the adrenals and gonads) is the mutated gene and the type-I isoenzyme (transcribed in the periphery) would maintain its activity and be responsible for the residual conversion of Δ^5-3β-hydroxysteroids to Δ^4-3-ketosteroids. Indeed, the molecular abnormalities causing clinical 3β-HSD deficiency have been localized exclusively to the type-II isoenzyme. Additionally it is expected that mutations do not affect the type-I isoenzyme because it regulates progesterone production in the placenta, and lack of placental progesterone production would not be compatible with fetal survival. Numerous mutations in the coding region of the 3β-HSD gene have been identified by sequence analysis, including missense, nonsense, and frameshift mutations, have been detected in homozygous and compound heterozygous patients. Their functional characterization has helped define the functionally important regions of the 3β-HSD gene.

Molecular Pathophysiology A reproducible correlation exists between the impairment of the enzymatic activity caused by each mutation and the patients' clinical abnormalities. This is particularly true regarding the presence of salt-wasting forms of the disease in which no residual enzymatic activity is detected. Molecular analysis of the 3β-HSD gene of these patients has shown the presence of nonsense mutations (causing the synthesis of prematurely truncated proteins) and missense mutations (causing the replacement of critical amino acids). Mutations causing salt wasting are frequently localized in exon 4. One of the few patients of this group with minimal residual enzymatic activity (0.1–0.3%) was a compound heterozygous carrying two missense mutations (Leu108Trp and Pro186Leu). The presence of such low level of activity is most likely inadequate to prevent the development of salt wasting.

In patients with nonsalt-wasting forms of the disease, there is residual 3β-HSD activity ranging from 1 to 10%, a level that appears to permit enough mineralocorticoid synthesis to prevent salt wasting. Interestingly, in patients with this milder form of the disease there has not been description of premature stop codons, which are expected to completely abolish 3β-HSD activity, but only of missense or splicing mutations. The mutated amino acid residues are conserved in all members of the vertebrate 3β-HSD isoenzymes described.

Therapy Therapy involves replacement with glucocorticoids and, if required, mineralocorticoids. Sufficient androgens should be given early in life to correct the microphallus and allow surgical treatment of hypospadias. Normal replacement doses should be given at the time of puberty.

17α-HYDROXYLASE 17,20-LYASE DEFICIENCY Two important steps of the steroidogenic pathway are regulated by the enzyme 17α-hydroxylase 17,20-lyase (CYP17). The first reaction consists in the 17α-hydroxylation of pregnenolone and progesterone into 17α-hydroxypregnenolone and 17α-hydroxyprogesterone. These C_{21} steroids undergo cleavage of the C-17,20 carbon bond via the 17,20-lyase reaction during the second step, to yield the C_{19}-steroids DHEA and androstenedione.

More than 140 cases with 17α-hydroxylase/17,20-lyase deficiency have been reported; most are affected by the complete and a minority by the partial form of the disease. Also, a number of patients with isolated 17,20-lyase deficiency (ILD) have been described.

Clinical Features Of the enzymatic activities catalyzed by CYP17, 17α-hydroxylase is critical for the production of both glucocorticoid and sex steroids, whereas 17,20-lyase, is critical for the production of sex steroids only. In theory defects of CYP17 activity could occur as isolated deficiencies of 17α-hydroxylase or 17,20-lyase or as combined 17α-hydroxylase/17,20-lyase deficiency. In practice, only cases with complete or partial 17α-hydroxylase/17,20-lyase deficiency have been described, whereas ILD has been only recently accepted as an independent entity.

In the complete form of CYP17 deficiency, the deficient production of cortisol is associated with a compensatory overproduction of ACTH, which stimulates the synthesis of large amounts of corticosterone, usually found at concentrations 50- to 100-fold higher than normal, and 11-deoxycorticosterone (DOC) and 18-hydroxycorticosterone. Although corticosterone and DOC have a lower affinity to the glucocorticoid receptor than cortisol, their activity is sufficient to prevent the development of overt adrenal insufficiency. As a result of the increased production of corticosterone, DOC and 18-hydroxycorticosterone, affected patients develop retention of water and salt, hypokalemic alkalosis, and hypertension. Suppression of renin and of aldosterone production is usually a feature; however, a few individuals with normal or elevated aldosterone have been reported in the Japanese literature. Deficient production of sex steroids is associated in these patients with hypogonadism and a compensatory overproduction of gonadotropins. Because normal levels of T are necessary during fetal life for the development of the normal male sexual phenotype, affected patients manifest a range of abnormalities of the external genitalia, from an apparent female phenotype with a blind ending vagina to hypospadias or micropenis. The Wolffian derivatives can be hypoplastic or normal, the Müllerian derivatives are

normally involuted, and hypoplastic testes may be located intra-abdominally, in the inguinal canal, or in the scrotum. Usually, patients with some form of virilization are thought to have partial deficiency of CYP17 activity. There is lack of correlation between the severity of hypertension and hypokalemia and that of hypogonadism, suggesting that the various mutations of CYP17 can affect formation of C_{21} or C_{19} compounds in different ways.

Patients with ILD do not have hypertension and hypokalemia because adrenal 17α-hydroxylase is normal, and there is adequate production of cortisol. However, in view of 17,20-lyase deficiency, sex steroid production is decreased to a minimum. In 46,XY individuals, this leads to pseudohermaphroditism, intra-abdominal testes, and lack of pubertal development.

Diagnosis CYP17 deficiency should be considered in every 46,XY patient with a family history of pseudohermaphroditism that suggests an autosomal-recessive inheritance. It is usually recognized in young adults with hypertension, hypokalemia, and ambiguous genitalia. The diagnosis of 17α-hydroxylase deficiency can be confirmed by demonstrating increased serum concentrations of pregnenolone, progesterone, corticosterone, DOC, and 18-hydroxycorticosterone, associated with increased urinary excretion of their respective glucuronidated metabolites. Plasma renin activity, serum cortisol, and aldosterone are usually suppressed and ACTH is elevated. Affected males have low T and elevated gonadotropins. The response to hGC and ACTH stimulation tests are impaired. This steroid pattern applies to patients with combined CYP17 deficiency. In patients with ILD clinical symptoms are usually limited to the sexual phenotype. An important feature of this latter group of patients is the presence of normal serum level of cortisol and DOC and of their urinary metabolites. However, because of the presence of 17,20-lyase deficiency, these patients have increased serum levels of progesterone, 17-OH-progesterone and 17-OH-pregnenolone, increased urinary levels of pregnanetriolone, and decreased serum levels of T and of its precursors.

Genetic Basis The human $P450_c17$ gene (CYP17) is a single copy gene, located on chromosome 10q24-25. It consists of eight exons and seven introns spanning 6569 bases. Full length cDNA clones have been isolated from adrenal and testicular sources, and have the same nucleotide sequence. When the cDNA clones encoding this enzyme were expressed in cultured cells, the expressed protein displayed both 17α-hydroxylase and 17,20-lyase activities. The molecular and functional analyses of several mutations of the CYP17 gene show that the genetic lesions of 17α-hydroxylase deficiency are random events and that there are not structural features of the gene predisposing to specific abnormalities. Functional analyses of mutations from patients affected by the complete form of CYP17 deficiency show that most impair both 17α-hydroxylase and 17,20-lyase activities, further demonstrating that this gene encodes a protein possessing both enzymatic activities. Only a limited number of mutations have been reported more than once and were detected in unrelated individuals of Guamaian and German-Dutch descent, indicating that this disorder is genetically heterogeneous, unless associated with a specific ethnic group.

Molecular Pathophysiology The description of the molecular defects and functional abnormalities affecting patients with the complete and incomplete forms of CYP17 deficiency and ILD has elucidated several aspects of this disease. Activation of CYP17 involves a chain of actions including proper anchorage of the enzyme onto the microsomal membrane, heme binding, substrate binding, transfer of electrons from NADPH-cytochrome P-450 oxidoreductase, and O_2 binding. Mutations specifically affecting heme, substrate binding, and electron transferring have been identified.

Combined CYP17 Deficiency Numerous mutations resulting in loss of both 17α-hydroxylase and 17-20-lyase activity have been identified in the CYP17 gene. Premature termination codons resulting from nonsense mutations or from other abnormalities of the open reading frame (including deletions or insertions of DNA) lead to truncated forms of the protein, which, by being deprived of the C-terminal heme-binding domain, becomes functionally inactive. Complete loss of enzymatic function in three patients with missense mutations has identified residues Ser_{106}, His_{373} and Arg_{440} as critical for the accomplishment of both 17α-hydroxylase and 17-20-lyase activities. Of note is the speculation that the mutation occurring in amino acid residue 106 may affect substrate binding, whereas the two other mutations (His_{373} and Arg_{440}) affect heme binding.

Partial Combined CYP17 Deficiency Partial deficiency of 17α-hydroxylase and 17-20-lyase has been studied in two patients. One of these patients was a boy with ambiguous genitalia, carrying two different CYP17 mutant alleles: one resulting in an Arg_{239}Stop nonsense mutation and the other causing a Pro_{342}Thr missense mutation. The residual activity of these two alleles was, respectively, 0 and 20% of normal. These data, together with the functional analysis of a 46,XY female with homozygous premature termination codons (with residual functional activity of 0%) and of her normally virilized heterozygous father (thought to have a residual functional activity of 50%), have been useful to understand the amount of 17α-hydroxylase activity necessary for the development of the male sexual phenotype. Because the boy with ambiguous genitalia had a residual activity of 20% and the normally virilized individual described earlier was thought to have a residual activity of 50%, it would appear that the threshold activity necessary to change the sexual phenotype from female to ambiguous male is between 0 and 20%, and to change from ambiguous to normal is between 20 and 50%.

Isolated 17,20-Lyase Deficiency (ILD) The existence of this syndrome was initially in doubt, because molecular genetics studies in one of the first patients described demonstrated that his mutation was responsible for loss of both 17α-hydroxylase and 17-20 lyase activities. However, the report of two 46,XY Brazilian hermaphrodites with a hormonal picture characterized by normal amounts of 17-hydroxysteroids and severely reduced sex steroids and C_{19} precursors, led to conclusive evidence that this syndrome does exist. Abnormalities in the interaction of CYP17 with redox partner proteins P450-oxydoreductase and cytochrome-b_5 form the biochemical basis for the syndrome of ILD. The unifying mechanism causing ILD consists in the neutralization of positive charges in the redox partner binding site, which results in inhibition of electron transferring from NADPH cytochrome P450 oxidoreductase. In support of this hypothesis, mutagenesis of several positively charged residues of the redox partner binding site, such as Arg347His (or Arg346Ala in the rat sequence), Arg358Gln, Lys89Asn, and Arg449Ala, is associated with selective loss of 17,20 lyase activity.

Treatment consists in replacement with cortisol, which accomplishes suppression of ACTH followed by the normalization of DOC, corticosterone, and 18-hydroxycorticosterone, and by the normalization of renin and aldosterone levels. Adult 46,XY individuals reared as females require estrogen replacement and removal of the abdominal gonads to prevent their malignant

Table 45-3
Features of Isoenzymes With 17β-HSD Activity

Type	*17β-HSD deficiency*	*Size/No. amino acids*	*No. exons*	*Chromosome localization*	*Tissue localization*	*Cellular localization*	*Preferred substrate*	*Preferred cofactor*	*Catalytic preference*
1	Normal	327	6	17q21	Ovaries, placenta	Cytosol	Estrone, estradiol	NADPH	Reduction
2	Normal	387	5	16q24	Endometrium, placenta, liver	Microsomes	androgens, estrogens	NAD+	Oxidation
3	Mutated	310	11	9q22	Testis	Microsomes	androgens, estrogens	NADPH	Reduction
4	Normal	736	24	5q2	ubiquitous	Peroxisomes	estrogens	NAD+	Oxidation

7	Normal			6p21.3	Ovaries, testes, kidney		Estradiol, testosterone and dihydro-testosterone		

HSD, hydroxysteroid dehydrogenase.

degeneration. Adult 46,XY individuals raised as males require androgen replacement, surgical correction of their external genitalia, and, if necessary, orchidopexy.

17β-HSD DEFICIENCY The enzyme 17β-HSD catalyzes the conversion of androstenedione, DHEA, and estrone into T, androstenediol, and estradiol, respectively. As such, it converts two weak precursors, androstenedione and estrone, into two potent hormones, T and estradiol, that, on interacting with high affinity with their receptors, induce their biological effects. The reaction catalyzed by 17β-HSD is reversible. The reduction of the 17 keto group is thought to occur mainly in the testis and ovary, in which it is required for the synthesis of T and estradiol. The oxidation reaction, thought to occur in several peripheral tissues, is important for the inactivation of these two hormones.

Seven different isoenzymes with 17β-HSD activity have been isolated and designated 1 through 5 and 7 through 8 according to the chronological order of their identification. They have different biochemical features, and are expressed in different tissues (Table 45-3). Interestingly, isoenzymes 1 and 3 favor the reduction reaction, whereas types 2 and 4 favor the oxidation reaction. Isoenzymes 2 and 4 have ubiquitous tissue distribution, whereas isoenzymes 1 and 3 are expressed in a more selective way. The mRNA of the type-1 isoenzyme is present in the ovary and placenta, whereas the type-3 mRNA has been detected almost exclusively in the testis. Mutations of type-3 isoenzyme have been associated with 17β-HSD deficiency.

Clinical Features A significant number of patients with classic 17β-HSD deficiency have been reported. The prevalence of the syndrome is particularly elevated in the Gaza strip, in which it is estimated that 1 in 100–150 individuals is affected. The pattern of inheritance is autosomal-recessive. At birth these patients present with female external genitalia, absent Müllerian and normal Wolffian duct derivatives, and undescended testes. Based on this phenotype, gender assignment is female in almost every case. At puberty certain aspects virilize (developing a deep voice, large phallus, and various degrees of body and facial hair) and other aspects feminize (developing variable degree of gynecomastia). Some of these individuals have undergone a change in gender role behavior in parallel with the virilization occurring at the time of puberty. Impaired 17β-HSD activity explains the abnormal virilization of the external genitalia at birth, the elevated serum level of androstenedione and decreased T, and the enhancement of pituitary gonadotropin production. A milder form of late-onset 17β-HSD deficiency has been identified in three adult patients with gynecomastia and hypogonadism in a study of 48 subjects with idiopathic pubertal gynecomastia. However, DNA sequence analysis of the coding sequence of type-3 17β-HSD has not yielded any abnormality in these patients.

Endocrine Features and Diagnosis The diagnosis should be considered in 46,XY patients presenting with pseudohermaphroditism inherited with an autosomal-recessive pattern. Plasma androstenedione, estrone, and gonadotropins levels are elevated, whereas T and dihydroT are decreased or in the low normal range. Steroid hormone metabolism has been studied in the testes of several affected subjects, and the conversion of androstenedione to T was consistently abnormal. However, other authors have found that the oxidative reaction catalyzed by 17β-HSD was normal in cultured fibroblasts obtained from one patient.

Most of these patients are diagnosed at puberty, when they are referred for failure to menstruate, or because they develop a mixed pattern of virilization and feminization. The diagnosis of 17β-HSD deficiency is more challenging in the newborn. However, the correct interpretation of the endocrine data, and use of dynamic endocrine tests such as the hCG stimulation tests should permit the diagnosis of this disorder in any age group.

Genetic Basis Because of its biochemical characteristics and tissue distribution, type-3 17β-HSD was considered to be a good candidate to cause the clinical abnormalities of 17β-HSD deficiency. Subsequent analysis has identified mutations of this gene in families with the typical phenotypic, endocrine, and genetic features of the syndrome. The mutations detected included missense mutations, splice junction abnormalities, and a small deletion resulting in a frameshift. Patients with the syndrome were most frequently homozygous, but heterozygous, and compound heterozygous have been described as well. The mutation Arg80Gln has been detected in three unrelated families, including a member of the large kindred from the Gaza strip and two Brazilian families. Considering the high incidence of 17β-HSD deficiency in the Gaza strip, screening

programs for this mutation may be worthwhile there to detect heterozygosity or for prenatal diagnosis. The real frequency of this mutation in the entire Arab population of the Gaza strip could be very high, considering that homozygous females are asymptomatic, have normal internal and external genitalia, undergo normal sexual development, and have unimpaired fertility.

Molecular Pathophysiology Many of the mutations described have been recreated in vitro and their activity studied in transfected cells. Some are completely inactivating. However, in agreement with biochemical studies performed in the cultured genital skin fibroblasts, mutation Arg80Gln retains a small amount of activity. Detailed analysis of the enzymatic activity of this mutant has revealed a 100-fold decreased affinity for the cofactor NADPH, localizing at least a portion of the NADPH-binding domain to the region surrounding residue 80. These developments in the molecular biology of 17β-HSD deficiency have permitted understanding of why these patients undergo virilization at the time of puberty. The consensus is that androstenedione, produced by the testes in supraphysiological concentrations at puberty, provides the substrate for the extraglandular production of T by one of the other 17β-HSDs that are not impaired in this disorder. However, some clinical features of 17β-HSD deficiency are not completely explained. For instance, it is not clear why the embryonic structures of the developing male genitalia respond to the hormonal abnormalities created by 17β-HSD deficiency in a different way. In this disorder the Wolffian derivatives undergo almost normal virilization during embryogenesis, whereas the external genitalia do not virilize at all, suggesting the presence of an alternative pathway for T biosynthesis *in utero*.

Treatment Patients who are not diagnosed at birth are usually raised as female, and treatment consists of gonadectomy followed by estrogen replacement at the time of expected puberty. When the diagnosis is correctly identified in early infancy and gender reassignment is possible, the patients should receive T treatment at pediatric doses and genitoplasty early in infancy and be replaced with adult doses of T at the time of expected puberty. The basic enzymatic defect persists, and impaired spermatogenesis is present during adulthood.

TYPE-2 5α-REDUCTASE DEFICIENCY The enzyme 5α-reductase is involved in the conversion of T into his powerful 5α reduced metabolites dihydroT. Two isoenzymes have been isolated that share this enzymatic activity, and have been designated types-1 and 2 5α-reductase. The clinical syndrome is associated with mutations of the type-2 isoenzyme (Chapter 44).

HYPOGONADOTROPIC DISORDERS

Several congenital and acquired disorders (*see* Table 45-1) account for hypogonadotrpic hypogonadism (HH). Their common denominator consists in the impaired production of GnRH or of gonadotropins by the hypothalamus and/or pituitary gland. This, in turn results in failure to stimulate the correct production of gonadal steroids, and in a spectrum of clinical manifestations that vary, depending on whether the abnormality developed before birth, before puberty, or after puberty (*see* Table 45-2).

HYPOGONADOTROPIC DISORDERS ASSOCIATED WITH ISOLATED GONADOTROPIN DEFICIENCY

GPR54 DEFICIENCY In primates, the HPG axis is active during neonatal life. It is followed by a period of dormancy during childhood, and it is again triggered to function at puberty. Mechanisms regulating the period of dormancy during childhood, and the awakening at puberty have been unclear. However, knowledge of the central mechanisms regulating sexual maturation at puberty has significantly improved. Based on the clinical observation that patients with HH have partial or complete absence of LH pulsation, and normal responsiveness to physiological replacement with exogenous GnRH, it was established that the defect of endogenous GnRH lies at the level of its synthesis, secretion or activity. Thus, linkage analysis of affected families, and identification of candidate genes has permitted the identification by two groups of GPR54 as a new gene regulating pubertal development. GPR54, a G protein-coupled receptor for a ligand called kisspeptin-metastin, is expressed in the human brain, pituitary gland, and placenta, and was found to have mutations in 4 of 113 cases of HH. Conclusive evidence that GPR54 is part of the pathway triggering pubertal development came from the characterization of the phenotype of a $Gpr54^{-/-}$ mouse. In this mouse, beside lack of pubertal development both in males and females, no significant differences were found between normal and mutant mice in the concentration of GnRH in hypothalamic extracts, and normal ability to synthesize FSH and LH at the level of the pituitary gland. Because both patient and mice with this genetic defect were able to respond to exogenous GnRH with an appropriate, or in the case of a patient, increased release of LH, GPR54 may regulate the release of GnRH at the level of the hypothalamus. The mechanism is still unknown, however, the discovery of GPR34 opens a large number of avenues to further understand the mechanism of how puberty is triggered. For instance, future investigations on potential abnormalities in the biosynthesis/release of the ligand kisspeptin-metastin or on the signaling pathway activated by its interaction with GPR34, have the possibility to uncover new mechanisms of how puberty is triggered and further causes of hypogonadotropic hypogonadism.

KALLMANN SYNDROME The first description of Kallmann syndrome (KS) dates to 1856 by Maestre de San Juan, but it was not until the original description by Kallmann in 1944 that the disease was recognized as an inherited entity. It is found in 1/10,000 newborn males, and in 1/50,000 newborn females, and occurs in both sporadic and familial forms. Sporadic cases are more frequent than familial cases. Owing to its predominance in the male sex, it was initially thought that KS is an X-linked disorder. However, there is convincing evidence that additional forms exist that demonstrate autosomal-recessive and autosomal-dominant forms of transmission. In agreement with this heterogeneous inheritance, abnormal genes have been detected in the X chromosome (*KAL1*) and, in patients with the autosomal-dominant form, in chromosome 8 (*KAL2*). *KAL1* (anosmin-1) and *KAL2* (fibroblast growth factor receptor-1 [FGFR-1]) have been located in the Xp22.3 and 8p11.2-p12 regions, respectively. The gene responsible for the autosomal-recessive form of KS (*KAL3*) has not been identified.

Embryology of the LH-RH Neurons Molecular events associated with the migration of the GnRH-secreting neurons during embryogenesis are intimately connected with the pathogenesis of KS. These neurons originate in the epithelium of the olfactory placode, from where they migrate into the brain by the twelfth week of gestation along the pathway of the developing olfactory tract, represented by the olfactory, terminalis, and vomeronasal nerves. The GnRH neurons enter the brain through the nervus terminalis and vomeronasal, and then course into the septal-preoptic

area and the hypothalamus. The normal migration of the GnRH neurons depends on genes located in Xp22.3, the same area of the X chromosome that is deleted in patients with the X-linked form of KS. This was demonstrated in a fetus with KS and a deletion of Xp22.3, in whom GnRH expressing neurons were not found in the hypothalamus, but were instead identified beneath the forebrain, within the dural layers of the meninges and on the cribriform plate. When the migration is completed, there are fewer GnRH neurons in the brain (~1500), than there were in the nose at the beginning of this process, probably because many cells die or differentiate into other cell types during migration. Only after reaching their final destination do the GnRH-containing neurons acquire the capacity to secrete GnRH.

Clinical Features and Diagnosis Individuals affected by KS can sometimes be recognized before puberty because of the presence of microphallus and/or cryptorchidism, heralding fetal T deficiency. Others are recognized at puberty when they present with delayed appearance of the secondary sex characteristics and gynecomastia or for the development of eunuchoid features. Abnormalities observed in KS other than those related to hypogonadism include hyposmia, anosmia, cleft lip, or cleft palate. Other symptoms occasionally described are sensory neural deafness, ocular motor abnormalities, abnormal spatial visual attention, mirror movements of the hands (bimanual synkinesia), cerebellar dysfunctions, congenital cardiac abnormalities, choanal atresia, cleft palate or lips (more commonly seen in the autosomal-recessive form), pes cavus deformity, and unilateral or, in some cases, bilateral renal aplasia. Mental retardation has been described, however, the genotype analysis of these patients showed large deletions on Xp22.3 that extended beyond the Kallmann locus. On the contrary, patients with mutations restricted to the Kallmann locus tend to have normal intellectual function. Regarding the prevalence of anosmia, one of the cardinal symptoms of KS, it was reported that no patient of molecularly confirmed X-linked KS has intact smell although not every patient is aware of it and that tests may be needed for its detection. In contrast, others have reported that anosmia is not present in every patient, and in some large series this feature is absent in up to 50–60% of the cases. Affected females usually have partial or complete anosmia. Some KS patient also manifest other diseases, like chondrodysplasia punctata, ichthyosis, short stature, ocular albinism, and mental retardation, which are associated with large chromosomal deletions, usually of the distal short arm of the X chromosome.

Hypogonadism is due in KS to reduced secretion of GnRH by the hypothalamus; many KS individuals have adequate response of LH and FSH after sufficient priming of the pituitary with exogenous GnRH, although in some cases inadequate responses of LH and FSH to the administration of GnRH and of T to hCG have been shown. Subjects with documented X-linked KS usually have apulsatile LH secretion, whereas those with autosomal-modes of inheritance demonstrate more variably abnormal GnRH-induced LH pulses. The decreased secretion of GnRH results in an abnormal secretory pattern of LH pulses, ranging from decreased or absent amplitude to diminished frequency. In the complete form of GnRH deficiency, LH and FSH deficiency is severe, and no evidence of sexual maturation is evident. In the incomplete form, (known as the fertile eunuch syndrome), there is both normal FSH and low LH, or partial defects in both, with some degree of germ cell maturation. Laboratory tests reveal low serum FSH and LH level, and low T. However, a large degree of heterogeneity in the serum levels of FSH and LH can be observed. On MRI, bilateral agenesis of the olfactory bulbs or sulci can be seen in greater than 50% of the cases.

The diagnosis is suggested by the typical clinical picture and laboratory tests that demonstrate hypogonadotropic hypogonadism. The most challenging differential diagnosis is with delayed puberty. Important criteria are to show the presence of anosmia or hyposmia, any other associated congenital defect or positive family history for KS. However, the separation of these two entities may require a prolonged period of observation, detailed laboratory investigations, and MRI scans of the head. Testicular biopsies of males show decreased number of germ cells and a spermatogenic state at the primary spermatocyte stage. Leydig cells are not histologically identifiable. Urine gonadotropins have been reported as low in some patients tested. Early diagnosis is important because treatment with chorionic gonadotropin can correct cryptorchidism and establish fertility probably in an age-dependent manner.

Genetic Basis and Molecular Pathophysiogy Using positional cloning techniques, two independent groups isolated the gene for KS (*KAL1*) that is located at the Xp22.3 interval. Evidence that this gene is responsible for KS came from the observation that in some affected patients it contained extensive deletions, or point mutations. The presence of a highly conserved *KAL1* homologue in the Y chromosome has somehow delayed the development of mutations scanning strategies, however, point mutations within the 14 exons of the gene have been detected in a number of patients. In a series of 101 patients with idiopathic hypogonadotropic hypogonadism, 59 had true KS (hypogonadotropic hypogonadism and anosmia/hyposmia), whereas, in the remaining 42, no anosmia was evident. Of the 59 KS patients, 21 were familial and 38 were sporadic cases. Mutations in the coding sequence of *KAL1* were identified in only three familial cases (14%) and four of the sporadic cases (11%) suggesting that confirmed mutations in the coding sequence of the *KAL1* gene occur in the minority of KS cases, and that most cases of KS are caused by other defects. Sequence analysis of the *KAL1* gene product, the extracellular matrix protein called anosmin-1, has provided interesting insights into the pathogenesis of KS. Anosmin-1 is 680 amino acids long and seems to play a key role in the migration of GnRH neurons and olfactory nerves to the hypothalamus. Owing to the lack of a transmembrane domain or a phosphatidyl inositol anchorage site, it is thought to be an extracellular matrix molecule. Of two important motifs in the search for homologies, the first is a four-disulfide core domain found in a number of proteins with protease inhibitory activity that is located in the N-terminal part of the molecule. The second is a region of similarity with the fibronectin type III repeat, found in numerous adhesion molecules involved in axon to axon interaction or in neuronal migration. Based on these sequence homologies, anosmin-1 may represent an extracellular matrix factor that possesses both antiprotease and adhesion (or antiadhesion) functions. This protein may play a critical role in the migration process involving the olfactory and GnRH neurons during embryogenesis. Its absence or abnormal function in KS may help to explain the double clinical defect (hypogonadism, anosmia) observed in many of these patients. In addition, abnormalities of anosmin-1 could also explain some of the other, less frequent, manifestations of the disease. RNA *in situ* hybridization studies have demonstrated *KAL1* mRNA expression in the Purkinje cells of the cerebellum, the nucleus of the oculomotor

nerve, the mesonephros and facial mesenchyme, which correlates with the presence in some KS patients of cerebellar dysfunction, eye movement defects, unilateral renal aplasia, and cleft palate.

The *KAL1* gene does not explain the autosomal-type of inheritance in some KS patients. Loss-of-function mutations in the FGFR-1 gene, located in chromosome 8p11.2-11.1, has been described in cases with the autosomal-dominant form of KS (*KAL2*). In four familial cases and eight sporadic cases, heterozygous mutations of FGFR-1 were detected: one nonsense mutation, two frameshift mutations, two donor splice-site mutations, and seven missense mutations. FGF signaling is involved in a variety of developmental processes, including organogenesis. Interactions between FGF, the FGF receptor and heparan sulfate proteoglycans are necessary for the induction of receptor dimerization and autophosphorylation of intracellular tyrosine residues that may stimulate tyrosine-kinase activity in the receptor, or serve as docking sites for downstream signaling molecules. The mutations in FGFR-1 could hinder the formation of functional receptor dimers interfering with the normal development of the olfactory bulb. It is also possible that, in subjects with KAL-1 mutations, anosmin-1 is involved in FGF signaling by binding to heparan sulfate proteoglycans that are essential for FGFR-1 dimerization, and that the higher prevalence of the disease in males is because of gender difference in anosmin-1 dosage, because KAL1 partially escapes X inactivation. Based on this, it would be expected that the higher production of anosmin-1 in females maintains FGFR-1 signaling also in conditions of haploinsufficiency. In agreement with this hypothesis, in four of the five families in whom FGFR-1 mutations were detected, the abnormality was transmitted by an asymptomatic mother.

HH FROM BIOLOGICALLY INACTIVE MEMBERS OF THE HP AXIS

Abnormalities occurring in the sequences of the genes encoding GnRH, the GnRH receptor (GnRHR), LH or FSH have the potential to explain some cases of idiopathic HH or infertility in males. As discussed later, individuals with mutations of all these genes, except GnRH, have been described in patients. These mutations are rare, because they severely affect fertility. However, because heterozygous mutations of these genes do not affect fertility, occasional homozygous or compounded heterozygous have been detected, and have elucidated the functions of the two gonadotropins in conditions in which the activity of one of them has been selectively eliminated. Unlike the gonadotropin receptor genes in which mutations causing both loss- or gain-of-function have been identified, mutations occurring in the genes of the HP axis are invariably inactivating.

GnRH GENE MUTATIONS Evidence supporting the possibility that mutations of the GnRH gene are associated with hypogonadotropic hypogonadism is illustrated by the hpg mouse, an animal model with hypogonadism and infertility because of a deletion of the GnRH gene. In this animal model, reintroduction of a wild type GnRH gene restores a normal phenotype and reproductive functions. Despite a significant number of studies, no mutations in the sequence of the GnRH gene have been detected in humans so far.

GnRH RECEPTOR MUTATIONS The GnRHR gene is located in chromosome 4q21.2. It consists of three exons and encodes a heptahelical transmembrane G protein-coupled receptor. On binding GnRH, GnRHR activates phospholipase C, which then causes intracellular accumulation of inositol triphosphate, mobilization of calcium, and eventually release of LH and FSH. Mutations of GnRHR represent the first identified autosomal-recessive cause of HH. Prevalence is 17 and 40% among all sporadic and autosomal-recessive cases of HH, respectively. Identified mutations associate with a broad spectrum of phenotypes, ranging from the mild abnormalities seen in the fertile eunuch syndrome, to severe cases of complete GnRH resistance. Regardless of the phenotypic impairment, all these patients have normosmia. Male patients display small testes and micropenis, whereas cryptorchidism is observed in some cases. T, LH, and FSH levels are usually low, although in patients affected by the syndrome's incomplete form, the concentration of these hormones can be within the normal range. Studies using GnRH stimulation have confirmed that many of these patients have the incomplete form of the syndrome, as only 25% failed to respond to a single IV injection of 100 μg. Similar conclusions can be reached in patients tested with pulsatile administration of GnRH; lack of any response was observed in 50%, whereas the remaining exhibited loss of spontaneous LH pulsatility or reduced amplitude of LH peaks with normal frequency. Most affected patients are compound heterozygotes, and mutations in Q106R and R262Q represent hot spots identified in unrelated pedigrees. Homozygosity is usually associated with a more severely affected phenotype. Expression of mutated receptors in heterologous cells has shown either GnRH-binding defects, or decreased activation of phospholipase C. In many cases the mutated receptors maintained some activity, and this explains the lack, in some patients, of a typical phenotype.

MUTATIONS IN THE CODING SEQUENCE OF GONADOTROPIN SUBUNIT GENES Four glycoprotein hormones are known, LH, FSH, hCG, and thyroid-stimulating hormone (TSH). They are composed of a common α-subunit and a specific β-subunit, which undergo coupling through noncovalent interactions. Subsequently, each dimer undergoes post-translational modifications consisting in glycosylation at a variety of sites. FSH is essential in males to stimulate Sertoli cell function and spermatogenesis, whereas LH induces T production by the Leydig cells.

No germ-line mutation in the common α-subunit gene has been identified. Only one somatic mutation has been detected in this protein in a patient affected by a carcinoma. The resulting mutated common α-subunit was unable to couple with the β-subunit of the other glycoprotein hormones. The fact that no human germ-line mutations of the common α-subunit have been detected probably implies that they are lethal, as they would prevent the formation of all glycoprotein hormones and of the vital functions mediated by some of them.

MUTATIONS OF THE β-SUBUNIT OF THE LH GENE In males, only one case of hypogonadism with infertility has been associated with mutations of the LH gene. The propositus of this study was a 17-yr-old patient with a hormonal profile showing low T, high immunoreactive LH, and normal FSH. A testicular biopsy revealed arrest of spermatogenesis, and the absence of Leydig cells. When this patient was treated with exogenous hCG, a normal increase in T secretion occurred, which was in contrast with the initial diagnosis of primary hypogonadism. Subsequently, the LH of this patient was found to be devoid of biological activity using a dispersed Leydig cell bioassay, suggesting the production of an immunologically active but biologically inactive LH molecule. Sequence analysis of the coding sequence of the LH gene revealed the patient to be homozygous for a missense mutation, Q to R at amino acid residue 54. Functional experiments have shown

that this mutation impairs the ability of the resulting LH to bind and activate its receptor. This study was extended to other members of the family, including three maternal uncles and the mother of the propositus, and has elucidated how heterozygous carriers of both sexes manifest clinically. The mother, an obligate heterozygote, underwent normal puberty and was fertile. The three heterozygous maternal uncles underwent normal puberty, reported normal libido and sexual performance, and had a normal physical examination. However, their serum T concentration was low on several occasions, and at the time of the study they were childless. Therefore, given the limited nature of the pedigree, it would appear that heterozygous mutations of the LH gene do not present with important clinical abnormalities in the female sex, but may be associated with infertility in males.

Although mutations of the LH gene causing hypogonadism and infertility have only been detected in one male patient, the description of this case report has permitted a better understanding of the physiological role played by LH during the embryological development of the male sexual phenotype. The proband of this study was born with normal masculinization of his genitalia and with descended testes. Thus, LH may not be critical for normal male sexual development, and during embryogenesis adequate amounts of androgens from the adrenals or the testes are produced, probably under the stimulation of placental hCG. Pituitary LH starts having a role in regulating testicular function only after birth, which explains why this patient was born with a normal phenotype, but failed subsequently to produce the T necessary to induce pubertal development.

Variants of the β-Subunit of the LH Gene A relatively common variant of the β-subunit of the LH gene was identified as a consequence of anomalous LH assay results that employed a variety of monoclonal antibodies to detect LH in serum in a normally cycling woman who had two children. One of the antibodies, raised against an epitope present only in the intact LH dimer, failed to detect any LH-related immunoreactivity in this woman. Sequence analysis identified a genetic variant (V-LH) of the gene consisting of two missense mutations in the same allele: W8R and I15T. This V-LH allele has been found in Japan, in 28% of the normal Finnish population, 28.3% of Australian aborigines, and >10% of Northern Europeans. Consequences of these two mutations are that I15T introduces an additional glycosylation signal, whereas W8R is responsible for the lack of immunoreactivity of V-LH to the specific antibody described earlier. The V-LH form is more active than wt-LH, but has a shorter half-life of 26 vs 48 min. Interestingly, eight point mutations have been identified in the promoter of the V-LH allele, which account for an increased transcription/synthesis of the gene. Thus, the decreased half-life of the V-LH allele is somehow compensated by increased synthesis. Although this allele has been related to recurrent spontaneous abortions, menstrual irregularities, and polycystic ovarian disease in females, in males it has been associated with a delay in the progression of puberty in boys and with increased prevalence in elderly men of low T and high LH concentrations.

MUTATIONS OF THE β-SUBUNIT OF THE HCG GENE Of the six hCG β-subunit genes present in the human genome, only number five is highly expressed. Sequence analysis of this gene has identified a V79M mutation in 4.2% of the general population. This polymorphism has been detected only in the heterozygous form. This mutated β-subunit of the hCG gene is less likely to associate with the common α-subunit, however the activity of the resulting dimer is normal. The fact that this polymorphism was present only as a heterozygous character implies that it is probably lethal when present in both alleles.

MUTATIONS OF THE β-SUBUNIT OF THE FSH GENE Mutations in the sequence of the β-subunit of the FSH gene have been reported in women with a phenotype characterized by primary amenorrhea, absence of thelarche, and infertility. Replacement with exogenous FSH induced follicular maturation, ovulation, and pregnancy. In view of its central role in spermatogenesis but not steroidogenesis, infertility would be the abnormality expected to be associated with inactivating FSH mutations in males. In agreement with this, all patients described were referred initially for work up of azoospermia. The first patient presented with azoospermia, normal puberty, absent FSH, normal LH and T, and had a C82R mutation (not studied in vitro). The second patient had delayed puberty, and endocrine studies showed undetectable FSH, low T, and elevated LH in addition to azoospermia. Similarly to one of the females described, he was found to have a 2 bp deletion in codon 61. The first patient was treated without success with exogenous FSH, suggesting that his azoospermia potentially was caused by unidentified abnormalities. Based on the expected phenotype of FSH deficiency, it is not clear why the second patient presented with Leydig cell hypofunction. The possibility that FSH may be required also for steroidogenesis is a possibility, however, because other models of FSH inactivation (such as inactivating mutations of the FSH receptor) and the other patient with a mutation the β-subunit of the FSH gene did not have abnormalities in testicular androgen synthesis. Additional cases need to be identified to better understand the role of FSH action in males.

HYPOGONADOTROPIC HYPOGONADISM FROM MUTATIONS OF GENES CAUSING COMBINED PITUITARY HORMONE DEFICIENCIES

Abnormalities of transcription factors required for ontogenesis of the pituitary gland can cause HH with or without deficiencies of other pituitary hormones. Pituitary transcription factors associated with combined pituitary hormone deficiency have been described and include the PROP1, HESX1, and LHX3 genes. Patients with anomalies of these genes are affected by variable forms of hypopituitarism presenting with a clinical spectrum ranging from GH deficiency to panhypopituitarism. Usually ACTH secretion is spared.

HESX1mutations are associated with septo-optic dysplasia. The clinical manifestations are clearly present when both alleles are affected; however, heterozygous mutations of this gene have been described in association with milder forms of hypopituitarism. Functional analysis of HESX1 genes mutagenized to incorporate the mutations detected in patients was performed in heterologous cells and showed altered DNA-binding activity of this transcription factor.

Mutations of LHX3 are associated with hypopituitarism and a form of rigid cervical spine that prevents dissociation of head and trunk movements. Pituitary hypoplasia is usually present, and detectable by MRI. The mutations described prevent the transcriptional activity of this homeobox gene by inhibiting its DNA-binding ability.

PROP-1-deficient patients have an autosomal-recessive form of GH, TSH, prolactin, and gonadotropin deficiency. From a molecular point of view, PROP-1 fails to work as a transcription factor in response to missense mutations or deletions of the coding

sequence. PROP-1 expression in the developing pituitary gland is necessary for the expression of PIT1, another important transcription factor for pituitary development. However, unlike patients with inactive PROP-1, PIT1 deficiency is associated with lack of GH, prolactin and TSH, but not of LH and FSH secretion.

HYPOGONADOTROPIC HYPOGONADISM FROM MUTATIONS OF GENES ASSOCIATED WITH OBESITY

LEPTIN AND LEPTIN RECEPTOR Mutations of the leptin and leptin receptor genes are associated with morbid obesity, insulin resistance, hyperphagia, and hypogonadotropic hypogonadism. Although these mutations are extremely rare, they have been instrumental in clarifying the role played by leptin and leptin-R in controlling food intake. Interestingly, patients with mutations of the leptin gene have been treated with recombinant leptin and this therapy has achieved not only weight normalization, but also induction of puberty. Although these data clearly describe a central role for the leptin–leptin receptor axis in the induction/progression of puberty, it is not clear whether leptin has a direct action on hypothalamic structures regulating pubertal development, or if it sensitizes the hypothalamus to the action of other neuropeptides.

PROHORMONE CONVERTASE-1 Prohormone convertase-1 (PC1) is an endopeptidase required for the post-translational modification of hormones required for the normal initiation/maintenance of puberty. A patient with a compound heterozygous lesion of the PC1 gene has been described with a clinical presentation consisting of extreme obesity, HH, adrenal insufficiency and hypoinsulinemia. Interestingly, the levels of precursor hormones such as proinsulin and POMC were elevated, suggesting that lack of PC1 activity is associated with an inability to correctly process prohormones into the final, active product. HH would therefore be the consequence of a defective processing of hormones or neuropeptides involved in the development of normal HP anatomy and physiology.

HYPOGONADOTROPIC HYPOGONADISM ASSOCIATED WITH CENTRAL NERVOUS SYSTEM DISORDERS

Several congenital syndromes exist in which central nervous system disorders are associated with hypogonadotropic hypogonadism (Table 45-4). One hypothesis is that these disorders may be the consequence of a spectrum of congenital abnormalities simultaneously disrupting the neuronal pathways for the GnRH neurons in the hypothalamus and normal CNS development. The identities and function of the gene(s) responsible for this group of syndromes are unknown.

PRADER–WILLI SYNDROME Prader–Willi syndrome (PWS) is an unusual condition occurring in 1 of every 10,000–25,000 newborns. It is generally sporadic, although families with more than one case have been described. At least four genetic abnormalities are associated with PWS, and each of them leads to a common mechanism of disease consisting in silencing the expression of paternal genes consists between 15q11-q13. The most common genetic abnormality described in 70–75% of PSW patients is a large deletion of 15q11-q13, which is paternal in origin. An alternative mechanism observed in 25% of the cases consists of maternal uniparental disomy. Under these circumstances the presence of a second structurally normal maternal chromosome 15 does not complement the missing paternal chromosome, and the result consists in production of the same PWS phenotype observed in the case of large deletions of paternal origin. Of PWS patients, 5% inherit a copy of chromosome 15 from each parent, but they have abnormal DNA methylation and gene expression throughout the imprinted 15q11-q13 region. Finally, a few rare cases have a balanced translocation in 15q11-q13. The described mechanism of disease suggests that the maternally inherited PWS gene(s) are silent and only the paternally inherited PWS gene(s) are expressed. Because a parallel clinical condition known as the Angelman syndrome has been described in which the segment of DNA between 15q11-q13 is only paternal, both maternal and paternal contributions of chromosome 15q11-q13 are required for normal development. This pattern of inheritance—when expression of a gene depends on whether it is inherited from the mother or the father—is called genomic imprinting. The mechanism of imprinting is uncertain, but it may involve DNA methylation.

Table 45-4
Syndromes Associated With Central Nervous System Disorders

Syndrome	*Clinical and genetic features*
Prader–Willi	See text
Möbious	See text
Laurence-Moon-Biedl	See text
Börjeson-Forssman-Lehman	X-linked mental retardation (XLMR) syndrome, mapped to Xq26-27. Associated with ptosis, hypotonia, mental retardation, hypogonadism
LEOPARD	Lentigenes, ECG conduction defects, ocular hypertelorism, pulmonic stenosis, retarded growth, deafness, hypogonadism
Rud's	Mental retardation, epilepsy, hypogonadism, ichthyosis
Loewe's	XLMR syndrome mapped to Xq26. Associated with cataracts, renal tubular acidosis, hypogonadism, hypotonia mental retardation.
Carpenter's	Obesity, acrocephaly, craniosynostosis, agenesis of the hands and feet

Clinical Features The PWS phenotype is characterized by muscular hypotonia, infantile feeding problems or failure to thrive, childhood obesity associated with insatiable appetite, carbohydrate intolerance/type 2 DM, short stature, mental deficiency, infantile hypotonia, small hands and feet, a characteristic face, and hypogonadism. The latter is present in 95% of the cases, is mostly because of GnRH deficiency, and is associated with cryptorchidism, micropenis, and scrotal hypoplasia. Some of these patients have undergone testicular biopsy, and the microscopic picture consisted in few germ cells, thickening of the tubular basement membrane, and presence of Leydig cells. Puberty is generally delayed, and in some individuals it never occurs. Premature puberty has been described in two cases. Pubertal growth spurt and bone maturation are also compromised in PWS. GH secretion is impaired, partly resulting from a reduced level of circulating sex steroids, and partly resulting from an intrinsic depression of GH level. The responses of serum gonadotropin concentrations to a single GnRH bolus are usually attenuated, however long-term treatment with clomiphene or GnRH may stimulate gonadotropin secretion. These observations suggest the possibility that in PWS

gonadal function is impaired in part by a hypothalamic defect preventing normal production of GnRH, and in part to primary testicular dysgenesis and poor spermatogenesis.

Genetic Basis Several of the genes in the PWS deletion region are subject to genomic imprinting *(SNRPN, ZNF127, IPW, PAR1, PAR5, PW71,* and *NECDIN*). This explains that the PWS phenotype only results when the paternally contributed PWS region is absent. However, the precise cause of PWS is unknown. The only identified protein products are those for the *SNRPN* and *ZNF127* genes. *SNRPN* is a small ribonuclear protein involved in alternative mRNA splicing; gene expression occurs only in the paternally inherited chromosome and is primarily in brain and heart.

No abnormal gene product associated with PWS has been identified. Considering the role played by SNRPN in mRNA splicing and the complex phenotype of PWS, one is tempted to speculate that a malfunctioning SNRPN contributes to PWS by altering the expression of several different and unrelated genes. A mouse model of PWS has been developed with a large deletion that includes the SNRPN region and the PWS "imprinting center" and shows a phenotype similar to infants with PWS.

These and other molecular biology techniques may lead to a better understanding of PWS and the mechanisms of genomic imprinting.

Whether any of these genes is directly involved in the phenotype of PWS is under investigation.

Treatment Treatments are carried on throughout the life of these patients, beginning at birth when they receive enteric gastric tube feeding because of their feeding difficulties. It is important to prevent excessive weight gain, because this is associated with increased risk of type 2 DM and of cardiovascular diseases. GH replacement has a positive effect on linear growth, which appears to be sustained for up to 4 and 5 yr. Patients should undergo correction of their cryptorchidism to prevent future development of testicular neoplasia. Whether sex steroids replaced is appropriate for these patients is controversial. It would be desirable to promote development of the secondary sexual characteristics and bone mass; however, these patients are also known for behavioral problems such as temper tantrums and violent outbursts. The general consensus is that low replacement doses of T should be offered, and if aggressiveness increases, T treatment should be discontinued.

LAURENCE–MOON–BIEDL SYNDROME This syndrome has traditionally included the association of retinitis pigmentosa, obesity, mental retardation, polydactyly, spastic paraparesis, and hypogonadism. Two syndromes with different manifestations are recognized. The Laurence–Moon syndrome, associated frequently with spastic paraparesis and rarely with polydactyly, and the Bardet–Biedl syndrome, with frequent occurrence of dystrophic extremities and renal disease, and rare neurological manifestations. Hypogonadism is present in both syndromes, manifesting as microphallus, hypospadias and undescended testes. There is disagreement on the origin of testicular failure as cases of both primary and secondary hypogonadism have been reported. The disease is transmitted as an autosomal-recessive character, as indicated by a consanguinity rate of 48% among parents of affected patients in one series, and by a male to female ratio of 47/41 by combining two large studies.

MÖBIOUS SYNDROME Möbious syndrome, also known as congenital oculofacial paralysis, is associated with multiple cranial nerve paralyses (III, IV, V, IX, X, XII) mental retardation, gait disturbances, peripheral neuropathy, and hypogonadism. Gonadotropin deficiency has been documented in several patients; however, considering the normal gonadotropin response to GnRH, GnRH deficiency is likely to constitute the primary defect. It is transmitted as an autosomal-dominant trait, although sporadic cases have also been described. The clinical characteristics of other syndromes belonging to this group of diseases are summarized in Table 45-4.

HYPOGONADOTROPIC HYPOGONADISM ASSOCIATED WITH ADRENAL INSUFFICIENCY

ADRENAL HYPOPLASIA CONGENITA Adrenal hypoplasia congenita (AHC) is a rare congenital disorder, in which HH is associated with adrenal insufficiency. The AHC gene was cloned from the dosage-sensitive sex reversal region of the human chromosome Xp, which when duplicated produces feminization of 46,XY individuals. The gene contains two exons, and encodes a protein known as DAX-1 (DSS-AHC critical region of the X chromosome, gene 1). The AHC gene is located in Xp21, in close proximity to genes associated with mental retardation, Duchenne muscular dystrophy, and glycerol kinase deficiency. Thus, AHC is frequently associated with Duchenne muscular dystrophy, glycerol kinase deficiency, or mental retardation.

Clinical Features AHC usually presents with symptoms of adrenal insufficiency early in infancy or childhood, because of an inappropriate development of the adrenal glands. This presentation may be confused with CAH. However, unlike CAH patients, AHC is associated with lack of hyperandrogenism, and absent response to exogenous corticotropin. At birth, the testes are undescended in up to 50% of infants with AHC. However, failure to develop secondary sexual characteristics at puberty is the typical presentation. Heterogeneity in the clinical presentation represents another feature of this syndrome. For example, in some individuals adrenal insufficiency becomes apparent only during adulthood, and in others HH may be only partial. Additionally, in some pedigrees the same mutation has manifested itself with a large spectrum of phenotypes, ranging from adrenal insufficiency to HH, or absence of a distinctive phenotype.

Genetic Basis DAX-1, a new member of the nuclear hormone receptor superfamily, is deleted in AHC deletion patients, and point-mutated in AHC nondeletion patients. It is a putative transcriptional silencer, whose endogenous ligand has not been identified. It is essential for the development of the pituitary gonadotrophs and adrenal cortex, and it inhibits the transcription of SF-1. It regulates gonadotropin secretion both at the hypothalamic and pituitary level. Dynamic tests of affected individuals indicate defective GnRH production and pulsatile secretion of LH. Based on studies performed at different ages in affected individuals, the effects of DAX-1 on gonadotropin secretion are detectable only after puberty. More than 80 mutations of the DAX-1 gene have been identified in affected individuals, and they consist in frameshift, nonsense, and missense mutations, most of which are located in the COOH-terminal region of the molecule. Sequence analysis of the DAX-1 gene also has been performed in 100 males with HH of unknown etiology, but no mutations were detected suggesting that in the general population affected by HH, DAX-1 abnormalities are uncommon, unless the subject is affected by concomitant adrenal insufficiency. Targeted inactivation of the DAX-1 mouse analog (Ahch) has been performed, and the resulting normal phenotype in female mice indicates that unlike initial speculations DAX-1 is not an ovary-determining gene. Interestingly,

lack of Ahch in male mice results in progressive degeneration of the testicular germinal epithelium, suggesting that it has an essential role in spermatogenesis.

ANATOMIC DISORDERS ASSOCIATED WITH HYPOGONADOTROPIC HYPOGONADISM

A large number of anatomic disorders are associated with HH (*see* Table 45-1). Infiltration of the pituitary by inflammatory lesions, as in the case of lymphocytic hypophysitis, or by granulomatous diseases, such as in sarcoidosis, tuberculosis, and histiocytosis X are well described causes of gonadotropin deficiency. Other disorders are tumors developing in the HP region, including nonsecretory or secretory pituitary adenomas, craniopharyngiomas, dysgerminomas, metastases, meningiomas, hamartomas, or hypothalamic tumors. They act by the local compression and destruction of the gonadotroph.

Panhypopituitarism can also be the consequence of pituitary apoplexy. This condition has been described in patients affected by pituitary tumors, DM, in patients harboring lesions producing increased intracranial pressure, and in the setting of radiotherapy and anticoagulation. Residual LH and FSH deficiency following pituitary apoplexy has been described in 76 and 58% of patients, respectively, and diminished T secretion in 85% of the subjects investigated in a large study. The mechanism is thought to reflect the direct destruction of the adenohypophysis by the apoplexy.

MALE INFERTILITY

Approximately 15% of couples are unable to conceive during 1 yr of unprotected intercourse resulting in approx 2.4 million couples in the United States diagnosed each year with infertility. A male factor is solely responsible for the infertility in approx 30% of the couples and in 20% of couples there are combined male and female factors present. Thus, a male factor is implicated in approx 50% of the cases of infertility. Specialized diagnostic tests in addition to the standard semen analysis assist in the laboratory evaluation of the infertile male. With the development of advanced assisted reproductive techniques, there are treatment options for the infertile couple.

The evaluation of an infertile couple often begins at presentation to a physician (because many couples have delayed parenthood because of their careers and are older), although traditionally, couples were advised to return after 12 mo of unprotected intercourse with no conception. History and physical examination are the first steps. A preliminary laboratory examination rapidly and cost-effectively ascertains if a male factor is present and helps develop a plan for additional laboratory evaluation and treatment. Only 1.1% of men seeking evaluation for male infertility have an identifiable endocrinopathy. Nearly one-fourth are diagnosed with idiopathic infertility and an additional 25–30% have infertility associated with varicocele, reflecting the poor understanding of the molecular mechanisms of fertility.

OBSTRUCTIVE AZOOSPERMIA A diagnosis of obstruction should be entertained for men with no sperm in the ejaculate (azoospermia) with low semen volume. Although vasectomy and hernia repair are the most common causes of obstruction, an infectious etiology is sometimes implicated for epididymal obstruction. These causes of male infertility are usually treatable with surgical anastomosis procedures such as vasovasostomy or vasoepididymostomy. Similarly, a transurethral resection of ejaculatory duct cyst can restore patency of the seminal tract. Nevertheless, there are other conditions that lead to genital tract obstruction caused by some genetic abnormalities such as congenital bilateral absence of vas deferens (CBAVD).

EJACULATORY DYSFUNCTION Ejaculatory defects also can prevent of sperm delivery to the female reproductive tract. Retrograde ejaculation results from a neurological deficiency and is seen following retroperitoneal or transurethral prostate surgery and in men with DM. Retrograde ejaculation occurs when the bladder neck does not close during ejaculation. As a result, the seminal fluid is forced from the posterior urethra into the bladder. Diagnosis is straightforward. A large number of sperm will be present in the post-ejaculatory urine of men with retrograde ejaculation.

Bladder exstrophy/epispadias can be associated with ejaculatory and erectile dysfunction resulting from a developmental defect in the closure of the lower anterior abdominal wall. Spermatogenesis is not deficient in these patients; accordingly, couples may still conceive using sperm retrieval from the testis or epididymis in combination with an assisted reproductive technology.

The genetic basis of myelodysplasia that results in a characteristic spinal dysraphism, commonly referred to as spina bifida, is thought to be multifactorial. Emission and/or antegrade ejaculation failure is frequently associated with a concomitant negative impact on fertility. Spermatogenic deficiencies are present in some patients, but their association with myelodysplasia is not clear.

Prune-belly syndrome is thought to be caused by a mutation in a gene involved in the canalization of the anterior/posterior urethral junction. This syndrome most commonly occurs in males and results in lax abdominal wall musculature, genitourinary tract malformations, and cryptorchidism. Male infertility results from ejaculatory dysfunction and spermatogenic deterioration.

OTHER CAUSES OF EUGONADAL GERM CELL FAILURE Chromosomal abnormalities are approx 10-fold more frequent in infertile men (5.8%) as compared to the fertile population (0.5%). Chromosomal abnormalities can be structural or numerical. Of the abnormalities found in infertile men, 4.2% occurs with the sex chromosomes, whereas 1.5% occurs on the autosomes. The gain or loss of an entire single chromosome results in aneuploidy. When the entire chromosomal content is multiplied, a polyploid state is present. Rearrangement or translocation of chromosome fragments , as in Robertsonian translocations, or deletions of single genes or portions of a chromosome are examples of structural abnormalities.

The incidence of defects in chromosome number is increased in the sperm of infertile men compared with fertile men, although these infertile men have a normal somatic karyotype. This suggests mosaicism between somatic and nonsomatic tissues or mitotic or meiotic defects during spermatogenesis. Using multicolor fluorescence *in situ* hybridization on morphologically normal sperm from infertile patients, sperm with a normal morphology according to Kruger's Strict Criteria cannot be used to identify sperm with a normal chromosomal complement. Indeed, an increased rate of autosomal-trisomies and sex chromosomal aneuploidies are present in the offspring after ICSI with sperm from infertility patients. Klinefelter syndrome (47XXY, 48XXXY, 49XXXXY, mosaic 46XY, and 47XXY) is the most common cause of nonobstructed azoospermia. Other numerical chromosomal defects include XX male (infertile) and XYY (variable phenotype-may be fertile). Clinically, fluorescence *in situ* hybridization is used to detect anueploidy in the sperm of patients contemplating assisted reproduction.

Similarly, structural chromosomal abnormalities are more common in patients with nonobstructive azoospermic and severely oligospermic men compared with fertile men. A Robertsonian translocation consists of the exchange of entire chromosomal arms between two chromosomes, and this structural defect occurs 8.5-fold more often in infertile patients. A reciprocal translocation, the mutual exchange of chromosomal fragments between two chromosomes, occurs as frequently as a Robertsonian translocation. The phenotype is variable with sperm densities ranging from normal to azoospermia for these translocation patients.

Because abnormal karyotypes are relatively common in infertile men (7–13% of patients with idiopathic infertility), testing for chromosomal abnormalities using routine karyotyping with high-resolution banding cytogenetics is recommended for males having sperm densities <5 million/mL. Prenatal genetic diagnosis is advised for those couples with known genetic abnormalities.

Y CHROMOSOME DELETION The Y chromosome is divided into a long arm (Yq) and a short arm (Yp) but remains the smallest chromosome in the human genome with 60 million bp. The genetic information on the Y chromosome is important for male sex determination and for normal spermatogenesis. The pseudoautosomal-regions located at both ends of the Y chromosome pair with their homologous regions on the X chromosome during meiosis, although the remainder of the Y chromosome does not undergo meiotic recombination. This characteristic has complicated genetic analysis of the Y chromosome genes by targeted deletion of specific genes, although new approaches were proposed. Analysis of the Y chromosome reveals that the male-specific region of the Y chromosome, MSY, comprises 95% of the length of the chromosome and is made up of X-transposed sequences that are 99% homologous to sequences on the X chromosome, X-degenerate sequences that are remnants of ancient autosomes, and ampliconic regions in which sequence pairs demonstrate 99% homology. The testis-determining factor (SRY) located on the proximal portion of Yp is crucial for testes formation in early development. Deficiency or absence of the SRY gene results in sex reversal with a 46XY phenotype. Alternatively, there is a small portion of 46XY females who are SRY positive owing to a defect at a different sex reversed locus (SRVX) on the X chromosome. Defects in other autosomal-and X-linked genes, including those required for normal androgen biosynthesis and metabolism, are also required for normal male sexual differentiation. Although not critical for survival (females lack the Y chromosome), there are genes such as those for stature, crown tooth size, and depression that are not involved in sexual differentiation or male reproduction on the Y chromosome as well.

Over 20 yr ago it was proposed that there was a region on the Y chromosome called the AZF located at Yq11. It was hypothesized that this region contains genes that control spermatogenesis because there were small deletions present in some azoospermic men. These regions have been mapped and consist of three distinct intervals that are associated with variable degrees of spermatogenic impairment: AZFa, AZFb, and AZFc; an AZFd interval is debated to reside between AZFb and AZFc.

The AZFa region contains pseudogene sequences homologous to genes at Xp22 in the proximal portion of the chromosome. Other genes located in this region include the human homologue of the *Drosophila* development fat facets gene (DFFRY renamed *USP9Y*), the Dead box on the Y gene, DBY, the ubiquitously transcribed tetratricopeptide repeat gene on the Y, UTY, and AZFaT1. DDFRY is widely expressed in many tissues in the body in the human, whereas expression of the mouse homologue is testis specific. A homologous copy of *USP9Y* (DDFRY) is present on the X chromosome. Deletion or point mutation of *USP9Y* results in decreased spermatogenesis and although the function is not completely understood, it is thought that the *SUP9Y* regulates protein turnover. DBY is deleted more frequently than *USP9Y* in infertile men with a hypospermatogenesis or Sertoli-cell-only syndrome testicular histology. In contrast, many Y chromosome "microdeletions" are relatively large. Thus, for example, deletion of both *USP9Y* and *DBY* results consistently in Sertoli-cell-only syndrome.

RNA binding motif protein on the Y (*RBMY*, located in AZFb) consists of 30 genes and pseudogenes that are further subdivided into six subclasses (*RBMY1–RBMY6*). This gene possibly functions in RNA metabolism. In a mouse model with targeted deletion of the murine homologue of *RBM*, male sterility results suggesting that it may be associated with infertility in a small percentage of infertile men. Chromodomain protein on the Y (*CDY*) is another multicopy gene thought to be involved in chromatin modifications that occur during meiosis in the male.

Deleted in azoospermia *(DAZ*) is perhaps the most well-known spermatogenesis gene on the Y chromosome as it was the first candidate spermatogenesis gene identified in the AZFc region. *DAZ* locus is complex, consisting of a multigene family with considerable variation in number and sequence of repeats between individuals. The *DAZ* protein is expressed mainly in postmeiotic germ cells suggesting a role in post-transcriptional control during the later stages of differentiation. The gene has been highly conserved throughout evolution. Deletion of the *Drosophila* equivalent, *boule*, results in azoospermia, and this evolutionary conservation of function suggests a critical role in spermatogenesis. In the mouse, a homologue of *DAZ, dazla* is present on chromosome 17 (an autosomal-chromosome, not on the Y). The murine *dazla* is expressed in both male and female germ cells and when deleted results in absence of gamete production. Studies suggest that during evolution the *DAZ* gene migrated to the Y chromosome after the divergence of the New World monkeys. The human has homologous genes on both the Y and an autosome. The autosomal-homologue of *daz*, *DAZLA*, is mapped to chromosome 3p24 and like the Y DAZ is expressed specifically in the testis with significantly lesser abundance of mRNA levels in the ovary. Other genes in the AZFc region include testis transcript Y2, TTY2, and basic protein Y2. These genes share characteristics with *DAZ* in that they are Y-specific genes in multiple copies and exhibit testis specific expression although their exact function remains unknown.

Large deletions of the Y chromosome can be detected by high-resolution cytogenetics. Today most laboratories use a PCR technique using sequence-tagged sites (STSs) to detect microdeletions on the Y chromosome. The STSs flank a portion of DNA that is amplified by PCR and then identified by molecular size on an agarose gel. The number of STSs used by a clinical laboratory may vary but should at least span interval 6 and AZFa, b, c, d regions thought to be involved in spermatogenesis. As even these amplified fragments are fairly large, small microdeletions of individual genes or mutations may not be detected by this approach; thus, a normal analysis indicates only that no large deletions of the Y chromosome are present.

CRYPTORCHIDISM Cryptorchidism is the most common birth defect in boys with an incidence rate between 1 and 10%. It is characterized by failure of testicular descent into the scrotum

during development and it is causative in a significant percentage of men (3.4%) seeking diagnosis at an infertility clinic. The etiology is likely multifactorial and complex. Androgens and their receptor are necessary, but not sufficient, for testicular descent, but the exact role of androgens remains unknown. In addition to androgen, Müllerian inhibiting substance may also be instrumental in testicular descent. It is thought that the gubernaculum actively contracts to pull the testicle downward such that transection of the genitofemoral nerve prevents testicular descent in some species. Others showed that the testicle descends without gubernacular attachments and proposed that intra-abdominal pressure is more important. Others propose that the epididymis guides the testicle out of the inguinal canal and into the scrotum.

Cryptorchidism is associated with decreased spermatogenesis resulting (at least in part) from the elevated temperature present in the testis when it is not properly located in the scrotum. Of men with unilateral cryptorchidism approx 30% (28–82%) and of those with bilateral cryptorchidism approx 50% (44–100%) present with oligospermia. Even though sperm density is decreased, fertility rates are 81.4 and 50% of couples in whom the male had unilateral and bilateral cryptorchidism, respectively. Cryptorchid testicles that are left undescended until after puberty function poorly and fertility potential is not improved by postpubertal repair.

As mentioned, the etiology of cryptorchidism is multifactorial. Although many of these cases remain unexplained there are some familial cases of cryptorchidism suggesting a genetic etiology for those cases. Genetic defects (*HOXA10, INSL3, GREAT* as well as defects affecting steroidogenesis and androgen actions) have been identified in a few cryptorchid patients.

CBAVD AND OTHER TYPES OF DUCTAL OBSTRUCTION

CBAVD is one of the most common abnormalities of the extratesticular ductal and ejaculatory systems and is part of the phenotypic spectrum of cystic fibrosis. Cystic fibrosis is an autosomal-recessive disorder and diagnosis can be challenging as the gene is large and the phenotype can be caused by more than 500 different mutations and two intron polymorphisms in the CF transmembrane conductance regulator (CFTR) gene. Both quantitative and qualitative deficiencies influence the production of the CFTR protein. Patients presenting with CBAVD often exhibit nonfunctional seminal vesicles and ejaculatory ducts with associated male infertility. It is notable that most patients with CBAVD do not exhibit the characteristic respiratory and gastrointestinal defects associated with cystic fibrosis. Despite the genital tract obstruction, spermatogenesis is usually normal. Accordingly, sperm obtained from the testis or epididymis can be used for ICSI. However, transmission of the CFTR gene mutation to the offspring is a significant concern.

Laboratory genetic screening for CFTR gene mutations must be performed and both the CBAVD patient and the female partner must be evaluated. It is important to know whether the female partner is a carrier to provide some insight into the risk of cystic fibrosis inheritance by the potential offspring. Testing is problematic because of the large size of the gene. Even the best clinical genetic diagnostic laboratory regularly assesses only about 30 of the most common mutations. This means that a normal CFTR analysis does not ensure that a mutation is not present, only that one of the 30 most common mutations are not present. An abnormal CFTR test result will confirm a cystic fibrosis diagnosis, but a normal test result does not ensure a total absence of CFTR mutations. The noninvasive sweat test, which determines the amount of chloride in the sweat, is a functional assay of cystic fibrosis. Nevertheless, the test often leads to inconclusive results when results are in the "borderline" range. False-positive results can occur if confounding diseases are present, such as adrenal insufficiency, hypothyroidism, diabetes insipidus, or renal failure. A positive sweat test performed on at least two different dates is required to diagnose cystic fibrosis. Finally, mutations can be present in the CFTR gene that do not change chloride levels, potentially leading to a false-negative test result. Accordingly, despite the power of the clinical laboratory screening tests in this genomic era, there are significant limitations to the tests.

Today, all patients with CBAVD are thought to have the genital form of cystic fibrosis described earlier. In contrast, whereas those men presenting with unilateral absence of the vas deferens are also considered at risk and should undergo testing for CFTR mutations, the absence of a kidney on the same side usually reflects renal agenesis resulting from a Wolffian (mesonephric) duct defect. Conversely, if vasal agenesis is a component of the phenotype, polymorphism of a region of thymidines in intron 9 of the CFTR gene should also be analyzed (5T allele). This polymorphism results in less efficient processing of the CFTR mRNA ultimately resulting in a lower amount of protein. It is critical that both partners of the CBAVD couple planning to attempt a pregnancy with ICSI undergo testing for CFTR mutations and receive genetic counseling.

46 Ovarian Diseases

Elizabeth A. McGee and Tammy L. Loucks

SUMMARY

This chapter discusses ovarian diseases such as the failure of ovarian follicular function that results in infertility. Failure of follicle formation or early follicle loss can result in failure of pubertal progression and severe early osteoporosis. Less severe disruption or later follicle loss can result in premature ovarian failure or early menopause. Disruption of the normal balance of hormone production can alter the ovarian cycle and adversely affect other organ systems such as the central nervous or cardiovascular systems.

Key Words: Atresia; estrogen; follicle; hyperandrogenism; infertility; luteal regression; oocytes; oogonia; ovary; polycystic ovarian syndrome.

INTRODUCTION

The primary function of the human ovary is the production of fertilizable gametes, a role essential for the survival of the human species. Ovarian gametes are surrounded by somatic cells in a structure known as a follicle. The follicle is the essential unit of the ovary, providing both oocytes (eggs) and the steroid hormones necessary for female physical development and reproduction. The process of folliculogenesis involves the growth and maturation of the egg and division and differentiation of the somatic cells to the point of ovulation or release of a mature oocyte. Folliculogenesis takes many months—not just the 4 wk of a menstrual cycle. Failure of ovarian follicular function results in infertility. Failure of follicle formation or early follicle loss can result in failure of pubertal progression and severe early osteoporosis. Less severe disruption or later follicle loss can result in premature ovarian failure (POF) or early menopause. Disruption of the normal balance of hormone production can alter the ovarian cycle and adversely affect other organ systems such as the central nervous or cardiovascular systems.

Ovarian gametogenesis has been described as intricate and delicately balanced. Although complicated, this process is also characterized by multiple redundancies providing robustness to the process that allows for compensation for isolated gene defects. Many processes that occur in embryonic development are also necessary for follicle development and normal ovarian function. Genes that regulate other developmental processes might also have a role in follicle development.

OVARIAN FUNCTION

PRIMORDIAL GERM CELLS In the third week after fertilization, germ cells arise in the yolk sac endoderm at the caudal aspect of the embryo. Germ cell derivation requires interaction between the layers of extraembryonic tissues. Several bone morphogenic proteins seem to have essential roles in germ cell designation, but are not sufficient to establish germline determination. Because of increased interest in stem cells, many groups are investigating genes that are required to establish germ cell identity and competence and this area of research will likely have rapid progress.

Once germ cells are designated, they begin to migrate to the gonadal ridge, which at this stage consists of coelomic epithelial mesenchyme and elements of the mesonephros. The presumptive ovaries are indistinguishable from presumptive testes at this point in development. The specific factors that govern formation of the gonadal ridge are not known, but the expression of the orphan nuclear receptor SF1, the DAX gene product (which might be regulated by SF1), and the transcription factor WT1, i.e., the product of the Wilms' tumor gene, are all required early in this process. Members of the HOX gene family might also play a role in gonadal ridge development. Although sex-determining region Y plays a key role in testicular differentiation in the male, genes that play a similar role in directing ovarian development have not been identified. Differentiation of the ovary is generally believed to begin approx 2 wk later than the testes become identifiable in males. Ovarian differentiation is thought to proceed by default when testis-determining factors are absent and germ cells are present. Unlike the testis, which can form in the absence of germ cells, formation of a functional ovary requires the interaction of meiotic germ cells with the gonadal ridge and mesonephros. If germ cells do not reach the presumptive ovary and begin meiosis, the gonadal tissue degenerates into a fibrous streak.

The regulation of germ cell migration to the gonadal ridge is not completely defined, but adhesion molecules, including fibronectin, laminin, and the integrins, likely play a role. Transforming growth factor (TGF)-β has been suggested to be a chemotactic factor released by the gonadal ridge, whereas tumor necrosis factor (TNF)-β has been suggested as an early germ cell mitogen that with leukemia-inhibitory factor (LIF) could prevent premature differentiation during migration.

The receptor c-kit and its ligand have been extensively studied in germ cell migration in mice. A transmembrane protein with tyrosine kinase activity encoded by the dominant white spotting (W) locus, c-kit is expressed by primordial germ cells. The kit ligand,

called stem cell factor (SCF) or mast cell growth factor, is encoded by the steel locus and is expressed by cells along the germ cell migration pathway from the yolk sac to the genital ridge. Mutations in cell surface SCF, such as Steel-dickie and Steel-panda, result in the decreased ability of germ cells to migrate to the genital ridge and decreased survival of the cells that do arrive. Many W mutations result in female sterility or decreased numbers of primordial follicles, but some mice with these mutations are fertile, even in the face of reduced receptor kinase activity or reduced c-kit mRNA expression. Though c-kit and its ligand are thought to have a critical role in germ cell migration and proliferation, the lack of a uniform phenotype in these mutants suggests a more complex system with other modulating factors involved. Mutations affecting the function of c-kit in humans result in piebaldism, but do not appear to be associated with female infertility. These observations emphasize that details of the regulation of the process of germ cell migration might differ in different species, even among mammals.

Evidence suggests that the germ cells might have intermediate targets en route to the gonadal ridge. Studies of germ cell migration in both zebra fish and mice demonstrate that germ cell migration as target sites related to the pronephros early in migration. It is unclear if there are distinct waves of germ cells that localize differently or if the primordial germ cells localize to intermediate targets on the way to the gonad. The chemokine stromal cell-derived factor (SDF)-1 is expressed in sites in which primordial germ cells migrate and the receptor CXCR4 is on the germ cells. Germ cells migrate to ectopic sources of SDF-1, and germ cells with the *odysseu*s mutation of CXCR4 fail to undergo directional migration. These genes have not been studied in humans, but might be promising candidates for regulating human germ cell migration. It is possible that several pairs of molecules are involved in ensuring germ cell migration like c-kit/kit ligand and SDF-1/CXCR4 with overlapping functions. If so, then single point mutations or deletions will not likely be found that result in dramatic reproductive phenotypes in humans. Instead, subtle alterations resulting in phenotypes that are more difficult to recognize are more likely to occur, such as premature menopause or subfertility.

There have also been genes described in drosophila, zebra fish, and mice that are involved in apoptosis of ectopic germ cells. The drosophila gene *scattershot* promotes both migration of germ cells to the gonad and apoptosis of improperly located germ cells. The *outsiders* gene does not affect the germ cell complement in the gonad, but does regulate apoptosis of germ cells outside the gonad. Other gene families with prominent roles in development (such as Hox and Forkhead) also likely play a role in germ cell migration and survival. Table 46-1 lists genes with proposed roles in germ cell and ovarian formation. Further study is needed to determine if these genes have a role in human ovarian development.

Some germ cell tumors in women are believed to arise from germ cells that failed to migrate successfully to the gonad and escaped the usual fate of apoptosis. These tumors can be found at sites near the normal germ cell migration path, including the mediastinum, adrenal, and both the small and large intestinal mesenteries, as well as in more remote sites such as the pineal gland. Further study of these tumors, and of the migration of germ cells in animal models, might give additional insight into the regulation of germ cell migration, survival, and tumorigenesis.

OVARIAN COLONIZATION AND PRIMORDIAL FOLLICLE FORMATION After reaching the genital ridge, the primordial germ cells, now called oogonia, must continue to both proliferate and survive. Oogonia become invested by a single layer of flat, pregranulosa cells derived from the rete ovarii to form primordial follicles. If they fail to be surrounded by these pregranulosa cells, oogonia undergo apoptosis. The receptor c-kit and its ligand, SCF, might play a role in oogonial survival, because apoptosis can be blocked in vitro by added SCF. Other factors implicated in the regulation of oogonial apoptosis include LIF and related molecules oncostatin M and ciliary neurotropic factor, as well as interleukin (IL)-4 and basic fibroblast growth factor. The role of these factors in human germ cell migration, proliferation, and survival has not been defined.

In the human embryo, germ cells reach the gonadal ridge by the seventh week of gestation. Oogonia increase their number by mitosis from approx 10,000 by the sixth week to 6×10^6 by twentieth week gestation, at which time their number peaks and the rate of mitosis declines and eventually ceases. By 11–12 week, some oogonia have begun their transformation into oocytes by entering

meiosis; they progress to the dictyotene stage of the first meiotic prophase in which they remain arrested until they are ovulated. Oocytes that do not enter meiosis undergo apoptosis. Formation of primordial follicles (Fig. 46-1A) begins at approx 16 wk gestation and is complete by 6 mo after birth.

Other factors might also play a role in follicle formation. Involvement of gonadotropins or other pituitary factors in the process of follicle formation is suggested by the poorly organized rete ovarii and inefficient follicle formation in monkeys that were hypophysectomized *in utero*. The Booroola Merino and Inverdale strains of sheep, studied because of their increased rate of multiple gestations, have delayed, or defective follicle formation. Homozygotes for the Booroola mutation $FecB^B$ show delayed follicular formation and growth, whereas homozygotes for the Inverdale mutation $FecX^I$ show a total failure of development past the primary stage. The FecB gene has been identified as the type-I receptor for bone morphogenic protein (BMPRIB). FecX has been localized to a region that contains BMP15, also known as growth and differentiation factor (GDF)-9B. It is not clear what role these factors play in human folliculogenesis.

INITIAL RECRUITMENT AND EARLY FOLLICLE GROWTH Primordial follicles (*see* Fig. 46-1A) can begin further development at any time after their formation, or they might remain dormant for more than 50 yr. As a primordial follicle begins to mature, the granulosa cells become cuboidal and divide to form several layers around the oocyte (Fig. 46-1B). The zona pellucida, a glycoprotein layer around the oocyte that is formed by both granulosa cells and the oocyte, appears as the granulosa cells differentiate. A distinct theca layer begins to condense around the follicle and becomes vascularized. Because the theca is separated from the avascular granulosa by a basement membrane, access of serum proteins to the granulosa and oocyte is functionally limited. As both the granulosa and theca cells continue to divide and the oocyte increases in size, a fluid collection known as the antrum develops within the granulosa layer. Follicular fluid is a transudate from the thecal vasculature, but also contains proteins secreted by granulosa cells, many of which are paracrine factors important for continued follicular development.

How primordial follicles are maintained in a relatively static condition for decades and then induced to grow and differentiate is poorly understood. Primordial follicles do not demonstrate differentiated function, suggesting that these follicles or the surrounding stroma either express suppressors, or fail to express activators, of the genes that initiate follicular development. When small portions of ovary are removed and grown in organ culture, most of the primordial follicles begin growth all at once. This suggests that when primordial follicles are within the ovary, there is suppression of their activation that is not present in the organ culture environment.

It has been hypothesized that interaction of oocytes and granulosa factors might play a role in initiating follicle growth. Two factors that might be involved in this process are c-kit and GDF-9. In the mouse, GDF-9 and the closely related GDF9B are expressed in oocytes at the primary through preovulatory follicle stages, and are necessary for follicular development past the early secondary stage. Female mice deficient in GDF-9 are infertile and resistant to gonadotropin stimulation, despite the expression of gonadotropin receptors in their ovaries. Granulosa cells secrete kit ligand and the c-kit receptor is expressed by oocytes. When cultured ovarian fragments are treated with kit ligand, there is increased primordial follicle activation. GDF-9 treatment enhances kit ligand expression in granulosa cells, but kit ligand treatment inhibits oocyte expression of GDF-9 and GDF-9B (also known as BMP-15). Some investigators have hypothesized that complex negative and positive feedback loops regulate oocyte–granulosa interactions and that the balance of these factors is what ultimately controls the initiation of follicle growth. Experiments with reconstituted follicles incorporating granulosa or oocytes missing various factors implicate the oocytes as playing a critical role in upregulating expression of granulosa-derived factors that continue the process of follicle development.

Suppression of growth might be as important a factor in controlling folliculogenesis as active initiation of growth. A candidate suppressor of granulosa cell differentiated function is the product of the Wilms' tumor gene, WT1, a zinc-finger transcription factor. In rodents, high levels of WT1 are expressed in the gonadal ridge and in the granulosa cells of primordial follicles and lower levels in primary and early secondary follicles, but minimal levels in more developed follicles. WT1 represses the expression of inhibin-α, insulin-like growth factor (IGF)-II, IGF-I receptor, early growth response gene 1, PAX-2, platelet-derived growth factor (PDGF)-A, colony stimulating factor 1, and TGF-α. By suppressing the expression of growth and differentiation genes, WT1 might act on early follicles as a "stasis factor," and as the level of WT1 falls, the rate of follicular development increases. Further studies should elucidate the regulation of WT1 expression, as well as the interaction of WT1 with other genes involved in follicular development. Though positive and negative regulators of growth and development might have a role in initial follicle development, why one follicle grows and another nearby follicle remains dormant is still a mystery.

DYNAMICS OF FOLLICLE GROWTH Once entering the growing pool, most growing follicles progress to the antral stage, at which point they inevitably undergo atresia. After puberty, a small number of the antral follicles can be rescued by gonadotropins to continue growth, and normally one Graafian follicle is formed each month in preparation for ovulation. Antral follicles (2–5 mm in diameter) develop into Graafian follicles in only 14 d during the follicular phase of the menstrual cycle, although more than 85 d are needed for late secondary follicles to grow into preovulatory follicles. In addition, it has been estimated that more than 120 d are needed for primary follicles to grow into the secondary stage and even longer for the development of primordial follicles into primary follicles. Thus, several menstrual cycles are required for progression through the early stages of follicle development. Follicles are exposed to multiple cycles of gonadotropin fluctuations through their development. The role of cyclic, rather than tonic, gonadotropins has not been investigated in early follicle development.

Early follicular growth can occur in the absence of gonadotropin stimulation, as evidenced by the presence of preantral follicles in the ovaries of anencephalic infants as well as in gonadotropin-deficient patients. Although larger antral follicles are clearly dependent on gonadotropin for further mitosis and differentiation as well as protection from apoptosis, several in vitro studies of rodent follicles have suggested a role for follicle-stimulating hormone (FSH) in earlier follicle development as well, perhaps in conjunction with activin or other factors. Many factors such as IGF-1, TGF-β, Müllerian inhibitory substance, bone morphogenic proteins, keratinocyte growth factor, fibroblast growth factors FGFs, hepatocyte growth factor, and vascular endothelial growth factor VEGF have been proposed to affect preantral follicle growth and development (Table 46-2). Growth Factor Actions

Growth factor	*Action*
Tyrosine kinase receptors	
Insulin/IGF-I/IGF-II	Possibly increase early follicle growth; enhance gonadotropin-stimulated steroidogenesis; enhance LHR expression
Epidermal growth factor-TGF-α	Stimulate GC proliferation; inhibit FSHR(GC); and LHR(thecal cell) expression; inhibit steroidogenesis and inhibin secretion
FGF	Stimulate GC proliferation; inhibit TC steroidogenesis; stimulate angiogenesis
SCF	Germ cell migration, proliferation and survival; oocyte growth?; meiosis inhibition?
PDGF	Enhance TC proliferation; inhibit TC steroidogenesis
VEGF	Stimulate angiogenesis
Nerve growth factor	Possible role in early follicle development
Keratinocyte growth factor	GC mitogen; suppress apoptosis
Hepatocyte growth factor	GC mitogen
Serine–threonine kinase receptors	
inhibin[a]	Augment thecal steroidogenesis
activin	Augment progesterone production; enhance FSH action
MIS	Promote meiosis, follicle growth
TGF-β	Follicle growth; inhibit thecal $P450_{c17}$; inhibit differentiation
GDF-9[a]	Initiation of follicle development?
7-TM G protein linked receptors	
Gonadotropin-releasing hormone	Promote meiosis; promote apopotosis
Vasoactive inhibitory protein	Early follicle growth and differentiation
Pituitary adenylate cyclase-activating protein	Early follicle growth and differentiation
Cytokines	
IFN-γ	Decrease granulosa steroidogenesis; promote apoptosis
TNF-α	Decrease granulosa steroidogenesis; induce LIF/IL-1 expression
IL-1	Increase prostaglandins; decrease progesterone; prevent premature follicle rupture?
IL-2	Suppress ovulation; augment progesterone production
IL-6/IL-11/OSM/LIF	Promote germ cell survival; suppress FSH action

[a]Inhibin and GDF-9 are included with the serine–threonine kinases because of homology. Their receptors have not yet been described. FGF, fibroblast growth factor; FSH, follicle-stimulating hormone; FSHR, follicle-stimulating hormone receptor; GC, granulosa cell; GDF, growth and differentiation factor; IFN, interferon; IGF, insulin-like growth factor; IL, interleukin; LHR, luteinizing hormone receptor; LIF, leukemia-inhibitory factor; MIS, Müllerian inhibitory substance; $P450_{c17,}$ 7a-hydroxylase/17,20-lyase; PDGF, platelet-derived growth factor; SCF, stem cell factor; TC, theca cell; TGF, transforming growth factor; VEGF, vascular endothelial growth factor.

specific factors are not clearly established. There is considerable functional overlap between the different factors and possibly interaction of their signal transduction pathways. In this area the redundancies of function make it difficult to establish a role for each factor in follicle development, because no one factor is indispensable. Functional genomics and proteomics might help clarify the complex interactions of growth factors and their downstream signaling in early follicle development.

THE OVARIAN CYCLE The pulsatile secretion of FSH and luteinizing hormone (LH), which begins at puberty initiates the cyclic ovarian function that results in the menstrual cycle. Cyclic gonadotropins lead to the maturation of a single dominant follicle per ovulatory cycle, its ovulation and transformation into a corpus luteum, and then the regression of the corpus luteum in the absence of pregnancy. The ovarian cycle is normally 26–30 d in length and has been classically divided into a follicular phase and a luteal phase, each of roughly 14 d, separated by ovulation at midcycle (Fig. 46-2). For reference, the first day of menstrual bleeding is designated cycle day 1. The follicular phase, which begins with the onset of menses, is characterized by the selection of one member of a cohort of developing early antral follicles to become the dominant follicle. This follicle becomes the largest follicle in either ovary, reaching a diameter of 20 mm or more before ovulation, and it secretes increasing amounts of estrogen. The dominant follicle can be identified by vaginal sonography by cycle day 6 and it has established an estrogen-dominant follicular

Figure 46-1 **(A)** Primordial follicles just below the epithelium of the ovary (dark arrows) with clusters of transitional and primary follicles (open arrow). **(B)** Primary follicles (P) and a secondary follicle with an oocyte (O) surrounded by granulose cells (G) with an external theca layer (T). **(C)** A slightly larger follicle that is beginning to develop an antrum (A). **(D)** A maturing Graafian follicle, with a large antrum (A), a cumulus (C) surrounding the oocyte (O), with well-developed granulose and theca layers. **(E)** Higher magnification of the follicular wall of a preovulatory follicle. The granulose layer is separated from the thickened theca layer by the basement membrane (B). Just beneath the basement membrane, a rich vascular network (dark arrows) is developing. **(F)** An atretic follicle, with cellular debris or apoptotic bodies (dark arrows) visible in the antrum.

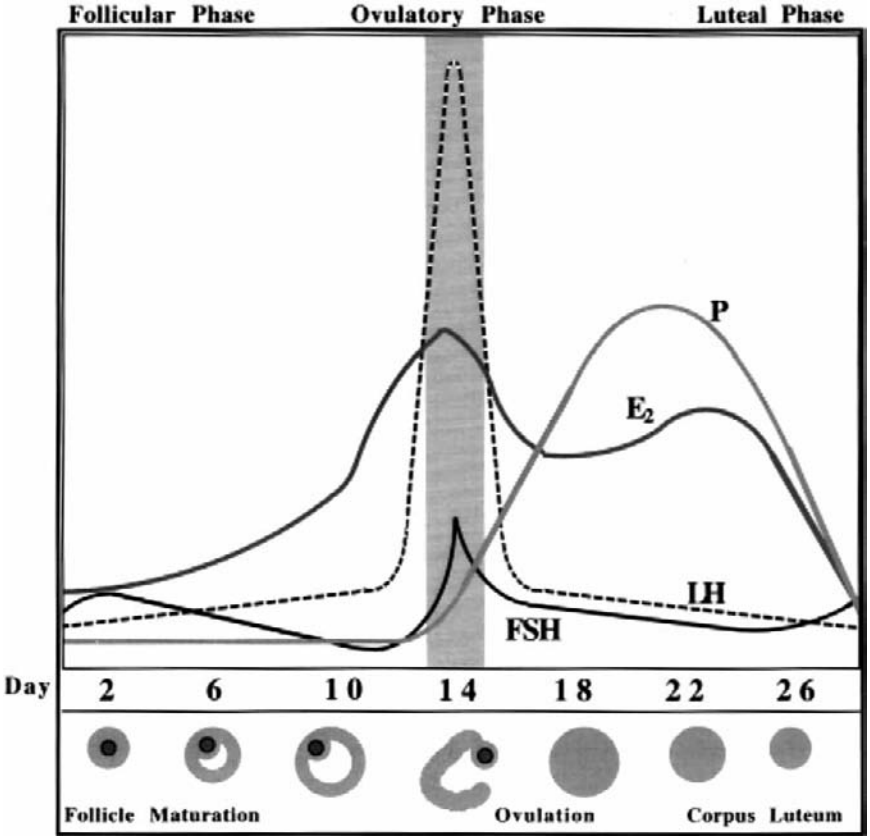

Figure 46-2 The serum levels of estrogen (E), progesterone (P), follicle-stimulating hormone (FSH) and luteinizing hormone (LH) throughout the follicular and luteal phases of the ovarian cycle. (Modified from Carr BR. The ovary, in Textbook of Reproductive Medicine.)

microenvironment by cycle day 8. The luteal phase, which begins at the time of ovulation, is characterized by the organization of the corpus luteum from the remaining granulosa and theca cells of the dominant follicle. The corpus luteum produces the large quantities of progesterone necessary to sustain an early pregnancy.

FOLLICULAR STEROIDOGENESIS Only healthy, dominant follicles produce significant quantities of estrogen. Follicular steroidogenesis requires the cooperation of both granulosa and theca cells and the stimulation of these cells by FSH and LH, respectively. FSH and LH are heterodimeric glycoprotein hormones produced by the pituitary. They share a similar α-subunit but contain distinct but related β-subunits. The receptors for FSH and LH are also distinct but homologous proteins, each of which is a member of a family of receptors that have seven membrane-spanning regions and transmits its signal by activating a guanosine triphosphatase designated Gs (Fig. 46-3). Binding of gonadotropin to its receptor thereby activates adenylate cyclase and increases generation of cAMP, an activator of the protein kinase A pathway of signal transduction. Although the role of FSH and luteinizing hormone receptors in steroidogenesis is well established, LH has been suggested to have additional functions resulting from the activation of the phosphoinositol or protein kinase C pathways, perhaps through AKT.

Because all of the enzymes required for estrogen synthesis from cholesterol are not present in significant quantities in either the granulosa or theca alone, both cell types must participate in this process. Theca cells, which have receptors for LH but not FSH, respond to LH stimulation by producing the enzymes P450 cholesterol side chain cleavage (P450scc) and 17α-hydroxylase/17,20-lyase ($P450_{c17}$), as well as cholesterol transport proteins. Cholesterol is metabolized to pregnenolone by $P450_{scc}$ and then to dehydroepiandrosterone (DHEA) by $P450_{c17}$ (*see* Fig. 46-3). DHEA is converted to androstenedione by the action of hydroxysteroid dehydrogenase 3β-(HSD). Androstenedione diffuses out of the theca cell, across the follicular basement membrane, and into granulosa cells, in which it is converted into estradiol through the action of the enzymes P450 aromatase and 17β-hydroxysteroid dehydrogenase. Both of these enzymes are upregulated by FSH. This cooperation in estrogen biosynthesis between theca and granulosa cells has been termed the two-cell model of ovarian steroidogenesis.

FOLLICULAR SELECTION AND DOMINANCE In a spontaneous cycle, usually only one follicle is selected to become dominant and eventually ovulate, whereas the remaining antral follicles undergo atresia. How a follicle escapes the fate of atresia and assumes dominance is not well understood. The understanding of this process has been considerably enhanced by observing the results of ovulation-induction treatment in infertile women. Such therapies work by increasing circulating FSH, of either exogenous or endogenous origin, and thereby often result in multiple dominant follicles in a single cycle. Greater than normal FSH levels appear to "rescue" follicles in a developing cohort that might otherwise have undergone atresia, lending credence to the concept that FSH plays a critical role in this process. In a natural ovulatory cycle, circulating FSH begins to rise at the end of the luteal phase, in association with decreasing serum levels of estrogen and inhibin, a granulosa-derived protein that inhibits pituitary FSH release. This FSH increase advances the growth of the leading cohort of follicles. By cycle day 6, the estrogen and inhibin secreted by these growing follicles lead in turn to a decrease in

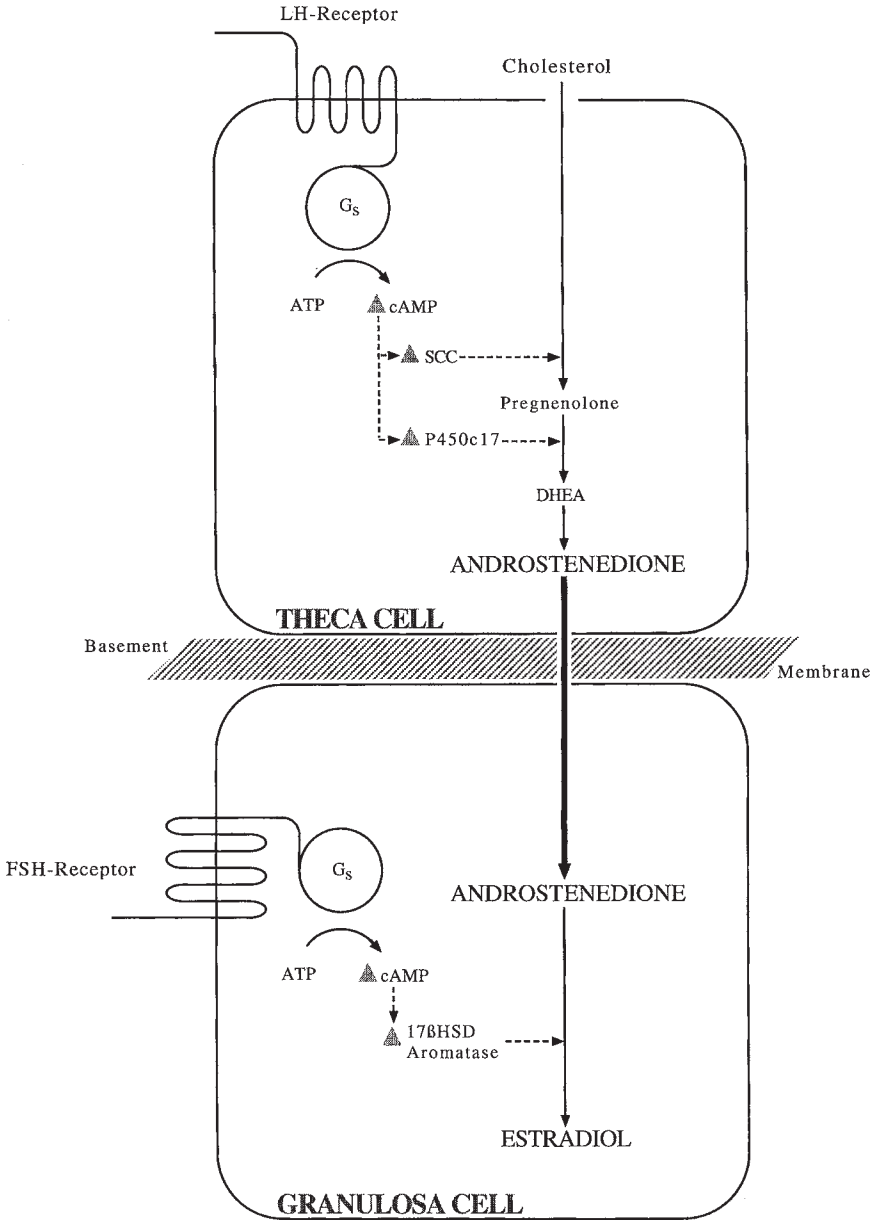

Figure 46-3 The cooperation of the granulosa and the theca cells in the production of estrogen from cholesterol.

serum FSH (*see* Fig. 46-3), which coincides with a slowing of growth and the eventual atresia of the nondominant follicles. The role of FSH in preventing follicular atresia is supported by studies of granulosa cell apoptosis in vitro.

FSH stimulates granulosa cell expression of several proteins that could function in a positive feedback loop to promote development of the dominant follicle. Foremost of these is the LHR. The induction of LH responsiveness in the granulosa is critical to allow the dominant follicle to ovulate in response to the midcycle LH surge and subsequently to develop into a corpus luteum. It also might allow intracellular cAMP levels to be maintained in the face of declining FSH stimulation. FSH also induces granulosa cells to increase production of other proteins that modulate follicular function. An example is inhibin, which acts on the theca to augment androstenedione biosynthesis as well as on the pituitary to decrease FSH output, thereby slowing the development of nondominant cohort follicles.

The exact process of selection of the dominant follicle from its cohort of recruited follicles is unknown. Research into this question has focused on the regulation of luteinizing hormone receptors, the process of angiogenesis in growing follicles, the role of cytokines and growth factors in the synergistic regulation of follicle growth and steroidogenesis, and the regulation of aromatase by steroid metabolites. The role of the balance in intracellular second messenger pathways and receptor crosstalk is also being investigated.

Numerous putative autocrine and paracrine ovarian regulatory factors have been investigated. Much information has accumulated on the action of such factors on ovarian tissues in vitro (*see* Table 46-2), and clearly such proteins have a role in modulating gametogenesis and steroidogenesis. However, the ability of a factor to elicit a response in an isolated in vitro system does not necessarily imply that it can elicit the same response in a dynamic organism with multiple modulatory influences. The role of individual factors in vivo has been technically more difficult to establish,

because many of these factors exist in families with multiple receptors and ligands that can potentially compensate for another factor rendered inactive. Genetic knockout techniques, though helpful, can also produce systemic effects that prevent the demonstration of a clear ovarian role of the nonfunctional gene. Targeted transgenic studies in which the alteration of gene expression can be limited both developmentally and anatomically will likely aid in clarifying the intraovarian role of many substances. The difficulties encountered in identifying the roles of each ovarian paracrine factor suggest that the redundancy in the reproductive system has evolutionary significance in that it reduces the dependence of the reproductive process on any single gene product.

FOLLICULAR ATRESIA Once a primordial follicle leaves the quiescent state and enters the growth phase, it must progress inevitably to either ovulation or loss through atresia. The vast majority of ovarian follicles are lost through atresia. Atresia can occur at any stage of follicle development, but the early antral stage appears to be particularly susceptible. Atresia of antral follicles has been well studied in several animal models and involves granulosa cell apoptosis. Apoptosis thus plays a major role during folliculogenesis and dominant follicle selection, in addition to its role in the reduction of oocyte number in the fetal ovary. Apoptosis is usually associated with degradation of chromosomal DNA into oligonucleosomal fragments by the activation of a Ca^{2+}/Mg^{2+}-dependent endonuclease.

The regulation of susceptibility to and prevention of apoptosis is dependent on the developmental stage of the follicle. Many factors can prevent apoptosis of preovulatory follicles, such as IL-1, fibroblast growth factors, epidermal growth factor and IGFs. But these factors are less able to protect smaller antral follicles or preantral follicles. FSH is the most potent antiapoptotic factor for the smaller antral follicles, but does not prevent apoptosis in follicles prior to the antral stage. By contrast activation of the cGMP pathway does prevent induced apoptosis in preantral follicles. The varying ability of growth factors, cytokines and hormones to block apoptosis at different developmental stages might play an important role in folliculogenesis and in limiting the number of follicles ovulated per cycle. For instance, the dependence of small antral follicles on FSH for development and survival provides an important bottleneck in folliculogenesis. There is a marked increase in the rate of follicle atresia in this group of follicles just as FSH becomes the most potent survival factor. Thus follicles at this stage are exquisitely sensitive to fluctuations of FSH during the menstrual cycle.

A number of molecules have been implicated as intracellular mediators of apoptosis in granulosa cells. Members of the Bcl-2 family of apoptosis regulatory proteins, which includes Bcl-2, Mcl, Bax, Bcl-x-long, and Bcl-x-short, are expressed by granulosa cells of humans and other species. Granulosa cell expression of Bax mRNA was decreased by gonadotropin treatment and increased in serum-free follicle culture, but Bcl-2 expression was unaffected. The tumor suppressor p53, which can promote apoptosis, was localized to granulosa cells only in atretic follicles, and its expression was increased in serum-free follicle culture and decreased by treatment with gonadotropins. Caspases are also present in granulosa cells. Inhibitors of caspases can block apoptosis in granulosa cells and oocytes. Studies of the regulation of mediators of apoptosis are ongoing and are beginning to be performed in primates. These studies might prove invaluable in understanding the role of apoptosis in human folliculogenesis and in preventing abnormally high rates of follicle loss to apoptosis.

OVULATION As the dominant follicle matures, it produces increasing amounts of estrogen, thereby effecting positive feedback on the pituitary gonadotrophs to produce the midcycle gonadotropin surge. The LH surge begins about 36 h and peaks about 10 h before ovulation; it triggers the major events of ovulation, including resumption of meiosis, cumulus expansion, cumulus-oocyte expulsion, and luteinization. The underlying regulation of these seemingly independent events has been studied intensively by those interested in both fertility control and infertility treatment. The duration of the LH surge is critical in triggering the events of ovulation; in primates, LH levels must be maintained for 18–24 h for oocyte maturation to occur, but for 34–48 h for optimal granulosa luteinization and corpus luteum function. Surge levels of LH are also necessary for the expression of prostaglandin-related genes in the rodent ovary.

In the developing follicle, resumption of meiosis is inhibited by a communication between the cumulus cells and the oocyte. In vitro, meiosis resumes in oocytes from antral follicles if the cumulus is removed or in response to cAMP. Atretic follicles of some species might exhibit meiosis briefly, as the granulosa cells lose function. Follicular fluid and granulosa cell-conditioned media both can inhibit meiosis of oocytes in vitro. These findings have led to the suggestion that granulosa cells produce an oocyte maturation inhibitor (OMI) under gonadotropin regulation. The identity of OMI has remained elusive. Hypoxanthine, a purine derivative, can inhibit meiosis in vitro and has been suggested to be the physiological OMI. Other candidate OMIs include inhibin and Müllerian inhibitory substance. Alternatively, the inhibition of meiosis might be a result of the functional relationship between the granulosa and the oocyte, and maturation might follow its physical disruption. This issue has not been resolved.

During the process of ovulation, the cumulus–oocyte complex loses its connection to the mural granulosa cells and probably briefly floats freely in the follicular fluid. At this time the follicular circumference is expanding, but the intrafollicular pressure does not increase. For the oocyte to be ovulated and reach the fallopian tube, it must pass through the mural granulosa layer, the follicular basement membrane, the theca layer, the ovarian stroma, and the surface epithelium of the ovary. This process is simplified because the enlarging follicle migrates (or expands) to the periphery of the ovary, adjacent to the surface epithelium.

Prostaglandins of the E and F series are elevated in follicular fluid before ovulation; and in rats prostaglandin synthetase is regulated by LH. The exact function of prostaglandins in ovulation is not known, but high doses of prostaglandin synthetase inhibitors interfere with ovulation in humans.

The process of ovulation has been compared with the inflammatory response of wound healing. As in wound healing, plasminogen activators (PA) play a role in the tissue remodeling that occurs during ovulation and formation of the corpus luteum. The regulation of the PA system at the time of ovulation has been characterized in the rat. Tissue plasminogen activator (tPA) is secreted by rat granulosa cells and produced but not secreted by the theca. Production of both tPA and an inhibitor, called plasminogen activator inhibitor (PAI), are stimulated by the gonadotropin surge; but PAI mRNA expression peaks approx 6 h after rats are given human chorionic gonadotropin (hCG) as a surrogate LH surge, whereas tPA expression does not peak until 12 h after hCG; thus, the inhibitor is likely present before the production of the activator. Before ovulation, tPA mRNA and protein are expressed at

high levels by the granulosa, whereas PAI is expressed strongly by the preovulatory theca and surrounding interstitium. After hCG, follicles enlarge rapidly and protrude from the ovarian surface. At 12 h after hCG, thecal expression of PAI in the portion of the follicle closest to the ovarian surface is lower than in the rest of the follicle. Granulosa expression of tPA in this region is greater than in the rest of the follicle. This temporal and spatial differential expression of tPA and its inhibitor could allow plasmin, which is generated from plasminogen from both serum and follicular fluid, to thereby activate collagenases only at the site of the stigma, in which the cumulus–oocyte complex escapes from the follicle. The localized follicular expression of interstitial and type-IV collagenases and their inhibitors also appears to be regulated by LH.

Experimental disruption of the components of the PA system by several methods decreases the efficiency of ovulation, but seldom results in complete ovulatory suppression. Transgenic mice lacking either tPA or urokinase (uPA) gene function are fertile and have no obvious reproductive phenotype. Animals derived from these lines and lacking both functional genes have impaired wound healing. Although they are still fertile, early studies suggest that they ovulate at a decreased rate. The lack of clear inhibition of ovulation in the absence of PAs suggests that, as with follicle growth, the process of ovulation is also governed by redundant regulatory systems.

THE LUTEAL TRANSITION After the release of the oocyte, the follicle begins its transition to the corpus luteum, the endocrine organ of pregnancy. The factors regulating this metamorphosis are not entirely understood, but the quality of luteal function is correlated with the adequacy of the follicular phase of the cycle. Studies of human granulosa and luteal cells cultured in vitro implicate the absolute level of intracellular cAMP in driving the cellular events of luteinization. The relatively lower levels of cAMP generated by FSH induce cell growth and replication, but the higher levels generated in response to LH lead to cessation of cell division and increased steroidogenesis. This cAMP effect might be augmented by other second messenger pathways activated by LH. A 43-kDa cAMP response-element binding protein is expressed in growing primate follicles, but not in corpora lutea, and correlates with expression of proliferating cell nuclear antigen. Differential expression of cAMP response-element binding protein might be another mechanism by which cAMP can exert different responses in the same tissue at different times.

Another key step in the formation of the corpus luteum is angiogenesis, the growth of numerous small vessels into the previously avascular granulosa. vascular endothelial growth factor, which stimulates proliferation of capillary endothelial cells, is expressed by human granulosa-luteal cells under positive regulation by LH. Other angiogenic factors, including basic fibroblast growth factor and PDGF, might also be involved in this process. Vascularization allows the granulosa direct access to serum-derived growth factors and hormones, as well as to low-density lipoprotein cholesterol used as a precursor for progesterone synthesis.

Progesterone, the principal product of the corpus luteum, is necessary both to prepare the uterine endometrium for implantation and to maintain early gestation. The LH surge induces large increases in granulosa cell steroid acute regulatory protein, $P450_{scc}$, and 3β-HSD expression, which lead to more efficient synthesis of progesterone. The human corpus luteum, unlike that of some other mammals, continues to secrete estrogen in addition to progesterone, particularly during the midluteal phase (*see* Fig. 46-3). The human corpus luteum is also distinctive, in that 17-hydroxy-progesterone is not a substrate for the lyase function of $P450_{c17}$, as it is in many other species. Therefore the metabolism of pregnenolone either to progesterone by 3β-HSD or to androstenedione (an estrogen precursor) by $P450_{c17}$ is a key branch point in luteal steroid production and the regulation of these enzymes could be a critical determinant of luteal steroid products.

LUTEAL REGRESSION In the absence of pregnancy, the corpus luteum begins to degenerate spontaneously after 2 wk. Luteal regression is classically described in two phases: functional regression and structural regression. Functional regression involves decreased production of progesterone and decreased expression of steroidogenic enzymes. Structural regression is more prolonged and involves apoptosis. Both spontaneous and experimentally induced luteal regression are associated with morphological apoptosis or oligonucleosomal DNA fragmentation. Although prostaglandins have been implicated in spontaneous luteal regression in nonprimate species, the mediators of luteolysis in primates have not been definitively identified. Macrophages, lymphocytes, and their secretory products (cytokines), as well as prostaglandins, might also play a role. Macrophages and lymphocytes invade the corpus luteum and become more numerous as the corpus luteum ages. Cytokines, including interferon-γ of lymphocyte origin and TNF-α of macrophage origin, decrease steroidogenesis by luteal cells from human, rat, and cow. Fas antigen has been localized to the human corpus luteum, suggesting its involvement in luteal regression. Regulators of functional and structural luteolysis might be different in the primate as the role of the corpus luteum is different in mammals with a menstrual cycle. The human corpus luteum exists for 2 wk in a nonpregnant cycle. Rodent corpora lutea secrete progesterone for less than a day before the next estrous cycle begins. Ongoing studies in primates are likely to shed more light on the regulators of luteal regression in humans.

OVARIAN SENESCENCE Menopause refers to the permanent cessation of menses. Ovarian function generally follows a gradual decline, with cyclical bleeding becoming increasingly irregular. Only approx 10% of women experience an abrupt natural cessation of menses. Women might ovulate during the menopausal transition, but bleeding during this interval is often the result of fluctuations in estrogen levels not related to ovulation and luteal demise. Therefore, a patient's memory of the timing of her last menstrual period might not be an accurate estimation of the cessation of ovulatory function. Several prospective studies of ovarian function during the menopausal transition are under way and should provide more information about ovulatory function and menopause.

Primordial follicles are believed to enter the growth phase at a relatively constant rate and are gradually depleted over time. There is excellent evidence; however, that their rate of loss increases as menopause approaches. This accelerated loss, predicted to begin on the average at age 38 yr, is associated with a decrease in inhibin and an increase in FSH serum levels. It has also been demonstrated that some women experience wide fluctuations in estrogen levels for several years leading up to the menopause. It is not understood why the rate of follicular loss increases at this age, but it might be dependent on the mass of the declining primordial follicle pool. Ongoing studies of unilaterally ovariectomized women, who have a decreased follicle pool, might shed light on this question.

Studies of reproductive senescence in transgenic mice have provided some interesting insights into the role of the follicle pool. Mice with mutations that result in a smaller initial pool of primordial

follicles have earlier senescence. Mice that have slower entry of primordial follicles to the growing pool do not always have delayed reproductive senescence and might even have POF. However, mice that have mutations or deletions that result in defective apoptosis in the ovary do have a delay in the timing of ovarian failure. Those with alterations in antiapoptotic molecules, like Bcl-2 have earlier ovarian failure. Functional studies of interruption of the apoptosis pathway in the ovaries of primates are ongoing and might reveal important information on the role of apoptosis in the maintenance and protection of the primordial pool of follicles that will have direct relevance for humans.

CONCLUSION Human ovarian tissue has been difficult to obtain for regulatory studies of folliculogenesis, luteinization, and luteolysis, and significant differences exist between humans and nonprimate animal models. For this reason, primate models continue to be important in the study of these processes. However, the use of new technologies, which allow the evaluation of smaller amounts of tissue, and the development of cell lines and long-term tissue culture techniques, are allowing more in-depth studies of human tissues involving the regulation of follicular growth and atresia, ovulation, luteinization, and steroidogenesis.

OVARIAN DYSFUNCTION

DISORDERS OF INCREASED OVARIAN FUNCTION

McCune–Albright Syndrome McCune–Albright syndrome (MAS), or polyostotic fibrous dysplasia, is caused by a postzygotic mutation in the GNAS1 gene encoding the α-subunit of $G_s\alpha$, a G protein that stimulates adenylate cyclase. The resulting sporadic activation of G protein-linked processes throughout the body leads to diverse manifestations, including bony lesions, café-au-lait skin lesions, and endocrine dysfunction. In the ovary, the activating mutation of the adenylate cyclase system leads to the premature development of relatively normal-appearing follicles, which include a thecal component and can secrete estrogen, independent of gonadotropin stimulation. As a result, half of girls affected with MAS exhibit signs of isosexual precocity, often presenting with vaginal bleeding. Follicles grow and produce estrogen in the absence of FSH stimulation. Often progesterone is produced as the follicles enlarge, suggesting that premature luteinization and LH-like effects are stimulated. Because there is no LH surge, the follicles do not ovulate but regress, thus explaining the relapsing and remitting manifestations of precocity in MAS girls and irregular cycles in women. Both bilateral and unilateral ovarian involvement has been reported. Normal pregnancies have been reported in adult women with MAS who had developed isosexual precocity in childhood, but infertility and subfertility are also common. Infertility might result as a direct effect on the ovary or because of dyssynchronous hormonal stimulation of the endometrium reducing the likelihood of implantation. Long-term evaluation of larger numbers of these patients is needed to accurately evaluate their fertility potential. It is possible that some cases of idiopathic gonadotropin-independent sexual precocity might be localized manifestations of mutations similar to that in MAS, but this has not been demonstrated.

Granulosa Cell Tumors Granulosa cell tumors represent 5–10% of all ovarian neoplasms and can be divided into two types, juvenile and adult, on the basis of histology and age of occurrence. Juvenile tumors are diagnosed in the first three decades of life, whereas adult-type tumors often present after menopause. About 5% of all granulosa cell tumors are diagnosed before the normal age of puberty. These tumors are generally multicystic and only rarely malignant. When these tumors occur prepubertally, approx 80% produce sufficient estrogen to result in isosexual precocity; they account for about 10% of isosexual precocity in girls. Some of these tumors also produce inhibin, indicative of differentiated granulosa cell function. Serum inhibin levels are often used in surveillance for tumor recurrence.

Many investigators have evaluated possible genes involved in granulosa cell growth and apoptosis as culprits in the evolution of granulosa cell tumors. Most studies have not differentiated between the two types possibly limiting the ability to interpret their data. It seems reasonable that juvenile and adult tumors are different enough to have different etiologies. Juvenile tumors are well differentiated and occur early when FSH levels are low. Adult tumors peak after menopause, a time when FSH levels are often very elevated. Several studies have searched for activating mutations of the follicle-stimulating hormone receptor (FSHR) or Gs_α-subunit in juvenile granulosa cell tumors, but no mutation has been identified. Mutations of the growth-inhibiting WT1 gene have been associated with juvenile granulosa cell tumors. Some syndromes involving abnormal tissue growth, such as Proteus Syndrome or Ollier Disease have also been associated with juvenile granulosa cell tumors. In rats, selective activation of the estrogen receptor-β has been associated with granulosa cell tumors, but estrogen receptor-β mutations have not been described in humans, although estrogen receptor-β expression is noted to be high in adult granulosa cell tumors.

In the adult-type granulosa cell tumor, mutations have been identified in the G_i-subunit of regulatory G proteins, although the physiological significance of these mutations has not been established. It is uncertain why the inability to turn off a normally transcribed stimulatory signal, as with the G_i mutation previously described, should be manifested as tumor in later life, whereas the uncontrolled activation of the same signal, in MAS, is manifested as a relatively normal-appearing follicle earlier in life. Further studies are necessary to elucidate the regulatory events involved in the stimulation of follicular growth by cAMP. Further studies of juvenile and adult granulosa cell tumors will likely yield important new information regarding both granulosa tumorigenesis and normal follicle developmental regulation.

Multifollicular Ovulation Twin and higher-order multiple gestations have long been a source of general curiosity and scientific interest. Monozygotic twinning results from the division of a single zygote after fertilization and is believed to be primarily related to zygote factors, with possible contributions from uterine and implantation factors. The incidence of monozygotic twinning has been relatively constant over time and among diverse ethnic groups. By contrast, the incidence of dizygotic twinning, which results from the separate fertilization of two ovulated eggs, varies among ethnic groups and has fluctuated over time. Although the study of genetically identical monozygotic twins has been of great interest because of the ability to examine the effect of different environments on the same genetic background, ovarian physiologists are understandably more interested in dizygotic twinning as a resource to evaluate the mechanisms determining the ovulatory quota. In every species a relatively constant number of oocytes are released each cycle, the ovulatory quota. This results in the distinct average litter sizes of a species or strain. In humans, usually only a single fertilizable egg is produced per cycle, though this control can be overridden by agents that increase gonadotropin stimulation of the ovary.

Variations in the incidence of dizygotic twinning fueled discussion of the possibility of the underlying molecular mechanisms involved. Dizygotic twins have been noted to occur with a frequency as high as one in eight pregnancies in some African populations and as low as 1 in 400 in some Pacific Rim countries. The incidence of twinning varies over the reproductive life span, with a higher frequency noted in the later reproductive years. Twinning also occurs with a high frequency within some families. Pharmaceutical agents to induce and augment spontaneous ovulation are associated with increased rates of multifollicular ovulation and multifetal pregnancy. One of these, clomiphene citrate, acts as a partial estrogen antagonist, thereby decreasing the negative feedback of estrogen on pituitary FSH secretion. This increase in FSH secretion presumably promotes ovulation by rescuing some recruited follicles that would otherwise have undergone atresia. Injections of FSH, as either human menopausal gonadotropins or purified or recombinant FSH, similarly stimulate development of increased numbers of follicles. The ability to induce superovulation pharmacologically and produce large numbers of mature oocytes in a single cycle has been critical in the development of in vitro fertilization and other assisted reproductive technologies. The introduction of these therapies for the infertile couple has fueled the study of the control of follicular growth, selection, dominance, and atresia.

Is there a molecular explanation for the increased ovulatory quota in families or population clusters with high rates of twinning? Mothers of twins have been studied in search of hormonal differences that could result from a genetic mutation and would be reflected in increased FSH action on the ovary. Some studies have shown higher levels of both estrogen and FSH in the follicular phase in mothers of twins, whereas inhibin levels might be either normal or elevated. Examination of familial twin clusters has revealed no mutations in the FSH-β, gonadotropin-releasing hormone (GnRH), GnRH receptor, inhibin-α, PPARγ, peroxisome proliferators-activated receptor (PPAR)γ, LH-β, and FSHR genes. No other mutation has been found in humans that could account for the apparent increased gonadotropin activity and enhanced follicular survival.

Further understanding of the molecular basis of the ovulatory quota has resulted from genetic studies of two strains of sheep with large litter size, the Booroola Merino and the Inverdale. The Booroola gene mutation, designated $FecB^B$, is autosomal and is associated with an increased number of ovulations in the heterozygous state and a further increase in the homozygote. The altered physiology results in maturation of larger numbers of follicles of a smaller size, with no net difference in total granulosa cell mass compared with wild-type Booroolas. Serum FSH is slightly elevated, but no other abnormalities in the hypothalamic-pituitary-ovarian axis are detectable. The Inverdale mutation, $FecX^I$, is X-linked. $FecX^I$ heterozygotes, like $FecB^B$ heterozygotes and homozygotes, show an increased number of antral follicles, but homozygotes display failure of ovarian development and have streak gonads.

FecB was identified as BMPRIB and FecX as GDF9B/BMP15. Though linkage analysis of the Australian twins cohorts has ruled out BMPRIB association with twinning in this population, these studies have increased interest in the role of the BMP family in follicle regulation. Further findings in this field are anticipated.

Hyperreactio Luteinalis Hyperstimulation of follicle development is a well-recognized side effect of treatment with exogenous gonadotropins. The hyperstimulation syndrome consists of greatly enlarged ovaries that are extremely fragile, ascites, depleted intravascular volume, and even pulmonary effusion. The "leaky capillaries" that are the culprit of the shifts in intravascular volume are thought to result from ovarian derived vasoactive factors secreted after the LH surge. Rare spontaneous cases of hyperstimulation that occur well after ovulation, during the first trimester of pregnancy have also been described. This condition is known as hyperreactio luteinalis and is usually associated with pregnancies with extremely high hCG levels, such as molar pregnancy or multiple gestations. It was thought that the elevated hCG could cross-react with the FSHR and activate it, though this explanation was controversial. Mutations in the FSHR have been described that result in hyperreactio luteinalis even with normal first trimester levels of hCG. Studies of binding and activation of the mutant receptors demonstrate that as little as 10 IU/mL concentration of hCG can activate the mutant receptors, whereas the wild-type receptor is minimally activated by 10,000 IU/mL hCG. The kinetics of FSH binding and activation of the receptors is not substantially different between the mutant receptors and wild-type controls. The described families had normal fertility, emphasizing normal FSH action in stimulating follicle development. Symptoms are only present in early gestation when hCG is present in high enough levels to cause hyperstimulation. Surprisingly, the mutations are not in the extracellular binding domain of the receptor, but in the serpentine portion in the cell membrane. It is hypothesized that the mutations allow a more relaxed configuration of this large transmembrane receptor that allows the low-affinity hCG binding to stabilize the receptor in its active form, thus resulting in the abnormal activation of the FSHR during pregnancy.

DISORDERS OF DIMINISHED OVARIAN FUNCTION

A number of disorders lead to diminished ovarian function. The spectrum of ovarian phenotypes of these disorders, which can include lack of estrogen production, menstrual acyclicity, and infertility, often overlaps, leading to confusion both in classifying these disorders and in determining their molecular basis. Diminished ovarian function is traditionally classified by its time of onset relative to menarche, but many disorders might have their origin in fetal life or childhood and remain unrecognized until clinical presentation when a girl fails to exhibit estrogen-induced secondary sexual characteristics at the time of expected puberty. A developmental approach to the classification of diminished ovarian function might be more helpful in understanding and recognizing these naturally occurring functional ovarian defects.

Ovarian Dysgenesis Absolute ovarian failure can result from improper ovarian development during embryogenesis. As discussed, ovarian development depends on complex interactions between germ cells and components of the gonadal ridge, and interference with either component will result in ovarian dysgenesis, with fibrous streaks devoid of germ cells replacing the ovaries. Patients with streak ovaries are sexually infantile and generally have elevated serum gonadotropins by the time of expected puberty, because they lack normal negative feedback from ovarian estrogen and inhibin.

The most common cause of gonadal dysgenesis is Turner's syndrome, or monosomy X (Chapter 42). The lack of a second X chromosome results in streak gonads and numerous characteristic somatic features, including shield chest, widely spaced nipples, and lymphatic abnormalities. In Turner's syndrome, germ cells apparently migrate normally to the ovaries, but primordial follicles are not formed efficiently and germ cells are lost. Gonadal dysgenesis

in girls with Turner's syndrome could potentially result from a defect at any of the stages of follicle formation, including the entry of oocytes into meiosis and the association of oocytes with granulosa cells.

Gonadal dysgenesis also occurs in women with two apparently normal X chromosomes. Several disorders that include craniofacial abnormalities are associated with ovarian dysgenesis, including an interstitial deletion of chromosome 2q found in a girl with ovarian dysgenesis, mental retardation, craniofacial abnormalities, and cardiac defects. Deletions of chromosome 3q have also been associated with gonadal dysgenesis and ovarian failure. Large chromosomal deletions might interfere with the process of pairing in meiosis, resulting in early germ cell loss. However, gonadal dysgenesis also occurs with apparently normal karyotypes. In Denys–Drash syndrome, a mutation in the WT1 gene is associated with renal malformations, Wilms' tumor, and gonadal dysgenesis. Most cases of this syndrome are in genetic males, but a few have been reported in genetic females.

Sensorineural deafness and blepharophimosis have also been associated with lack of ovarian function. Blepharophimosis ptosis epicanthus inversus syndrome is caused by mutations in the forkhead transcription factor gene FOXL2 (3q23) and is characterized by eyelid and ocular muscle abnormalities in combination with lack of ovarian function. As further understanding is gained of the regulation of patterning in development, other genes with unexpected roles in ovarian failure might be discovered.

Failure of Ovarian Function In another group of disorders, the ovaries might be formed normally but still not function adequately. This might result from deficiency of specific factors regulating the initiation of follicle growth, such as GDF-9. Alternatively, normally formed but unresponsive ovaries have been shown to result from mutations affecting gonadotropin function.

An FSHR mutation was identified among a group of Finnish women selected because of primary or early secondary amenorrhea. Initial study of these women suggested a recessive pattern of inheritance, and linkage analysis of multiplex families mapped the trait to chromosome 2p, the known location of the FSHR gene. Sequencing the FSHR gene in affected individuals revealed a mutation in exon 7, which encodes a portion of the extracellular domain of the receptor. In expression studies, this mutant receptor was unable to stimulate cAMP production in response to FSH. Further analysis of the receptor in the expression system demonstrated apparently normal ligand binding affinity but extremely low levels of receptor expression. The authors concluded that the recessive disorder leading to amenorrhea resulted from either abnormal FSHR trafficking or increased receptor degradation.

Though LHR defects have long been recognized as a cause of testicular Leydig cell hypoplasia, an inactivating mutation of LHR was associated with anovulation in a woman who apparently exhibited secondary sexual characteristics at puberty but had a small uterus and never had regular cyclic menses. Three of her sisters were XY pseudohermaphrodites with normal female external genitalia and absent Leydig cells on gonadal histology. The LHR in all four of these patients contained a homozygous mutation that created a stop codon in the third intracellular loop, resulting in a nonfunctional receptor. The index patient's history demonstrates that LHR function is not essential for estrogen production in quantities sufficient for breast development, despite being necessary for ovulation and luteinization.

There are also isolated reports of mutations associated with gonadotropin subunit defects. Hypergonadotropic hypogonadism has been reported in a woman with a homozygous mutation in the FSH-β gene that results in an FSH molecule unable to bind to its receptor. Her fertility was restored with exogenous FSH treatment. In contrast to female heterozygotes with the FSHR mutation described earlier, which often have large families, this patient's mother, an obligate heterozygote, was subfertile and had ovulatory dysfunction. It is possible that the presence of a defective FSH molecule interfered with the function of the normal protein, thereby reducing the efficiency of follicle growth and ovulation.

Defects in the enzymes necessary for estrogen biosynthesis can also result in sexual infantilism, but ovarian stimulation and in vitro fertilization have been performed successfully in some patients with estrogen deficiency, indicating that estrogen is not necessary for human preovulatory follicle development though it might play a role in oocyte maturation.

Premature Ovarian Failure POF, also called premature menopause, is clinically defined as the loss of ovarian function before the age of 35 yr despite adequate gonadotropin stimulation. Generally this term is applied to women who have undergone normal pubertal sexual maturation and have experienced some degree of cyclic ovarian function. Premature ovarian senescence can result from either an abnormally small initial endowment of primordial germ cells or increased germ cell loss with time.

A number of X-linked conditions are associated with POF. Although Turner's syndrome usually results in severe early germ cell loss and gonadal dysgenesis, some germ cell survival can occur in ovaries of women with X-chromosome mosaicism or partial deletions, allowing for short-lived ovarian function including normal puberty and even, rarely, fertility. Two X-chromosome loci have been linked to POF by the study of translocations in affected families: POF1, at Xq26–q28, and POF2, at Xq13.3–q21.1. The specific genes at these loci responsible for this phenotype have not been identified though a mutation in a human homolog of the Drosophila "diaphanous" gene has been associated with POF2. It has also been hypothesized that the break points of the X chromosome in this critical region cause aberrations in pairing or X inactivation during folliculogenesis that might result in apoptosis at meiotic checkpoints.

Another X-chromosome locus that might be associated with ovarian senescence is the fragile X gene, fragile X mental retardation protein, which maps to Xq28. The fragile X syndrome is caused by a lack of fragile X mental retardation protein protein resulting from an amplification of CCG triplet nucleotide repeats within the promoter region of this gene. Males with fragile X syndrome exhibit mental retardation, facial dysmorphism, and macroorchidism. Female fragile X carriers show an increased rate of premature menopause and an increased rate of dizygotic twinning, which might be an epiphenomenon of the increase in gonadotropins as ovarian senescence approaches. It is unclear how these observations are related to the fragile X genotype. Although fragile X mental retardation protein might play a role in germ cell proliferation in the testis, its role in the ovary has not been demonstrated. If it affects the efficiency of primordial follicle formation, a mutation at this locus might lead to a decrease in the overall follicular complement and, thus, an earlier cessation of cyclic ovarian function.

Any defect that decreases the efficiency of formation of primary follicles, resulting in a smaller starting pool of follicles, could potentially lead to POF, even if follicles were depleted at a normal rate. Increased atresia of oocytes in primordial follicles in

the fetus or of small follicles at a later time could also lead to POF. Dysregulation of the complex mechanisms that regulate ovarian apoptosis could be a factor, although no such defects have been demonstrated in women. However, studies in mice that block the function of pro-apoptotic molecules have delayed reproductive senescence. Further studies of familial POF clusters might reveal defects in factors regulating cell–cell interaction, cell growth, or apoptosis.

Progressive Ovarian Damage Galactosemia is an autosomal-recessive metabolic disorder characterized by a deficiency of galactose-1-phosphate uridylyltransferase, leading to an inability to metabolize galactose and the accumulation of potentially toxic galactose-1-phosphate in tissues. Treatment with dietary galactose restriction improves or prevents the development of abnormalities of the liver, kidney, eye, and central nervous system. Ovarian failure develops over several years in association with follicular depletion. The time of its onset is variable and might depend on the age of institution of dietary treatment. Both primary amenorrhea and rare pregnancies have been observed. The gonadotropins produced by these women are biologically active, despite the fact that galactose is present in the carbohydrate moiety of normal gonadotropins. The gonadotropin receptors are probably also normal, because ovulation can occur and testicular function in males with galactosemia is normal. The molecular basis for the accelerated depletion of ovarian follicles in galactosemia is unknown.

Autoimmune disorders might also cause progressive ovarian damage and lead to POF. POF might occur as an isolated autoimmune endocrinopathy, or it might be associated with other known autoimmune diseases of the endocrine system, including Hashimoto's thyroiditis, insulin-deficient diabetes, and Addison's disease. Histological examination of the ovaries in women with autoimmune POF often reveals a lymphoplasmacytic infiltrate involving growing but not primordial follicles. Abnormal ovarian monocytes and fibroblasts have been reported, as well as altered serum cytokine profiles. Although antiovarian antibodies have been described in some cases of POF, they are not consistently directed against any single antigen. Of interest, preliminary studies have suggested that the fragile-X-related gene product might be an autoantigen within the ovary. Ovarian failure often follows a relapsing and remitting course and pregnancies can occur, occasionally after prolonged absence of ovarian function. It is hoped that ongoing longitudinal studies of these patients will provide more information about the etiology and most effective treatment for this frustrating and unpredictable condition.

POLYCYSTIC OVARY SYNDROME In 1935 Stein and Leventhal published a case series describing women with enlarged ovaries containing many cysts. These women tended to be amenorrheic, hirsute, obese, and infertile. When they underwent resection of part of each ovary (wedge resection) many patients experienced a restoration of menstrual cyclicity. Because that landmark report, the polycystic ovarian syndrome (PCOS) has been a constant arena of study for reproductive biologists and gynecologists. With the discovery of the long-term effects of hyperandrogenemia and hyperinsulinemia on the health of these women, and the emergence of Syndrome X, the study of PCOS has entertained more widespread interest.

Despite decades of study and an enhanced understanding of the complexity of this syndrome, the etiologies of these phenomena remain elusive. Though it appears to be a heritable condition, it is also likely to be mulifactorial in nature. Susceptibility loci might include genes involved in steroid production and metabolism, insulin signaling, and regulation of folliculogenesis.

PCOS defined in the clinical setting as chronic anovulation in association with clinical and/or biochemical evidence of ovarian hyperandrogenism. The condition affects an estimated 5–10% of reproductive age women and is a common cause of secondary amenorrhea. In addition to menstrual irregularities and androgen excess, women with PCOS frequently present with insulin resistance and are at risk for type-II diabetes. They also can express features of metabolic cardiovascular syndrome including central adiposity, obesity, lipid abnormalities, and hypertension, though a thin PCOS phenotype has also been described. It has been suggested that psychological symptoms might also be a feature of PCOS.

Proposed etiologies of PCOS have included fundamental alteration of steroid biosynthesis, insulin resistance secondary to a postreceptor defect, intrinsic alteration of the hypothalamic pituitary drive, and abnormal control of follicular apoptosis resulting in persistent follicles. None of these hypotheses alone explains all of the sequelae associated with PCOS.

The Polycystic Ovary There has been a dichotomy in the criteria for diagnosing PCOS in the United States and Europe. In Europe the typical sonographic appearance of greater than eight small subcapsular cysts along with increased stromal density has been considered sufficient for the diagnosis of PCOS. However, in the United States, biochemical evidence of hyperandrogenism and irregular menses are often the criteria used to assign the diagnosis of PCOS without regard to the ovarian morphology. This can lead to confusion when comparing studies using different definitions, and careful attention to the inclusion criteria is thus required when evaluating the literature regarding PCOS.

Cystic ovaries have been reported in up to 20% of normal women with regular menstrual cycles, but nevertheless are a key feature of PCOS. Ovaries of PCOS women contain twice the number of follicles as control ovaries from cycling women. Though these follicles have an elevated estrogen to androgen ration, they are not atretic as would be expected in control ovaries. This had led to the consideration that there is an abnormality in apoptotic regulation of these follicles. Granulosa cells from these follicles have a reduced number of FSHRs compared with follicles from control ovaries, suggesting a reduced ability to respond to FSH stimulation. However, when granulosa cells from polycystic ovary cysts are grown in culture, FSHR expression can be stimulated and aromatase induced. Women with PCOS are often extremely sensitive to ovarian stimulation with exogenous gonadotropins. The number of small antral follicles at the beginning of an ovulation induction cycle is a risk factor for the ovarian hyperstimulation syndrome.

Women who undergo a reduction in ovarian mass through unilateral oophorectomy, Stein and Leventhal's original wedge resection, or the more modern "ovarian drilling" with laser or electrocautery often will have resumption of menstrual cycles and even restoration of fertility for a time. Traditionally it was thought that the ovarian reductive procedures worked because of a reduction in the androgen-producing ovarian stroma, however, more thought is being given to the effects of the follicles themselves. When women with PCOS approach menopausal age, they undergo the same reduction in the follicle pool as normal women. Some investigators have reported increased menstrual regularity and a reduction in serum LH and androgen levels as PCOS women approach the perimenopause.

Hyperandrogenism Hyperandrogenism is a hallmark of PCOS. Elevated testosterone is generally thought to result from excessive androstenedione produced by the ovarian theca. In vitro, theca from PCOS ovaries produces more androstenedione than theca from normal ovaries. Acne and hirsuitism result from the increased presence of C19 steroids that can be metabolized to dihydrotestosterone at the level of the hair follicle. Androstenedione can also be metabolized to estrogens in the peripheral tissues. This results in a tonic level of estrogen that can be in the midfollicular range. Tonic estrogen unopposed by progesterone is a major risk factor for endometrial hyperplasia and cancer.

The elevated androgens also result in down-regulation of sex hormone binding globulin. Reduction of sex hormone binding globulin results in a reduction in bound testosterone and increased relative free testosterone. Elevated androgens are thought to play a role in the adverse health effects described in PCOS women, such as increased cardiovascular and small vessel disease. However, these effects might also be indirect and related more to the elevated low-density lipoprotein cholesterol and decreased antioxidants seen in polycystic ovary women. Oral contraceptives are effective in modulating many of the effects of PCOS, not just in protecting the uterus from hyperplasia. Oral contraceptive use increases sex hormone binding globulin, thus resulting in a reduction of the "free testosterone," even in rare cases when total testosterone remains elevated. Whether early and consistent OCP use in the treatment of PCOS can diminish the long-term adverse health effects seen in PCOS has not yet been established.

Hypothalamic/Pituitary Inputs A key characteristic of PCOS is altered gonadotropin secretion. Classically, LH levels are elevated but FSH levels are in the normal range, though the elevated LH/FSH ratio is no longer necessary or sufficient to make the diagnosis of PCOS. The classic description of the "vicious cycle" of altered hypothalamic/pituitary/ovarian axis feedback involves the conversion of ovarian androstenedione to estrogen in the peripheral compartment. The resulting tonic estrogen levels enhance pituitary LH secretion, whereas suppressing FSH secretion. Elevated LH continues the cycle by stimulating excessive thecal androgen production. Though increased LH pulse frequency and amplitude have been demonstrated by many investigators, LH drive in PCOS might be less responsive to suppression by exogenous sex steroids and there might also be reduced sensitivity to endogenous steroid feedback, particularly progesterone.

Attention has been given to neurotransmitters mediating GnRH activation. Opiodergic and dopaminergic regulation are thought to be intact in women with PCOS. However, γ-amino-butyric acid (GABA) is elevated in the cerebrospinal fluid of women with PCOS compared with ovulatory controls. It has been suggested that either GABA could be acting in an excitatory fashion and stimulating GnRH neurons or the increased GABAergic tone functions as a compensatory response restraining GnRH. In animal models, GABA is excitatory to GnRH neurons when acting through the GABA A receptor. Further studies are warranted to clarify the role of the GABAergic system in PCOS.

The Insulin Connection Insulin resistance is commonly found in women with PCOS and it has been estimated that approx 10–15% of women with PCOS will develop diabetes. Hyperinsulinemia is observed in both lean and obese women with PCOS and is because of increased insulin secretion in response to peripheral insulin resistance. The insulin resistance is thought to result from a postreceptor defect because receptor number and binding affinity have been reported to be normal. Though the metabolic action of insulin is altered in PCOS, some investigators have reported that the mitogenic effects of insulin are intact.

There are insulin receptors in the ovary as well as IGFI and IGFII receptors present. IGFs are also produced in the ovary and are thought to be autocrine and paracrine factors involved in follicle development and steroid production. The IGF binding protein family is also present in ovarian follicles and might affect growth factor availability as well as have independent regulatory functions. Insulin and insulin-like growth factor increase FSH-stimulated steroid enzyme expression in both granulosa and theca cells in tissue or organ culture. There is an increase in ovarian stroma in women with PCOS, and it is hypothesized that the elevated insulin levels acting either through the insulin receptors or the IGF receptors results in increased growth of the stroma/theca of the polycystic ovary. Insulin and IGFs enhance the production of androstenedione from ovarian theca. Furthermore, when insulin-sensitizing agents are given to women with PCOS, not only do serum insulin levels fall, but androgen levels are also reduced.

The relationship between insulin, androgens, and ovarian function is, without question, complex. Women with insulin resistance and type II diabetes do not necessarily exhibit reproductive impairment. Further, women with cystic ovaries and/or hyperandrogenism are often reproductively "normal" and do not display insulin resistance. Women with PCOS who have undergone surgical ovarian reduction often experience a reduction in androgen levels and a restoration of ovarian cyclicity without a compensatory correction in insulin action. Interestingly, women with PCOS often begin to ovulate in response to insulin sensitizing agents such as metformin or activators of PPARγ. Unlike surgical intervention, which has no demonstrated effect on insulin, reduction of serum insulin levels has the effect of reducing androgens in PCOS. Yet not all women with PCOS exhibit insulin resistance. In obese women with PCOS and insulin resistance, weight loss can result in reduced serum insulin and androgen levels as well as return of ovulation and fertility. Yet, thin women can have PCOS and insulin resistance and changes in weight seem to have no effect on them.

These issues emphasize the syndromic nature of PCOS and point toward multifactorial etiologies (involving hypothalamic, steroidogenic, intraovarian, and metabolic factors) that result in a final common pathway of hyperandrogenic anovulation.

PCOS Genetics It is generally agreed that PCOS has a genetic component, but the mode of inheritance is not well understood, hampered in part by an unidentified male phenotype. Several studies have investigated relationships with different genes and the PCOS phenotype. One investigated 37 candidate genes involved in steroidogenesis, insulin action, gonadotropin regulation, and obesity to characterize candidate genes implicated in the etiology of PCOS. Of these, follistatin and CPY11A (P450 side-chain cleavage) were revealed as potential as markers. Although the relationship of CYP11A was not significant following statistical adjustment, other studies have indicated its potential as a marker for altered androgen secretion characteristic of PCOS.

The variable number tandem repeats in the insulin gene might represent a susceptibility locus for PCOS, though the statistical analysis has been questioned. A polymorphism in the D3 dopamine receptor was found with increased frequency in hyperandrogenic, dysovulatory Hispanic women, and was associated with resistance to ovulation induction with clomiphene. However, this correlation was not confirmed in a larger population of Caucasian women.

Polymorphisms in the IL-6 gene promoter are more common in women with hyperandrogenism. In general, there has been no universal genetic marker identified for PCOS.

PCOS is clearly more than a reproductive disorder. It is characterized by multiple endocrine and metabolic derangements that can lead to chronic, negative health effects in afflicted women. Further understanding of its etiology is necessary so that improved screening, prevention, and treatment interventions can be developed to improve the overall health of women with PCOS.

CONCLUSION

The mechanisms that direct germ cells in the yolk sac to migrate to the gonadal ridge and become enclosed in a follicular apparatus, and then direct these follicles to grow in controlled cohorts during 50 yr or more, are far from being completely identified. More is known about the effects of gonadotropins and growth factors on cohorts of follicles recruited to the final steps of preovulatory development, but the exact molecular mechanisms governing dominance, ovulation, and luteinization also remain to be clarified. Tissue remodeling is clearly of prime importance in the cycling ovary, but it is apparently regulated by multiple redundant systems. The importance of normal ovarian function to the overall health of women is becoming more appreciated. The systemic consequences of prolonged hypoestrogenemia in untreated gonadal failure or of the hyperandrogenism of PCOS emphasize the role of the ovary in long-term women's health issues. As knowledge of the processes involved in normal folliculogenesis advance, a more precise picture of the myriad causes of ovarian dysfunction will become apparent.

UCP	uncoupling protein
WAT	white adipose tissue

47 Gastrointestinal Regulation of Food Intake

Patrick Tso and Min Liu

SUMMARY

The gastrointestinal tract regulates food intake by sending and receiving signals from the brain both through humoral and neural pathways. This system works efficiently because body weight remains remarkably constant over time despite the slight tendency to gain weight as some individual's age. Ghrelin, a peptide secreted by the stomach, promotes food intake and is located ideally to monitor the volume of food and liquid ingested. Cholecystokinin is released by enteroendocrine cells of the duodenum postprandially and plays an important role in the secretion of pancreatic enzymes and the contraction of the gallbladder to release bile into the duodenum to aid digestion and nutrient absorption. Additionally, cholecystokinin is a satiety signal that appears to play a role in the regulation of food intake. Apolipoprotein AIV (apo AIV) might be an important signal in regulating food intake and the absorption of fat. It appears to participate in the packaging and secretion of chylomicrons. Apo AIV probably works peripherally and centrally to inhibit food intake. When nutrients reach the lower small intestine, they stimulate the secretion of peptide YY (PYY), glucagon-like peptide-1, and potentially other signals as well. Their function is to simultaneously reduce food intake and gastric emptying.

Glucagon-like peptide-1 and PYY might work directly on inhibiting food intake or indirectly by boosting the production of apo AIV, which is true for PYY. Contrary to long-standing beliefs, secretion of these peptides occurs early after food ingestion, thereby slowing gastric emptying and allowing for slower delivery of food to the small intestine for digestion and absorption. Understanding how this highly integrated system works might provide solutions to the obesity epidemic in affluent countries.

Key Words: Apolipoprotein AIV; cholecystokinin; gastrointestinal; ghrelin; glucagon-like peptide-1; peptide YY.

INTRODUCTION

The amount and type of food consumed by most individuals varies from meal to meal. Emotions, social pressures, time of day, convenience, exercise, and cost are a few of the many factors that determine what and how much people eat. Interestingly, despite so many interacting variables, our body weight remains remarkably stable and varies little over long periods. Because changes in body weight depend on both caloric intake and energy expenditure, maintenance of body weight implies that intake is equal to energy consumption, helping to achieve a constant body weight. This chapter integrates the functions of selected gastrointestinal (GI) peptides that regulate food intake to present a cohesive view of how food intake is physiologically regulated by the GI tract.

To understand the regulation of food intake, it is important to appreciate the many signals that are involved in initiating hunger and in terminating eating. "*Satiety*" is defined as "*sufficiency, or satisfaction, as full gratification of appetite or thirst, with abolition of the desire to ingest food or liquid*." Satiety signals are distinct from the longer-acting adiposity signals. Adiposity signals, leptin and insulin, are mostly involved in the long-term regulation of food intake and energy metabolism as dictated by energy needs and the amount of energy stores (adipose tissue) in the body. In contrast, satiety signals are released by the GI tract resulting from the ingestion of food, participate in the digestive process, and provide signals to the nervous system that influence behavior. A primary purpose of these signals is to match "the capacity of the GI tract to process the ingested food" to "food intake," thereby ensuring that the GI tract is functioning optimally without being overwhelmed. This chapter discusses these signals from the proximal to the distal GI tract. The effects of the cephalic phase (the sight and smell of food) and its involvement in food intake regulation are not included.

GHRELIN

PRODUCTION Ghrelin is the ligand for stimulating the release of growth hormone from the pituitary through a G protein coupled receptor. It is a peptide of 28 amino acids in which the serine 3 residue is n-octanoylated. The O-n-octanoylation at serine 3 is essential to all of ghrelin's activity. Ghrelin secretion is induced by fasting and inhibited by refeeding or the ingestion of alcohol. Daily peripheral administration of ghrelin results in body weight gain in both mice and rats. Ghrelin is made from specific cells in the stomach and present most abundantly in the fundus of the stomach. Additionally, ghrelin is made by the small intestine.

PHYSIOLOGICAL FUNCTIONS Administration of peripheral or central ghrelin stimulates food intake as well as gastric acid secretion. Plasma ghrelin levels increase before each meal and fall to a nadir 1 h following the cessation of a meal. This finding is consistent with ghrelin's hypothesized role to stimulate food intake. Plasma ghrelin levels of subjects participating in a diet-induced weight reduction program rose following intervention consistent with increased appetite and tendency to regain lost weight. Ghrelin levels have also been investigated following gastric bypass surgery.

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

For instance, a reduction in circulating ghrelin levels among patients following gastric bypass is observed compared to their presurgery levels, consistent with the tendency of gastric bypass patients to eat less and therefore lose weight. Contrary to these studies, others have reported circulating ghrelin levels to increase following gastric bypass surgery. Reasons for these differences are unclear but might be related to the extent and/or exact site of surgical intervention.

In a clinical study of 24 patients having short bowel syndrome, circulating ghrelin was found to decrease. This decrease was proposed to result from tissue mass reduction in these patients and their subsequent inability to secrete ghrelin. In two separate studies, patients with Prader–Willi syndrome were found to have very high circulating levels of ghrelin, which is consistent with their enormous appetites and massive obesity. The circulating level of ghrelin is decreased in obese subjects and an inverse relationship exists between percentage of body fat and the circulating fasting ghrelin concentration.

How endogenous ghrelin secretion is turned on or off is not understood, nor is the function of endogenous ghrelin. However, a picture is emerging based on exogenous ghrelin, which appears to be an important hormone in initiating food intake, consistent with the observation that endocrine cells that secrete ghrelin are present in the stomach while other meal-related stimuli are active (such as gastric distension). With fasting or restriction of food intake, ghrelin secretion is high, so concern to induce eating. Following ingestion of food, its role in inducing food intake has been accomplished and so the secretion of ghrelin is markedly reduced. Patients with Prader–Willi syndrome probably have a genetic dysregulation of ghrelin secretion that causes them to behave differently from other obese humans who have an inverse relationship between percentage of body fat and plasma ghrelin. Although this hypothesis is compelling, it is based only on observed correlations.

CHOLECYSTOKININ

PRODUCTION Cholecystokinin (CCK) is a hormone secreted by the enteroendocrine cells in the upper small intestine in response to the presence of amino acids and fatty acids in the lumen.

PHYSIOLOGICAL FUNCTIONS The proposal that CCK plays a role in the regulation of food intake came from the demonstration that intraperitoneal administration of CCK caused satiety in rats. Exogenous CCK is also a satiety factor in man. Compared with a saline infusion, the infusion of the C-terminal octapeptide of CCK (CCK-8) suppresses liquid food intake without obvious outward side effects. CCK-8 also decreases solid food intake in man.

The satiety effect of CCK has been further characterized in animal models. In rodents, the inhibitory effect of CCK on food intake involves the vagus nerve, as abdominal vagotomy attenuates its satiety effect. Chemical denervation of the intestinal sensory nerves by capsaicin treatment also significantly reduces peripheral CCK-induced satiety. Further, convincing evidence exists that satiety caused by peripheral CCK administration involves CCK_A receptors in the periphery.

Despite evidence from both animals and humans demonstrating that exogenous CCK helps regulate food intake, this possible physiological role of endogenous CCK has been challenged because of the relatively small change that occurs in its circulating level following a meal. That is, the changes in the circulating level of CCK during a meal are significantly below the level of circulating CCK needed to achieve satiety by exogenously administered CCK. Nonetheless, endogenous secreted CCK plays a role in the regulation of food intake based on experiments involving the CCK receptor antagonist, devazepide. In both primates (rhesus monkeys) and rats, a blockade of the CCK type A receptor by devazepide increases food intake. That endogenous CCK plays a role in the regulation of food intake has been further supported by studies using Otsuka Long-Evans Tokushima Fatty rats. These obese and diabetic rats have a defective CCK_A receptor. Otsuka Long-Evans Tokushima Fatty rats, having disordered food intake, consume a larger meal size than wild-type rats. Chronic ingestion of larger meal size increases daily food intake resulting in obesity when extended over a long interval.

Evidence suggests that CCK does not act alone, but instead interacts synergistically with other signals to regulate food intake. For instance, while subthreshold doses of either CCK-8 or leptin alone do not affect food intake, together they significantly reduce the intake of food. The combined action of CCK and leptin is mediated peripherally involving capsaicin-sensitive sensory fibers. Reduction in food intake is mediated by the coadministration of CCK and leptin is mediated by both the peripheral action of CCK and a central action of leptin. Reduction in food intake by exogenously administered CCK is significantly smaller in animals fed a diet high in fat over a long period. Further, reduction of gastric emptying by CCK is also attenuated in animals fed a high-fat diet over a substantial time. Thus, it is possible that the blunted response to CCK in animals chronically fed a diet high in fat might contribute to the dysregulation of food intake and thus account for associated obesity.

APOLIPOPROTEIN AIV

PRODUCTION Apolipoprotein AIV (apo AIV) is a protein secreted by the enterocytes of the small intestine. The small intestine's production of apo AIV is regulated physiologically, decreasing with fasting and increasing with lipid feeding. Both mono- and polyunsaturated fatty acids stimulate the secretion of apo AIV by the small intestine to the same degree. Furthermore, bile diversion significantly reduces apo AIV synthesis by the intestinal mucosa. Thus, intact enterohepatic circulation is necessary for maintaining normal basal secretion of apo AIV by the gut. In vivo studies show that the synthesis and secretion of apo AIV by the GI tract are also regulated by peptides secreted by the lower small intestine, one candidate being peptide YY (PYY). PYY is secreted by the endocrine cells in the lower intestine in response to lipid absorption, which in turn stimulates the production and secretion of apo AIV by the jejunum. Unlike the stimulation of apo AIV production by lipid absorption in the jejunum, stimulation of apo AIV production by PYY is posttranscriptional, i.e., there is increased synthesis without a change in the mRNA level.

PHYSIOLOGICAL FUNCTIONS Evidence suggests that Apo AIV regulates food intake. The first report of apo AIV as a satiety factor investigated rats with intravenous cannulas, who were fasted for 24 h and then infused intravenously with either saline, fasting lymph (lymph collected from fasting animals), or chylous lymph (lymph collected from animals actively absorbing fat). Food intake was then monitored. Animals receiving lymph from fasted rats consumed food comparable to animals that received saline. However, animals administered intravenous intestinal lymph from rats actively absorbing lipid had profound inhibition of food intake. These data suggested the presence of an active component(s) in chylous lymph that inhibits food intake, which was demonstrated to be apo AIV. Intravenous administration of 200 μg of apo AIV

(a physiological dose) inhibited food intake to the same degree as chylous lymph in 24-h food-deprived rats. This unique function had not been previously ascribed to apo AIV. Moreover, it is not a function that is shared by apo AI. Hence apo AIV might be a circulating signal released by the small intestine in response to fat feeding and responsible for the anorectic effect associated with the ingestion of lipids.

Circulating apo AIV might affect the brain. Administration of apo AIV into the third ventricle of the brain in animals inhibited food intake in a dose-dependent manner. Further, the removal of apo AIV from the cerebrospinal fluid by using apo AIV antibodies caused rats to eat during the middle part of the light phase, a time when they normally do not eat. Hence, evidence exists that apo AIV can act centrally to reduce food intake.

Apo AIV inhibits gastric acid secretion and gastric motility. Two studies found food intake to be significantly inhibited by a physiological dose of apo AIV. The action of apo AIV is not limited to its central action as apo AIV administered peripherally inhibits gastric motility.

Both apo AIV mRNA and apo AIV protein are present in the rat hypothalamus. Hypothalamic apo AIV appears to be highly regulated as it decreases with fasting and increases with the infusion of lipid into the stomach. Thus, hypothalamic apo AIV appears to change in synchrony with serum apo AIV, and both are significantly higher in *ad libitum*-fed than in food-deprived rats. That hypothalamic apo AIV is involved in regulating food intake is further supported by the observation that administration of AIV antiserum into the third ventricle of *ad libitum*-fed rats significantly reduces hypothalamic apo AIV mRNA. Additionally, it results in animals consuming food at a time when they normally do not eat (during the middle of the light cycle). Neither administration of apolipoprotein AI antiserum nor nonbinding normal goat serum influenced food intake.

If endogenous apo AIV participates in the regulation of food intake, then apo AIV knockout animals would be expected to become obese from consuming excess food. To test this hypothesis, the growth, feeding behavior, and fat absorption of apo AIV knockout mice were measured; all were reported as normal. However, male mice showed increased food intake following an 18 h fast. Preliminary data indicate the apo AIV knockout mice gained excess weight over a period of weeks when fed a diet high in fat (40% butterfat) relative to wild-type controls. Using the lymph-fistula mouse model, apo AIV knockout mice adequately digest, absorb, and transport a modest lipid load into lymph. However, when lipid load is increased, these animals have delayed formation and secretion of chylomicrons by the intestinal mucosa. The importance of apo AIV in the normal formation and secretion of chylomicrons has been studied. Air bubble surfactometry and drop volume tensiometry were used to study the involvement of apo AIV in chylomicron assembly; apo AIV plays an important role in stabilizing the surface of expanding chylomicrons intracellularly. Also, overexpression of apo AIV in newborn swine intestinal epithelial cells greatly enhances intestinal fat absorption by promoting chylomicron formation and secretion. Thus, in addition to its role in inhibiting food intake, apo AIV also plays an important role in the formation and secretion of chylomicrons.

The regulation of jejunal apo AIV synthesis and secretion by PYY has potential physiologic significance. The distal intestine plays an important role in the control of upper GI function, especially the stomach. Nutrients, including lipids, when delivered to the ileum cause a slowing of gastric emptying, decreased intestinal motility and transit, and decreased pancreatic secretion. The presence of nutrients in the ileum also inhibits food intake. The mechanism responsible for producing these effects has been collectively termed the "ileal brake" and is believed to relate to the release of one or more peptide hormones from the distal intestine. PYY is an obvious candidate for this inhibitory effect on food intake because it is secreted from the distal intestine when lipid is infused. Such effects have traditionally been considered operative only during the abnormal delivery of undigested nutrients to the distal gut, such as would occur in the malabsorptive state. The upper small intestine is considered the primary site for the absorption of fat and the lower small intestine is thought to absorb fat only when fat malabsorption occurs in the upper small intestine, but this idea has been challenged. In both rats and dogs, nutrients frequently reach the distal gut soon after the ingestion of lipids even under normal conditions because of rapid gastric emptying during the early phases of food ingestion. Consequently, it appears that a much greater length of intestine is involved in the absorption of lipid and conditions, than previously recognized. Thus, the "ileal brake" might play an important role in the normal control of gut function and the control of lipid absorption. Once the homeostatic "ileal brake" phenomenon begins, the upper small intestine is unquestionably the primary site for the absorption of fat. It is tempting to speculate that apo AIV might contribute to the "ileal brake" phenomenon because PYY is a potent stimulant of apo AIV formation and secretion by the jejunum.

GLP-1 AND PYY

PRODUCTION Glucagon-like peptide-1 (GLP-1) is synthesized by endocrine cells located in the ileum and colon. It is secreted in response to nutrient ingestion and plays multiple roles in metabolic homeostasis following nutrient absorption.

Initial studies of GLP-1 biological activity utilized the full length N-terminal extended forms of GLP-1 (1–37 and $1–36^{amide}$), which have low biological activity. Later, it was recognized that removal of the first six amino acids resulted in a shorter version of the GLP-1 molecule with substantially greater biological activity. GLP-1 is rapidly degraded in the blood by dipeptidyl peptidase. PYY is a peptide secreted by the same endocrine cells in the ileum that secrete GLP-1. The release of PYY by these enteroendocrine cells is stimulated by the presence of nutrients in the ileum including carbohydrates and fat.

PHYSIOLOGICAL FUNCTIONS GLP-1 (7-36) amide, when administered centrally, causes profound reduction in food intake. In healthy human subjects, intravenous infusion of graded doses of synthetic human GLP-1 resulted in a dose-dependent reduction in food intake. These normal human subjects reported less hunger and early satiety during the period of GLP-1 infusion.

However, humans infused intravenously with GLP-1 showed a marked reduction in gastric emptying and only an insignificant effect on food intake was observed. Central administration of GLP-1 produced conditioned taste aversion in rodents. Unlike leptin, central administration of GLP-1 resulted in aversive side effects. Additional experiments are warranted to interpret this apparent discrepancy in the function of GLP-1 as a satiety factor against its role as a taste aversive factor. The aversive and caloric effects of GLP-1 might be caused by differential activation of distinct receptor populations in the brain, providing the answer.

Peripheral injection of PYY (3–36) in rats significantly inhibits food intake, and this action is probably mediated through the Y2 receptor as PYY failed to inhibit food intake in Y2 receptor null mice. Electrophysiological recordings show that PYY inhibits electrical activity of hypothalamic neuropeptide neurons, thus resulting in the activation of hypothalamic pro-opiomelanocortin neurons. Infusion of physiological doses of PYY decreased appetite and food intake significantly.

Both PYY and GLP-1 hormones are released when the ileum is exposed to nutrients. These hormones are thought to slow gastric emptying and gastric acid secretion. Their major digestive function is to prevent the lower small intestine from becoming overwhelmed by newly ingested nutrients. Thus, they complement apo AIV in regulating the amount of food consumed as well as the amount of food emptied by the stomach. Because PYY stimulates jejunal apo AIV synthesis and secretion and this action is mediated through the vagus nerve, it is possible that PYY's role in the regulation of food intake is mediated partly or totally through apo AIV. However, it is unclear whether GLP-1 affects apo AIV synthesis in the gut.

48 Cellular Regulation of Lipolysis

ALLAN GREEN

SUMMARY

Lipolysis is the pathway by which adipocyte triglycerides are hydrolyzed and mobilized as free fatty acids, during periods when energy expenditure exceeds caloric intake. Hormone-sensitive lipase is the major enzyme involved in regulation of lipolysis. Numerous hormones acutely regulate lipolysis, but the most physiologically important are insulin (inhibitory) and catecholamines (stimulatory). Hormone-sensitive lipase is activated by phosphorylation in response to stimulatory hormones through a cAMP-mediated cascade. Conversely, insulin and other hormones that inhibit lipolysis decrease phosphorylation of hormone-sensitive lipase. Lipolysis can also be regulated over the longer term by changes in gene expression in response to growth hormone, cytokines, insulin, and glucose.

Key Words: Adipose tissue; adipocytes; fat metabolism; free fatty acids; glycerol; hormone-sensitive lipase; lipid metabolism; lipolysis; perilipin; triglyceride.

INTRODUCTION

In humans and other mammals, energy is stored primarily as glycogen in skeletal muscle and liver, and as triglyceride in adipose tissue. An average adult stores only about 1500 calories as glycogen, but even a fairly lean adult can store more than 100,000 calories as triglyceride. Glycogen and triglyceride, therefore, serve to maintain energy requirements between meals and during short bursts of exercise (primarily glycogen) and during longer periods of food deprivation or during prolonged exercise (primarily triglyceride).

When required, triglyceride is mobilized from adipose tissue by a highly regulated process known as lipolysis. Lipolysis proceeds in a stepwise fashion to release three molecules of free fatty acid (FFA) and one molecule of glycerol from each triglyceride molecule. FFA and glycerol are released into the interstitial space, and eventually into the circulation. Glycerol is metabolized primarily in the liver, but FFA are oxidized by most tissues. Indeed many tissues will oxidize FFA in preference to glucose; a mechanism known at the glucose–fatty acid cycle, hence "sparing" glucose during a prolonged fast for those tissues that have an absolute requirement for glucose, such as the brain, kidney medulla, and erythrocytes.

Circulating FFA concentrations are determined mostly by the rate of adipose tissue lipolysis. Although FFA are an excellent oxidative substrate for energy-requiring processes, they are also extremely toxic. At higher concentrations FFA can have adverse effects on membrane function, and are cardiotoxic. It is thought that high circulating FFA is a major contributor to life-threatening ventricular arrhythmia during an acute myocardial infarction. At lower concentrations FFA induce insulin resistance, increase hepatic glucose output and have adverse effects on pancreatic β-cell function. Evidence suggests that excess adipose tissue lipolysis and consequent elevations in FFA are central to the insulin resistance of obesity, and a key factor in development of type-2 diabetes. For these reasons, it is essential that lipolysis is a tightly regulated process, to supply FFA only when needed for oxidation in other tissues.

STORAGE OF TRIGLYCERIDES White adipose tissue accounts for the majority of triglyceride storage in adult humans. White adipocytes are the primary cell within the white adipose tissue, with the remaining cells (blood vessels, connective tissue, and so on) collectively known as the stromal-vascular cells. Within white adipocytes, insoluble triglyceride is stored as a single droplet that occupies most of the cell. A small rim of cytoplasm, containing the nucleus, mitochondria, and other cellular components, surrounds the triglyceride droplet. Adipocytes are almost spherical, but a small "bulge" can often be observed on one side of the cell, which contains the nucleus. The triglyceride droplet is coated with a variety of proteins, including perilipins and lipotransins; some of which are involved in regulation of lipolysis (*see* Perilipins).

EXPERIMENTAL MODEL SYSTEMS Adipocyte lipolysis results in release of both fatty acids and glycerol. Fatty acids can be re-esterified back to triglyceride. By contrast, adipocytes cannot reutilize glycerol, because they do not express glycerol kinase. For this reason, in vitro studies of lipolysis are almost always performed by measuring the rate of glycerol release, rather than fatty acids. Glycerol can be readily assayed using a variety of enzymic and colorimetric techniques.

Lipolysis has been studied in a variety of whole tissue, isolated cell, and tissue culture systems. Each technique has advantages and disadvantages. Early studies, performed with whole fat pads or minced tissue, led to the widespread use of the rat epididymal fat pad, which was originally used because it is very thin and therefore metabolites, oxygen, and carbon dioxide readily diffuse in and out of the tissue. In 1964, a method was developed for isolation of adipocytes from rat epididymal fat pads by collagenase

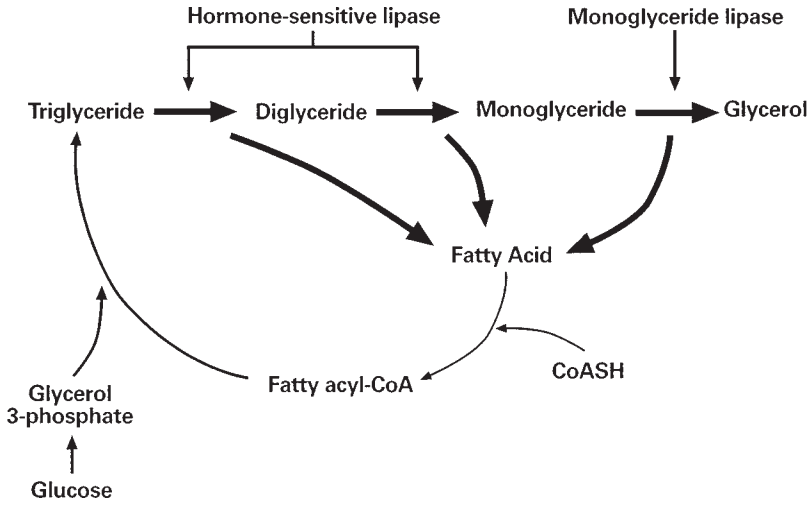

Figure 48-1 Pathways for lipolysis and re-esterification in adipocytes. Triglyceride is hydrolyzed sequentially to diglyceride, monoglyceride, and glycerol, by the actions of hormone-sensitive lipase and monoglyceride lipase. Adipocytes release both glycerol and FFAs, but a portion of the latter can be re-esterified to triglyceride. The glycerol backbone is derived through glycolysis from glucose, rather than glycerol, because adipocytes do not express glycerol kinase.

digestion. In this technique, pieces of adipose tissue are incubated with crude bacterial collagenase, which liberates the adipocytes. This method is particularly convenient because on low-speed centrifugation these cells float to the top of the tube, whereas other cells sediment to the bottom. Slight variations of this technique have been used for studies of adipocyte metabolism for more than 40 yr. The technique has been modified to allow primary culture of these cells, so that they can be studied in vitro for up to a week or more. The collagenase digestion technique can be used to study adipocytes from different anatomic sites, including adipose tissue from human subjects obtained during surgery, liposuction, or biopsy.

Several cell lines can be maintained in tissue culture and then treated with various agents in vitro to induce their differentiation into adipocytes. The most widely used have been the 3T3-L1 and 3T3-F442A cells, originally derived from mouse fibroblasts. Such cells have the advantage that they can be experimentally manipulated and passaged in vitro before differentiation. Major disadvantages are that they are heteroploid, transformed cell lines that may or may not be representative of true adipocytes. However, these cells have been extremely useful for studies of adipocyte differentiation.

Another technique based on isolation of preadipocytes from human adipose tissue allows these cells to be maintained in tissue culture, and then induced to differentiate in vitro using methods similar to those used in the 3T3-L1 cells. Several promising findings have been reported using this technique.

PATHWAY OF LIPOLYSIS AND RE-ESTERIFICATION A triglyceride molecule consists of a glycerol backbone to which is esterified three long-chain fatty acids. Triglycerides are hydrolyzed sequentially, primarily by two enzymes (Fig. 48-1). An enzyme known as hormone-sensitive lipase (HSL) is responsible for removing two of the three fatty acids. That is, HSL hydrolyzes both triglycerides and diglycerides. The rate-limiting step for lipolysis is removal of the first fatty acid by HSL and, as the name implies, multiple hormones and other agonists alter the activity of this enzyme. A second enzyme, monoglyceride lipase, is responsible for hydrolysis of the third fatty acid to liberate free glycerol, and has little or no ability to hydrolyze either triglyceride or diglyceride.

A portion of the fatty acids released from adipocytes can be re-esterified to triglyceride. This process of lipolysis and re-esterification can form a so-called substrate cycle between triglyceride, fatty acids, and back to triglyceride. In this re-esterification process, the source of the glycerol backbone is glycerol 3-phosphate derived from glucose, rather than glycerol itself, because adipocytes do not express glycerol kinase.

REGULATION OF THE RATE OF LIPOLYSIS

Mechanisms for regulation of the rate of lipolysis can be broadly categorized into two classes. First, there are mechanisms by which the rate of triglyceride breakdown can be varied dramatically over the short term, i.e., seconds to minutes. Second, overall rates of lipolysis can be regulated on a more long-term basis, altering total triglyceride breakdown over hours, days, or longer.

SHORT-TERM REGULATION OF LIPOLYSIS A number of hormones can readily stimulate lipolysis in adipocytes in vitro by a factor of 10- to 20-fold, or more. These stimulatory hormones include the catecholamines, adrenocorticotropic hormone, glucagon, vasoactive intestinal peptide, thyroid stimulating hormone, and the natriuretic peptides. Conversely, lipolysis can be inhibited by a variety of agents, including adenosine, E-series prostaglandins, catecholamines acting at α_2-adrenergic receptors, dopamine, adenosine receptor agonists, nicotinic acid, and insulin. However, the only hormones with a generally accepted role in short-term regulation of lipolysis in humans are the catecholamines and insulin.

The majority of the hormones that stimulate or inhibit lipolysis do so through a cyclic adenosine 5′-monophosphate (AMP)-dependent mechanism, as illustrated in Fig. 48-2. Most of these hormones alter cellular cyclic AMP concentrations through classical G protein-coupled mechanisms. The receptors involved are typical G protein-coupled receptors, consisting of seven transmembrane domains, with the N-terminal sequence outside the cell, and the C-terminus forming a cytoplasmic tail. Stimulatory receptors activate the stimulatory G protein known as G_s, whereas receptors that inhibit lipolysis activate the inhibitory G protein, G_i. These in turn either activate or inhibit adenylyl cyclase, which produces cyclic

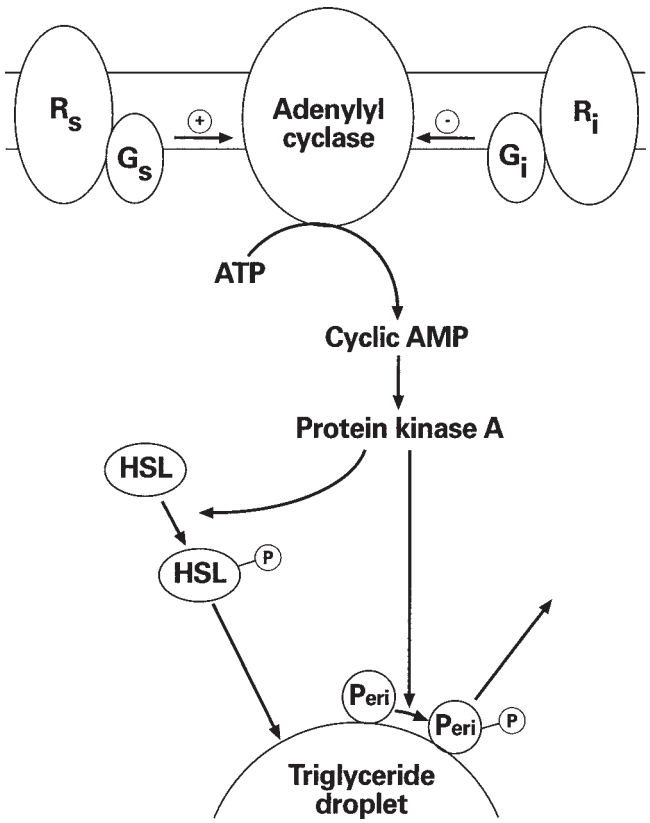

Figure 48-2 G protein-coupled receptor regulation of lipolysis. Stimulatory receptors (e.g., β-adrenergic receptors) couple through activation of G_s to increase cyclic AMP concentrations, activate PKA and phosphorylate both hormone-sensitive lipase and perilipin (Peri). The phosphorylated perilipin migrates away from the triglyceride droplet, hence increasing the accessibility of the lipid droplet to phosphorylated HSL, which migrates to the droplet, hence increasing the rate of lipolysis. Conversely, inhibitory receptors (e.g., A_1-adenosine receptors) couple through G_i to inhibition of cyclase, which decreases cyclic AMP concentrations, eventually leading to inhibition of lipolysis. P, phosphate ion.

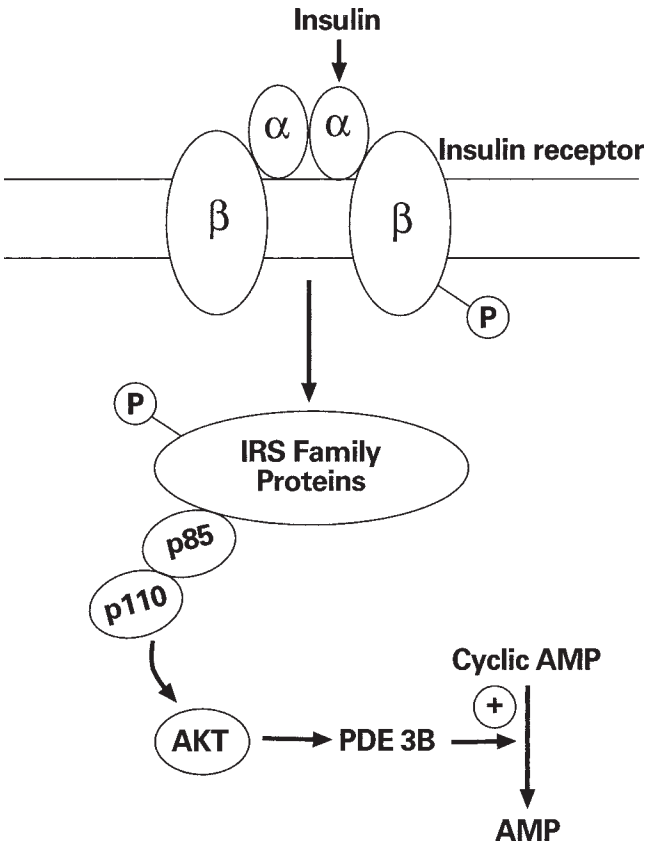

Figure 48-3 Mechanism by which insulin inhibits lipolysis. Insulin binds to the α-subunit of the insulin receptor, which induces autophosphorylation of the β-subunit. This results in tyrosine phosphorylation of various members of the insulin receptor substrate family, which binds and activates PI-3 kinase. This results in activation of Akt, leading to activation of phosphodiesterase-3B. PDE3B activation results in hydrolysis of cyclic AMP, leading to inhibition of lipolysis. P, phosphate ion.

AMP from the substrate, ATP. Cyclic AMP activates protein kinase A (PKA), which phosphorylates and activates HSL.

Stimulation of Lipolysis Catecholamines are the major class of hormones that activate lipolysis in adipose tissue. They activate lipolysis through typical β-adrenergic receptors. Adipocytes express β_1- and β_2-adrenergic receptors, similar to those found in other tissues. However, adipocytes also express a third, atypical form, the β_3-adrenergic receptors. These β_3-adrenergic receptors are expressed predominantly in brown adipose tissue, but to a smaller degree in white adipocytes.

The natriuretic family of peptides is best known for its involvement in blood pressure regulation. Receptors for atrial, brain, and C-type natriuretic peptides have been reported on rodent adipocytes, and these peptides stimulate lipolysis in human (but not rodent) adipocytes, both in vivo and in vitro. The second messenger responsible for this effect is cyclic guanosine 5′-monophopshate (GMP), rather than cyclic AMP. However, the physiological significance of this is not known. There are numerous other receptors on adipocytes, which, when activated, can stimulate lipolysis. Again, the physiological relevance of these receptors is not clear.

Inhibition of Lipolysis There are a number of G protein-coupled receptors that inhibit lipolysis by decreasing cyclic AMP concentrations. Many of these are members of the G protein-coupled receptor family, with the seven transmembrane domain structure described earlier. The best described in this class are A_1-adenosine and α_2-adrenergic receptors. In addition, E-series prostaglandins are potent inhibitors of adenylyl cyclase and lipolysis in adipocytes (in contrast to most tissues, in which these prostaglandins increase cyclic AMP concentrations). Catecholamines can inhibit lipolysis by acting at α_2-adrenergic receptors. Finally, nicotinic acid is a potent pharmacological inhibitor of lipolysis. Although it is well established that nicotinic acid inhibits lipolysis through a G protein-coupled mechanism, the receptor to which it binds has not yet been identified.

Physiologically, there can be little doubt that insulin is the most important hormonal inhibitor of lipolysis. In the fed state, circulating insulin is sufficient to maximally suppress adipocyte lipolysis. The mechanism by which insulin inhibits lipolysis differs from that of the G protein-coupled receptors. Most of the metabolic actions of insulin (stimulation of glucose transport, glycogen synthesis, fatty acid synthesis, and so on), including inhibition of lipolysis, involve activation of an enzyme, phosphatidyl inositol-3 kinase (PI-3 kinase). PI-3 kinase activation arises from a complex signaling pathway, starting with insulin binding to its receptor (Fig. 48-3). The insulin receptor is a tetrameric glycoprotein,

consisting of two α-subunits and two β-subunits, joined by disulfide bonds. The α-subunits possess cysteine-rich regions, which bind insulin. Insulin binding to the α-subunit results in activation of a tyrosine kinase activity in the β-subunits, resulting in autophosphorylation and activation of the receptor. Once phosphorylated, the insulin receptor tyrosine phosphorylates several intracellular substrates including insulin receptor substrate (IRS)-1, IRS-2, IRS-3, and IRS-4 and products of the shc gene. Phosphorylated substrates of the insulin receptor then bind and regulate a number of effector molecules that contain so-called SH2 (src-homology 2) domains, and hence initiate intracellular cascades of phosphorylations and dephosphorylations that lead to the various metabolic and mitogenic actions of insulin. One of these is the enzyme PI-3 kinase, which seems to be central to the metabolic actions of insulin. PI-3 kinase is made up of a p110 catalytic subunit, and a p85 regulatory subunit. Activation of PI-3 kinase results from dissociation of these two subunits.

Activation of PI-3 kinase results in various events, including activation of a low Km, cyclic GMP-inhibitable phosphodiesterase called phosphodiesterase-3B. This activation may be mediated through protein kinase B (also known as Akt). This increased phosphodiesterase activity lowers cyclic AMP concentrations, leading to a decrease in the activity of HSL, as described later.

Autocrine/Paracrine Regulation of Lipolysis Adipose tissue has traditionally been viewed as an inert tissue whose main function was to store energy in the form of triglyceride and release energy in the form of FFAs. Although this is clearly a major function, it has become clear that adipose tissue produces many hormones, cytokines, and metabolites that can have profound effects throughout the body. Such hormones include leptin, resistin, angiotensinogen, tumor necrosis factor (TNF)-α, insulin-like growth factor I, adiponectin, adenosine, and prostaglandins. Many of these hormones are secreted into the bloodstream, but some appear to act primarily in an autocrine or paracrine fashion. Isolated adipocytes release sufficient adenosine that, in the absence of any other added agent, the rate of lipolysis is almost fully suppressed. Addition of adenosine deaminase (which converts adenosine to the much less active inosine) to suspensions of rat adipocytes stimulates lipolysis to a similar extent as does isoproterenol, suggesting that endogenous adenosine can have a profound effect on adipocyte lipolysis. Similarly, E-series prostaglandins likely have an autocrine role in regulation of lipolysis.

TNF-α, expressed in adipose tissue, and at higher levels in adipocytes from obese subjects, is thought to have an important role in the etiology of insulin resistance in obesity. However, TNF-α circulates at extremely low concentrations in both lean and obese subjects, raising the possibility that the more important effect of adipocyte-derived TNF-α is within the adipose tissue itself. TNF-α increases the rate of lipolysis (*see* Cytokines) and hence this is likely an example of autocrine or paracrine regulation.

G Proteins in Regulation of Lipolysis Adipocytes express various G proteins at high concentrations. Hormones that stimulate adenylyl cyclase do so by activating G_s. Adipocytes express two forms of $G_s\alpha$, of approx 47 and 43 kDa. These isoforms arise from alternative splicing of mRNA from a single gene. As in other tissues, G_s can be ADP-ribosylated and activated by treatment of the cells with cholera toxin. The subsequent increase in cyclic AMP dramatically increases the rate of lipolysis.

A_1-adenosine receptors, and others that inhibit adenylyl cyclase, are also classical G protein-coupled receptors. Effects of these inhibitory agonists are blocked by pertussis toxin, known to ADP ribosylate and inactivate at least six G protein α-subunits. Each of these has in common a cysteine residue located four amino acids from the C-terminus, which is the site for toxin-catalyzed ADP-ribosylation. These pertussis toxin-sensitive G proteins include at least two forms of G_o, and three subtypes of G_i: G_i1, G_i2, and G_i3. The only pertussis toxin substrates detectable in adipocytes are the α-subunits of G_i1, G_i2, and G_i3. These isoforms are products of separate genes, but are highly homologous and of a similar size (40–41 kDa). The question of which isoform of G_i is/are responsible for inhibition of adenylyl cyclase has not been resolved. In vitro evidence using recombinant G proteins has demonstrated that each is capable of inhibiting adenylyl cyclase, but whether each is involved in vivo is unknown.

Adenylyl Cyclase Adenylyl cyclase is central to the action of the majority of hormones and neurotransmitters that both stimulate and inhibit lipolysis. The notable exception is likely insulin, as described earlier. Adenylyl cyclase catalyzes the conversion of ATP to cyclic AMP, the archetypal, and first recognized cellular second messenger.

The classical mechanism by which agonists activate and inhibit lipolysis is that adenylyl cyclase is activated by $G_s\alpha$, and inhibited by $G_i\alpha$. Through such a mechanism, hormones that stimulate cyclase, and hence lipolysis, do so by activating G_s to liberate $G_s\alpha$. Conversely, hormones that inhibit lipolysis do so by activating G_i, thus liberating $G_i\alpha$, which inhibits cyclase and hence lowers cyclic AMP and inhibits lipolysis.

At least nine isoforms of adenylyl cyclase have been cloned. These are large, membrane-bound proteins. All of the cloned isoforms are stimulated by $G_s\alpha$. Therefore, the classical view of stimulation of lipolysis by lipolytic hormones such as epinephrine is probably correct, although perhaps not complete. However, the various isoforms of adenylyl cyclase vary markedly in their response to $G_i\alpha$, with some being insensitive to inhibition. Conversely, some are activated by G protein β/γ-subunits, which would be liberated by activation of either G_s or G_i (as well as other G proteins). Furthermore, certain adenylyl cyclases are activated by Ca^{2+}/calmodulin, whereas others are inhibited by Ca^{2+}, in a calmodulin-independent manner. Adipocytes express most, or perhaps all of these isoforms. Differences in the expression of these adenylyl cyclase isoforms may be part of the explanation for very different responses of adipocytes from different anatomic sites to lipolytic and antilipolytic stimuli. However, the physiological significance of the complexity of adenylyl cyclase regulation has not been established.

Protein Kinase A Acute activation of lipolysis by cyclic AMP is mediated through activation of PKA, also known as A-kinase. PKA is a heterotetrameric protein, consisting of two regulatory and two catalytic subunits. The regulatory subunits serve to maintain PKA in an inactive state, and binding of cyclic AMP to these regulatory subunits results in dissociation and hence activation of the enzyme. PKA also has various isoforms, including at least two forms of the regulatory subunit and three isoforms of the catalytic subunit. The function of this enzyme is to phosphorylate appropriate substrates within the cell on activation by cyclic AMP. In adipocytes, the major proteins phosphorylated in response to PKA are HSL and perilipin.

Hormone-Sensitive Lipase HSL is a soluble enzyme of approx 84 kDa. The human enzyme has 775 amino acid residues. The activity of HSL is markedly increased by phosphorylation, and deactivated by dephosphorylation. In addition to its role in adipose tissue lipolysis, it is thought that HSL serves as the neutral

cholesterol ester hydrolase activity important in steroidogenesis. Consistent with this, HSL is expressed abundantly in adipose tissue and steroidogenic tissues, and to a much smaller degree in heart and skeletal muscle.

An intriguing recent finding is that mice with targeted disruption of the HSL gene are phenotypically not unlike normal mice. The greatest abnormalities are in steroidogenesis, consistent with the putative role of this enzyme in hydrolysis of neutral cholesterol esters. Triglyceride lipase activity both in vivo and in vitro is blunted, but not absent. These findings suggest that there are one or more other HSL(s) yet to be identified.

HSL is a cytoplasmic protein. On activation, for example by a catecholamine, the cascade of events described earlier results in activation of PKA, which phosphorylates HSL. Activation and inactivation of HSL results from phosphorylation and dephosphorylation of a single serine residue, Ser-563 in the rat sequence. This has been termed the regulatory site, and the surrounding sequence is typical of a PKA substrate. A second serine residue, only two amino acids away from the regulatory site (Ser-565) can also be phosphorylated. This is termed the basal site because its phosphorylation does not appear to be influenced by hormones. From in vitro studies it appears that phosphorylation of site 2 prevents phosphorylation of site 1, suggesting a regulatory role. Phosphorylation of HSL results in its translocation from the cytoplasm to the lipid droplet, in which it hydrolyzes triglyceride.

Perilipins In the "basal" state, the lipid droplet within the adipocyte is coated with several proteins, including the perilipins, which are important in hormonal regulation of adipocyte lipolysis. These perilipins (perilipin A and perilipin B) coat the lipid droplet, and impair access of HSL to the triglyceride. The two forms present in adipocytes arise through alternative splicing of mRNA from a single gene, and perilipin A is the prevalent form in adipocytes. Studies with perilipin knockout mice have demonstrated that adipocytes from perilipin deficient animals have elevated basal lipolysis, but dramatically blunted response to lipolytic agonists.

Like HSL, perilipins are phosphorylated in response to increased cyclic AMP levels, and this phosphorylation results in their translocation to the cytoplasm, resulting in increased access of HSL to the lipid droplet.

LONG-TERM REGULATION OF LIPOLYSIS The mechanisms described earlier are likely important in short-term, minute-to-minute regulation of lipolysis. Much less is known of mechanisms that regulate lipolysis on a more long-term basis. However, it is known that lipolysis can be regulated chronically by a number of mechanisms. For example, expression of HSL decreases in obese subjects after weight loss, and fasting increases expression of this enzyme. Aging and obesity are both associated with long-term alterations in adipose tissue lipolysis. Various hormones, and especially cytokines, chronically alter the rate of lipolysis. Such alterations are increasingly recognized as important in development of insulin resistance, which may be at least partly secondary to excess fatty acid release from adipose tissue and subsequent effects on skeletal muscle and liver metabolism.

Growth Hormone Growth hormone can increase the rate of adipocyte lipolysis. Depending on the experimental system studied, this effect depends on concomitant treatment with a glucocorticoid, usually dexamethasone. The growth hormone-induced increase in lipolysis is slow to develop, on the order of hours. The mechanism is related to redistribution of G_i from the membrane to an intracellular compartment, hence decreasing its ability to inhibit adenylyl cyclase. However, details of the mechanism by which growth hormone causes this redistribution of G_i are not known.

Cytokines Various cytokines increase the rate of adipocyte lipolysis, especially TNF-α and IL-6. These cytokines are produced by adipocytes, and so this may be an example of autocrine or paracrine regulation of lipolysis. TNF-α is known to be overexpressed in the adipose tissue of obese humans, and this adipocyte-derived TNF-α is likely involved in the insulin resistance of obesity. TNF-α has direct effects on insulin signaling, but also increases the rate of adipocyte lipolysis. The resulting increase in circulating FFAs may be more important in development of insulin resistance than the direct effect on the insulin signaling cascade.

Details of the mechanism by which TNF-α increases the rate of adipocyte lipolysis are unknown. However, activation of the TNF receptor is required. This leads to activation of two mitogen-activated protein kinases, known as extracellular signal-regulated kinases 1 and 2. Activation of the transcription factor, nuclear factor (NF)-κB, is also thought to be necessary for the lipolytic effect of TNF-α. NF-κB is a ubiquitously expressed transcription factor central to the inflammatory response. Therefore its involvement in the lipolytic effect of TNF-α may partially explain the relationship between chronic inflammation and insulin resistance. Exactly how activation of NF-κB relates to lipolysis is unknown, but two mechanisms have been proposed. One is that a decrease in the cellular concentration of perilipin allows for higher rates of lipolysis, because perilipin normally limits the access of HSL to the triglyceride droplet. A second is that TNF-α chronically decreases the cellular concentration of the various isoforms of G_i, which may release tonic inhibition of adenylyl cyclase, thus chronically increasing the rate of lipolysis.

Insulin and Glucose Insulin is the most important acute inhibitor of lipolysis. However, prolonged incubation of adipocytes with insulin (several hours) actually increases the rate of lipolysis. Furthermore, this stimulatory effect of insulin is dependent on glucose. Neither glucose nor insulin alone causes this chronic stimulatory effect. Rather, the combination of high glucose and high insulin increases both basal and isoproterenol-stimulated rates of lipolysis, possibly from increased expression of HSL. Whether this is because of the insulin or the glucose is unknown. Each can regulate the expression of many genes, but it is possible that the insulin increases lipolysis primarily by increasing the rate of glucose uptake into the cell, and it is the glucose that increases expression of HSL and hence lipolysis. This effect likely contributes to the well-documented phenomenon of "glucose toxicity" that worsens insulin resistance in hyperglycemic subjects. In this scenario, hyperglycemia would contribute to excess lipolysis, and hence excess circulating FFA. The elevated FFA would then impair insulin action, further exacerbating the hyperglycemia.

CONCLUSION

Adipocyte lipolysis can be stimulated and inhibited by numerous mechanisms, involving a variety of hormones, neurotransmitters, and cytokines. The mechanisms of action of many of these agents at the cellular and molecular levels are becoming well understood. However, the physiological significance of many of these systems has not been determined. The major physiologically significant hormones in humans are insulin and the catecholamines. The increased rate of lipolysis during fasting is primarily because of a decline in circulating insulin concentrations and insulin resistance, and a slight increase in circulating catecholamines and

increased lipolytic sensitivity to β-adrenergic stimulation. Nonetheless, it seems unlikely that the numerous receptors that can couple to stimulation and inhibition of lipolysis in vitro have no physiological significance in vivo, and perhaps further investigation will clarify their role.

This chapter focused on cellular and molecular mechanisms, and treated the adipocyte as a homogeneous population. It is important to emphasize, however, that adipose tissue is heterogeneous in nature. Adipocytes in different adipose tissue depots may have different functions and express different ratios of the various components of the proteins involved in regulation of lipolysis. Adipocytes can express three stimulatory β-adrenergic receptor subtypes, together with inhibitory α_2-adrenergic receptors, plus other stimulatory and inhibitory receptors, different isoforms of G_s and G_i, at least nine forms of adenylyl cyclase, multiple PKA isoforms, and so on. This complex heterogeneity may allow different adipose tissue depots to mobilize FFA differently during fasting or prolonged exercise. Such differences between tissues may explain, for example, why different individuals store adipose tissue in different anatomic sites, why certain fat cell depots are relatively resistant to weight loss, and why excess central (visceral) adipose tissue poses a greater medical risk than does peripheral adipose tissue.

Excess adipose tissue lipolysis is increasingly recognized as central to development of insulin resistance and heart disease. These diseases, and others associated with obesity, are now the second leading causes of preventable premature death in the United States. Therefore, it is likely that further research on the mechanisms responsible for regulation of lipolysis will provide valuable new leads to treating and preventing some of leading causes of death.

49 Fat-Induced Insulin Resistance and Atherosclerosis

GUENTHER BODEN

SUMMARY

Physiological elevations of plasma free fatty acid (FFA) levels cause peripheral (muscle), hepatic, and vascular insulin resistance, whereas lowering of plasma FFA levels improves peripheral insulin sensitivity in diabetic and nondiabetic subjects. FFA-induced insulin resistance in muscle is produced by defects in insulin-stimulated glucose transport and/or phosphorylation and in glycogen synthesis, which develop over 2–6 h. Development of these defects is temporally associated with accumulation in liver and in muscle cells of diacylglycerol (DAG) and activation of serine/threonine kinases including protein kinase C (PKC) and inhibitor of κB-kinase. In nondiabetic, obese subjects, FFA-induced insulin resistance is fully or nearly fully compensated by FFA-mediated stimulation of insulin secretion. In patients with type 2 diabetes mellitus (T2DM), FFA-mediated stimulation of insulin secretion is impaired; hence, FFA-induced insulin resistance needs to be compensated by hyperglycemia. Acute elevation of plasma FFA levels also activate the proinflammatory and proatherosclerotic inhibitor of κB/nuclear factor κB pathway in muscle and liver and this might play a role in the pathogenesis of atherosclerotic vascular disease and nonalcoholic fatty liver disease. Normalizing plasma FFA levels is, therefore, proposed as an approach to reduce insulin resistance and the risk for type 2 diabetes, atherosclerotic vascular diseases and nonalcoholic fatty liver disease.

Key Words: Atherosclerosis; diacylglycerol; FFA; hepatic and peripheral insulin resistance; inflammatory cytokines; inhibitor of κB (IκB) kinase; nonalcoholic fatty liver disease; nuclear factor κB pathway; protein kinase C; type 2 diabetes.

INTRODUCTION

Excessive body fat accumulation (obesity) has become a major public health problem in the United States where approximately two-thirds of the adult population is overweight. Many animal and human studies have shown that obesity causes insulin resistance. It is therefore not surprising that obesity is a strong risk factor for type 2 diabetes (T2DM) and that the epidemic of obesity was accompanied by a similarly strong increase in T2DM.

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

Although it is not yet entirely clear how obesity causes insulin resistance/T2DM, it has become apparent that elevated plasma levels of free fatty acids (FFA) play a major role. The evidence for this can be summarized as follows:

1. Most obese people have elevated plasma FFA levels.
2. Acutely raising plasma FFA levels decreases insulin-stimulated glucose uptake, i.e., causes acute insulin resistance (Fig. 49-1).
3. Chronic elevation of plasma FFA levels also produces insulin resistance, as shown when previously elevated plasma FFA levels were normalized for 12 h. Doing so normalized insulin sensitivity in obese nondiabetic individuals and improved insulin sensitivity in obese patients with T2DM.

ORGAN LOCATION OF FFA-INDUCED INSULIN RESISTANCE

SKELETAL MUSCLE FFA-induced insulin resistance takes place mostly in skeletal muscle, develops approx 2–4 h after an increase of plasma FFA and disappears approx 4 h after FFA have returned to normal, is dose dependent and affects all people similarly including healthy men and women, pregnant women, and elderly patients with T2DM (Fig. 49-2). Thus, a rise in plasma FFA from approx 400 to 800 p*M*, as can occur after a fat-rich meal, will reduce by approx 50% the effect of a postprandial insulin load (~500 p*M*).

LIVER Acute elevations of plasma FFA levels also inhibit insulin suppression of hepatic glucose production, i.e., cause hepatic insulin resistance. Acute suppression of hepatic glucose production by insulin involves primarily inhibition by insulin of glycogenolysis. FFA produced hepatic insulin resistance by inhibiting insulin suppression of glycogenolysis (Fig. 49-3).

ENDOTHELIAL CELLS FFA also produce endothelial cell (EC) dysfunction. For instance, insulin increases leg blood flow through nitric oxide mediated vasodilation, although FFA inhibits this insulin-mediated vasodilation. Interestingly, this inhibition was only observed when rates of insulin-mediated glucose uptake were also reduced by FFA, which suggested that there was a metabolic link between insulin's effect to dilate skeletal muscle vasculature and its effect to promote glucose uptake. Together these results suggest that FFA can produce EC

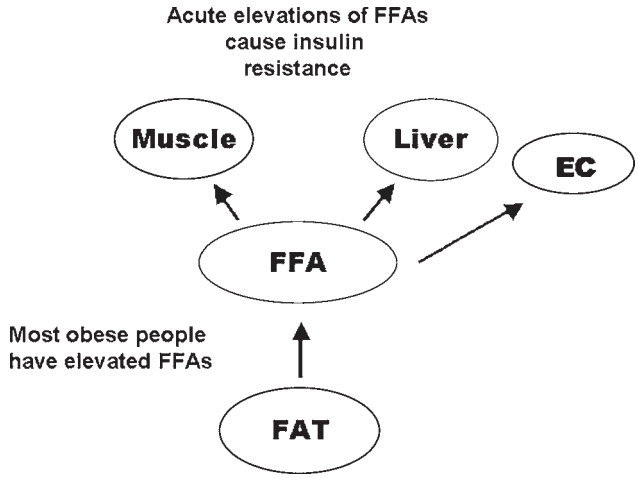

Figure 49-1 Proposed mechanism of obesity-induced insulin resistance. Excessive fat accumulation (obesity) is associated with increased plasma FFA levels, which cause insulin resistance in skeletal muscle, liver and in endothelial cells.

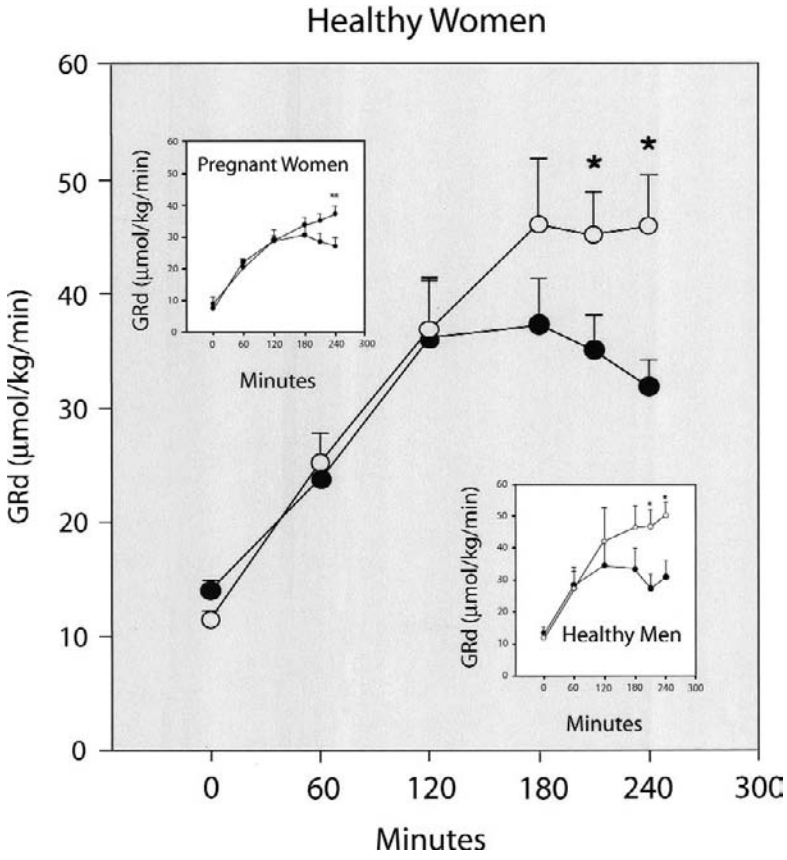

Figure 49-2 Isotopically determined ([3-^{3}H] glucose, glucose uptake (G_{Rd}) before and during 4 h of euglycemic-hyperinsulinemic clamping with coinfusion of either Liposyn II plus heparin (closed circle) or saline plus glycerol (open circle) in nine healthy women. dysfunction and may contribute to the development in hypertension in obesity and T2DM.

EFFECTS OF FFA ON INSULIN SECRETION

FFA-induced insulin resistance in muscle and liver could result in hepatic overproduction and peripheral underutilization of glucose, theoretically leading to a rise in plasma glucose concentration and eventually to diabetes in all obese people with elevated plasma FFA levels. This, however, is not the case. Only approx 50% of all overweight/obese subjects ever develop impaired glucose tolerance or diabetes. In the remaining 50%, FFA increase insulin secretion sufficiently to compensate for the FFA mediated insulin resistance.

Acute increases in plasma FFA do increase insulin secretion. Prolonged increase in plasma FFA (48 h) also potentiates glucose-stimulated insulin secretion. In fact, they stimulate insulin secretion

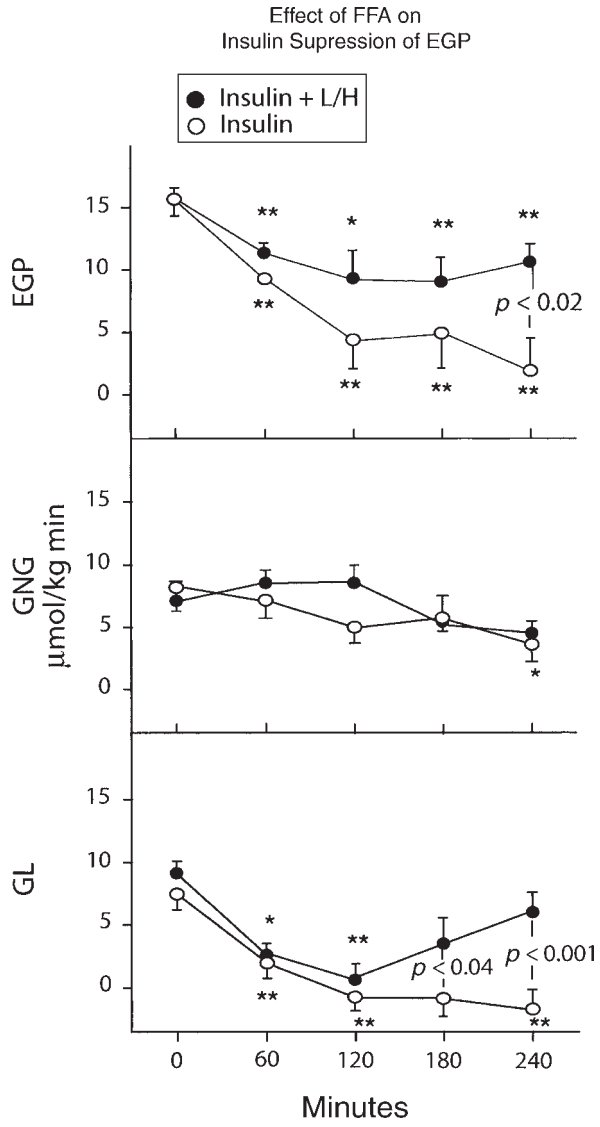

Figure 49-3 Effects of euglycemic-hyperinsulinemic clamping in normal volunteers (closed circle, $n = 6$) and without (open circle, $n = 7$) lipid/heparin (L/H) infusion on endogenous glucose production (EGP), gluconeogenesis (GNG) and glycogenolysis (GL). *$p < 0.05$, **$p < 0.01$ compared with basal values. †$p < 0.05$, 120- and 180- vs 240-min values. precisely to the extent necessary to compensate for the FFA-induced insulin resistance. Moreover, acute or prolonged (12 h) lowering of elevated plasma FFAs resulted in a 30–50% decrease in insulin secretion suggesting that chronically elevated plasma FFAs supported between 30 and 50% of basal insulin secretion in these individuals. Thus, it appears unlikely that physiological elevations of plasma FFA levels in humans are lipotoxic to β-cells as had been proposed based mainly on in vitro and animal studies. If they were, T2DM would develop in most obese people, namely in those who have elevated plasma FFA levels.

MECHANISM

Muscle In skeletal muscle (which accounts for >80% of insulin-stimulated glucose uptake) the primary FFA-induced defect, resulting in the development of insulin resistance, consists of inhibition of insulin-stimulated glucose uptake and/or phosphorylation (Fig. 49-4). This defect develops 2–4 h after an acute rise in plasma FFA. FFA also inhibits carbohydrate oxidation,

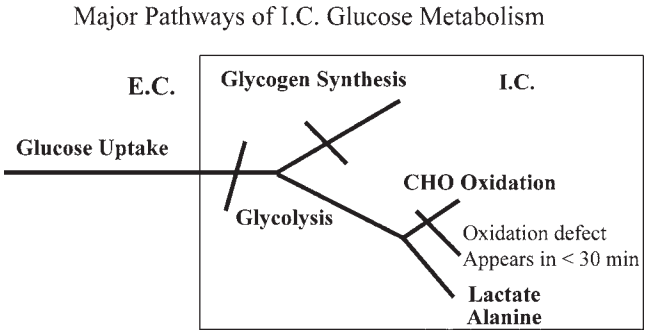

Figure 49-4 Defects of glucose utilization produced by free fatty acids. The inhibition of carbohydrate (CHO) oxidation was the earliest demonstrable effect. It developed immediately after lipid infusion but did not inhibit insulin-stimulated glucose uptake or glycolysis. The inhibition of glucose transport or phosphorylation (or both) developed after 3–4 h, whereas the inhibition of glycogen synthesis developed after 4–6 h of high plasma levels of free fatty acids. Transport defects appear after 2–4 h associated with a decrease in P13 kinase suggests a defect in insulin signaling. EC, extracellular; IC, intracellular.

which can be demonstrated immediately after a rise in plasma FFA levels. The carbohydrate oxidation defect, however, is unlikely to directly cause insulin resistance as it precedes by several hours the onset of insulin resistance.

The DAG/PKC/IRS-1/2 Hypothesis The long delay of 2–4 h between an acute rise in plasma FFA and the onset of insulin resistance appears to be related to the gradual accumulation within muscle cells of diacylglycerol (DAG) and of long chain acyl-CoA. In healthy volunteers an acute rise in plasma FFA from a basal level of approx 400 to a postprandial level of approx 800–1000 µM resulted in a severalfold intramyocellular accumulation of long-chain acyl-CoA, DAG and triglycerides and inhibited insulin stimulation of phosphoinositide (PI)-3 kinase, an enzyme essential for insulin stimulation of glucose uptake. Both long-chain acyl-CoA and DAG are potent allosteric activators of protein kinase C (PKC), a serine/threonine kinase that inhibits insulin signaling by decreasing tyrosine phosphorylation and by increasing degradation of the insulin-receptor substrate 1/2 (IRS-1/2).

Thus, one mechanism by which FFA can produce insulin resistance involves a defect at the level of IRS-1/2 and consists of a decrease in IRS-1/2 tyrosine phosphorylation and an increase in IRS-1/2 degradation resulting in a failure to activate PI-3 kinase (Fig. 49-5). Whether this defect is caused by PKC and/or other serine/threonine kinases remains to be established.

Other Mechanisms Other less well-established mechanisms include:

1. FFA-induced changes in the fatty acid composition of muscle membrane phospholipids, which could result in changes in membrane fluidity and insulin resistance.
2. FFA-induced activation of the hexosamine pathway causing insulin resistance.
3. FFA-induced inhibition of glucose transporter 4 transcription or message stability.

Liver FFA-induced hepatic insulin resistance in rats is associated with increased hepatic DAG content, increased activities of at least two serine/threonine kinases (PKC δ and IKK-β), activation of the proinflammatory nuclear factor (NF)-κB pathway and expression of several inflammatory cytokines including tumor necrosis factor (TNF)-α, IL-1β, IL-6, and MCP-1. As FFA-induced

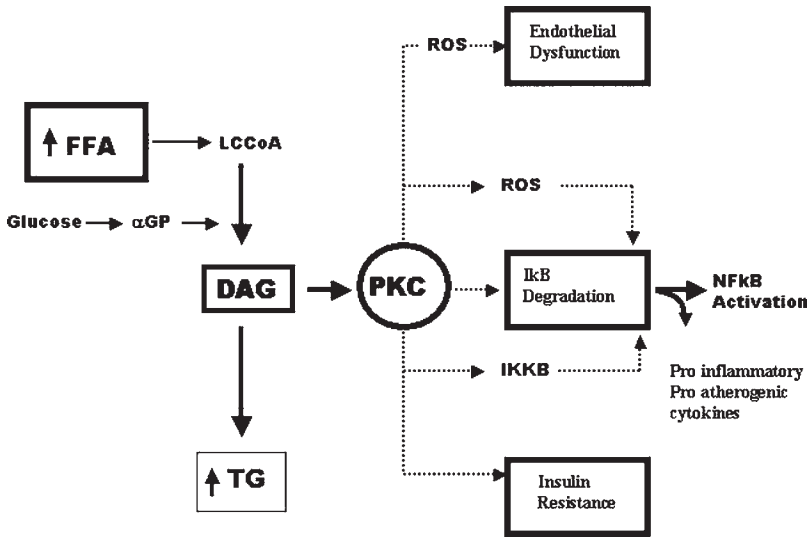

Figure 49-5 Hypothetical mechanisms of FFA-induced peripheral (muscle) and hepatic insulin resistance, endothelial dysfunction and promotion of the proinflammatory and proatherogenic IκB/NFκB pathway. ROS, reactive oxygen species; IκB, inhibitor of NF-κB; PKC, protein kinase C; IkκB, IκB kinase B; NF-κB, nuclear factor-κB; IRS-1/P13K, insulin receptor substrate 1/PI-3 kinase; LCCoA, long-chain fatty acyl CoA; DAG, diacyl glycerol; TG, triglyceride; α GP, α-glycerophosphate.

insulin resistance in human muscle is associated with similar changes in DAG content, PKC and NF-κB activities, it appears that the same or similar mechanisms are operative in both liver and muscle. In addition, the development of insulin resistance in muscle and liver occurs with a similar 2- to 4-h delay after elevation of plasma FFAs.

Endothelial Cells In vitro studies revealed that palmitate increases production of reactive oxygen species in isolated endothelial cells and that this process involves activation of PKC and NADPH oxidase and can be, at least partly, inhibited with Wortmannin, an inhibitor of PI-3 kinase. Because PI-3 kinase is required for insulin-stimulated glucose transport, the data suggest that FFA block insulin stimulation of glucose uptake and vasodilation via related mechanisms (Fig. 49-5).

FFA AND ATHEROSCLEROSIS

Obesity/T2DM are part of the so-called metabolic syndrome that also includes hypertension, dyslipidemia, and hyperuricemia. All these conditions are risk factors for atherosclerotic vascular disease and are associated with insulin resistance. It has, therefore, been suspected that insulin resistance might be an important cause of atherosclerosis although the molecular/biochemical nature of the connection between insulin resistance and atherosclerosis has remained largely unknown. Interestingly, acute FFA-induced insulin resistance is accompanied by a sharp reduction in cytosolic IκB-α in human muscle. IκB-α is the physiological inhibitor of NF-κB. A decrease in IκB-α, therefore, leads to activation of the proinflammatory and proatherogenic NF-κB pathway (Fig. 49-5). As inflammatory processes are now recognized to play a pivotal role in the pathogenesis of coronary artery disease, activation of this pathway by FFA could explain at least some of the increased prevalence of coronary artery disease in obese patients with T2DM.

CLINICAL RELEVANCE

FFA-induced insulin resistance has physiological and pathophysiological relevance. For instance, the FFA-induced insulin resistance may be important during starvation to preserve precious carbohydrate resources for oxidation by the central nervous system. In pregnancy, FFA rise because of an increase in maternal fat deposition during the early part of pregnancy and because of increased plasma levels of lipolytic gestational hormones. The resulting insulin resistance of the mother preserves carbohydrates for the growing fetus. In contrast, in obesity, there is no need to spare glucose and the FFA-induced insulin resistance becomes counterproductive promoting hyperglycemia and development of atherosclerosis.

50 Metabolic and Molecular Aspects of Sarcopenia

W. Todd Cade and Kevin E. Yarasheski

SUMMARY

Sarcopenia refers to the loss of skeletal muscle protein mass and function that occurs with advancing age. Sarcopenia impairs motor function, and is associated with dysregulated substrate metabolism and reduced quality of life in the elderly. This chapter outlines several phenotypic alterations that are associated with sarcopenia, and considers several physiological processes and molecular level signaling pathways that may be dysregulated and involved in the pathogenesis of sarcopenia. The pathogenesis is complex and multifactorial. A better understanding of the underlying mechanisms will help identify potential therapeutic targets, and lead to better treatments for sarcopenia.

Key Words: Aging; falls; gerontology/geriatrics; muscle atrophy: muscle weakness; physical frailty.

INTRODUCTION

Sarcopenia is defined as an involuntary loss of skeletal muscle mass and function that occurs with advancing age. It has been associated with muscle weakness resulting in an increased prevalence of falls, loss of function and independence, and higher morbidity. As the population of the elderly increases, sarcopenia and disability will become an increasingly more important health issue. There are 39 million Americans over the age of 65 with an expected increase of 6 million in the next 10 yr.

The pathogenesis of sarcopenia is multifactorial. Disuse atrophy from physical inactivity can reduce mitochondrial function, enzyme activity, energy reserves, and increased susceptibility to reactive oxygen species (ROS)-induced damage. Dysregulation of muscle amino acid metabolism and protein turnover can result from inactivity, inadequate nutrition, and/or altered transcriptional or translational control of muscle protein synthesis. Traumatic injury may induce alterations in central nervous system function and neural stimulation and lead to muscular changes. Illness and medications frequently taken with advancing age can cause hormonal changes and reduced muscle blood flow. Other alterations such as disrupted expression of essential regulatory genes and inflammatory cytokine dysregulation might also contribute to sarcopenia in the older population.

MUSCLE COMPOSITION CHANGES WITH ADVANCING AGE

Skeletal muscle mass typically declines with advancing age. However, total body weight does not decline because of a corresponding accumulation of body fat. Depending on the method of measurement, muscle mass losses of up to 42% have been reported between the ages of 30 and 80 yr, with the most rapid decline after age 50. This loss of muscle appears to account for the majority of protein loss associated with aging. The loss of muscle mass is primarily resulting from a loss of individual muscle fibers, up to 50% reduction in total fiber number and preferential atrophy of type-II muscle cells. Myosin heavy chain (MHC) 2a and 2x mRNA expression declines with advancing age. Type-II fibers are fast-twitch fibers with a high glycolytic capacity and are subdivided into type-IIA and type-IIB fibers. Type-I fibers are slow-twitch fibers with a high oxidative capacity because of a high mitochondria and capillary density. Type-I fibers are primarily made up of MHC I, type-IIA fibers are primarily made up of MHC 2a, and type-IIB fibers are primarily made up of MHC 2x. A preferential atrophy of type-II fibers might account for the strength losses seen with aging.

A decline in motor units also occurs with advancing age. A motor unit includes one motor neuron and the muscle fibers that it innervates; this loss of motor units implies the loss of functional motor neurons and might account for the decrease in muscle fibers that occurs with aging. The loss in motor units may be caused by a decreased capacity for reinnervation after motor neuron loss.

A decrease in proliferating myogenic precursor satellite cells in skeletal muscle during aging is likely to contribute to sarcopenia and muscle atrophy. Satellite cell clones derived from older people proliferate to a lesser extent in vitro than those obtained from younger people. Satellite cell number modestly declines with aging in rodents, but this phenomenon does not appear to occur in the muscles of elderly humans. Nonetheless, satellite cell proportions increase with resistance exercise training in both 20–30 yr old and 65–75 yr old men and women. The reduced regenerative capacity of injured muscles in older people suggests that satellite cell proliferative capacity might be impaired with advancing age.

REDUCED RATE OF MUSCLE PROTEIN SYNTHESIS

Muscle protein is essential for muscle function and provides amino acids for other metabolic processes. In vivo measurements of muscle protein synthesis and breakdown rates have been

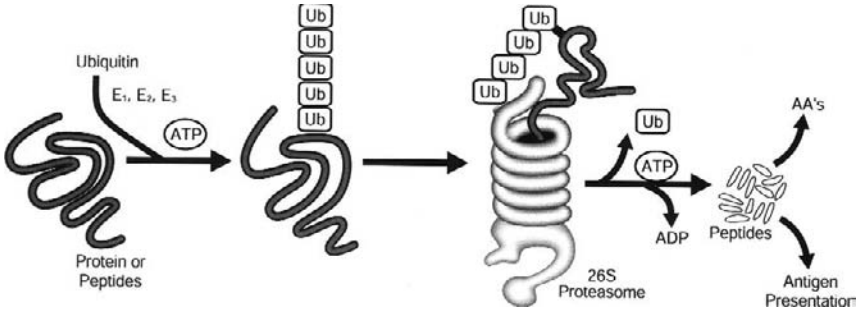

Figure 50-1 The Ub-proteasome pathway plays a role in muscle proteolysis. AAs, amino acids; E1, ubiquitin activating enzyme; E2, ubiquitin conjugating enzyme; E3, Ub-protein ligase; Ub, ubiquitin. Adapted from Lecker SH et al. (2000), Mitch WE et al. (1996), Jagoe RT et al. (2001), Solomon V et al. (1998), and Coux O et al. (1996).

advanced by using isotope labeled amino acid tracer methods and arteriovenous substrate balance across a limb. Skeletal muscle protein turnover rate decreases with advancing age. Skeletal muscle, the body's largest protein pool, accounts for approx 80% of cell mass and 30% of whole-body protein turnover in lean young adults. At age 75 yr, skeletal muscle accounts for only 40% of fat-free mass and less than 20% of whole-body protein synthesis. Human and animal muscle protein synthetic rates have been extensively studied, whereas muscle protein breakdown rate has been more difficult to quantify. Although controversial, existing evidence suggests that advancing age is associated with a reduced rate of muscle protein synthesis, whereas the rate of muscle proteolysis is less affected. The rate of mixed muscle protein synthesis (myofibrillar + mitochondrial + sarcoplasmic) is reduced (by ~30%) with advancing age. This reduction might account for the strength deficits observed in the elderly. The synthetic rates of individual muscle proteins are also reduced with advancing age. The synthetic rate of MHC, the primary contractile protein, is reduced in both middle-aged (~55 yr) and older people (~77 yr). The synthetic rate of mitochondrial proteins (detailed below) is reduced in middle-aged people, but no further reduction is seen in the older population. These findings suggest that age-induced decrements in mitochondrial and contractile function might be attributed to decreased rates of mitochondrial and MHC protein synthesis.

Although total sarcoplasmic protein synthesis rate is not affected, individual sarcoplasmic proteins decrease with advancing age. Studies in rodents show that the turnover rate of two calcium regulatory proteins, Ca-ATPase transporter and the ryanodyne receptor, are reduced by advancing age.

PROTEOLYTIC SIGNALING PATHWAYS AND SARCOPENIA

Many characteristics of sarcopenia such as muscle atrophy, weight loss, body composition changes, and muscle weakness are also observed in cachectic states, such as cancer, AIDS, uremia, uncontrolled diabetes, and sepsis. In these conditions, amino acids released from muscle protein breakdown are used as an energy source. The regulation of skeletal muscle atrophy and hypertrophy are altered in many of these cachectic conditions, and might provide clues about the mechanism(s) for age-associated muscle wasting. In many patients with cachexia, the muscle cell's capacity to break down proteins is enhanced through alterations in regulatory enzymes, signaling pathways, and transcriptional regulators.

The lysosomal enzyme system is predominantly involved in degradation of surface membrane and extracellular proteins. Lysosomes contain several acid-sensitive proteases such as cathepsin B, H, D, and other acid hydrolases. Lysosomal enzymes are activated in the absence of insulin or essential amino acids. However, an increase in lysosomal enzyme activity does not appear to be a primary contributor to sarcopenia.

The ATP-dependent ubiquitin (Ub)-proteasome system is responsible for the majority of skeletal muscle intracellular proteolysis. This system is involved in the breakdown of abnormal proteins, short-lived regulatory factors, and long-lived (contractile) proteins. In this pathway, proteins marked for degradation are covalently linked to Ub, an energy-requiring (ATP hydrolysis) step (Fig. 50-1). Ubiquitination requires a series of enzymes (E1, E2, and E3). E1 is important for Ub activation. E2 represents a group of Ub-carrier proteins which are involved in the process of linking Ub to the ε-amino group of a lysine residue in the protein marked for degradation or a previously attached Ub molecule. This process is catalyzed by E3, a Ub-protein ligase that contains specific binding sites for E2, one to two Ub molecules, and for the protein substrate. The Ub-protein complexes are transferred to the 20S, 600 kDa proteasome in which deubiquitination and protein degradation take place. The proteasome is a barrel-shaped structure made up of four-stacked rings that contain seven subunits each surrounding a central cavity. Of the four stacked rings, the two inner rings (β) surround the region in which degradation takes place and the two smaller outer rings (α) include the protein entry region in which the Ub is removed and unfolded proteins enter the proteasome. Here, proteins are degraded into peptide fragments of 3–25 residues that are released into the cytosol and rapidly hydrolyzed into individual amino acids (*see* Fig. 50-1).

Fasting, denervation atrophy, glucocorticoid treatment, acidosis associated with chronic renal failure, and insulinopenia all induce muscle protein catabolism and all are associated with activation of the Ub-proteasome pathway. Additional indicators of Ub-proteasome activation in muscle include increased muscle content of Ub-protein conjugates, increased Ub and Ub-subunits mRNA expression, increased Ub-carrier proteins (E2s) mRNA expression, and increased susceptibility to synthetic proteasome inhibitors. Moreover, two genes that encode Ub ligases, MuRF1 (muscle ring finger protein 1) and MAFbx (muscle atrophy F-box protein or atrogin-1), have been implicated in the process of muscle atrophy. MuRF1$^{-/-}$ and MAFbx $^{-/-}$ (gene knockout) mice undergo significantly less denervation-induced muscle atrophy than wild-type mice. MuRF1 acts by binding to and disrupting the sarcomeric protein titin. This and evidence obtained from MuRF1 overexpressing mice suggest that this gene product is an important regulator of skeletal muscle atrophy.

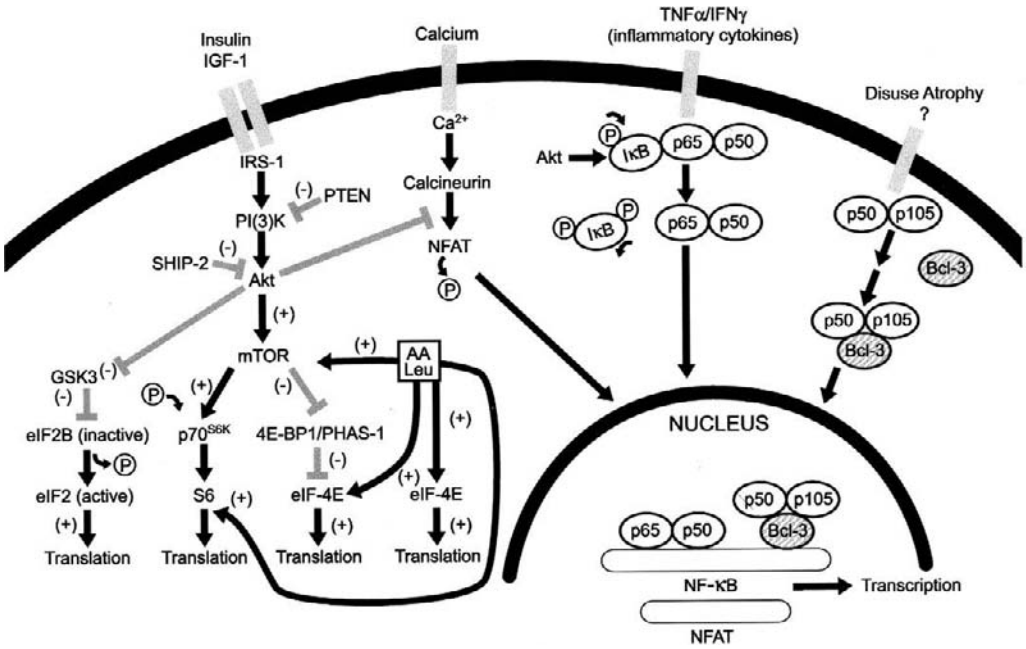

Figure 50-2 Intracellular signaling pathways that are potentially involved in muscle atrophy and hypertrophy associated with various clinical conditions. → indicates activation; ⊣ or ⊨ indicates inhibition. Adapted from Nader GA et al. (2002), Bodine SC et al. (2001), Goberdhan DC et al. (1999), Rommel C et al. (2001), Dupont-Versteegden EE et al. (2002), Guttridge DC et al. (2000), and Hunter RB et al. (2002).

PROTEIN TRANSLATION AND SIGNALING PATHWAYS

Several other factors and signaling pathways appear to be involved in muscle atrophy and hypertrophy. Insulin and insulin-like-growth factor (IGF-1) bind to a similar membrane receptor and initiate a signaling cascade that enhances protein translation. IGF-1 expression in muscle is increased with resistance exercise training and IGF-1 overexpressing transgenic mice have skeletal muscles that are twice as large as those from wild-type mice. Circulating IGF-1 levels and muscle IGF-1 mRNA expression decline with advancing age and likely contribute to sarcopenia. Direct injection of IGF-1 into muscle following immobilization conserves muscle protein and reduces the severity of muscle atrophy. Insulin and IGF-1 bind to a membrane receptor and cause a conformational change in the receptor tyrosine kinase. This results in transphosphorylation and secondary phosphorylation of the insulin receptor substrate (IRS-1), which in turn activates phosphatidyl-inositol-3 (PI-3) kinase. Evidence suggests that the PI-3 kinase/protein kinase B (Akt) pathway (Fig. 50-2) is involved in mediating skeletal muscle hypertrophy and atrophy. Phosphatidyl-inositol-3,4,5-triphosphate, a membrane-binding site for the serine/threonine kinase Akt, is initially activated by PI-3 kinase. Following activation by 3′-phosphoinositide-dependent protein kinase-1 (PDK-1), Akt mediates phosphorylation of several substrates involved in protein synthesis, gene transcription, and cell proliferation. The active form of Akt (Akt-1) regulates skeletal muscle hypertrophy in vitro and in vivo systems. Deletion of Akt-2 activity has been associated with a diabetic phenotype and possible impairments in glucose transport, another condition often associated with advancing age. The lipid-binding site on the Akt molecule is regulated by at least two factors: SH2-containing inositol-5-phosphatase (SHIP) 1-3; and phosphatase and tension homolog detected on chromosome 10 (PTEN) (*see* Fig. 50-2). Overexpression of phosphatidylinositol-3,4,5-triphosphate dephosphorylates SHIP1-3 and PTEN and results in decreased cell size and inhibition of hypertrophy.

Signals downstream from PI-3 kinase and Akt are involved in skeletal muscle hypertrophy and atrophy. Inhibition of the Akt target mTOR (mammalian target of rapamycin) blocks phosphorylation of downstream targets $p70^{S6}$ kinase ($p70^{S6K}$) and 4E-binding protein 1/phosphorylated heat- and acid-stable protein-1 (Fig. 50-2), and prevents hypertrophy. Moreover, another substrate of Akt/mTOR, glycogen synthase kinase 3β (GSK3β) (Fig. 50-2), has also been implicated as a mediator of hypertrophy. Akt phosphorylation inactivates GSK3β, which induces hypertrophy in skeletal myotubes. Evidence suggests that cytosolic phospholipase A_2 ($cPLA_2$) is a negative regulator of the IGF-1 pathway, and $cPLA_2$ knockout mice have cardiac and skeletal muscle cells that are 20–25% larger than wild-type mice. Many cellular regulators of muscle hypertrophy and atrophy have been identified and these might also play a role in sarcopenia.

Other pathways that may potentially be involved in sarcopenia include the calcineurin-NFAT (nuclear factor of activated T cells) pathway, β-adrenergic signaling, and the NF-κB pathway. Calcineurin is activated by an increase in intracellular calcium (Ca^{2+}) and calmodulin concentrations, in which it can dephosphorylate members of the NFAT family, specifically the NFATc1 isoform. NFAT then translocates to the nucleus and mediates gene transcription (Fig. 50-2). Disuse atrophy has been associated with increased calcineurin and NFAT translocation to the nucleus. When slow-twitch muscle calcineurin activity was inhibited by cyclosporin A, the muscle began to express fast-twitch proteins and properties. This suggests that activation of the calcineurin-NFAT pathway might contribute to the induction of slow fiber type genes resulting in a slow oxidative phenotype. Because advancing age is associated with selective type II fiber atrophy, the role that this pathway plays in sarcopenia is not clear.

β_2 adrenergic agonists also appear to block skeletal muscle atrophy and induce hypertrophy. The cyclic adenosine monophosphate system involvement via Gα3 activation or the PI-3 kinase/Akt via Gβ/γ protein activation appears to be involved in β-2 mediated hypertrophy. Furthermore, the NF-κB transcription factor (p65/p50) inhibits skeletal muscle differentiation through the expression of cyclin D1 and is activated by tumor necrosis factor (TNF) and interferon (IFN)-γ, two cytokines associated with cachexia and other inflammatory diseases (Fig. 50-2). TNF also appears to inhibit myogenesis through decreased differentiation in MHC and protein levels of MyoD. However, NF-κB may also be activated during disuse atrophy by factors other than cytokines. This disuse activation appears to involve factors p50, Bcl-3, and c-Rel and might be associated with an upregulation of survival genes (Fig. 50-2).

MITOCHONDRIAL DYSFUNCTION

Mitochondrial DNA (mtDNA) is a 16-kb circular genome that encodes 22 tRNAs, 2 rRNAs, and 13 polypeptides involved in the electron transport chain. Mitochondria provide the majority of energy (ATP) used for muscle contraction as well as many other metabolic functions. Mitochondrial protein synthesis is regulated at multiple levels. Approximately 15% of mitochondrial respiratory chain proteins are encoded by mtDNA, whereas the others are encoded by nuclear DNA. Muscle mitochondrial protein synthesis rate is reduced in middle-aged adults. Similarly, mitochondrial oxidative enzyme activities, electron transport chain function, ATP, and creatine phosphate (PCr) concentrations decline with advancing age. These findings suggest that impairments in mitochondrial function may contribute to reduced muscle endurance and aerobic capacity frequently found in the elderly.

MITOCHONDRIAL DNA ALTERATIONS

The association between declines in mitochondrial enzyme activity and protein synthesis, and sarcopenia are not clear, but might be associated with alterations in mtDNA. This theory of aging is based on the hypothesis that chemical alterations to mtDNA occur and accumulate throughout life. The mitochondrion is the site of cellular respiration and oxidative metabolism. Estimates indicate that approx 2% of the oxygen consumed is converted to superoxide free radicals in the electron transport process. MtDNA may be particularly susceptible to oxidative damage because it is in close physical proximity to ROS generated during electron transport. Also, mtDNA is not protected by histones and it has a poor repair efficiency. Oxidative damage to mtDNA bases occurs 10–20 times more than in nuclear DNA. The polymerase chain reaction technique has been used to detect low-abundance alterations/mutations/deletions in mtDNA sequences that are associated with advancing age. Whether alterations in muscle mtDNA provide the basis for the pathogenesis for sarcopenia is under investigation.

"Common" mtDNA deletions are defined as deletions that are common among different animals or tissues. Initial investigations of mtDNA alterations identified an age-related "common deletion:" an increase in a specific 4977-bp mtDNA deletion mutation. It extended from nucleotides 8483–13,459 of the mitochondrial genome and was flanked by a 13-bp direct repeat. This deletion was determined to be associated with aging when it was found in older individuals but not in infants or fetal tissue. Although it is not clear if this "common deletion" causes sarcopenia, it may be involved because the highest levels of this deletion were found in older nerve and muscle tissues. Additional examinations have also identified other mtDNA deletions. Moreover, it was determined that multiple mtDNA deletions were common, they were not limited to specific areas of the genome, and they did not extend to or appear to be distributed in an uneven, mosaic pattern throughout the muscle fiber. The mechanisms for mtDNA deletions are unclear; however, multiple hypotheses have been proposed.

A relationship between deletion mutations and an abnormal phenotype of the muscle fiber has been observed, suggesting physiological significance of mtDNA abnormalities. These deletions were associated with electron transport chain-deficient areas of the fiber and a decreased fiber cross-sectional area. Moreover, this phenotype was associated with fiber breakage which may also suggest a susceptibility to muscle damage with aging.

Other mtDNA modifications have been reported. Nucleotide modifications, specifically oxidized modifications, in the mtDNA increase with aging in a variety of species as well. One modification in particular, 8-hydroxydeoxyguanosine (8-OH-dG), increases with age in various tissues, including muscle, in humans as well as other species. Nucleotide point mutations in the mtDNA, although rare, have also been reported to be associated with aging. However, the estimated frequency of mtDNA point mutations appears to be low (0.1–2.4%) with advancing age and their physiological significance in sarcopenia is not clear.

OTHER POTENTIAL CONTRIBUTORS TO SARCOPENIA

Other endocrine and inflammatory factors appear to alter muscle protein synthetic and proteolytic pathways, and might contribute to sarcopenia. Glucocorticoids activate catabolic responses by increasing mRNA expression of Ub and Ub-subunits. Insulin is involved in both muscle proteolysis and protein synthesis. Insulin is generally thought to inhibit muscle proteolysis. Conversely, it appears that there is a minimum level of insulin required for protein synthesis, specifically following exercise. Excess thyroid hormone T_3 levels induce muscle proteolysis. The inflammatory cytokines TNFα, IL-1, and IL-6 activate muscle proteolysis. Muscle TNFα protein and mRNA levels are elevated in physically frail elders and inversely correlated with the rate of muscle protein synthesis. Resistance exercise training reduced muscle TNFα levels and increased the rate of muscle protein synthesis in frail elders. TNFα may interfere with the pretranslational assembly of muscle protein; stimulate inducible nitric oxide expression through NF-κB activation, thereby increasing oxidative damage to the muscle, increase Ub conjugation of proteins, and induce muscle cell death through apoptosis or necrosis.

CONCLUSION

Several molecular mechanisms for muscle atrophy and hypertrophy have been identified. However, it is not known whether these pathways contribute to the pathogenesis of muscle wasting (sarcopenia) with advancing age, and what are the most effective interventions (hormone, nutrient, muscular activity, and pharmacological) to suppress muscle proteolysis and activate protein synthesis. Exercise training and augmenting muscle IGF-1 expression increase muscle protein synthesis and mass in senescent muscle. Pharmacological interventions that inhibit TNFα, SHIP-2, GSK3β, or proteasome activity, or activate Akt, mTOR, or $p70^{S6k}$ need to be tested for efficacy in senescent muscle.

51 Adipose Tissue Development and Metabolism

Sheila Collins, Yushi Bai, and Jacques Robidoux

SUMMARY

Excess body fat is associated with many medical complications and obesity has become a major health problem in the United States and most other industrialized countries. The existence of adipose tissue as a specialized organ reflects the mechanism developed by organisms over time to cope with irregular and unpredictable supplies of nutrients. This ability to store fat was probably a survival feature of *Homo sapiens*; however, excess body fat has become a major heath problem. This chapter will briefly examine development and metabolic functions of adipose tissue and how these processes are regulated.

Key Words: Adipose tissue; β-adrenergic receptors; brown adipose tissue; peroxisome proliferator-activated receptor-γ; triglyceride; white adipose tissue.

INTRODUCTION

The existence of adipose tissue as a specialized organ reflects the mechanism developed by organisms over time to cope with irregular and unpredictable supplies of nutrients. The ability to store fuel as body fat was particularly important in omnivorous mammals, and was probably a key survival feature of *Homo sapiens*. However, excess body fat is associated with many medical complications and obesity has become a major health problem in the United States and most other industrialized countries.

The mechanism(s) responsible for the link between obesity and metabolic diseases, such as insulin resistance and diabetes, is not completely known but is likely to involve abnormalities in free fatty acid metabolism. In general, the rate of fatty acid release into the systemic circulation is greater in obese than lean persons. In addition, an ever-increasing array of adipose tissue-derived cytokines and endocrine factors has been identified with suspected actions on insulin sensitivity and the cardiovascular system. In contrast, extreme deficiencies in body fat, such as lipodystrophy, also cause metabolic abnormalities including insulin resistance and diabetes. Therefore, it is important to understand the development and metabolic functions of adipose tissue and how these processes are regulated.

ADIPOSE TISSUE: CELL TYPES AND DEPOTS

Adipose tissue has been classified into two major types based on gross appearance, cell type-specific gene expression, and predominant type of adipocytes: white adipose tissue (WAT) and brown adipose tissue (BAT). WAT is named for its white/yellowish color. It contains adipocytes with a single large lipid inclusion (termed "unilocular"), resulting in displacement of the cytoplasm and the nucleus into a thin rim surrounding the lipid droplet. However, even among WAT depots there can be significant differences in metabolic and hormonal sensitivity.

BAT is named for its "brown" color, which is derived from a rich blood supply and an enormous number of mitochondria per cell. In overall appearance, the adipocytes in BAT are smaller than white adipocytes and are characterized by numerous small lipid inclusions (termed multilocular). Although recognized anatomically as a special organ structure, in the early 1960s the true function of BAT was realized when it was proposed to be thermogenic. Since then, substantial work has shown that BAT is uniquely capable of responding to various environmental stimuli to generate heat from stored metabolic energy. In response to sympathetic nervous system (SNS) activation, BAT undergoes an orchestrated hyperplastic and hypertrophic expansion, increased blood flow, and recruitment of lipid and carbohydrate fuels for oxidative metabolism. A unique and critical element of this thermogenic mechanism for dissipation of the proton gradient in brown fat mitochondria is owing to a brown fat specific mitochondrial uncoupling protein, also called "thermogenin." This mitochondrial protein, termed uncoupling protein 1, allows controlled proton leakage across the mitochondrial inner membrane that generates heat at the expense of respiration-coupled ATP production. The uncoupling activity in brown fat mitochondria is "activated" by free fatty acids that are released as a result of catecholamine-stimulated lipolysis.

BAT is most abundant in newborn mammals and is principally involved in heat production. In the human fetus, BAT is located in the dorsal cervical, axillary, suprailiac, and perirenal regions. With increasing age and size, true homogeneous BAT depots disappear. This is also true for large mammals such as dogs and nonhuman primates. However, brown adipocytes can also be found within white fat depots in the adult of all these species, particularly in the intra-abdominal and intrathoracic areas, but relatively rarely in the subcutaneous depot. In the common small laboratory animals,

such as mice and rats, BAT is prominent in the interscapular and axillary areas from birth through adulthood. In fact, in newborn rodents BAT is the only adipose tissue, and it is only with suckling of the lipid-rich milk that WAT depots begin to appear. In addition, brown adipocytes are present within WAT depots, such as the perigonadal, perirenal, and mesenteric fat of adult rodents. Cold challenge or treatment with certain thermogenic agents further provokes the elaboration of brown adipocytes in laboratory animals; patients with pheochromocytoma possess large amounts of BAT owing to chronic catecholamine stimulation.

ADIPOGENESIS: PREADIPOCYTE COMMITMENT AND DIFFERENTIATION

Understanding the fundamental factors that send cells along an irreversible program of highly specialized gene expression to form a specific tissue type requires the study of pluripotent cells. The adipogenic cell lines created in the 1970s provided the technical basis to permit isolation of adipocyte-specific genes and identify their regulatory factors. Many key transcription factors that promote adipogenesis have been identified. They include the family of CCAAT/enhancer binding proteins (C/EBP), peroxisome proliferator-activated receptor-γ (PPARγ) and the sterol regulatory element binding protein family. The expression of the C/EBPs and PPARγ2 genes occurs in a cascade-like fashion during adipocyte commitment and differentiation. Data from studies conducted in cell culture models and in genetically modified animals show that agents or manipulations that interfere with the expression of these factors can inhibit adipocyte differentiation, or result in an incomplete state of differentiation.

PPARγ2, which is expressed at high levels in adipose tissue, is particularly important for adipocyte differentiation. Failure to express PPARγ2 prevents adipogenesis, and providing PPARγ2 to PPARγ-deficient cells fully restores their capacity for differentiation.

In addition to PPARγ2, C/EBPα is required to express the full complement of genes that define the mature adipocyte phenotype. The relative importance of C/EBPα in regulating adipocyte differentiation may be different in brown and white adipocytes. C/EBPα–/– mice, in which vital hepatic expression of C/EBPα was preserved, had intact interscapular BAT, but no evidence of WAT in any depot. This observation demonstrated a clear molecular distinction between the developmental fates of white and brown adipocytes.

ROLE OF THE SYMPATHETIC NERVOUS SYSTEM AND β-ADRENERGIC RECEPTORS IN LIPOLYSIS

The amount of triglyceride stored in adipose tissue reflects the cumulative sum over time of the differences between energy intake and expenditure. The net efflux of nonesterified fatty acids from adipose tissue fluctuates between periods of relative stimulation (e.g., after an overnight fast or during a bout of exercise) and relative suppression (e.g., after a meal). Both WAT and BAT are innervated by the SNS. However, because sympathetic innervations are more abundant in BAT than in WAT, neural-derived norepinephrine is presumed to play a greater role in BAT, whereas catecholamines derived from the circulation play a relatively greater role in WAT. However, there can also be significant levels of norepinephrine in the immediate vicinity of the nerve terminals in WAT.

The role of the SNS in the control of lipolysis includes the α-adrenergic receptors (αARs) and β-adrenergic receptors (βARs) as the recipients of these catecholamine signals. They are members of the large family of G protein-coupled receptors that are integral membrane proteins of the plasma membrane. There are three subtypes of βARs (β_1AR, β_2AR, and β_3AR), all of which are expressed in white and brown adipocytes. However, the relative proportions of these subtypes vary between species, fat depots, and metabolic status. For example, rodent species possess abundant levels of the β_3AR and lesser amounts of the two other subtypes, whereas the reverse is true in humans, although there is clearly a need to examine intra-abdominal depots in normal humans more carefully.

The control of lipolysis (Fig. 51-1) by the βARs is principally initiated by the sequential activation of adenylyl cyclase and cAMP-dependent protein kinase, ultimately culminating in the phosphorylation of hormone sensitive lipase and perilipin A. In addition to the β-adrenergic stimulation of lipolysis, catecholamines can also be antilipolytic themselves through their interaction with the α_2ARs and its resulting inhibition of cAMP production. The balance between the relative amounts of the βAR and α_2AR can thus determine the relative efficacy of catecholamines for triglyceride hydrolysis. In that respect, there is some evidence from experimental studies in animals and humans that a shift to a higher α_2/β ratio can contribute to net lipid storage. The lipases and lipid droplet binding proteins that control triglyceride hydrolysis are targets of the signaling cascades initiated by the adrenergic receptors. However, there are likely to be additional, unidentified, lipases and lipid droplet scaffolding proteins with regulatory roles (e.g., the S3-12 protein).

ADIPOCYTE-DERIVED CYTOKINES

Until the mid-1990s, adipose tissue was generally regarded to be a passive storage depot for excess caloric intake. The discovery of leptin as an adipose-derived hormone that informs on the status of energy reserves has provided a new perspective on adipose tissue biology. In the ensuing years there has also been a deeper appreciation that a large number of cytokines and growth factors are secreted from adipose tissue. One of the molecules isolated independently by several groups that have received intense investigation is now commonly referred to as adiponectin. There is excitement over the possibility that it might be an important player in the regulation of insulin sensitivity in other tissues such as skeletal muscle and liver. Plasma levels of adiponectin are reduced in obese persons and patients with type-2 diabetes or coronary artery disease.

Markers of inflammation are also increased in obese humans and many animal models. For example, mRNA levels of tumor necrosis factor-α and interleukin-6 are elevated in human adipose tissue. Similarly, monocyte chemoattractant protein 1 mRNA is overexpressed in the adipose tissue of genetically obese mice compared with wild type littermates. Although it was presumed these molecules were solely produced by the adipocyte, studies utilizing transcriptional profiling by microarray have added a new dimension to this issue. In one approach, a comparison among preadipocytes, adipocytes, and macrophages for common patterns of gene expression showed that the preadipocyte profile is much closer to the macrophage than to the adipocyte profile. In another study, profiled transcript expression in perigonadal adipose tissue suggested that the percentage of cells expressing the macrophage marker F4/80 significantly and positively correlated with both adipocyte size and body mass. This has raised the question regarding the relative contribution of the adipose tissue vs the macrophage as a source of these inflammatory mediators (Fig. 51-2). Irrespective

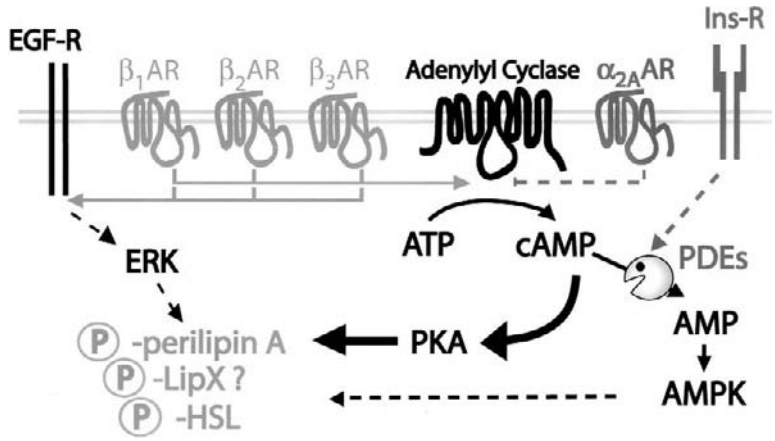

Figure 51-1 Positive and negative control of lipolysis through the actions of catecholamines and insulin. The three β-adrenoceptor (βAR) subtypes respond to the catecholamines, epinephrine, and norepinephrine by increasing cAMP levels, which in turn can activate the cAMP-dependent protein kinase (PKA). Targets of PKA include hormone sensitive lipase (HSL), perilipins and perhaps additional lipases (LipX). Each βAR can also activate ERK MAP kinase by different mechanisms, but each involves recruitment of a tyrosine kinase growth factor receptor such as EGF-R. ERK contributes to lipolysis but its targets are still under investigation. Catecholamines also activate the α_2-adrenoceptor (α_{2A}AR) to inhibit adenylyl cyclase activity and lower overall cAMP levels. Insulin through its receptor (Ins-R) also acts to oppose the stimulating effects of cAMP in part by increasing the activity of phosphodiesterases (PDEs), a by-product of which is AMP, which could activate AMP kinase.
(Note: Re: LipX?—adipose triglyceride lipate [V6*ATGL*] was recently discovered as a key BAR-regulated lipase in fat [Zimmerman, 2004].)

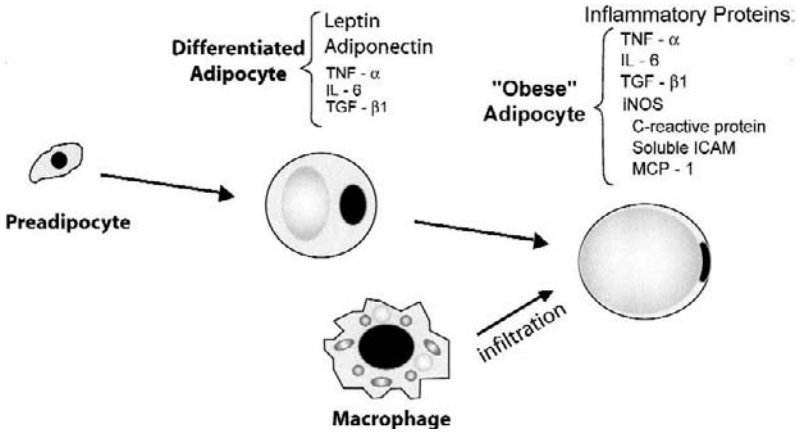

Figure 51-2 Proposed functions of adipocytes in different metabolic states. In the early differentiated stage, adipocytes secrete large amounts of hormones with insulin-sensitizing properties, and small amounts of cytokines. In the obese state, large lipid-filled adipocytes continue to produce leptin, but significantly less adiponectin. There is significant macrophage infiltration that together with adipocytes secretes enhanced amounts of proinflammatory cytokines.

of whether the macrophage existing in adipose tissue under the condition of obesity is owing to preadipocyte conversion or recruitment, it might still contribute to a proinflammatory milieu within adipose tissue. Moreover, once set into motion, this situation could perpetuate a vicious cycle of ever more macrophage recruitment, production of inflammatory cytokines, and impairment of adipocyte function.

CONCLUSION

The knowledge of adipocytes has advanced from being considered an inert storage depot for excess energy to a member of the endocrine system. Advances in modern molecular biology are revising previously well-established biochemical events in adipocytes, such as catecholamine stimulation of lipolysis and thermogenesis. Continued progress in adipocyte biology will provide a better understanding of the role of fat cells in the pathogenesis and pathophysiology of metabolic disorders.

In: Science—The Philosophy of Ingersoll.

SUMMARY

Hepatitis C virus (HCV) infection infects nearly four million people in the United States alone, is the most common cause of chronic liver disease, and also a common indication for liver transplantation in most of the larger transplant centers in this country. HCV infection is an immensely important public health problem. Rapid scientific advancements have been made in this area and our understanding of the virology, disease pathogenesis, diagnosis, diversity of clinical presentations, natural history, treatment, and prevention is evolving rapidly. This chapter will provide the reader with an update review of the various scientific and clinical aspects of HCV and the associated diseases.

Key Words: Assays; clinical; diagnostics; epidemiology; genotypes; hepatitis C; molecular; prevention; serology; treatment; viral hepatitis; virology.

HISTORY OF NON-A AND NON-B HEPATITIS/HEPATITIS C

Viral hepatitis has been a part of recorded history since the time of Hippocrates. Over the centuries, epidemics have devastated military and civilian communities throughout the world. The discovery of the Australia antigen by Blumberg and his colleagues in 1965 and its subsequent association with hepatitis B virus (serum hepatitis) heralded the onset of an accelerated era of hepatitis research. The discovery by Feinstone in 1973 of hepatitis A virus, the agent responsible for infectious hepatitis, failed to explain the large number of undefinable cases of posttransfusion hepatitis. Thus, the concept of non-A, non-B hepatitis (NANBH) developed in the early 1970s after the identification of hepatitis A and B made it obvious that many cases of hepatitis, particularly posttransfusion hepatitis, could not be accounted for, by either of these viruses.

In 1989, 14 yr after the initial proposal of the existence of such an infective agent, the virus responsible for virtually most, if not all, parenteral NANBH was identified by Choo et al. The breakthrough led to an explosion of research and discoveries about the virus, now designated as hepatitis C virus (HCV), and the disease, NANBH now called hepatitis C. This chapter will highlight the role of molecular tools in the discovery of the virus, in the study of the virus and disease, in our understanding of the epidemiology and the virus–host interplay in clinical presentation, in the development of diagnostic tests, and perspectives in the treatment of hepatitis C.

DISCOVERY OF HCV

Advancements in the field of molecular biology provided the tools to search for the parenteral NANBH agent. In 1982, research workers from Chiron Corporation, in conjunction with the Center of Disease Control, initiated attempts to clone the NANBH virus genome from infectious chimpanzee liver homogenates and plasma using molecular techniques including subtractive hybridization methods. After screening more than 25×10^6 clones, it became apparent that the concentration of the putative NANBH virus nucleic acid in these samples was less than the limit of detection for such an approach. They proceeded to pool plasma samples from a chronically infected chimpanzee and titrated the infectivity of the pooled sample in other animals. A pool containing 10^6 chimpanzee infectious doses/mL was obtained for further studies.

Following extensive ultracentrifugation that was sufficient to pellet down the smallest of known infectious agents, total nucleic acid was extracted. Although an RNA virus was suspected from the results of physicochemical experiments, both extracted RNA and DNA were converted to cDNA and the fragments were cloned into a recombinant bacteriophage vector to form a cDNA library and expressed in the *Escherichia coli* bacteria. This library was screened with sera from patients with unequivocal NANBH in order to detect clones expressing NANBH viral peptides. More than one million clones were screened and five reactive clones were identified. One of these clones (5-1-1) coded for an antigen that bound circulating antibodies present in the serum of patients infected with NANBH. Importantly, chimpanzees infected experimentally with the NANBH agent, seroconverted to show reactivity to the 5-1-1 polypeptide following the onset of hepatitis, whereas those animals infected with either hepatitis A virus or hepatitis B virus did not seroconvert to this peptide. The other four clones obtained from the original screening were later shown not to have derived from the NANBH agent. Using the 5-1-1 clone as a probe, three other overlapping clones encoding at least a portion of the viral protein were identified. Another clone, c100-3, was constructed from these clones and expressed as a superoxide dismutase fusion protein in yeast for the

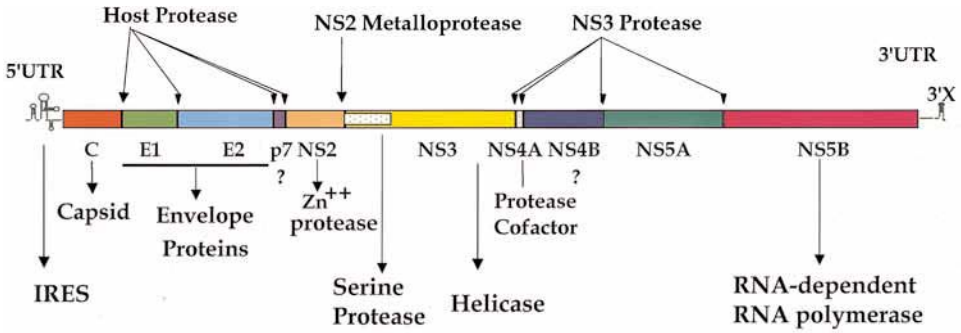

Figure 52-1 Genomic organization of HCV. The genome is around 9600 nucleotide long. The 5′ end consisted of an untranslated region (UTR) containing an internal ribosomal entry site (IRES), which is essential for viral initiation of polypeptide translation. The genome encodes a single open reading of around 3010 amino acids. The 5′ end of the genome consists of the structure genes, including capsid, two envelope proteins (E1 and E2) and p7. The junctions between the structural genes were cleaved by host proteases. Nonstructural (NS) gene 2 encodes a Zn^{2+} metalloprotease that cleaves the junction between NS2 and NS3. The viral protein NS3 consists of two enzymatic activities. The amino one-third is a serine protease, which cleaves the junction between the remaining NS part of the HCV polypeptide. The carboxy two-thirds encodes a helicase that is critical in the unwinding of the double-stranded RNA during viral replication. NS4A is a cofactor for NS3 protease. The functions of NS4B and NS5A are unknown but they are believed to be involved in the viral replication complex. The hydrophobic nature of NS4B suggests that NS4B might serves as a membrane anchor. NS5B encodes the viral RNA-dependent RNA polymerase. The terminal part of 3′ UTR consists of a highly conserved 98 nucleotide sequence which is believed to be critical for the binding of the replication complex and initiation of replication.

development of immunoassay for the detection of antiviral antibody. Both the 5-1-1 and c100-3 clones hybridized only with the RNA extracted from the infected liver, indicating that this agent was an RNA virus. The nucleotide sequence of the genomic RNA was determined by isolating overlapping cDNA clones using hybridization probes based on the sequence of previous clones. After 10 yr, the clinical description of parenteral NANBH, the agent was finally identified and named HCV.

In a parallel series of experiments at around the same time, research workers from Japan also cloned a portion of the viral genome from nucleic acids extracted from 100 L of pooled human sera derived from patients with clinical NANBH. A total of 29 clones were isolated, of which the sequences of 12 clones were later found to be similar to those cloned by the American team.

VIROLOGY OF HCV

STRUCTURE HCV is an enveloped virus of approx 50 nm in diameter visualized in electron microscopy. Immune electron microscopy has demonstrated both HCV core and envelope polypeptides in these particulate structures. HCV consists of a positive strand RNA encapsidated by the core (nucleocapsid peptides) in possibly icosahedral configuration, which is then covered by an envelope, made up of two viral glycoproteins (E1 and E2). The negative strand of HCV is produced as a replicative intermediate during replication, and is considered as a marker of ongoing viral replication.

GENOMIC ORGANIZATION HCV is a single-stranded positive sense RNA virus within the Flaviviridae family, which consists of positive strand RNA viruses encoding a single long polypeptide that is cleaved posttranslationally (Fig. 52-1). The genome of HCV is approx 9600 nucleotides and contains a single open reading frame encoding a large viral polypeptide precursor of around 3000 amino acids with regions at the 5′ and 3′ ends that are not translated. The cleavage of this protein by cellular and viral proteases results in a series of structural [nucleocapsid (C, p21) and the envelope 1 (E1, gp31) and envelope 2 (E2, gp70)], and nonstructural (NS) proteins (NS2, NS3, NS4A, NS4B, NS5A, and NS5B). The NS2 peptide is a metalloprotease essential for the cleavage of the viral NS2/NS3 junction. The amino-terminus region of NS3 encodes a viral serine protease that is important in posttranslational cleavage of viral peptides from NS3 to NS5. The carboxyl two-third portion of NS3 functions as a helicase, which is essential for unwinding of viral RNA during replication. The NS5B protein functions as a viral RNA-dependent RNA polymerase. The function of the NS5A protein is unknown, but recent observations suggest that it has a role in the regulation of replication. The untranslated 5′ terminal region (5′UTR) and portions of the 3′ untranslated region (3′UTR) are the most conserved parts of the HCV genome and contain signals for replication and translation. The noncoding 5′ terminal region that consists of 349–352 bases has a highly complex secondary RNA structure with four stem root structures and contains an internal ribosomal entry site, the internal viral initiation for polypeptide synthesis. The 3′NTR of HCV consists of a hypervariable segment of approx 420 nucleotides, a poly-U element variable in size, and a recently discovered additional highly conserved region of 98 nucleotides, which is believed to be essential for replication.

The positive strand RNA of HCV has three potential functions: (1) as a template for synthesis of negative strand RNA during replication; (2) as a template for translation of viral proteins; (3) as genomic RNA to be packaged into new virions. As HCV replicates from RNA to RNA, there is no DNA intermediate and therefore, should have no potential for integration into the host cell genome.

REPLICATION Early events in viral binding to cell surface are still poorly understood. Knowledge of the mechanism of replication comes in part from studies in chimpanzees, and in part from extrapolation of the mechanisms adopted by other flaviviruses. HCV RNA is detectable within 3 d of infection in chimpanzees, and persists in serum during the peak of serum alanine transaminase (ALT) elevation. This is associated with the appearance of viral antigens in infected hepatocytes, the major site of HCV replication. The importance of extrahepatic reservoirs (such as peripheral blood mononuclear cells) of HCV replication is uncertain, and technical issues related to the specificity of methods cloud current studies. Through the low fidelity of viral polymerase and

the host selection pressure, HCV mutates rapidly in adaptation to the changing virus–host interaction.

The cleavage of the viral polyprotein is achieved by host signal peptidase and two viral proteinases (NS2 and NS3). The function of the viral serine protease, which is located at the amino-terminus region of NS3, is enhanced by its cofactor NS4A. The viral replication machinery is established, when the nonstructural proteins are translated, cleaved cotranslationally, folded and assembled, which will then bind to the 3′NTR to initiate the replication. Mechanisms of viral packaging and release from the hepatocyte are poorly understood but host secretory mechanisms might be utilized by HCV for packaging and release of virions through budding from the Golgi apparatus.

GENOTYPES AND QUASISPECIES Like many other RNA viruses, HCV has an inherently high mutational rate through the poor fidelity of its viral polymerase that results in considerable heterogeneity throughout the genome; in addition, proofreading for mutations that is possible with double-stranded DNA does not occur on the RNA genome. However, constant virus–host interaction leads to clustering of molecular evolution, resulting in distinct distribution of the extent of sequence variations between isolates (Fig. 52-2). The first distinct diversion of the isolate is referred to as genotype. Each variation has different implications (e.g., silent or synonymous vs amino acid substitution or nonsynonymous) and the frequency of occurrence has also substantial impact to the virus fitness. When these are being considered using molecular evolutionary analysis, it appears that HCV isolates can be classified into different genotypes (clades). Current analysis showed that there are 6 major "types" (designated by Arabic numbers) with sequence similarities from 66 to 69% and more than 90 different "subtypes" (designated by a lower case letter) within these types, with sequence similarities from 77 to 80%. In this scheme, the first variant cloned by Choo et al. is designated type 1a.

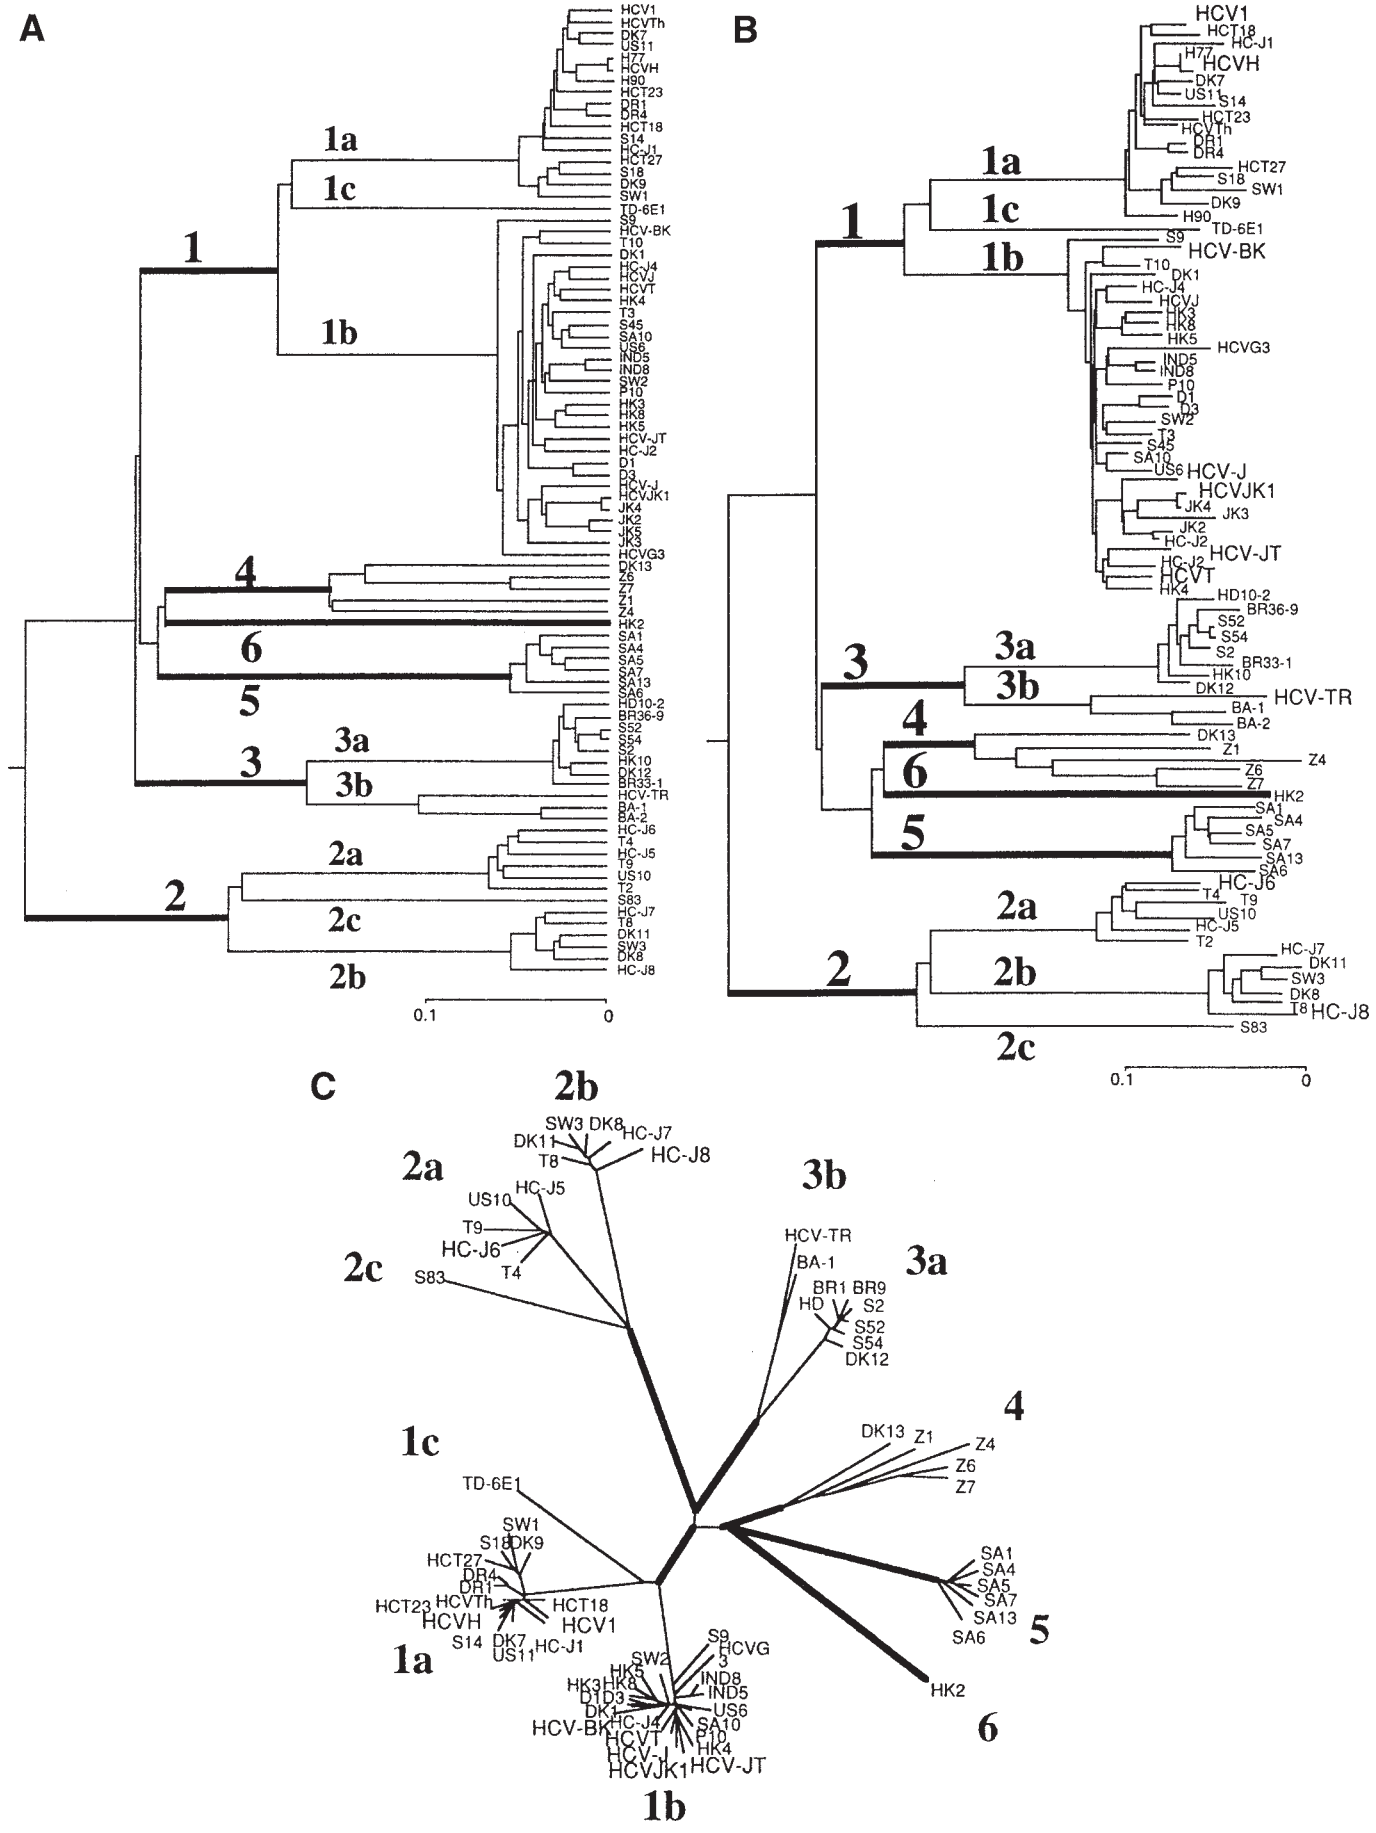
Different HCV genotype infections have different geographic distribution, associated with different mode of acquisition and differences in responsiveness to antiviral therapy. The association between genotype and disease severity is not unclear. Nonetheless, all HCV genotypes have been found to be hepatotropic and pathogenic, and similar levels of viremia exist between patients infected with different genotypes. In the United States, genotype 1 is the most prevalent (approx 70% with an equal distribution of subtypes 1a and b). Genotypes 2 (10%) and 3 (6%) are less common.

Even within an individual patient, HCV exists as a collection of closely related, yet heterogeneous sequences, called quasispecies. The rate of nucleotide substitution varies significantly between various genomic regions, with an overall substitution rate of 10^{-2} mutations/nucleotide/yr. The highest proportion of mutations has been found in the E1 and E2 regions at both the nucleotide and the amino acid level, particularly in the hypervariable region (at the amino terminus end of E2. Even though this region only represents a minor part of E2/NS1 region, it accounts for about 50% of the nucleotide changes and 60% of the amino acid substitutions within the envelope region. The quasispecies nature of HCV might be one of the mechanisms by which the virus escapes immune responses. Other virus–host interaction might also play a role in the viral quasispecies evolution. The clinical significance of genotypes and quasispecies continues to be an active area of investigation.

CHIMERAS, REPLICONS, AND INFECTIOUS CLONES Although an efficient cell culture system has not been developed, both replicons (capable of RNA amplification but not production of mature viruses) and chimeric viruses have been developed to enhance our understanding of HCV replication and gene expression. These experimental systems are helpful in the discovery and development of novel antiviral therapies. Infectious HCV clones demonstrated to infect chimpanzees have also been developed. These molecular tools will no doubt contribute to the understanding of the virus–host interactions, in both the mechanism of viral persistence and liver damage, and also to the development of improved antiviral therapies.

EPIDEMIOLOGY

The availability of molecular tools to detect antibody to HCV and viremia (i.e., HCV RNA) has allowed us to better define the epidemiology of HCV infection. In this section, the latest epidemiological findings are summarized. It has to be noted that different diagnostic tools are required for different settings and also other clinical factors, including coinfection with human immunodeficiency virus, might require other molecular tools in the overall evaluation of these patients.



INCIDENCE AND PREVALENCE OF INFECTION The worldwide seroprevalence of HCV infection, based on the detection of antibody to HCV (anti-HCV), is estimated to be 3%. However, marked geographical variation exists, ranging from around 1–2% in North America and 10–14% in North Africa. In the United States, the estimated seroprevalence of anti-HCV is approx 1.8% in the general population or 0.6% in volunteer blood donors. The incidence of acute hepatitis C is falling, from an estimated 180,000 cases per year in the mid-1980s (peak incidence) to approx 30,000 new cases per year in 1995, mainly attributed to risk reduction through blood donor screening, better education and the introduction of syringe-exchange programs. Currently less than 15,000 cases per year are identified attributable to harm reduction in high-risk communities.

TRANSMISSION The modes of transmission of HCV infection can be divided into percutaneous (blood transfusion and needlestick inoculation) and nonpercutaneous (sexual contact, perinatal exposure). The latter group might represent occult percutaneous exposure. Blood transfusion from unscreened donors and injection drug use are the two risk factors that were well documented. HCV was shown to be the etiological agent in more than 85% of cases of posttransfusion NANBH.

Percutaneous Transmission With the introduction of donor screening through anti-HCV testing, the risk of transfusion-related hepatitis has declined significantly, to approx 0.01–0.001% per unit of blood transfused, accounting for only 4% of all acute HCV infections.

The prevalence of HCV infection in injection drug users is 48–90%. Unlike transfusion-associated hepatitis, the prevalence of HCV associated with injection drug use has not declined and this population remains an important reservoir of HCV infection.

Figure 52-2 (opposite page) Phylogenetic tree for HCV isolates as constructed by **(A)** unweighed pair grouping method with arithmatic mean (UPGMA), **(B)** neighbor-joining method (NJ), and **(C)** maximal likelihood method (ML). Note that all HCV isolates clustered together into the same branch by all three methods. Based on this analysis, HCV can be classified into six major genotypes (given as 1–6; also called clades) and a series of subtypes (given as a, b, and so on).

Chronic hemodialysis is associated with both endemic cases and, more rarely, sporadic outbreaks of HCV infection, with most studies showing a prevalence of 10–30%. Serological assays (testing for anti-HCV) might underestimate the prevalence of HCV infection in this relatively immunocompromised population and virological assays (for HCV RNA by polymerase chain reaction amplification [PCR] or transcription-mediated amplification [TMA]) might be necessary for more definitive diagnosis in dialysis patients.

Anti-HCV seroconversion rates have been 0–4% in longitudinal studies of health care workers with documented needle-stick exposures to anti-HCV-positive patients. If a sensitive, qualitative assay for HCV RNA is employed to detect infection, the risk of HCV acquisition after percutaneous exposure is up to 10%. Transmission might also occur from health care worker to patient. Because acute infection is often subclinical, nosocomial transmission might occur with greater frequency than has previously been recognized.

Nonpercutaneous Transmission The nonpercutaneous modes of transmission include transmission between sexual partners and perinatal transmission. Nonpercutaneous transmission is inefficient; this is particularly true for sexual transmission of HCV, which although infrequent, clearly occurs. Sexual partners of low-risk index subjects without liver disease and without high-risk behavior (injection drug use or promiscuity) have anti-HCV prevalence ranging from 0 to 7%. Coinfection with human immunodeficiency virus and other high-risk behavior are associated with an increased risk with anti-HCV prevalence between 11 and 27%.

The efficiency of perinatal transmission of HCV infection is low, with a risk estimated to range between 0 and 10%. Because antibody to HCV can be passively transferred from mother to infant, detection of HCV viremia (i.e., HCV RNA) by a sensitive qualitative assay for HCV RNA in the infant should be the diagnostic tool of choice. Testing of the infant for anti-HCV before 18 mo is not recommended. The risk posed to the infant from breastfeeding is believed to be negligible.

SPORADIC HCV INFECTION In earlier epidemiological reports, approx 40% of patients were reported to be without identifiable risk factors. More recent data suggest that the source of transmission is considered to be unknown for less than 10% of the newly identified patients. The high rate of unknown risk factors in previous reports might have been related to patients' denial of high-risk behavior. It is postulated that factors like alternative routes of illicit drug use (e.g., intranasal cocaine use), tattooing and body piercing, and other high-risk behavior involving body secretion/blood contact might be responsible for some of these cases.

PATHOGENESIS

VIRAL PERSISTENCE HCV causes chronic infection in more than 45–80% of the infected patients. One determinant of viral persistence appears to be the quasispecies nature of the virus, which allows HCV to have the flexibility to evade the host defense and evolve consistently to adapt to the new environment. Other factors might include

1. Inadequate innate immune response.
2. Insufficient induction or maintenance of the immune response.
3. Viral evasion from efficient immune responses through mechanisms such as infection of immunologically privileged sites, viral interference with antigen processing or other immune responses, viral interference of the effectiveness of antiviral cytokines.
4. Amount of virus in inoculums.
5. Induction of immunological tolerance.

HEPATOCELLULAR DAMAGE In general, viral infection can produce cellular injury by direct cytopathicity and indirect immune-mediated injury. Viral factors might play a role in the pathogenesis of disease. Viral proteins might directly impact cellular function. A correlation between serum HCV RNA levels and lobular inflammatory activity was reported but not all studies demonstrated such a correlation. A lack of correlation does not exclude the possibility of a direct cytopathic mechanism, as liver cell injury might require a certain critical level of intracellular HCV protein accumulation. Support for this comes from a report of severe liver dysfunction in an immunocompromised transplant recipient who, despite exhibiting subfulminant liver failure, had only moderate inflammation on biopsy yet very high levels of HCV viremia.

Immune-mediated mechanisms have also been implicated in HCV-induced hepatocellular damage. HCV infection elicits both innate and HCV-specific immune response, including antibody response and virus-specific CD8+ and CD4+ T-lymphocytes. Whereas, the cellular immune response is believed to play an important role in HCV pathogenesis, the importance of the antibody response in generating liver damage is less clear.

The HCV-specific CD8+ T-cell response is polyclonal, and directed against different epitopes of both structural and NS regions of the viral polyprotein, (core, envelope, NS3, NS4, and NS5) in the context of different major histocompatibility complex alleles. Recent studies using major histocompatibility complex tetramers estimated the frequency of HCV-specific CD8+ T-lymphocytes to range from 0.01 to 1.2% of total CD8+ T-lymphocytes. The CD4+ T-cell response against HCV is also multispecific and frequently found in patients with chronic hepatitis C. However, this CD4+ T-cell response is likely impaired as the proportion of chronic carriers able to mount an effective CD4+ T-cell response to HCV is very small.

Liver-infiltrating CD8+ and CD4+ lymphocytes are detected in portal, periportal, and lobular areas in patients with chronic HCV infection. CD8+ lymphocytes predominate, suggesting that cytotoxic T-lymphocytes (CTLs) are the main perpetrators of hepatocellular injury. Intrahepatic CD8+ lymphocytes recognizing multiple epitopes of the putative HCV core, E1, E2/NS1, and NS3 genomic regions have been cloned from chronically infected patients, and might represent a high proportion of the intrahepatic T-cell infiltrate. HCV-specific CD4+ T cells are rich in the liver, and the majority of these are intrahepatic CD4+ T cells secrete cytokines typical of Th1 cells, favoring HCV CD8+ T-cell activity in liver. Patients with detectable intrahepatic CTL activity show lower levels of viremia, higher ALT values, and more active liver disease than those without HCV-specific CTLs, suggesting a correlation between the CD8+ T-cell response and the degree of hepatocellular injury. Most of the intrahepatic HCV-specific CD8+ T-cells express the activation molecule CD69, which shows a very low expression in circulating virus-specific CD8+ T cells, suggesting that these cells become activated in the liver through their recognition of appropriate presentation of HCV-related epitopes.

CLINICAL FEATURES

HCV is an important public health problem because it is a major cause of chronic hepatitis, cirrhosis, hepatocellular carcinoma (HCC), and need for liver transplantation worldwide.

ACUTE AND CHRONIC INFECTION HCV accounts for about 20% of cases of acute hepatitis. Acute infection is rarely seen in clinical practice, as the vast majority of patients experience no clinical symptoms whereas others might present with nonspecific symptoms such as fatigue, nausea, and vomiting, indistinguishable from symptoms of other types of acute viral infections. HCV RNA appears in the blood within 2 wk of exposure and is followed by an increase in serum ALT levels (i.e., an indicator for hepatocellular damage) several weeks later. Serum ALT levels might exceed 1000 IU/L in 20% of the patients, and generally follow a fluctuating pattern during the first month. In those patients who develop jaundice, peak bilirubin levels are usually less than 12 mg/dL, and typically resolve in 1 mo. Fulminant hepatitis is very rare.

Approximately 45–80% of infected patients do not clear the virus by 6 mo and develop chronic hepatitis. Of these, the majority will have elevated or fluctuating ALT levels, whereas in one-third, persistently normal ALT values exist, despite continued liver injury and detectable viremia in the majority. The overwhelming complaint of patients with chronic infection is fatigue. The severity of this symptom is not necessarily related to the severity of the underlying liver disease. Other nonspecific symptoms include depression, nausea, anorexia, abdominal discomfort, and difficulty with concentration. Once patients develop liver cirrhosis, they are at risk for complications of portal hypertension (ascites, gastrointestinal bleeding, encephalopathy, and so on). Jaundice is rarely seen in chronic infection until significant hepatic decompensation has occurred. Liver transplantation should be considered when patients develop complications of portal hypertension or evidence of hepatic synthetic failure (reduction in serum albumin, rise in serum bilirubin, and/or prolongation of the prothrombin time as calculated as International Normalized Ratio [INR]).

EXTRAHEPATIC MANIFESTATIONS Approximately 1–2% of HCV-infected patients have extrahepatic manifestations. Reported extrahepatic manifestations include essential mixed cryoglobulinemia (that can result in membranoproliferative glomerulonephritis, leukocytoclastic vasculitis, peripheral neuropathy, and other organ injury), porphyria cutanea tarda, focal lymphocytic sialadenitis, Mooren's corneal ulcers, lichen planus, and diabetes mellitus. Some of these associations were clinical correlations and the exact causal relationship and the mechanism of the disease progress has not been established. In the case of essential mixed cryoglobulinemia and membranoproliferative glomerulonephritis, immune complexes induced by HCV (typically positive for rheumatoid factor) have been postulated to be the causal link. Anti-HCV antibodies are positive in 50–90% of patients with essential mixed cryoglobulinemia. In addition, cryoglobulins are found in about half of the patients infected with HCV and high concentration of HCV RNA has been found in the cryoprecipitate. Nonorgan specific autoantibodies are also frequently detected in patients with chronic HCV infection (antinuclear antibodies with a titer >1/40 in 21%, antismooth muscle antibody with a titer >1/40 in 21%, and antiliver kidney microsomal antigen in 5%).

DIAGNOSTICS

A number of immunological and molecular assays have been developed for the detection and assessment of hepatitis C status. The immunological or serological tests identify the presence of anti-HCV antibodies, which indicates previous exposure to the virus without differentiating between acute, chronic or resolved infection. In contrast, the molecular or virological assays detect specific viral nucleic acid sequences (HCV RNA), which indicate ongoing presence of the virus. Although serological assays are typically used for screening and first-line diagnosis, molecular/virological assays are needed in certain situations with the aim of confirming infection and/or monitoring therapy.

SEROLOGICAL TESTS There are two types of anti-HCV assays, the enzyme immunoassay (EIA) and the recombinant immunoblot assay (RIBA). Both detect antibodies against different HCV antigens from the core and nonstructural proteins and were developed using recombinant HCV antigens. Serological assays are typically used for screening and first-line diagnosis. Three generations of EIAs have been developed with increasing sensitivity. As first-generation EIAs lack sensitivity and specificity, confirmatory RIBAs were systematically used in samples positive in EIA. With the newer assays and the increased use of molecular assays, confirmatory RIBAs are seldom needed.

Screening Assays The latest EIA-3 assay uses recombinant antigens from the core, NS3/4A (c200) and NS5 (EIA-2 does not have this capture antigen) regions to provide better sensitivity for the detection of antibody to HCV. Even with these new assays, specificity might need to be confirmed in some populations, especially, those with low-risk. In this setting, confirmatory tests, typically molecular testing, are generally helpful.

Confirmatory Assays The RIBA tests use the same antigens as the corresponding EIA tests but in a strip or immunoblot assay format. Their sensitivity is generally lower than for EIA assays, but their specificity is better because the reactivity specific for the capture antigen can be visualized. The 4-antigen RIBA-2 (RIBA HCV 2.0 Strip Immunoassay, Chiron Corporation) was approved by the United States Food and Drug Administration in June 1993. This assay incorporated antigens 5-1-1, c100-3, c22-3, c33c and SOD (superoxide dismutase, as a control). With this assay, a specimen is considered positive if two bands or more are detectable, representing at least the presence of antibodies to two different HCV-derived capture antigens. If a specimen reacts with bands from only one region, such as 5-1-1 and c100-3 (both from the NS4 region), it is considered indeterminate. If a specimen reacts with the SOD band in addition to two or more HCV antigen bands, the result is also considered indeterminate. The third generation assay, RIBA-3 (RIBA HCV 3.0 Strip Immunoassay, Chiron Corporation) includes two recombinant antigens (c33c and NS5) and synthetic peptides from the nucleocapsid (c22) and the NS4 (c100-3) regions. It has been approved for use by blood banks as a supplemental test for EIA-3-positive samples. This new RIBA format is able to identify correctly HCV-negative and HCV-positive results in those samples that are RIBA-2 indeterminate.

VIROLOGICAL TESTS As HCV cell culture systems have not been established, detection of viral RNA in serum has been used as a direct marker of the virus. Qualitative HCV RNA assays are optimized to produce maximal signal regardless of the amount of input HCV RNA. In comparison, quantitative assays are developed to yield reproducible and accurate quantification values regardless of the input concentration of virus. Thus, these two types of assays are developed differently. Viral detection (i.e., qualitative result) is accomplished by target amplification methods such as the PCR-based AMPLICOR assay (Cobas Amplicor HVC Kit, Roche Diagnostics) or by the TMA-based VERSANT assay (Versant HCV RNA 3.0 Assay, Bayer Diagnostics). The qualitative PCR test for HCV might detect as few as 50 International Units (IU)/mL. The VERSANT assay employing TMA has a sensitivity

of 10 IU/mL. To achieve these results, specific procedures directed to preserving the integrity of HCV RNA should be followed carefully, including separation of serum or plasma from whole blood within 4 h of venipuncture, and rapid storage of specimens at –70°C.

Qualitative assays for HCV RNA are used for confirmation of diagnosis and for assessment of viral clearance at the end of therapy and at follow-up to therapy (i.e., 6 mo after cessation of therapy). Ninety-five percent of viral loads at baseline are within the range of 33,500–3,700,000 IU/mL; therefore, the sensitivity of either of the qualitative assays should be sufficient to detect HCV RNA in a confirmatory application. In comparison, the TMA-based assay detected HCV RNA in (7–30% of) relapsers at the end of treatment when the PCR-based assay detected none. In this setting, very high sensitivity is important in detection of residual HCV RNA at the end of therapy.

The quantitative HCV RNA tests allow measurement of viral load and they are useful in monitoring the effectiveness of antiviral therapy and in evaluating the course of clinical disease. The branched DNA (bDNA) VERSANT assay (Bayer Diagnostics) uses capture and target probes directed to the conserved 5′ UTR and core regions in a microwell format. HCV RNA captured to the microwell supports the formation of very large hybridization complexes that include synthetic branched DNA oligonucleotides (signal amplification). These large hybrids contain many copies of probes that are labeled with alkaline phosphatase. Following addition of a chemiluminescent substrate, light is emitted in proportion to the number of HCV RNA molecules in the original specimen; the quantity of HCV RNA is determined by comparison of chemiluminescence from the specimen with a standard curve containing calibrators with known amount of target. The third generation assay, registered with the FDA, has been shown to measure down to 615 IU/mL with a dymanic range of over 4 logs (upper limit of detection 7.7×10^6 IU/mL).

The Amplicor HCV Monitor, v 2.0 quantitative assay provides a semiquantitative measurement of viral RNA. HCV RNA is reverse transcribed and amplified by end point PCR (i.e., with a specific number of amplification cycles) using primers from the most conserved region (in 5′ UTR) of the HCV genome. This reaction produces very large numbers of double-stranded DNA that has the same sequence as a portion of the HCV RNA in the specimen. The assumption is that the amount of amplicon produced is directly proportional to the amount of HCV RNA in the specimen. A quantitation standard (with a known number of HCV RNA targets) is added to each specimen and coamplified with the target. An internal control also is added to each specimen and is used to indicate if there are inhibitors of the RT-PCR steps in the reaction. A microwell plate detection system with chemiluminescent label is used for quantification of amplicons produced. The amount of viral RNA present in the amplified sample is calculated based on the signal from HCV RNA in the specimen and on the signal generated from the quantification standard. The lower limit of detection of the AMPLICOR assay is approx 600 IU/mL.

Recently, kinetic or real-time PCR methodologies have been applied to quantification of HCV RNA. Amplification by PCR is geometric and nucleotide and/or enzyme might become rate limiting during the reaction; the rate of accumulation of amplicons might decrease during the reaction and with higher input numbers of HCV RNA. Thus, end point PCR assays have a limited dynamic range of 2.5–3 $\log_{10}$ units. In comparison, real-time PCR assays are carried out like end point assay except that signal from amplicons is detected during amplification. The fractional PCR cycle in which signal exceeds a critical threshold value (Ct), marks the start of the exponential phase of target amplification. A lower Ct indicates a higher input concentration of HCV RNA. The quantity of HCV RNA in a specimen is calculated based on the Ct for the specimen and the Ct for the Quantification Standard (with a known number of HCV target molecules). Alternatively, quantification might be based on the Ct for the specimen and the Ct's for a series of calibrators. Fluorescence energy transfer is used in many probe systems, including TaqMan, employed with the real time PCR technology. The assay is designed to avoid the problems associated with rate limitation resulting from enzyme and/or nucleotide depletion and, thus, is reported to be linear. Roche Molecular Systems and Abbott Diagnostics employ real time PCR in their Analyte Specific Reagents or kits. Bayer Diagnostics currently is developing assays that employ real time technologies.

Quantitative assays are employed in monitoring the efficacy of therapy often by showing changes in viral load between baseline (i.e., start of therapy) and during therapy. Linearity of assay response (i.e., degree to which the assay standard curve approximates a straight line) provides the clinician and patient accurate results regardless of the level of virus; changes in viral load reflect actual changes in the patient. The bDNA-based assay is linear (slopes of about 1) whereas the Amplicor HCV Monitor assay might exhibit nonlinear performance at viral loads greater than 500,000 IU/mL. Real-time PCR-based assays are linear.

An immunoassay that provides quantification values for HCV core antigen has been introduced as an indirect measure of viral load. This assay has a sensitivity of approx 20,000 IU/mL. Thus, the 2-$\log_{10}$ stopping rule at week 12 of therapy is employed in assessing nonresponse could be employed only in patients with viral loads of ≥2,000,000 IU/mL at baseline. To date, this assay has limited application because it is an indirect measure of virus and it is considerably less sensitivity than are the quantitative assays.

To permit universal standardization of HCV RNA quantitation units, a recent collaborative study established the World Health Organization (WHO) International Standard for HCV RNA quantitation. A lyophilized genotype 1 sample was accepted as the candidate standard and was assigned a titer of 10^5 IU/mL. This standard has been used to calibrate HCV RNA panels and by industrial manufacturers to express HCV RNA load in IU/mL in their assays (226). The goals of standardization are to allow for generalization of findings from clinical studies with one assay to patient management with all of the assays and to permit clinicians to use results from any of the assays in monitoring patients.

HCV GENOTYPING Differentiation of the HCV genotypes is accomplished by direct sequencing, differential PCR using type-specific primers, detection of PCR products with type-specific probes (available commercially, the Line Probe Assay), restriction fragment length polymorphism analysis, and serotyping with type-specific antibody. These techniques use targets in the 5′ UTR, NS4, NS5, and core regions. Of the many methods available for genotyping, direct sequencing coupled with phylogenetic tree analysis is regarded as the gold standard. However, sequencing methods are technically demanding and time-consuming. A study comparing sequencing, type-specific primers, serotyping, and restriction fragment length polymorphism analysis, demonstrated more than 90% concordance between methods.

SELECTION OF SEROLOGICAL AND VIROLOGICAL TESTS Initial diagnostic testing of HCV infection is currently made by detecting specific antibody by EIA. For low-risk patients, a negative EIA test is sufficient to rule out infection. A positive EIA for low-risk patients should be confirmed by RIBA assay or molecular testing. For high-risk patients, individuals with recent exposure or immunocompromised patients (including HIV, chronic hemodialysis patients, transplant patients), a negative EIA should be confirmed and molecular test such as PCR or TMA-based qualitative test is the choice.

SCREENING IN BLOOD BANKS With the latest EIA and RIBA assays, the number of false positive or indeterminate test results is very low. One major limitation of these assays however is the existence of a window period by which the patient might transmit the virus before antibodies are detectable. With recent assays, the average delay is approx 80 d. For this reason, many blood banks throughout the world have instituted testing all donors with qualitative PCR or TMA assays.

DIAGNOSIS IN IMMUNOCOMPROMISED PATIENTS Antibody tests underestimate the prevalence of HCV infection in immunocompromised populations and detection of viral RNA is frequently required for diagnosis. Antibody assays also lack sensitivity in the transplant setting, as these patients are immunosuppressed. Molecular/virological assays for HCV RNA are the assays of choice.

LIVER HISTOLOGY The range of histological findings in patients with chronic HCV infection is broad, from minimal periportal lymphocytic inflammation to active hepatitis with bridging fibrosis, hepatocyte necrosis, and frank cirrhosis. Steatosis, lymphoid aggregates, and bile duct damage are frequently found in the liver biopsies of patients with this infection, but there is considerable overlap with the histological findings in patients with chronic HBV infection and occasionally with autoimmune hepatitis. The role of a liver biopsy in the management of HCV-infected patients is still not settled although most physicians perform a liver biopsy before initiating treatment. This recommendation is waning somewhat for patients with genotypes 2 and 3, in which the viral response is much higher with a shorter course of therapy. The potential risks associated with a liver biopsy (1:3000 chance of bleeding, 1:12,000 chance of death) contrast with the importance of the information generated by this means. Recent consensus conferences have stated that a liver biopsy is recommended in patients with chronic hepatitis C and abnormal serum ALT levels so that correct staging and grading can be performed. This information is particularly relevant when considering antiviral therapy or when other causes of liver disease might be present. A posttreatment liver biopsy is not necessary as most trials have demonstrated that viral sustained response is generally associated with stable or improved histological findings. In patients with normal serum ALT levels, liver biopsy might also provide information about the stage of disease, particularly if antiviral therapy is being considered. Although fibrosis progression appears to be slow in these patients, only 20% have an absolutely normal liver, and a small percentage (<15%) have significant liver damage, and it is in these patients that treatment might be undertaken. In patients in whom the diagnosis of cirrhosis is established (ascites, splenomegaly, spider angioma, low platelet count, low prothrombin time, reduction of portal flow speed, nodularity of the liver), histological confirmation is usually not needed.

NATURAL HISTORY

An understanding of the natural history of infection is essential for guiding physicians when counseling patients about their prognosis and assessing the need for therapeutic intervention. Infection with HCV, once established, persists in the vast majority. Disease progression is largely silent with patients often identified only on routine biochemical screening or during the course of blood donation. The natural history of chronic HCV infection, as evaluated through different approaches (e.g., through referral centers, military recruits, pregnant women who received HCV contaminated immunoglobulins, and children with cardiac surgery who acquired HCV through transfusion), appears to show that HCV usually is a slowly progressive disease in 10–25% of the patients, and these patients might develop end-stage liver disease more than two to three decades. The remaining patients will have a benign evolution over decades.

For factors associated with disease progression, age (older than 40 yr), male gender, obesity (fatty liver), and increased alcohol intake (>50 g/d) have been documented as associated variables. Immunosuppression is clearly linked with more aggressive disease. Patients with humoral immunodeficiency (hypo γ-globulinemic patients) or cellular immune impairment (liver or kidney transplant recipients, HIV infected patients with low CD4 count) have shown rates of liver disease progression significantly faster than those observed in immunocompetent patients.

For patients with compensated HCV-related cirrhosis, the prognosis of patients in the short-term might be good. Actuarial survival is 91% at 5 yr and 79% after 10 yr in the absence of clinical decompensation. Survival drops to 50% at 5 yr among those who develop clinical decompensation. The cumulative probability of developing an episode of clinical decompensation is approx 5% at 1 yr, increasing to 30% at 10 yr from the diagnosis of cirrhosis. The risk of developing HCC is 1–4%/yr once cirrhosis is established.

For patients with persistently normal serum ALT levels (around one-third of the patients), most will have some degree of histologicaly proven chronic liver damage ranging from mild chronic hepatitis to cirrhosis. Disease progression appears to be slower in these patients than in those with abnormal serum ALT levels, and progression to cirrhosis is unlikely.

For renal transplant recipients, elevated serum ALT levels are more common in anti-HCV positive than in anti-HCV negative patients (median 48 and 14%, respectively). There are also reported differences in patient and graft survival between anti-HCV positive and anti-HCV negative kidney transplant recipients, the increased mortality being related to liver dysfunction.

HCV is evolving as an important issue in liver transplantation. Chronic HCV infection is the most common indication for liver transplantation in the United States. Recurrence of HCV following liver transplantation is universal. Viremia level increased by one log after liver transplantation. In a small proportion of patients (5%), an accelerated course of liver injury leading to rapid development of liver failure, reminiscent of that previously described in HBV-infected recipients with fibrosing cholestatic hepatitis has been observed. Disease progression is significantly faster than that observed in immunocompetent patients, and the time to develop cirrhosis is short in this population. Although histological evidence of liver injury will develop in approximately half of the patients within the first year posttransplantation, severe graft dysfunction in the short-term is infrequent. With longer follow-up (5–7 yr), a significant proportion of patients, ranging from 8 to

30%, develop HCV related graft-cirrhosis. The risk of decompensation once the transplant patient has developed clinically compensated cirrhosis is approx 40% at 1 yr.

For patients coinfected with HCV and human immunodeficiency virus undergoing active antiretroviral therapy, chronic hepatitis C is a growing cause of morbidity and mortality in this population. It was also observed that hepatic decompensation develop more rapidly in coinfected patients than in those with HCV infection alone but the mechanism responsible for this clinical observation was not known.

TREATMENT

The primary goal of therapy is to eradicate infection early in the course of the disease to prevent progression to end-stage liver disease and eventually to HCC. However, this is a long-term goal and cannot be measured in short-term clinical studies. In this context, normalization of serum ALT levels, loss of HCV RNA, and improvements in histological findings have been employed as the current standard therapeutic end points. Current data suggest that the achievement of these end points will translate into long-term benefit from therapy, as measured by reduction in the rate of disease progression, reduction in the need for liver transplantation, reduction in rate of development of HCC and improvement in survival. Indeed, several studies have shown that in patients with sustained biochemical and virological responses, the durability of the response is more than 95% for up to 10 yr. A lesser goal of therapy is to reduce the secondary spread of infection by eradicating the viremia.

Interferon-α based regimens constitute the cornerstone of our current antiviral therapies. There are several types of interferon-α available, including recombinant forms (interferon α-2a, α-2b, and consensus interferon) and naturally occurring forms (lymphoblastoid interferon). Interferons are naturaly occurring proteins, which exert a wide array of antiviral, antiproliferative, and immunomodulatory effects. For years, interferon-α given in monotherapy was the standard treatment in patients with chronic hepatitis C, with results considered modest at best. A modified version of interferon, pegylated interferon-α, which consists of interferon-α bound to a molecule of polyethylene glycol of varying length and with different order of branches has been developed. This process of pegylation increases the half-life of the molecule and reduces the volume of distribution. This altered pharmacokinetic profile provides more uniform and prolonged plasma levels, which in turn have led to weekly dosing of this product. Such a profile with better drug exposure is leading to better therapeutic efficacy compared to the unmodified interferon-α.

Ribavirin is a broad-spectrum antiviral agent with activity against both DNA and RNA viruses. In immunocompetent patients with chronic HCV infection, ribavirin resulted in improved serum ALT levels but the effect was transient and no significant direct antiviral activity was observed. Ribavirin is known to induce hemolysis, a side effect that is dose limiting. Because of this side effect, ribavirin is contraindicated in patients with a past history of myocardial infarction or cardiac arrhythmia. Ribavirin is also potentially teratogenic and patients and partners are required to avoid pregnancy during therapy and for 6 mo after cessation of treatment. Ribavirin has a long cumulative half-life. It is excreted by the kidney and cannot be removed by hemodialysis. Hence, ribavirin is contraindicated in patients with a serum creatinine of greater than 1.5 mg/dL.

Although neither interferon-α nor ribavirin monotherapy is very effective in the treatment of chronic HCV infection, the combination of these two drugs improves the treatment response rate by many folds and is currently the gold standard for the treatment of chronic HCV infection in individuals who have not received any previous treatment (i.e., treatment naive). The current recommendation for patients with HCV genotype 1 infection is pegylated interferon-α injection (dosing depends on the preparation: 180 μg weekly for pegylated interferon-α2a; and 1.5 μg/kg weekly for pegylated interferon-α2b) for 48 wk in combination with oral ribavirin (1000–1200 mg daily with pegylated interferon-α2a and 800 mg daily with pegylated interferon-α2b). Trials using pegylated interferon-α2a have compared safety and efficacy of 800 mg vs 1000–1200 mg of ribavirin daily, and for genotype 1 infection, results suggest superiority of the higher dose. Given these findings, it is likely that 1000–1200 mg of ribavirin is necessary for optimizing outcomes in these patients whether given in combination with pegylated interferon-α2b or -α2a. The recommendation for patients with HCV genotypes 2 and 3 infection is similar to patients with HCV genotype 1 infection except that 24 wk of therapy, and a dose of ribavirin at 800 mg appear adequate. Overall, the long-term sustained response (defined as normal serum ALT and with no detectable HCV RNA 6 mo after cessation of therapy) is around 55%. For patients with HCV genotype 1 infection, the long-term sustained response is around 40% and for patients with genotypes 2 and 3 infection, the long-term sustained response is around 80%. Adherence to full dose and duration of therapy can improve the sustained virological response rate by another 10%.

Factors associated with a better treatment outcome include low pretreatment serum HCV RNA levels, genotypes 2 and 3 infection, absence of cirrhosis, female gender and age less than 40 yr. African-Americans have generally been shown to respond less well to treatment than Caucasians, whether the treatment is interferon or pegylated interferon plus ribavirin. It should also be noted that with the current combination of pegylated interferon-α and ribavirin therapy, patients with HCV-related cirrhosis and patients with "transition to cirrhosis" have shown similar response rate as noncirrhotic patients, although there have been few studies focusing specifically on outcomes in patients with advanced liver disease. Thus, the presence of clinically compensated cirrhosis should not exclude patients from antiviral therapy.

Regarding indications, theoretically all patients with ongoing HCV infection with persistent elevation of serum ALT levels are potential candidates of antiviral therapy. However, given that (1) our therapies are still imperfect in terms of efficacy, and are associated with significant side effects; and (2) the natural history of hepatitis C is benign in the majority of patients, both physicians and patients need to evaluate the potential benefit, the costs, and the risks before initiating therapy. Ironically, patients with the lowest likelihood of progression are precisely the ones who are most likely to respond. In contrast, those with the least likelihood of responding or with the least tolerance of side effects of treatment are often the ones with the greatest need. In patients with a low chance of disease progression (immunocompetent, less than 40 yr of age, female gender, no alcohol consumption, minimal histological inflammation, and fibrosis), there are as many arguments to recommend starting treatment as there are to defer treatment until safer and more effective therapies are available.

There are certain situations in which the guidelines regarding treatment are not yet well developed, in part because studies in

certain patient populations are still underway and complete results have not yet been published in the peer-reviewed literature. These include patients with active substance abuse (alcohol and injection drug use), those with clinically decompensated cirrhosis, those with very mild liver disease and those with coinfection with other viruses such as HIV and/or hepatitis B. As the need for treatment is high in many of these subpopulations, results from carefully conducted clinical trials are greatly needed. Clearance of virus in a larger percentage of patients might ultimately require the development of HCV therapies with different mechanisms of action to those that are currently available.

At present, combination therapy using the nonpegylated interferon in combination with oral ribavirin has been approved for the treatment of children with chronic HCV infection. Patients with HIV coinfection are frequently being treated in the context of randomized controlled trials. Preliminary data suggest that although sustained viral clearance is achievable, overall responses to peginterferon plus ribavirin are lower than those observed in HIV-negative patients. Interferon has produced short-term improvement in the signs and symptoms of cryoglobulinemia in those patients demonstrating a virological response, although recurrence of viremia and cryoglobulinemia is the rule when treatment is discontinued. Interferon has been used successfully in the treatment of HCV-associated membranoproliferative glomerulonephritis. There is a theoretical rationale for treating patients with acute HCV infection as the majority will develop persistent infection and chronic liver disease. The few studies that have been conducted in patients with acute HCV have used different dosage and duration of interferon therapy. Whereas, most are uncontrolled case series, high rates of remission have also been reported. The Manns study showed clearance of virus in 98% of a small number of treated patients; these patients were selected for the presence of icterus.

In patients who have relapsed after a course of interferon monotherapy, combination therapy is the treatment of choice. There are no FDA-approved treatments for nonresponders to previous treatment with interferon alone, or interferon-α/ribavirin combination therapy. If retreatment is undertaken with peginterferon plus ribavirin in those who have failed a previous course, viral clearance is achievable, particularly in patients with genotype non-1 infection, those who have failed previous interferon monotherapy rather than interferon plus ribavirin combination therapy and those who have demonstrated some degree of treatment sensitivity with a reduction in HCV RNA levels during the first course of therapy.

Monitoring before and during therapy is important in the overall management of patients with chronic HCV infection. Before starting therapy, blood tests should be conducted to establish baseline status, including liver biochemistry, complete blood count, viral load (with a quantitative HCV RNA test), and thyroid-stimulating hormone level. A pregnancy test is needed to rule out pregnancy before initiating ribavirin therapy in women. Strongly worded counseling needs to take place for partners who potentially could be involved in conception during ribavirin treatment to utilize a dual method of contraception to prevent pregnancy. HCV genotyping will help in selecting the best treatment strategy (i.e., dosage of ribavirin and duration of therapy). During the first month of therapy, a complete blood count should be done weekly as most side effects occur within this period of time, particularly hemolytic anemia related to ribavirin therapy. Approximately 9–23% of patients, depending on the ribavirin dose, will have a fall in hemoglobin to less than 10 g/dL with a mean decrease of approx 3 g/dL. As dose reductions of ribavirin have the potential to compromise response to combination therapy, adjunctive treatments such as erythropoietin are being increasingly used to manage side effects in patients receiving HCV treatment. After the first month, liver biochemistry and a complete blood count should be performed monthly, and thyroid-stimulating hormone level every 3 mo. Modifications of doses should be done according to the severity of side effects. The recent NIH Guidelines recommend that viral load should be assessed at week 12 of therapy. Several studies of therapy with pegylated interferon plus ribavirin showed that patients in whom the viral load did not decrease by at least 2 $\log_{10}$ almost invariably (97–100% negative predictive value) were nonresponders with the full course of therapy. At the end of treatment and at 6 mo postdiscontinuation of treatment, serum HCV RNA testing with sensitive, qualitative assay should be carried out to assess treatment response. If sustained response is achieved, it is recommended that serum HCV RNA testing be performed annually for at least 2 yr after completion of therapy. A repeat liver biopsy following treatment is rarely necessary.

Newer therapies are being developed for anti-HCV infection. A number of the HCV viral peptides in the replication machinery are good targets for novel therapy development. Current efforts are focusing on targeting HCV internal ribosomal entry site, NS3 protease, NS3 helicase, and NS5B RNA-dependent RNA polymerase. Molecular approaches utilizing antisense, ribozyme, and small inhibitory RNA directed against the HCV genome are also being tested. A number of immunomodulators are also being tested for their ability to booster the host immune response. These include HCV-specific immune stimulation, i.e., therapeutic vaccine, as well as non-HCV specific immunomodulation using various cytokines. Efforts are also directed at developing a safer version of ribavirin, a prodrug of ribavirin that is predominately released by the deaminase enzyme system in the liver.

PREVENTION

GENERAL MEASURES As there is no effective prophylactic vaccine and no effective postexposure prophylaxis, major efforts should be placed on counseling both HCV-infected patients and those at risk of infection on the general measures. Adequate sterilization of medical and surgical equipment is mandatory. Efforts should also be made to modify injection practices involved in folk medicine, rituals, and cosmetic procedures. Persons at high-risk of HCV infection such as recipients of blood/blood product transfusions before 1990, drug users, and sexual partners of persons infected with HCV should be tested for antiHCV. HCV-infected patients should be instructed to avoid sharing razors and toothbrushes and to cover any open wounds. Given the low rate of vertical transmission, pregnancy is not contraindicated in HCV-infected women. No recommendations have been issued regarding the mode of delivery. Breast-feeding is not contraindicated. It is recommended that HCV-infected patients be vaccinated against hepatitis A and B, given the increased risk of severe liver disease if superinfection with these viruses occurs.

PASSIVE IMMUNOPROPHYLAXIS Immune serum globulin has not been studied clinically in the prevention of HCV infection. Nevertheless, there are several lines of evidence suggesting that such measures are unlikely to be effective. Studies from the 1970s of immune serum globulin as a measure of prophylaxis against posttransfusion NANBH failed to demonstrate any signif-

icant benefit. The neutralizing immune response to HCV infection even in healthy adults appears to be weak and hence it would seem unlikely that immune serum globulin would contain sufficient neutralizing antibody to be effective. Finally, HCV has an inherently high nucleotide substitution rate that would predictably facilitate rapid escape from humoral immune recognition. Despite this scientific rationale, polyclonal immunoglobulins containing anti-HCV are being tested to decrease the incidence of recurrent HCV viremia 1-yr post-transplantation, preliminary results have not been encouraging and long-term protection has not been reported. Whether such immune sera will be protective in the setting of exposure to virus remains to be determined.

ACTIVE IMMUNOPROPHYLAXIS Vaccine development for HCV appears to encounter the same difficulties encountered in the development of human immunodeficiency virus vaccine. The absence of natural protective immunity in chimpanzees that recovered from HCV infection to challenges with both heterologous and homologous strains of virus bodes poorly for vaccine development. Nevertheless, neutralizing antibodies to HCV can be elicited during natural infection and have been demonstrated to be effective at preventing viral transmission to experimental animals, when used to neutralize virus in vitro. Substantial efforts are currently directed to the development of prophylactic HCV vaccines.

"Science has radically changed the conditions of human life on earth. It has expanded our knowledge and our power but not our capacity to use them with wisdom"

53 Molecular Diagnostics in Hepatitis B

Scott Bowden and Stephen Locarnini

SUMMARY

An estimated 400 million people are chronically infected with hepatitis B virus (HBV) and many will suffer serious liver disease as a consequence. HBV is an enveloped, partially double-stranded DNA virus, which replicates via reverse transcription of an RNA intermediate. The error rate of the reverse transcriptase generates a heterogeneous population of variants, endowing HBV with the ability to evade immune or antiviral selection pressure. Whereas HBV infection can be diagnosed by serological assays, the introduction of new antiviral agents to treat chronic infection requires monitoring by sensitive DNA amplification assays designed for quantification of HBV DNA in serum and liver tissue.

Key Words: Antiviral therapy; drug resistance; HBV ccc DNA; HBV genome organization; HBV genotypes; HBV viral load.

INTRODUCTION

More than 400 million people worldwide are chronically infected with the hepatitis B virus (HBV), making hepatitis B one of the most common infectious diseases. Of these chronic carriers, only 1–2% will annually spontaneously clear hepatitis B surface antigen (HBsAg). Ultimately, more than half of the HBsAg-positive patients will die of hepatocellular carcinoma (HCC) or liver failure. Host factors such as age, immunosuppression, and gender can contribute to patient outcome. Over the past decade there has been increasing interest in the role of virological factors such as load and specific mutations in particular regions of the viral genome on the clinical course and outcome of persistent infection.

HBV is an enveloped, partially double-stranded DNA virus, which is the prototype member of the family *Hepadnaviridae*. The virus replicates its DNA genome via an RNA intermediate, an unusual strategy that generates a heterogeneous population of genetic variants during the normal course of infection and provides enormous potential for adaptation to changing environments and response to particular selection pressures. This property endows the virus with the ability to evade host immunity and resist conventional antiviral strategies. However, the extreme genetic economy of the HBV genome, achieved by the use of overlapping reading frames, is a major constraint on HBV evolution and as such could be exploited to improve existing therapeutic approaches, in particular by the use of combination treatments targeting different parts of the virus life cycle. Studies on the pathogenesis of chronic hepatitis B (CH-B) have revealed a complex interaction between the virus, the hepatocyte, and the host's immune response. This chapter describes the organization of the HBV genome, the role of the proteins it encodes, and the common variants produced by exogenous selection pressure. New antiviral therapies available for the treatment of CH-B are discussed with the molecular technologies necessary to assess their efficacy. Finally, promising techniques for investigating the intricacies of the HBV life cycle in the liver are highlighted.

THE VIRUS AND ITS GENOME

VIRION MORPHOLOGY Three types of virus-associated particles are found in serum of an HBV-infected individual. (1) HBV virions measuring 42 nm in diameter, comprising an outer envelope formed by the HBsAg. This envelope surrounds an inner nucleocapsid consists of the hepatitis B core antigen (HBcAg) that contains the packaged viral genome and an endogenous viral DNA polymerase; (2) abundant spherical particles of approx 22 nm in diameter that are in a 10^4–10^6-fold excess over the HBV virions; and (3) filamentous structures of approx 20–22 nm in diameter and of variable length. The latter two forms of subviral particles consist of virus-derived glycoproteins (GP) of HBsAg and do not contain the HBV genome and are thus not infectious. The purified 22 nm particles are highly immunogenic and when administered to normal individuals in the form of the hepatitis B vaccine, are able to induce a neutralizing anti-HBs antibody response.

HBV GENOME The HBV genome is a circular, partially double-stranded relaxed circular DNA molecule of approx 3200 nucleotides (nt) in length (Fig. 53-1). The two linear DNA strands are held in a circular configuration by a 226-bp cohesive overlap between the 5′ ends of the two DNA strands that contain two 11-nt direct repeats called DR1 and DR2. All known complete HBV genomes are gapped, nicked, and circular, comprising 3181–3221 nt depending on the genotype (Table 53-1). Within the virion, the minus strand of the genomic DNA has a fixed length with defined 5′ and 3′ ends, and a terminal redundancy of 8–9 nt. The minus strand is not a closed circle and has a nick near the 5′ end of the plus strand. The viral DNA polymerase is covalently bound to the 5′ end of the minus strand. The 5′ end of the plus strand contains an 18-base long oligoribonucleotide, which is capped in the same manner as mRNA. The 3′ end of the plus strand is not at a fixed position so most viral genomes contain a single-stranded gap region of variable size from 20 to 80% of the genomic length, which may be filled in by the endogenous viral DNA polymerase.

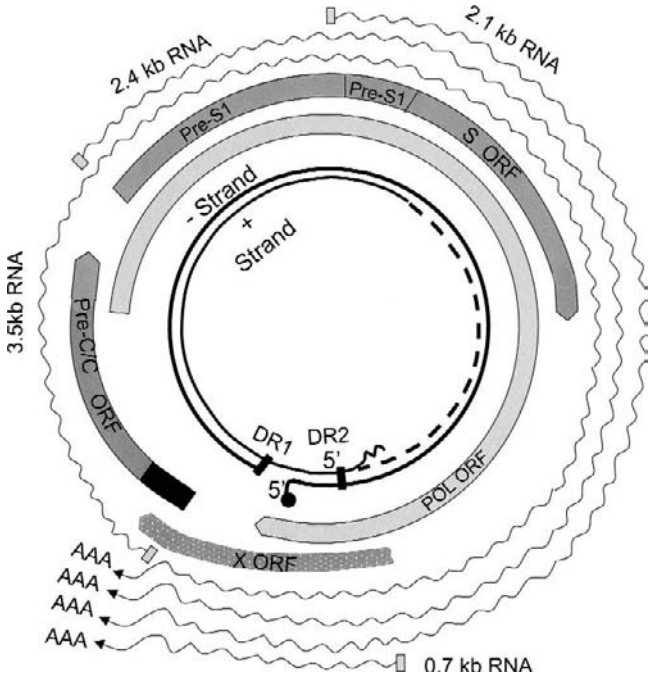

Figure 53-1 The organization of the hepatitis B virus genome. The inner circles represent the complete minus-sense strand of the genomic DNA with the viral polymerase attached to the 5′ end and the incomplete plus-sense strand with the capped RNA oligonucleotide at the 5′ end. The direct repeat sequences are designated DR1 and DR2. The four open reading frames (core [Pre-C/C], envelope [Pre-S/S], polymerase [POL], and X) are shown as the discrete thicker arrows around the genomic DNA. The outer thin circular lines depict the viral RNA transcripts, the core and pgRNA (3.5 kb), the Pre-S mRNA (2.4 kb), the S mRNA (2.1 kb) and the X mRNA (0.7 kb). Note that the transcripts all end at a common polyadenylation site (AAA).

The minus strand of HBV encodes four major open reading frames (ORFs) that carry all the protein-coding capacity of the virus: the envelope (pre-S1, pre-S2, and S), the core, the X protein and the polymerase. These overlap in a frame-shifted manner with one another, so that the minus strand is read 1.5 times. The longest ORF encodes the viral polymerase (Pol) whereas the ORF for the envelope (Pre-S/S) gene is completely located within the Pol ORF. The ORF for the core (Pre-Core/Core–Pre-C/C) and X genes partially overlap the Pol ORF. HBV is able to encode more than one protein from an ORF by using multiple internal AUG or start codons, creating additional start sites for protein biosynthesis. Thus, nested sets of proteins with different N-termini are synthesized. This gene overlap, although genetically economical, places constraints on the mutation and evolution rates.

Regulatory Elements Controlling Viral Replication Multiple regulatory elements involved in the regulation and expression of each individual HBV gene are located throughout the whole length of the viral genome. Because every region of the HBV genome is a protein-encoding sequence, all *cis*-acting regulatory elements reside within gene sequences. HBV genomic expression is regulated by two enhancers (*Enh*I and II), four promoters, a glucocorticoid response element, a negative regulatory element, and a CCAAT element. The four promoters, consists of the basal core promoter (BCP), the Pre-S1, Pre-S2/S, and X promoters, control the corresponding four major mRNA species of 3.5 kb (Pre-C/C and pregenomic [pg] RNA), 2.4 kb (Pre-S1 mRNA), 2.1 kb (Pre-S2/S mRNA), and 0.7 kb (X mRNA) (*see* Fig. 53-1). HBV transcription is dependent to a large extent on liver-enriched transcription factors. All of these mRNA species are capped, unspliced, and share a common polyadenylation signal. Three other regulatory elements that also control HBV replication are located on the viral RNAs: the polyadenylation signal, posttranscriptional regulatory element, and the encapsidation signal (ε). The pgRNA serves as the template for reverse transcription.

Regulation of viral gene expression also occurs at the level of translation. The pgRNA serves as the mRNA not only for the viral core protein but also for the viral polymerase, which initiates from an AUG located in the distal portion of the core gene, although not in the same reading frame as core. Reading of the polymerase ORF appears to be inefficient compared to that of the core ORF. However, because core particles are assembled from 240 core subunits and only one or perhaps two polymerase proteins, pgRNA may serve as an mRNA for the translation, on average, of approx 200–300 core polypeptides before allowing the translation of a polymerase polypeptide. Because the polymerase preferentially binds to the 5′ end of its own mRNA to initiate reverse transcription and packaging, synthesis of the polymerase is probably sufficient to stop further translation of the pregenome.

Pre-S/S ORF HBsAg comprises the small (SHBs), medium (MHBs), and large (LHBs)-sized proteins (Fig. 53-2), all of which exist in two forms differing in their degree of glycosylation. N-linked glycosylation and glucosidase processing are necessary for virion, but not subviral particle secretion. The 22-nm spherical form contains approx 89% of SHBs, 10% of MHBs, and 1% of LHBs. The filamentous forms consist of the same ratio of proteins as the virion envelope, comprising approx 70% of SHBs, 10% of MHBs, and 20% of LHBs.

The 2.4-kb mRNA transcript encodes the LHBs whereas the 2.1-kb mRNA transcript encodes the MHBs and SHBs (*see* Fig. 53-2). The synthesis and assembly of the viral envelope, the small particles, and filaments occur in the endoplasmic reticulum (ER) membranes with the resultant assembled viral proteins budding into the ER lumen. The SHBs domain is 226 amino acids long and is the most abundant protein of the three HBV-associated particles. The SHBs are found in glycosylated (GP27) and nonglycosylated (P24) forms. They contain a high number of cysteine residues that are crosslinked with each other, forming a conformational loop that is the major antigenic determinant of the HBsAg (from amino acid residues 98–170), referred to as the major hydrophilic region. The most characterized mutation associated with vaccine escape, sG145R, is located within this region.

The MHBs containing the Pre-S2 domain are a minor component of the virion or subviral particles and consists of SHBs with a 55 amino acid N-terminal extension. The MHBs are either doubly or singly glycosylated (GP36 and GP33) and are required for virus secretion. However, this protein is not required for infectivity or virus assembly. The MHBs are considerably more immunogenic than SHBs, and Pre-S2-containing HBs particles generated from animal cell lines have been used in some countries as a prophylactic vaccine. The LHBs contain an additional 108 or 119 amino acids (depending on the subtype/genotype; *see* Table 53-1) in comparison to MHBs at its N terminus. The LHBs are mainly glycosylated (GP42) and myristylated, and are essential for viral infection, assembly, and release. A small amount of this protein is nonglycosylated (P39). A number of B- and T-cell epitopes have been mapped to LHBs, MHBs, and SHBs. The Pre-S1 region contains

Table 53-1
Overview of the Eight Major Genotypes of HBV

Genotype	Subtype	Genome length (nt)	HBV Proteins (no. of amino acids)			Frequency of mutation[a]		Global distribution
			PreS1[b]	Pol	Core	PC	BCP	
A	adw2, ayw1	3221	119	845	185	Uncommon (C1858)	Common	Western Europe, USA, Central Africa, India
B	adw2, ayw1	3215	119	843	183	Common (T1858)	Common	Japan, Taiwan, Indonesia, China, USA
Bj	adw2, aywl	3215	119	843	183	Common	Uncommon	Japan
Ba	adw2, aywl	3215	119	843	183	Low	Uncommon	China, Taiwan, Indonesia, Vietnam
C	adw2, adr, ayr	3215	119	843	183	Common T/C1858	Common	East Asia, Taiwan, Korea, China, USA, Japan, Polynesia
D	ayw	3182	108	832	183	Common T1858	Common	Mediterranean region, India, USA
E	ayw	3212	118	842	183	ND	ND	West Africa
F	adw, ayw	3215	119	843	183	Uncommon (C1858)	ND	Central and South America, Polynesia
G	adw	3248	108	842	195	Very common (insertion)	ND	USA, Europe
H	adw	3215	119	843	183	ND	ND	Central, South America

HBV, hepatitis B virus; ND, not described; Pol, polymerase.
[a]PC, Precore mutations such as G1896A; BCP, basic core promoter mutations such as A1762T, G1764A; common (up to 50% of isolates); uncommon (less than 10% of isolates); very common (most isolates).
[b]Pre-S2, 55aa; S, 226aa.

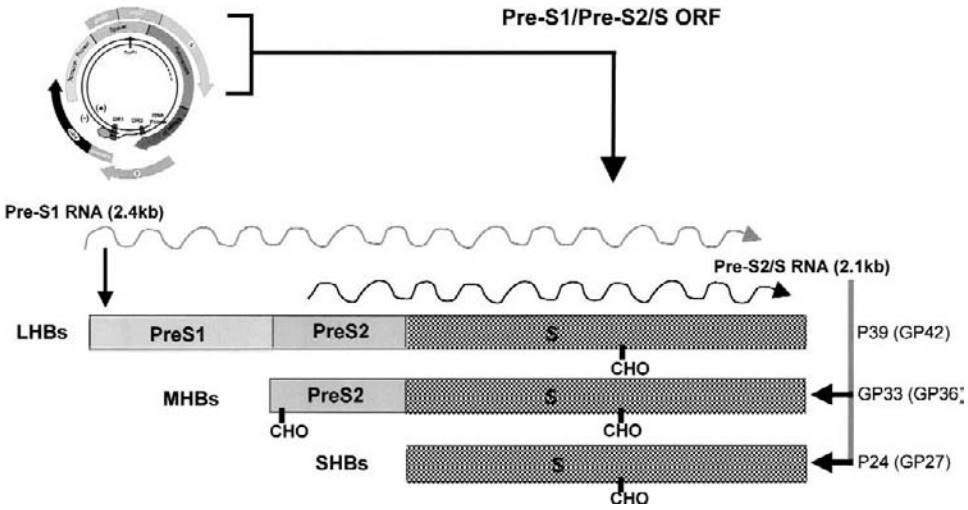

Figure 53-2 Pre-S1/Pre-S2/S open reading frames. The Pre-S/S open reading frame can be divided into Pre-S1, Pre-S2, and S domains by three in-frame start codons. The proteins encoded by the open reading frame are expressed from two mRNA transcripts. The larger 2.4-kb Pre-S1 mRNA leads to expression of the large-sized proteins, whereas the Pre-S2/S 2.1-kb mRNA encodes medium-sized proteins and small-sized proteins. MHBs are translated using the first start codon and SHBs from the internal start codon. LHBs can be detected as a nonglycosylated species (P39) but its major form is glycosylated (GP42). SHBs are found in both glycosylated (GP27) and nonglycosylated (P24) forms, whereas MHBs are glycosylated either at one (GP33) or two (GP36) sites.

two important epitopes. One at amino acid residues 58–100 is thought to be recognized by antibodies involved in viral clearance. The other, at residues 21–47 is thought to be the hepatocyte binding domain. The N terminus of Pre-S2 can bind to the fibronectin found in liver sinusoids, providing some degree of host tissue specificity. Interestingly, most of the Pre-S2 is not essential for viral replication or virion infectivity whereas only residues 109–113 are indispensable.

There are four different alleles within the *S* gene: r, d, y, and w. The determinants d/y and w/r are mutually exclusive, thus forming two allelic groups. The "a" determinant (amino acid residues 107–149) is part of all HBs subtypes and can be divided into two alleles that differ at amino acid 126 being either threonine or isoleucine. The main subtypes are designated ayw, ayr, adw, and adr. The clinically most important determinant of HBsAg is the "a" determinant (Fig. 53-3). During the natural course of infection,

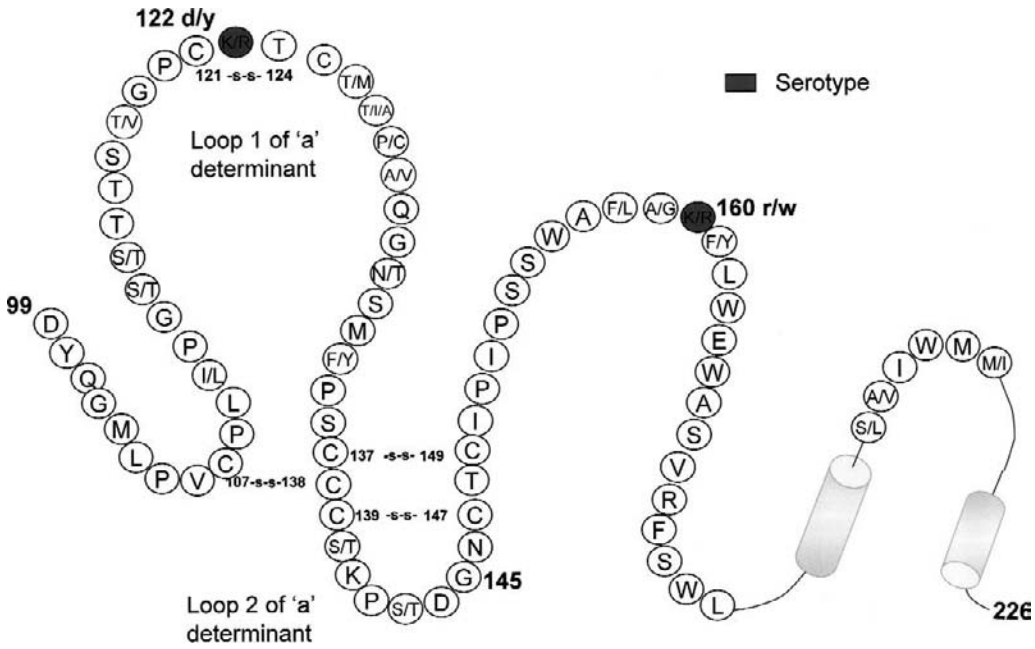

Figure 53-3 Schematic model of hepatitis B surface antigen. The two loops of the "a" determinant are stabilized by disulphide bridges (s–s) between cysteine residues. The C-terminal end of the protein has two alpha helices (shown as cylindrical structures). Serotype-specific epitopes are located in the "a" determinant. A point mutation that converts K122 to R122 (K122R) changes the *d* subtype to *y* and a similar mutation at K160R changes subtype *w* to *r*. These produce the four major subtypes of hepatitis B virus—*adw, adr, ayw,* and *ayr*. The location of the glycine residue that is modified to arginine (G145R) in virus associated with vaccine escape is shown. (Modified from Wallace et al., 1997.)

antibodies against all the determinants are produced, but only the antibodies against the "a" determinant are protective against a challenge with other HBV subtypes. The "antigenic" conformation of the "a" determinant is regarded as a two-loop structure stabilized by disulphide bridges between Cys-107 and Cys-138 (first loop) and Cys-139 and Cys-147 (second loop) whereas Cys-137 binding to Cys-149 stabilizes the interaction (*see* Fig. 53-3). If this conformation is altered, then anti-HBs produced previously against the native "a" determinant are no longer protective.

Pre-C/C ORF The Pre-C/C ORF encodes the core protein (P21), which is the major polypeptide of the nucleocapsid and is expressed as the HBcAg (Fig. 53-4). The HBc protein is 183, 185, or 195 amino acids long, depending on the genotype of the virus (*see* Table 53-1). ORF C is preceded by a short, upstream, in-phase ORF known as the precore region from which the soluble hepatitis Be antigen (HBeAg) is synthesized (*see* Fig. 53-4). Both the core (HBcAg) and precore (HBeAg) proteins are targets for immune-mediated viral clearance mechanisms.

Translation of the precore region from the 3.5-kb Pre-C/C mRNA results in a 25-kDa polypeptide. The first 19 amino acids of the precore protein represent a secretion signal that allows for the translocation of the precore protein into the lumen of the ER (*see* Fig. 53-4). The signal sequence is cleaved off by a host cell signal peptidase and the protein is secreted through the ER and Golgi apparatus. A further modification of the C terminus results in the secretion of a heterogeneous population of proteins (15–18 kDa), which is serologically defined as HBeAg. The precore protein is not essential to viral replication and thus can be regarded as an "accessory protein."

The HBc protein is translated in the cytosol from the 3.5-kb pg mRNA after which these proteins initially form dimers, followed by multimerization to form the nucleocapsid. The HBc protein has been crystallized and the nucleocapsid protein has been mapped using cryoelectron microscopy. The multimerization of the HBc protein can occur independently of the encapsidation of the pgRNA–Pol complex. The core protein can be divided into two major domains, the N-terminal assembly domain (up to amino acid 144) and the C-terminal arginine-rich region involved in RNA–DNA binding interactions. The core protein can self-assemble into capsids, and two icosahedral shells of different sizes have been observed: particles with a $T = 3$ symmetry containing 90 homodimers of 32 nm, and particles with a $T = 4$ symmetry consisting of 120 homodimers of 36 nm.

Pol ORF The *Pol* gene is the longest ORF, spanning almost 80% of the genome, and overlaps the three remaining ORFs (*see* Fig. 53-1). Codons 834–845 in the Pol ORF have sequence homology to known reverse transcriptases (rts) and most parts of the ORF are essential for viral replication. The Pol protein is translated from the pgRNA (*see* Fig. 53-4). The 90-kDa product of the Pol ORF is a multifunctional protein that has at least four domains: (1) the N-terminal domain that encodes the terminal protein, which is covalently linked to the 5′ end of the minus strand of virion DNA. This part of the Pol ORF is necessary for priming minus-strand synthesis; (2) an intervening domain with no specific recognized function, referred to as the spacer or tether region; (3) the third domain that encodes the RNA- and DNA-dependent DNA polymerase activities, i.e., the rts; and (4) the C-terminal domain that encodes RNase H activity that cleaves the RNA in the RNA/DNA hybrids during the reverse transcription process.

The terminal protein's role in protein priming reverse transcription includes the provision of the substrate tyrosine at amino acid 63 of the HBV Pol for the formation of the covalent bond between the enzyme and the first nucleotide (G) of the minus-strand DNA. The DNA polymerase domain contains the amino-acid motif YMDD,

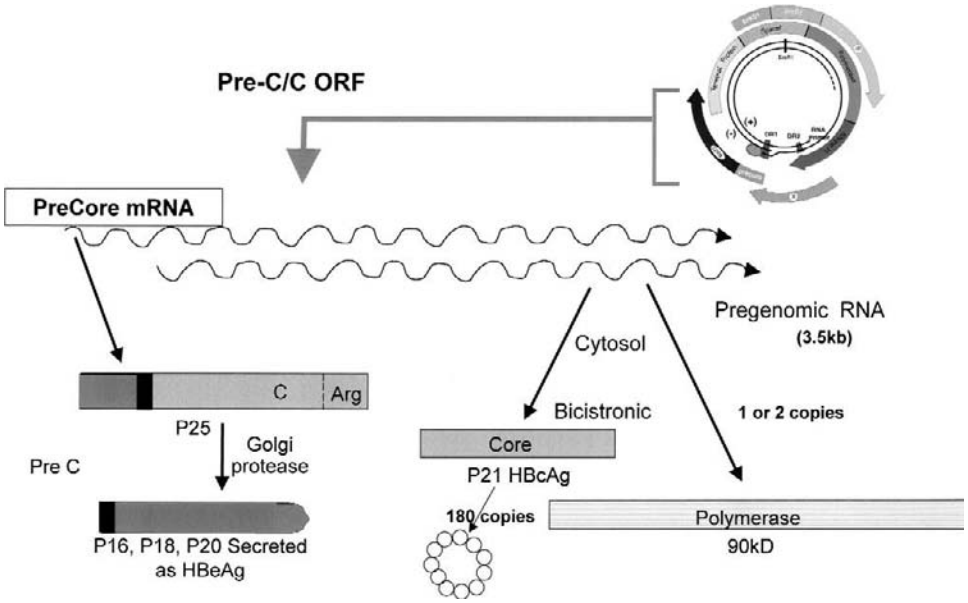

Figure 53-4 Core (Pre-C/C) open reading frame. The pregenomic RNA acts as a bicistronic mRNA. It codes for the polymerase protein and, by using an internal start codon, it also produces a translation product corresponding to the core protein (hepatitis B core antigen or P21). Multiple copies of the core protein can self-assemble into particles. Initiation of translation from the precore mRNA leads to production of a precore polypeptide (P25). The N terminus of this polypeptide has a signal sequence that targets it to the secretory pathway. The signal sequence is cleaved off by a host cell signal peptidase and the C terminus of the polypeptide is further cleaved by Golgi proteases to produce a heterogeneous population of proteins (P16, P18, and P20) known collectively as hepatitis Be antigen.

which is essential for rt activity. The RNase H domain, as well as being involved in degrading the RNA template, has other functions, including playing a role in viral RNA packaging, optimizing the priming of minus-strand DNA synthesis and in elongation of the minus-strand viral DNA.

Several cytotoxic T-lymphocyte (CTL) epitopes have been mapped to the polymerase protein. Six CTL epitopes within the rt or the RNase H domains of the viral polymerase have been described in patients with acute hepatitis. The epitope (GLSRYVARL) appears most relevant for interferon responsiveness and viral clearance. It has been suggested that Ser-457, Ala-461, or Arg-462 are contact sites for the T-cell receptor. If these critical amino acids are changed by mutation, then the T-cell receptor binding activity will be reduced and the CTL-mediated immune response attenuated and/or blunted.

The advent of nucleoside per nucleotide analog treatment has resulted in the outgrowth of otherwise minor quasispecies with mutations in the HBV *Pol* gene. Antiviral resistance to lamivudine (LMV) has been mapped to the YMDD locus in HBV Pol. Using the newly described nomenclature system, the major mutations within the rt gene that were selected during LMV therapy results in changes designated rtM204I/V (domain C, methionine at position 204 replaced by isoleucine or valine) with or without rtL180M (domain B). The domain B mutation rtL180M is also selected during famciclovir treatment. Recently, the development of adefovir (ADV)-resistant HBV with changes in the domain D (rtN236T) and domain B (rtA181T/V) of the viral polymerase has been described as has entecavir resistant virus with changes in domains B and C (rtS184G and rtS202I).

X ORF The X ORF produces a 0.7-kb mRNA transcript encoding a polypeptide 154 amino acids in size (HBx) with a predicted molecular weight of 16–19 kDa (*see* Fig. 53-1). When first identified, the function of the X protein was unknown and thus, the X designation was assigned. HBx is the second accessory protein of HBV and is dispensable for virus production in vitro, but is a critical component of the infectivity process in vivo. The C-terminal portion of the protein seems to be associated with the transactivating properties of X whereas the N terminus appears to act as a negative regulator of transactivation. HBx can act in the cytosol and in the nucleus. HBx behaves as a transcriptional transactivator for a number of viral and cellular gene promoters through direct interaction with transcription factors such as RPB5 subunit of RNA polymerase II, TATA-binding protein, and ATF/CREB (nuclear pathways). The cytoplasmic pathways are divided into protein kinase C (PKC)-dependent and -independent mechanisms. HBx interacts directly with inactive cytosolic PKC thereby activating it. In the PKC-independent cytosolic pathway, HBx is involved in the activation of signal transduction pathways, such as the Ras/Raf/MAP kinase cascade. The Ras pathway leads to the phosphorylation and activation of the transactivating domain of *c-jun*.

HBx is a multifunctional viral regulator that modulates transcription, cell responses to protein degradation, and signaling pathways. Such regulation of viral and cellular genes affects viral replication and viral proliferation, directly or indirectly. HBx has been implicated in the development of HCC and affects cell cycle checkpoints, cell death, and carcinogenesis. Although the precise mechanism remains uncertain, the HBx-associated transactivation activity may lead to alterations in cellular gene expression that contribute to cell transformation. HBx can bind to and inactivate the transcription factor and tumor suppressor, p53. In addition, the HBx can dampen the immune response by interfering with the ubiquitin-proteolysis pathway following binding with a 26S proteasome complex.

VIRAL GENOTYPES

There are eight recognized genotypes of HBV designated A to H, which vary by 8% at the nucleotide level over the entire genome.

These HBV genotypes have unique insertions or deletions. For example, HBV genotype A varies from the other genotypes by an insertion of 6 nt in the terminal protein region of the polymerase gene, whereas HBV genotype D has a 33-nt deletion in the spacer region of the polymerase gene, and HBV genotypes E and G have a 3-nt deletion in the same region (*see* Table 53-1). HBV genotype G also has a 36-nt insertion in the N terminus of the core gene. Genotype H has been defined and is most similar to genotype F. The HBV genotype designation is based on the entire genomic sequence. Thus, it is more reliable than the serological subtype nomenclature used previously, which was based on the immunoreactivity of particular antibodies to a limited number of amino acids in the envelope protein. The relationship between the four major HBV subtypes (*adw, adr, ayw,* and *ayr)* and genotypes has been determined (*see* Table 53-1).

Important pathogenic and therapeutic differences do exist among HBV genotypes. For example, genotype C is associated with more severe liver disease than genotype B in Taiwan, whereas genotype D is associated with more severe liver disease than genotype A in India. Genotypes C and D are associated with a lower response rate to interferon therapy compared with genotypes B and A. Recombination between two HBV genotypes has been reported for genotypes B and C and genotypes A and D generating even more diversity. Furthermore, there is evidence for the widespread distribution of related hepatitis viruses in primates, implying that these viruses may have a common origin and that cross-species transmission of hepadnaviruses may have occurred among hominoids.

COMMON HBV MUTANTS

Viral and host factors, as well as exogenous selection pressures, typically define the predominate species in an infected individual. Exogenous pressures include nucleoside per nucleotide analog treatment, as well as immune-based intervention such as hepatitis B immunoglobulin, and vaccination. The presumably immune-based selection pressure that results in the reduction or loss in HBeAg and eventual elimination of HBsAg are probably responsible for the selection of particular mutants such as those associated with CH-B.

Viral rts lack proofreading function and are inherently error-prone, which ensures that HBV populations exist in the host as heterogeneous mixtures known as quasispecies. The HBV mutation frequency has been estimated to be approx $1.4–3.2 \times 10^{-5}$ nt substitutions/site/yr, approx 10-fold higher than other DNA viruses. The magnitude and rate of virus replication are also important in the process of mutation generation, with the total viral load in serum frequently approaching 10^{11} virions/mL. Most estimates place the mean half-life of the serum HBV pool at approx 1–2 d, so that the daily rate of *de novo* HBV production may be as great as 10^{11} virions. The high viral loads and turnover rates, coupled with poor replication fidelity, all influence mutation generation and the extent of the HBV quasispecies pool. However, these are less than for other retroviruses, mainly because of the constraints imposed by the overlapping reading frames.

MUTATIONS IN THE BCP REGION AND PRECORE GENE Two major groups of mutations have been identified that result in reduced or blocked HBeAg expression. The first major group includes a translational stop codon mutation at nt 1896 (codon 28: TGG; tryptophan) of the precore gene. The single base substitution (G-to-A) at nt 1896 gives rise to a translational stop codon (TGG to TAG; TAG = stop codon) in the second last codon (codon 28) of the precore gene located in the ε structure. The ε structure is a highly conserved stem loop structure critical in viral replication, with the nucleotide G1896 forming a bp with nt 1858 at the base of the stem loop. In HBV genotypes B, D, E, G, and some strains of genotype C, the 1858 is a thymidine (T) (*see* Table 53-1). Thus, the stop codon mutation created by G1896A stabilizes the ε structure (T–A). In contrast, the precore stop codon mutation is rarely detected in HBV genotype A, F, and some strains of HBV genotype C, as the nucleotide at position 1858 is a cytidine (C), maintaining the preferred Watson–Crick basepairing (G–C). Other less common mutations have been found such as precore codon 17 (G1862T), which can alter the processing of the precore proteins in the Golgi apparatus. Interestingly, the mutation at the precore codon 29 (G1899A) has been found in isolation or in association with the G1896A or G1862T, but its significance is unclear as it has no translational effect.

The second major group of mutations affects the BCP at nt1762 and nt1764 resulting in a transcriptional reduction of the Pre-C/C mRNA. Mutations in the BCP, such as A1762T plus G1764A, may be found in isolation or in conjunction with precore mutations, depending on the genotype. The double mutation of A1762T plus G1764A results in a decrease in HBeAg production, but not disappearance and interestingly, an increase in viral load. In general, this pattern of mutation is often found in genotype A-infected individuals. BCP mutants display reduced binding of liver-specific transcription factors resulting in less Pre-C/C mRNA transcripts and, thus, less precore protein. However, this mutation does not affect the transcription of pgRNA or the translation of the core or polymerase protein. By removing the inhibitory effect of the precore protein on HBV replication, the BCP mutations appear to enhance viral replication by suppressing Pre-C/C mRNA relative to pgRNA.

MUTATIONS IN THE CORE GENE The core protein can be divided into two major domains, the N-terminal domain up to amino acid position 144, and the functionally important arginine-rich C-terminal domain. The C-terminal domain (up to amino acid 164) is required for encapsidation of the pgRNA and seems to stabilize the capsid by protein–nucleic acid interactions. The remaining C terminus (up to amino acid 173) appears important for the synthesis of plus-strand DNA and subsequent genomic replication.

The core protein contains a number of important B-cell and CTL epitopes. During the elimination phase of CH-B, escape mutations within those epitopes are readily selected. These "hot spots" have been linked to major CTL (aa 18–30) and T-helper (T_H) cell (aa 50–70) regions and to two B-cell (HBc/eI and HBc/e2) epitopes at residues 75–90 and 120–140, respectively. The HBcAg and HBeAg are highly cross-reactive at the T-cell level. The HBeAg probably presents immunogenic epitopes to the T cells, thus "protecting" the HBcAg-expressing hepatocytes against the immune system. After selection of the HBeAg-negative mutant(s), the epitopes of the HBcAg come under intense pressure from the immune system. Thus, the frequency of core gene mutations is typically associated with the presence of precore stop codon mutations, HBeAg-negativity, and active liver disease.

MUTATIONS IN THE X GENE The X-ORF overlaps the C terminus of the *Pol* gene and the N terminus of the *C* gene (*see* Fig. 53-1). Depending on the extent of the mutation(s) within the X region, mutations can affect three genes at once. X-region deletions can create fusion proteins between the pol and the core proteins (PC-proteins) or between the pol and a 3′-truncated HBx (PX-proteins).

Typically, mutations in the X region involve the regulatory elements that control replication. Because the BCP encompasses nts

1742–1802 and overlaps with the X gene in the concomitant reading frame, the A1762T plus G1764A BCP mutations also cause changes in the X gene at xK130M and xV131I. Additionally, nearly all deletions/insertions in the BCP shift the X-gene reading frame and lead to the production of truncated X proteins. These shortened X proteins lack the domain in the C terminus (aa 130–140) that is required for the transactivation activity of HBxAg.

The two direct repeat sequences, DR-1 and DR-2, lie within the BCP sequence and are considered important in reverse transcription. Between DR-1 and DR-2 lies the cohesive end region of the HBV genome and this appears to be a preferred site for viral integration into host DNA. Interestingly, the cohesive end region near DR-1 contains a preferred cleavage site for topoisomerase I that can catalyze illegitimate recombinations between HBV and cellular DNA; following viral integration, deletions in this region have been found.

MUTATIONS IN THE ENVELOPE GENE The Pre-S sequences exhibit the highest heterogeneity of the HBV genome. Point mutations, deletions, and genetic recombinations within the *Pre-S* genes have been identified in HBV DNA sequences analyzed from the sera of chronic carriers. Deletions within the Pre-S region can affect the S promoter causing an imbalance in envelope assembly resulting in intracellular retention and accumulation of HBsAg. Viral genomes, which cannot synthesize Pre-S2 proteins, occur frequently, and can be the dominant virus populations in chronic carriers. The Pre-S2 region overlaps the spacer region of the Pol protein that is not essential for enzyme activity. It has been speculated that the loss of the highly immunogeneic Pre-S2 protein reflects an immunological escape mechanism.

All hepatitis B vaccines contain the major HBsAg, and an immune response to the major hydrophilic region located from residue 99–170 induces protective immunity. Mutations within this epitope have been selected during vaccination and also following treatment of liver transplant patients with hepatitis B immunoglobulin. Most isolates have a mutation from glycine to arginine at residue 145 of HBsAg (sG145R) or aspartate to alanine at residue 144 (sD144A). The sG145R mutation has been associated with vaccine failure. Mutations that abolish or alter the two-loop structure of the "a" determinant can affect anti-HBs binding. Such effects include changes in the hydrophobicity, the electrical charge, the acidity of the loops, addition of possible additional N-glycosylation sites (glycine-130 to Asn), or changing the stability of the disulphide bridge (Cys-147 to Gly). Finally, mutations near the "a" determinant, such as an insertion of eight amino acids between Thr-123 and Cys-124, two amino acids between Cys-121 and Lys-122 or of arginine between Pro-120 and Cys-121 can disturb the secondary structure of the "a" determinant.

POLYMERASE MUTATIONS: ANTIVIRAL DRUG RESISTANCE The advent of nucleoside per nucleotide analog treatment has resulted in the outgrowth of otherwise minor quasispecies with mutations in the HBV *Pol* gene. Antiviral resistance to LMV has been mapped to the YMDD locus, the catalytic site in the C domain of HBV polymerase, whereas resistance to ADV is associated with mutations in the D domain of the enzyme. Mutations within the rt gene that were selected during LMV therapy cause changes that are designated rtM204I/V/S (Domain C) +/–rtL180M (Domain B), whereas rtN236T (D-domain) and rtA181T are the major changes associated with ADV-resistant virus.

Lamivudine Resistance LMV resistance increases progressively during treatment at rates between 14 and 32% annually, approaching 100% after 48 mo treatment. Factors that increase the risk of development of resistance include high pretherapy serum HBV DNA levels and ALT levels and incomplete suppression of viral replication. LMV resistance does not confer cross-resistance to ADV.

Mutations that confer LMV resistance decrease in vitro sensitivity to LMV from at least 20-fold to greater than 100-fold. The rtM204I substitution has been detected in isolation, but rtM204V and rtM204S are found only in association with other changes in the B or A domains. Numerous other secondary changes in the rt sequence also occur in conjunction with rtM204V/I/S, and some of these are probably compensatory.

Lamivudine resistance is mainly owing to steric hindrance resulting from the replacement of the methionine residue in the YMDD motif with either of the branched amino acids valine or isoleucine, which decrease the ability of the polymerase to bind the nucleoside analog in the deoxynucleotide triphosphate binding pocket relative to the natural substrate.

Adefovir Dipivoxil Resistance HBV resistance to ADV occurs less frequently (approx 2% after 2 yr, 5% after 3 yr, and 16% after 4 yr) than resistance to LMV. ADV resistance is conferred by substitution of threonine for asparagine at codon 236 (rtN236T), which is located in the D domain of the polymerase a change that does not significantly affect sensitivity to LMV, and/or the rtA181V/T change, which is located in the B domain of the enzyme. The mechanism of resistance by N236T has been determined to be indirect perturbation of the triphosphate binding site whereas indirect steric hindrance accounts for resistance owing to rtA181V/T. Both mutations, either together or separately, decrease sensitivity to the drug by less than 10-fold.

Entecavir Resistance Resistance to entecavir has been observed in two patients who had already failed to respond to LMV. The viral load increase was associated with clinical deterioration and rising levels of serum ALT. Sequencing of the HBV pol gene at the time of viral breakthrough confirmed LMV resistance and identified several unique mutations associated with entecavir resistance.

- Patient A: rtI169T (B-domain) and rtM250V (E-domain).
- Patient B: rtT184G (B-domain) and rtS202I (C-domain).

These changes have been confirmed to be associated with entecavir resistance by using in vitro phenotypic assays.

Telbivudine Resistance Telbivudine is the β-L isomer of thymidine. After 24 wk of therapy, it results in a 4–6 log drop in HBV DNA levels. Resistance occurred at the rate of 5% per annum and resulted in the selection of the rtM204I mutation, indicating cross-resistance with LMV.

Pol-Env Link The envelope gene lies completely within the *Pol* gene but in a frame-shifted manner. Thus, mutations in one gene have the potential to affect the product(s) of the other gene. For example, some mutations in the *Pol* gene that confer drug-resistance affect the immunogenicity of the envelope gene products (Fig. 53-5). Conversely, immune selection can influence antiviral drug sensitivity. Cases of transmission of drug-resistant HBV have been reported. The clinical and public health importance of drug resistance is clear; improved treatment strategies are urgently required to ensure prevention of resistance.

Pathogenicity of Drug Resistant HBV: Role of Compensatory Mutations Compensatory mutations that partly or wholly restore the level of viral fitness have been documented during therapy for HIV infections and similar scenarios have been described for HBV.

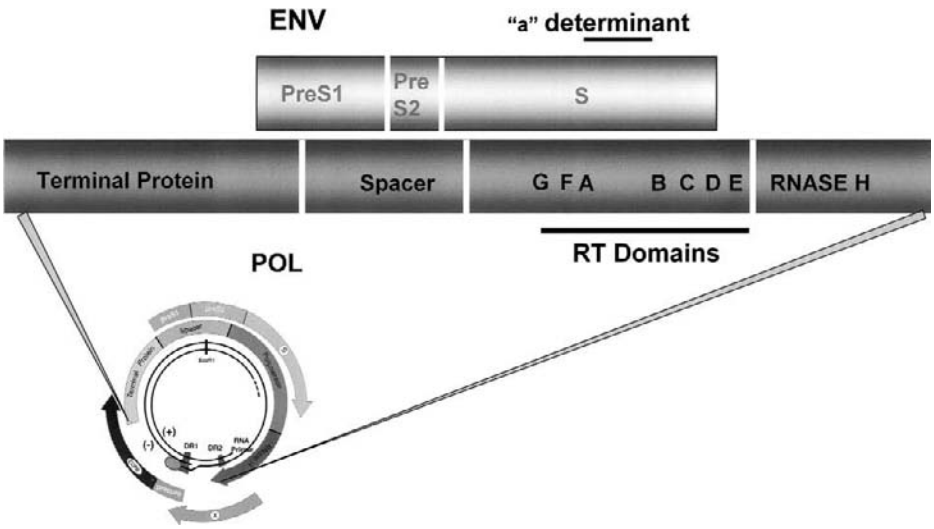

Figure 53-5 The Pol–Env link. The genomic organization of HBV is such that the Pre-S/S open reading frame (ENV) is completely overlapped by the polymerase (POL) open reading frame. Resistance to nucleoside/nucleotide analogs is caused by changes in the reverse transcriptase domain of the polymerase and this has the potential to select viruses with changes in the overlapping *S* gene, which may affect the *a* determinant. Similarly, changes to the *S* gene caused by immune selection may have the ability to modify drug sensitivity by altering the *Pol* gene and affecting the RT domain.

A high frequency of the co-occurrence of rtL80V/I (domain A) and rtL180M has been observed in conjunction with the M204V/I changes that confer LMV resistance in treated Japanese patients (genotype C). The presence of double and triple changes was associated with higher viral loads, increased LMV resistance, and disease exacerbation. Longitudinal studies showed that the mutations responsible for these sequence changes occurred almost simultaneously, just before viral breakthrough and also that the mutants were displaced by wild-type genotype C HBV after completion of therapy.

Similar observations have been recorded for liver transplant patients who developed life-threatening HBV recurrence. HBV isolates from these patients had compensatory mutations that enhanced their in vitro replication efficiency in the presence of LMV. Even greater enhancement and drug dependency occurred when mutations resulting in sG145R or sP120T, key changes in the envelope protein, were also present.

Mutations that abolish or decrease the expression of HBeAg affect replication efficiency. HBeAg-negative CH-B, which is common in the Mediterranean region, is usually characterized by lower serum HBV DNA levels than those found during HBeAg-positive CH-B. A group of HBeAg-negative CH-B patients have been studied who were infected with genotype D HBV that contained both BCP and precore stop codon mutations. Development of LMV resistance in these patients was associated with relatively rapid increases in viremia, frequently culminating in biochemical breakthrough, severe hepatic flares, and disease progression. In vitro studies confirmed that the presence of the typical precore mutation (G1896A) could compensate for the replication deficiency in LMV-resistant HBV quasispecies. Several case studies have confirmed that drug resistant HBV mutants are capable of causing severe, even fatal, disease, challenging the notion that drug resistant HBV mutants, and other minority quasispecies are benign.

These reports and the observed enhanced replication of HBV in the presence of LMV as well as the precore mutant have led to the conclusion that multiple mutations are continually selected during inadequate antiviral therapy and that these can act as compensatory mutations having the potential to restore replication competence.

MOLECULAR DIAGNOSTICS—SERUM COMPARTMENT

The natural history of CH-B can be divided into replicative and nonreplicative stages. As there is no practical measure of HBV infectivity, assays of serum HBV DNA by sensitive molecular methods have provided an indication of the level of viral replication. Also, the detection of particular viral proteins in an infected liver by immunohistochemical techniques can indicate the presence of active replication.

Development of potent chemotherapy to control CH-B, primarily using nucleoside per nucleotide analogs, has made it necessary to use more sophisticated methods for monitoring their effectiveness than traditional biochemistry and serology markers. Sensitive nucleic acid tests (NATs) are available to detect HBV DNA, employing signal or target amplification technologies, and each has advantages and disadvantages. Generally, the signal amplification assays have reduced sensitivity compared to the target amplification assays, which in turn suffer from a restricted upper range. Furthermore, the various assays may express the results in different units making comparisons difficult and highlighting the need for standardization.

New generation amplification assays have become commercially available that have been standardized to the World Health Organization international reference standard. These include an improved chemiluminescent signal amplification assay (Bayer VERSANT HBV 3.0 test) and assays exploiting the greater dynamic range intrinsic to kinetic or real-time PCR (Roche COBAS TaqMan HBV test and Artus RealArt HBV LC PCR reagents) (Fig. 53-6).

BAYER VERSANT HBV 3.0 TEST This amplification assay employs a series of sequential nucleic acid hybridization steps to produce a chemiluminescent signal that is proportional to the amount of HBV DNA in the original sample. The first step involves denaturation of the partially double-stranded HBV DNA so that

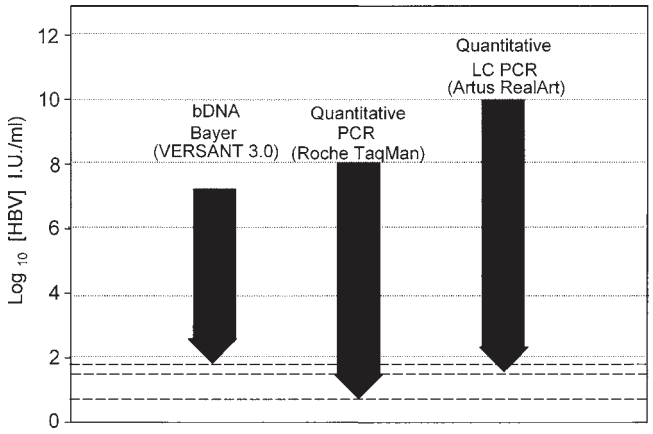

Figure 53-6 Dynamic range (expressed in IU/mL) of commercially available quantitative hepatitis B virus DNA assays. The Bayer VERSANT 3.0 bDNA assay relies on signal amplification whereas the Roche TaqMan and Artus RealArt assays rely on target amplification by real-time polymerase chain reaction.

target synthetic DNA oligonucleotides (probes) can bind to single-stranded portions of the HBV DNA. The target probes are a mix of two separate oligonucleotides and each oligonucleotide has two binding regions. Both have a region for specific hybridization to HBV DNA; one probe also has region to hybridize to a capture probe that is immobilized on the plastic surface of a microwell plate and the other probe has a portion complementary to a highly branched synthetic oligonucleotide (hence bDNA), which is subsequently added to the mix. The branches of the bDNA oligonucleotides are designed to have repeat sequences that allow multiple hybridization of another oligonucleotide (label probe) that is conjugated with alkaline phosphatase. On addition of a chemiluminescent substrate, a signal is generated and by comparison to a standard curve, a viral load can be determined. The assay has a wide dynamic range reporting in both copies/mL and International Units (IU)/mL. The lower limit of the assay is 357 IU/mL (2×10^3 copies/mL) and the upper limit is 17,587,100 IU/mL (10^8 copies/mL).

Signal amplification assays do offer some advantages over the target or nucleic acid amplification assays. There is no need for an extensive sample preparation to purify the DNA and because no amplicons (amplified subunits of DNA) are generated, there is no need for the stringent contamination control procedures employed for target amplification assays such as PCR.

ROCHE COBAS TAQMAN HBV TEST This commercial assay supercedes the previous COBAS AMPLICOR HBV MONITOR assay, which relied on coamplification of a modified HBV DNA standard of known copy number to allow quantification. The MONITOR end point PCR assay suffered from a limited upper dynamic range mainly because of the saturation effects inherent in such technology. The development of real-time or kinetic PCR has overcome many of these deficiencies. In kinetic PCR, product is detected as it accumulates by the use of fluorescent-based detection chemistry. This allows a signal to be monitored following each thermal cycle without having to sample directly from each tube, which also reduces the contamination risks. The Roche COBAS TaqMan HBV test uses a dual fluorophore labeled probe that is designed to anneal to one strand of the HBV sequence generated from the PCR primers. The reporter fluorophore's emissions are extinguished by the nearby downstream quencher fluorophore, resulting in no signal being produced. However, as the Taq DNA polymerase generates the complementary strand, the endonuclease activity of the enzyme cleaves the reporter off the probe and its emissions are no longer quenched, resulting in a measurable signal. The signal is proportional to the amount of amplicons generated, which is proportional to the amount of original target. Quantification is achieved using a linearized HBV plasmid Quantitation Standard DNA, which is incorporated with each sample and is carried through sample preparation, amplification and detection steps. The linear range of the assay is from approx 30 IU/mL to an upper limit of 1.1×10^8 IU/mL.

ARTUS REALART HBV LC PCR REAGENTS This kit contains ready-for-use reagents for the quantification of HBV DNA by real-time PCR specifically using the Roche LightCycler™ instrument (Roche Diagnostics, Mannheim, Germany). The assay uses the fluorescence resonance energy transfer technology to monitor the fluorescence intensity. Dual probes are used where the 3′ end of one probe has a donor fluorophore and the 5′ end of the second probe has an acceptor fluorophore. The probes are designed to hybridize adjacent to one another on a strand of HBV DNA. If specific HBV DNA is present, on excitation the donor fluorophore transfers energy to the acceptor that emits a signal of defined wavelength for detection. The kit also provides an internal control, which is added to the lysed sample, to monitor DNA purification and to check for any inhibition of the PCR. Quantification is achieved by reference to a standard curve generated from supplied controls. The dynamic range of the assay is from 2×10^2 to an upper limit of 10^9 IU/mL.

VIRAL LOAD—CLINICAL SIGNIFICANCE HBV DNA can be detected in acute infection before any serological marker and this may be of some use in the investigation of nosocomial outbreaks. In practice, acute infection can be diagnosed by serological detection of HBcIgM and usually HBsAg is also present. In chronic infection, the presence of HBeAg is a reliable indicator of active replication. Seroconversion from HBeAg positive to anti-HBe was presumed to be part of the immunoelimination phase of CH-B that preceded virus clearance and loss of HBsAg. Instead, it became evident that many patients without HBeAg had HBeAg-negative CH-B in which disease was ongoing, although characteristically it was associated with a lower viral load than the HBeAg-positive CH-B.

A number of workers have attempted to examine whether there is a threshold level of HBV DNA that can be used to discriminate between active and inactive disease, because markers such as HBeAg and serum transaminase levels have proved inadequate. It has been proposed some patients could be characterized as having inactive disease when they have detectable HBsAg, but without HBeAg and no transaminase elevations, and have HBV DNA levels below 10^5 copies/mL (approx 2×10^4 IU/mL). However, as previously demonstrated, many cases of HBeAg-negative CH-B have transaminase flares, meaning that there must be a greater reliance on HBV DNA levels. Evaluation of a large group of untreated patients with HBeAg-negative CH-B using regular testing of transaminase levels and histological examination when indicated, led to the conclusion that HBV DNA levels of 3×10^4 copies/mL (approx 6×10^3 IU/mL) represented a better cut off to classify a patient into the inactive carrier state.

The ability to measure HBV DNA levels has also allowed strategies to be designed to reduce the risk of virus transmission from HBV-infected healthcare workers (HCWs) to patients. Clearly, if all HCWs who were HBsAg positive were excluded from performing exposure prone procedures, there would be little

opportunity for HBV transmission. However, it can be argued that the loss of expertise of highly qualified and experienced HCWs does affect the health care system, particularly in developing countries where replacement personnel may not be available. Thus, efforts have been made to establish guidelines for the management of HBV-infected HCWs based on HBV DNA levels. Many countries exclude HBeAg-positive HCWs from certain health care duties but HBV transmission has been documented to take place from HCWs negative for HBeAg. A European consensus panel agreed that each country could individually determine a HBV DNA level cut off for HCWs performing exposure prone procedures but proposed that a maximum level of 10^4 copies/mL (approx 2×10^3 IU/mL) would provide a balanced risk management strategy. This value would take into account that transmission rarely occurred with viral loads greater than 10^5 copies/mL (approx 2×10^4 IU/mL) and provided a 1 log safety margin to account for possible intermittent flares of activity, assay variation or early development of resistance while on anti-HBV therapy. Others consider this to be a conservative estimate and counter propose that a level of 10^5 copies/mL (approx 2×10^4 IU/mL) is associated with a minimal increase in risk.

VIRAL LOAD—USES IN ANTIVIRAL THERAPY Histological examination of liver tissue and determination of serum transaminase levels are both important measures to use in assessing a patient's eligibility for antiviral therapy. Importantly, detection and quantification of serum HBV DNA should also be one of the prerequisites for eligibility because it provides the clinician with a practical tool to monitor the effectiveness of treatment.

Kinetics of Viral Load Decay on Therapy One of the most promising areas in the evaluation of antiviral therapy is the examination of the kinetics of decline in viral load. Serial viral load measurements from patients prior to therapy show that viremia is maintained at an approximately constant level, even though that level can vary from patient to patient. This indicates that there is a dynamic equilibrium between virus production and clearance that maintains this steady-state relationship. The equilibrium is disturbed by the introduction of antiviral therapy and the analysis of the rate of decline in viral load allows predictions to be made about drug efficacy using mathematical models. In simplified models, there are at least two phases of viral load decay. The initial phase corresponds to clearance of circulating virus; the rate, and magnitude of the decline reflects the drug's efficacy. The second slower phase is thought to correspond to the eradication of infected cells. For HBV, this most likely represents immune elimination of infected cells, possibly aided by natural cell turnover. Unlike the viral dynamics of other blood-borne viruses, such as HIV or HCV, there appears to be greater variation in the phases with HBV infection and more complex mathematical models have been developed to explain these features. It is hoped that application of these models will provide predictive data on treatment outcome and allow the design of more effective treatment regimes.

Monitoring Effectiveness of Treatment Treatment of chronic HBV infection with either LMV or ADV produces a rapid decrease in viremia, corresponding to the first phase of viral decay. A small proportion of patients show loss of HBeAg and normalization of serum transaminase levels. However, during the second slower phase, drug-resistant virus can appear. The emergence of drug resistance may be signaled by clinical deterioration or increasing serum transaminases. A superior indicator of the development of resistance is a relapse of HBV DNA levels in the face of ongoing therapy. Development of resistant virus can be confirmed by sequence analysis of the polymerase gene after PCR amplification in which characteristic mutations have been reported for many of the newer anti-HBV agents. A sensitive reverse hybridization line probe assay is also available but this detects only the common mutations that confer LMV resistance. Although empirically an increase in HBV DNA levels on therapy may be presumed to be resulting from the development of resistant virus, it is also important to verify that it is not because of noncompliance.

Defining End Points The development of nucleoside per nucleotide analogs as anti-HBV agents has prompted reappraisal of the traditional end points used to assess drug efficacy. For treatment with interferon, HBeAg loss or seroconversion 6 mo after therapy usually defines successful response. Treatment with the new anti-HBV agents produces a rapid decline in viremia, often to levels undetectable by even the new generation NATs. HBeAg seroconversion is uncommon and may be reversible when treatment ceases and is thus an unreliable marker. Histological examination of liver tissue can be useful but biopsies are invasive and cannot be performed on a frequent basis. Consideration has been given to using serum HBV DNA levels as an efficacy end point and although it has proven a useful tool, there is insufficient correlation with treatment responses to justify its use as a sole predictor.

OCCULT INFECTION Several case reports have described how some patients show clinical evidence of CH-B infection, despite remaining serologically HBsAg-negative. The use of sensitive NATs demonstrated that in many instances the presence of HBV DNA could be detected. Cases such as these were defined as having occult HBV infection. Several explanations have been proposed to account for the contradictory testing profile. One possibility was that mutations in the surface gene were sufficient to allow HBsAg to evade serological detection. However, studies employing sequence analysis have shown there are few instances of changes to the relevant epitopes of HBsAg. Furthermore, although mutations to regulatory elements in the HBV genome may have an indirect effect on HBsAg synthesis, these too appear to be rare.

The most significant finding in most studies of occult infection is that of a very low level of virus replication. This may be because of an incomplete immune response that allows a low level of virus replication or even an enduring cellular response that requires a low level of persistent virus replication. The clinical significance of occult hepatitis B has not been determined, although it appears that transmission of infection from patients with occult infection can occur.

QUASISPECIES Rt, an essential enzyme in the life cycle of HBV, lacks proofreading capacity and results in an estimated mutation rate of 10^{-3}–10^{-5} misincorporations per nucleotide copied. Mathematical analysis of viral load decay following antiviral therapy predicts greater than 10^{11} virus particles are produced per day. These features of HBV replication mean that heterogeneous genetic variants are generated, which are termed quasispecies. Quasispecies generation is a continuous process with competition and selection resulting in evolutionary flexibility. For HBV, the quasispecies diversity is constrained by overlapping reading frames, meaning that a mutation modifying a protein encoded by one reading frame can have a deleterious effect in the overlapping reading frame. Nevertheless, the high rates of virus production ensure that a large number of viable mutants are produced. Under selection pressure, such as from the host immune system or antiviral therapy, high quasispecies variability allows a

rapid response resulting in a new dominant quasispecies that can be further refined by selection.

QUANTIFICATION OF HBsAg HBV infection leads to overexpression of HBsAg, which is found in vast excess over virions in the blood. Before development of automated assays, quantifying HBsAg was carried out by modifying radioimmunoassays or by Laurell electrophoresis. In acute hepatitis B, peak concentrations of HBsAg decrease within 16–20 d in resolving infection as the host immune system responds. In patients with acute hepatitis B who become carriers, no such decrease is seen. Automated assays have been adapted to the quantification of HBsAg, allowing greater throughput of samples. Using such assays, HBsAg levels were found to be higher in HBeAg-positive CH-B carriers than in HBeAg-negative CH-B carriers. Importantly, HBsAg levels in both sets of patients showed a good correlation with serum HBV DNA levels, potentially providing an inexpensive alternative to the HBV DNA NATs, worthy of further investigation.

MOLECULAR DIAGNOSTICS—LIVER COMPARTMENT

IMMUNOHISTOCHEMISTRY Components of HBV that reflect replication can be demonstrated in liver biopsy sections using specialized techniques. Various HBV DNA and RNA replicative intermediates can be demonstrated by PCR and/or *in situ* hybridization. Viral proteins such as HBsAg, HBcAg, HBeAg, HBx, and Pre-S proteins can all be demonstrated by immunohistochemistry. Immunodetection of HBsAg and HBcAg in hepatocytes can provide useful information about the replicative status of HBV and is usually performed as part of a histopathological diagnosis of patients with CH-B. The pattern of antigen distribution relates somewhat to the stage of infection. Patients in the nonreplicative phase have little or no demonstratable HBcAg in the liver. In the replicative phase, HBcAg is found in the hepatocyte nuclei, and when replication is very high, in the cytoplasm as well. Cytoplasmic HBcAg tends to correlate with the activity of the liver disease. HBsAg is found in the hepatocyte cytoplasm, but it tends to be inversely related to the amount of HBcAg and to the disease activity. Patients with abundant HBcAg generally have less HBsAg overall and less per cell than those with little or no HBcAg. Patients in the nonreplicative phase of infection, with integration of HBV DNA into the hepatocyte genome, often have hepatocytes with abundant cytoplasmic HBsAg. These cells have uniformly pale, eosinophilic cytoplasm with a "ground-glass" appearance on routine hematoxylin-eosin stains. In immunostains they appear dark and discrete, compared to the pale and diffuse staining pattern of the replicative phase. Both surface and core antigens typically have a patchy distribution within the liver, and more than one pattern may be found in the same biopsy.

The cellular localization of HBcAg and HBeAg generally coincide but there are important differences at a subcellular level. HBeAg is usually detected in the nucleus and/or cytoplasm and intense or strong cytoplasmic HBeAg-staining is associated with a high serum HBV DNA level and inactive liver disease. HBcAg can also be detected in the nucleus and/or cytoplasm, but strong cytoplasmic HBcAg expression is typically associated with active liver disease. The proportion of hepatocytes expressing HBsAg correlates inversely with viremia and HBsAg and HBcAg are usually expressed independently within the lobule. Thus, cytoplasmic HBcAg (and not HBeAg) is the target for immune system-mediated cytolysis of hepatocytes. Cytoplasmic HBeAg is not associated with liver damage, but instead with high levels of HBV replication. Finally, the degree of expression of HBcAg in the hepatocyte nucleus does reflect the level of viral replication in CH-B

INTRAHEPATIC HBV COVALENTLY CLOSED CIRCULAR DNA HBV infection is not directly cytopathic, so HBV DNA can persist in the hepatocyte as long as the cell survives. In an interesting study, a commercially available HBV PCR assay was modified to investigate the levels of HBV DNA in frozen liver tissue. Subgroups of patients with CH-B were examined, including those with active replication, as defined by detection of serum HBV DNA and liver HBcAg reactivity, and those with "suppressed" replication, which included patients on antiviral therapy and patients coinfected with hepatitis D virus. Although patients with active virus replication had the highest levels of intrahepatic viral DNA, patients with suppressed HBV activity maintained relatively high levels of intrahepatic HBV DNA. The mean difference in serum HBV DNA levels between the two groups was more than 300-fold, whereas the mean difference in intrahepatic DNA levels was only approx 3-fold.

It is likely that the major component of the intrahepatic HBV DNA in the suppressed patient groups is the covalently closed circular (ccc) replicative form found in the nucleus. This viral form is produced from the partially double-stranded genomic HBV DNA found in the viral nucleocapsid. On infection, the genomic DNA is transported to the hepatocyte nucleus in which it is converted by host cell enzymes into a fully double-stranded form. From this, a ccc DNA molecule is generated that associates with cellular histones and other nuclear proteins to form a viral minichromosome. This viral replicative form, the HBV ccc DNA, remains in the nucleus and serves as the transcriptional template for HBV RNA production. The hepatocyte RNA polymerase II transcribes all the viral mRNA from the HBV ccc DNA, including the terminally redundant primary transcript, the pgRNA. This RNA molecule is encapsidated in precursors of the virus core and is reverse transcribed by the viral polymerase to form the single-stranded minus-sense DNA. The RNA is degraded by the viral RNase H and the remaining minus-strand DNA becomes the template for the synthesis of a plus-strand DNA of variable length.

Assembled nucleocapsids containing the partially double-stranded HBV DNA can follow either of two pathways. They can become enveloped by the HBV surface proteins and be secreted from the cell or be recycled back to the nucleus in which the HBV DNA is converted into ccc DNA as part of an intracellular conversion pathway to maintain a ccc DNA pool. Once a pool of 5–50 copies has been established, nucleocapsids associate with envelope proteins, rather than being recycled, and leave the cell as virions. The determinant of which pathway the nucleocapsid follows appears to be the amount of pre-S protein. The greater the number of viral ccc DNA molecules, the greater the level of RNA transcripts, resulting in more pre-S protein available to associate with nucleocapsids.

The pool of viral ccc DNA molecules in the cell nucleus is the likely reason for the relapse of viremia after treatment with nucleoside and nucleotide analogs. HBV replication does not use a semiconservative mechanism, thus, antiviral therapy with such agents can only affect newly synthesized DNA and not the pre-existing HBV ccc DNA pool. Elimination of viral ccc DNA might be achieved if production of new virions could be completely blocked; ccc DNA would be eventually lost by either decay or death of the infected hepatocyte. Two major means of removal of viral ccc DNA have

been proposed, a cytokine-induced noncytolytic clearance of virus from infected cells, and the killing of infected cells by virus-specific cytotoxic T cells.

The critical role played by intrahepatic viral ccc DNA has motivated researchers to develop assays for its detection and quantification. Assays for hepadnaviral ccc DNA have been developed for the woodchuck and duck hepatitis B models and applied to the investigation of the mechanism of clearance of infection. Studies using the woodchuck model showed that in transient infection a high proportion of infected hepatocytes were destroyed and replaced by uninfected cells, derived by cell division from the remaining infected hepatocytes. Some support that this mode of eradication of infection also occurs with antiviral therapy has been shown in chronically infected woodchucks treated with nucleoside analogs. The amount of viral ccc DNA decreased substantially whereas the amount of residual integrated viral DNA remained the same, suggesting a turnover of infected hepatocytes and compensatory accumulation of uninfected cells. Furthermore, in chronically infected ducks treated with a cytotoxic antiviral drug, the loss of infected hepatocytes was more rapid and showed in surviving animals that cell death and regeneration of uninfected cells play a role in recovery from infection.

For the assessment of HBV ccc DNA, a selective PCR assay was devised. Techniques that may have been applicable with animal models may not necessarily apply to patients in which the amount of sample available is limited, usually biopsy tissue, and the copy number of viral ccc DNA is low. Assays have been adapted to the real-time PCR format that provides for a greater dynamic range and more accurate quantification. In contrast to some of the studies in animal models, investigation of 48 wk treatment with the nucleotide analog ADV showed that there was a significant decrease in HBV ccc DNA levels, yet the number of immunostaining cells remained similar to that of pretreatment. This suggests a role for a noncytolytic mechanism of clearance rather than destruction of infected cells. Consistent with this is the finding of a more rapid elimination of HBV ccc DNA than that of HBsAg-positive hepatocytes in HBV infected chimpanzees. However, this phase of the elimination was followed by a second phase in which there was a peak of hepatocyte turnover and a surge of interferon-γ $CD8^+$ T cells associated with loss of remaining viral ccc DNA. The study illustrates that the two mechanisms of eradication of infection, noncytopathic clearance of intracellular virus and immune-mediated destruction of hepatocytes, are not mutually exclusive.

PCR assays for HBV ccc DNA can have many uses. In patients being treated for CH-B, assessing the level of viral ccc DNA may indicate drug efficacy and help decide treatment duration. Insights into the mechanisms of elimination of HBV ccc DNA may identify potential targets for intervention. Assays require further standardization and validation before they can be considered part of a patient management strategy.

CONCLUSIONS

Hepatitis B is a vaccine preventable disease, yet it remains the commonest form of viral hepatitis and a worldwide public health problem. Acute infection can produce symptoms including fever, jaundice, and malaise that may spontaneously resolve within 6 mo. A number of people do not resolve the infection and become chronic carriers; this group is at risk of developing severe complications such as cirrhosis and HCC. Chronic carriers also represent a pool of infectious virus. Infection acquired early in life is likely to lead to chronic infection, so in countries hyperendemic for hepatitis B, transmission from chronically infected mothers to their babies helps perpetuate the carrier cycle.

Despite the availability of an efficacious vaccine that prevents HBV infection, help for those who already have CH-B relies on control of their disease by antiviral chemotherapy. The first effective antiviral agent used to treat CH-B was α-interferon. It is effective in eliminating HBV infection in a proportion of patients but is associated with considerable side effects. This has led to the search for other less toxic agents for the control of CH-B.

HBV replicates by reverse transcription of an RNA transcript. This provides the opportunity for inhibition of replication by nucleoside and nucleotide analogs, many of which have been previously evaluated for the treatment of HIV infection. Antiviral therapy with agents such as LMV and ADV result in a dramatic drop in serum HBV DNA levels, which has required the development of sensitive NATs to assess their efficacy. The replication strategy of HBV also means that a heterogeneous population of genetic variants, or quasispecies, is generated although this is constrained to some degree by the genomic organization of overlapping reading frames, which allows the virus to respond to the selection pressure placed on it by antiviral therapy. Here too technology can play a role in being able to detect clinically significant variants, particularly detection of the early development of resistance. Combination therapy with nucleoside per nucleotide analogs has been an effective approach to combat problems associated with resistance in the treatment of HIV infection and this has already been initiated against CH-B in preliminary clinical trials. Treatment with interferon has been revisited with the development of pegylated versions that reduce the frequency of injection and appear to show improved efficacy. The use of sensitive and standardized NATs will be important in determining optimal combination therapy and may play some role in defining therapeutic end points.

Assessment of liver damage can be determined by the histological examination of tissue from a liver biopsy. Immunohistochemical demonstration of viral proteins can also provide some indication of the stage of HBV replication. Molecular technology has been applied to the investigation of HBV replication in liver tissue. A number of assays have been developed to measure the replicative intermediate HBV ccc DNA. These assays need to be validated and standardized before their full potential can be realized. The ability to measure this important intermediate may provide information on treatment efficacy and an understanding of the mechanisms involved in the elimination of viral ccc DNA.

Further studies of HBV replication may shed light on the nature of other chronic viral infections. Analysis of the results from patients treated with combination therapy could provide a basis for improved combination therapy for treatment of HIV infection, rather than vice versa, as is the current situation. Likewise, an understanding of how HBV causes immune-mediated liver disease may aid in the prevention of complications such as cirrhosis and HCC caused by hepatitis C virus. Clearly, many questions remain to be answered with this fascinating pathogen.

54 Hereditary Hemochromatosis

Francesca Ferrara, Elena Corradini, and Antonello Pietrangelo

SUMMARY

Iron is a major component of the Earth's crust, but its own chemistry greatly limits utilization and also sets the basis for its toxicity. Hereditary hemochromatosis (HH) is the most common cause of iron overload in humans. For much of the twentieth century, HH was regarded as a monogenic disorder characterized by excess tissue deposits of iron inevitably producing organ damage. This view has been shattered by the identification of similar phenotypes associated with mutations of at least four different iron-metabolism genes (*HFE, TfR2, HAMP, HJV)* and the increasing appreciation of the disease's multifactorial nature.

Key Words: Hereditary hemochromatosis (HH); *HFE*; hepcidin; hemojuvelin; iron; TfR2.

INTRODUCTION

Iron is a major component of the Earth's crust, but its own chemistry greatly limits utilization and also sets the basis for its toxicity. The capacity of readily exchanging electrons in aerobic conditions makes iron essential for fundamental cell functions, such as DNA synthesis, transport of oxygen and electrons, and cell respiration. However, because humans have no means to control iron excretion, excess iron, regardless of the route of entry, accumulates in parenchymal organs, and threatens cell viability.

A number of disease states are caused by excessive accumulation of iron in the body (Table 54-1). The term "primary" identifies diseases owing to a recognizable hereditary defect in proteins directly involved in iron homeostasis, as opposed to conditions in which iron overload is secondary to known factors or diseases.

Hereditary hemochromatosis (HH) is the most common cause of iron overload in humans. The discussion of other rarer primary iron-overload disorders is beyond the scope of this chapter. Ferroportin-associated iron overload, erroneously classified as type-4 hemochromatosis in genetic tassonomy is likely the most common cause of hereditary hyperferritinemia beyond classic HH. The disorder, clinically recognized in 1999, has distinctive genetic, pathological, and clinical features (Table 54-2).

HISTORICAL ASPECTS

The term "hemochromatosis" was introduced in 1889 to describe autopsy findings of massive tissue deposits of iron associated with multiple organ damage, particularly cirrhosis. In 1935 a critical review of reported cases concluded that the syndrome was hereditary and that excess tissue iron was the cause of the organ pathology. By the mid 1970s, HH had been recognized as an autosomal-recessive disorder linked to the HLA-A3 region of the short arm of chromosome 6 (4, 5), and in 1996 it was attributed to the newly discovered "hemochromatosis gene" (*HFE*).

GENOTYPES AND PHENOTYPE

The basic features of the HH syndrome can be produced by pathogenic mutations of four different iron metabolism genes (*see* Table 54-2). Depending on the gene involved, and its physiological role in iron homeostasis, the HH phenotype varies, ranging from massive early-onset iron loading with severe organ disease (e.g., associated with homozygous mutations of *HAMP* or *HJV*) (historically known as *juvenile hemochromatosis)*, to the milder adult-onset phenotype characterizing classic *HFE* and transferrin receptor 2 *(TfR2)*-related forms. Phenotypic penetrance of "juvenile" HH genes appears to be high, whereas that of "adult" HH genes is lower. In general, adult HH phenotypes are also particularly subject to the modifying effects of host-related and environmental factors, such as alcohol abuse or chronic liver insult (Fig. 54-1). "Intermediate phenotypes" can result from combined heterozygous or homozygous mutations of multiple hemochromatosis genes. Increased risk of clinically expressed disease may indeed occur in patients with heterozygous mutations of both adult and juvenile HH genes. The variety of genotypes that can produce an HH phenotype highlights the importance of defining the disease clinically as a unique entity and avoiding classification into subtypes based exclusively on genetic diversities.

ADULT ONSET HH: HFE- AND TFR2-RELATED *Classic* HH is the most frequently inherited metabolic disorder found in whites, with a genetic prevalence ten times higher than that of cystic fibrosis. It is associated with mutation of the *HFE* gene located on chromosome 6, in most cases a single-base transition leading to substitution of tyrosine for cysteine at position 282 (C282Y) of the HFE protein. The clinical impact of another less common HFE mutation, H63D (aspartic acid for histidine at position 63), appears to be limited, and yet, 1–2% of C282Y/H63D compound heterozygotes seem predisposed to disease expression. C282Y is thought to have originated by chance in a single ancestor inhabiting northwestern Europe some 2000 yr ago. The genetic defect caused no serious obstacle to reproduction and may even have conferred some advantages such as resistance to dietary iron deficiencies

and certain infectious diseases. It was passed on and spread through population migration. C282Y homozygosity is found in approx 5/1000 of individuals of northern European descent.

All C282Y homozygotes are genetically predisposed to a chain of events that may culminate in severe multiple organ damage, but it is impossible to predict whether and to what extent this risk will be expressed (*see* Fig. 54-1). A small percentage of C282Y homozygotes never present signs of altered iron metabolism.

Symptomatic patients generally present during midlife, often with nonspecific complaints (e.g., unexplained fatigue, joint pain). Liver disease (with manifestations ranging from hepatomegaly and/or moderate hypertransaminasemia to cirrhosis and even hepatocellular carcinoma) usually predominates but endocrine (diabetes, hypogonadotropic hypogonadism, impotence, hypothyroidism), cardiac (arrhythmias, heart failure), and joint disease (destructive arthritis) is also common.

Although very few cases have been described, the iron-overload phenotype associated with mutations of *TfR2* appears to be similar to that of classic *HFE*-related HH.

JUVENILE-ONSET HH: HEPCIDIN- AND HEMOJUVELIN-RELATED The *juvenile onset hereditary hemochromatosis* (J-HH) phenotype is much more severe (*see* Table 54-2). Plasma iron loading and tissue iron excess (reflected, respectively, by increased transferrin saturation and serum ferritin values) are evident early in life in both sexes. Symptomatic organ disease occurs as early as the first decade, and, although liver involvement is a constant, diabetes, hypogonadotropic hypogonadism, cardiomyopathy, arrhythmias, and heart failure are much more evident. Death (usually because of intractable heart failure) before the age of 30 yr is not uncommon.

J-HH is rare. Cases have been linked to homozygous mutations of the *HAMP* gene, which encodes hepcidin, an antimicrobial peptide synthesized by hepatocytes that plays a major role in human iron metabolism, but most cases of J-HH are because of mutations of the *HJV* (formerly *HFE2*) gene located on chromosome 1. The most common mutation is a G320V substitution in the *HJV* gene product, hemojuvelin, whose function is unknown.

PATHOGENESIS

A gradual and progressive expansion of the plasma iron compartment (reflected by high saturation of circulating transferrin) is the earliest detectable biochemical abnormality in all forms of HH. This alteration is evident at birth and progressive, but, at least for the adult HH form, does not cause problems during childhood and adolescence in male and in menstruating females owing to high growth demands and iron losses, respectively. These protective mechanisms do not seem to take place in the juvenile form where uncontrolled iron expansion leads to rapid tissue iron overload. Although increase of plasma iron pool in enteral or transfusion-induced iron overload is normally followed by increased iron excretion, this compensatory response fails in HH, probably because the intestinal cells that are eliminated contain little or no iron or ferritin. As a result, the total iron entering the plasma largely exceeds loss and, as plasma iron concentrations reaches critical levels, iron begins to accumulate in the parenchymal cells of the liver, where stores more than 25,000–30,000 mg can be found (normal value is <1000 mg), and other organs. If this deposition is not halted, and particularly if the organ is subjected to other cytotoxic (e.g., viral, oxidant) insults, cell damage, and organ disease develop (Fig. 54-2).

KEY PLAYERS: HFE, TFR2, HEPCIDIN, AND HEMOJUVELIN Human iron homeostasis depends on the coordinated functions of numerous genes, whose precise roles are, in many cases, still obscure. The hemochromatosis genes are good examples.

HFE is a major histocompatibility complex class I-like protein whose ancestral peptide-binding groove is too narrow to allow antigen presentation. It is also incapable of binding iron. Newly synthesized HFE binds to β2-microglobulin, an event necessary for its expression on the cell surface and endosomal membranes, where it interacts with transferrin receptor 1 (TfR1), the major receptor for transferrin. By disrupting a disulfide bond in HFE that is critical for its binding to β2-microglobulin, C282Y impairs HFE/TfR1 interaction. Unfortunately, the biological significance of this interaction is unclear. Early in vitro studies indicated that wild-type HFE diminished TfR1's ligand-binding affinity and competed with transferrin for iron uptake, whereas later studies suggest that HFE normally facilitates, rather than hinders, TfR1-mediated cellular uptake of transferrin-bound iron. It seems that HFE might also bind to other uncharacterized proteins and/or exert direct effects on endosomal iron transport.

The TfR2 was cloned in 1999. It displays 66% homology with TfR1, and in transfected cells, it mediates uptake of transferrin-bound iron, possibly through a mechanism similar to that described for TfR1. It differs from the latter receptor in its in vitro affinity for transferrin (25- to 30-fold lower), its high expression by hepatocytes, and the fact that this expression is not downregulated by hepatic iron overload. It is thus possible that TFR2 continues to mediate uptake of transferrin-bound iron by the liver after TFR1 is downregulated by iron overload, but the significance of such an activity is unclear.

Judging from the severity of the J-HH phenotype it appears clear that hepcidin and hemojuvelin play a more central role in iron homeostasis than either HFE or TfR2. Hepcidin is an antimicrobial peptide synthesized by hepatocytes in response to inflammatory stimuli and also iron overload. Evidence from transgenic mouse models indicates that it is the principal downregulator of intestinal absorption, placental transport, and macrophage release of iron, although the underlying basic mechanisms are unrecognized.

Table 54-2
Primary Iron Overload Disorders in Humans

Disorder	*Affected gene(s) (symbol/ location)*	*Known or postulated gene product function*	*Iron accumulation mechanism*	*Genetic trait*	*Epidemiology*	*Clinical onset (decades)*	*Main clinical manifestation*	*Clinical course*
Hereditary hemochromatosis	Hemochromatosis gene *(HFE/*6p21.3*)*	Interaction with transferrin receptor 1 Iron uptake?	Increased plasma influx	Autosomal-recessive	Affects Caucasians of northern European descent Highly prevalent	4°–5°	Liver disease	Mild
	Transferrin-receptor 2 *(TfR2/*7q22*)*	Uptake of iron-bound transferrin?			Rare			
	Hepcidin antimicrobial peptide *(HAMP/*19q13.1*)*	Downregulation of iron efflux from macrophages, enterocytes, placenta			Rare	2°–3°	Endocrine and cardiac disease	Severe
	HJV (or HFE2) (hemojuvelin) (1p21)	Modulator of hepcidin synthesis/ activity?			Rare			
Ferroportin - associated iron overload	Solute carrier family 40 (iron-regulated transporter), member 1 *(SLC40A1/*2q32*)*	Iron export from cells including macrophages, intestine, placenta	Decreased iron efflux	Autosomal-dominant	Present in different ethnic groups worldwide	4°–5°	Liver marginal anemia	Mild
Acerulo-plasminemia	Ceruloplamsmin *(CP/*3q23-q25*)*	Iron export from cells	Decreased iron efflux	Autosomal-recessive	Very rare	2°–3°	Neurological manifestations	Severe
A(hypo)transferrinemia	Transferrin *(Tf/*3q21*)*	Iron transport in the bloodstream	Increased iron influx	Autosomal-recessive	Very rare	1°–2°	Anemia	Severe

Excess tissue iron has also been attributed to mutation in the regulatory region of H ferritin in a unique pedigree, but this single observation awaits validation.

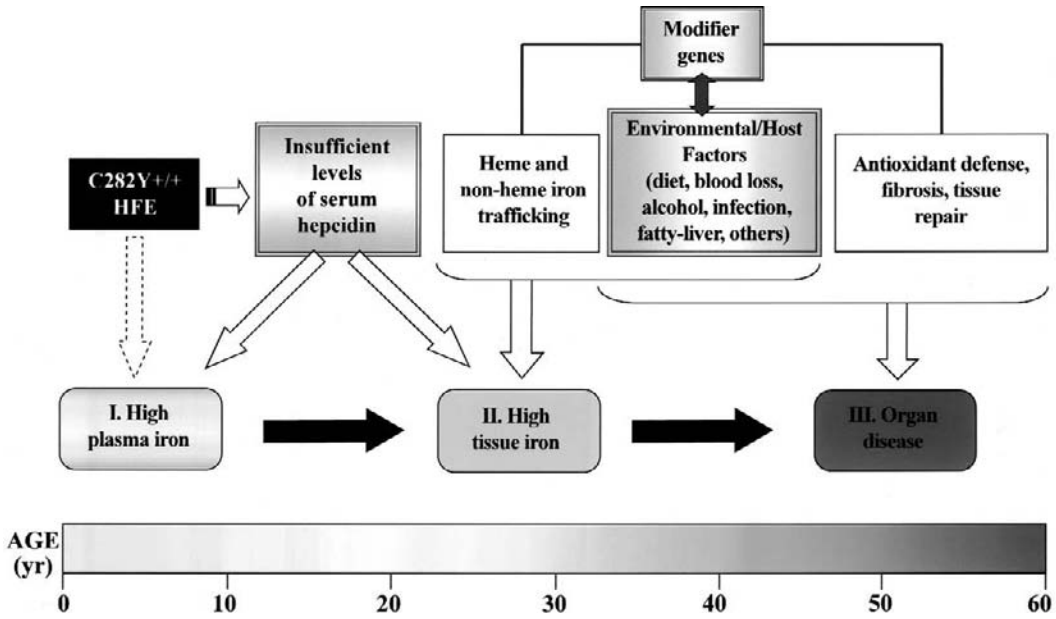

Figure 54-1 A pathogenic model for HFE-related hemochromatosis. In expressing C282Y homozygotes, there is a slow but progressive expansion of the plasma iron compartment that is rarely evident before adulthood. Its progression can be accelerated by host/environmental factors such as high dietary iron intake or attenuated by active iron utilization and/or loss. Circumstantial evidence indicates that the level of circulating hepcidin is an important pathogenic factor, whereas a direct pathogenic role of mutant HFE is speculative (dotted arrow). In some cases, disease expression never goes beyond this "biochemical phase" but in over half of all C282Y homozygotes, the plasma iron overload is followed by progressive accumulation of iron in parenchymal tissues of the liver and other organs. The rate of deposition is also influenced by various factors, including circulating levels of hepcidin and activity of genes involved in tissue traffic of heme (e.g., hemopexin and haptoglobin) and nonheme iron. In a limited percentage of cases, and usually in males during midlife, organ disease develops. This outcome is related to the toxic effects of free iron but is greatly facilitated by other concomitant cytotoxic insults and individual hypersusceptibility to oxidant damage and fibrogenesis.

Very little is known about the function of the newly identified hemojuvelin, but observation suggests that it is a modulator of hepcidin expression.

PATHOGENESIS OF *HFE*-RELATED HEMOCHROMATOSIS: THE HEPCIDIN MODEL The progressive expansion of the plasma iron pool that characterizes HH is the result of an increased transfer of iron to the blood compartment from enterocytes (i.e., increased intestinal absorption), and in all probability from reticuloendothelial macrophages as well. The latter are normally a much more important source of plasma iron than either enterocytes or hepatocytes. One of the paradigmatic features of HH is the presence of relatively iron-deficient enterocytes and reticuloendothelial macrophages where expression of iron proteins and iron carriers mimics iron deficiency. Abnormal iron transfer in classic *HFE*-HH was once attributed to a defective interaction of HFE with TfR1 in intestinal crypt cells; the resulting iron deficiency of crypt cells would program absorbing enterocytes derived from these cells to take up more iron from the digestate. This model has been challenged by studies in murine hemochromatosis that have suggested that the main site of the basic abnormality of HH may reside in the liver. This idea has been further reinforced by the the discovery of hepcidin, a liver-secreted peptide, and its association with the J-HH phenotype. The absence of hepcidin synthesis, a main repressor of iron efflux from intestine and reticuloendothelial system, would naturally lead to a major loss of control over iron release by enterocytes and macrophages, which is consistent with the massive iron loading typical of J-HH. A similar, but less severe, picture might be the result of impaired regulation of hepcidin expression. Indeed, inappropriately low hepatic expression and/or serum levels of hepcidin have been documented in HFE-HH patients and in HFE knockout mice. In murine hemochromatosis, hepatic iron deposition can be prevented by hepcidin overexpression. These findings have led to the proposal of a model in which hepcidin emerges as a central pathogenic factor in classic HH. Although circumstantial evidence indicates that HFE may be required for hepcidin synthesis, the details of this relation are unclear.

HEPCIDIN AS COMMON PATHOGENIC DENOMINATOR IN ALL FORMS OF HH Hepcidin's involvement has been documented (if not fully characterized) in two phenotypic variants of HH (hepcidin- and HFE-related), and these findings raise the attractive hypothesis that it might be a common pathogenetic denominator in all forms of this syndrome (*see* Fig. 54-2). Although the function of hemojuvelin is unknown, hepcidin levels are depressed in individuals with *HJV* mutations, suggesting that hemojuvelin is probably a hepcidin modulator. And given the phenotypic severity of *HAMP*- and *HJV*-related HH, it probably plays a major role in this sense: loss of HJV-mediated regulation might completely preclude enhanced hepcidin synthesis in response to increasing plasma iron, with results resembling those caused by the loss of hepcidin itself (*see* Fig. 54-2).

As for TfR2, no data on hepcidin levels in *TfR2*-HH have been reported. Its putative role in hepatocyte uptake of iron is difficult to reconcile with the HH phenotype observed in humans with pathogenic TfR2 mutations and in *TfR2*-knockout mice. TfR2 does not seem to interact with HFE, and its intestinal expression is controversial, but its persistent hepatic expression during iron overload might reflect a contribution to the regulation of hepcidin synthesis in this setting. HFE and TfR2 may be independent

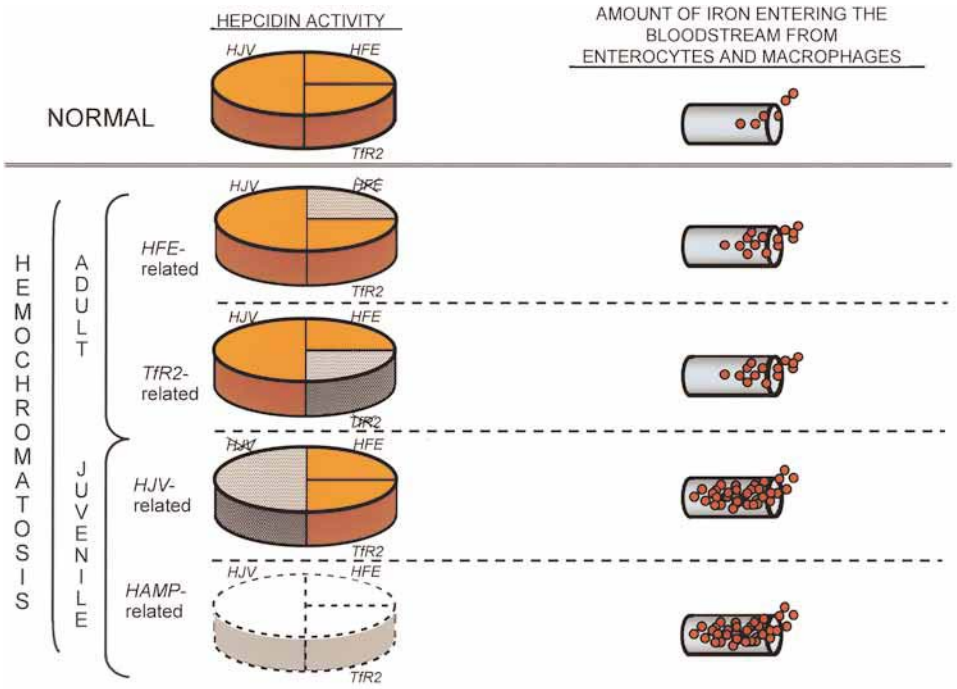

Figure 54-2 A unifying pathogenic model for all forms of hereditary hemochromatosis/hepcidin as common denominator. In this model HFE, transferrin receptor 2, and HJV are each independent but complementary modulators of hepcidin activity (pie chart); this activity is ultimately responsible for the rate of iron release from intestine and macrophages into the bloodstream. Relevant contribution of each gene to hepcidin synthesis/activity has been arbitrarily set in the figure. Owing to the severity of HJV-related hemochromatosis, hemojuvelin is likely the major regulator of hepcidin function. Loss of either HFE or TfR2 (e.g., *HFE*- or *TfR2*-related hereditary hemochromatosis) will result in appreciable increase or iron influx into the bloodstream, whereas residual hepcidin activity is sustained by normal HH genes. Owing to its dominant effect on hepcidin synthesis/activity, loss of hemojuvelin (e.g., *HJV*-related HH) will cause a much more dramatic effect on iron release from macrophages and enterocytes. Similarly, complete loss of hepcidin (e.g., *HAMP*-related HH), in spite of normal HFE, TfR2, and HJV, will inevitably lead to uncontrolled, massive release of iron into the circulation.

but complementary modulators of hepcidin activity. If so, the loss of one might be partially compensated by the presence of the other, and in the presence of normal *HAMP* some hepcidin upregulation could thus be achieved (*see* Fig. 54-2).

The scenario depicted above also allows intriguing speculation on more subtle phenotypic differences that could result from various combinations of HH-gene mutations.

CONCLUSION

For much of the 20th century, HH was regarded as a monogenic disorder characterized by excess tissue deposits of iron inevitably producing organ damage. This view has been shattered by the identification of similar phenotypes associated with mutations of at least four different iron-metabolism genes (*HFE, TfR2, HAMP, HJV)* and the increasing appreciation of the disease's multifactorial nature. HH is an autosomal-recessive disorder of iron metabolism, polygenic in nature, characterized by early progressive expansion of the plasma iron compartment, followed by progressive parenchymal iron deposits with the potential for severe organ damage, nonimpaired erythropoiesis, and optimal response to therapeutic phlebotomy. These features distinguish HH from all other known iron overload states in humans. Regardless of the underlying genetic variability, HH should be considered a unique clinicopathological syndromic entity and not divided into subtypes based exclusively on genetic criteria.

The precise molecular mechanisms responsible for the HH metabolic abnormality in the presence of nonfunctional HH genes and the interplay of HFE, TfR2, hemojuvelin, and hepcidin in the control of iron trafficking, remains to be elucidated. Animal genetics and availability of murine models of HH will likely solve many of the unanswered questions in HH.

55 Pancreatic Exocrine Dysfunction

David C. Whitcomb and Jonathan A. Cohn

SUMMARY

Pancreatic exocrine dysfunction can present clinically either as an acute illness, a destructive process, or a condition such as pancreatic insufficiency or chronic abdominal pain. Acute pancreatitis is associated with injury to the pancreas through direct trauma, occasional viral infections, hyperlipidemia, cholelithiasis, alcohol abuse, hypercalcemia, or other factors that trigger intrapancreatic trypsinogen activation in susceptible individuals or that activate the immune system directly. Research is moving toward developing new methods to prevent idiopathic pancreatitis in highly susceptible individuals. Gene testing can already identify asymptomatic individuals in whom the risk of developing pancreatitis is increased by several 100-fold.

Key Words: Cystic fibrosis (CF); hereditary pancreatitis (HP); pancreatic exocrine dysfunction; Shwachman–Diamond Syndrome (SDS).

INTRODUCTION

The pancreas is a retroperitoneal gland with both endocrine and exocrine functions. Pancreatic endocrine secretions are released from the islets into the circulation where they are essential for regulating intermediary metabolism. Pancreatic exocrine secretions (pancreatic juice), produced by the concerted action of pancreatic acinar and ductal cells, are delivered into the duodenum via a ductal system where they are essential for normal digestion of complex nutrients. Different pancreatic enzymes promote the efficient digestion of carbohydrates, lipids, proteins, and other nutrients (Table 55-1). Many of these digestive enzymes have the potential to digest components of the pancreas itself. Such autodigestion is normally prevented by several mechanisms. For example, most digestive enzymes exist in an inactive (proenzyme, i.e., zymogens) form until they reach the duodenum. Other mechanisms either prevent activation of proenzymes inside the pancreas, inhibit enzymes such as trypsin directly, limit diffusion of prematurely activated digestive enzymes, or rapidly flush activated digestive enzymes out of the ductal system. If any of these protective mechanisms fails, this can increase susceptibility to recurrent acute pancreatitis and lead to chronic pancreatitis.

Pancreatic exocrine dysfunction can present clinically either as an acute illness (acute pancreatitis), a destructive process (chronic pancreatitis), or a condition (pancreatic insufficiency, chronic abdominal pain, and so on). Acute pancreatitis is associated with injury to the pancreas through direct trauma, occasional viral infections, hyperlipidemia, cholelithiasis, alcohol abuse, hypercalcemia, or other factors that trigger intrapancreatic trypsinogen activation in susceptible individuals or that activate the immune system directly (e.g., an infection). The clinical course of acute pancreatitis is variable, and is related to both the degree of pancreatic injury and intensity of the inflammatory response.

The primary risk factors for chronic pancreatic diseases are genetic, through classic Mendelian diseases or complex genetic traits that together predispose susceptible individuals to chronic inflammation, fibrosis, and pancreatic dysfunction. The major Mendelian genetic diseases include hereditary pancreatitis (HP), cystic fibrosis (CF), some forms of early onset chronic pancreatitis associated with homozygous *SPINK1* mutations, and Shwachman–Diamond syndrome (SDS). In these conditions, the responsible gene is known and information is rapidly emerging concerning the role of the gene's protein product in normal pancreatic physiology and mutation-associated dysfunction that leads to pancreatic pathology.

ACUTE PANCREATITIS

Acute pancreatitis is defined clinically as pancreatic inflammation characterized by the sudden onset of abdominal pain in association with elevation of pancreatic enzyme concentration in blood or urine. In approx 80% of the cases, acute pancreatitis is *mild* and recovery is expected. However, in the remaining cases, acute pancreatitis is *severe* and can produce potentially life-threatening complications. The keys to clinical management are early recognition of a severe episode of acute pancreatitis, anticipation of complications, and prevention of recurrence.

CLINICAL FEATURES Acute pancreatitis usually causes epigastric abdominal pain of acute onset. The pain tends to be constant and may radiate to the mid-back. Vomiting occurs in 80% of cases and provides little pain relief. Abdominal tenderness with guarding occurs in half of cases but tends to be less severe than anticipated based on either the severity of pain or the degree of pancreatic inflammation (by abdominal CT, MRI, or ultrasound) and this discrepancy between symptoms and signs on the physical examination results from the retroperitoneal location of the pancreas.

DIAGNOSIS In a patient presenting with typical abdominal pain, a serum amylase or lipase level more than 2.5 times the upper limit of normal strongly suggests the diagnosis of acute pancreatitis.

CT with intravenous contrast is the most sensitive method of assessing the degree of pancreatic injury, pancreatic necrosis, and local extrapancreatic complications. Nonetheless, most experts recommend that the initial diagnosis is made on clinical and laboratory grounds rather than by CT because intravenous contrast worsens the severity of pancreatic injury early in the course of pancreatitis in animal models. In most cases, acute pancreatitis is associated with an identifiable cause, with gallstones and alcohol ingestion being the most common factors in adults (Table 55-2), and trauma, structural anomalies, viruses, medications, and systemic diseases being most common in children. Early identification of the cause of pancreatitis may prove beneficial in preventing ongoing pancreatic injury and also in preventing recurrence.

MOLECULAR PATHOPHYSIOLOGY The first advance in understanding the nature of acute pancreatitis came in 1896 when Chiari proposed that pancreatic inflammation was triggered by digestive enzyme-mediated autodigestion of the pancreas rather than infection. This hypothesis has proven to be correct in most cases of acute pancreatitis, although viral and bacterial pancreatitis also occur. In the cases in which premature activation of digestive enzymes appears to play a central role, the problem may occur anywhere along the pathway between the site of digestive proenzyme (zymogen) synthesis within the acinar cell to the ampula of Vater where the zymogens normally enter the duodenum.

In pancreatic physiology, trypsin is the key molecule controlling zymogen activation. Many protective mechanisms focus on limiting the activation of trypsinogen (the proenzyme) to trypsin (the active enzyme) and on eliminating active trypsin from within the pancreas. Activation of trypsin normally occurs in the intestinal lumen where an intestinal brush border enzyme, *enterokinase,* cleaves a small trypsinogen activation peptide from trypsinogen to generate trypsin. Trypsin also activates trypsinogen, and trypsin efficiently activates all other pancreatic digestive enzymes. This process is desirable in the intestine but disastrous within the pancreas.

Trypsin activity is controlled within the pancreatic acinar cell by being synthesized in the inactive form as trypsinogen. Human trypsinogen can slowly autoactivate to trypsin, which can initiate the zymogen activation cascade. This is prevented by three mechanisms. The first is packaging of zymogens within dense granules in a semicrystallized form that is separated from some of the lysozomal enzymes that have the capacity to directly activate trypsinogen. The second is synthesis of pancreatic secretory trypsin inhibitor (PSTI), also know as serine protease inhibitor Kazal type 1 (SPINK1). This specific trypsin inhibitor is regulated as an acute phase protein and the ratio of SPINK1 to trypsin is therefore dependent on the status of the immune system and inflammation. The third mechanism is trypsin autolysis. The trypsin molecule has two globular domains connected by a peptide chain containing an arginine at codon 122. This arginine serves as target for a second trypsin and therefore serves as a self-destruct site when R122 is exposed. Cleavage at this site permanently inactivates trypsin (Fig. 55-1). Accessibility of R122 to cleavage appears to be regulated by calcium. Low calcium levels (e.g., inside the acinar cell) favor autolysis whereas high levels (e.g., inside the pancreatic duct

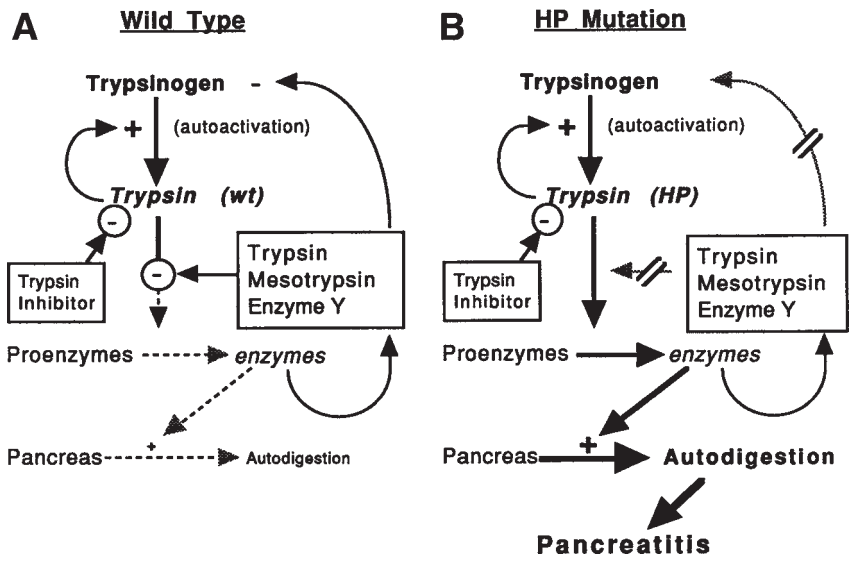

Figure 55-1 Model of trypsin self-destruct mechanism preventing pancreatic autodigestion. **(A)** Autoactivation and enzymatic activation of trypsinogen generate trace amounts of active trypsin within pancreatic acinar cells. Active trypsin is inhibited by a limited supply of trypsin inhibitor. If trypsin activity exceeds the inhibitory capacity of PSTI, then proenzymes, including mesotrypsin and enzyme Y, are activated. These enzymes feed back to inactivate wild-type trypsinogen, trypsin, and other zymogens. **(B)** Activation of mutant (HP) trypsin in amounts that exceed the inhibitory capacity of PSTI results in activation of proenzymes. Because the Arg 117 cleavage site for trypsin-like enzymes is replaced by His in the HP mutant trypsin, trypsin continues to activate trypsinogen and other zymogens unabated, leading to autodigestion of the pancreas and pancreatitis.

and duodenum) prevent autolysis. Thus, trypsin activity regulates zymogen activation and calcium levels regulate trypsin survival.

If calcium levels are improperly regulated within the pancreatic acinar cell then conditions favor prolonged survival of trypsin, leading to zymogen activation, pancreatic autodigestion, and pancreatitis. Because the acinar cells use calcium as the primary second messenger system, intracellular hypercalcemia can occur with hyperstimulation of the pancreas, with hypercalcemia during normal pancreas stimulation, with impaired calcium removal as can occur with mitochondrial injury or other problems such as occurs with significant alcohol exposure. If trypsinogen is released from the pancreas and becomes activated, the high calcium levels in the pancreatic juice eliminate the autolysis protection mechanism. However, the ductal system is protected both by SPINK1 inhibition of small amounts of active trypsin and by rapid flushing of the duct with bicarbonate-rich fluid secretions generated by ion efflux from the duct cells through CF transmembrane conductance regulator (CFTR). Conditions that dampen recognition of trypsin activation that inhibit CFTR and duct cell function, or that decrease SPINK1 inhibitory capacity increase susceptibility to acute pancreatitis. Finally, if active digestive enzymes escape from the pancreatic acinar cells and ducts into the intracellular space or plasma, they are inactivated by hepatocyte-derived α_2-macroglobulin and α_1-protease inhibitors. Thus, multiple protective strategies exist to prevent trypsinogen from being activated and to prevent trypsin from activating zymogens and initiating pancreatic autodigestion.

Acute pancreatitis from zymogen activation and autodigestion likely cause limited injury compared with the severe effects of the inflammatory response. The release of the products of digestion trigger the immune system with the release of a cascade of proinflammatory mediators including interleukin (IL)-1, IL-2, IL-6, IL-8, tumor necrosis factor-α, and platelet activating factor, which often leads to a systemic inflammatory response syndrome (SIRS). If pancreatic injury is mild, then the inflammatory response is self-limited and the process is contained. However, if pancreatic injury is severe, then a more intense inflammatory response ensues. This SIRS is responsible for many of the local and systemic complications of acute pancreatitis including a hypermetabolic state, decreased peripheral vascular resistance with increased cardiac output, pulmonary complications of hypoxia and adult respiratory distress syndrome, and renal injury. After the acute phase the pancreas begins to heal. However, it may take months before pancreatic function returns to normal. Thus, acute pancreatitis progresses through three general phases: an *acute injury* resulting from a variety of causes, a characteristic *inflammatory response* that depends on the severity of injury and intensity of the immune response, and finally a *healing* phase.

GENETIC PREDISPOSITION A growing number of genes are being associated with *susceptibility* to acute pancreatitis and recurrent acute pancreatitis. In addition, *modifier* genes (including genes that regulate the immune response) may determine clinical course of acute pancreatitis. Many of the primary genetic defects that cause recurrent acute pancreatitis eventually lead to chronic pancreatitis. These include mutations in the trypsinogen gene (*PRSS1*), the *SPINK1* gene, and mild-variable mutations in the *CFTR* gene (*see* Chronic Pancreatitis and Pancreatic Insufficiency). Genetic predisposition to hypertriglyceridemia and hypercalcemia also lead to recurrent acute and chronic pancreatitis.

HP is inherited as an autosomal-dominant trait with 80% penetration and variable expression. Hundreds of kindreds have been identified since the genetic nature of this disorder was recognized by Comfort and Steinberg in 1952. The cause of HP was determined after the gene was localized to chromosome VII and then identified as cationic trypsinogen (protease, serine 1, *PRSS1*) by sequencing of candidate genes. Cationic trypsinogen is the most common isoform of trypsinogen. It accounts for two-thirds of trypsin activity, with anionic trypsinogen (PRSS2) accounting for another one-third and mesotrypsinogen (PRSS3) accounting for

less than 5%. An arginine to histidine (R > H) substitution caused by a mutation in codon 122 (R122; initially reported as R117H using the standard chymotrypsinogen numbering system), was found in the initial five families used to map the gene. The mutation was identified at the critical trypsin autolysis site, and was therefore hypothesized to be a gain-of-function mutation that prevented prematurely activated trypsin from being eliminated, leading to zymogen activation and pancreatitis. Since then, other *PRSS1* mutations have been identified in hereditary and occasionally sporadic pancreatitis, and these mutations may either enhance trypsinogen activation or diminish autolysis. The R122H and N29I mutations are, by far, the most common trypsinogen mutations.

The *SPINK1* gene codes for a specific trypsin inhibitor, PSTI. The *SPINK1* N34S single-nucleotide polymorphism (SNP) is linked with several other SNPs and, therefore, forms a haplotype. The N34S haplotype is common in most populations, ranging from 1 to 4% of control alleles. Homozygous *SPINK1* N34S mutations markedly increase the risk of recurrent acute pancreatitis and chronic pancreatitis, especially in children. Several other mutations, including M1T, P55S, R65Q, and R67C and a number of intronic or promoter region mutations are also occasionally seen. *SPINK1* mutations are common in patients with childhood onset pancreatitis and in tropical pancreatitis, although in the majority of cases only heterozygous mutations are identified. It is likely that one or more additional gene mutations and/or specific environmental factors are required to cause pancreatitis in these cases, suggesting in many cases that recurrent acute and chronic pancreatitis represent complex genetic disorders.

The *CFTR* gene codes for an anion channel located on the apical surface of pancreatic duct cells. This ion channel promotes the movement of chloride, bicarbonate and fluid into the duct lumen. Fluid secretion at this site is critical for flushing the zymogen proteins out of the pancreas and into the intestine. Severe mutations in both *CFTR* alleles lead to minimal fluid secretion and CF (*see* Genetic Basis). Milder mutations in one allele with a severe mutation in the other provide enough CFTR function for borderline pancreatic function, but there may not be enough reserve for clearing the ducts if trypsinogen activation is significant, or if the outflow tract has high resistance (e.g., in pancreatic divisum), and, therefore, may predispose patients to recurrent acute pancreatitis.

The three genes previously mentioned are the best studied examples of genes that increase susceptibility to acute pancreatitis. Other genes are under investigation that do not increase the risk of pancreatitis, but may alter the severity of the clinical course, and therefore act as modifier genes.

MANAGEMENT Mild pancreatitis tends to be a self-limited process. Treatment is supportive and includes pancreatic rest (nothing by mouth), intravenous hydration, and analgesics. Patients usually recover within 3 d, and can be discharged from the hospital when oral intake is adequate.

By contrast, severe pancreatitis can result in life-threatening complications requiring aggressive management. Because these patients are at risk for sudden death, intensive care unit admission is often indicated during the initial phase of severe acute pancreatitis with SIRS. To predict which patients with acute pancreatitis are most likely to develop life-threatening complications, several prognostic schemes have been developed (Table 55-3). These schemes are useful for identifying the subset of patient with acute pancreatitis for whom intensive monitoring is most important. The major scoring systems and markers of severity are directed at quantitating the inflammatory response to pancreatitis or assessing multiorgan system injury rather than quantifying amount of pancreatic injury. The best tools for predicting a severe clinical course include the APACHE-II score of more than 7 or IL-6 more than 400 pg/mL at admission, neutrophil elastase more than 300 mcg/L or Trypsinogen 2 > 35 nmol/L at 24 h, or Ranson/Glasgow score more than 2 or C-reactive protein more than 150 mg/L at 48 h.

Table 55-3
Prognostic Criteria in Acute Pancreatitis

Ranson criteria[a]
On admission
Age over 55 yr
Leukocyte count over 16,000/mm^3
Blood glucose over 200 mg/dL
Serum LDH over 350 IU/L
Serum GOT (SGOT/AST) over 250 IU/dL
First 48 h
Hematocrit decreases over 10%
BUN rises over 5 mg/dL
Serum calcium below 8 mg/dL
Arterial PO_2 below 60 mmHg
Base deficit over 4 mEq/L
Estimated fluid sequestration more than 6 L
Glasgow criteria[a]
On admission
Age over 55 yr
WBC count over 15,000/μL
Glucose over 180 mg/dL
BUN over 45 mg/dL
PO2 over 60 mmHg
Albumin less than 3.2 g/dL
Calcium less than 8 mg/dL
LDH more than 600 IU/L

[a]Each factor is one point. Three or more points suggest severe acute pancreatitis.

Early recognition of a severe course is a key to the management of the most common life-threatening complications of severe acute pancreatitis. Cardiovascular collapse and respiratory failure each may occur rapidly and require aggressive support. Multiorgan failure may develop as a consequence of the hypermetabolic state as nutritional stores are depleted, and early nutritional support should be considered. Nutrition can be delivered by total parenteral nutrition or preferably via a nasojejunal feeding tube. Sepsis and infected pancreatic necrosis also commonly occur and are life-threatening complications. Prophylactic broad spectrum antibiotics such as imipenem or cefuroxime may reduce the frequency of these serious infectious complications. Surgery is needed if pancreatic necrosis becomes infected.

FUTURE DIRECTIONS Because the injury phase of acute pancreatitis is usually brief and early recognition is difficult, prevention is important. Understanding the sites and mechanisms of early enzyme activation, the factors controlling the inflammatory response and the resulting pathological events may be helpful in limiting pancreatic damage when pancreatic injury occurs. Insights into the mechanism regulating the immune system and identification of SNPs that predict a severe course will be invaluable in determining clinical management strategies.

Because genetic susceptibility genes have been identified, transgenic animal models can be developed to aid in the study of human pancreatitis, and strategies to prevent HP and other forms of pancreatitis can also be developed.

CHRONIC PANCREATITIS AND PANCREATIC INSUFFICIENCY

Chronic pancreatitis is a destructive process characterized by the permanent loss of exocrine function. Typical features include persistent pancreatic inflammation leading to fibrosis, pancreatic atrophy, and ductal dilatation and distortion. In adults, the most common cause of chronic pancreatitis and of pancreatic insufficiency is alcohol. In children, pancreatic insufficiency often occurs without inflammation; the leading causes of this clinical presentation are CF and SDS.

Pancreatic insufficiency occurs when digestive enzymes fail to reach the intestine. This can occur because of pancreatic destruction (e.g., chronic pancreatitis), blockage of the pancreatic duct (e.g., pancreatic cancer), surgical removal of the pancreas, or failure of enzyme synthesis (e.g., SDS).

As noted, mutations in *PRSS1*, *SPINK1*, and *CFTR* markedly increase susceptibility to recurrent acute pancreatitis. Molecular epidemiology and family studies demonstrate that in these cases, recurrent acute pancreatitis leads to chronic pancreatitis. The same pattern of recurrent acute pancreatitis in alcoholics appears to lead to alcoholic chronic pancreatitis, and susceptibility to alcoholic pancreatitis may also have a genetic link.

The prototype disease causing pancreatic insufficiency is CF. CF is a common disease with an incidence of 1/3000 in US Caucasians. Of patients with CF, approx 85% develop pancreatic insufficiency, and pancreatic dysfunction is such a prominent feature of CF that the disease was initially termed fibrocystic disease of the pancreas.

CLINICAL FEATURES The most important manifestations of pancreatic insufficiency result from malabsorption of incompletely digested nutrients. Malabsorption of fat and fat-soluble vitamins is usually prominent, leading to steatorrhea associated with delayed growth in children or weight loss in children or adults. In patients with CF, meconium ileus or pulmonary symptoms often suggest the diagnosis before pancreatic insufficiency is evident. The clinical features of CF are discussed in Chapter 27. In adults, the most common cause of pancreatic insufficiency is chronic pancreatitis. Prominent symptoms include chronic midepigastric pain (often postprandial), weight loss largely because of food avoidance, and steatorrhea. In addition, diabetes mellitus sometimes accompanies pancreatic insufficiency resulting from CF or advanced chronic pancreatitis.

DIAGNOSIS A diagnosis of pancreatic insufficiency is suggested by the combination of steatorrhea (malabsorption of at least 7%, and typically of 20–50%, of ingested fat during a 72-h stool collection) with normal bowel mucosal morphology (by biopsy) and function (e.g., D-xylose absorption). The diagnosis is supported by a clear response to pancreatic enzyme replacement therapy. When the diagnosis is uncertain, the reference standard for documenting pancreatic insufficiency is the "tubed" secretin test. In this test, the duodenum is intubated to measure the amount of bicarbonate and fluid secreted by the pancreas in response to secretin. Pancreatic insufficiency can also be detected by noninvasive tests such as the dual-label Schilling test, the Bentiromide test, Sudan stain of stool, or fecal human elastase testing. Because the available elastase test distinguishes between human and nonhuman forms of the enzyme, this test can detect pancreatic insufficiency in patients who are receiving pancreatic enzyme replacement therapy, but it is less useful for monitoring responses to this therapy.

In children and young adults with pancreatic insufficiency, a diagnosis of CF is most commonly established by the sweat test (quantitative pilocarpine iontophoresis) or by CF gene testing. In children with pancreatic insufficiency, the differential diagnosis includes SDS (an autosomal-recessive condition associated with neutropenia—*see* below) and rare enzyme deficiencies (e.g., congenital lipase deficiency).

In adults, pancreatic insufficiency most often results from chronic pancreatitis. Although the most common cause of chronic pancreatitis is alcohol abuse, a substantial minority of cases are associated with an identifiable genetic, environmental, or surgical etiology, or remain idiopathic. The diagnosis of chronic pancreatitis is usually supported by evidence of pancreatic atrophy, ductal dilatation or calcification, or a mass/pseudocyst as detected by abdominal imaging procedures (sonogram, CT, MRI, magnetic resonance cholangiopancreatography, or endoscopic retrograde cholangiopancreatography). It is noteworthy that serum amylase and lipase levels are elevated in acute pancreatitis, but that these tests are often within or below normal limits in patients with pancreatic insufficiency or chronic pancreatitis, even during episodes of acute pain.

GENETIC BASIS The genetics of CF is presented in Chapter 27. Briefly, the inheritance pattern of CF is autosomal-recessive, the gene causing CF was mapped to chromosome VII by linkage analysis, and this gene was identified by positional cloning. The protein product of this gene was named the CFTR based on the anticipated function of the protein. The *CFTR* gene contains 27 exons, spans 250 kb, and encodes an integral membrane protein containing 1480 amino acids. In many types of epithelial cells, CFTR regulates ion fluxes across the plasma membrane by functioning as a cAMP-regulated anion channel and as a regulator of other ion transport proteins. As an anion channel, CFTR conducts chloride, bicarbonate, or both, depending on the tissue.

Since the CF gene's discovery in 1989, roughly 1000 different *CFTR* mutations have been associated with CF. In European Caucasians, one mutation, ΔF508, accounts for 60–70% of CF-causing alleles. About half of US CF patients are ΔF508 homozygotes; these individuals have low levels of residual CFTR function (<2% of normal) and almost always have pancreatic insufficiency. By contrast, pancreatic sufficiency is common in patients with CF lung disease who have genotypes causing somewhat less severe loss-of-function (e.g., with 5% residual CFTR function).

These genotype–phenotype correlations have been extended to *CFTR* genotypes causing milder loss-of-function. When residual CFTR function is roughly 5–20% of normal, CF lung disease does not occur and sweat testing is usually normal. Nonetheless, individuals with this level of residual CFTR function have a high risk (40 times normal) of developing idiopathic chronic pancreatitis, and males with these genotypes have an increased risk of infertility. These cases of pancreatitis tend to be sporadic and they are mainly associated with *CFTR* compound heterozygous genotypes consisting of one mutation causing nearly full loss-of-function (usually ΔF508) plus a milder mutation affecting the other *CFTR* allele (often a splice variant).

Pancreatitis or male infertility develops in only a minority of individuals who have *CFTR* compound heterozygous genotypes. This indicates complex inheritance and suggests that disease

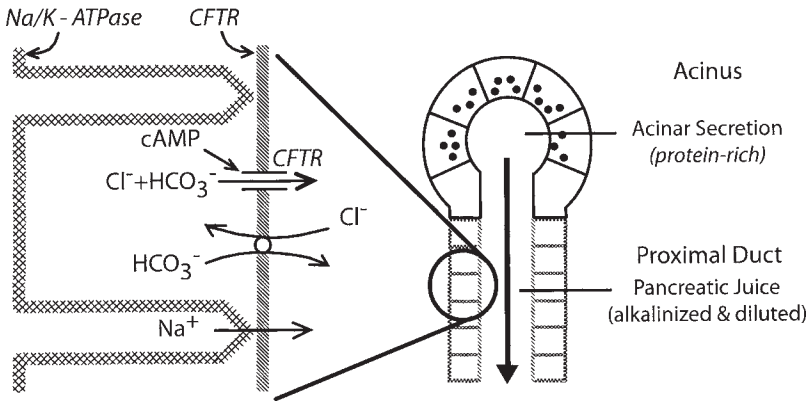

Figure 55-2 A model summarizing the role of the cystic fibrosis transmembrane conductance regulator during exocrine secretion by the pancreas. CFTR normally occurs at the apical membranes of the epithelial cells lining the small pancreatic ducts. Initially, it was known that CFTR transports Cl^- and that duct cells also contain apical anion (Cl^-/bicarbonate) exchangers. Accordingly, early models implicated anion exchange as a final step for bicarbonate transport. However, CFTR is now known to transport both bicarbonate and Cl^-. Models suggest that when CFTR is activated, the CFTR anion channel accounts for most bicarbonate secreted into the duct lumen. Bicarbonate secretion directly alkalinizes the pancreatic juice and it draws Na^+ and H_2O into the lumen, thereby diluting the pancreatic juice. In cystic fibrosis, the absence of CFTR causes defective dilution and alkalinization of the pancreatic juice as it flows through the duct, leading eventually to obstruction of the ducts by inspissated secretions. (Adapted from Marino CR, Matovcik LM, Gorelick FS, Conn JA. Localization of the cystic fibrosis transmembrane conductance regulator in pancreas. J Clin Invest 1991;88:712–716 with permission © 1991 and reproduced with permission of American Society for Clinical Investigation.)

susceptibility is modified by factors other than the CFTR genotype. One factor modifying the risk of idiopathic pancreatitis is the *SPINK1* N34S allele. Pancreatitis risk seems to be independently increased by having the *SPINK1* N34S allele and by having two abnormal *CFTR* alleles; susceptibility is highest in individuals with both abnormalities.

Most sporadic cases of chronic pancreatitis are related to alcohol use. Because pancreatitis occurs in only a small minority of heavy drinkers, individuals seem to vary in their susceptibility to alcoholic pancreatitis. Even though much of this variation may be heritable, the genetic basis for this is poorly understood.

Apart from CF, inherited forms of pancreatic insufficiency are rare and include SDS and HP. The genes responsible for these diseases have been identified. These genes have not been implicated in sporadic chronic pancreatitis.

In children, SDS is the second most common cause of pancreatic insufficiency. SDS is an uncommon autosomal-recessive disorder affecting acinar cell enzyme production. Typical features include pancreatic insufficiency, cyclic neutropenia, skeletal defects, short stature, and normal sweat electrolytes. The SDS disease gene has been mapped to chromosome 7q11 and named the Shwachman–Bodian–Diamond syndrome gene (*SBDS*). The *SBDS* gene has five exons and is predicted to encode a protein of 250 amino acids that may participate in mRNA processing. In most cases of SDS, the genetic defect is a conversion mutation from a pseudogene. Nearly 90% of the affected individuals have mutations in the *SBDS* gene that are identical to the abnormal DNA sequence in the pseudogene. The most common of these mutations are 183–184TA>CT and 258+2T>C.

The penetrance and phenotypic expression of patients with SBDS mutations is variable. In severe cases, pancreatic insufficiency with malabsorption, steatorrhea, or failure to thrive may develop in the first year of life. Mild cases of SDS are seen more often in young men, probably because of greater parental concern about short stature among males. Nearly half of SDS patients showed moderate age-related improvement in pancreatic function leading to pancreatic sufficiency. Cyclic neutropenia is also common and typically leads to infections (e.g., recurrent otitis media, sinusitis, pneumonia, osteomyelitis, urinary tract infections, skin infections, and lymphadenitis). Less common findings include myelodysplastic syndromes, acute leukemias, and a variety of skeletal abnormalities.

MOLECULAR PATHOPHYSIOLOGY CF pancreatic disease is associated with characteristic pathological and physiological abnormalities. Obstruction of the intralobular pancreatic ducts is an early pathological event and impaired pancreatic secretion of bicarbonate is an early physiological defect. These findings suggest that CFTR may normally function to prevent obstruction of the intralobular ducts and to promote bicarbonate secretion. These concepts are supported by available data concerning the localization of CFTR in human pancreas. The predominant site of CFTR mRNA and protein in pancreas is in the cells lining the proximal ductules. Within these duct epithelial cells, CFTR protein is predominantly detected as a component of the apical plasma membrane.

The distribution of CFTR in pancreas supports the model shown in Fig. 55-2, which postulates an important role for CFTR-associated anion channels in the regulation of ductal secretion. According to this model, secretory stimuli act via cAMP to activate CFTR and thereby open Cl^-/bicarbonate channels at the apical membrane of the duct cell. Because of the driving force provided by the Na^+,K^+-ATPase at the basolateral membrane, opening apical anion channels results in the movement of Cl^- and bicarbonate across the apical membrane, leading to the movement of Na^+ and water into the lumen, and thereby diluting the pancreatic juice. This model suggests that CFTR in the duct cell contributes to the normal dilution and alkalinization of pancreatic juice. In humans with CF, the ultimate result of the absence of CFTR at this site is a defect in the dilution and alkalinization of the protein-rich acinar secretions in the duct lumen, leading to failure to flush zymogens out of the duct and formation of protein plugs, thereby to pancreatic injury in CF.

Uncertainty remains concerning the precise mechanism by which pancreatic injury results from defective dilution and alkalinization of the pancreatic juice in CF. Dilution and alkalinization

both may help to prevent precipitation of proteins as the pancreatic juice flows through the ducts. Beyond this, data from in vitro models suggests that alkalinization of the lumen of the pancreatic duct system may also be important for maintaining normal acinar cell function during exocytosis. Finally, ductal fluid secretion tends to flush zymogen proteins out of the pancreas.

In CFTR-related idiopathic chronic pancreatitis, inadequate ductal CFTR function also probably plays an early role in pathogenesis. Maintaining flow through the ducts may be especially important in individuals who have increased risk for intraductal trypsin activation (e.g., resulting from PSTI mutations). When these individuals also have reduced CFTR function (e.g., resulting from CFTR mutations), flow through the pancreatic duct is slow and this promotes injury by prolonging pancreatic exposure to any activated trypsin that occurs in the duct lumen. Thus, mutations of the *CFTR* and *PSTI* genes tend to have additive (independent) impact on pancreatitis risk. This agrees well with the distinct sites in the exocrine pancreas for the protein products of these genes: CFTR is ductal whereas PSTI is acinar.

In SDS, the primary site of pancreatic injury is the acinus rather than the duct. Acinar replacement is prominent; inflammation and gland destruction are atypical. Thus, the exocrine insufficiency of SDS mainly affects enzyme secretion rather than bicarbonate secretion, whereas the opposite pattern is seen in CF.

MANAGEMENT Pain control is often the predominant issue in treating chronic pancreatitis. Structural causes for pain include ductal obstruction resulting from strictures, tumor, pseudocysts, or stones, and a parenchymal compartment syndrome in which exocrine tissue is encased by fibrosis. Pain resulting from structural causes is typically intermittent and often occurs when serum cholecystokinin levels increase after a fat- or protein-rich meal. Medical therapy for this type of pain can include using gastric acid suppression, pancreatic enzyme supplements, and narcotics to reduce pancreatic secretion, whereas surgical options include procedures designed to relieve areas of ductal obstruction or fibrotic encasement. Chronic pancreatitis can also cause pain because of inflammation. This pain can be severe and unremitting, and surgical resection and celiac ganglion ablation are important management options.

Pancreatic insufficiency and diabetes mellitus are also common problems in chronic pancreatitis. Pancreatic enzyme replacement is the cornerstone of therapy for pancreatic insufficiency. Widely used enzyme preparations include a combination of lipase, amylase, and proteases. Because lipase is rapidly degraded at low pH, replacement enzymes are commonly administered either as enteric-coated microspheres or in combination with an H_2-receptor antagonist. Moderate enzyme doses are usually sufficient to achieve partial correction of steatorrhea with marked improvement in nutrition. Complete correction of steatorrhea is usually not possible even when very high enzyme doses are administered. High enzyme doses should be used with caution because they have been associated with colonic strictures. The management of diabetes is reviewed in Chapter 32.

The high prevalence of *CFTR* and *PSTI* mutations in idiopathic pancreatitis suggests that many patients with this condition could benefit from genetic testing. Potential benefits include helping patients understand their disease, promoting prompt detection of extrapancreatic CFTR-related conditions, identifying CF carriers for genetic counseling, and identifying occasional CF patients in whom pancreatitis occurs before the onset of lung disease. *CFTR* gene testing may also improve medical care in cases in which physicians might otherwise suspect undisclosed alcoholism as the cause of pancreatitis. *CFTR* mutation testing is more likely to be positive in younger CF patients who have extrapancreatic evidence of reduced CFTR function (e.g., borderline sweat testing). False-negative tests are more likely in non-Caucasians because the assays widely used for CF carrier screening are less sensitive in these populations. It is also unclear if the limited number of *CFTR* gene mutations that are included in CF screening panels is sufficient for determining risk of pancreatitis.

FUTURE DIRECTIONS Research is moving toward developing new methods to prevent idiopathic pancreatitis in highly susceptible individuals. Gene testing can already identify asymptomatic individuals in whom the risk of developing pancreatitis is increased by several 100-fold. As more is learned about the subsets of *CFTR* and *PSTI* genotypes associated with highest pancreatitis risk, the predictive power of gene testing will continue to improve, enabling identification of highly susceptible individuals prior to the onset of their first pancreatitis symptoms. Once identified, these individuals can be studied to learn about early events in the pathogenesis of this condition as a key step toward developing and evaluating preventive therapy. Specific questions being addressed by ongoing research include the following: Is the risk of pancreatitis increased in CF carriers who have one normal CFTR allele? Should CFTR-related idiopathic pancreatitis be classified as a form of CF? Can CFTR or PSTI gene testing be used to guide therapy in patients with pancreatitis? Do individuals with CFTR or PSTI mutations have increased susceptibility to alcoholic or drug-related pancreatitis?

SUMMARY

The study of inflammatory bowel diseases (IBD) has advanced greatly, with the identification of the first disease susceptibility gene for Crohn's disease, the tentative identification of other susceptibility loci for IBD, the creation of new animal models of IBD using gene knock out and transgenic technology, and the application of cellular and molecular techniques to develop novel therapies for IBD. This chapter summarizes the important molecular and genetic developments relevant to the study of IBD, celiac sprue, lactase deficiency, glucose–galactose malabsorption, and abetalipoproteinemia as several prominent examples of how molecular technology can help advance the practice of gastrointestinal medicine.

Key Words: Abetalipoproteinemia; celiac sprue; Chrohn's disease; glucose–galactose malabsorption; inflammatory bowel diseases (IBD); lactase deficiency; ulcerative colitis.

INTRODUCTION

The application of molecular biological and genetic techniques to the study of the luminal gastrointestinal tract epithelium has led to exciting advances in several broad areas. The study of inflammatory bowel diseases (IBD) has advanced greatly, with the identification of the first disease susceptibility gene for Crohn's disease, the tentative identification of other susceptibility loci for IBD, the creation of new animal models of IBD using gene knockout and transgenic technology, and the application of cellular and molecular techniques to develop novel therapies for IBD. The molecular mechanisms underlying intestinal digestion and absorption of nutrients have been further clarified by the cloning and characterization of enterocytic genes that play critical roles in the digestion and absorption of luminal nutrients. Their chromosomal localization, structure, and regulation of expression have been at least partially characterized. These studies have provided the groundwork for understanding the pathophysiology of several rare but well-described genetic disorders of small intestinal transport, and have begun to clarify the mechanisms underlying more common gastrointestinal problems such as lactase deficiency. This chapter summarizes the important molecular and genetic developments relevant to the study of IBD, celiac sprue, lactase deficiency, glucose–galactose malabsorption, and abetalipoproteinemia as several prominent examples of how molecular technology can help advance the practice of gastrointestinal medicine.

INFLAMMATORY BOWEL DISEASE

CLINICAL PRESENTATION The IBDs include Crohn's disease and ulcerative colitis. These are chronic inflammatory disorders of the gastrointestinal tract that are manifested by symptoms of diarrhea and abdominal pain. Although the clinical presentation may be quite similar, important differences in their underlying pathophysiology result in unique complications and long-term sequelae. In ulcerative colitis, the colon is the primary affected organ, but Crohn's disease can occur in any part of the gastrointestinal tract from mouth to anus. Ulcerative colitis is characterized by a predominantly superficial mucosal inflammation. In Crohn's disease, the inflammatory process is transmural and granulomatous, affecting all layers of the gastrointestinal tract, from mucosa to serosa.

The etiology of these disorders is unknown. The identification of C-terminal caspase recruitment domain (CARD15/NOD2) as a Crohn's disease susceptibility factor has supported the roles of genetic factors and immune responses to luminal gut flora in its pathogenesis (*see* IBD Gene Discovery). A variety of disease-susceptibility chromosomal loci have been identified by linkage analysis of families with IBD. Several of these contain immune regulatory gene clusters. Studies of mice with targeted disruption of cytokine or T-cell receptor genes, or of chimeric transgenic mice in which there is disruption of the N cadherin gene or overexpression of tumor necrosis factor (TNF)-α, have provided promising new models of IBD. These novel systems may help clarify the etiology and pathogenesis of these disorders and aid in the design of new therapeutic agents.

EPIDEMIOLOGY There are marked geographic differences in the incidence of IBD. The highest incidence rates are found in northern Europe and North America among Caucasians, ranging from 2 to 10/100,000. Prevalence of ulcerative colitis in these regions is 37–246 cases/100,000 person-years, and Crohn's disease is 26–199 cases/100,000. The incidence of IBD in southern Europe, Asia, and the developing world is low but has been rising. IBD appears to be more common in Jews of European or Ashkenazic origin, but not of Sephardic (African and Mediterranean) origin. The peak age of onset is from 15–25 yr, and a second peak between 55 and 65 yr of age has been suggested. There is a slight female predominance in the prevalence of both disorders. Although the disease is most common in Caucasians, the incidence in African Americans appears to be increasing, and in some pediatric studies reaches that of Caucasians.

Asian and Hispanic Americans continue to have a lower incidence of IBD. Environmental risk factors include cigarette smoking, which increases the risk of Crohn's disease but appears to be protective in ulcerative colitis. Other studies support the possible involvement of mycobacteria in Crohn's disease pathogenesis.

CROHN'S DISEASE

Location of Disease, Signs, and Symptoms Crohn's disease can affect any part of the gastrointestinal tract. The most frequently involved sites are the ileocolon (40%), the small intestine alone (30%), or the colon alone (25%). Other regions of the gastrointestinal tract may also be involved, including the mouth, esophagus, and stomach. Anal involvement is common. Inflammation may involve the bowel in a segmental fashion, with "skip" areas of normal small and large intestine intermixed with patches of inflamed mucosa. Symptoms resulting from the inflammatory process include abdominal pain (especially in the right lower quadrant owing to terminal ileal involvement) and diarrhea. Other frequent symptoms include fever, weight loss, and malaise. A variety of extraintestinal manifestations including arthritis, uveitis/iritis, and skin diseases such as erythema nodosum and pyoderma gangrenosum are associated with IBD. Signs of active Crohn's disease include right lower quadrant abdominal fullness, mass or tenderness, and a chronically ill appearance.

There are multiple causes of diarrhea in Crohn's disease. Enhanced secretion occurs in the small bowel and colon because of inflammation. Patients with ileal disease or ileal resection may malabsorb bile salts, as specific receptors and transport proteins are expressed only in the ileum. Unabsorbed bile acids then enter the colon in which they produce a secretory diarrhea. Extensive terminal ileal involvement or resection of greater than 100 cm of ileum results in fatty acid diarrhea because of excessive loss of bile salts that cannot be replaced by enhanced hepatic production. Fat malabsorption may also result from bacterial overgrowth because of strictures of the small bowel leading to deconjugation of bile salts. Crohn's disease has also been associated with lactase deficiency, resulting in maldigestion of milk and milk products. Undigested lactose then produces an osmotic diarrhea.

Complications The transmural inflammatory process characteristic of Crohn's disease leads to many complications. Inflammation may lead to ulceration through all layers of the bowel, resulting in the formation of fistulous tracts. Fistulas can form between the gut and any neighboring organ. Enteroenteric, enterocolonic, and enterocutaneous fistulas are frequently found in Crohn's disease. Less common are enterovesicular and enterovaginal fistulae. Strictures of the small or large bowel may result from chronic inflammation and can lead to intestinal obstruction. If severe and unremitting despite conservative management, strictures may require surgical resection to permit the continuation of normal enteral nutrition.

Perforation of the small bowel or colon may precipitate the onset of an acute abdomen requiring immediate surgical intervention. Alternatively, perforations and fistulas may produce intra-abdominal abscesses, another common complication of Crohn's disease. Abscesses may occur anywhere in the peritoneal cavity and must be drained to control sepsis.

Patients who have undergone surgical resection or who have extensive small bowel inflammation, fistulas, or strictures may suffer from short bowel syndrome with excessive diarrhea, volume loss, and malabsorption. These patients frequently require treatment with total parenteral nutrition to maintain a normal nutritional and fluid and electrolyte status. As indicated, loss of functional ileum may lead to fat malabsorption. Because of these complications, surgery is avoided whenever possible.

Kidney stones are most frequently made up of oxalate and are found in patients with ileal disease and fat malabsorption. Calcium, which normally binds to oxalate to produce insoluble calcium oxalate, is instead bound by fatty acids. This leads to the formation of sodium oxalate, which is readily absorbed through the colon, leading to hyperoxaluria and stone formation.

ULCERATIVE COLITIS

Location of Disease, Signs, and Symptoms Ulcerative colitis is characterized by a continuous mucosal inflammatory process affecting the colon. Inflammation may be confined to the rectum alone (ulcerative proctitis), may extend from the rectum to the left colon, or may involve the entire colon. Unlike Crohn's disease, at least part of the rectum is always involved and the inflammatory process is continuous in affected areas (i.e., there are no "skip" regions). Abdominal pain, diarrhea, and gastrointestinal bleeding are common clinical presentations of this disorder. Anorexia and weight loss are occasionally present but are not common. Unlike Crohn's disease, which frequently follows a low-grade, chronic course, ulcerative colitis patients may present with fulminant colitis necessitating urgent colectomy. Physical findings include abdominal tenderness and grossly bloody stool on rectal examination. In fulminant cases, abdominal distention, massive hemorrhage, fever, and tachycardia may be present.

Complications *Toxic megacolon* may occur in patients with acute fulminant colitis. The colon becomes atonic and dilated resulting from severe inflammation and can perforate if untreated. Toxic megacolon requires emergent surgical consultation and in many cases, removal of the colon. *Strictures* may result from chronic inflammation. *Colon cancer* is an important complication of long-standing ulcerative colitis. Although the precise risk of colon cancer is not clear, it is increased in patients with disease for greater than 8–10 yr, and is higher in patients with pancolitis compared with left-sided colitis alone. To prevent colon cancer either prophylactic colectomy or yearly colonoscopic screening for dysplasia/cancer is recommended depending on the patient's preference and disease activity. An important advance has been the development of the ileoanal anastomosis. Instead of an ileostomy, bowel continuity is maintained by creating an ileal reservoir in place of the rectum. This has led to greater acceptance for surgical options in the treatment of ulcerative colitis.

Extraintestinal Manifestations There are multiple extraintestinal manifestations of IBD, including arthritis, skin and ocular diseases, liver involvement, kidney stones, and osteoporosis. The arthritic complaints include colitic arthritis, ankylosing spondylitis, and sacroiliitis. The large joints are generally involved in colitic arthritis. Arthritic complaints generally respond to adequate treatment of the bowel disease. Symptoms resulting from ankylosing spondylitis and sacroiliitis may be severe and more refractory to treatment. Skin manifestations of IBD include pyoderma gangrenosum and erythema nodosum. Ocular diseases are predominantly uveitis and episcleritis. Liver involvement may manifest as sclerosing cholangitis or pericholangitis. Cholesterol gallstones occur in Crohn's disease if there is ileal involvement or after resection, resulting in bile salt malabsorption. Finally, kidney stones may form in patients with small intestinal Crohn's disease and fat malabsorption, and are usually made up of calcium oxalate or urate. Osteoporosis may result from chronic fat malabsorption leading to calcium and vitamin D deficiency and from chronic corticosteroid therapy.

DIAGNOSIS

History and Physical Examinations A history of bloody diarrhea, abdominal pain, and fever should lead to a strong suspicion for ulcerative colitis. Symptoms in Crohn's disease are frequently more indolent and chronic, including intermittent diarrhea and fevers, abdominal pain, and weight loss. Physical findings in ulcerative colitis may include abdominal tenderness, and in fulminant disease, distention, decreased bowel sounds and an acute abdomen. In Crohn's disease, abdominal tenderness and an inflammatory abdominal mass may be present, particularly in the right lower quadrant. The perianal and perirectal regions should be examined for signs of fistulization and abscess. Signs of extraintestinal disease, including arthritis, ocular inflammation, and skin nodules or ulcers may be detected.

Laboratory and Pathological Examinations There is no specific laboratory test that is diagnostic of ulcerative colitis or Crohn's disease. An elevated white blood cell count can be seen in active disease or may be an indicator of sepsis because of perforation or abscess formation in Crohn's disease. Anemia may result from gastrointestinal bleeding or nutrient deficiencies (e.g., vitamin B12 owing to ileal Crohn's disease, decreased iron absorption in duodenal Crohn's disease). Erythrocyte sedimentation rate may be elevated in active disease. Nutritional parameters such as blood total protein and albumin levels may also be deranged in Crohn's disease.

Pathological specimens (endoscopic biopsies or surgical resection) may reveal evidence of active inflammation. Characteristic of colitis are crypt abscesses, in which neutrophils invade the crypts. Granulomas are more characteristic of Crohn's disease. Crypt atrophy and distortion are also seen, as is acute and chronic inflammation with lymphocytes and eosinophils, and mucin depletion. Ulceration of the mucosa occurs in ulcerative colitis, but the presence of transmural inflammation is most characteristic of Crohn's disease.

Radiological and Endoscopic Studies Evaluation of the mucosa for the presence of active disease can be achieved by endoscopic examination. In patients with symptoms of colitis, colonoscopy may aid in the initial diagnosis and is required to determine the extent of disease activity. The mucosal surface is observed for the presence of erythema, edema, granularity, friability, and ulceration. The extent of colonic involvement may help differentiate Crohn's disease from ulcerative colitis. The presence of "skip" areas, in which normal mucosa is intermixed with inflamed mucosa, is most characteristic of Crohn's disease, whereas in ulcerative colitis, inflammation is continuous. During colonoscopy, the terminal ileum may be entered and evaluated for involvement by Crohn's disease. Direct visualization of the upper gastrointestinal tract by routine upper endoscopy or small bowel enteroscopy may also help to establish the presence of Crohn's disease.

Radiological examination is an important part of the diagnostic evaluation of patients with IBD. Contrast studies are useful for detecting strictures and fistulae, as well as assessing disease activity in regions of the small intestine that are inaccessible to routine endoscopy. Patients with ulcerative colitis may demonstrate typical findings on barium enema, including straightening and shortening of the colon, loss of normal haustrations, and inflammatory polyps or malignancy. Mucosal detail is more difficult to assess with radiography, and endoscopic examination is generally preferred. In patients with very active colitis, radiographic examination is avoided because of the fear of inducing toxic megacolon owing to the introduction of air and barium. Similarly, colonoscopic testing is performed with caution and usually in a limited manner. Computerized axial tomographic scanning is an important diagnostic modality particularly for abscess detection in Crohn's disease. If accessible, CT-directed drainage of abscess collections may be performed.

GENETIC BASIS As confirmed by the discovery of the *CARD15/NOD2* gene mutation that confers susceptibility to Crohn's disease (*see* IBD Gene Discovery), genetic factors clearly play a role in the pathogenesis of IBD. Genetic predisposition to Crohn's disease was suggested by studies indicating an increased incidence in families, specific ethnic groups, and in twins. Of patients with IBD, approx 10–20% have a family history, and the risk for first degree relatives to develop IBD is 2–5%. Twin studies indicate that monozygotic twins have a higher concordance rate than dizygotic twins. The complex clinical manifestations of these diseases suggest a heterogeneous genetic basis.

MOLECULAR PATHOPHYSIOLOGY The etiology of the IBDs is unknown. One widely accepted hypothesis is that IBD results from an abnormal host immune response to normal gut components such as microflora, nutrients, or cellular constituents. Intestinal bacterial flora is postulated to be particularly important in activating the mucosal immune system in IBD. This may also be accompanied by a primary defect in gut permeability that allows antigens to nonspecifically "leak" through the mucosa and thereby stimulate an inflammatory response.

IBD GENE DISCOVERY: CARD15 AND IBD SUSCEPTIBILITY GENES A major advance in the study of Crohn's disease pathophysiology has been the identification of *CARD15/NOD2* as the first Crohn's susceptibility gene. *CARD15/NOD2*: encodes an intracellular protein that is involved in bacterial detection via peptidoglycan recognition. *CARD15/NOD2*: may play an important role in generating a protective response following exposure to bacteria. There are three genetic variants associated with Crohn's disease; 10–30% of patients with Crohn's disease are heterozygotes for one of these variants, and a smaller percentage of patients are homozygous or compound heterozygotes for these mutations. Yet, even homozygotes have only a 1 in 25 risk for developing disease, indicating the requirement for additional genetic and/or environmental factors. Interestingly, *CARD15/NOD2*: mutations are most consistently associated with the presence of ileal disease.

Other susceptibility loci for IBD have been identified by whole genome scanning techniques. There are presently seven loci, termed IBD1-7, that meet linkage criteria. These chromosomal regions include, for example, human leukocyte antigen (HLA) and cytokine gene clusters, which have been postulated to fit the role of disease susceptibility genes. However, the specific genes and mutations have not been identified.

Animal Models of IBD The specific role of a gene can be determined in the whole animal in "loss of function" experiments that utilize embryonic stem cell techniques. Mutations in specific target genes can be created in these cells to delete the gene or produce a sequence that encodes a nonfunctional protein. The mutated stem cells are injected into a mouse blastocyst and grown in a host mouse. Heterozygous mice are then backcrossed to create homozygous mutants.

In this manner, targeted deletion of various immune mediator genes has been performed. Interestingly, when interleukin (IL)-2, IL-10, major histocompatibility complex (MHC) class II or T-cell receptor α- or β-genes are deleted, gross inflammation of the bowel is produced in mice. IL-2 is produced by activated T cells and is an important regulator of immune responses. It increases T-cell

Table 56-1
Comparison of Crohn's Disease and Ulcerative Colitis

Clinical feature	*Crohn's disease*	*Ulcerative colitis*
Site of involvement	Entire gastrointestinal tract	Colon only
Pathology	Transmural inflammation, granulomas	Mucosal inflammation
Extraintestinal manifestations	Skin	Skin
	Eyes	Eyes
	Joints	Joints
Complications	Strictures, fistulae, abscesses	Strictures, colon cancer, toxic megacolon
Treatment	Surgical removal of diseased segments avoided because of disease recurrence	Surgical removal of diseased colon is curative

proliferation, leads to differentiation of B cells, and activates macrophages, natural killer cells, and lymphokine-activated killer cells. IL-10 is produced by T-helper cell subset 2, macrophages, keratinocytes, Ly-1 B cells, and thymocytes. It increases MHC class-II expression on B cells, and suppresses macrophage activation in vitro. IL-10 inhibits IL-1, IL-6, and TNF-α production by activated macrophages. Deletion of the IL-2 or IL-10 gene produces inflammation of the intestine, but with different clinical features. Deletion of IL-2 led to colonic disease, with diarrhea, rectal prolapse, and bleeding. Pathological examination of the colon showed crypt abscesses, ulceration, goblet cell depletion, and epithelial dysplasia. MHC class-II expression, normally limited to the small intestine, was seen in the colon. In contrast, deletion of IL-10 led to a chronic enterocolitis affecting the entire gastrointestinal tract with growth retardation and iron deficiency anemia. Mucosal inflammation with villus loss, mucosal gastrointestinal erosions, and crypt hyperplasia were found in small intestine and colon. MHC class-II expression was aberrantly enhanced in a small bowel and colonic epithelium. The onset of disease in the majority of mice was relatively rapid; by 3–4 wk, growth retardation was noted.

Interestingly, in both models, maintenance in a pathogen-free environment greatly diminished the intestinal inflammation. IL-10 mice had disease limited to the proximal colon only, and IL-2 mice were free of disease. A third model of IBD was generated in T-cell receptor α- or β-mutants, which lack αβ-T cells. These mice developed colonic inflammation but no diarrhea or bleeding. TNF has been implicated as a key pathogenic mediator in Crohn's disease and a model of TNF overexpression has been developed. These $TNF^{\Delta ARE}$ mice bear an endogenous deletion in the 3′AU rich region in the TNF gene resulting in high circulating TNF levels. These mice develop a specific Crohn's disease-like phenotype with chronic transmural ileitis.

Not only can immune cell defects produce intestinal inflammation, but disruption of the protective epithelial barrier may also lead to IBD. A dominant-negative N-cadherin mutant was linked to an intestine specific promoter and thus was selectively disrupted in the gut, in villus as well as crypt cells. This resulted in markedly decreased expression of E-cadherin with gross disruption of the epithelial barrier and severe mucosal inflammation. The small intestine was selectively affected with lymphoid hyperplasia, blunted villi, cryptitis and crypt abscesses, mucosal ulcerations, and eventually adenoma formation.

Although these models of IBD are diverse, they support several hypotheses regarding the etiology of these disorders. Disruption of the epithelial barrier can lead to intestinal inflammation even in the presence of a normal immune system. Selective immune defects that lead to the unopposed action of B cells can produce inflammation of the gut. Also the intestine is clearly vulnerable to inflammation because of constant external antigen exposure and the presence of luminal substances.

MANAGEMENT

Medical Therapy Because the underlying cause of IBD is still unknown, therapy is presently directed toward controlling the intestinal inflammatory response (Table 56-1). One of the mainstays of treatment is oral and enema compounds containing 5-aminosalicylic acid (5-ASA), available in several different forms. These compounds are effective in the treatment of mild-to-moderate ulcerative or Crohn's colitis as single agents. They are used in conjunction with corticosteroids in the treatment of severe disease. Although their precise mechanism of action is unknown, they are thought to inhibit leukotriene synthesis via their inhibition of neutrophil lipoxygenase, particularly leukotriene B4. *Sulfasalazine* was the first of these agents and consists of 5-ASA bound to a sulfapyridine residue to prevent its premature absorption in the small intestine. Colonic bacteria are required to release the 5-ASA component. However, many side effects result predominantly from the sulfapyridine component, including dose-related effects, such as headache, nausea, vomiting, anorexia, fever, and rash. Idiosyncratic, hypersensitivity responses include rash, hemolytic and aplastic anemia, and agranulocytosis. Also, long-term usage in young men is frequently limited by its adverse effects on sperm count and morphology. Therefore, several compounds have been formulated containing 5-ASA alone, with various modifications to facilitate its delivery to the small intestine and colon, or preferentially to the ileum and colon, without excessive systemic absorption before reaching its preferred site. These include *Pentasa*, *Asacol*, and *Dipentum*. Pentasa and Asacol are released by pH-dependent mechanisms. Pentasa is an ethylcellulose-coated form of mesalamine (5-ASA) that is released throughout the small intestine and colon. Asacol is coated with an acrylic-based resin that dissolves at pH 7.0 or greater, facilitating its release only at the terminal ileum and colon. Dipentum consists of two 5-ASA molecules linked by an azo bond that is cleaved in the colon. These newer formulations clearly have fewer side effects than sulfasalazine and, thus, have

led to an expanded pharmacological armamentarium. Mesalamine in enema form (Rowasa enemas) is a valuable treatment for ulcerative proctitis.

Corticosteroids are important in the therapy of moderate to severe IBD because of their broad anti-inflammatory actions. They are used in the treatment of active ulcerative colitis as well as Crohn's disease of the small and large bowel. Owing to the numerous side effects attendant with chronic glucocorticoid usage, long-term therapy for IBD is avoided. There is no data supporting its use in maintaining disease remission, unlike 5-aminosalicylate containing compounds in colitis.

Antibiotics are critical for the treatment of infectious complications of Crohn's disease, such as sepsis, abscess formation, and small bowel bacterial overgrowth. Metronidazole has been used successfully to treat perianal disease and colonic Crohn's disease. With the recognition of the importance of bacterial flora in Crohn's pathogenesis, antibiotics have increasingly been used as treatment for active disease.

Immunosuppressive agents such as azathioprine and its metabolite, 6-mercaptopurine, are used in Crohn's disease and to a lesser extent, in ulcerative colitis, for steroid-dependent and poorly controlled patients. Treatment is generally begun in patients who cannot be tapered from corticosteroids because of recurrent symptoms and who have major side effects, such as osteoporosis, hypertension, cataracts, glucose intolerance, and so on. Alternatively, immunosuppressive agents may be added to treat the patient with refractory disease inadequately treated with corticosteroid and 5-ASA compounds. Immunosuppressive agents are also used in patients with ulcerative colitis and refractory proctitis, but less commonly.

Other agents for active ulcerative colitis and Crohn's disease include methotrexate and cyclosporine. There are data that support the use of intravenous cyclosporine for severe colitis as a last-ditch medical effort to avoid surgical intervention. Methotrexate may be used as an alternative medication for steroid-dependent patients to induce and maintain a steroid-free remission.

The addition of infliximab, a chimeric monoclonal antibody to human TNF-α, has remarkably expanded the Crohn's disease treatment repertoire and is an excellent example of how understanding the molecular pathophysiology of disease leads to improved treatment regimens. As indicated, TNF is a major proinflammatory immune regulator with a prominent role in Crohn's disease. Infliximab infusion can induce remission in refractory Crohn's disease and can heal fistulous disease. Optimal treatment regimens, designed to maximize efficacy and minimize side effects, are being developed. This drug has been approved to maintain remission in Crohn's disease.

Surgical Treatment In fulminant ulcerative colitis that is refractory to medical therapy, total colectomy may be unavoidable. In addition, surgical resection may be required for corticosteroid-dependent patients with ulcerative colitis who have major steroid-induced side effects. Colectomy may also be performed in patients with colonic dysplasia or carcinoma, or prophylactically to prevent colon cancer in patients with >10 yr history of active ulcerative colitis. As an alternative to prophylactic colectomy, yearly colonoscopic screening for colon cancer may be performed after 8–10 yr of disease. The major problems with this approach are that cancers in ulcerative colitis arise from flat mucosa and, therefore, may be missed and accurate grading of dysplasia is difficult. Colectomy is curative in ulcerative colitis and ileoanal anastomotic procedures eliminate the need for an ileostomy. This surgical procedure is not an option for patients with Crohn's disease, as there is a high incidence of recurrent disease in the ileal pouch leading to diarrhea, bleeding, pain, severe malfunction of the pouch, and eventually, the need for revision. In addition, surgery is *not* curative in Crohn's disease because it recurs commonly in all parts of the intestinal tract. Therefore, the approach to patients with Crohn's disease is very cautious and surgical intervention is avoided whenever possible. However, limited resection is often performed to relieve obstruction resulting from strictures to repair perforations or for abscess drainage.

FUTURE DIRECTIONS Significant research developments include the generation of animal models that recapitulate many of the features of human IBD, the identification of CARD15 mutations in CD, and the localization of new chromosomal susceptibility loci for IBD. The novel mouse models have proven useful for elucidating the pathogenesis of these disorders and for designing more effective therapies. The identification of the gene(s) that are responsible for the familial risk of IBD will undoubtedly continue to be a major research focus, as the key to developing new diagnostic and therapeutic approaches.

CELIAC SPRUE

Celiac sprue (also called celiac disease or gluten-sensitive enteropathy) is a chronic disease of the small intestinal mucosa resulting from exposure to dietary proteins contained in wheat, rye, and barley. The alcohol soluble component of wheat-derived gluten, or gliadin, and similar proteins derived from rye, barley, and oats, are toxic to the mucosa of susceptible individuals. In classic celiac sprue, the small bowel demonstrates complete villus atrophy and marked crypt hyperplasia, resulting in malabsorption and diarrhea. It is clear that specific host genetic factors are required in combination with exposure to gliadin to damage the epithelium. Linkage to histocompatibility antigen loci has been recognized for many years. The antigen recognized by the antiendomysial antibody has been identified as tissue transglutaminase. Data suggest that deamidation of gliadin proteins by tissue transglutaminase is required for the generation of epitopes that are recognized by CD4+ T cells. A specific 33 amino acid peptide has been identified that is derived from alpha gliadin by digestion with gastric and pancreatic enzymes, is not further proteolyzed into smaller fragments despite continued exposure to these enzymes, reacts with tissue transglutaminase and induces gut-derived T cells from patients with celiac sprue. These discoveries may have therapeutic implications to permit the development of a novel, antigen-specific immunotherapy.

CLINICAL PRESENTATION Patients with celiac sprue exhibit a broad spectrum of clinical presentations. In children, the disease tends to occur in the first 3 yr of life. In adults, the peak incidence is in the third decade, but may occur at any age. In the classic clinical presentation, extensive loss of normal villi throughout the small intestine leads to gross malabsorption and steatorrhea, severe weight loss, wasting, multiple vitamin deficiencies, and abdominal distention. The vitamin deficiencies may lead to anemia (B12, folate, iron), or a bleeding diathesis (vitamin K). Neurological symptoms such as peripheral neuropathy and paresthesias are also common. In other cases, patients may be asymptomatic or complain only of mild abdominal discomfort, malaise, bloating, and diarrhea. Those with more patchy proximal intestinal involvement may present simply with iron or folate deficiency, or osteomalacia. Relatives of patients with celiac sprue who are screened for the disease often have mild illness or may be completely asymptomatic.

Celiac sprue is frequently associated with other disorders. Dermatitis herpetiformis is characterized by severely pruritic papulovesicular lesions of the skin. The majority of afflicted patients show intestinal biopsy findings characteristic of celiac sprue. These patients are often only mildly affected by the gut lesion and may even be asymptomatic. Isolated nutrient deficiencies may be the only clinical manifestation. Both the intestinal and skin lesions resolve with gluten withdrawal.

Other diseases that are associated with celiac sprue include insulin-dependent diabetes mellitus (50-fold higher incidence of celiac disease in patients with diabetes), thyroid disease, and selective IgA deficiency, which share similar HLA haplotypes. Complications of celiac sprue include the development of T-cell lymphoma or other gastrointestinal malignancies. Ulcerative jejunoileitis is a serious complication resulting in ulceration and stricture of the small bowel with bleeding, perforation, and obstruction. Finally, patients may become refractory to removal of gluten from the diet and may require treatment with corticosteroids or immunosuppressive agents.

EPIDEMIOLOGY Celiac sprue is most prevalent in Caucasians, particularly in Northern Europe. The highest prevalence has been reported in Ireland at a frequency of 1/300 but the more typical incidence in Europe is 1–2/10,000 population. Asians from India and Pakistan are also frequently affected, but the disease is rare in Japanese, Chinese, and Africans. A study of Minnesota residents who were symptomatic and had celiac sprue documented by biopsy and response to a gluten-free diet revealed an incidence of celiac sprue of 1.2/100,000 person-years in the United States, with a prevalence of 21.8/100,000. Studies have indicated a decrease in the prevalence of childhood celiac sprue in several European countries, perhaps because of changes in feeding or other unidentified environmental factors.

DIAGNOSIS A valuable test for the diagnosis of celiac sprue is the small intestinal biopsy. Forceps biopsies of the duodenum or proximal jejunum can be obtained during routine upper endoscopy or peroral capsule biopsy techniques may be used. Biopsy should be performed before the initiation of gluten withdrawal and can also be repeated after removal of gluten from the diet to document an adequate response. Typical findings on biopsy are absence or atrophy of villi, crypt elongation and hyperplasia, and increased immune cell infiltrate. There is a marked increase in intraepithelial lymphocytes and infiltration of the lamina propria with lymphocytes, eosinophils, and macrophages. Because the biopsy findings in celiac sprue are not unique and can be seen in tropical sprue, lymphoma, viral or eosinophilic gastroenteritis, common variable immunodeficiency, or parasitic infection, the clinical response to removal of gluten in conjunction with biopsy is critical for definitively making the diagnosis. Rechallenge with gluten and rebiopsy is rarely recommended (except in equivocal cases).

Antibody tests are used in conjunction with small bowel biopsy to confirm the diagnosis. Serum antigliadin antibodies are positive in approx 90% of patients with untreated sprue but are also found in other disorders such as sarcoidosis and rheumatoid arthritis. Antiendomysial antibodies, which are recognized to be directed against the autoantigen tissue transglutaminase, are also elevated in patients with histological abnormalities on biopsy, detecting more than 95% of untreated patients. Tissue transglutaminase antibodies are virtually pathognomonic of celiac disease.

GENETIC BASIS Genetics plays an important role in celiac sprue, but in conjunction with environmental and other factors. Approximately 8–12% of family members of patients with celiac sprue are also affected, as determined by intestinal biopsy. Interestingly, only 50% of all family members with abnormal biopsies manifest symptoms of the disease. In identical twins, there is 70% concordance for celiac sprue, indicating that factors other than genetics play a role in disease susceptibility.

The linkage of celiac sprue with specific MHC genes has been recognized for years. There is a strong association with HLA class-II haplotypes, particularly HLA DQ2 and HLADQ8. In Northern Europeans, the DR w17 and DQ w2 serological specificities are very common. HLA DQ2 is present in 90% of patients with celiac sprue. Molecular analysis indicates that a specific DQ α- and β-chain molecule encoded by DQA1*0501 and DQB1*0201 is found in 99% of Scandinavians with sprue. In southern European populations, the same HLA-DQ molecule is expressed on an HLA-DR7 and DR5 (or DR11/DR7, DR12/DR7) haplotype, as opposed to HLA DR3, DQ2 (or HLA-DR17) in northern Europeans. These molecules are necessary but not sufficient for developing the disease, because HLA identical siblings have only 40–50% concordance for this disease, and only a small percentage of the population that carries these alleles develops sprue. In addition, some populations do not demonstrate the same very high percentage of patients with HLA-DQ2, but instead are DR4 positive. Sequence analysis of the HLA DQ alleles from patients with celiac disease revealed no mutations when compared with normal individuals. This suggests that molecules encoded in regions outside of this HLA locus are required for generating the disease and there may be different genetic subgroups.

MOLECULAR PATHOPHYSIOLOGY The biochemistry of gluten and gliadin has been intensively studied to identify the protein moieties that are responsible for toxicity. The alcohol soluble component of gluten, gliadin, appears to be responsible for the disease. Several reports have shown that there are three peptides derived from alpha gliadin (located between amino acids 57 and 75, with the sequences PFPQPQLPY, PQPQLPYPQ, and PYPQPQLPY) that are deamidated by tissue transglutaminase and are recognized by CD4+ T cells from patients with celiac disease. Reports suggest that deamidation is required for T-cell stimulation, as it results in the production of negatively charged amino acids that are required for binding to the HLA-DQ2 molecule. A 33 amino acid peptide was identified that is derived from alpha gliadin by digestion with gastric and pancreatic enzymes, is not further proteolyzed into smaller fragments despite continued exposure to these enzymes, reacts with tissue transglutaminase and induces gut-derived T cells from patients with celiac sprue. However, it is likely that other peptides can also induce disease, as indicated by the diversity of antigenic responses in children.

Based on its sequence homology to A-gliadin, another environmental factor that may play a role in the pathogenesis of celiac sprue is a history of adenovirus 12 infection. There is a region of homology between the adenovirus serotype 12 E1b protein to A-gliadin that spans 12 amino acids, with eight identical residues. In addition, almost 90% of patients with untreated celiac sprue had serological evidence of prior adenovirus 12 infection, compared with only 17% of disease controls. These data suggest that mechanisms of molecular mimicry may be involved in the pathogenesis of this disorder, in which T cells recognize peptides in common to gliadin and viral proteins. However, adenovirus 12 DNA has not been detected in intestinal samples, and peptide challenge with an

oligopeptide derived from the homologous region has not been shown to produce intestinal injury.

MANAGEMENT Removal of all gluten from the diet is the primary therapy for celiac sprue. Wheat, rye, oats, and barley-containing products must be eliminated from the diet because gluten and other related prolamins can produce injury. This restricted diet must be maintained lifelong. Patients may initially exhibit lactose intolerance because of villus atrophy and brush border enzyme deficiency, but this should resolve with treatment.

DISORDERS OF SMALL INTESTINAL ABSORPTION AND TRANSPORT

The brush border of the small intestinal enterocyte contains disaccharidases, peptidases, and transport proteins that are responsible for the absorption of ingested nutrients. Progress has been made in clarifying the molecular basis of several disorders characterized by selective malabsorption of carbohydrates or lipids. This section presents a summary of advances in understanding the pathophysiology underlying several of the more common of these defects.

LACTASE DEFICIENCY

Clinical Features and Epidemiology Lactase is one of the best-studied of the brush border enzymes. It is responsible for the hydrolysis of lactose into glucose and galactose. Several clinical categories of lactase deficiency have been described. Congenital lactase deficiency is a rare autosomal-recessive disorder, resulting in milk intolerance from birth. Much more common is the onset of diminished enzyme activity in childhood or adolescence and lasting into adulthood, also known as adult-onset hypolactasia. Loss of brush border lactase activity may also result from other small intestinal disorders, such as Crohn's disease, celiac sprue, viral illnesses, or other infections.

Loss of lactase activity beginning in childhood/adolescence occurs in the majority of humans throughout the world except for Caucasian populations. In particular, most white northern Europeans and their descendants in North America and Australia (populations that were traditionally cattle farmers and thus persistent milk drinkers) retain high lactase activity lifelong. The prevalence of lactase deficiency throughout the world supports the hypothesis that the decline in lactase activity with age is a normal event in response to weaning, common to all land mammals. Persistence of lactase activity has therefore been postulated to be the result of a genetic mutation that occurred in milk-drinking populations, leading to a survival advantage because milk-drinkers might be healthier.

Ingestion of milk and milk products in deficient individuals leads to abdominal pain, diarrhea, bloating, and excessive flatulence because of unabsorbed lactose in the lumen. This results in increased small bowel fluid. Fermentation of lactose in the colon produces hydrogen, methane, and carbon dioxide gas. Removal of lactose-containing products in the diet leads to resolution of these symptoms.

Diagnosis A *lactose tolerance test* may be performed, which consists of administering 50 g of lactose orally. If sufficient lactase activity is present, blood glucose levels will rise by more than 20 mg/dL during a 2-h period. Lactase deficiency is diagnosed by the lack of serum glucose elevation and frequently, the onset of symptoms of malabsorption, with gas, diarrhea, bloating, and abdominal pain. If the serum glucose increases yet symptoms also occur, one must consider occult diabetes mellitus. Alternatively, a trial of dietary lactose avoidance may be attempted. After restriction of oral intake of milk and milk products, the patient is assessed for symptom resolution. Finally, small bowel biopsy allows for definitive diagnosis, but is unnecessary given the adequacy of the other two approaches.

Genetic Basis and Molecular Pathophysiology As determined by population and family studies, adult-onset hypolactasia is an autosomal-recessive trait, and persistence of lactase activity is autosomal-dominant. The molecular basis for lactase persistence/nonpersistence has been the subject of intensive investigation. In the majority of studies, lactase-specific activity and protein levels correlate very well with mRNA, indicating transcriptional regulation of lactase expression. A single-nucleotide polymorphism located at –14 Kb upstream from the start of lactase transcription, in the intron of another neighboring gene known as minichromosome maintenance (which plays a role in cell-cycle control), is highly associated with lactase persistence in Finnish populations. Individuals with low lactase activity were homozygous for a cytidine at this site, whereas lactase persistent individuals had either C/T or T/T. Another association was noted at a single-nucleotide polymorphism at –22018, with a G to A substitution. These substitutions were also associated with higher levels of lactase mRNA expression. Thus *cis*-acting elements appear to be responsible for the persistence/nonpersistence phenotype, based on differences in level of expression of lactase from one allele compared with the other. Studies have also focused on characterizing transacting factors that regulate lactase expression, because, for example, levels of NF-LPH-1, an intestine-specific transactivator that binds to a sequence close to the TATA box, are high in newborn pigs with high lactase activity and low in adult pigs with low lactase activity. Still other data suggest that there is a second phenotype of lactase deficiency, in which post-translational processing of lactase-phlorizin is altered. Thus, the precise molecular mechanisms underlying lactase persistence/nonpersistence are under investigation.

Management The treatment of symptomatic lactase deficiency consists of removal of lactose-containing nutrients from the diet (Table 56-2) and/or the use of oral enzyme replacement therapy. It is preferable to continue some milk and dairy food ingestion because of their rich calcium stores, especially in children and in women who are prone to osteoporosis. Lactase oral preparations are available in capsules or tablets and can be chewed. Replacement pills are taken with meals and titrated to diminish symptoms. Lactase may also be added directly to milk and ingested after an overnight incubation, or pretreated milk can be purchased.

Future Directions The ready availability of oral lactase capsules and the ease of treatment of symptoms by dietary avoidance or supplementation makes more sophisticated approaches to treatment, such as gene therapy, unnecessary. The major research interest still lies in determining how epidemiological observations are linked to genetics; i.e., what are the genetic alterations that lead to lactase persistence in the milk-drinking populations of the world, and are there differences among different ethnic or racial groups. These are questions of great interest to population and evolutionary geneticists.

GLUCOSE–GALACTOSE MALABSORPTION

Clinical Features Glucose–galactose malabsorption is a rare congenital disorder in which enterocytic transport of glucose and galactose is absent, because of mutation of the gene encoding the

Na^+/glucose cotransporter sodium glucose transporter (SGLT)-1. This disease is characterized by the onset of profuse watery diarrhea in newborns that responds to the removal of dietary sources of glucose and galactose. Diarrhea usually develops within 4 d of birth. The diarrhea is so severe that dehydration is frequent. As in other diseases of carbohydrate absorption, the presence of unabsorbed sugars leads to an increase osmotic load in the small intestine with increased luminal fluid. Laboratory findings include an acidic stool pH because of colonic bacterial metabolism of unabsorbed sugar. In addition, sugar is found in the urine, consistent with the expression of SGLT-1 in the kidney. Oral monosaccharide tolerance tests reveal that absorption of glucose and galactose but not fructose is impaired.

Genetics and Molecular Pathophysiology Glucose–galactose malabsorption is an autosomal-recessive disease. The precise incidence of this disorder has not been determined but it is clearly rare, as indicated by the few case reports in the literature. Frequently, there is a history of consanguineous marriage.

Expression cloning of the cDNA that encodes SGLT-1, the Na^+/glucose cotransporter provided a major breakthrough in understanding pathophysiology of this disorder. Specific mutations in SGLT-1 lead to loss of transporter function in humans, resulting in glucose and galactose malabsorption. Analysis of cDNA reverse transcribed from RNA from intestinal biopsies of two affected sisters showed a single missense mutation, with a single base change from G to A at position 92, changing an aspartate to an asparagine. Their parents were heterozygous for this mutation. The autosomal-recessive inheritance of this disorder was confirmed. The mutant SGLT1 mRNA was expressed in *Xenopus laevis* oocytes and compared with the normal SGLT1 mRNA for ability to transport a glucose analog, α-methyl-D-glucopyranoside. As anticipated, the mutant SGLT1 demonstrated no detectable transport activity.

Subsequently, 30 other patients have been screened for mutations in SGLT1. The mutations included missense, nonsense, and frameshift mutations, and some occurred in splice sites at intron–exon boundaries. Two areas were identified as "hot spots" for missense mutations, between residues 289–304 and 369–405. Analysis of the mutant proteins indicated that loss of transporter activity was owing either to the production of truncated or nonfunctional protein, to defective trafficking of the transporter, or to defects in the transport cycle. The SGLT1 gene has been localized to chromosome 22 on the distal q arm.

Management The treatment of glucose–galactose malabsorption is the immediate removal of lactose, glucose, and galactose containing substances from the diet. Fructose is well tolerated, and a fructose-based formula is substituted with rapid resolution of symptoms. There are reports of increasing tolerance to glucose and galactose with age. Rechallenge with small amounts of these sugars may be possible.

Future Directions The cloning of the SGLT-1 cDNA and the identification of naturally occurring mutations has already led to notable advances in the knowledge of the basic mechanisms of sugar transport. The regulation of expression of this and other cotransporters, their mode of insertion in the membrane, and structure–function correlation are all possible to address in the research laboratory. With the identification of the SGLT1 gene, gene therapy may eventually be considered. However, in the near future, this is unlikely because of the relative ease of treatment by elimination diets as well as the rarity of this disorder.

ABETALIPOPROTEINEMIA

Clinical Features Abetalipoproteinemia is a rare disorder, characterized by the absence of apolipoprotein (apo) B containing lipoproteins in plasma. Patients present in infancy with diarrhea resulting from severe fat malabsorption, poor weight gain, and acanthocytosis. Atypical retinitis pigmentosa and spinocerebellar degeneration become apparent at older ages. Ocular symptoms include decreased night and color vision, and neurological signs of ataxia, spastic gait and dysmetria, loss of deep tendon reflexes, and decreased vibratory and proprioceptive sense appear in the second decade. Spontaneous hemorrhage characteristic of a bleeding diathesis may occur because of vitamin K deficiency.

Diagnosis The hallmark of this disorder is an abnormal plasma lipid profile in association with signs of spinocerebellar degeneration and a pigmented retinopathy. Total cholesterol and triglyceride plasma levels are extremely low and there is an absence of apo B containing plasma lipoproteins, including chylomicrons, very low-density lipoproteins, and low-density lipoproteins. Most patients are anemic because of enhanced hemolysis of abnormal red blood cells (acanthocytes). Fat malabsorption leads to deficiency of fat soluble vitamins. In particular, vitamins E, K, and A are affected as they are transported in chylomicrons. Vitamin E deficiency is most severe because its absorption from the intestine, transport to the liver, and circulation in the plasma are dependent on apo B containing lipoproteins. Vitamin E deficiency is clinically important because it is thought to be responsible for the development of neurological and retinal sequelae. Intestinal biopsy reveals lipid laden enterocytes but normal villi, and is useful for distinguishing this disorder from other intestinal illnesses associated with fat malabsorption.

Genetics and Molecular Pathophysiology Abetalipoproteinemia is a rare autosomal-recessive disorder. Consanguinity is common in these families. An absence of plasma lipoproteins

containing apo B led to the hypothesis that this disorder is because of a defect in the *apo B* gene. However, linkage between apo B and abetalipoproteinemia in families has not been established by restriction fragment length polymorphism analysis and defects in the *apo B* gene have not been identified. Because assembly or secretion of apo B containing lipoproteins were most likely defective in this disorder, the microsomal triglyceride transport protein (MTP) was examined in affected individuals. This gene, located on chromosome 4q22-24, encodes a protein that catalyzes the transport of triglyceride, cholesteryl ester, and phospholipid between membranes. It is a heterodimer made up of a protein disulphide isomerase and a unique 97-kd subunit that appears to be responsible for the lipid transport activity. This larger subunit shares homology with lipovitellin 1, a member of the lipid-binding lipovitellin complex that serves as a source for lipid in the developing embryo. MTP activity and particularly the 97-kd subunit, normally present in microsomes from liver and intestine, are absent in intestinal biopsies from patients. Sequence analysis of cDNA and genomic DNA from patients with abetalipoproteinemia revealed homozygous frameshift and nonsense mutations in the gene encoding the 88-kd subunit, resulting in truncated proteins. Two missense mutations have also been identified. Analysis of additional patients indicated frameshift and splice site mutations, most of which lead to the formation of a truncated protein. Transfection of Cos-1 cells with mutant MTP cDNAs lacking part of the carboxy terminus shows decreased lipid transfer activity, supporting the hypothesis that alterations of this protein are the primary cause of abetalipoproteinemia.

Management A low-fat diet and supplementation with high doses of vitamin E as well as vitamins A and K are required. In particular, it is critical to avoid vitamin E deficiency as this appears to be the primary cause of the severe and irreversible neurological and ocular changes characteristic of this disease.

Future Directions The cloning of the cDNA encoding the MTP raises the possibility of gene therapy in the future. Although many of the devastating neurological and ocular sequelae may be avoided by high doses of vitamin E, there may be a role for gene replacement in refractory patients. Also, rapid, definitive diagnosis is crucial, so that prenatal screening of siblings may be useful. Finally, because patients with MTP deficiency have very low cholesterol and triglyceride levels, identification of selective inhibitors of its activity may prove a valuable addition to the treatment of hypercholesterolemia.

57 The Molecular Mechanisms of *Helicobacter pylori*-Associated Gastroduodenal Disease

PETER B. ERNST

SUMMARY

In 1984, Barry Marshall and Robin Warren proposed a role for *Helicobacter pylori* in gastroduodenal disease leading to an avalanche of research intended to prove or disprove their theory. The result has been a series of advances that have updated our understanding of these diseases and completely modernized the clinical approach to their management. In recognition of this impact, Marshall and Warren received the Nobel Prize for Physiology or Medicine in 2005. This chapter summarizes some important findings that have advanced our knowledge in this field with emphasis on the host response and the immunopathogenesis of gastroduodenal disease.

Key Words: Adaptive immunity; B cells; bacterial colonization; cytokines; epithelium; gastric; immunopathogenesis; innate immunity; persistence; T cells.

INTRODUCTION

In 1984, Marshall and Warren proposed a role for *Helicobacter pylori* in gastroduodenal disease. The result has been a series of advances that have updated the understanding of these diseases and completely changed the clinical approach to their management. Many aspects of the pathogenesis of these diseases have been dissected to the molecular level with key pathogenic mechanisms being validated by the association of some genes with the development of gastric cancer. There has been particular emphasis on understanding the molecular structures associated with the organism and their role in modifying the host responses. The gastric immune and inflammatory response have emerged as key elements in the pathogenesis of gastritis and epithelial cell damage that are accepted as being an integral component in the disease process. This chapter summarizes some of the important findings that have advanced the knowledge in this field, with special emphasis on the host response.

Gastric secretions have evolved to facilitate the acid and peptic degradation of luminal contents. This environment precludes the successful colonization by most micro-organisms but *H. pylori* has evolved to survive in this niche. Although *H. pylori* colonizes the majority of humanity, the lack of colonization by a more diverse flora may have limited the selective pressures shaping the evolution of gastric immune and inflammatory responses. Therefore, most research has focused on the interaction between a single species of bacteria and the host response. This approach has forced investigators to compare their findings in the stomach to observations in other tissues infected with a range of organisms.

Epidemiological studies have provided convincing evidence that *H. pylori* is associated with, and indeed responsible for, several gastroduodenal diseases ranging from a generally benign, subclinical gastritis to peptic ulcers and several types of gastric cancer. Advances from experiments manipulating the organism and examining its interaction in cell lines or animal models have shown that infection activates multiple pathways leading to changes in epithelial cell morphology, tight junctions, cytokines, and epithelial cell turnover. Clearly, the molecular pathogenesis involves many factors and complementary interactions among the bacteria and various elements of the host response.

EPIDEMIOLOGY

The majority of new *H. pylori* infections occur in children; however, in the absence of specific clinical signs associated with infection, the details concerning the mode of transmission are less clear. Vomitus, saliva, and feces are the presumed sources of direct transmission particularly in crowded housing conditions. Generally, infection correlates inversely to socioeconomic conditions as lifetime infection rates in countries with a strong economy have dropped toward 10%, although rates in countries with emerging economies approach 80–90%. Once established, the infection persists for life unless antibiotic therapy is administered.

Most infected individuals experience subclinical gastritis although gastroduodenal ulceration may occur in 10–15% of the infected population. Gastric cancer is less frequent with approx 1% of infected individuals developing adenocarcinoma whereas even less experience gastric maltoma. In fact, *H. pylori* has been recognized as a type-I carcinogen by the World Health Organization. One study has even suggested that *H. pylori* is a necessary condition for noncardia gastric cancer. The geographic distribution of these

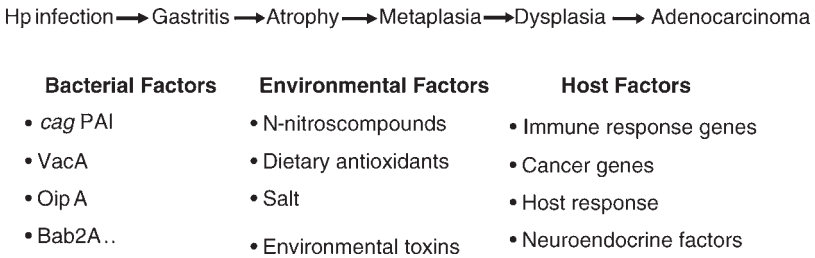

Figure 57-1 Proposed pathogenesis for gastric cancer associated with *Helicobacter pylori* infection. Originally, a multi-step pathogenesis was proposed for gastric cancer that began with gastritis and progressed to atrophy, metaplasia, dysplasia, and sometimes cancer. With the recognition of *H. pylori* as a major cause of gastric cancer, the etiology has been identified. Because not everyone infected with *H. pylori* develops gastric cancer, several modifiers have also been identified. The perception is that gastric cancer arises from multiple "hits" that include oxidative stress and environmental toxins that increase mutation rates. Diet, bacterial factors, and genes regulating the host response likely affect the degree of oxidative stress and DNA damage. Once key genes are mutated, the enhanced epithelial growth associated with infection drives the tumor proliferation. OipA, outer inflammatory protein A; cag PAI, cag pathogenicity island; VacA, a vacuolating cytotoxin.

diseases suggest that gastric cancer is more common in Asian and Latin American countries whereas duodenal ulcers occur more frequently in Western Europe and the United States or Canada. Paradoxically, chronic infection in Africa is not associated with cancer and remains the "African Enigma." These interesting patterns imply that regional differences in bacterial strain or environmental factors have a significant impact on the outcome of infection (Fig. 57-1). Studies examining the impact of strains on inflammation and disease have yielded several interesting associations (discussed later) but the predictive value of specific bacterial factors remains limited as most "virulent" strains can also be found in many asymptomatic subjects. The variation in the host response also affects outcome as genetic studies in humans suggest that mutations leading to an increase in gastric immune/inflammatory responses are associated with gastric cancer. Thus, the collective evidence points to a multifactorial process in the pathogenesis of the diseases associated with this infection.

PATHOGENESIS

BACTERIAL PATHOGENESIS

Colonization *H. pylori* is a Gram-negative, flagellated organism that produces a number of enzymes including catalase and urease, which help neutralize host responses and favor colonization. The ability of the organism to adapt to the harsh pH in the gastric lumen has been illuminated by investigators who have examined the changes in *H. pylori* gene expression following exposure to low pH. A major change was observed in the expression of genes that control motility. Investigators were able to observe that the increase in the expression of genes encoding proteins involved in the motility apparatus led to enhanced movement. In addition, there was an increased expression of the genes encoding urease and the other proteins associated with the optimal function of this enzyme.

The urease produced by *H. pylori* displays an adaptation to the gastric milieu in that it has two different pH values at which its function is optimal—one being the predictable pH 7.2 and the other pH 3.0. Because this enzyme functions well at a low pH, it was originally proposed that urease reached the extracellular environment in which it could metabolize urea into NH_3 that in turn buffers protons in the gastric lumen. An elegant study suggested that the enzyme functions mostly within the bacteria to generate ammonia ions that will buffer the H^+ ions as they reach the cytoplasm of the organism.

Thus, on infection, *H. pylori* adapts to the gastric pH to produce the molecular machinery required to neutralize the acid as well as to escape quickly to the relatively safe confines beneath the mucus blanket. In this niche, *H. pylori* enjoys some of the same cytoprotective mechanisms that the host epithelium uses for the maintenance of its structural integrity and function. Moreover, the organism is well equipped to continue to adapt to changes in its niche. Clearly, understanding the detailed molecular machinery that controls the expression and function of bacteria 1 genes such as those encoding the flagellar or urease proteins will have the potential to provide novel therapeutic targets that could impair the survival of the organism in the acidic gastric environment.

Attachment *H. pylori* shows a strict tropism for gastric epithelium that could reflect positive selection by gastric epithelial cells, for example, the tissue-specific expression of receptors. Alternatively, intestinal epithelial cells could negatively select for colonization because of the production of antimicrobial factors that discourage *H. pylori* growth. The latter possibility would be of interest as the controlled expression of any putative antimicrobial factor by epithelial cells could provide a novel therapeutic approach for vaccine-based therapies. In fact, several naturally produced proteins that exhibit an antimicrobial effect have been examined in the infected gastric mucosa *H. pylori* also decreases the expression of the antibacterial molecule "secretory leukocyte protease inhibitor." Thus, it is not clear if the effects of *H. pylori* on the expression of these molecules in the gastric niche limit the concentration of *H. pylori* to tolerable levels or whether they confer a selective advantage by inhibiting the growth of other species.

The CAG Pathogenicity Island Once *H. pylori* has established itself in its preferred niche, the organism must attach to host cells and possibly damage them enough to ensure that sufficient nutrients can be obtained in the subsequent inflammatory exudate or transudate (Fig. 57-2). Consequently, studies have been directed toward understanding the receptors for this organism and their effects on epithelial cell signaling. The most studied interaction involves a stretch of DNA referred to as the *cag* pathogenicity island (*cag* PAI). Genes within the *cag* PAI encode proteins that provide a type-IV secretion apparatus that allows bacterial macromolecules to translocate into the host cell.

The intact *cag* PAI of *H. pylori* plays a significant role in virulence in humans as evidenced by researchers who described the role of *cagE*, a gene that appears to be essential for a functioning bacterial secretion system. This study showed an increase in

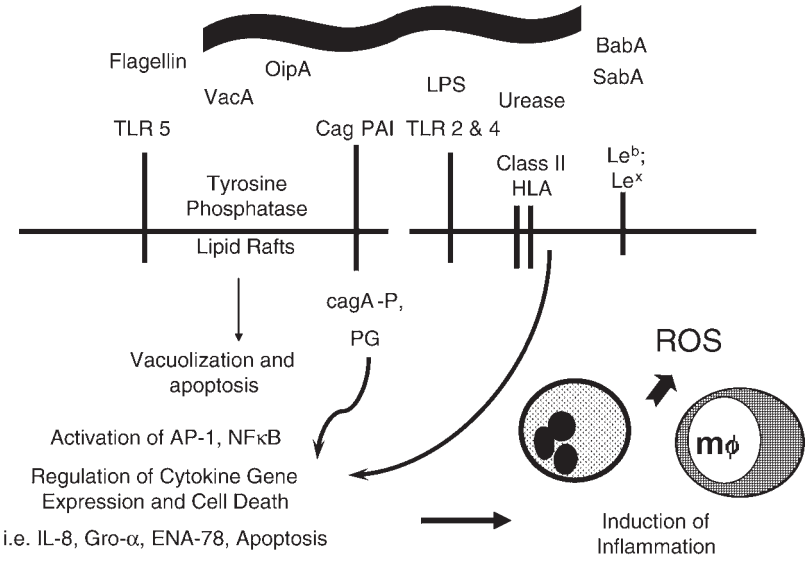

Figure 57-2 Potential interactions between *H. pylori* and gastric epithelial cells. This figure summarizes the best-known interactions between bacterial products and host cell receptors that have been described in the text. Any of these potential interactions could enhance bacterial binding although secreted bacterial products may also engage the receptors. These interactions allow the epithelial cell to transduce a signal to the host indicating that a luminal infection is present that may represent some danger. One aspect that is evident is that few bacterial/epithelial cell interactions have been validated in vivo or linked to specific signaling pathways that result in a known epithelial cell response. It is also evident that no single pathway is responsible for all changes in epithelial cell responses. Furthermore, it is clear that the bacterial effects on epithelial cell signaling are insufficient to explain the magnitude of the gastritis and the local or systemic consequence that are attributed to *H. pylori*. Hence, these interactions complement the effects of cytokines, neuroendocrine influences, and other signals emanating from the lamina propria. cag PAI, cag pathogenicity island; IL, interleukin; OipA, outer inflammatory protein A; PG, peptidoglycan Vac A, a vacuolating cytotoxin.

duodenal ulceration in children carrying strains expressing *cagE* in association with higher levels of gastric IL-8. This report validates a study in vitro in which mutations of the gene encoding *picB* (now referred to as *cagE*) abrogated the ability of *H. pylori* to induce IL-8. Furthermore, infecting gerbils with a mutated strain that lacked CagE production reduced the severity of gastritis substantially. Gastric ulceration developed in virtually all of the gerbils infected with the wild-type strain but in none of the animals infected with the *cagE* mutant. Finally, intestinal metaplasia and gastric cancer developed in some gerbils with wild-type infection but not in animals infected with the *cagE*-negative mutant. These findings were confirmed and extended by showing that a *cag*-positive *H. pylori* strain induced severe gastritis, apoptosis, atrophy, and gastric ulceration in gerbils. The investigators then used the *H. pylori* whole genome microarray to identify differences in gene content between specific *H. pylori* strains. Naturally occurring or experimentally induced mutations of the *H. pylori cag* region were associated with decreased gastric mucosal inflammation in vivo, and this was correlated to reduced potency in activating IL-8 gene expression or apoptosis in vitro.

Attachment Via Lewis Antigens Le antigens expressed by host cells may serve as the major receptor for bacterial binding. A technically sophisticated experiment has shown that mice genetically engineered to express increased levels of Le^b had more severe gastritis although there was no effect on bacterial load. Other experiments have demonstrated that specific bacterial gene products, most notably BabA, act as the bacterial ligand for the Le^b receptor. Another adhesion molecule expressed by *H. pylori*, SabA, binds weakly to sialyl Le^x (sLe^x) antigens. This interaction may be significant in the maintenance of persistent infection as the sLe^x antigens emerge on gastric epithelial cells in response to inflammation.

The reciprocal interaction between bacterial Le antigens and the host has also been examined. The expression of Le^x structures by *H. pylori* lipopolysaccharide (LPS) promotes adhesion to the gastric epithelium. However, isogenic mutants of the bacteria that do not express the fucosyl transferases necessary for Le^x and Le^y expression infected mice and bound human gastric epithelial cells comparably.

Although some of the approaches supporting a role for the Le antigens on host cells are very elegant, the hypothesis has been challenged. In addition, there are data showing that the binding of *H. pylori* to epithelial cells freshly isolated from human gastric biopsy specimens is unaffected by the Le antigen expression whereas less than half of the strains tested in infected subjects express the SabA adhesion that binds sLe^x. Another approach to establish the role of the interaction between Le^b and BabA has been epidemiological studies. Some investigators have data suggesting that the *babA2* genotype may be found preferentially in strains of *H. pylori* that are more likely to be associated with inflammation, duodenal ulcer, and gastric cancer. However, the importance of Le^b as a receptor has been discounted by several reports that have not observed an increase in infection in subjects with the Le^b phenotype. Moreover, individuals who do not express Le^b can clearly be infected with *H. pylori* and other studies report that the majority of strains infecting the subjects studied expressed the *babA2* gene and did not induce ulcers or cancer. It is possible that the product of the *babA2* gene has other functions besides binding Le^b that would contribute to its association with disease. The lack of direct evidence that molecules bearing the glycoconjugates mediate signaling events or facilitate other signaling mechanisms weakens any argument for a significant role in the pathogenesis of the infection. Hence, Le antigens can only be considered as a subset of receptors within a broad array of molecules that can bind *H. pylori*.

Attachment Via Molecules Associated With Immune/Inflammatory Responses *H. pylori* can also bind to the complex of invariant chain and class II major histocompatibility complex (MHC) molecules expressed on the surface of gastric epithelial cells. The class II MHC molecules were the first epithelial cell receptor shown to directly affect signaling in host cells as urease binds to epithelial cells via class II MHC and is sufficient to induce apoptosis. Using transfected cells lines, investigators showed that class II MHC molecules were sufficient to allow host cells to bind *H. pylori*. Furthermore, these molecules are expressed *in situ* by gastric epithelial cells at increased levels during infection and their expression is increased in response to interferon (IFN)-γ. Because *H. pylori* is also well known for inducing cytokine production in the epithelium, these studies were extended and showed that both cytokine production and apoptosis are mediated through class II molecules, suggesting the class II MHC complex serves an important role in binding and signaling.

A class of molecules known as pathogen-associated molecular receptors (PAMPs) have also been examined for a role in binding *H. pylori*. These receptors include the Toll-like receptors (TLRs). Eleven such TLRs have been identified and it appears that each has a relative specificity for various bacterial molecules. For example, TLR4 is able to recognize the LPS of many bacteria. Cytokines and *H. pylori* particles increase the expression of TLR4. *H. pylori* LPS stimulates monocytes and gastric epithelial cell responses in guinea pigs, presumably via TLR4. TLR5 is another PAMP that binds bacterial flagellins and similarly induces a signaling response that would trigger acute inflammation. *H. pylori* produces flagellin that binds this ligand and activates a response in vitro. Other PAMPs, including TLR2 are activated by highly purified *H. pylori* LPS, and together these receptors may bind bacterial products in order to enhance bacterial binding as well as cell signaling. It should be remembered that gastric epithelial cell lines that do not express TLRs still respond well to *H. pylori* as evidenced by IL-8 production. Thus, it remains to be shown if these receptors and their required accessory molecules are expressed and functional *in situ*.

Other Receptors Several other binding mechanisms have been explored. For example, many strains of *H. pylori* express a vacuolating cytotoxin, VacA, which can attach to epithelial cells via an interaction with a protein tyrosine phosphatase. Volumes have been written on the structure and function of VacA and its association with disease. For example, specific VacA alleles (S1, m1) are associated with disease and the induction of epithelial cell apoptosis so the importance of the interaction between VacA and its receptor appear to have significant importance in the pathogenesis of gastroduodenal disease.

A gastric trefoil protein known as trefoil factor 1 (TFF1) serves as a receptor for *H. pylori*. This molecule is expressed predominantly in the gastric mucosa and may account for some of the gastric tropism. Interestingly, when the expression of TFF1 is decreased in genetically engineered mice, the animals develop a spontaneous, antral adenoma suggesting that TFF1 provides an element of control over gastric epithelial cell growth. The attachment of *H. pylori* to this molecule could impair its function (mimicking the decreased expression in the animal models) thus favoring the proliferation of epithelial cells and the subsequent development of cancer in some infected subjects.

Collectively, these studies suggest that *H. pylori* uses many distinct receptors and all of these receptors likely provide complementary attachment mechanisms that facilitate colonization and enhance other interactions, such as the function of the type-IV secretion system. As a consequence of these interactions, a series of signaling processes initiate the host response to this infection. The ensuing inflammation may favor bacterial survival by increasing bacterial receptors, providing serum transudate as a source of nutrients and inducing antibacterial proteins that impair competition from other organisms that may try to colonize the more accommodating niche provided by a chronic infection with *H. pylori.* The relative role of the various receptors will emerge only when there is a more comprehensive understanding of the distinct binding interactions and their respective impact on epithelial cell signaling.

THE IMMUNOPATHOGENESIS OF *H. PYLORI* William Osler suggested that "patients seem to die not of their infection but of the body's response to it." With *H. pylori*, sterilizing immunity does not occur following natural infection despite the presence of a robust, inflammatory response. The importance of the host response in disease is supported by the observations that heterogeneity in the regions of the genome that control the magnitude of inflammation is associated with gastric cancer linked with *H. pylori* infection. These associations began with the report that polymorphisms in the regions controlling IL-1β were associated with an increased incidence of hypochlorhydria—a presumptive precursor associated with gastric cancer. IL-1 has been previously reported as a potent inhibitor of gastric acid secretion, so an increase in IL-1 not only drives inflammation but leads to a physiological state that precedes gastric cancer development. Importantly, this study has been replicated in a Japanese population in which IL-1β polymorphisms were not only associated with gastric cancer but also a decrease in duodenal ulcer recurrence whereas others reported increased gastric IL-1, more severe gastritis, gastric atrophy, and colonization with *H. pylori* strains that are associated with gastric cancer. If the hypothesis is correct, then other proinflammatory gene polymorphisms could be predicted to be associated with increased gastritis as well as cancer and indeed, this appears to be the case. Other genes that regulate the magnitude of the inflammatory response, including IL-10, tumor necrosis factor (TNF)-α and IL-8 have also been associated with the sequence of events leading to cancer. Thus, the host response and tissue remodeling following infection is directly responsible for a significant component of the disease associated with *H. pylori*. The most compelling of these studies provides evidence that the gene is not only mutated, but the mutation changes the expression of the cytokine and the tissue levels in affected subjects reflect the predicted change. More of these studies are being performed and additional insight into the role of the immune response as well as specific immune molecules should emerge.

How Epithelial Cells Recognize and Respond to "Danger" Because the overwhelming bulk of the antigenic mass associated with *H. pylori* infection resides in the lumen, the gastric epithelial cells have been examined for the mechanisms by which they "register" that an infection has occurred. The epithelial response to infection is complicated as it is driven by several molecular component parts of the bacterium, the signaling linked to specific receptors that recognize these components as well as the local concentrations of hormones, neurotransmitters, immune/inflammatory cytokines, and mediators or stromal responses. The epithelial cell responses include changes in epithelial cell morphology (the hummingbird phenotype), disruption of the tight-junctional complexes, the production of cytokines, increased epithelial cell proliferation, increased rates of epithelial cell death via apoptosis, and the induction of numerous genes that reflect the stress

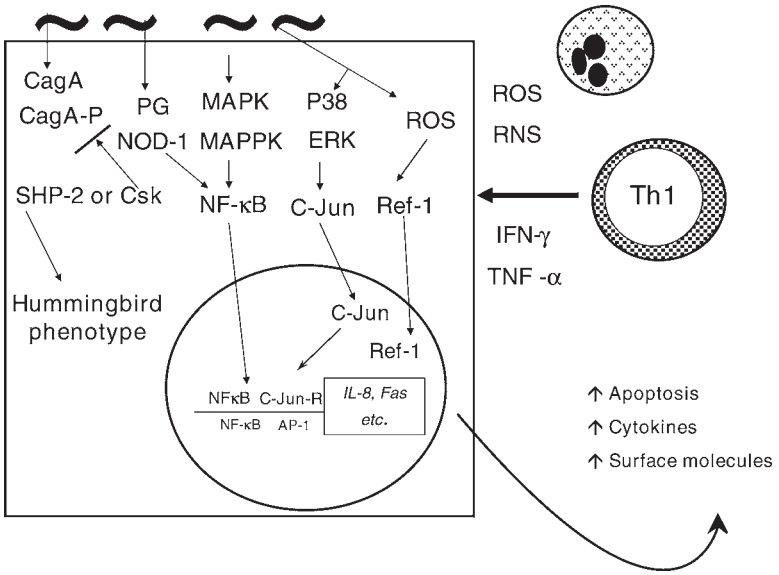

Figure 57-3 An overview of signaling responses of gastric epithelial cells during *H. pylori* infection. Several signaling pathways have been studied using intact organisms or specific bacterial products. Substantial crosstalk exists between the respective pathways triggered by bacteria or host response molecules. Some of the major events that have been characterized include the pathways involving the translocated CagA in the development of the hummingbird phenotype; the differential role of the outer inflammatory protein A (OipA) and the *cag* pathogenicity island in signal transduction; the effects of intact *H. pylori* on extracellular ERK; P38 as well as Jun n-terminal kinase mitogen-activated protein kinases; and the role of oxidative stress in modifying transcription factors by reduction via redox factor-1 (ref-1), which reduces C-Jun to C-Jun-R. Together, these pathways provide specific targets for novel therapies that interfere with the control of phosphorylation, the transactivation by transcription factors or the control of oxidative stress. IFN, interferon; TNF, tumor necrosis factor.

encountered in response to infection. It should be appreciated that, similar to other multi-factorial diseases, it is a significant scientific challenge to dissect the various pathogenic processes that culminate in peptic ulcers or gastric cancer and it is still premature to rank some pathways over others in terms of their relative importance.

Changes in Gene Expression The best overview of the epithelial cell response can be ascertained from studies examining the broad changes in the expression of hundreds of genes as assayed with high-throughput gene expression systems. These techniques provide a powerful approach to evaluate changes in the expression of a large number of genes in response to specific conditions, such as bacterial strain. When you combine the effects of bacteria with proinflammatory mediators found in gastric tissue during infection, well in excess of 1000 genes are affected. Detailed analysis of the effects of infection, different cell lines and various inflammatory mediators is needed over a wide range of time points that would be relevant to the condition epithelial cells face in vivo. The genes of immediate interest are those that regulate the immune/inflammatory response, epithelial cell turnover including apoptosis and proliferation, as well as those affecting physiological properties in the stomach. Eventually, the genes that are less obviously connected to the understanding of epithelial cell homeostasis may emerge as being the most important. Although a detailed study of these genes is interesting on its own, the mechanisms regulating these changes may be more relevant for identifying points in the pathogenesis that can be targeted for therapeutic intervention (Fig. 57-3).

Effects of Infection on Transcription Factor Activation The expression of genes in epithelial cells stimulated with *H. pylori* is regulated by transcription factors that in turn are controlled by a series of signaling mechanisms. Although many transcription factors are activated in response to infection, nuclear factor (NF)-κB, and activator protein 1 (AP-1) have been studied in the most detail. These transcription factors regulate the expression of a wide variety of proinflammatory cytokines and cellular adhesion molecules that are induced in response to the infection or the local cytokine milieu. *H pylori* activates NF-κB in gastric epithelial cells both in vitro and in vivo. In patients with *H. pylori* gastritis, gastric epithelial cell NF-κB activity was markedly enhanced and this correlated with the intensity of neutrophil infiltration and IL-8 protein levels. This pathway is of particular interest given the association between polymorphisms in the *il-8* gene that lead to increased mucosal IL-8 expression, inflammation, and other premalignant changes associated with gastric cancer. In addition, several strains of *H. pylori* are associated with both disease and increased IL-8 production, so understanding the transcription factors controlling IL-8 provides important insight into the pathogenesis of disease.

One of the novel concepts just emerging in the context of *H. pylori* infection is the role of oxidative stress in the control of gene expression. Reactive oxygen and nitrogen species are generated in response to infection (described later). Although their role as antimicrobial mediators is understood, their function in the control of gene transcription deserves attention. One molecule that plays a key role in regulating redox-sensitive signaling is apurinic/apyrimidinic endonuclease-1 or redox factor-1 as it is also called. This molecule is expressed in gastric epithelial cells during infection with *H. pylori*, and studies show that it is important for the full activation of AP-1 and NF-κB as well as IL-8 production in response to *H. pylori*. This pathway is important in the optimal activation of many other transcription factors including p53 and activating transcription factor so it is likely that the significance of redox-sensitive signaling in the pathogenesis of diseases associated with *H. pylori* will become more evident.

***Signaling Pathways Activated in Response to* H. Pylori** *H. pylori* infection is linked to the activation of NF-κB and AP-1 in gastric epithelial cell lines by several signaling mechanisms. These include p21-activated kinase 1, which associates with and activates Nck-interacting kinase thereby activating the kinases inhibitor of kappa kinase α and inhibitor of kappa kinase β leading to phosphorylation and degradation of the inhibitory protein IκBα and the release of activated NF-κB. Mitogen-activated protein (MAP) kinase cascades regulate a range of cell functions including proliferation, inflammatory responses and cell survival. *Cag*-positive *H. pylori* activates the extracellular signal-regulated kinase (ERK), Jun n-terminal kinase and p38 MAP kinase pathways, and ERK and p38 regulate IL-8 production in gastric epithelial cells. The VacA toxin is sufficient to induce the phosphorylation of p38 and ERK1/2 although this signaling pathway seems to be independent of the vacuolization induced by this toxin. Kinases such as ERK and p38 can participate in the activation of the transcription factor AP-1 and the regulation of several genes that encode proteins that drive inflammation. FR167653, a p38α MAP kinase inhibitor, reduced both neutrophil infiltration and gastric mucosal injury in *H. pylori*-infected Mongolian gerbils. Thus, not only is p38 MAP kinase important in regulating the host inflammatory response to *H. pylori* infection, but this and other kinases can become therapeutic targets that attenuate inflammation and the ensuing tissue damage associated with infection.

Although infection with intact bacteria stimulates several signaling pathways, more attention is given to the role of specific virulence factors such as those associated with the *cag* PAI because *H. pylori* that carry the *cag* PAI are associated with increased IL-8 expression in gastric mucosal biopsy specimens. The only identified effector protein able to translocate via the *cag* PAI is the CagA protein. Following its translocation into the cytoplasm, CagA is tyrosine phosphorylated by host Src kinases and interacts with SHP-2—a phosphatase involved in cell signaling and regulating epithelial cell morphology—as well as Grb2 and C-terminal SRC kinase (Csk). Interaction with Grb2 results in the activation of the Ras/ERK pathway that contributes to an increase in proliferation whereas the activation of C-terminal SRC kinase may provide a negative feedback on CagA phosphorylation. Heterogeneity in the phosphorylation sites within CagA may vary by geographic distribution and results in an altered ability to interact with SHP-2 and modify intracellular signaling. It is intriguing to speculate that heterogeneity in the CagA protein may account for some of the geographic differences in disease. Researchers would suggest that interference with SHP-2 signaling favors gastric hyperplasia. Together, these studies point to fascinating molecular interactions to be investigated in the context of gastric cancer.

H. pylori can stimulate IL-8 directly via other bacterial factors. One such factor is designated outer inflammatory protein A (oipA), which induces epithelial cell IL-8 production, and does not appear to depend on the *H. pylori cag* PAI. Strains that express *oipA* were related to bacterial density, mucosal IL-8 levels, neutrophil infiltration, and clinical presentation. However, little activation of epithelial cell signaling via NF-κB occurs in the absence of the *cag* PAI. Subsequent studies have shown that specific bacterial products led to the activation of different transcription factors that collaborate to enhance IL-8 production. For example, the *cag* PAI and *oipA* are both required for the full activation of IL-8 but the former achieves this through both NF-κB and AP-1, whereas the latter was required to recruit activation by a STAT1-IRF1-ISRE response element. Although the *cag* PAI facilitates the translocation of CagA, this bacterial protein *per se* has no effect on IL-8 and it is likely that other bacterial proteins translocate and contribute to the *cag* PAI-dependent signaling leading to IL-8 production. Together, these experiments illustrate the level of complexity that is emerging as individual bacterial factors are being aligned with overlapping or distinct signaling pathways that will define the epithelial cell phenotype during infection.

Beyond the Epithelium—Host Responses in the Lamina Propria Although several epithelial receptors for *H. pylori* have been described, they do not appear to fully account for the magnitude of the inflammatory response to an organism that resides predominantly in the lumen. Some bacteria may infect epithelial cells whereas significant amounts of bacterial material may "leak" around epithelial cells and reach the lamina propria in which it can activate underlying phagocytes including neutrophils and macrophages. One candidate bacterial factor is the *H. pylori* neutrophil-activating protein (HP-NAP). This is a 150-kDa decamer protein that stimulates chemotaxis of monocytes and neutrophils. It also promotes neutrophil adhesion to endothelial cells and NADPH oxidase complex assembly at the plasma membrane, leading to subsequent production of reactive oxygen intermediates. In the context of the inflammatory environment during *H. pylori* gastritis, an additional observation made by investigators was that TNF-α and IFN-γ primed neutrophils and potentiated the effect of HP-NAP.

With the recruitment and activation of macrophages and neutrophils, other inflammatory mediators are released. As mentioned, reactive oxygen intermediates, NO, and some of its metabolites are important in the host defense against microbes. Increased expression of iNOS, the inducible isoform of NO synthase, is observed in the gastric mucosa during infection with *H. pylori*. NO and O_2^-, which may be produced by infiltrating neutrophils, react to form peroxynitrite, $ONOO^-$, a potent oxidant and reducing agent. Although these products have potent antimicrobial effects, uncontrolled or inappropriate production, however, could play a role in the gastric mucosal damage observed during *H. pylori* infection. For instance, the catabolism of urea by urease provides CO_2 that rapidly neutralizes the bactericidal activity of the peroxynitrate and forms $ONO–OCO_2$. Thus, urease may sustain bacterial colonization, however, this reaction enhances the nitration potential of $ONOO^-$ and may favor mutagenesis.

Cytokines from the epithelial cells complement those released in the lamina propria. For example, neutrophils are not only activated by IL-8 but also by other chemokines such as ENA-78 and Gro-α that can be produced by the epithelium, the adjacent myofibroblasts, or the macrophages within the lamina propria. Other cytokines are induced in macrophages, for example, urease induces TNF-α and IL-6 whereas heat shock protein 60 induces IL-6. Intact bacteria can induce the production of chemokines that recruit T cells as well as IL-12 and IL-18—two cytokines that favor the selection of T-helper (Th)1 cells. Thus, intact bacteria or bacterial factors trigger a broad cytokine response within the lamina propria as well.

Gastric T-Cell Responses As adaptive responses develop, different Th cell subsets emerge as defined by characteristic patterns of cytokine secretion. At the risk of oversimplifying many complicated signaling events, Th1 cells promote cell-mediated immune responses mainly through the production of IFN-γ and TNF-α, whereas Th2 cells produce IL-4, IL-5, IL-10, and

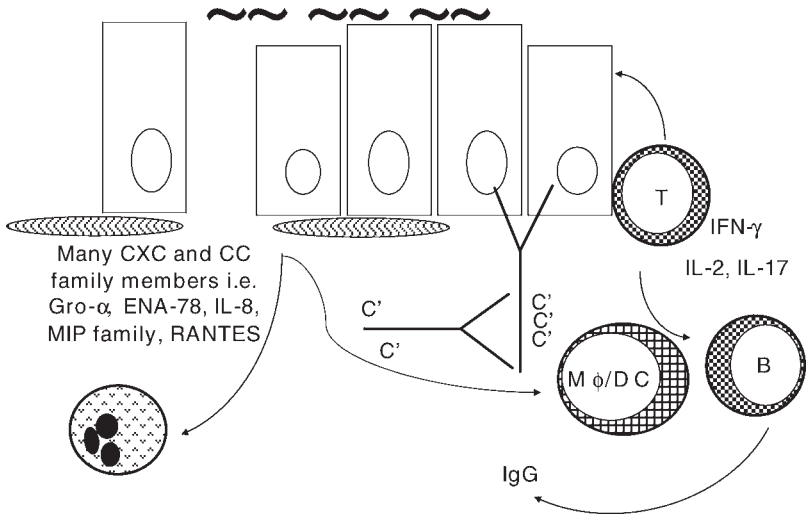

Figure 57-4 The immunopathogenesis of gastritis and epithelial cell damage. This figure shows the various means by which the gastric immune and inflammatory responses mediate epithelial cell damage. First, through direct effects, Th1 cells can induce epithelial cell death via Fas/Fas ligand interactions. T-cell-derived cytokines not only enhance the induction of apoptosis but also upregulate the expression of receptors such as class II major histocompatibility complex increase bacterial binding and favor the induction of apoptosis by *H. pylori*. In addition, Th1 cells complement the effects of *H. pylori* by stimulating epithelial cells to produce cytokines that recruit and activate neutrophils. In turn, activated neutrophils impart an oxidative stress that damages epithelial cells as well as cellular DNA. Finally, gastric T cells can modulate B-cell responses possibly leading to the production autoantibodies including those of the IgG class that can activate complement (C') and contribute to immune-complex-mediated inflammation. From this model, it is clear how genetic polymorphisms that increase the expression of cytokines that drive inflammation (i.e., IL-1β, tumor necrosis factor-α, IL-8) or decrease the expression of those that prevent inflammation (i.e., IL-10) contribute to an increase in gastritis. As gastritis is believed to favor the development of adenocarcinoma, it makes sense that these polymorphisms are associated with increased rates of gastric cancer. IFN, interferon, IL, interleukin; TNF, tumor necrosis factor.

transforming growth factor-β. The Th2 cells can promote mucosal IgA or IgE responses as well as diminish the inflammation caused by Th1 cytokines.

Th1 Cells Predominate in the Stomach Studies suggest that the gastric mucosa is preconditioned to favor Th1 cell development because IL-12- and IFN-γ-producing cells are present at baseline and increase during infection. One hypothetical explanation is that infection selectively blocks Th2 development. In fact, *H. pylori* can interfere with Stat6 activation by IL-4, which could impair Th2 development. *H. pylori* infection is also associated with increased gastric IL-18 transcripts in the antral mucosa. This effect is independent of the *cag*-status of the infecting strain. Thus, IL-12 and IL-18 may contribute to the predominant Th1 response observed during *H. pylori* infection. Other cytokines that enhance Th1 responses, such as IL-23 and IL-27, remain to be studied in human tissue.

Interactions between bacteria, epithelial cells, and intercellular mediators play an important role in controlling the host response. This principle was demonstrated in a study characterizing the IL-17 response to infection. Biologically active IL-17, a cytokine produced by activated $CD4^+$ T lymphocytes, is increased in the mucosa of *H. pylori*-infected patients. IL-17 is capable of activating NF-κB and MAP kinases that can initiate IL-8 expression by gastric epithelial cells thereby providing a positive feedback to epithelial cells and additional neutrophil recruitment. In addition, the activation of transcription factors by IL-17 may contribute to the increased levels of numerous other proinflammatory cytokines and enzymes observed during *H. pylori* infection, such as IL-1β, TNF-α, and cyclooxygenase-2. Similarly, Th1 cells produce IFN-γ and TNF-α that can increase the expression of many genes in the epithelium including IL-8. Thus, the gastric T-cell response can complement the direct effects of the bacteria on the epithelium.

Pathogenic Effects of Th1 Cells The inability of Th1 responses to clear infection suggests that T-cell activation may contribute to more severe gastroduodenal diseases (Fig. 57-4). This idea is supported by animal studies showing that protective immunity induced by vaccines for *Helicobacter* spp rely on Th cells other than Th1 cells possibly including Th2 cells. Other studies have implicated the Th1 cytokines IFN-γ and TNF-α in the activation of epithelial cell gene expression including IL-8 production. In addition, these cytokines enhance bacterial binding, apoptosis, as well as inflammation, atrophy and dysplasia in an animal model. Th1 cytokines, such as IFN-γ and TNF-α, also augment *H. pylori*-induced gastric epithelial death via apoptosis. Further, TNF-α, IFN-γ, and IL-1β upregulate gastric mucosal Fas antigen expression. Because Th1 cells express higher levels of FasL than Th2 cells, the relative increase in Th1 cells during *H. pylori* infection may induce epithelial cell death through Fas–FasL interactions.

Although B cells have been studied the most in the context of autoreactivity, proton-pump-specific Th1 cells in the gastric mucosa may act as effector cells in the targeted destruction of the H^+,K^+-ATPase in autoimmune gastritis. However, during *H. pylori* infection, in the absence of any organ-specific autoimmunity, T cells reactive to H^+,K^+-ATPase were not detected. This led to the conclusion that T-cell autoreactivity arises more selectively.

Potential Beneficial Effects of Other Th Subsets In contrast to the pathogenic effects of Th1 cells, the anti-inflammatory effects of cytokines associated with Th2 cells, or possibly other regulatory subsets of Th cells can attenuate gastric inflammation. More direct evidence suggests that IL-4 can decrease gastritis and

the effects of this cytokine may be mediated by the release of somatostatin. These interesting studies illustrate the important convergence of the flora, the host response, and other physiological mediators to modulate mucosal homeostasis. Additional studies will determine if the manipulation of T-cell responses can control the changes in epithelial cell atrophy and dysplasia in these animal models.

The fact that the gastric response can be modified by Th2 cells raises the question regarding the role of other T-cell subsets, such as regulatory T cells (Treg), in the pathogenesis of disease associated with *H. pylori* infection. Depletion of Treg in neonatal mice leads to autoimmune gastritis implying that Treg play an important role in the control of gastritis. The report that infection with *H. pylori* improves the autoimmune gastritis induced in neonatal mice suggests that infection may indeed stimulate a subset of anti-inflammatory T cells that impair excessive inflammation that could otherwise lead to the spontaneous clearance of the organism. There are several precedents for this in immunity and future studies may prove such a mechanism exists for prolonging *H. pylori* infection.

Gastric B-Cell Responses Normally, antibodies in the gastrointestinal tract are of the IgA isotype, as IgA antibodies are highly adapted for mucosal protection. IgA has structural features that allow them to be transported selectively into the lumen with mucosal secretions, resist acid proteolysis and enzymatic degradation, and block bacterial attachment or neutralize toxins in the lumen. Moreover, they confer protective immunity without activating complement and stimulating deleterious amounts of inflammation. During infection with *H. pylori*, IgA producing cells are increased; however, IgG and IgM are also detected along with activated complement. Therefore, local immune complexes may be contributing to gastroduodenal inflammation and tissue damage during infection.

Direct evidence for autoantibody production in response to *H. pylori* requires the identification of the self-antigens that are recognized by these antibodies. Given the structural homology between Le antigens on *H. pylori* and host cells, an obvious hypothesis is that these antigens will contribute to the described autoreactive responses. Indeed in the mouse models, immunization with *H. pylori* induces antibody-producing cells that recognize $Le^{x/y}$ that are capable of inducing gastritis. Furthermore, an antibody response directed to gastric parietal cells during *H. pylori* infection correlates with increased corpus atrophy. In addition, ferrets naturally infected with *H. mustelae* generate antigastric antibodies that recognize parietal cells. The cellular target for these antibodies in mice appears to be the β-chain of the gastric H^+,K^+-ATPase localized in the parietal cell canaliculi in the corpus. Anti-Le antibodies have been described in humans and occur independently of the Le phenotype of the host. However, they do not appear to account for autoreactivity. Thus, it seems logical that autoantibodies induced in mice may recognize different targets within the gastric mucosa and may even cross-react with human gastric tissue. However, the autoantibodies induced in humans may have a completely different specificity.

Independent reports have shown that gastric antibodies can resemble rheumatoid factors because they recognize other antibodies. Thus, a complex of antibodies recognized by adjacent antibodies could trigger immune complex-mediated inflammation. Other investigators have shown that antibodies associated with *H. pylori* infection recognize gastric epithelial cells. Moreover, monoclonal antibodies that recognize *H. pylori* cross-react to both human and murine gastric epithelial cells. Adoptive transfer of monoclonal antibodies to recipient mice induces gastritis as does the transfer of B-cells recognizing heat shock proteins from subjects with maltoma. Two groups have suggested that the level of autoantibodies in humans correlates with the severity of the gastritis. Thus, direct and indirect evidence supports the idea that autoantibodies can be induced during infection.

Is There an Immunological Basis for Persistence? With few exceptions, infection with *H. pylori* persists for the life of the host unless there is some intervention with antibiotics. This has led investigators to ask if a form of immunological avoidance or tolerance exists that prevents immunity from developing. Although infection leads to the recruitment and activation of innate responses that could lead to potentially protective, adaptive responses, there is evidence that *H. pylori* disrupts the processes that could contribute to immunity. As discussed, several bacterial factors including catalase and urease antagonize innate host responses. Virulent strains of *H. pylori* also impair phagocytosis. The VacA toxin impairs antigen presentation by macrophages by inhibiting the Ii-dependent pathway mediated by newly synthesized class II MHC molecules. Moreover, *H. pylori* express antigenic molecules that mimic host molecules, such as Lewis antigens, and self-antigens normally stimulate T cells to release cytokines that protect from autoimmune reactions. However, the cytokine profile associated with *H. pylori* infection does not obviously resemble the expected version in a tolerant environment. For example, IL-4, IL-10, and transforming growth factor-β (which could mediate an anti-inflammatory effect) are not expressed to the same levels as the proinflammatory cytokines like IFN-γ and TNF-α. That is not to say that the expression of potentially anti-inflammatory cytokines that exists is not sufficient to impair immune responses and favor persistence but some additional data are required to support this model. Additionally, the infected gastric mucosa is characterized by chronic, active inflammation. Thus, tolerance, if it has occurred, may be relative.

Some evidence for a role in immune avoidance for the persistence of *H. pylori* can be found in animal models in which infection is cleared by immunization procedures that induce a substantial amount of gastritis. It remains to be determined if immunity is resulting from a higher degree of inflammation than what is observed in response to "natural" infection or whether protection results from a specific and selected response induced by the immunization.

Another perspective is that the T-cell responses may not be inappropriate but they may lack a level of coordination necessary to achieve immunity. Some groups have demonstrated that the bacteria are able to inhibit the growth of T cells and actually lead to the induction of apoptosis. This process has been demonstrated using cell lines and attributed to very specific patterns of gene expression including the induction of FasL and Fas on T cells that would enable apoptosis to proceed. Although studies suggest this can occur directly in a redox-sensitive manner, other reports suggest that peptides from *H. pylori* activate monocytes to produce oxygen radicals that impair the expression of CD3 zeta chain of the T-cell receptor complex as well as induce T-cell apoptosis. Support for the loss of T cells by apoptosis is given by the presence of apoptotic T cells in the gastric mucosa as well as the expression of Fas and FasL that was detected on biopsy specimens by immunohistochemistry.

VacA impairs T-cell growth and function independently of apoptosis in a T-cell line by inhibiting nuclear translocation of a transcription factor activation required for IL-2 production. Related studies illustrate the complexity of these events as the effects on cell lines differ from T cells isolated from human peripheral blood in that the toxin impairs IL-2-dependent expansion in freshly isolated T cells but not IL-2 production nor their survival. Others have shown that exposure of human T cells to *H. pylori* decreases their proliferative response by decreasing the expression of the CD3 zeta chain of the T-cell receptor complex.

These reports support the model that *H. pylori* interferes with normal T-cell activation in several ways; however, the answer may lie in the T cells within the gastric mucosa because cell lines and peripheral blood are a model that is often not replicated within the tissue. For example, some antigen-specific T-cell responses can be induced in the gastric mucosa. Nonetheless, it is still possible that the effect of the organism as well as the cytokine milieu disrupt the coordination that is required for the development of an effective, antigen-specific T-cell response.

CONCLUSION

The evidence presented above illustrates several changes associated with *H. pylori* infection that contribute to gastritis and alterations in epithelial cell biology. It is clear that these responses are induced by many different factors, which points to the importance of several pathways and the lack of an exclusive target that deserves preferential attention. There is the chance that a "final common pathway" may emerge as a key target that advances the understanding of the complex pathogenesis of gastroduodenal diseases. Insights at the molecular level will improve the understanding of the pathogenesis of these disorders and provide novel opportunities for diagnosis, treatment and modeling of gastrointestinal diseases consequential to chronic inflammation.

Abbreviations

VII. NEPHROLOGY

AA	arachidonic acid
ACE	angiotensin-converting enzyme
ACEi	angiotensin-converting enzyme inhibitors
Ach	acetylcholine
ADAM-2	a disintegrin domain and metalloproteinase
ADCC	antibody-dependent cell-mediated cytotoxicity
ADMA	asymmetric dimethyl arginine
AGEs	advanced glycation end products
AICD	activation-induced cell death
AIF	apoptosis inducing factor
AIPs	aldosterone-induced proteins
Akt	protein kinase B
Ang	angiotensin
AP-1	activator protein-1
Apaf-1	apoptotic protease-activating factor-1
APC	antigen-presenting cell
AQP2	aquaporin-2
ARF	acute renal failure
AT1-R	angiotensin II type 1 receptors
ATPase	adenosine triphosphatase
AVP	vasopressin, also called antidiuretic hormone
AVPR2	arginine vasopressin 2 receptor
BH4	the reduced form of tetrahydrobiopterin
Bk	bradykinin
BMP	bone morphogenetic protein
BP	blood pressure
Ca++	calcium
CAAX box	a methylated cysteine residue followed by two aliphatic residues, followed by any residue at the C-terminal end of a protein
cAMP	cyclic adenosine monophosphate
CAT	cationic amino acid transporter
cGMP	cyclic guanosine monophosphate
cNOS	constitutive NOS
Co-Smad	Smad4
COX	cyclooxygenase
COX-1	cyclooxygenase-1
COX-2	cyclooxygenase-2
CTL	cytotoxic T-lymphocytes
DAG	diacylglycerol
DCs	dendritic cells
dDAVP	desmopressin
DI	diabetes insipidus
DTH	delayed type hypersensitivity
ECM	extracellular matrix
EDRF	endothelium-derived relaxing factor
E_m	membrane potential
ENaCs	epithelial Na channels
Endo G	endonuclease G
eNOS	endothelial or type III NOS
ERK	extracellular signal regulated kinase
GC	guanyl cyclase
GEF	guanine nucleotide exchange factor
GFR	glomerular filtration rate
G-kinase	CGMP kinase
GTP	guanidine triphosphatase
H_2O_2	hydrogen peroxide
HGF	hepatocyte growth factor
HLA	human leukocytic antigens
IAPs	inhibitor of apopotosis
ICAM-1	intracellular adhesion molecule 1
IC_{Ca++}	intracellular calcium
ICMT	isoprenyl-cysteine-*O*-carboxy-methyl-transferase
IFN	interferon
IL	interleukin
IL-8	interleukin-8
iNOS	inducible or type II NOS
IP_3	1,4,5-inositol trisphosphate
IκB	inhibitor of κB
I-Smads	inhibitory Smads
JNK	Jun N-terminal kinase
L	ligand
L-NAME	L-Nitro arginine methyl ester
$LT\alpha^{-/-}$	splenectomized, lymphtoxin α-deficient mice
$LT\beta R^{-/-}$	lymphotoxin β-receptor-deficient mice
MAP	mitogen-activated protein
MAPK	mitogen-activated protein kinase
MCP-1	monocyte chemoattractant protein-1
MEK	mitogen-activated protein
MEK-1	MAP kinase/ERK kinase
MEKK-1	mitogen-activated protein kinase kinase 1
MHC	major histocompatibility complex
MHC-II	major histocompatibility complex II
Mn	mitochondrial
MREs	mineralocorticoid response elements
MURF1	muscle ring finger
NADPH	nicotine adenine dinucleotide phosphate
NDI	nephrogenic diabetes insipidus
Nedd4	a specific ubiquitin ligase: *n*eural-precursor-cell-*e*xpressed-*d*evelopmentally *d*ownregulated protein
NF-κB	nuclear factor-κB
NK	natural killer

nNOS	neuronal or type I NOS
NO	nitric oxide
NO_2^-	nitrate
NOS	nitric oxide synthase
NOS-2	inducible NOS
$O_2^{\bullet -}$	superoxide anion
$ONOO^-$	peroxynitrite
PAMPS	pathogen-associated molecular patterns
PDE-II	phosphodiesterase-II
PDE-III	phosphodiesterase-III
PDK1/2	phosphatidylinositol-dependent kinases
PDZ	PSD-95, Discs-large, 20-1
PG	prostaglandin
PGE_2	prostaglandin E_2
PGH_2	prostaglandin H_2
PGI_2	prostacyclin
PGI_2-S	prostacyclin synthase
PI-3-kinase	phosphatidylinositol 3-kinase
PIP_2	phosphatidylinositol bisphosphate
PIP_3	phosphatidylinositol trisphosphate
PKC	protein kinase C
PKG	protein kinase G
PLA_2	phospholipase A_2
RAGE	receptor for advanced glycation end products
RANTES	regulated on activation, normal T-cell expressed
RBCs	red blood cells
ROS	reactive oxygen species
R-Smads	receptor-regulated or receptor-associated Smads
SAH	*S*-adenosyl-homocysteine
SDMA	symmetric dimethyl arginine
SGK	serum-and-glucocorticoid-dependent kinase
SHR	spontaneously hypertensive rat
SLC	secondary lymphoid chemokine
Smads	signaling pathways of TGF-β
SOD	superoxide dismutase
SR	sarcoplasmic reticulum
TβRI	type I serine/threonine kinase receptors
TβRII	type II serine/threonine kinase receptors
TCR	T-cell receptor for antigen
TCRz	T-cell receptor 2 chain
TGF	transforming growth factor
TGF-β	transforming growth factor-β
Th	CD4 helper
TLR	toll-like receptor
TNF	tumor necrosis factor
TNFR	tumor necrosis factor receptor
TRAIL (DR4)	TNF-related apoptosis inducing ligand
Treg	the CD4+ T-cell constitutively expressing CD25+ on its surface
TxA2	thromboxane A2
UbC	ubiquitin C3 subunit gene
UT-B	the RBC-facilitated urea transporter
V_2R	V_2-receptors
VSMCs	vascular smooth muscle cells

58 Nitric Oxide Synthase and Cyclooxygenase in the Kidneys

CHRISTOPHER S. WILCOX

SUMMARY

Three isoforms of nitric oxide synthase (NOS) and two of cyclooxygenase (COX) are expressed in the normal kidney. Neuronal (type I) NOS is expressed heavily in the macula densa, where it blunts the tubuloglomerular feedback response that increases afferent arteriolar tone in proportion to distal NaCl delivery and in the cortical and inner medullary collecting ducts where it impairs tubular Na^+ entry. Endothelial (type III) NOS is expressed in endothelial cells where it mediates the endothelium-derived relaxing factor response and in the thick ascending limb, where it inhibits tubular NaCl reabsorption. Inducible (type II) NOS is widely expressed after cytokine challenge. It participates in cell death following sepsis or ischemia of the kidney. COX-1 is expressed in endothelial and smooth muscle cells of renal vasculature and in the medullary collecting ducts where it antogonizes arginine vasopressin and inhibits Na^+ reabsorption. COX-2 is expressed in the macula densa cells and adjacent thick ascending limb where it enhances renin section and inhibits tubular NaCl reabsorption. NOS and COX isoforms interact extensively to fulfill their major roles of adapting renal function to changes in salt and water intake or blood pressure.

Key Words: Tabuloglomerular; feedback; hypertension; nitric oxide; prostaglandin; oxidative stress.

INTRODUCTION

Nitric oxide synthase (NOS) and cyclooxygenase (COX) are molecular targets that mediate important actions in the kidney. They are coexpressed in many vascular and epithelial cells, and mediate vasoconstriction, tubular reabsorption, renin secretion, and mediator release. Interactions are discussed at the end of this chapter.

NITRIC OXIDE SYNTHASE

ISOFORMS NOS catalyzes the two-step oxygenation of arginine via hydroxyarginine to citrulline and NO. The enzyme has a K_m for L-arginine in the low micromolar range, consumes molecular O_2, oxidizes NADPH, and has a requirement for the reduced form of tetrahydrobiopterin (BH_4), flavine adenine dinucleotide, and flavine mononucleotide. Under conditions of reduced availability of substrate or BH_4, O_2 is incompletely reduced with the preferential formation of superoxide anion ($O_2^{\cdot-}$) rather than NO. This converts NOS from a source of the antihypertensive, anti-inflammatory NO to the prohypertensive, proinflammatory $O_2^{\cdot-}$.

Three NOS isoforms have been cloned from the kidney. Two of these, neuronal (n) or type-I NOS and endothelial (e) or type-III NOS, are expressed constitutively. A third isoform, inducible (i) or type-II NOS, has low or absent basal expression in most organs, but is subject to major induction during sepsis, inflammation, or cytokine stimulation. However, in the kidney, constitutive (c) NOS isoforms have transcriptional and post-transcriptional regulation and sufficient iNOS is expressed basally to regulate normal renal function. A second important distinction between cNOS and iNOS concerns their activation. Both enzymes have an absolute requirement for calcium (Ca^{2+}) and calmodulin, but, although changes in intracellular calcium ($IC_{Ca^{2+}}$) regulate cNOS, Ca^{2+} and calmodulin are tightly bound to the active site of iNOS whose regulation is effectively independent of changes in $IC_{Ca^{2+}}$.

These differences provide a molecular explanation for the different functions of these two classes of enzymes. cNOS is preformed in cells, subject to rapid activation/inactivation via changes in $IC_{Ca^{2+}}$ or enzyme phosphorylation mediated via Akt, and generates discrete, low-level (nanomolar) bursts of NO, which function in an autocrine or paracrine manner. In contrast, renal iNOS has some basal activity, but is capable of substantial transcriptional upregulation during stimulation with cytokines or growth factors to produce large (micromolar) sustained concentrations of NO that dictate changes in whole organ function that persist for hours or days. The kidney is unusual in its high basal rate of generation of cytokines, which may be the explanation for iNOS expression in the normal kidney.

NO GENERATION AND METABOLISM NO is a mediator of the endothelium-derived relaxing factor (EDRF) response. Investigators showed that EDRF is inactivated rapidly at high pO_2, but this is prevented by superoxide dismutase (SOD), which metabolizes O_2^- to hydrogen peroxide. They concluded that EDRF is a labile mediator subject to rapid oxidative bioinactivation. Chemiluminescence was used to demonstrate unequivocally that NO from the aorta is released by acetylcholine and functions as an EDRF. NO is the source of endogenous nitrate (NO_2^-) generation.

Molecular Targets for NO in Renal Blood Vessels Signaling pathways have been defined whereby NO activates guanyl cyclase (GC) to generate cyclic guanosine monophosphate (cGMP). This

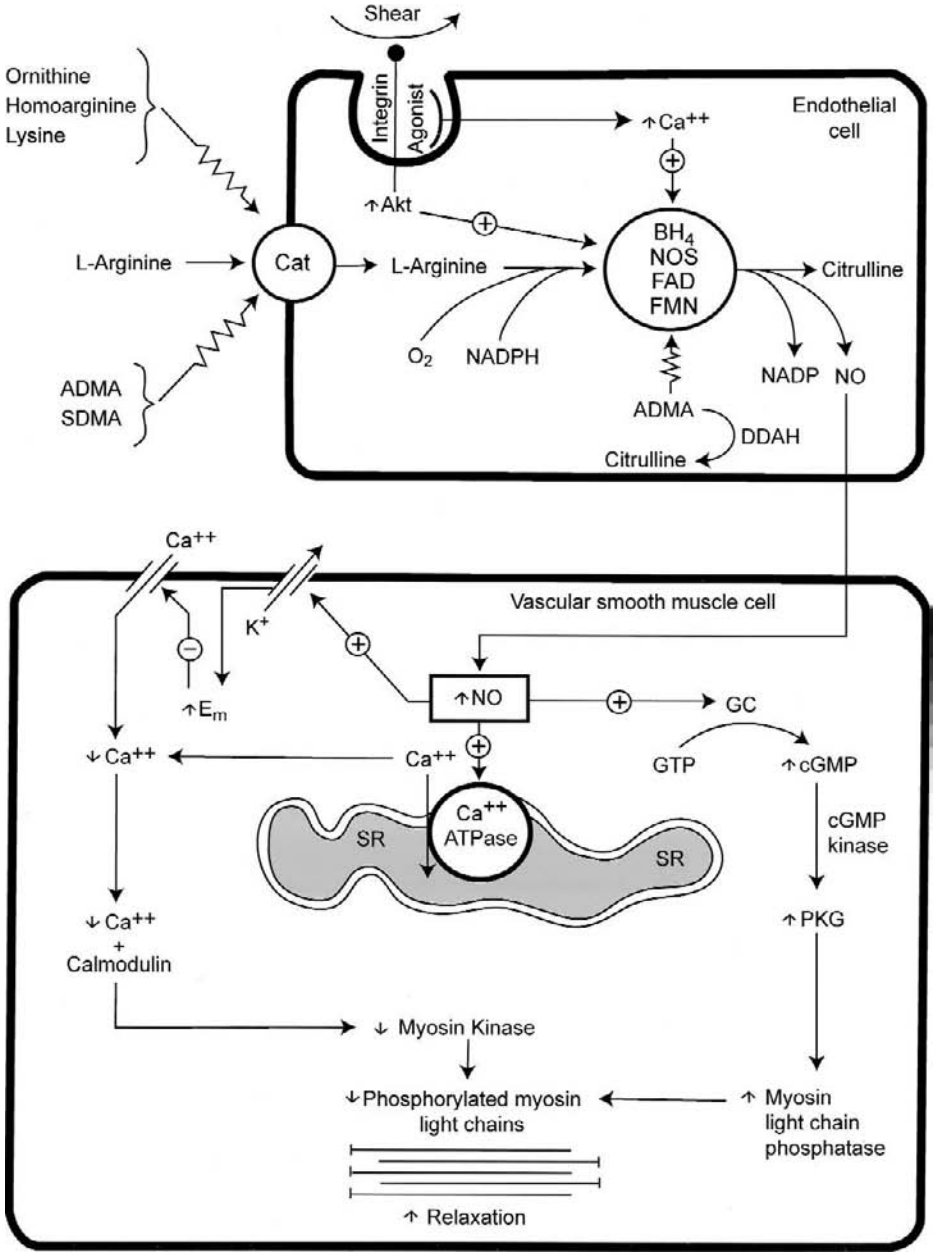

Figure 58-1 Cell diagram showing some pathways for NOS regulation in endothelial cells and for NO action in VSMCs. For details, *see* Molecular Targets for NO in Renal Blood Vessels.

activates cGMP kinase (G kinase) to stimulate protein kinase G (PKG) (Fig. 58-1). PKG activates myosin light chain phosphatase that dephosphorylates one of the light chains of each myosin head, which is also called the regulatory chain. This dephosphorylation dissociates the cross-bridges between the myosin head and the actin filaments, and prevents the attachment–detachment cycling of the myosin head with the actin filament. This leads to relaxation of the vascular smooth muscle cells (VSMCs) that is detected in pharmacological studies as an EDRF response. NO also reduces $IC_{Ca^{2+}}$ in VSMCs.

NO directly activates (1) a Ca^{2+} ATPase on the membrane of the sarcoplasmic reticulum, thereby sequestering cytoplasmic Ca^{2+} in the SR; (2) a Ca^{2+}-dependent K^+ channel in the cell membrane, thereby increasing the membrane potential (E_m); (3) inactivating L-type voltage-gated Ca^{2+}-channels; and (4) sodium–potassium ATPase. In addition, NO inhibits phospholipase C, causing decreased turnover of phosphoinositides.

NO can interact with many other heme-centered enzymes. For example, NO changes the affinity of hemoglobin for O_2. NO binds to thiol groups, forming *S*-nitrosothiols that modify the actions of the target protein and stabilize NO by protecting it from oxidative attack, thereby prolonging its biological action. The interaction of NO with $O_2^{\cdot-}$ forms peroxynitrite ($ONOO^-$) which effectively terminates many of NO's actions. However, $ONOO^-$ is a potent oxidative and nitrosative agent that attacks tyrosine epitopes to form nitrotyrosine modification of proteins. These can be detected immunologically to provide insight into $O_2^{\cdot-}$ and NO interactions in the kidney. Nitrotyrosine modification can also alter function. For example, prostacyclin synthase (PGI_2-S) is inactivated by $ONOO^-$ at a concentration of only 50 n*M*.

Molecular Targets for NO in the Tubular Cells NO interacts with heme-centered enzymes, such as GC, expressed in tubular and juxtaglomerular cells to generate cGMP. cGMP can inhibit

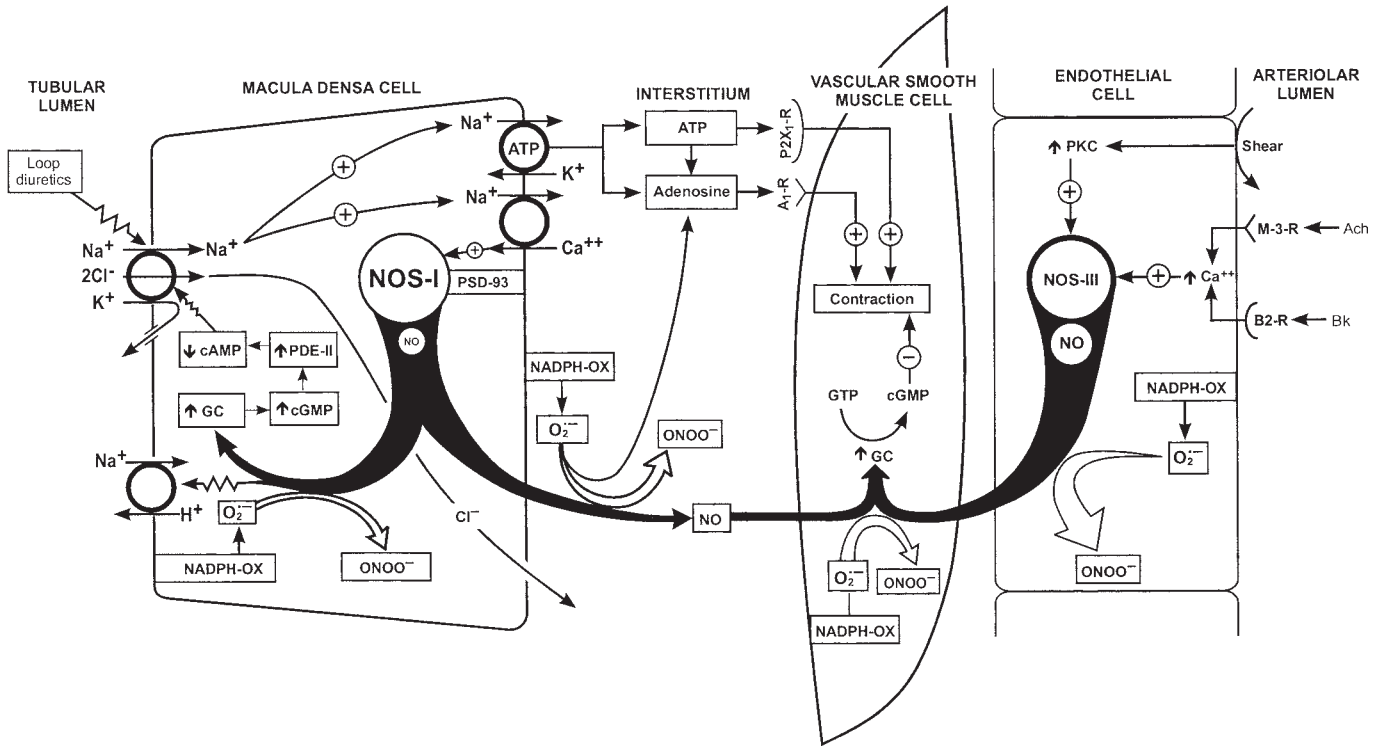

Figure 58-2 Cell diagram showing some pathways whereby NO generated by nNOS in the MD or eNOS in the vascular endothelium affects the tubuloglomerular feedback response or afferent arteriolar tone. For details, *see* Molecular Targets for NO in the Tubular Cells.

phosphodiesterase (PDE)-II in the cells of the thick ascending limb of the loop of Henle and the macula densa (MD). PDE-II metabolizes and inactivates cAMP (Fig. 58-2). The ensuing decrease in cAMP decreases the phosphorylation of the $Na^+/K^+/2Cl^-$ cotransporter in the luminal cell membrane, and thereby leads to its inactivation. NO also activates Ca^{2+}-activated K^+channels that increase E_m and thereby enhance Na^+ entry and reabsorption. Similar events in the juxtaglomerular cells of the afferent arteriole have complex effects on renin secretion. Renin secretion initially is decreased after NO by actions of cGMP to activate G-kinase and PKG. Later, renin secretion is stimulated via actions of cAMP to enhance protein kinase A. This occurs because NO inhibits PDE-III, thereby leading to a gradual increase in cAMP accumulation.

NO Measurement NO released into the bloodstream reacts rapidly with hemoglobin to form nitrosohemoglobin which, on reduction, releases NO_2^- which can be further oxidized to NO_3^-. Cellular release of $NO_2^- + NO_3^-$ (NO_x) and renal excretion of NO_x during consumption of a NO_x-deficient diet are methods to quantitate NO generation. NOS activity in the tissues can be studied directly from the release of labeled citrulline from labeled arginine, from the partial pressure of NO measured with a porphyrinic NO-sensitive electrode, by the use of fluorescent dyes, such as diaminofluorescein-2, which are trapped within cells and fluoresce on reaction with NO, by spectrophotometric changes that occur when NO interacts with test proteins such as hemoglobin, by generation of NO signaling molecules such as cGMP, and from functional responses to blockade of NOS with competitive antagonists such as L-nitroarginine methyl ester.

Distribution of NOS Isoforms in the Kidney Type-I (neuronal) NOS is heavily expressed in MD cells. Other sites include the cortical and inner medullary collecting ducts and Bowman's capsule of the glomerulus. There is a lower level of expression in the efferent arteriole. Type-III (endothelial) NOS is expressed primarily in the endothelial cells of the arterioles and capillaries of the kidney. eNOS is expressed also in the cells of the thick ascending limb, collecting ducts, and proximal tubules. Type-II (inducible) NOS can be widely expressed in the glomeruli, vessels, and tubules on challenge with lipopolysaccharide or cytokines. Basal expression is apparent in cells of the thick ascending limb, and the proximal and distal nephron.

Regulation of NO Generation and Action NO generation is closely regulated. Cellular arginine uptake is mediated via cationic amino transporters (CATs) expressed on cell membranes (Figs. 58-1 and 58-2). There is competition for transport among the cationic amino acids, such as ornithine, lysine, and homoarginine, and with the dimethyl arginines, asymmetric dimethyl arginine (ADMA), and symmetric dimethyl arginine. All of these can inhibit arginine uptake and NO action (Fig. 58-1). Endothelial NOS in vascular endothelial cells is activated by a rise in $IC_{Ca^{2+}}$ by agonists, such as acetylcholine, acting on M-3 receptors or bradykinin (Bk) acting on B_2 receptors. Sheer stress is transduced by integrins expressed in caveolae, which activates Akt-1 which phosphorylates and activates eNOS. NOS activity in tubular or vascular cells can be inhibited by lack of availability of essential cofactors, notably BH_4, which, during oxidative stress, is converted to the inactive form, dihydrobiopterin.

ADMA is an endogenous inhibitor of NOS and CAT. ADMA (but not symmetric dimethyl arginine, which is ineffective as a NOS inhibitor) is metabolized to citrulline by dimethylarginine dimethylaminohydrolase (DDAH), which is widely expressed in the kidney at sites of NOS expression.

The tubuloglomerular feedback response is a unique renal mechanism, whereby delivery and reabsorption of Cl^- at the MD

segment leads to the elaboration of a mediator that vasoconstricts the adjacent afferent arteriole. Mediators include adenosine acting on type-1 receptors and adenosine triphosphate acting on purinergic type-2 receptors. The tubuloglomerular feedback response contributes to renal autoregulation and to adaptation of renal hemodynamics to changes in salt intake. Defects in tubuloglomerular feedback underlie salt-sensitive hypertension. Neuronal NOS also is activated in the MD during Cl^- reabsorption. The ensuing increase in NO generation blunts the tubuloglomerular feedback response both by inhibiting vasoconstriction of the adjacent afferent arteriole and by inhibiting the generation of the tubuloglomerular feedback signal by blocking the luminal Cl^- transporter (Fig. 58-2). An overactive tubuloglomerular feedback response in the spontaneously hypertensive rat (SHR) or the Dahl salt-sensitive rat can be ascribed to a blunted NO action in the juxtaglomerular apparatus because of enhanced inactivation of NO by $O_2^{\cdot-}$. This overactive tubuloglomerular feedback response likely contributes to renal vasoconstriction and hypertension.

Activation mechanisms for nNOS have been studied in the MD. Basal activity is negligible, but becomes substantial during delivery and reabsorption of NaCl at this segment. Reabsorption via the luminal $Na^+/K^+/2Cl^-$ cotransporter increases cell $[Na^+]$, which activates basolateral Na^+/Ca^{2+} countertransport, thereby increasing $IC_{Ca^{2+}}$ and activating NOS. nNOS is coexpressed with a protein having a postsynaptic density of 93 along the basolateral aspect of the MD cell. Its interaction with the PDZ domain on nNOS dimerizes and activates the enzyme (Fig. 58-2).

NO is inactivated rapidly in renal tubular epithelial cells by interaction with $O_2^{\cdot-}$. NADPH oxidase is responsible for much of the $O_2^{\cdot-}$ generation in the renal cortex. As studied most fully in the leukocyte, this enzyme requires assembly of a complex of five protein subunits with a small guanidine triphosphatase activating protein rac-1. When activated, NADPH oxidase reduces O_2 to $O_2^{\cdot-}$. All the major protein components of NADPH oxidase are expressed in VSMCs and endothelial cells of the renal vessels and in the distal nephron, most prominently in the MD. Other prominent sites of NADPH oxidase expression include interstitial fibroblasts and mesangial cells (Fig. 58-2). Expression of NADPH oxidase along the luminal aspect of MD and thick ascending limb cells may protect the luminal cotransporters from phosphorylation and inactivation by NO, whereas expression in the interstitium, VSMC, and endothelial cells limits the access of NO generated in the MD or the endothelial cells to GC expressed in the VSMCs of the adjacent afferent arteriole (Fig. 58-2). Thus, the expression and activation of NADPH oxidase are important factors that limit the biological actions of NO in the juxtaglomerular apparatus.

Regulation of NOS Expression A low salt intake increases the expression of nNOS in the MD and renal cortex, but reduces its expression in the cortical collecting ducts. Despite its upregulation during salt restriction, the expression of nNOS in the MD is unresponsive to angiotensin (Ang) II infusion or to blockade of Ang II type-1 receptors (AT1-Rs). The upregulation of nNOS may be a response to reduced bioactive NO, because NO inhibits NOS activity and expression. The expression of nNOS in the MD is downregulated in the reduced renal mass model of chronic renal insufficiency, but is upregulated in several models of hypertension, including the poststenotic kidney of rats with Goldblatt hypertension and the SHR. However, oxidative stress that accompanies hypertension in these models enhances $ONOO^-$ deposition and prevents the action of NO to vasodilate the afferent arteriole. In contrast, nNOS is upregulated in the MD in models of early insulinopenic diabetes mellitus, where it mediates glomerular hypertension and hyperfiltration via blunting of the vasoconstrictive tubuloglomerular feedback response.

Expression of eNOS in endothelial cells of the afferent arteriole also is upregulated by salt restriction but, unlike nNOS in the MD, this can be ascribed to Ang II action on AT1-R, because it is prevented by blockade of AT1-R with losartan. eNOS expression is upregulated in models of early insulinopenic diabetes mellitus and in some models of hypertension, such as the SHR.

Dietary salt restriction upregulates nNOS expression in the MD. However, its activity in the regulation of afferent arteriolar tone is absent, but can be restored by microperfusion of the NOS substrate, L-arginine, into the MD. The limitation of NOS activity in the MD during salt restriction by arginine availability can be ascribed to a reduced plasma arginine concentration and a reduced cellular uptake of L-arginine from the tubular lumen. Hepatic cells metabolize available arginine to ornithine and urea and thereby limit plasma levels of arginine. During dietary salt restriction there is an upregulation of the high-capacity CAT transporter for arginine expressed on hepatic cells. This may enhance hepatic arginine uptake from the portal system sufficiently to facilitate its metabolism and restrict its plasma level. The reduced plasma levels of arginine are accompanied by increases in ornithine and in urea appearance. Dietary salt restriction reduces the expression of CAT-2A in the thick ascending limb and MD cells of the loop of Henle. This restricts the uptake of arginine from the tubular fluid into these cells and contributes to the reduced activity of nNOS during salt restriction. These adaptations may be important because reduced NOS activity could contribute to the reduced renal blood flow and the enhanced renal NaCl reabsorption during salt deficiency.

Despite overexpression of nNOS in the MD, and of eNOS in the endothelium, the renal blood flow, and the tubuloglomerular feedback of the SHR are independent of NOS, as indicated by little or no response to blockade of NOS with drugs such as L-nitroarginine methyl ester. NOS activity in the juxtaglomerular apparatus of the SHR is not limited by the availability of arginine or BH_4 but can be restored in full by microperfusion into the juxtaglomerular apparatus of the antioxidant SOD mimetic, tempol.

The renal oxidative stress in the SHR and the Ang II infused rat or mouse has been attributed to an upregulation of NADPH-oxidase that is mediated by AT1-R. Ang II upregulates the $p22^{phox}$ and Nox-1 components of NADPH oxidase in the kidney, but downregulates Nox-4 and extracellular and mitochondrial-SOD. Ang II type-2 receptors have contrary effects and therefore are protective of the development of oxidative stress.

Renovascular Actions of NO The renal preglomerular (afferent) and postglomerular (efferent) arterioles are vasodilated tonically by NO, as indicated by a sharp increase in their resistances during blockade of NOS. An enhanced renal NO generation contributes to renal vasodilatation in normal pregnancy, during infusion of amino acids, and in early diabetes mellitus. Conversely, a reduced NO bioactivity contributes to renal vasoconstriction in many models of hypertension, such as prolonged Ang II infusion in the rat, the SHR, lead-induced hypertension, and the Dahl salt-sensitive rat and in models of chronic renal failure. There is a reduced total body NO generation in humans with essential hypertension and chronic renal failure. The NO that dilates the renal afferent arteriole may derive either from the adjacent vascular endothelial cell or the adjacent MD cell (Fig. 58-2). Despite these

widespread effects of NO to regulate afferent arteriole tone, NO is not implicated in renal autoregulation.

Role of NO in Tubular Function Most investigators have concluded that NO reduces tubular NaCl and fluid reabsorption. However, this is often complicated by secondary effects. For example, the increase in blood pressure (BP) that accompanies NOS inhibition systems reduces tubular NaCl reabsorption. Effects of NO on segmental NaCl tubular reabsorption are controversial. Both stimulation and inhibition have been reported in the proximal tubule and collecting ducts. Blockade of NOS in the proximal tubule can impair luminal Na^+/H^+ exchange leading to impaired reabsorption of Na^+ and HCO_3^- and development of a metabolic acidosis contrast. Stimulation of NO generation from eNOS in the adjacent peritubular capillary endothelium by Bk enhances basolateral HCO_3^- uptake. Higher concentrations of NO in the proximal tubule inhibit Na^+/K^+ ATPase. In the collecting ducts, NO, via cGMP, inhibits the luminal entry of Na^+ via the epithelial sodium channel, but also paradoxically can enhance Na^+ entry secondary to an increase in the basolateral potassium conductance that hyperpolarizes the cell. Studies in the thick ascending limb of the loop of Henle uniformally demonstrate inhibition owing to blockade by NO of the luminal $Na^+/K^+/2Cl^-$ cotransporter, Na^+/H^+ exchanger, and K^+ channel and the basolateral Na^+/K^+ ATPase. NO increases cGMP and cAMP, which promote phosphorylation and inactivation of the luminal transporters (Fig. 58-2). NO likely derived from nNOS within mitochondria in tubular epithelial cells competes with O_2 for cytochrome-*c* reductase and diminishes cellular O_2 usage. A reduction in NO in the kidney increases O_2 usage and reduces the efficiency with which the kidney uses O_2 for tubular Na^+ reabsorption. Consequently, there is a fall in the pO_2 of the kidney cortex.

Effects of NO on Renin Secretion NO has site- and time-dependent effects on the secretion of renin from the afferent arteriole. NO can stimulate renin secretion from the juxtaglomerular cells via inhibition of PDE-III and elevation of cAMP, or may inhibit it via the cGMP/PKG pathway. Activation of nNOS in the MD by luminal perfusion of L-arginine enhances the secretion of renin. This may represent the effects of MD NO to activate COX-2 whose product, prostacyclin (PGI_2), stimulates renin secretion. In contrast, acute activation of eNOS in endothelial cells leads to cGMP-dependent inhibition of renin secretion. However, during prolonged stimulation of eNOS, the initial inhibition is followed by enhanced release.

Role of NO in Pathophysiology and Disease A decrease in intrarenal NO activity in blood vessels, the MD and renal tubules accompanies many models of hypertension and contributes to renal vasoconstriction and enhanced tubular NaCl reabsorption. Inhibition of NOS in normal animals shifts the relationship between BP and salt so as to induce salt sensitive hypertension. In contrast, correction of oxidative stress in hypertensive models with an SOD mimetic that enhances NO bioactivity shifts the relationship back to the normal state, thereby correcting salt sensitivity and lowering BP. An increase in NO in the kidney contributes to hyperfiltration in models of early diabetes mellitus. In models of postischemic or endotoxic renal insufficiency, where oxidative stress is prominent, massive overproduction of NO in the kidney is implicated in the associated tubular damage that may be mediated by $ONOO^-$.

CYCLOOXYGENASE

COX is a fatty acid mono-oxygenase. It is widely distributed in the kidney and elsewhere. On cell activation by increased sheer stress, transmural pressure, peptides such as Ang II, Bk, or endothelin, cytokines or hypoxia, phospholipase A_2 hydrolyzes membrane phospholipids to free arachidonic acid that is metabolized by COX to prostaglandin (PG) endoperoxides. The initial COX product is prostaglandin G_2 but this is rapidly rearranged to the stable prostaglandin H_2 (PGH_2), which not only activates thromboxane-prostanoid receptors, but also is the substrate for three important classes of enzymes. Prostaglandin E_2 synthase generates prostaglandin E_2 (PGE_2), PGI_2-S generates PGI_2, and thromboxane A_2 synthase generates TxA_2.

COX ISOFORMS IN THE KIDNEY Two COX isoforms are expressed in the kidney. COX-1 is widely expressed constitutively in body tissues. In most organs, COX-1 is responsible for basal PG synthesis. COX-2 is termed inducible because in most organs there is negligible basal COX-2 expression until stimulation with lipopolysaccharide or cytokines when COX-2 becomes the predominant source of PGs. However, as with NOS, the kidney is unusual in having high basal expression of the inducible isoform, which contributes importantly to basal renal PG productions.

COX-1 is located in the endoplasmic reticulum of the endothelial and VSMCs of the afferent and efferent arterioles and larger arteries, and in the glomerulus, the medullary collecting ducts, and medullary interstitial cells. Major sites of COX-2 expression include the MD cells, some adjacent thick ascending limb cells and medullary interstitial cells. COX-2 is expressed more widely in the embryonic kidney. Mice with targeted disruption of the gene for COX-2, but not COX-1, suffer nephron hypoplasia and renal atrophy, implying an important role for COX-2 products in renal development.

REGULATION OF COX ACTIVITY COX activity is enhanced by peroxides, but high concentration of $O_2^{\cdot-}$ leads to its irreversible inactivation. In low concentrations, NO stimulates COX activity and vascular PGI_2 generation. However, in high concentrations, as during iNOS induction, NO can inactivate COX. COX-1 activity is determined by the availability of arachidonate. The net effect of inhibition of COX-1-derived PGs in the blood vessels is usually vasoconstriction, likely owing primarily to inhibition of PGI_2 synthesis in resistance vessels. COX-1 activity in the collecting ducts is increased by arginine vasopressin (AVP). An ensuing increase in PGE_2 activates adenylate cyclase to generate cAMP which antagonizes the effects of AVP to enhance water permeability and terminates other effects of AVP. PGE_2 also inhibits the activity of the luminal Na^+ entry channel. Thus, blockade of COX-1 enhances tubular reabsorption of fluid and NaCl.

COX-2 activity is determined by enzyme expression, which is stimulated by serum, growth factors, lipopolysaccharide, tumor promoters, and peptides that include Ang II, Bk, and endothelin, whereas glucocorticoids inhibit expression. COX-2 expression in the MD is stimulated by dietary salt restriction. Remarkably, this effect is enhanced during blockade of AT1-R which indicates that Ang II has a negative feedback effect on COX-2 expression at this site. In contrast, Ang II stimulates expression of COX-2 in the thick ascending limb and blood vessels. A reduction in extracellular $[Cl^-]$ at the thick ascending limb stimulates COX-2 expression by increasing p38 mitogen-activated protein kinase activity. Negative feedback inhibition of COX-2 expression in the MD by Ang II is signaled via nuclear transcription factor-κB and is reinforced by Ang II-induced aldosterone secretion, which also inhibits COX-2 expression. Expression of COX-2 in the interstitial cells of the renal medulla is enhanced by dehydration or an increase in interstitial osmolality. The ensuing increase in PGE_2

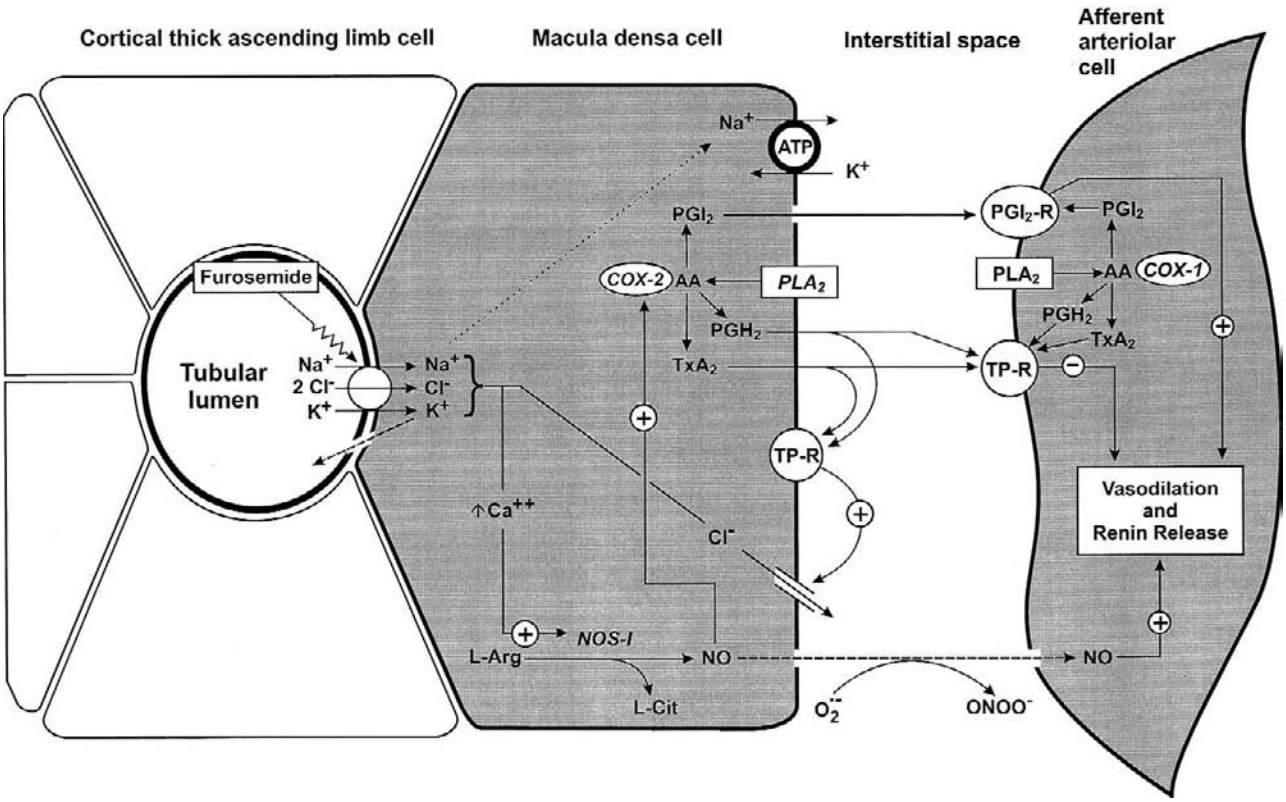

Figure 58-3 Cell diagram showing some pathways whereby nNOS and COX-2 in the MD interact to regulate afferent arteriolar tone. For details, *see* Interactions Between NOS and COX in the Kidney.

buffers the effects of AVP to enhance free water reabsorption in the collecting ducts. COX-2 expression in the MD is reduced by blockade of NOS and is increased by NO donors. However, a clear picture has not emerged of the inter-relationship of MD nNOS and COX-2 expression because the regulation of COX-2 by salt intake is relatively intact in the nNOS knockout mouse.

Renovascular Effects of COX Products The regulation of renal vascular resistance by COX-1 is of acknowledged importance, but is complicated by opposite effects of the vasoconstrictor PGs, PGH_2, and TxA_2 that activate the thromboxane-prostanoid receptors and of the vasodilator PG, PGI_2 that activates the PGI_2-R. Moreover, the actions of PGE_2 are transduced via four discrete receptors linked to vasodilator or vasoconstrictor pathways. The response to nonselective inhibition of COX generally is to reduce renal blood flow and the glomerular filtration rate (GFR) and to raise BP. This likely reflects predominantly inhibition of PGI_2 synthesis by COX-2 in the renal and systemic resistance vessels. During short-term Ang II infusion, the increased renal cortical and medullary vascular resistances are enhanced during blockade of COX-1, but are blunted during blockade of COX-2. These acute responses to Ang II likely represent phospholipase-A2 activation with arachidonic acid release and metabolism to predominantly vasodilator PGI_2 by COX-2 in the vascular endothelium. However, nonselective inhibition of COX during Cl^- loading to stimulate tubuloglomerular feedback, in models of renovascular hypertension, reduced renal mass hypertension and during prolonged infusion of Ang II, increases the renal blood flow and GFR and/or reduces the BP. These contrary consequences likely involve predominant effects of COX-2 blockade to inhibit PGI_2- and PGE_2-induced renin secretion, and to inhibit the generation of PGH_2 and TxA_2 that mediate vasoconstriction and enhanced tubuloglomerular feedback mediated via the thromboxane-prostanoid receptors. Importantly, nonselective inhibition of COX or selective inhibition of COX-2 either does not change, or more often increases the renal vascular resistance and the BP in normal human subjects or those with essential hypertension. As in animal models, nonselective inhibition of COX reduces BP in patients with renovascular hypertension.

Effects of COX Products on Tubular Reabsorption The predominant effect of nonselective inhibition of COX is a reduction in NaCl and fluid excretion and an increase in urine concentration. This likely reflects predominantly COX blockade in the collecting ducts that prevents the buffering by PGE_2 of AVP-induced increases in water permeability and Na^+ reabsorption.

Effects of COX Products on Renin Secretion Nonselective blockade of COX inhibits renin secretion profoundly. This likely represents predominant inhibition of COX-2-derived PGs that mediate MD-stimulated renin secretion. Indeed, COX-2 is upregulated by dietary NaCl restriction and in models of renal artery stenosis and mediates the accompanying increases in renin secretion.

Role of COX in Disease COX products have relatively little effect on renal function during normal salt intake. In contrast, nonselective COX inhibition leads to renal vasoconstriction and reduced GFR during dietary salt restriction, and to renal fluid and salt retention with edema or hypertension during dietary salt loading. The latter effect likely involves predominantly inhibition of COX-1-mediated reductions in NaCl and fluid transport in the collecting ducts. However, inhibition of COX-2 can increase BP in individuals with essential hypertension. In contrast, aspirin given to patients with renovascular hypertension reduces BP and renin secretion. Overproduction of COX products contributes to renin

secretion in patients with Bartter's syndrome. Nonselective inhibition of COX in human subjects or selective inhibition of COX-2 in animals impairs the natriuretic and diuretic response to loop diuretics. Overproduction of COX products in the glomerulus during glomerulonephritis, or the nephrotic syndrome, contributes to increased glomerular protein permeability and proteinuria. Enhanced generation of medullary COX products during severe potassium depletion or hypercalciuria leads to polyuria, dehydration, and failure to concentrate the urine, likely reflecting enhanced buffering of the effects of AVP in the collecting ducts by PGE_2. Following ureteral obstruction in the rat, there is initially overproduction of vasodilatory PGs that maintain the renal blood flow. However, during the subsequent days, cellular infiltration generates PGs with predominant vasoconstrictor action mediated through the thromboxane-prostanoid receptors. Renal vein constriction enhances renal PG synthesis that maintains renal blood flow. COX products contribute to the hyperfiltration in models of early diabetes mellitus, but during the established phase with the development of glomerulopathy, the predominant COX products are TxA_2 and PGH_2, which mediate protein kinase C-induced renal vasoconstriction, proteinuria, glomerular sclerosis, and renal insufficiency via the thromboxane-prostanoid receptors. Overall, COX products generally are not unique mediators of pathophysiology, but modulate the response to the disease process.

INTERACTIONS BETWEEN NOS AND COX IN THE KIDNEY

Although interaction between NOS and COX is widely acknowledged, its details remain controversial. Low levels of NO directly activate COX, enhance vascular PGI_2 generation, and transcriptionally upregulate COX-2 in the MD. In contrast, high levels of NO contribute to irreversible inactivation of COX. Within the MD cells (Fig. 58-3) an increase in NOS-1-derived NO can activate COX-2 to generate PGs that contribute to renin secretion from the afferent arteriole and modulation of the tubuloglomerular feedback response.

Because both inducible NOS (NOS-2) and COX-2 are highly inducible, these two isoforms are widely expressed in the tissues and kidneys during postischemic, nephrotoxic and shock syndromes, where they contribute to hypotension and renal insufficiency. The coincident production of large quantities of NO and $O_2^{\cdot-}$ will lead to widespread protein nitrosylation secondary to $ONOO^-$ formation, which likely contributes to structural and functional abnormality. Blockade of NOS-2 in a model of renal ischemia limits tubular damage whereas blockade of COX-2 in a model of chronic renal failure limits proteinuria and progressive renal damage. However, any beneficial effects of blockade of COX-2 must be weighed closely against the evidence that nonselective, or COX-2 selective, antagonists have been linked to a wide range of renal insults, including acute renal insufficiency, membranous glomerulonephritis, interstitial nephritis, and papillary necrosis. Therefore, these drugs are generally contraindicated in patients predisposed to these conditions.

CONCLUSION

NOS and COX fulfill many critical roles in the kidney in adapting normal renal function to changes in salt intake or BP. Although they can function individually, increasing emphasis is placed on interaction between these two systems. The outcome of NOS or COX activation is complex because it depends on isoforms and their expression within discrete nephron segments and, in the case of COX, can lead to products with widely divergent actions.

59 Hypertension and Sodium Channel Turnover

Douglas C. Eaton, Bela Malik, and He-Ping Ma

SUMMARY

Hypertension is an increase of blood pressure to levels greater than normal that arises because of a mismatch between the volume of the vascular tree and the volume of blood. Blood volume depends on total body sodium content, which is a balance between sodium intake and output. Total body sodium is controlled by variable excretion of sodium by the kidneys. To regulate sodium balance, the primary variable that the kidney monitors is not total body sodium, but rather systemic blood pressure. Renal regulation of blood pressure is via the release of the peptide hormone, renin from specialized renal cells. Release of renin ultimately leads to the production of angiotensin II. Angiotensin II increases total peripheral resistance and blood pressure and also leads to an increase in aldosterone. Aldosterone is a steroid hormone that increases sodium reabsorption in the distal nephron by activating epithelial Na channels (ENaCs). Thus, Hypertension is a defect in one of these elements that control total body sodium balance.

Key Words: Aldosterone; angiotensin II; degradation; hypertension; inositol lipids; KRas; "Liddle's" Syndrome; Nedd4; small G proteins; "ubiquitin" salt sensitive hypertension.

INTRODUCTION

Hypertension is a chronic increase of blood pressure to levels >140/90 mm Hg. Between 1988 and 1994, 23% of all Americans aged 20–74 were found to have hypertension. Hypertension is more common among African Americans; in the United States, nearly one in three African Americans has hypertension compared with one in four whites. African Americans develop high blood pressure earlier in life compared with whites and at every age have more severe consequences of high blood pressure. The estimated prevalence of high blood pressure for non-Hispanic, African Americans age 20 and older is 35% for men and 34.2% for women. For whites, the estimated prevalence of high blood pressure for men is 24.4 and 22% for women. Hypertension predisposes individuals to develop cardiovascular disease, renal disease, and cerebral vascular injury. According to the Centers for Disease Control and Prevention stroke alone killed 158,448 people (61.4% among women) in 1998 and accounted for about 1 of almost 15 deaths in the United States (http://www.cdc.gov/washington/overview/ heartstk.htm).

HYPERTENSION AND TOTAL BODY SODIUM BALANCE

The average American diet contains about 10 g of salt per day, but the amount of ingested salt can vary enormously. Despite large daily variations in salt intake, normal values of plasma sodium deviate little from the normal range of 135–145 mmol/L and, under normal circumstances, there is a critical balance of excretion that is exactly equal to the intake. There is some sodium in sweat and feces; the amount in sweat is incidental to maintaining thermal balance and the output in feces under physiological circumstances is generally small. Consequently, the control of total body sodium is due to variations in excretion by the kidneys. Urinary sodium concentrations are usually in the range of 10–40 mmol/L but can range from undetectable to >150 mmol/L. Thus, the kidney not only is the primary organ responsible for removing sodium from the body but it also maintains total body sodium balance and a normal blood concentration of sodium.

REGULATION OF TOTAL BODY SODIUM BALANCE BY THE KIDNEY The observation that the sodium content of the urine varies directly with the amount of ingested sodium shows that the kidney is responsible for sodium balance, but two questions remain: How does the kidney sense total body sodium and what are the mechanisms by which the kidney can adjust the urinary output of sodium to match ingested sodium? Surprisingly, the primary variable that the kidney monitors in regulating sodium balance is not total body sodium, but rather systemic blood pressure. Arterial blood pressure (sensed by carotid and aortic arch baroreceptors) and venous blood pressure (or volume) sensed by distension of atria alter sympathetic activity (decreased blood pressure/or extracellular volume increases sympathetic activity). This in turn, varies blood pressure in the afferent arteriole supplying the nephron, the primary functional unit of the kidney (Fig. 59-1), and is sensed by pressure-sensitive cells within the nephron. Changes at any of these sites are interpreted as a change in total body sodium because blood pressure, blood volume, and total body sodium are closely linked. Thus, regulation of total body sodium balance by the kidney is intimately related to and ultimately depends on renal regulation of blood pressure.

RENAL REGULATION OF SYSTEMIC BLOOD PRESSURE The primary site in the nephron that responds to both sympathetic activity and systemic blood pressure is the juxtaglomerular apparatus

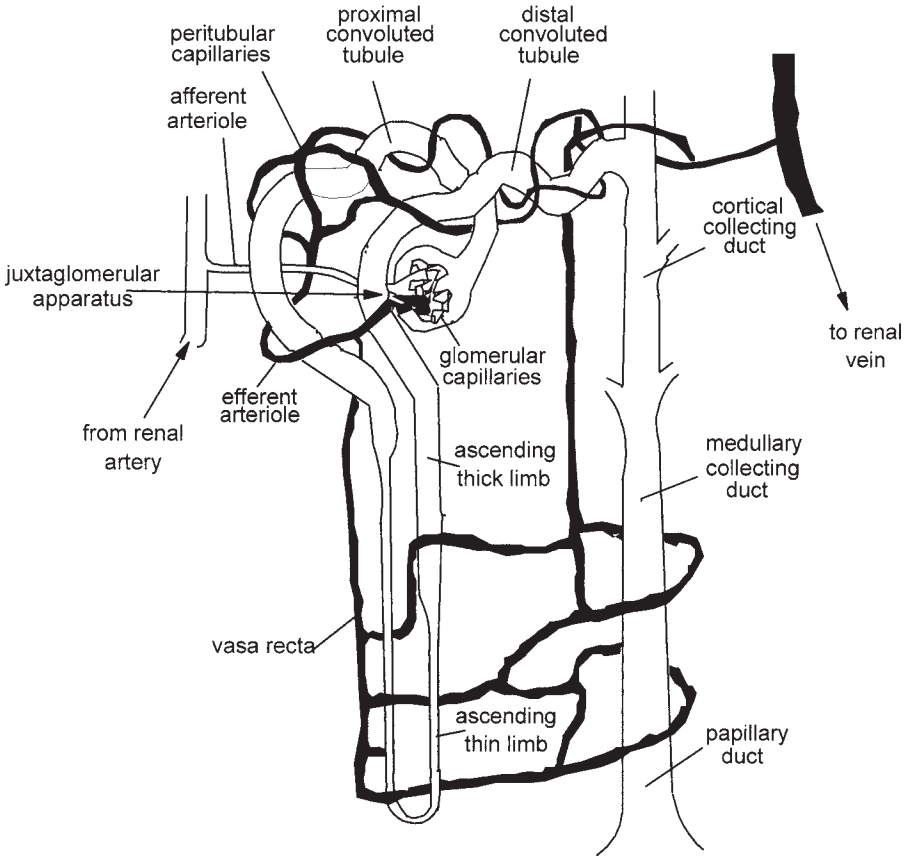

Figure 59-1 A schematic diagram of the nephron, the functional unit of the kidney. The nephron consists of the renal tubule and its associated blood supply. Blood entering the kidney from the renal artery (on left) enters the glomerulus through the afferent arteriole. The glomerulus acts as a filter that delivers about 20% of the blood volume to the proximal nephron as a cell-free, ultrafiltrate of plasma. Most of the glomerular filtrate is reabsorbed along the nephron so that only approx 1% of the original filtered amount remains to be excreted; however, the primary discretionary control of the amount of sodium present in the final urine is by control of sodium reabsorption in the distal nephron particularly aldosterone-mediated sodium reabsorption by the collecting tubule. The juxtaglomerular apparatus is the primary site at which the kidney senses systemic blood pressure and is the site for production of renin.

(*see* Fig. 59-1). Renal regulation of blood pressure primarily centers around release of the peptide hormone, renin, from specialized granular cells within the juxtaglomerular apparatus. When sympathetic activity increases owing to a fall in systemic blood pressure or if arterial pressure in the kidney decreases, the granular cells secrete renin. Release of renin initiates a complicated series of biochemical events. Renin is a proteolytic enzyme that splits circulating angiotensinogen (produced in liver) to form angiotensin I. Angiotensin-converting enzyme (ACE) present in endothelial cells of capillaries (especially in the pulmonary vasculature) cleaves angiotensin I to produce angiotensin II. Angiotensin II is a potent vasoconstrictor and increases total peripheral resistance and blood pressure. All of these events occur rapidly in response to a decrease in blood pressure. These responses represent a kidney-mediated, short-term correction for a decrease in blood pressure.

ALDOSTERONE REGULATION OF SODIUM BALANCE AND MEAN SYSTEMIC BLOOD PRESSURE In addition to this potential for short-term correction of blood pressure by angiotensin II, a sustained decrease in blood pressure is often associated with a decrease in blood volume suggesting a decrease in both total body sodium and water. The correction of a sustained decrease in blood pressure requires a decrease in excretion with increased renal reabsorption of salt and water until the blood volume returns to normal.

Part of this type of correction is a direct response to changes in blood pressure; a reduction in blood pressure leads to a lower volume of blood filtered by the glomerulus. This leads to less sodium filtered, an increase in the reabsorption of filtered sodium, and less Na excretion. Primary control of total body sodium is due to the action of the hormone, aldosterone. Aldosterone is a steroid hormone produced by adrenal cortical cells. Its primary effect is to increase sodium reabsorption in the distal nephron, particularly the collecting tubule (Figs. 59-1 and 59-2). The most important physiological factor controlling circulating levels of aldosterone is the circulating level of angiotensin II. As noted earlier, the kidney responds to a decrease in blood pressure by producing renin, a hormone that produces an initial short-term correction of blood pressure by promoting production of a vasoconstrictive agent, angiotensin II. Angiotensin II also stimulates the adrenal cortex to produce aldosterone. Aldosterone targets the distal nephron to increase sodium reabsorption and, thereby, increase total body sodium and blood volume producing a long-term correction of low blood pressure.

HYPERTENSION: A DISEASE OF ABNORMAL SODIUM BALANCE Hypertension is almost always associated with a blood volume and total body sodium content that are too high for

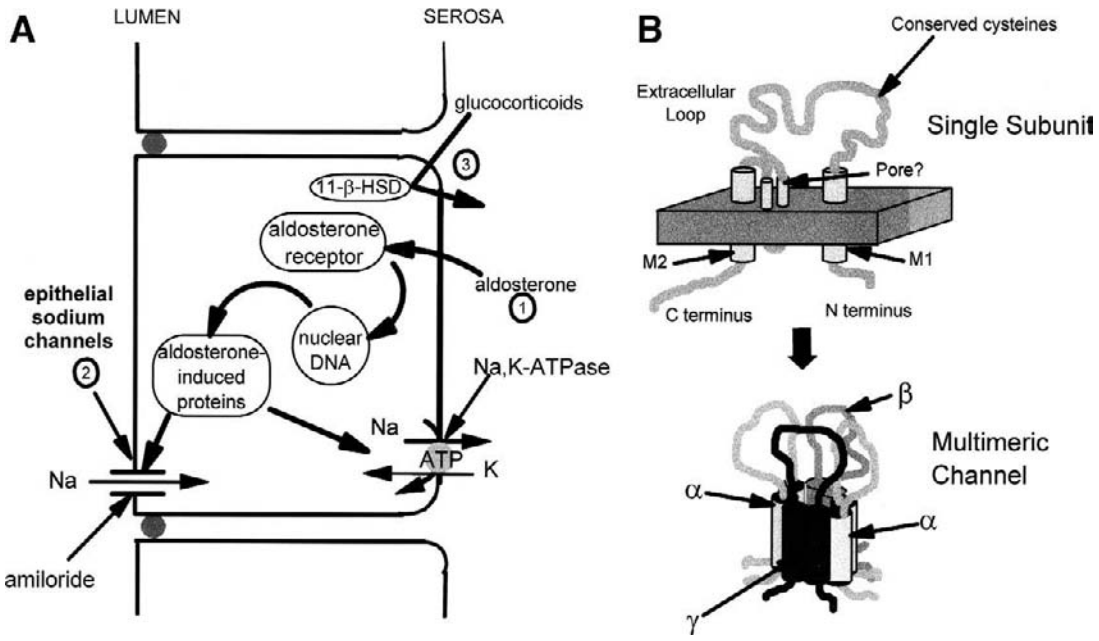

Figure 59-2 Mechanism of Aldosterone's Action and ENaC structure. **(A)** Aldosterone mechanism and pathology. Aldosterone enters principal cells **(A)** and interacts with cytosolic aldosterone receptors. The aldosterone-bound receptors interact with nuclear DNA to promote gene expression. The aldosterone-induced gene products activate sodium channels **(B)** and sodium pumps to increase sodium reabsorption. **(A)** Abnormalities of the adrenals and certain tumors can lead to primary hyper- or hypo-aldosteronism. **(B)** Loss of function mutations in sodium channels can lead to both pseudophypoaldosteronism; gain of function mutations produce pseudohyperaldosteronism (Liddle's syndrome). **(C)** Defects in 11-β-hydroxysteroid dehydrogenase **(C)** produces Apparent Mineralocorticoid Excess because glucocorticoids can then interact with aldosterone receptors to stimulate sodium channels. **(B)** Structure of ENaC. Each subunit has only two predicted membrane spanning domains, an unusual topology for an ion channel. Topologic analyses suggest that the amino and carboxy terminal regions of the ENaCs are cytoplasmic, and that each subunit has a large extracellular loop present among the membrane spanning regions. The α-, β-, and γ-ENaC have cysteine rich regions within putative extracellular loops, which are postulated to form intersubunit disulfide bonds that are important in oligomerization of Na channels. The three ENaCs also possess proline rich regions within their intracellular C-terminal domains that are important for interaction with accessory proteins that regulate the stability of functional channels in the apical membrane of renal cells. The three homologous ENaC subunit proteins form a heteromultimeric channel protein apparently made up of two α-, one β-, and one γ-subunit.

the physiological condition. In some cases, the reason for the excess blood volume is clear. For example, glomerular diseases often lead to inappropriate release of renin and an increase in angiotensin II and aldosterone levels with increases in collecting tubule sodium reabsorption, and ultimately, an increase in blood pressure. A tumor of the adrenal cortex can produce excess aldosterone causing an increase in blood pressure. A specific gain of function mutation in the sodium reabsorptive mechanism in the collecting duct also leads to excess sodium reabsorption and profound hypertension. Three examples illustrate types of defects that can complicate the control mechanism for maintaining total body sodium and mean blood pressure. First, excess renin production is a problem with the sensing mechanism for the system. Second, excess production of aldosterone is a defect in the signaling mechanism that lies between the sensor (pressure sensors in the large vessels and the kidney) and the effector (distal nephron sodium reabsorption); and the third example is a defect in the effector system (distal nephron sodium reabsorption). In each case, the defect is easily identified and correcting the underlying pathology usually corrects the hypertension. Table 59-1 provides a list of identifiable genetic defects in the regulation of sodium balance that lead to increases or decreases in blood pressure. Despite the relatively extensive list of known genetic defects, the etiology of hypertension is unclear. In most cases, renin angiotensin and aldosterone levels are normal or even reduced and yet blood pressure is elevated as if the set-point of the control loop sensing blood pressure and varying sodium reabsorption is inexplicably high. The relatively normal levels of circulating renin, angiotensin II, and aldosterone imply that the defect in the regulation of sodium reabsorption lies beyond aldosterone interacting with the cells of the collecting tubule. Hypertension research has attempted to define the components controlling sodium reabsorption in response to aldosterone.

MOLECULAR BIOLOGY AND STRUCTURE OF EPITHELIAL NA CHANNELS

cDNAs for epithelial Na channels (ENaCs) were originally described by investigators who used expression cloning methods to isolate three separate cDNAs from rat distal colon. They designated the three cDNAs α-, β-, and γ-rat ENaC. Coinjection into *Xenopus* oocytes with cRNAs prepared from all three cDNAs induces expression of amiloride-sensitive Na channels that possess characteristics virtually identical to those observed in renal cortical collecting tubule principal cells. The three subunits show limited sequence homology to each other although, across species, the same subunit has significant (70–90%), amino acid sequence homology (some regions do have only limited homology). Each subunit has only two predicted membrane spanning domains, an unusual topology for an ion channel. Topologic analyses suggest that the amino and carboxy-terminal regions of the ENaCs are cytoplasmic,

Table 59-1
Genetic Bases for Changes in Blood Pressure

Genetic bases for hypertension		
Syndrome	*Defect*	*Characteristics*
Apparent mineralocorticoid excess	Loss of function mutation of 11-β-hydroxysteroid dehydrogenase	Aldosterone receptors in renal principal cells are not only activated by aldosterone, but can be activated by normal levels of circulating glucocorticoids promoting constitutive sodium reabsorption with profound early-onset hypertension and growth arrest. Responsive to mineralocorticoid (aldosterone) receptor antagonists, for example, spironolactone, eplerenone.
Liddle's	Gain of function mutation in the β- or γ-subunit of ENaC	Constitutive sodium reabsorption regardless of circulating aldosterone levels with profound early-onset hypertension Responsive to Midamor (amiloride HCl).
T594M β–ENaC	Single amino acid mutation in β-subunit of ENaC with moderate gain of function	Increased collecting duct sodium reabsorption with mild to moderate hypertension. Most prevalent in individuals of African descent. Responsive to Midamor (amiloride HCl).
Glucocorticoid-remediable aldosteronism	Elevated aldosterone owing to an abnormal activation of aldosterone synthase by ACTH	Early-onset hypertension that can be controlled by administration of glucocorticoids (to reduce ACTH production).
Aldosterone synthase polymorphisms	Gain of function leading to increased circulating aldosterone	Increased sodium reabsorption with mild hypertension. Most prevalent in men. More prevalent in individuals of Japanese descent. Responsive to mineralocorticoid (aldosterone) receptor antagonists, for example, spironolactone, eplerenone.
11-β-hydroxylase deficiency	Loss of function mutation leading to abnormal accumulation of 11-deoxycorticosterone that activates aldosterone receptors	Activation of aldosterone receptors leads to sodium retention and early-onset hypertension. Associated accumulation of androgens leads to masculinization of females *in utero* and both sexes postnatally. May be responsive to the aldosterone receptor antagonist, eplerenone, but spironolactone would exacerbate androgenic effects.
Pseudohypoaldosteronism Type II (Gordon's syndrome)	Loss of function mutation in With No K [lysine] kinases	Loss of With No K [lysine] kinase (WNK) function leads to activation of distal nephron thiazide-sensitive sodium chloride cotransporter causing sodium retention, hypertension, and hyperkalemia. Responsive to thiazides.
α-Adducin polymorphism	Structural protein that activates Na K-ATPase	Increased Na pump activity modestly increases sodium reabsorption to produce mild hypertension.
Hypertension exacerbated in pregnancy	Mutation in mineralocorticoid receptor that makes receptor more sensitive to aldosterone	Early-onset hypertension greatly exaggerated by pregnancy because progesterone also binds to the mutant receptor and promotes additional sodium reabsorption. The aldosterone receptor antagonist, spironolactone, acts as an agonist for the mutant receptor; effect of eplerenone has not been examined.
SGK	Two activating mutations	SGK inhibits ENaC degradation so activation causes accumulation of ENaC and an increase in renal sodium reabsorption with consequent hypertension. Possibly responsive to Midamor (amiloride HCl).
Various single nucleotide polymorphisms in the genes for renin, ACE, and angiotensin II receptor	Presumably slightly altered function of the genes controlling angiotensin production and sensitivity	Statistically significant increases in blood pressure. Some single nucleotide polymorphisms are more prevalent. in African Americans, others more prevalent in European Americans, and a few prevalent in both populations. Responsive to ACE inhibitors (e.g., captopril, and lotensin) and angiotensin II receptor inhibitors (e.g., losartan), and volume reduction with thiazide diuretics.

Table 59-1 ***(Continued)***

Genetic bases for hypotension		
Syndrome	*Defect*	*Characteristics*
Pseudohypoaldosteronism type I (dominant)	Loss of function mutation of the mineralocorticoid receptor	Salt wasting, hypotension, severe neonatal symptoms.
Pseudohypoaldosteronism type I (recessive)	Partial loss of function mutation of the α-subunit of ENaC	Salt wasting, hypotension, hyperkalemia, excess fluid secretion from airways, loss of salt taste, serious symptoms at all ages.
Aldosterone synthase	Loss of function leading to decreased circulating aldosterone	Decreased sodium reabsorption with severe hypotension and occasionally shock because of reduced intravascular volume.
Steroid 21-hydroxylase	Loss of function leading to decreased synthesis of aldosterone	Decreased sodium reabsorption with severe hypotension and other endocrine abnormalities.
Gitelman's syndrome	Loss of function of distal nephron thiazide-sensitive NaCl transporter	Salt wasting and mild hypotension in homozygotes.

ACTH, adrenocorticotropin hormone.

and indicate that each subunit has a large extracellular loop present between the two membrane spanning regions. The α-, β-, and γ-ENaC have cysteine rich regions within putative extracellular loops that are postulated to form intersubunit disulfide bonds necessary for oligomerization of Na channels. The three ENaCs also possess proline-rich regions within their intracellular C-terminal domains that are important for interactions between the subunits and accessory proteins that regulate the stability of functional channels in the apical membrane of kidney cells.

CELLULAR REGULATION OF ENaC

Sodium transport across the Na^+ reabsorbing, tight epithelia such as the distal nephron or colon is the major factor determining total body Na^+ content and thus, long-term blood pressure regulation. Sodium reabsorption in the distal nephron is a two step process (Fig. 59-2). First, sodium enters renal cells from the tubular lumen through ENaCs that are positioned in the apical membrane. Sodium is then actively transported out of the cell by Na K-ATPase on the basolateral membrane.

ENaC ACTIVITY IS IMPORTANT FOR CONTROLLING BLOOD SODIUM LEVELS AND MEAN BLOOD PRESSURE ENaC is usually the rate-limiting step for Na^+ transport; and so represents the primary point for control of total body sodium balance and mean blood pressure. In fact, abnormalities in ENaC function can lead to disorders of total body Na^+ homeostasis, blood volume, blood pressure, and lung clearance (e.g., Liddle's syndrome and Pseudohypoaldosteronism Type I). An increase in ENaC activity or gain of function such as found in Liddle's syndrome leads to excessive salt reabsorption by the renal distal tubule, body fluid retention, and increased blood pressure. It has been suggested that in some African Americans with salt-sensitive hypertension, excessive sodium reabsorption is associated with ENaC hyperactivity. The clinical profile of these subjects includes low circulating levels of renin and angiotensin II and is consistent with this hypothesis. Also consistent is the observation that patients respond to treatment with diuretics like amiloride or triamterene whereas ACE inhibitors are ineffective. The control of ENaC activity, therefore, is important for understanding the pathophysiology of these disorders and hypertension in general.

REGULATION OF NA CHANNELS BY SMALL G PROTEINS The small G proteins are single subunit proteins ranging in size from approx 20–30 kDa. There are several major categories of small G proteins that can participate in many aspects of cellular function including cell growth and differentiation. The first small G proteins described were the Ras proteins: there are three major categories of Ras proteins, H-, N-, and K-Ras proteins. All Ras proteins are post-translationally modified by the attachment of lipophilic groups (usually isoprenyl residues) to the C-terminal end plus subsequent methyl esterification of the C-terminus; these modifications are necessary for the biological function of the protein. After they are conjugated to methyl and isoprenyl groups, Ras proteins can be activated by GTP. Interestingly, methylation of isolated patches of membrane causes an increase in the activity of ENaC. This methylation-induced activation of ENaC is augmented simply by raising the cytosolic content of GTP. Thus, methylation of apical membranes excised as cell-free patches leads to an increase in ENaC activity. The response to methylation is augmented by GTP indicating that the small G protein regulates ENaC activity.

Evidence shows that one specific Ras protein, K-Ras2A, is a target for methylation in kidney cells and that Ras methylation is induced by aldosterone. K-Ras does contain the consensus amino acid sequence for methylation, a CAAX box (a methylated cysteine residue followed by two aliphatic residues, followed by any residue at the C-terminal end of a protein). The process requires both GTP and methylation before K-Ras activity rises. Inhibition of K-Ras2A expression in kidney cells reduces ENaC activity whereas augmenting K-Ras expression increases ENaC activity. These results indicate that the mechanism by which K-Ras is activated and identification of the signaling molecules that are activated by K-Ras are important steps in the understanding ENaC activity regulation.

Activation and Regulation of K-Ras To be active, K-Ras must be methylated and changes in the rate of K-Ras methylation control the amount of membrane-associated K-Ras. Only the methylated, membrane-associated form binds GTP to increase its activity further. Thus, changes in the activity of the enzyme that methylates K-Ras, isoprenyl-cysteine-*O*-carboxy-methyl-transferase, alter K-Ras-induced ENaC activity. One way of regulating active, membrane-associated methyl transferases is to control the cytosolic

concentrations of the end product of methylation, S-adenosyl-homocysteine (SAH). SAH is produced when the endogenous methyl donor, S-adenosyl-methionine, transfers its methyl group to a target protein. SAH is a potent inhibitor of all methyl transferases. The primary determinant of the SAH concentration in cells is generally not the rate of SAH production by methyl transferases, but rather, the rate of their degradation by another enzyme, S-adenosyl-L-homocysteine hydrolase or SAH hydrolase. For this reason, the extent of protein methylation can be controlled by changing the activity of SAH hydrolase rather than altering the intrinsic activity of the methyl transferase. Increased activity of the methyl transferase (measured as a rise in V_{max}) does occur when there is protein kinase C-mediated phosphorylation of the methyl transferase. In response to aldosterone, there is an increase in the activity of SAH hydrolase ensuring that the activity of the methyl transferase is not inhibited by the accumulation of its enzymatic product, SAH. How the SAH hydrolase is activated in response to aldosterone is unclear, though additional transcription and translation are not necessary.

The Mechanism for K-Ras Activation of ENaC Although K-Ras2A is necessary for ENaC activation, the mechanism by which K-Ras activates ENaC is not clear. The simplest mechanism would be a direct interaction of ENaC with K-Ras. It is likely, however, that other signaling elements lie between Ras and ENaC (any such element would have to be closely associated with ENaC in cell-free patches because it is possible to activate ENaC via Ras methylation in such patches). The traditional effector for Ras is Raf kinase and notably, Raf activation could activate the mitogen-activated protein kinase pathway, which in turn can activate other genes. Activation of the mitogen-activated protein kinase pathway, however, actually inhibits ENaC activity so K-Ras activation of Raf kinase does not appear to be responsible for K-Ras-mediated activation of ENaC. Another pathway leading to direct activation of ENaC is K-Ras2A-mediated activation of inositol lipid kinases that produce phosphatidylinositol bisphosphate (PIP_2) and phosphatidylinositol trisphosphate (PIP_3). For example, Ras proteins are known to activate several lipid kinases including phosphatidylinositol (PI)-3-kinase and PIP-5-kinase. Application of PIP_2 or PIP_3 to the cytosolic surface of excised cell patches strongly activates ENaC via an increase in the probability of an open channel.

Regulation of Na Channels by Inositol Lipids PIP_2 and PIP_3 are ubiquitous components of eukaryotic membrane phospholipids. The traditional view of phosphoinositide metabolism suggests that PI is sequentially phosphorylated by PI-4-kinase and PI-5-kinase to produce PI-4,5-bisphosphate or PIP_2. Once formed, PIP_2 can be phosphorylated to produce PI-3,4,5-triphosphate or PIP_3 via PI-3-kinase or it can be hydrolyzed by phospholipase C to produce 1,4,5-inositol trisphosphate (IP_3) and diacylglycerol. It was previously assumed that the sole purpose of PIP_2 production was to act as a precursor for IP_3 whhereas the remaining diacylglycerol would activate protein kinase C. It is clear that PIP_2 is a signaling molecule by itself and can directly activate other effector and signaling proteins. In particular, PIP_2 can bind to ion channels and modify their activity. The best-studied interactions in this case are between PIP_2 and K channels. PIP_2 binds the C-terminal domains of these K channels to increase channel activity; PIP_2 is absolutely required for the gating of these K^+ channels. The binding of the anionic PIP_2 to K^+ channels appears to involve, but is not limited to, electrostatic interactions. PIP_2 also modulates the activity of ENaC through similar interactions with hydrophobic and positively charged residues in the cytosolic tails of the β- and γ-subunits.

PHOSPHOINOSITIDE METABOLISM IS IMPORTANT FOR ENaC ACTIVITY 4,5-PIP_2 is just one of the inositol phospholipids that are produced by different inositol lipid kinases. PI-3-kinase is present in kidney cells. Inhibition of this enzyme with a specific PI-3-kinase inhibitor, LY-294002, blocks the basal rate and insulin-stimulated rate of Na^+ transport. The products of PI-3-kinase include PI-3-P (PIP), PI-3,4-P (PIP_2), and PI-3,4,5-P (PIP_3). These observations imply that phosphoinositides are involved in regulation of ENaC activity.

THE MOLECULAR BASIS FOR ENaC REGULATION BY ALDOSTERONE The mineralocorticoid, aldosterone, is the primary hormonal regulator of total body sodium balance. Increases in the circulating levels of the steroid specifically increase Na^+ reabsorption at the apical membrane by a two-phase reaction: an initial phase that increases transport four- to sixfold in the first 2–6 h followed by a late phase at 12–48 h, which increases transport another three to fourfold. The mechanisms for the early and late phases appear to be different. Aldosterone, like other steroid hormones, enters target cells (in the case of the kidney, the major targets are the principal cells of the collecting duct) and binds to cytosolic, mineralocorticoid receptor complexes. In mammalian principal cells, mineralocorticoid receptors are not activated by circulating glucocorticoids, because the enzyme, 11-β-hydroxysteroid dehydrogenase, changes the glucocorticoid structure to a form that does not bind aldosterone receptors. The enzyme does not change the aldosterone structure. After binding aldosterone, there is a conformational change in the aldosterone receptor. In its new conformation, it acts as a DNA binding protein and interacts with mineralocorticoid response elements. Binding to the mineralocorticoid response elements leads to changes in gene expression. For example, an increase in Na^+ transport can be measured within 1 h of exposure to aldosterone, by a mechanism that depends on gene transcription and translation. The induced gene products are referred to as aldosterone-induced proteins. Aldosterone and increased intracellular sodium also promote expression of the sodium pump during long-term exposure.

Many attempts have been made to identify the aldosterone-induced proteins. The relationship between the genes identified and the mechanism by which aldosterone increases Na^+ transport is often unclear. Originally, it was hypothesized that aldosterone induces ENaC synthesis and insertion into the cell membrane. Although the evidence from electrophysiological measurements remains somewhat controversial, the available biochemical evidence suggests that the number of sodium channel proteins in the apical membrane does not change after aldosterone treatment (at least in the first 2–4 h when the increase in sodium transport is most dramatic). The evidence suggests instead that the early effects of aldosterone are indirect and that the proteins that are synthesized are modulatory proteins that convert poorly transporting ENaC in the apical membrane into channels that readily transport sodium.

The three homologous ENaC subunit proteins form a heteromultimeric channel protein apparently made up of two α-, one β-, and one γ-subunit (although there is some disagreement about the exact stoichiometry). The most obvious link between aldosterone and increased ENaC activity would be a post-translational modification of the channels leading to an increase in the probability that the channels are open and hence, transporting sodium. A second hypothesis is that most or all of the ENaC channel subunits are present but dispersed in the apical membrane and aldosterone promotes the assembly of a channel complex, which transports sodium.

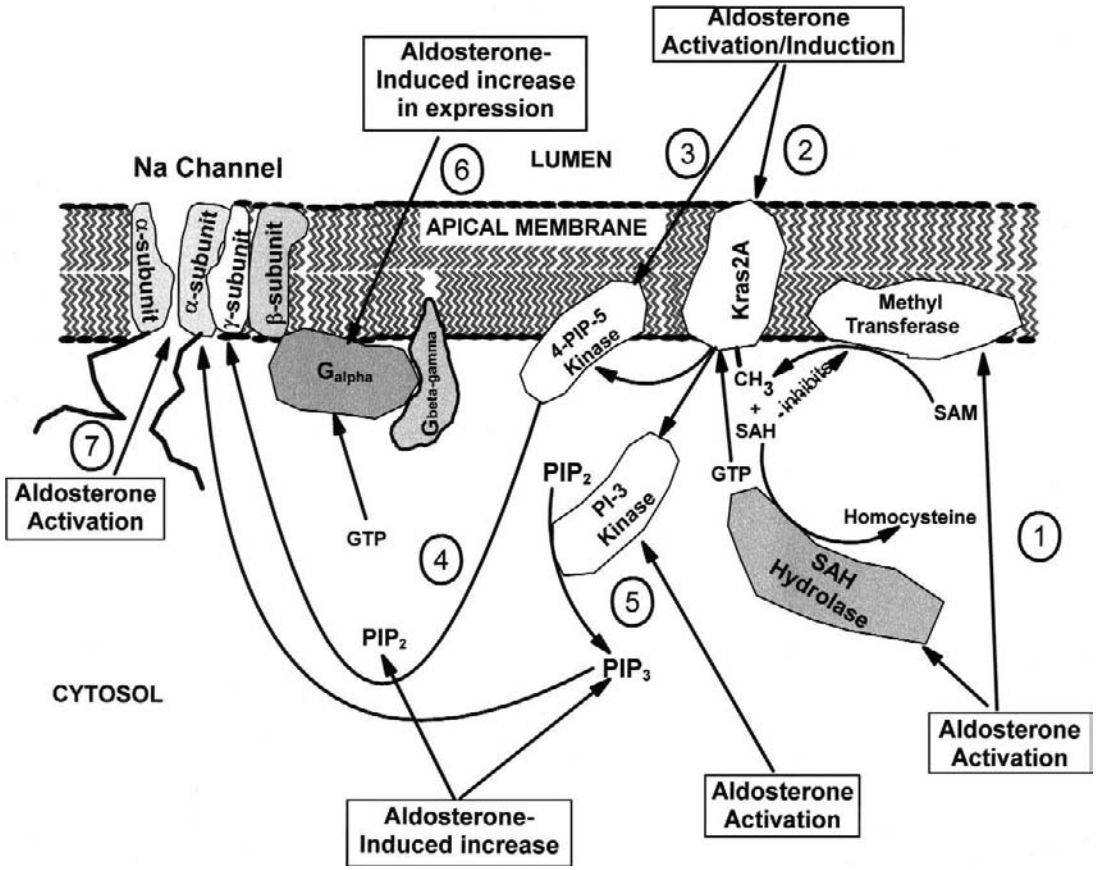

Figure 59-3 Schematic diagram of the short-term action of aldosterone. Aldosterone produces an increase in K-Ras2A protein **(A)**, but K-ras protein is inactive unless post-translationally modified by prenylation and methylation. The rate of methylation is usually a rate limiting step in K-Ras activation; therefore, aldosterone activation of the isoprenylcysteine-*O*-methyl transferase is critical for complete activation of K-Ras **(B)**. In contrast to K-Ras, however, aldosterone does not increase expression of methyl transferase. Rather, aldosterone activates protein kinase C and protein kinase C phosphorylates and activates methyl transferase. At the same time, aldosterone increases the activity of SAH hydrolase. This is critical for normal methyl transferase because one end product of the methylation reaction is SAH, which is a potent inhibitor of methyl transferases. Methylation can only proceed if SAH is hydrolyzed to homocysteine. Once K-Ras is methylated, the protein associates with the membrane and can be activated by a guanine nucleotide exchange factor: K-Ras is activated by aldosterone-induced increases in the Ras guanine nucleotide exchange factor, Sos. K-Ras activation leads to the activation of the inositol lipid kinase, 4-PIP-5-Kinase **(C)** that produces PIP_2, which directly activates ENaC **(D)**. PIP_2 is also metabolized by a second aldosterone-induced kinase, PI-3-Kinase **(E)** to produce PIP_3. PIP_3 can also directly activate ENaC, but also initiates the late phase of the aldosterone response **(F)**. Other events initiated by aldosterone involve heterotrimeric G proteins that are necessary for ENaC activation by a poorly understood mechanism **(G)**.

The mechanism for the long-term effect of aldosterone that increases sodium transport is also unclear. There is evidence that the total cellular amount of ENaC subunits may increase but whether this is owing to an increase in translation is unknown because changes in ENaC mRNA levels vary in different tissues. The long-term rise in ENaC activity could be due to an increase in translation, an increase in trafficking of subunits to the membrane, post-translational modifications of channels in the membrane, or less degradation of membrane channels.

THE MOLECULAR MECHANISM FOR THE SHORT-TERM EFFECTS OF ALDOSTERONE ON SODIUM TRANSPORT One possibility for the activation of sodium channels with little or no change in the number of channels is a post-translational modification that changes the open probability of channels already present in the surface membrane. The problem is that most of the usual post-translational modifications like phosphorylation seem to have no effect on channel activity or even decrease its activity. Other types of post-translational modifications, however, do appear in response to aldosterone and can alter sodium channel open probability (Fig. 59-3).

Aldosterone-Induced Methylation Activates ENaC The amount of sodium transport that can be measured in apical membrane vesicles obtained from kidney cells is markedly enhanced by prior application of agents that methylate membrane proteins. Application of aldosterone stimulates the methylation of membrane proteins whereas inhibition of methylation eliminates the effects of aldosterone. The isoprenyl-cysteine-*O*-carboxy-methyl-transferase responsible for K-Ras2A methylation is not an aldosterone-induced protein, but the intrinsic activity of the enzyme does increase in response to aldosterone (apparently via protein kinase C phosphorylation). In addition, the activity of the other enzyme intimately involved in protein methylation, SAH hydrolase, is increased by aldosterone. Taken together, it is clear that aldosterone-induced methylation modulates ENaC activity.

Some investigators have suggested that the target for methylation is an ENaC subunit, but the primary amino acid sequence of the subunits makes it difficult to accept this view. Almost exclusively, reversible methylation of signaling proteins occurs only at a restrictive consensus sequence: the so-called “CAAX” box. Even if there

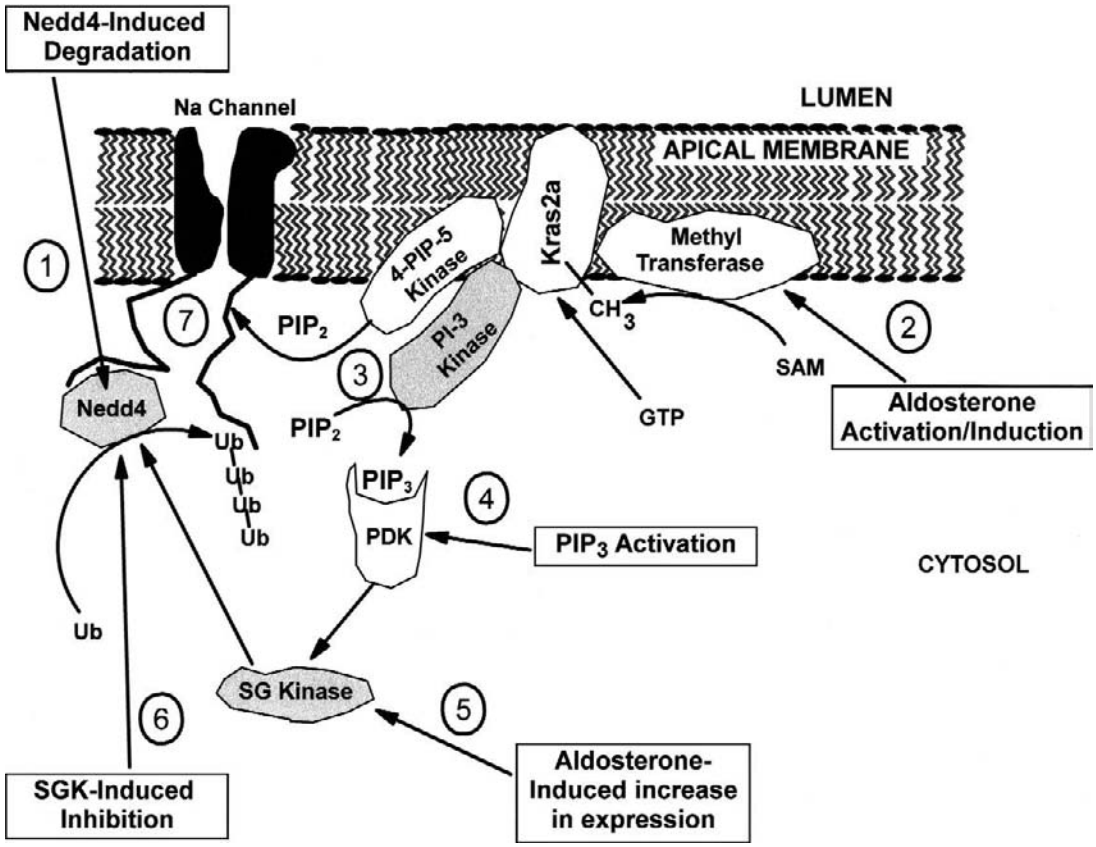

Figure 59-4 Schematic diagram of the long-term action of aldosterone. In the absence of aldosterone, there is little PIP_2 in the membrane so ENaC is inactive. In addition, Nedd4 ubiquitinates ENaC and promotes rapid internalization and degradation **(A)**. In the presence of aldosterone, all the initial short-term events depicted in Fig. 59-3 occur, starting at **(B)** and leading to an increase in PIP_2 and immediate activation of preexisting ENaC. The late aldosterone responses are initiated when PI-3-kinase is activated by K-Ras to metabolize PIP_2 to PIP_3 **(C)**. PIP_3 activates PDK1/2 **(D)**, which phosphorylates SGK, which has already been strongly induced by aldosterone **(E)**. SGK phosphorylates Nedd4 **(F)**. Phosphorylation of Nedd4 reduces its affinity for ENaC subunits and, thereby, reduces ENaC subunit ubiquitin conjugation. In the absence of ubiquitin conjugation, ENaC subunits are not internalized and degraded and accumulate in the surface membrane **(G)** in which they contribute to the aldosterone-induced increases in sodium transport.

were significant C-terminal proteolytic trimming of ENaC, there are no cysteine residues that would meet the criteria for methylation. There must be another target for aldosterone methylation.

K-Ras2A: An Aldosterone-Induced Protein and Target for Aldosterone-Mediated Methylation Proteins differentially expressed by aldosterone include one isoform of K-Ras, K-Ras2A. Methylation of K-Ras is required for its activation and Ras methylation is induced by aldosterone. K-Ras is methylated by an isoprenylcysteine methyl transferase. This enzyme requires the presence of an isoprenyl group conjugated to the cysteine of the CAAX box. Therefore, it is not surprising that inhibition of prenylation blocks the action of aldosterone.

K-Ras2A and Aldosterone Activate PI Lipid Kinases One of the genes induced by aldosterone and by K-Ras2A is PIP-5-kinase. An increase in PIP-5-kinase also leads to an increase in membrane PIP_2. Besides the 5-kinase, PI-3-kinase is activated by aldosterone whereas inhibition of PI-3-K activity blocks aldosterone-induced increases in Na^+ transport. Thus, the aldosterone-induced short-term increase in ENaC activity is due to an increase in anionic lipids that can directly activate existing ENaC channels.

THE MECHANISM FOR THE LONG-TERM EFFECTS OF ALDOSTERONE IN A6 CELLS The observation that PI-3-kinase is required for aldosterone activation at times longer than 4 h suggests an alternative mechanism is active following the initial PIP_2-mediated increase in open probability of ENaC. The product of PI-3-kinase, PIP_3, activates proteins that have PIP_3-binding domains (also known as pleckstrin homology or PH domains). Notable among these proteins are the PI-dependent kinases, PDK1/2. Because aldosterone increases PIP_3, aldosterone activates PDK1/2. Activation of PDK1/2 is interesting because one of the kinase's phosphorylation targets is another kinase, serum and glucocorticoid-dependent kinase (SGK). SGK is coded by an aldosterone-induced gene and the long-term effects of aldosterone require activation of SGK by a phosphorylation reaction. The kinase activity of SGK targets a variety of proteins including the ubiquitin ligase, neural-precursor-cell-expressed-developmentally downregulated protein (Nedd4). Nedd4 is intimately related to degradation of ENaC proteins in the surface membrane.

A Specific Ubiquitin Ligase, Nedd4, is Responsible for Ubiquitin Conjugation and Subsequent Degradation of ENaC in the Membrane For many proteins including ENaC, ubiquitin conjugation is a prerequisite for membrane internalization and subsequent degradation. In kidney cells, membrane-associated ENaC α- and β-subunits are ubiquitin conjugated (whether the γ-subunit is also conjugated to ubiquitin has not been determined) and the conjugates can be degraded by proteasomes. Ubiquitin-conjugation of ENaC subunits requires a specific ubiquitin ligase, Nedd4. Nedd4 was found to have the same localization pattern as

ENaC in principal cells present in the cortex and outer medulla of the collecting duct. Nedd4 apparently directly associates with ENaC to produce ubiquitin conjugation. Nedd4 can regulate the number of functional ENaC in the surface membrane because blocking Nedd4 synthesis with anti-sense oligonucleotides led to an increase in the trans-epithelial current. These results imply that Nedd4 is the ubiquitin ligase responsible for ENaC ubiquitination in native renal cells.

ENaC Degradation in Renal Epithelial Cells In kidney cells, proteasome inhibition increases the total amount of all ENaC subunits. The half-lives of the β- and γ-subunits in the total cellular pool is relatively short (1–3 h) but rises severalfold when proteasome activity is inhibited. Proteasome inhibition also increases amiloride-sensitive trans-epithelial current measured in kidney cells. This response is associated with an increase in the apical density of sodium channels as measured by patch clamp methods. There also is an increase in the number of ENaC subunits in the cell surface and an increase in the ubiquitin conjugation of ENaC proteins present in the surface membrane. The half-lives of membrane-associated (i.e., biotinylated β- and γ-ENaC) subunit increase markedly when proteasome activity is inhibited. The change is from 3.7 h for β-subunit or 7.5 h for γ-subunit to greater than 24 h. Because the half-life of α-subunits at the surface of native cells is at least 42 h, it is not clear if proteasome inhibition will also increase the half-life of α-subunits.

Aldosterone Regulation of ENaC Degradation Rate in Renal Cells Aldosterone increases the number of ENaC subunits on the apical surface of cultured kidney cells even in the absence of any significant change in mRNA levels for any of the subunits. This implies that aldosterone can alter ENaC degradation. Because aldosterone increases the amount and activity of SGK, and because SGK can phosphorylate Nedd4, aldosterone could impair degradation of ENaC by the proteasome because a phosphorylated Nedd4 would have a lower affinity for binding to ENaC subunits. Figure 59-4 provides a schematic view of a possible mechanism for the long-term action of aldosterone.

CONCLUSION

Aldosterone, the hormone primarily responsible for altering epithelial Na transport, apparently uses at least two mechanisms to regulate ENaC activity. The initial rapid response to aldosterone involves the production of PIP_2 (and PIP_3). These effectors rapidly increase the activity of ENaCs that are already in the surface membrane. Aldosterone also increases the number of functional channels in the surface membrane, at least in part, by reducing the degradation rate of ENaC and allowing an increase in the surface membrane pool of functional ENaC.

60 Nephrogenic Diabetes Insipidus

Water and Urea Transport

JEFF M. SANDS AND DANIEL G. BICHET

SUMMARY

Nephrogenic diabetes insipidus (NDI) is a rare disorder in which the kidney is unresponsive to the water-retaining action of vasopressin (antidiuretic hormone). Congenital NDI results from a genetic mutation in the V_2-receptor, AQP2, or other transport proteins, such as the UT-B urea transporter, involved in generating a hypertonic renal medulla. Acquired NDI most commonly results from lithium therapy, but can also result from prolonged hypercalcemia, protein malnutrition, hypokalemia, and following the release of unilateral or bilateral ureteral obstruction. The current therapeutic options for congenital NDI are limited and only partially beneficial in reducing the excessive urine output.

Key Words: Adenylyl cyclase; antidiuretic hormone; aquaporins (water channels); countercurrent exchange; countercurrent multiplication; diabetes insipidus; kidney medulla; lithium therapy; renal collecting duct; urea transporters; urine concentrating mechanism; vasopressin receptor.

INTRODUCTION

Patients with diabetes insipidus (DI) produce large quantities of dilute urine. DI can be "central," owing to failure of the posterior pituitary to make or secrete vasopressin (arginine vasopressin [AVP], also called antidiuretic hormone), or "nephrogenic," from failure of the kidney to respond to vasopressin. Nephrogenic DI (NDI) has many causes that fall into two general categories, failure of the collecting duct to respond to vasopressin and reabsorb water, and failure of the medulla to generate an osmotic gradient.

Water is reabsorbed by principal cells in the collecting duct (Fig. 60-1). Vasopressin binds to V_2-receptors (V_2R) in the basolateral membrane of principal cells. The V_2R is a seven transmembrane-spanning, G protein-coupled receptor. Activation of this receptor results in the generation of the second messenger cyclic adenosine 5´-monophosphate (AMP), activation of protein kinase A, and stimulation of the insertion of aquaporin-2 (AQP2) water channels into the apical membrane. AQP2 exists as homotetramers in the apical membrane, and at least one of the four AQP2 molecules needs to be phosphorylated at serine-256 for proper trafficking and regulation of water reabsorption. Water molecules enter the principal cell via AQP2 and exit via the related water channels AQP3 and AQP4 in the basolateral membrane. When the vasopressin stimulus is removed, AQP2 is removed from the apical membrane by endocytosis. These AQP2 molecules are recycled into new endosomes and wait for the next stimulus by vasopressin. Any abnormality in any of the steps involved in collecting duct water reabsorption results in NDI.

In addition to needing sufficient vasopressin and a normally functioning collecting duct, the medulla must generate an osmotic gradient for water reabsorption to occur (Fig. 60-2). In the outer medulla, NaCl is actively reabsorbed in the thick ascending limb of the loop of Henle by the Na^+-K^+-$2Cl^-$ cotransporter NKCC2/BSC1. Active NaCl reabsorption is critical for establishing a hypertonic medullary interstitium. Inhibiting this process with a loop diuretic results in isosmotic urine. In the inner medulla, NaCl is passively reabsorbed in the thin ascending limb, driven by the chemical gradients for urea and NaCl. The passive mechanism hypothesis requires that the concentration of urea in the inner medullary interstitium exceed that found in the lumen of the thin ascending limb. The urea concentration gradient permits the NaCl concentration in the interstitium to be lower than in the lumen of the thin ascending limb, thereby establishing a gradient for passive NaCl reabsorption in the absence of an osmotic gradient. Any abnormality in any of the steps involved in generating a hypertonic medulla results in NDI.

CONGENITAL NDI

About 90% of patients with congenital NDI are males with X-linked recessive inheritance (MIM 304800) who have mutations in the arginine vasopressin 2 receptor (*AVPR2*) gene that codes for the V_2R. The gene is located in chromosome region Xq28. In less than 10% of the families that have been studied, congenital NDI has an autosomal-recessive or autosomal-dominant mode of inheritance (MIM 222000 and 125800). In many of these families, mutations have been identified in the AQP2 gene, which is located in chromosome region 12q13 and codes for the vasopressin-sensitive AQP2 water channel. The clinical characteristics of NDI include hypernatremia, hyperthermia, mental retardation, and repeated episodes of dehydration in early infancy. Mental retardation, a probable consequence of repeated episodes of dehydration, was prevalent in 70–90% of the patients reported in the original studies.

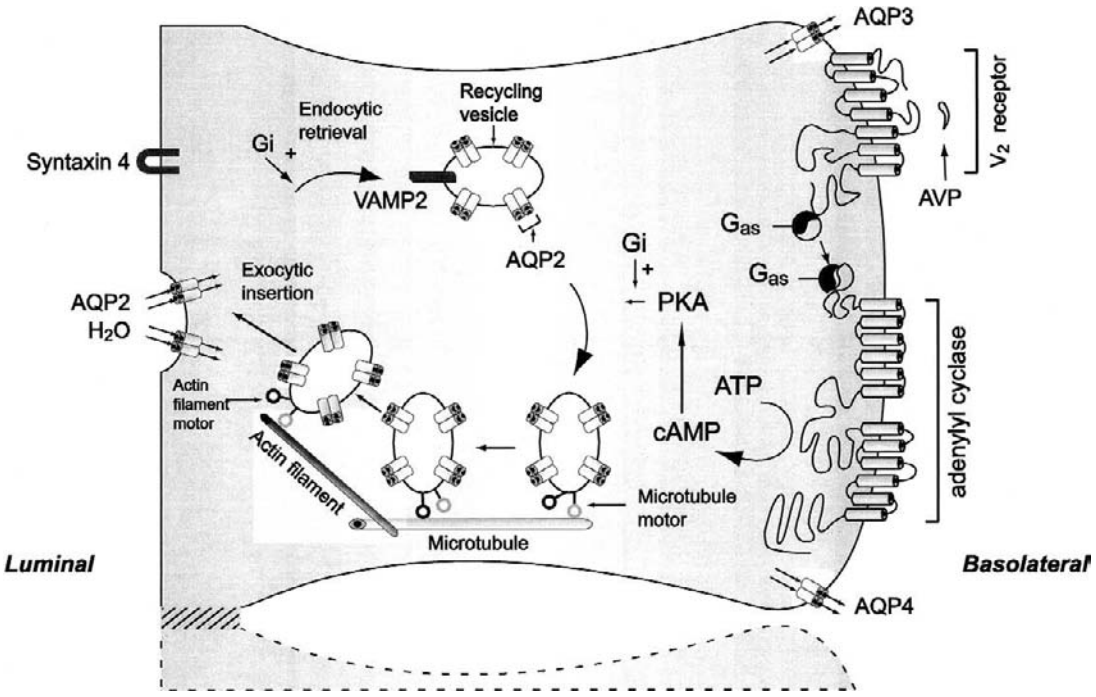

Figure 60-1 Schematic representation of the effect of vasopressin (AVP) to increase water permeability in the principal cells of the collecting duct. Note that Na^+ reabsorption, through the epithelial Na channel is not represented. Vasopressin is bound to the V_2-receptor (a G protein-linked receptor) on the basolateral membrane. The basic process of G protein-coupled receptor signaling consists of 3 steps: a hepta-helical receptor that detects a ligand (in this case, AVP) in the extracellular milieu, a G protein that dissociates into α-subunits bound to GTP and βδ-subunits after interaction with the ligand-bound receptor, and an effector (in this case, adenylyl cyclase) that interacts with dissociated G protein subunits to generate small-molecule second messengers. AVP activates adenylyl cyclase increasing the intracellular concentration of cyclic AMP (cAMP). The topology of adenylyl cyclase is characterized by two tandem repeats of six hydrophobic transmembrane domains separated by a large cytoplasmic loop and terminates in a large intracellular tail. Generation of cAMP follows receptor-linked activation of the heteromeric G protein (G_s) and interaction of the free G_s-chain with the adenylyl cyclase catalyst. Protein kinase A is the target of the generated cAMP. Cytoplasmic vesicles carrying the water channel proteins (represented as homotetrameric complexes) are fused to the luminal membrane in response to vasopressin, thereby increasing the water permeability of this membrane. Microtubules and actin filaments are necessary for vesicle movement toward the membrane. The mechanisms underlying docking and fusion of AQP2 bearing vesicles are not known. The detection of the small GTP-binding protein Rab3a, synaptobrevin 2, and syntaxin 4 in principal cells suggests that these proteins are involved in AQP2 trafficking. When vasopressin is not available, water channels are retrieved by an endocytic process, and water permeability returns to its original low rate. AQP3 and AQP4 water channels are expressed on the basolateral membrane.

However, data suggest that mental retardation is less prevalent and may have been overestimated in NDI patients. Early recognition and the subsequent treatment of congenital NDI with an abundant intake of water allows a normal lifespan with normal physical and mental development.

Two characteristics suggestive of X-linked NDI are the familial occurrence and the confinement of mental retardation to male patients. It is then tempting to assume that the family described by McIlraith and discussed by Reeves and Andreoli was affected by congenital NDI. Lacombe and Weil described an autosomal-dominant type of transmission without any associated mental retardation. The descendants of the family originally described by Weil were later found to have autosomal-dominant central (neurogenic) DI, a well-characterized entity secondary to mutations in the *prepro-vasopressin-neurophysin II* gene, MIM 192340. Patients with autosomal-dominant central (neurogenic) DI retain some limited capacity to secrete vasopressin during severe dehydration and the polyuric–polydipsic symptoms usually appear after the first year of life when the ability of the infants to seek water is more likely to be understood by adults. Other inherited disorders with mild, moderate, or severe inabilility to concentrate urine include Bartter's syndrome (MIM 601678) and cystinosis (MIM 219800).

NDI OWING TO V_2-RECEPTOR MUTATIONS

The majority (approx 90%) of patients with congenital NDI have the X-linked form; affected male patients do not concentrate their urine after the administration of vasopressin. Because recessive X-linked disease is rare, females are unlikely to be affected, but heterozygous females exhibit variable degrees of polyuria and polydipsia because of skewed X-chromosome inactivation. In Quebec, the incidence of this disease was estimated to be approx 8.8 per million male live births for the 10-yr period 1988–1997. A founder effect for a particular *AVPR2* mutation in Irish families of Scottish descent resulted in an increased prevalence of X-linked NDI in their descendants who emigrated to North America in 1761 on the Ship Hopewell. The incidence in Nova Scotia and New Brunswick has been estimated at 58 per million male live births for the 10-yr period 1988–1997. The W71X mutation was identified as the cause of NDI in the extended "Hopewell" kindred and in families in the Canadian Maritime provinces. The W71X mutations of these patients are probably identical by descent,

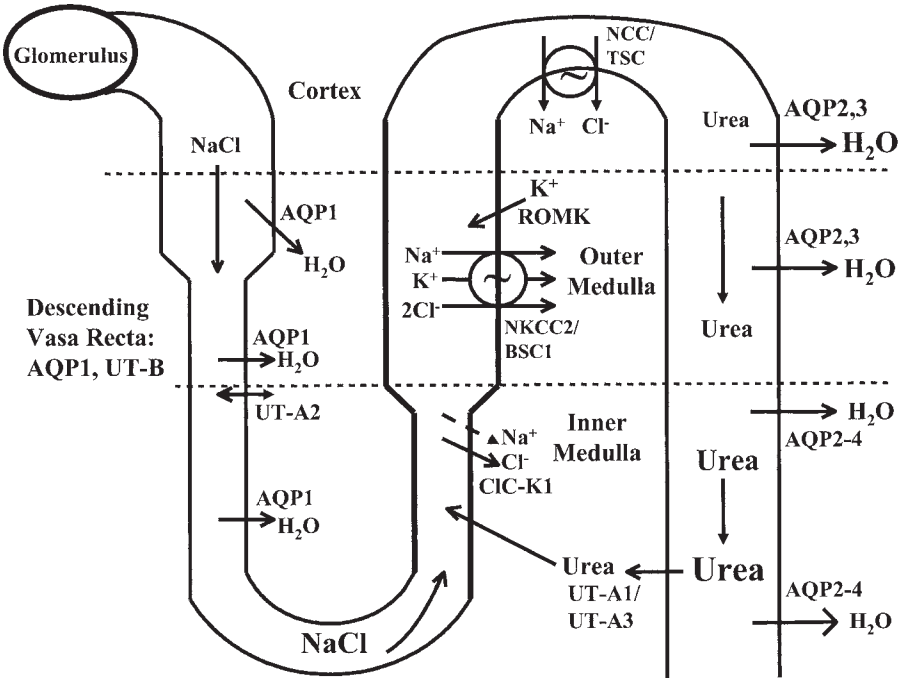

Figure 60-2 Diagram showing the location of the major transport proteins involved in the urine concentrating mechanism in the outer and inner medulla. UT, urea transporter; AQP, aquaporin; NKCC/BSC, Na^+-K^+-$2Cl^-$ cotransporter; ROMK, renal outer medullary K channel; ClC-K1, chloride channel; NCC/TSC, Na-Cl cotransporter.

although a common ancestor has not been identified in all cases. Among patients with X-linked NDI in North America, the W71X mutation is more common than any other *AVPR2* mutation.

To date, 183 putative disease-causing *AVPR2* mutations have been identified in 284 NDI families (Fig. 60-3; additional information is available from the NDI Mutation Database: http://www.medicine.mcgill.ca/nephros/). Half of the mutations are missense mutations: frameshift mutations owing to nucleotide deletions or insertions (25%); nonsense mutations (10%); large deletions (10%); inframe deletions or insertions (4%); splice-site mutations; and one complex mutation account for the remainder. Mutations have been identified in every domain of the AVPR2 receptor, but on a per nucleotide basis, about twice as many mutations occur in transmembrane domains compared with the extracellular or intracellular domains. Private mutations, recurrent mutations, and mechanisms of mutagenesis have been previously identified. The 10 recurrent mutations (D85N, V88M, R113W, Y128S, R137H, S167L, R181C, R202C, A294P, and S315R) were found in 35 ancestrally independent families. The occurrence of the same mutation on a different haplotype was considered evidence of recurrent mutation. In addition, the most frequent mutations — D85N, V88N, R113W, R137H, S167L, R181C, and R202C — occurred at potential mutational hot spots (a G-to-T or G-to-A nucleotide substitution occurred at a CpG dinucleotide).

When studied in vitro, most *AVPR2* mutations lead to receptors that are trapped intracellularly and unable to reach the plasma membrane. A few mutant receptors reach the cell surface but are unable to bind vasopressin or to properly trigger an intracellular cyclic AMP signal. *AVPR2* mutations are thus inducing a defect in intracellular protein transport, an increasingly recognized anomaly of hereditary disease-causing mutations. Of clinical interest, nonpeptide V_2R antagonists were found to facilitate the folding of mutant AVPR2 receptors and to increase urine osmolality in patients bearing the 62-64, R137H, and W164S mutations.

NDI OWING TO AQP2 WATER CHANNEL MUTATIONS

On the basis of dDAVP (desmopressin) infusion studies and phenotypic characteristics of males and females affected with NDI, a non-X-linked form of NDI with a postreceptor (postcyclic AMP) defect was suggested. A patient who presented shortly after birth with typical features of NDI but who exhibited normal coagulation and normal fibrinolytic and vasodilatory responses to dDAVP was shown to be a compound heterozygote for two missense mutations (R187C and S217P) in the AQP2 gene (Fig. 60-4). To date, 32 putative disease-causing *AQP2* mutations have been identified in 40 NDI families. By type of mutation, there are 69% missense, 19% frameshift owing to small nucleotide deletions or insertions, 6% nonsense, and 6% splice-site mutations (additional information is available in the NDI Mutation Database at http://www.medicine.mcgill.ca/nephros/.)

Reminiscent of expression studies done with AVPR2 proteins, misrouting of AQP2 mutant proteins has been shown to be the major cause underlying autosomal-recessive NDI. In contrast to the AQP2 mutations in autosomal-recessive NDI, which are located throughout the gene, the dominant mutations are predicted to affect the carboxyl terminus of AQP2. The autosomal-dominant family described by Ohzeki et al. was found to be heterozygous for the 721G mutation. The dominant AQP2-E258K mutation was retained in the Golgi apparatus, which differs from AQP2 mutants in recessive NDI that are retained in the endoplasmic reticulum. The dominant action of the AQP2-E258K mutation can be explained by the formation of heterotetramers of mutant and wild-type AQP2 that are impaired in their routing after oligomerization. Hetero-oligomerization of AQP2-727G with wild-type

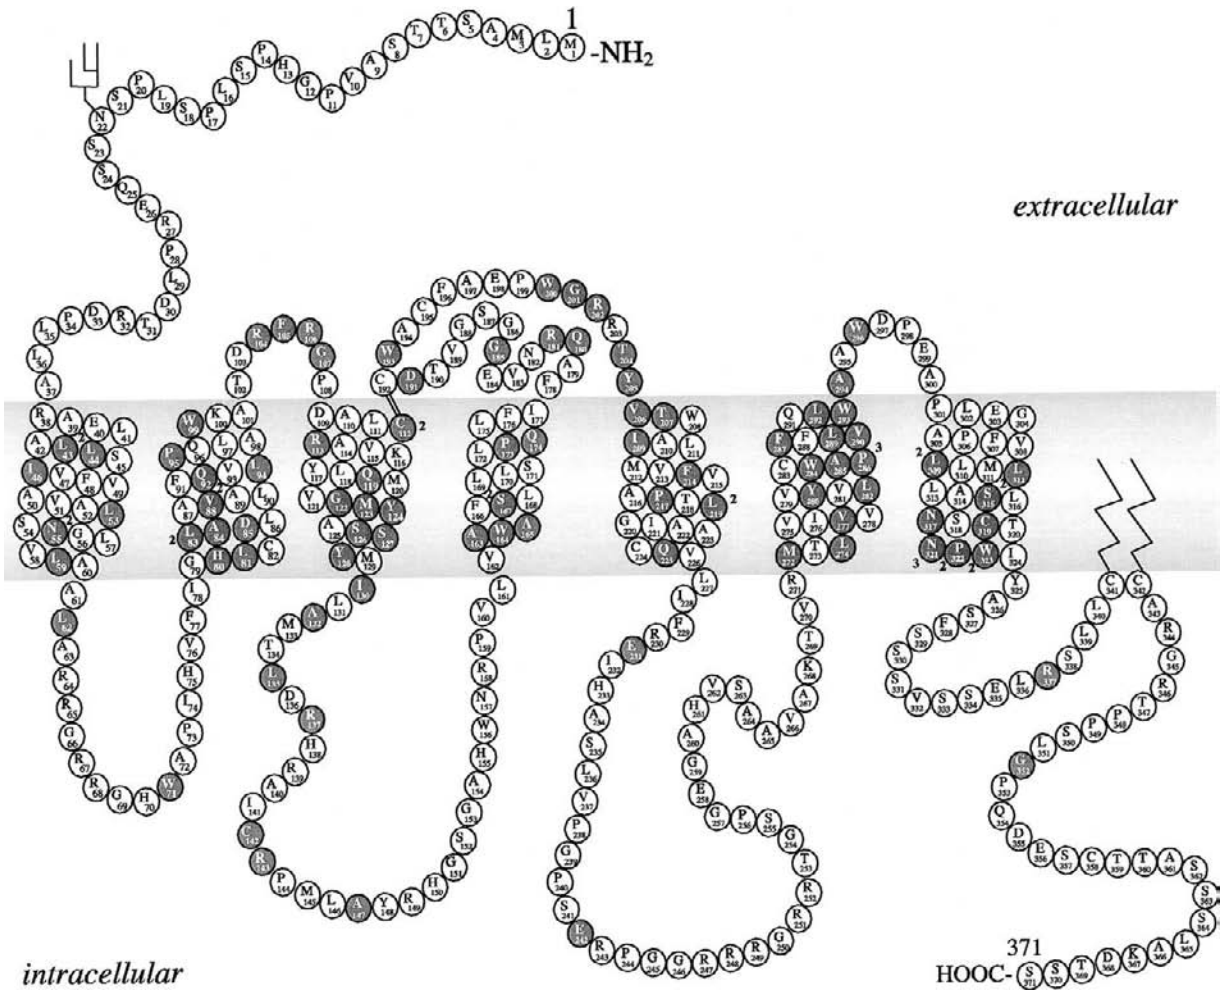

Figure 60-3 Schematic representation of the V_2-receptor and identification of 183 putative disease-causing *AVPR2* mutations. Predicted amino acids are given as the one-letter code. Solid symbols indicate missense or nonsense mutations, a number indicates more than one mutation in the same codon. The names of the mutations and extracellular, transmembrane, and cytoplasmic domains were defined according to recommended nomenclature. The common names of the mutations are listed by type. Eighty-nine missense, 18 nonsense mutations, 45 frameshift, 7 inframe deletions or insertions, four splice-site, as well as 19 large deletions, and one complex mutation have been identified. AQP2 and the consequent mistargeting of this complex to late endosomes/lysosomes results in the absence of AQP2 in the apical membrane, which can explain the dominant phenotype.

ROLE OF AQP2 IN ACQUIRED NDI

The acquired form of NDI is much more common, especially in adult medicine, than the congenital form of NDI, but it is rarely severe. The ability to elaborate hypertonic urine is usually preserved, in spite of the impairment of the maximal concentrating ability of the nephrons. Polyuria and polydipsia are therefore moderate (3–4 L/d). Lithium administration has become the most frequent cause of acquired NDI. A review reported this abnormality in at least 54% of 1105 unselected patients on chronic lithium therapy. Nineteen percent of these patients had polyuria, as defined by a 24-h urine output exceeding 3 L. Lithium inhibits adenylyl cyclase in a number of cell types including renal epithelia. The concentration of lithium in the urine of patients on well-controlled lithium therapy (i.e., 10–40 mmol/L) is sufficient to exert this effect. Measurements of adenylyl cyclase activity in membranes isolated from a cultured pig kidney cell line revealed that lithium in the concentration range of 10 mmol/L interfered with the hormone-stimulated guanyl nucleotide regulatory unit (G_s). The effect of chronic lithium therapy on the expression of AQP2 has been studied in rat kidney membranes prepared from the inner medulla. Lithium caused a marked downregulation that was only partially reversed by cessation of therapy, thirsting, or dDAVP treatment, consistent with clinical observations of slow recovery from lithium-induced urinary concentrating defects. Hypokalemia, hypercalciuria, low-protein diets, and the release of bilateral ureteral obstruction have also been shown to downregulate AQP2 protein expression in rat kidney medulla. In patients on long-term lithium therapy, amiloride has been proposed to prevent the uptake of lithium into the collecting ducts, thus preventing the inhibitory effect of intracellular lithium on water transport.

NDI OWING TO UT-B UREA TRANSPORTER MUTATIONS

Urea is a small but highly polar molecule that undergoes extensive hydrogen-bonding in aqueous solution. Despite the perception that urea is freely permeable across all cell membranes, its

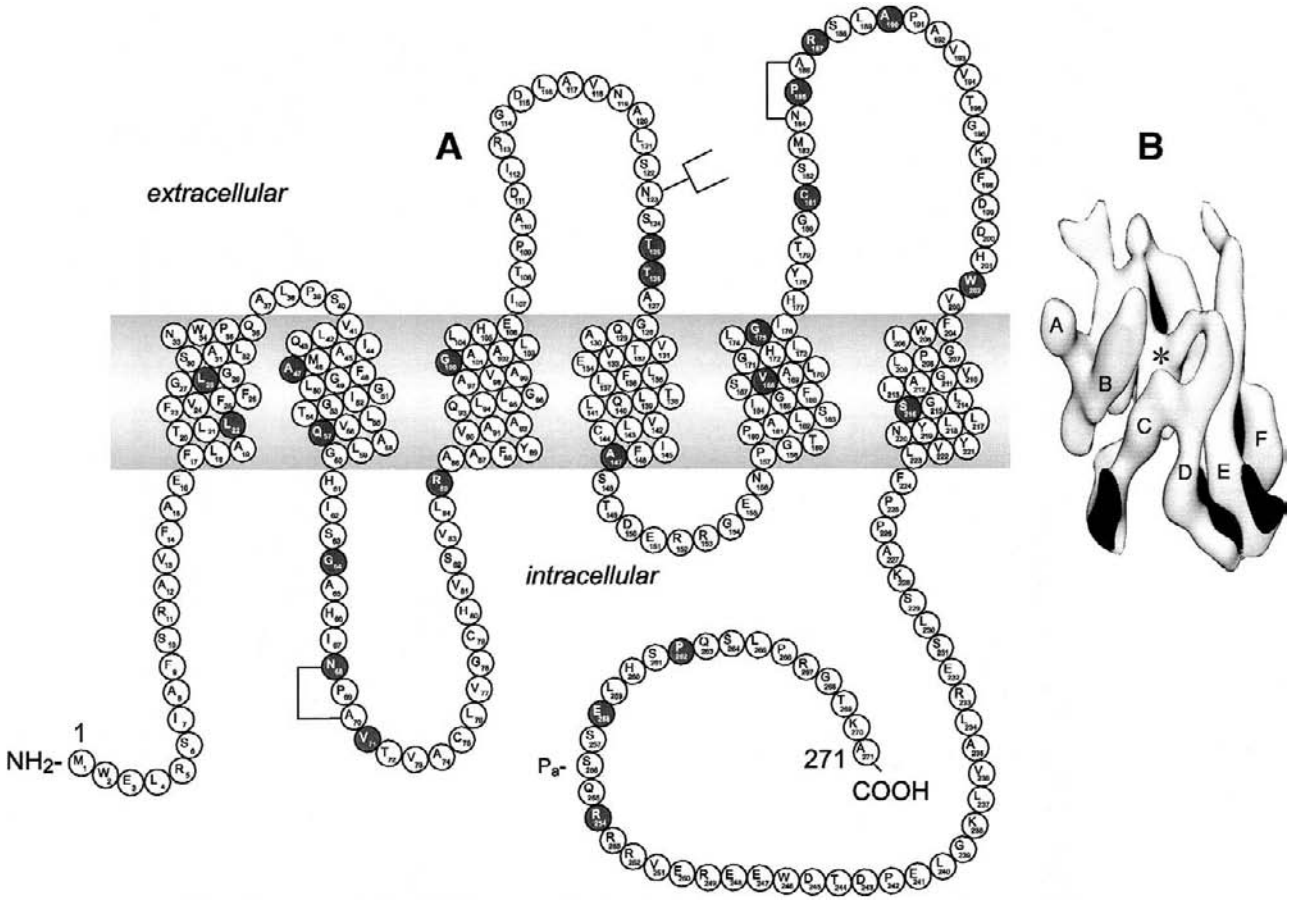

Figure 60-4 **(A)** Schematic representation of the aquaporin-2 (AQP2) protein and identification of 32 putative disease causing *AQP2* mutations. A monomer is represented with six transmembrane helices. The location of the protein kinase A phosphorylation site (Pa) is indicated. The extracellular, transmembrane, and cytoplasmic domains are defined according to Deen et al. (1994). Solid symbols indicate the location of the mutations. The common names of the mutations are listed by type. Twenty-five missense, two nonsense, six frameshift, as well as two splice-site mutation have been identified. **(B)** Schematic representation of the 3D structure of AQP2 by analogy to the X-ray crystallographic structure of AQP1. The asterisk indicates the position in which the molecular pseudo-twofold symmetry is strongest. (Reproduced with permission from Fujiwara TM, Bichet DG. Molecular biology of hereditary diabetes insipidus. J Am Soc Nephrol 2005;16:2836–2846.)

permeability across artificial lipid bilayers is low, as would be expected for a polar molecule. However, urea's permeability is not zero, and given sufficient time, it diffuses across cell membranes and achieves equilibrium in the steady state. In the kidney, red blood cells (RBCs) traverse the vasa recta, and tubule fluid traverses the collecting duct much too rapidly to permit urea concentrations to achieve equilibrium solely by passive diffusion. Rapid urea transport and the high urea permeability of RBC and terminal inner medullary collecting duct cell membranes were the initial evidence suggesting the presence of specific urea transporter proteins. The existence of urea transport proteins has been confirmed by the cloning of two urea transporter genes and several cDNA isoforms. In addition to RBCs and kidney, urea transporters are expressed in liver, testis, heart, and brain, and in some of these tissues, their abundance is altered in uremic rats.

UT-B is the RBC-facilitated urea transporter and was cloned from a human erythropoietic cell line. The UT-B gene (*SLC14A1*) gene is located on chromosome 18q12. It is about 30-kb long, contains 11 exons, and the coding region begins in exon four and extends through exon 11. Interestingly, the UT-B protein is also the Kidd (or Jk) antigen. The Kidd antigen is a minor blood group antigen, and several mutations involving exons six and seven of the UT-B/Kidd antigen (*SCL14A1*) gene have been reported. People lacking Kidd antigen have a form of congenital NDI as they are unable to concentrate their urine greater than 800 mOsm/kg H_2O, even following overnight water deprivation and exogenous vasopressin administration. These people lack UT-B-mediated urea transport in their RBCs and presumably also lack it in their descending vasa recta. Although no biopsy data are available to prove this assumption in humans, a UT-B knock-out mouse does lack urea transporter in both its RBCs and descending vasa rectae, and has impaired urea recycling and urine concentrating ability. Individuals lacking UT-B have congenital NDI because UT-B is necessary for efficient countercurrent exchange between the ascending and descending vasa recta, and any decrease in countercurrent exchange reduces urine concentrating ability.

ACQUIRED NDI OWING TO UT-A UREA TRANSPORTER DOWNREGULATION

The UT-A gene *SLC14A2* is located on chromosome 18, adjacent to the gene for UT-B. It is about 68 kb in length and contains 20 exons. The human gene is organized in a manner that is similar to the rat and mouse genes (*Slc14a2*) and is an atypical gene because it has two promoter elements, promoter I, which is

upstream of exon 1 and drives transcription of isoforms UT-A1, UT-A3, UT-A4, UT-A5, and UT-A6. and promoter II, which is located within intron 12 and drives transcription of isoform UT-A2. To date, no mutations in any of the UT-A isoforms have been reported in people. However, single nucleotide polymorphisms in UT-A2 are associated with variation in blood pressure in men, but not in women.

UT-A1 is the best studied and largest UT-A protein and is expressed in the apical membrane of the inner medullary collecting duct. UT-A1 is stimulated by cyclic AMP when expressed in *Xenopus* oocytes. UT-A3 is also expressed in the inner medullary collecting duct and stimulated by cAMP. A UT-A1/UT-A3 double knock-out mouse has a severe impairment in urine concentrating ability. Despite its name, UT-A2 was the first cloned urea transporter cDNA. UT-A2 is expressed in thin descending limbs and is not stimulated by cyclic AMP analogs. A UT-A2 knock-out mouse has a mild impairment in urine concentrating ability.

Lithium causes a marked reduction in AQP2 protein abundance. Lithium also causes a marked reduction in UT-A1 and UT-B protein abundances and interferes with vasopressin's ability to phosphorylate UT-A1. In inner medullary collecting ducts from normal rats, vasopressin rapidly increases UT-A1 phosphorylation and urea transport. However, in inner medullary collecting ducts from lithium-fed rats, vasopressin does not increase UT-A1 phosphorylation. Thus, lithium causes NDI by decreasing the abundance of several critical transport proteins involved in the urine concentrating mechanism, AQP2, UT-A1, and UT-B. The reduction in AQP2 decreases water reabsorption across the collecting duct apical membrane in response to vasopressin, thereby reducing transepithelial water reabsorption. The reduction in UT-A1 and phosphorylated UT-A1 decreases urea reabsorption across the inner medullary collecting duct in response to vasopressin, thereby reducing inner medullary interstitial urea accumulation, which reduces urine concentrating ability. The reduction in UT-B decreases urea recycling and the efficiency of countercurrent exchange, which reduces urine concentrating ability. Unfortunately, if lithium-induced NDI is not diagnosed quickly and lithium therapy stopped, the acquired NDI often becomes irreversible.

61 Glomerulonephritis and Smad Signaling

HUI Y. LAN AND RICHARD J. JOHNSON

SUMMARY

Transforming growth factor-β and its signaling pathway, Smads, is the major mechanism mediating fibrosis. However, the involvement of other signaling pathways and the interplay among these pathways in fibrosis remain largely unclear. In this chapter, we focus on the current understanding of the molecular basis of transforming growth factor-β signaling and its crosstalk pathways in renal fibrosis, which may be also applicable to a wide arrange of other disease conditions involving fibrosis. In addition, results from current studies also suggest that Smad signaling may be a final common pathway of fibrosis and targeting the Smad pathway may provide a new therapeutic strategy for tissue and/or organ fibrosis.

Key Words: Diabetes; fibrosis; gene therapy; hypertension; kidney disease; TGF-β; signaling pathways; Smads.

INTRODUCTION

Fibrosis is the final common pathway leading to end-stage disease in a variety of tissues and organs including heart, liver, lung, skin, and kidney, regardless of the initial causes of damage. The common pathological feature of fibrosis is the accumulation of extracellular matrix (ECM) in tissues. ECM is made from collagen types I, III, and IV, fibronectin, and laminin and this response is mediated by multiple factors, involving several signaling pathways. Reports have identified transforming growth factor (TGF)-β and its signaling pathway, Smads, as one of the major mechanisms mediating fibrosis. The involvement of other signaling pathways and the interplay among different pathways to produce fibrosis remain largely unclear. This chapter focuses on the understanding of the molecular basis of TGF-β signaling and its crosstalk pathways in producing fibrosis in the kidney. These pathways may also be applicable to a wide range of other conditions including pulmonary fibrosis, hepatic fibrosis and cirrhosis, and cardiovascular sclerosis.

TGF-β AND RENAL FIBROSIS

TGF-β, a multifunctional cytokine with fibrogenic properties, has long been considered a key mediator in the pathogenesis of renal fibrosis. Increased TGF-β expression is a feature of many human and experimental renal diseases, including diabetic and hypertensive nephropathy. TGF-β stimulates ECM deposition by increasing the synthesis of ECM proteins and acting to inhibit their degradation. In addition, TGF-β mediates renal fibrosis through the transformation of tubular epithelial cells to ECM-producing myofibroblasts. The important role of TGF-β in producing renal fibrosis is demonstrated by the finding that fibrosis can be induced by the overexpression of TGF-β_1 within the normal rat kidney. This fibrosis can be prevented or ameliorated by blocking TGF-β activity with a neutralizing TGF-β antibody, decorin, or by antisense strategies. In a number of experimental kidney disease models TGF-β plays a central role in renal fibrosis.

TGF-β SIGNALING

The discovery that Smad proteins are the intracellular mediators and regulators of TGF-β signaling has provided important insights into the specific mechanisms by which TGF-β mediates the fibrogenic response. As shown in Fig. 61-1, TGF-β exerts its biological effects by signaling through the type-I and -II serine/threonine kinase receptors, TβRI and TβRII. TGF-β binds to receptor II, which then recruits and phosphorylates TβRI. The activated TβRI directly initiates signals to downstream intracellular substrates, receptor-regulated Smads (R-Smads) including Smad2 and -3. Activated R-Smads interact with the common partner, Smad4 (Co-Smad), to form a heteroligomer and these complexes are translocated into the nucleus to regulate target gene expression and initiate the fibrogenic process. Activation of the TGF-β signaling pathway can also lead to the expression of inhibitory Smads (I-Smads) including Smad6 and -7. In mammals, Smad2 and -3 are TGF-β/activin-specific R-Smads, whereas Smad1/5/8 are the bone morphogenetic protein (BMP)-specific R-Smads. Smad4 is the only one that functions as a Co-Smad. Smad6 (preferential inhibitor of the signaling processes initiated by BMP) and Smad7 (a potent inhibitor of signaling initiated by TGF-β or BMP) both act as inhibitory factors (I-Smads) and function as antagonists of R-Smads and Co-Smad signaling. It has been shown that Smad7 can act by specifically inhibiting Smad2 and -3 phosphorylation. The inhibition results from blocking their access to TβRI or by causing degradation of TβRI. Thus, overexpression of Smad7 may be a strategy that will terminate TGF-β signaling, thereby blocking TGF-β-mediated fibrosis.

The structure of the Smad family is highly conserved. Smad2 and -3 are the two R-Smads that are activated by TβRI. They are structurally very similar, with 91% of their amino acid sequences identical. Both contain an N-terminal "mad homology 1" domain,

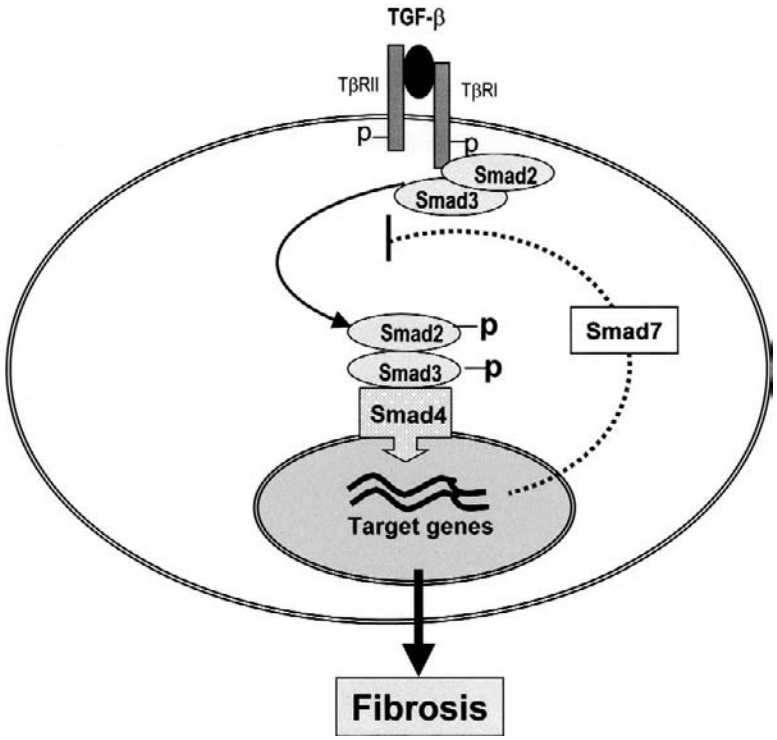

Figure 61-1 TGF-β signaling and fibrosis. Binding of TGF-β to receptor II causes phosphorylation of TβRI that results in phosphorylation of receptor-associated Smads (R-Smads), Smad2 and -3. Activated R-Smads form heteroligomers with the common partner Smad4 to translocate into the nucleus and regulate target gene expression including ECM genes and inhibitory Smad6 and -7. These I-Smads inhibit Smad2 and -3 phosphorylation by blocking their access to TβRI or by causing degradation of TβRI, thereby blocking TGF-β-mediated fibrosis.

which has DNA-binding activity, and a C-terminal mad homology 2 (MH2) domain that is responsible for translocation of the Smad complex into the nucleus in which it regulates transcription of target genes. TβRI-mediated phosphorylation of the C-terminal sequence of R-Smads, SSXS, leads to Smad2 and -3 activation. Smad4 lacks the SSXS sequence and therefore cannot be phosphorylated by the TβRI. The interaction between R-Smads (Smad2/3) and Co-Smad (Smad4) is primarily mediated by the mad homology 2 domain. Once within the nucleus, the Smads can function as transcriptional transactivators or coactivators, and may also directly bind to DNA, resulting in activation of the target genes that are the next step in producing fibrosis.

TGF-β SIGNALING IN RENAL FIBROSIS

It is clear that TGF-β mediates tissue fibrosis through Smad signaling pathway. Many ECM genes contain activator protein-1 binding sites in their regulatory regions; their induction by TGF-β has been shown to be Smad3 dependent.This conclusion is further supported by the finding that mice that are null for Smad3 are protected against radiation-induced fibrosis on the skin. In the context of fibrosis in the kidney, both Smad2 and -3 are strongly activated in human diabetic kidney (Fig. 61-2) or in the rat following obstruction of the kidney (Fig. 61-3). Activation of Smad2 and -3 within the kidney, therefore, can contribute to the development of glomerulosclerosis, tubulointerstitial fibrosis, and vascular sclerosis (Figs. 61-2 and 61-3), indicating that this TGF-β signaling system is a critical pathway leading to tissue fibrosis. In vitro, it has been shown that TGF-β-induced collagen matrix production by mesangial cells and tubular epithelial cells is mediated by Smad2 and -3. In addition, glucose-mediated collagen matrix production by mesangial cells, tubular epithelial cells, endothelial cells, or vascular smooth muscle cells is also dependent on the activation of Smad2 and -3. Activation of Smads is required for TGF-β-induced, tubular epithelial cell–myofibroblast transition, an important process for tubulointerstitial fibrosis. The functional role of Smad2 and -3 in initiating fibrosis is delineated by results demonstrating that blockade of Smad2/3 activation by overexpression of Smad7 results in abrogation of bleomycin-induced lung fibrosis in mice and in fibrosis following obstructive kidney disease in rats. All of these reports provide strong evidence supporting a critical role for TGF-β/Smad signaling in the development of tissue scarring.

The precise role of individual Smads and the interplay among them in initiating the fibrotic process remains largely unknown. Although both Smad2 and -3 are structurally very similar, their modes of actions and the phenotypes of Smad2 and -3 are distinct. Smad3 regulates gene activity directly by binding to DNA, whereas Smad2 activates transcription by binding to other transcription factors that, in turn, can bind DNA and modulate gene activity. The distinct activities of Smad2 and -3 are highlighted by the finding that $Smad2^{-/-}$ mice are embryonic lethal, whereas $Smad3^{-/-}$ mice are viable but have impaired immunity. Similarly, different genes are regulated by different Smads or combinations of Smads in vitro. For example, in mouse embryo fibroblasts, the induction of matrix metalloproteinase-2 by TGF-β is selectively dependent on Smad2, whereas the induction of c-*fos* is dependent on Smad3, and both Smad2 and -3 are required for inducing the plasminogen activator inhibitor-1. Interestingly, the absence of Smad3 has no effect on TGF-β-induced inhibition of mammary epithelial cell proliferation, but without Smad3 there is decreased cell apoptosis but no compensatory changes in the expression or

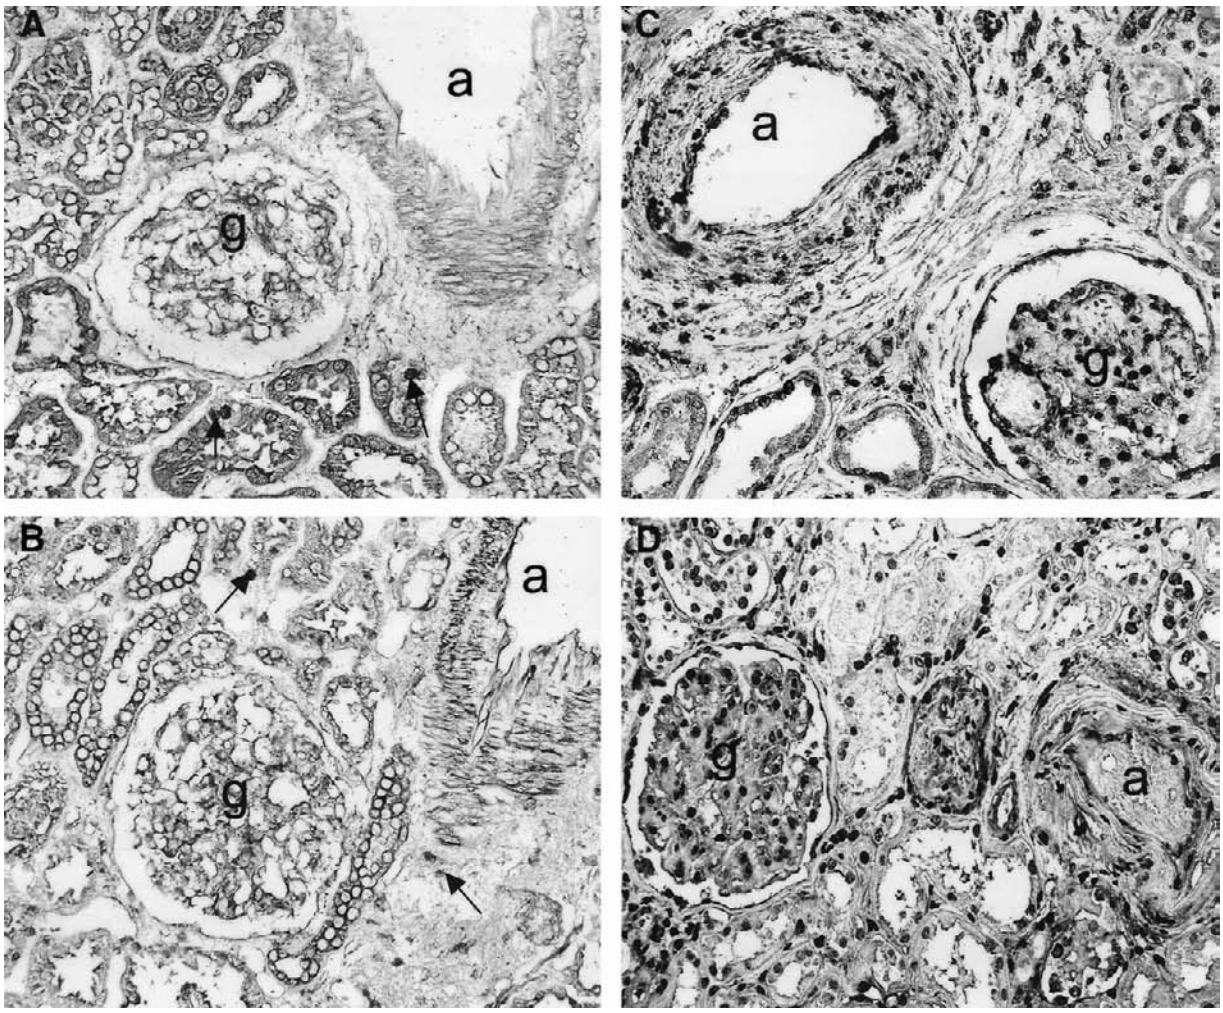

Figure 61-2 Smad2 and -3 activation in diabetic and hypertensive nephropathy. In the normal human kidney, activated Smad2 **(A)** and -3 **(B)** cells (black nuclear location) are rare (arrows). In contrast, in diabetic **(C)** and hypertensive **(D)** nephropathy, activation (black nuclear location) of Smad2 **(C)** and -3 **(D)** are prominent, contributing to glomerulosclerosis, tubulointerstitial fibrosis, and vascular sclerosis. (g, glomerulus; a, artery)

activation of Smad2. These findings suggest that epithelial cell Smad3 is not required for the influence of TGF-β on proliferation, but Smad3 contributes in a nonredundant manner to the induction of apoptosis. Interestingly, TGF-β-induced vascular endothelial growth factor expression by renal tubular epithelial cells depends on Smad3, but not Smad2, whereas TGF-β-induced thrombospondin-1 expression is stimulated by Smad2, but not Smad3. Although both Smad2 and -3 are required for TGF-β-induced tubular mesenchymal transition, Smad2 regulates a loss of an epithelial gene E-cadherin, but Smad3 contributes to *de novo* expression of a mesenchymal gene, α-SMA. Thus, Smad2 and -3 seem to work in a nonredundant manner, but both may be required in certain pathophysiological processes.

TGF-β-INDEPENDENT SMAD SIGNALING IN RENAL AND VASCULAR FIBROSIS

Smad2 and -3 can also be activated by a non-TGF-β-dependent pathway. Advanced glycation end products (AGEs), the molecules that are key mediators of diabetic complications, can also activate Smads directly and independently of TGF-β. For example, AGEs can induce a rapid activation of Smad2 and -3 in tubular epithelial cells, mesangial cells, or vascular smooth muscle cells; activation is evident at 5 min and peaks by 30 min. This rapid activation of Smads occurs in the absence of TGF-β and a neutralizing TGF-β antibody will not block AGE-induced Smad activation. Importantly, the finding that AGEs, but not TGF-β, can activate Smads in both TβRI and TβRII mutant cells supports the presence of a TGF-β-independent Smad signaling pathway as a mediator of renal and vascular complications of diabetes. The mechanism by which AGEs activate Smad directly and independently of TGF-β has been uncovered; AGEs signal through the receptor for AGEs (RAGE) to induce Smad activation rapidly via the extracellular signal-regulated kinase (ERK)/p38 mitogen-activated protein (MAP)-Smad crosstalk pathway. For example, AGE-induced activation of Smad2/3 can be blocked by a neutralizing anti-RAGE antibody or by specific MAP kinase (MAPK) inhibitors of ERK1/2 (PD98059) and p38 (SB203580). AGEs are able to activate Smad2/3 after exposure for 24 h via the TGF-β-dependent mechanism. Thus, AGEs could mediate diabetic complications directly via the MAPK-Smad signaling pathway or indirectly through the classic TGF-β-Smad signaling pathway. Interestingly, substantial inhibition of AGE-induced Smad activation and collagen production by inhibitors of ERK/p38 MAPK or, to a lesser extent, by an anti-TGF-β antibody indicates that the MAPK-Smad

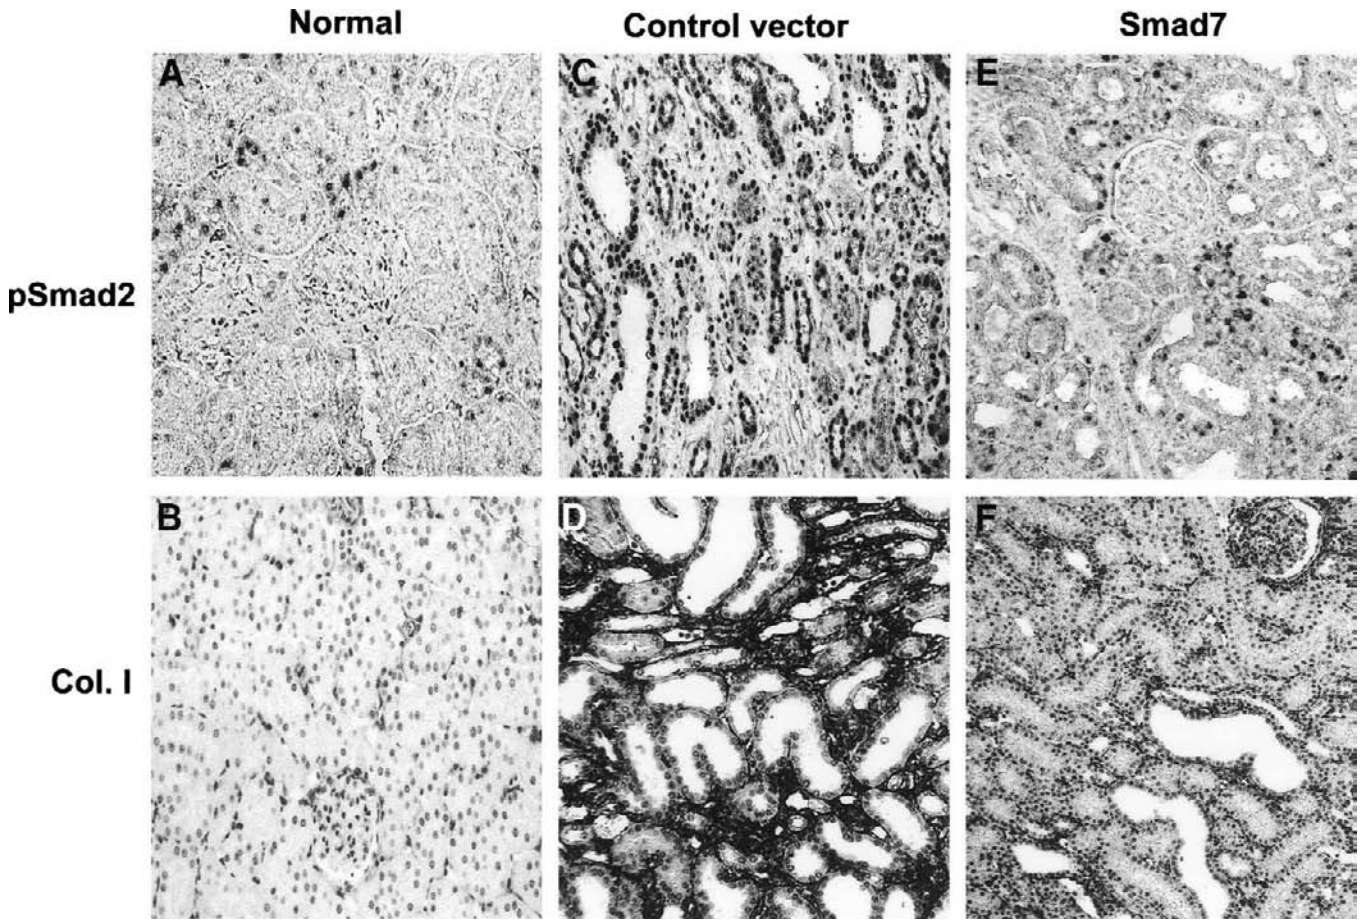

Figure 61-3 Overexpression of Smad7 inhibits Smad2 and -3 activation and renal fibrosis in a rat obstructive nephropathy. The left ureter was ligated and the left kidney was transfected with either Smad7 (treated animals) or empty vectors (control animals) in a mixture of Optison followed immediately by ultrasound as described. Smad7 transgene expression was induced by doxycycline in the drinking water for 7 d. In the normal rat kidney, phosphorylated Smad2 (pSmad2 nuclear location) are rare **(A)** with minor collagen I accumulation in tubulointerstitium **(B)**. In contrast, marked activation of pSmad2 is found in tubulointerstitium **(C)**, contributing to tubulointerstitial fibrosis **(D)**. Significantly, kidney treated with Smad7 substantially prevents Smad2 activation **(E)** and tubulointerstitial fibrosis **(F)**.

signaling crosstalk pathway is a key mechanism involved in the pathogenesis of AGE-mediated diabetic scarring. These findings also indicate that the Smad crosstalk pathway may play a critical role in development of the end-stage organ or in the tissue scarring characteristic of diabetes. Viewed in this fashion, anti-TGF-β therapy may not be sufficient to block diabetic complications.

The importance of MAPK-Smad signaling and crosstalk in initiating fibrosis has been demonstrated by finding a relationship between angiotensin (Ang)-II and Smads in the development of kidney and cardiovascular fibrosis. Preliminary studies demonstrate that, like AGEs, Ang-II-mediated collagen matrix production by both renal and vascular cells is Smad-dependent. Ang-II signals through its type 1 receptor to activate Smad2 and -3 within 5 min by a direct mechanism that is independent of TGF-β but dependent on ERK/p38 and MAPK. Ang-II is also able to activate Smad2 and -3 at 24 h, by a mechanism that is TGF-β dependent. Thus, activation of Smads via MAPK-Smad crosstalk pathways may be critical for developing diabetic- or hypertension-induced kidney and vascular sclerosis as shown in Fig. 61-2. In fact, increased Smad2 and -3 activation has been demonstrated in the scarred tissue that results following myocardial infarction; this activation was attenuated by Ang-II signals through its type-1 receptor antagonists. In an obstructive kidney of rats, Ang-II has been shown to play a role in generating renal fibrosis and blockade of Smad2 and -3 activation by the overexpression of Smad7 substantially inhibits renal fibrosis. Direct evidence for a role of Smads in Ang-II-mediated fibrosis comes from the observation that mice null for Smad3 do not develop Ang-II-induced cardiovascular cell or kidney scarring. Together, these studies constitute strong evidence that there is crosstalk between Ang-II (or AGEs) and TGF-β signaling pathways that result in cardiovascular and renal scarring. These data also demonstrate the importance of a functional interaction between the MAPK and Smad signaling pathways in the process of fibrosis. Smad signaling may be a common pathway for the pathogenesis of tissue scarring, as shown in Fig. 61-4.

Mechanisms whereby Smads act as signal integrators to form the crosstalk pathways among fibrogenic molecules have been suggested from a number of studies. This is a complicated area however, because activation of Smads can be regulated by other signaling pathways, such as the MAPK pathway, the Janus-activated kinase/signal transducer and activator of transcription

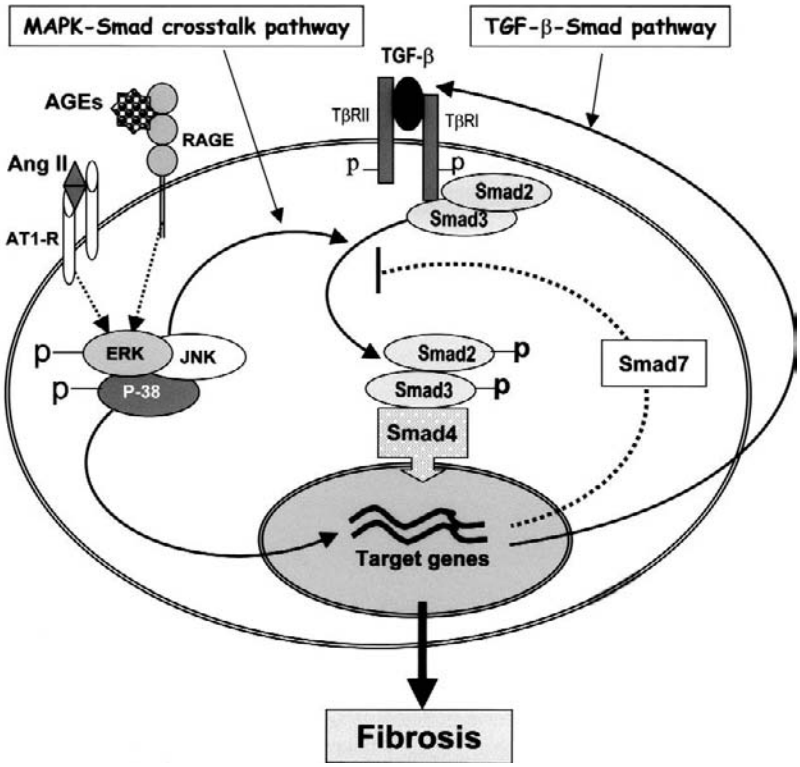

Figure 61-4 Smad signaling as a common pathway of fibrosis. Although TGF-β signals through TβRs to activate Smads to mediate fibrosis, both AGEs and Ang-II signal through their individual receptors to activate Smads via the MAP kinases (MAPK)-Smad signaling crosstalk pathway, in addition to the classic TGF-β-dependent Smad signaling pathway. Overexpression of the inhibitory Smad7 blocks Smad signaling and fibrosis generally.

pathway, and the nuclear factor-κB pathway. Of these pathways, the interaction between MAPK and Smad signaling pathways is the best delineated. It has been shown that signals derived from growth factor receptors with tyrosine kinase activities are capable of modulating Smad-dependent effects. Presently, the mechanism involves activation of a kinase downstream of mitogen-activated protein kinase (MEK)-1, the upstream activator of the ERK/MAPK pathway and results in the phosphorylation of Smad2. Phosphorylation of Smad1, -2, and -3 by Ras-activated ERK1/2 in its linker region will inhibit nuclear translocation of these transcription factors. In contrast, the intracellular kinase, mitogen-activated protein kinase kinase (MEKK)-1, can participate in Smad2-dependent transcriptional events. MEKK-1 is also capable of selectively activating Smad2-dependent transcriptional activity in cultured endothelial cells by a mechanism that is independent of TβRI-mediated responses. These responses do not require the presence of the C-terminal SSXS motif of Smad2, (the site of TβRI-mediated phosphorylation) and are positively regulated by the MEK1-ERK pathway. Activation of Smad2 by MEKK-1 results in enhanced Smad2–Smad4 interactions, nuclear localization of the Smad2–Smad4 complex, and the stimulation of Smad transcriptional coactivator interactions. Notably, overexpression of Smad7 can inhibit the MEKK-1-mediated stimulation of Smad2 transcriptional activity. For example, an inhibitor of the ERK1/2 pathway, U0126, or inhibitors of the p38 MAPK pathway, SB203580 and SKF86002, will block TGF-β-induced, aggrecan gene expression during chondrocyte differentiation. Other evidence for crosstalk between the ERK/MAPK pathway and the Smad pathways is that both pathways are required for TGF-β_1-induced, furin gene transactivation.

A variety of other kinases have been implicated in TGF-β signaling; jun N-terminal kinase (JNK) is rapidly activated by TGF-β in a Smad-independent manner and JNK can phosphorylate Smad3 outside of the SSXS motif. Smad3 phosphorylation by JNK will facilitate, both Smad3 activation by the TGF-β receptor complex, and its nuclear accumulation. In fact, JNK cooperates with the Smad signaling to induce Smad7 transcription via the activator protein-1 element, and hence inhibits ERK activity. These results indicate that inhibitory Smad7 is negatively regulated by ERK, but positively regulated by JNK. Thus, there is an interdependent relationship between the MAPK and Smad pathways in TGF-β-mediated transcription. Overall, signaling by TGF-β-like factors is regulated in both positive and negative pathways, and is tightly controlled temporally and spatially through multiple mechanisms at the extracellular, membrane, cytoplasmic, and nuclear levels. Positive regulation might prove to be critical for amplification of signaling by TGF-β and involve activation of R-Smads 2/3, whereas negative regulation may play an important role in restriction and termination of TGF-β signaling via activation of I-Smad7.

SMADS AS A CENTRAL PATHWAY OF FIBROSIS AND AS A NOVEL THERAPEUTIC TARGET FOR TISSUE SCARRING

As shown in Fig. 61-4, Smad signaling may act as a central pathway that leads to fibrosis regardless of the initial pathogenic

cause. Because Smad7 can act as a negative regulator of Smad signaling, overexpression of Smad7 might inhibit Smad2 and -3 activation to terminate Smad signaling and block Smad-mediated ECM production. In vitro, overexpression of Smad7 will block the fibrogenic effects of TGF-β in tubular epithelial or mesangial cells of the kidney. In vivo, overexpression of Smad7 using a gene transfer technique can inhibit Smad2 and -3 activation in bleomycin-induced TGF-β-dependent lung fibrosis or in a model of obstructive nephropathy in rats. A novel, effective, and inducible gene therapy that specifically blocks TGF-β/Smad signaling and fibrosis in obstructive nephropathy in rats, has been accomplished by transferring a doxycycline-regulated Smad7 using an ultrasound-microbubble-mediated system. This technique substantially increases the transfection rate and transgene expression by up to 1000-fold compared with the naked DNA transfer strategy. Using this technique, investigators transfected a doxycycline-regulated Smad7 gene into the kidney and induced the Smad7 transgene expression to a therapeutic level by controlling the doses of doxycycline in the drinking water. In the rat obstructive nephropathy model (Fig. 61-3), progressive renal fibrosis that is routinely induced by both TGF-β and Ang-II, is blocked by the expression of the doxycycline-induced Smad7 transgene. There also is complete inhibition of Smad2 and -3 activation plus complete inhibition of myofibroblast proliferation and collagen matrix production. In the rat diabetic nephropathy model, renal injury is mediated by multiple factors including AGEs, high glucose, TGF-β and/or Ang II. Overexpression of Smad7, however, results in complete inhibition of Smad2 and -3 activation and collagen matrix accumulation in both glomeruli and tubulointerstitium. Thus, Smad signaling could be a central pathway to organ fibrosis. Targeting Smad signaling could provide a therapeutic strategy to prevent or combat the scarring resulting in an end-stage organ.

Overexpression of Smad7 is also able to inhibit immune and inflammatory responses. Ultrasound-microbubble-mediated, doxycycline-induced Smad7 transgene expression results in substantial inhibition of inflammation in the kidney including suppression of inflammatory cytokines (IL-1, tumor necrosis factor-α), adhesion molecules (intercellular adhesion molecule-1and vascular cell adhesion molecule-1), chemotactic molecule (osteopontin), and macrophage and T-cell accumulation in the obstructed kidney model in rats. These changes are associated with inhibition of nuclear factor (NF)-κB activation and indicate that Smad7 may have a unique role in initiating antifibrosis and antiinflammatory and immunosuppressive effects. Inhibition of Smad2 and -3 by Smad7 may terminate fibrosis, but the ability of Smad7 to inhibit NF-κB activation may be a key mechanism by which Smad7 could act to resolve renal inflammation. It is possible that overexpression of Smad7 leads to an increase in IkBa, the endogenes inhibitor of NF-κB activity; the mechanism for Smad7 effects would involve inhibition of IkBa degradation resulting in inactivation of the survival factor, NF-κB. This response would result in cell apoptosis and suppression of NF-κB-driven inflammation.

It should be noted that extensive and uncontrollable overexpression of Smad7 could cause massive cell death through apoptosis, consistent with reports that Smad7 is an inducer of cell apoptosis. This response may be associated with inhibition of a survival factor NF-κB plus the activation of the JNK pathway. Consequently, it will be critical to control the degree of Smad7 transgene expression in order to maintain a physiological balance among the TGF-β, NF-κB, and JNK signaling crosstalk pathways when using a strategy involving overexpression of Smad7. The degree of Smad7 transgene expression could be controlled by varying the concentrations of doxycycline in vitro or in vivo if the inducible gene is used. Both the in vitro and in vivo results imply that inducible Smad7 gene therapy using the ultrasound-microbubble technique might provide a novel, safe, and effective therapeutic strategy for controlling or preventing both inflammatory and fibrotic diseases.

CONCLUSION

The discovery of TGF-β signaling through Smads has markedly improved the understanding of the molecular mechanisms that lead to tissue scarring. Identifying the activity of individual Smads may lead to improved understanding of the specific role for each Smad in the pathophysiologic process of fibrosis, inflammation, and even cancer. Identification of specific Smad-signaling crosstalk pathways will enable recognition of the molecular mechanisms and the complicated processes in the pathogenesis of diseases. In organ fibrosis, Smad signaling probably represents a common pathway of tissue scarring. In this case, TGF-β binds directly to its receptor, resulting in activation of Smad2 and -3 to induce extracelllular matrix production, whereas AGEs, Ang-II, and other growth factors/molecules could bind to their individual receptors to activate Smads via the MAPK-Smad crosstalk pathway. These responses ultimately lead to tissue injury. In contrast, overexpression of Smad7 can terminate Smad signaling by blocking Smad2 and -3 activation. This response would inhibit the fibrotic effects of TGF-β, high glucose, AGEs, and Ang-II. These findings suggest that fibrosis is regulated positively by Smad2 and -3, but negatively by Smad7. The ability of Smad7 to block experimental models of renal and lung fibrosis indicates that targeting Smad signaling may provide a new therapeutic strategy for tissue and/or organ fibrosis.

62 Interstitial Nephritis

CARLA ZOJA AND GIUSEPPE REMUZZI

SUMMARY

Chronic nephropathies with higly enhanced glomerular permeability to proteins are accompanied by tubulointerstitial inflammation and scarring and time progression to renal function deterioration. Proteins filtered through the glomerular capillary in excessive amount have intrinsic renal toxicity possibly linked to the subsequent process of proximal tubular reabsorption. Protein overloading of proximal tubular cells regulates transcription of nuclear factor-κB-dependent and nuclear factor-κB-independent genes. This forms endothelin-1, chemokines, and cytokines that are secreted into the renal interstitium and incite inflammatory and fibrogenic reaction. Autocrine pathways of activation of tubular epithelial cells contribute to interstitial injury and fibrosis.

Key Words: Chemokines; complement; interstitial inflammation; progressive nephropathy; proteinuria; proximal tubular cells; renal scarring; transforming growth factor-β; tubulointerstitial damage; ultrafiltered plasma proteins.

INTRODUCTION

Progression to end-stage renal failure is the final common pathway of many forms of glomerular disease, independent of the type of initial insult. Progressive glomerulopathies have persistently high levels of urinary protein excretion and tubulointerstitial lesions in common. There is evidence that the severity of tubular interstitial damage more strongly correlates with the risk of renal failure in comparison with the severity of glomerular lesions. Among the cellular mechanisms that may determine progression of kidney damage, regardless of etiology, excess proteins filtered from the glomerulus because of altered glomerular permeability, may initiate interstitial inflammatory reactions by stimulating the tubular synthesis of exaggerated amounts of vasoactive and inflammatory substances. These substances are released into the renal interstitium (Fig. 62-1). This chapter discusses the tubular cell-dependent pathways causing interstitial inflammation and fibrosis that are triggered by enhanced protein trafficking through the glomerulus to cause renal scarring and loss of function.

CHANGES IN GLOMERULAR HEMODYNAMICS INITIATE KEY EVENTS IN PROGRESSIVE NEPHROPATHY

Among the several theories about the pathophysiology of progressive nephropathies, Brenner et al. offered the most consistent unifying hypothesis. They suggested that the surviving nephrons undergo hemodynamic responses that serve to maintain glomerular filtration. These responses cause structural injury and, hence, a self-perpetuating cycle. A rat model of renal ablation was used to clarify how this adaptive response results in pathological mechanisms and nephron loss. With a reduction of renal mass, remnant intact nephrons in rats undergo hypertrophy and a lowering of arteriolar resistance leading to increased glomerular plasma flow. These changes result from a differential decrease in vessel tone, which is less pronounced in the afferent in comparison with the efferent arterioles. An adaptive increase in glomerular capillary hydraulic pressure results, yielding more filtrate per nephron. These changes become detrimental over months and years. Therapies that attenuate these adaptive responses also limit the decline in glomerular filtration rate and the structural damage. Angiotensin converting enzyme inhibitors (ACEi) reduce intraglomerular capillary pressure more than other antihypertensive agents; they also protect the kidneys of rats with renal mass reduction or experimental diabetes from progressive loss of kidney function. Glomerular hypertension leads to progressive renal injury in the long term because it enlarges the radii of the pores perforating the glomerular membrane; the mechanism at least partly involves angiotensin II. The enlargement of the pores impairs the size-selective function of the glomerular barrier and increases protein ultrafiltration.

ULTRAFILTERED PROTEINS AND TUBULOINTERSTITIAL INJURY

It had been suspected that proteins abnormally filtered through the glomerular capillary were more than a marker of the severity of renal lesions. These proteins could exhibit renal toxicity and contribute to progressive renal damage. Sequential analysis of renal biopsies of rats with adriamycin nephrosis or age-related proteinuria showed that the extent of glomerular lesions correlated with tubulointerstitial damage, which was preceded by the presence of protein reabsorption droplets in the cytoplasm of proximal tubular cells. These droplets were associated with focal breaks along the tubular basement membrane plus extravasation of the

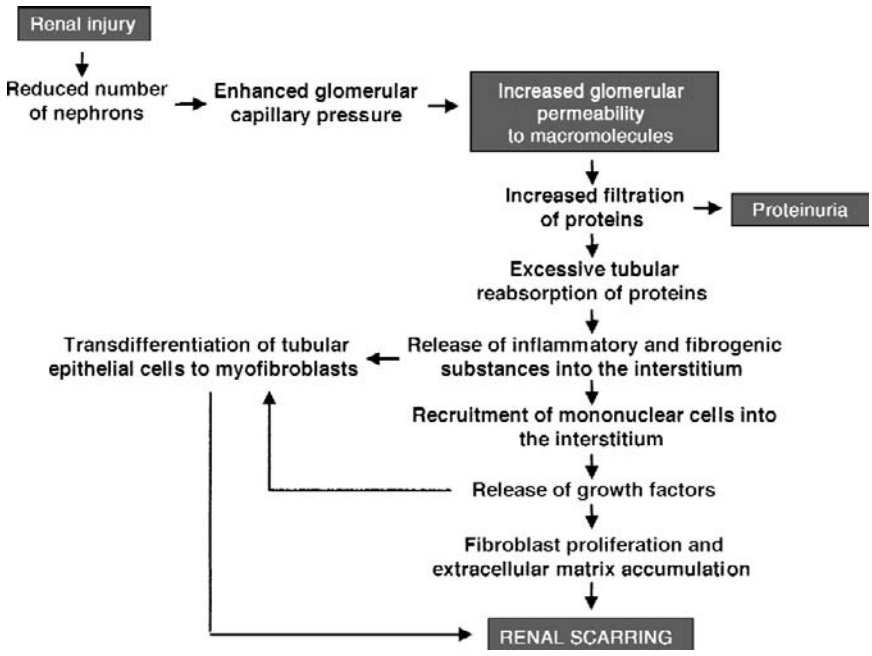

Figure 62-1 Schematic representation of the events that lead to tubulointerstitial inflammation and renal scarring in proteinuric nephropathy.

tubular cell contents into the renal interstitium. Implications from these studies are that protein reabsorption activates proximal tubular cells to promote interstitial infiltration of inflammatory cells and ultimately, renal fibrosis. The most convincing experimental evidence that proteins leaking into the urinary space trigger tubulointerstitial inflammation was provided by models of "overload proteinuria." This disorder follows repeated injections of albumin leading to an increase in glomerular barrier permeability and massive proteinuria. There are tubular changes consisting of heavy infiltration of macrophages and T-lymphocytes into the renal interstitium. Other evidence that protein reabsorption by proximal tubular cells participates in the development of interstitial inflammation derives from an analysis of the time-course and sites of protein accumulation and interstitial cellular infiltration in two models of proteinuric nephropathies. In rats with 5/6 nephrectomy, albumin, and immunoglobulin (IgG) are accumulated in proximal tubular cells and precede the interstitial infiltration of major histocompatibility complex II-positive cells and macrophages. The infiltrates develop at or near tubules that contain deposits of intracellular IgG. These patterns are also found in the model of passive Heymann nephritis. The conclusion is that the interstitial inflammatory reaction develops at the sites of protein overload, regardless of the type of glomerular injury. In both models there also is a link between excess plasma protein reabsorption in the proximal tubule and the expression of osteopontin, a cytokine that attracts mononuclear cells into the renal interstitium. Osteopontin was detected with IgG and the sites of adjacent infiltrates, suggesting that osteopontin is a mediator of a proximal tubule-dependent inflammatory pathway occurring because of tubular cell protein reabsorption.

The primitive amphibian, the axolotl, has no glomerulus so protein uptake by tubular cells can be studied in the absence of glomerular damage. Injection of proteins into the peritoneal cavity of the axolotl causes selective uptake and transient storage of proteins in tubular epithelial cells of nephrons. Protein-loaded tubules undergo luminal dilatation with deposition of protein sludge plus massive, diffuse accumulation of droplets containing proteins and lipids in the proximal tubular epithelial cells. Progressive focal accumulation of fibrous tissue occurs around the protein-storing tubules. There also is fibronectin and transforming growth factor (TGF)-β in the tubular epithelial cells and interstitial cells.

TUBULAR HANDLING OF PROTEINS

Proteins are reabsorbed by proximal tubules via processes that involve binding to the apical pole of these cells followed by internalization and lysosomal degradation of the protein to amino acids and small peptides. The initial step involves receptor-mediated endocytosis in clathrin-coated pits at the base of the microvilli. The coated pits are formed by a process involving clathrin adaptor proteins and other intracellular proteins yielding to endocytic vesicles called endosomes. Proton pumps present in the interior of these vescicles cause acidification and dissociation of ligands from the receptors. The receptors recycle to the luminal surface but the protein ligands are degraded by lysosomal enzymes.

Two endocytic receptors, megalin, and cubilin, have a major role in proximal tubule reabsorption of proteins. Megalin is a large, transmembrane glycoprotein, whereas cubilin is a peripherally attached glycoprotein. The two receptors interact to mediate reabsorption of filtered proteins, including carrier proteins that transport several vitamins or lipids. Megalin and cubilin are also coexpressed in the small intestine, the visceral yolk sac and the placental cytotrophoblast, and megalin is present in glomerular podocytes. Dysfunction of megalin or cubilin results in tubular proteinuria and changes in vitamin metabolism because of defective proximal tubular reabsorption of carrier proteins.

Megalin is a 600-kDa transmembrane glycoprotein belonging to the LDL receptor family, it is the most abundant endocytic receptor in the proximal tubule epithelium. It acts as a receptor for different protein ligands including albumin, insulin, prolactin, and vitamin-binding proteins. Megalin's endocytotic function is regulated by

heterotrimeric G protein-internalization signals (Gαi3, GAIP, and GIPC) that interact with the cytoplasmic tail of megalin. The tail portion of the molecule also contains Src-homology domains, PSD-95/Discs-larget20-1 (PDZ) domains and protein kinase phosphorylation sites, suggesting that megalin is involved in signal transduction. In fact, the mitogenic effect of albumin in proximal tubular cells seems to be mediated by activation of phosphatidylinositol 3-kinase and subsequent activation of p70 ribosomal protein S6 kinase.

Cubilin is a 460-kD peripheral membrane protein that binds albumin, transferrin, IgG light chains, and receptor-associated proteins. Cubilin has no transmembrane domain, suggesting that megalin mediates the endocytosis and intracellular trafficking of cubilin. There is evidence that the cubilin ligands, transferrin, and apolipoprotein A-I/high density lipoprotein, are not reabsorbed if anti-megalin antibodies or megalin anti-sense oligonucleotides are present to block megalin action. In megalin-deficient mice, transferrin accumulates on the luminal membrane of the proximal tubule cells but it is not internalized.

In patients, reduced renal expression of megalin occurs in Dent's disease when it expresses proteinuria and defective tubular re-uptake of filtered proteins. Disruption of ClC-5, the renal chloride channel, impairs proximal tubule endocytosis and causes a decrease in megalin expression in the proximal tubule. A decrease in megalin expression has been also described in a rat model of autosomal-dominant polycystic kidney disease.

EFFECTOR MECHANISMS MEDIATING PROTEIN OVERLOAD INJURY

Highlights of specific mechanisms that link excessive traffic of plasma proteins with interstitial injury have been identified using polarized proximal tubular cells. Protein overloading of cultured proximal tubular cells activates the transcription of genes encoding vasoactive, inflammatory, and fibrogenic molecules. For example, when high concentrations of proteins (delipidated or lipid-enriched albumin, IgG, and transferrin) are added to cultured cells, the synthesis of endothelin-1, a vasoconstrictor peptide involved in progressive renal injury is increased. Endothelin-1 stimulates renal cell proliferation and extracellular matrix production and is chemotactic for monocytes. The monocyte chemoattractant protein-1 (MCP-1) and regulated upon activation, normal T-cell expressed and secreted (RANTES), two chemokines that have potent chemotactic properties for monocytes/macrophages, and T-lymphocytes, are upregulated by albumin and other plasma proteins. Albumin exposure also induces the production of interleukin (IL)-8, a chemokine of the C-X-C family. IL-8 has potent chemotactic activity for neutrophils and lymphocytes. In analysis of kidney biopsies from patients with heavy proteinuria, IL-8 mRNA expression was found to be localized to proximal tubules; nonnephrotic subjects did not have excess tubular IL-8 mRNA.

Tubular epithelial cells organized as a continuous polarized cell layer can serve to separate the apical and basolateral cellular compartments. Cultured proximal tubular cells grown on filters in bicameral systems become polarized, develop microvilli on the apical membrane and tight junctions in the basolateral domain. Apical exposure of these cells to albumin leads to increased secretion of endothelin-1 and chemokines mainly toward the basolateral compartment of the cell. Consequently, the model could reveal mechanisms relevant to the tubulointerstitial inflammatory response and structural injury that is observed in response to proteinuria.

Fractalkine is a cell-membrane anchored chemokine that acts as an adhesive molecule to promote adhesion of mononuclear cells expressing the specific receptor, CX3CR1. Fractalkine has a CX3C-containing chemokine module on the top of a mucin-like stalk that is tethered to a transmembrane domain and has an intracytoplasmic tail. In addition, fractalkine may be cleaved to form a soluble chemo-attractant. Besides vascular endothelial cells and epithelial cells from lung and intestine, renal proximal tubular epithelial cells express fractalkine when stimulated by tumor necrosis factor. There is strong expression of fractalkine mRNA by tubules that are adjacent to inflammatory cell infiltrates in kidney biopsies from patients with acute renal allograft rejection.

Fractalkine is overexpressed in cultured proximal tubular cells when they are exposed to albumin, as well as in a murine model of protein overload proteinuria. For example, fractalkine mRNA levels in the kidney after protein overload were more than twice as high as control animal kidneys. Treatment of mice with an antibody against the CX3CR1 fractalkine receptor was found to reduce the accumulation of monocytes/macrophages in the renal interstitium. Fractalkine might contribute in proteinuric condition by directing mononuclear cells into the peritubular interstitium presumably by enhancing adhesion to favor interstitial inflammation and progression of renal insufficiency.

IN VITRO EVIDENCE FOR THE TOXICITY OF PROTEINS

Molecular mechanisms by which proteinuria can activate chemokine genes include nuclear transcription factors, such as NF-κB. The NF-κB/Rel family includes homodimeric or heterodimeric complexes composed of p50, p52, p65, c-rRel, and RelB proteins. The prototype, NF-κB, is composed of p50–p65 subunits. In resting cells, NF-κB exists in the cytoplasm as an inactive form bound to the protein inhibitor of κB (IkBα). Upon cell activation by cytokines, viruses, or oxidants, IkBα is phosphorylated by the IkB kinase complex and subsequently ubiquitinated and degraded. This process releases NF-κB, which is translocated into the nucleus for binding to specific DNA motifs in gene promoters. Cultured proximal tubular cells exposed to albumin develop a dose-dependent increase in NF-κB activation followed by the upregulation of RANTES, MCP-1, and IL-8; these responses were abrogated by NF-κB inhibitors. Moreover, when IkBα was induced in cells, exposure to albumin suppressed the expression of fractalkine mRNA indicating that NF-κB has a role in the activation of chemokine genes.

Reactive oxygen species can also serve as second messengers and activate NF-κB in response to albumin exposure. Both albumin and IgG elicit a rapid and sustained generation of hydrogen peroxide (H_2O_2) in human proximal tubular cells. Treatment with the antioxidant scavengers or metal chelators, dimethyl-thiourea, or pyrrolidine dithiocarbamate, can prevent H_2O_2 production and abolishes the enhancement of NF-κB activity that follows exposure of the cells to either protein. Treatment of tubular cells with exogenous H_2O_2 yielded a subunit pattern of NF-κB that is similar to that observed after protein challenge. In other cellular systems, oxidants are generated following protein kinase C (PKC) activation; activated PKC translocates from the cytoplasm to cell membrane and mediates reactive oxygen species production and NF-κB activation. In protein overloaded tubular cells, inhibitors of PKC prevented H_2O_2 generation and inhibited NF-κB-DNA binding activity. Oxidant scavengers or PKC inhibitors in turn, can prevent

MCP-1 and IL-8 gene upregulation induced by albumin, indicating that PKC and oxygen radicals generate critical signals for the expression of NF-κB dependent genes when tubular cells are exposed to protein overload.

IN VIVO EVIDENCE FOR PROTEIN TOXICITY

Evidence that proteinuria can activate transcription factors and expression of chemokines in vivo is available based upon results from experimental or human progressive nephropathies. In rats with protein-overload proteinuria, there is interstitial inflammation and tubular upregulation of MCP-1 and osteopontin. NF-κB activity is also increased in tubular epithelial cells. In rats with 5/6 nephrectomy, increased urinary protein excretion is associated with an increase in NF-κB activity in the remnant kidneys. There is strong nuclear staining for the p50 subunit of NF-κB in proximal tubular cells and in the sparse cells of the interstitium, only weak staining is found in the kidneys of control animals. MCP-1 mRNA upregulation preceded the accumulation of monocytes/macrophages and T-lymphocytes in the remnant kidney interstitium, suggesting that mononuclear cell recruitment may be the result of MCP-1-dependent mechanisms. In other models of proteinuric nephropathies, MCP-1 overexpression in the kidney precedes or coincides with the infiltration of mononuclear cells into the renal interstitium. Finally, administering a neutralizing anti-MCP-1 antibody to rats with tubulointerstitial nephritis was found to decrease macrophage infiltration, suggesting the possibility that MCP-1 is functionally important in eliciting an inflammatory response in the kidney interstitium.

If the interstitial inflammatory reaction is a consequence of the filtration and proximal tubular reabsorption of proteins, then limiting this enhanced protein traffic should also limit the biological effect of excessive tubular protein reabsorption and slow renal disease progression. The best means of testing this relationship in experimental animals or humans is by the use of ACEi. ACEi in rats with remnant kidneys was found to reduce urinary protein excretion, to suppress NF-κB DNA-binding activity almost completely and to reduce MCP-1 mRNA expression. The accumulation of mononuclear cells in the renal interstitium was also greatly limited. In an immune model of passive Heymann nephritis, a progressive increase in proteinuria is associated with a remarkable increase in renal NF-κB activity; this response was reversed by the early administration of an ACEi. The decrease in NF-κB activation was associated with downregulation of MCP-1 expression and a reduction in interstitial inflammation.

In line with the possibility that NF-κB activation has a role in tubulointerstitial injury in proteinuric rats, rats with adriamycin-induced nephropathy exhibited suppression of NF-κB and marked reduction of interstitial monocyte infiltration during chronic treatment with the NF-κB inhibitor, pyrrolidine dithiocarbamate. Likewise, when a recombinant adenovirus vector expressing the truncated form of IkBα that lacked the phosphorylation sites essential for the activation of NF-κB, was injected into renal arteries of rats with proteinuria, NF-κB activation in tubular cells and interstitial infiltration of mononuclear cells was prevented. Interstitial edema and fibrosis were also suppressed. Gene transfer of mutant IkB also suppressed the expression of profibrogenic TGF-β and matrix fibronectin. These results suggest the possibility that gene therapy targeting NF-κB could interrupt the process of tubulointerstitial injury.

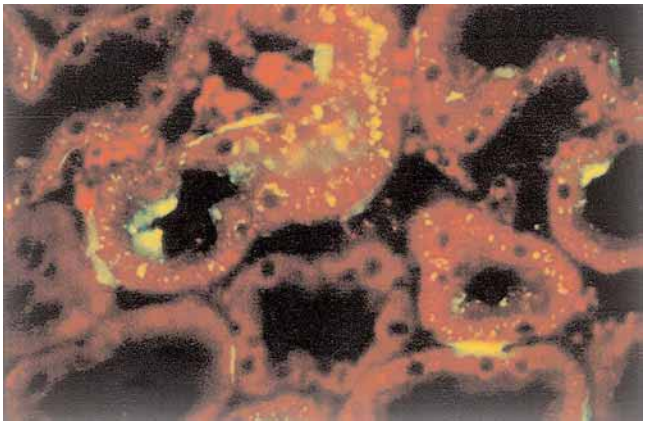

Figure 62-2 Section of remnant kidney tissue of rat at 30 d after renal mass reduction, double stained for C3 and MHC class II. Peritubular accumulation of MHC-II-positive cells preferentially occurs in the vicinity of tubular sites of C3 deposition and of intracellular accumulation of C3 in proximal tubular cells.

Analysis of renal biopsy specimens from patients with severe proteinuria revealed NF-κB activation in tubular epithelial cells. The degree of activation was correlated with the magnitude of proteinuria. There also was a concomitant upregulation of proinflammatory chemokines, MCP-1, RANTES, and osteopontin in tubular epithelial cells. Patients with a progressive disease had more intense expression.

THE PIVOTAL ROLE OF COMPLEMENT

Among secondary processes that lead to interstitial damage in proteinuric conditions, the activation of complement proteins in the proximal tubule excites proinflammatory responses. Complement factors filtered at the glomerulus of rats with protein overload proteinuria, renal mass ablation or aminonucleoside nephrosis can form deposits (C3, C5b-9) along the tubular lumen and within proximal tubular cells. Complement-depletion provided direct evidence for the deleterious effects of urinary complement components on the tubulointerstitium. C5-b9 can mediate the interstitial inflammation and fibrosis accompanying chronic proteinuric nephropathy. In rats with a severe form of the nephrotic syndrome, a congenital absence of C6 was found to reduce the degree of interstitial inflammation and improve renal function dramatically. In these C6-deficient rats, subtotal nephrectomy had markedly reduced evidence of tubulointerstitial injury and loss of renal function. Consequently, treatments directed at reducing the C5b-9 attack in tubular cells may slow disease progression and facilitate the recovery of renal function. The process of protein accumulation in proximal tubular cells is followed by interstitial infiltration of mononuclear cells that concentrate almost exclusively in regions containing C3 positive proximal tubules (Fig. 62-2). Treatment with ACEi prevents proteinuria and limits tubular accumulation of C3 and IgG as well as interstitial inflammation.

C3 is an essential component of both the classical and alternative pathways of complement activation. In vitro, proximal tubular cells exposed to human serum activated to develop C5b-9 membrane attack complex (MAC) neoantigen complexes on the tubular cell surface. These events cause marked cytoskeleton alterations including disruption of the network of actin stress fibers,

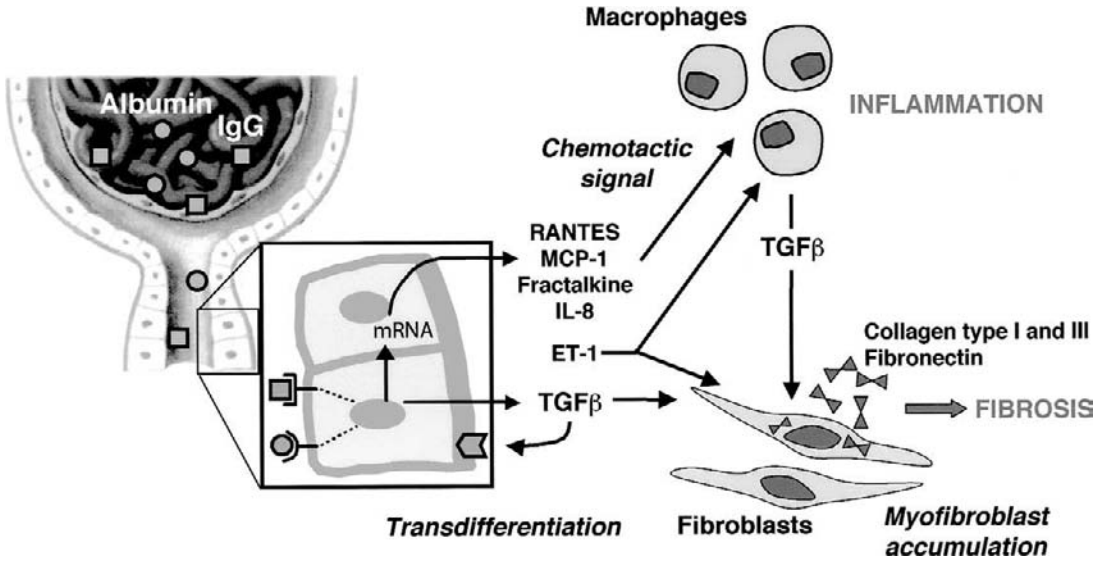

Figure 62-3 Cellular mechanisms of injury via exaggerated plasma protein uptake by proximal tubular cells, resulting in interstitial inflammation and fibrosis.

formation of blebs, and cytolysis. There also is production of superoxide anions, H_2O_2, and the synthesis of proinflammatory cytokines such as IL-6 and tumor necrosis factor-α. Besides activating complement, proximal tubular epithelial cells exposed to human serum can synthesize complement components including C3. In the kidney, complement is indeed synthesized and detectable at peritubular sites, suggesting that locally synthesized complement participates in tubulointerstitial damage. Incubation of proximal tubular cells with transferrin led to overexpression of C3 mRNA and to both apical and basolateral C3 secretion. Thus, proximal tubule cells exposed to serum can synthesize and release complement components as well as activate them.

PROFIBROGENIC SIGNALING FROM PROXIMAL TUBULAR CELLS LOADED WITH FILTERED PROTEINS

In experimental models of progressive renal disease, both the interstitial accumulation of myofibroblasts and phenotypic changes in tubular epithelial cells can contribute to the fibrogenic reaction. First, proinflammatory activation of tubular cells fosters the local recruitment of macrophages and lymphocytes. These cells release TGF-β, platelet-derived growth factor and other cytokines that may transform interstitial cells into myofibroblasts. Proximal tubular epithelial cells can interact with interstitial fibroblasts directly to promote fibrogenesis via the paracrine release of profibrogenic molecules. In vivo evidence that both the inflammatory, cell-dependent pathway and the tubular, paracrine pathway are activated is found in remnant kidneys of rats. When there is proteinuria, cells expressing the myofibroblast-associated marker α-smooth muscle actin (α-SMA), accumulate. Subsequently, focal staining for α-SMA occurs in proximal tubules, supporting the possibility that the same pathway may play a role in the epithelial–mesenchymal transformation or transdifferentiation of proximal tubular cells. Treatment of rats with the remnant kidney lesion using ACEi inhibits excess protein accumulation and interstitial inflammatory cell infiltration, and abrogates abnormal TGF-β_1 gene expression in tubular cells and myofibroblast accumulation.

TGF-β_1 is the most important cytokine leading to renal fibrogenesis; it induces epithelial mesenchymal transformation of tubular epithelial cells. High concentrations of albumin upregulate TGF-β_1 production in proximal tubular cells in culture. Other mediators of the fibrogenic response include platelet-derived growth factor and endothelin-1, which can activate α-SMA gene expression. Finally, growth factors such as hepatocyte growth factor and TGF-β_1 itself can contribute to the induction of fibrosis in vivo. In diabetic nephropathy, hepatocyte growth factor, and TGF-β were detected in proximal tubular fluid; upregulation of the expression of collagen type I and II as well as fibronectin occurs in interstitial myofibroblasts.

CONCLUSION AND FUTURE PROSPECTS

The tubulointerstitial damage that follows an injury to the glomerulus results from a complex interaction of biologically active factors that cause renal inflammation and scarring (Fig. 62-3). Experimental results have established that filtered proteins exert toxic response owing to overreabsorption by proximal tubular cells. The result of this toxicity is the release of mediators into the renal interstitium. Chemokines attract mononuclear cells and TGF-β can stimulate interstitial fibroblasts to deposit extracellular matrix components. Macrophages that accumulate at tubular sites of enhanced protein uptake can synthesize TGF-β and hence will induce tubular epithelial cells to acquire a mesenchymal phenotype.

Interstitial inflammation and fibrosis and ultimately progression of kidney damage can be limited by ACEi because they strengthen the glomerular barrier to proteins and limit proteinuria. Experimental and clinical data strongly suggest that remission of this process is achievable in some patients with chronic renal disease. Unfortunately, the delay between starting treatment and remission still leads to progression of many patients to end stage renal disease. For this reason, multi-drug strategies that simultaneously interrupt secondary pathways of progressive renal disease are needed to maximize renoprotection for the majority of patients with proteinuric nephropathies. For example, anti-TGF-β antibody plus chronic ACE inhibition

arrest proteinuria and renal injury in experimental diabetic nephropathy. This sort of strategy could lead to remission of the disease in patients who do not completely respond to ACE inhibitors.

ACKNOWLEDGMENT

The authors would like to thank Dr. Antonella Piccinelli for his invaluable help in preparing the manuscript.

63 The Pathophysiology of Acute Renal Failure

Didier Portilla, Gur P. Kaushal, Alexei G. Basnakian, and Sudhir V. Shah

SUMMARY

Acute renal failure (ARF) is a syndrome that can be defined as an abrupt decrease in renal function sufficient to result in retention of nitrogenous waste in the body. ARF can result from a decrease of renal blood flow, intrinsic renal parenchymal diseases, or obstruction of urine flow. There has been little progress in preventing and treating ARF, but with a better understanding of cell injury mechanisms and by carefully defining populations at risk for developing ARF, treatment strategies could be developed.

Key Words: ARF; GFR; inflammatory cells; kidney; mitochondria; sublethal cell injury.

INTRODUCTION

Acute renal failure (ARF) is a syndrome that can be defined as an abrupt decrease in renal function sufficient to result in retention of nitrogenous waste (e.g., blood urea nitrogen and creatinine) in the body. ARF can result from a decrease of renal blood flow (prerenal azotemia), intrinsic renal parenchymal diseases (renal azotemia), or obstruction of urine flow (postrenal azotemia). The most common intrinsic renal disease that leads to ARF is referred to as acute tubular necrosis (used interchangeably with ARF in this chapter), a clinical syndrome in which there is an abrupt and sustained decline in glomerular filtration rate occurring within minutes to days following an acute ischemic or nephrotoxic insult. Its clinical recognition requires exclusion of prerenal and postrenal causes of azotemia, followed by exclusion of other causes of intrinsic ARF (e.g., glomerulonephritis, acute interstitial nephritis, or vasculitis). Ischemic ARF is associated with a mortality rate of about 50% in hospitalized patients and 70–80% in patients in intensive care units. This rate has essentially remained constant over the last 50 yr. Although the high mortality rate is due in part to the presence of comorbid conditions, there is evidence that ARF is responsible for the high mortality rate. The most common pathophysiological mechanism involved in the development of ARF is the presence of a complex interplay between altered renal hemodynamics, inflammation, and tubular dysfunction (Fig. 63-1). Advances have improved the understanding of the mechanisms involved in the development of ARF.

ROLE OF THE VASCULAR ENDOTHELIUM

Blood flow to the kidney accounts for 25% of the cardiac output, the majority going to the kidney cortex with very small amounts going into the medullary portion of the kidney. Measurement of PO_2 in the medulla of normal kidneys reveals a relatively hypoxic region (PO_2 values as low as 5–15 mmHg). The critically low PO_2 coupled with high energy demands of the medullary portion of the kidney results in increased susceptibility of the cortico-medullary portion of the kidney to injury.

Following an ischemic insult, total renal blood flow is reduced to 40–50% of normal value during reperfusion both in animal models and in human ischemic ARF. This "no-reflow" phenomenon has been observed after ischemia in other organs as well. Using intravital videomicroscopy of renal microcirculation during the immediate reperfusion period, investigators demonstrated profound and sustained deceleration of blood flow yielding a temporary loss of capillary patency and shifts in blood flow through postischemic capillaries from orthograde to the retrograde direction. These patterns of capillary blood flow in the postischemic kidney may explain the mechanisms of no-reflow phenomenon. Other evidence of abnormal "vascular reactivity" in the ischemic kidney includes a profound loss of acetylcholine-induced vasodilatation of the ischemic renal vasculature, inhibition of vasorelaxation in response to stimuli that generate endothelium-derived relaxing factor, and reduced production of nitric oxide in response to bradykinin.

The potential role of endothelial cells in producing ischemia/reperfusion injury was suggested by the finding that endothelial cells undergo swelling to narrow the lumen. Other support for the ischemia/reperfusion pathophysiologic cause of ARF includes the significant improvement in the peritubular capillary blood flow in the postischemic period in animals that had been transplanted with human umbilical vein endothelial cells and human embryonic kidney cells which stably expressed human endothelial or type-III NO synthase (eNOS). The observation that endothelial cells can rescue the function of an ischemic organ illustrates the principle of cell–cell interaction in which the dysfunction of one cell type affects the functions of other cells. Furthermore, implantation of cells expressing the functional eNOS (even though the cells are not endothelial cells *per se*) can ameliorate renal dysfunction following acute ischemia, also implicating eNOS in the pathophysiology of ARF.

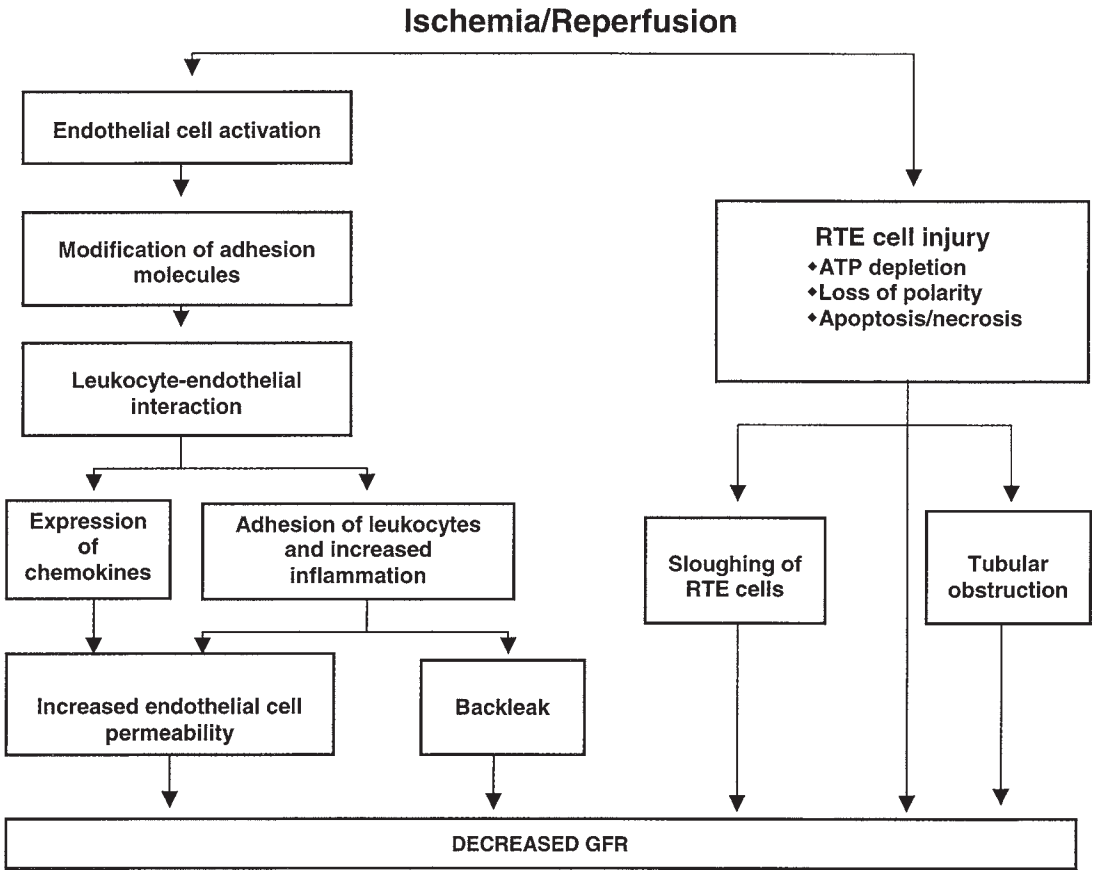

Figure 63-1 Complex interplay between altered renal hemodynamics, inflammation, and tubular dysfunction.

Study results provide further support for the role of microvascular endothelium in the pathophysiology of ischemic ARF. They demonstrated high circulating levels of von Willebrand factor (a marker for endothelial cell injury) plus increase in F-actin aggregates found in the basolateral aspects of renal microvascular endothelial cells within the first 24 h of ischemic injury. In addition, there were structural changes in vascular endothelial-cadherin at endothelial cell–cell junctions as early as 2 h, which were accompanied by a marked increase in microvascular permeability, resulting in interstitial edema. These observations implicate an important role of endothelial cells and could result in new therapeutic modalities for treatment of ARF.

PATHOLOGICAL ROLE OF INFLAMMATORY CELLS

Studies in experimental acute tubular necrosis previously suggested that inflammatory cells did not play an important role in renal tubular injury. Newer studies, however, support a role for inflammatory cells in ARF. Histological evaluation has shown that the accumulation of neutrophils occurs within the first 4 h and is maximal at 24–48 h of ischemia/reperfusion injury to the kidney. Most of the neutrophil accumulation occurs in the outer medulla and in the cortex. Leukocyte depletion achieved by antineutrophil serum protected the kidney, establishing a cause–effect relationship between neutrophil accumulation and tissue injury during ischemia/reperfusion. Studies using pharmacological agents support the idea that decreased neutrophil infiltration leads to prevention of ischemia/reperfusion injury. For example, administration of α-melanocyte-stimulating hormone has been associated with a reduction of neutrophil infiltration and kidney injury after ischemic/reperfusion.

The adherence of leukocytes to the vascular endothelium is an early critical process resulting in the outer medullary congestion present in ischemic ARF. Leukocytes increase endothelial permeability leading to erythrocyte aggregation and edema as well as obstruction of the vasa recta. Neutrophils also release reactive oxygen species, proteases, elastases, myeloperoxidase, and other enzymes that damage tissue. In addition, increases in leukotriene B4 and platelet-activating factor produced by monocytes or platelets can increase vascular permeability and upregulate the expression of adhesion molecules to promote further inflammation.

The adhesion of neutrophils to endothelial cells occurs through a complex series of events involving the presence of several classes of adhesion molecules including selectins, mucin and other selectin ligands and integrins, plus members of the Ig superfamily. CD11/CD18 integrins and intracellular adhesion molecule (ICAM)-1 are also important molecules participating in the pathogenesis of ischemic renal injury. Protection from ischemic/reperfusion injury occurs in animals that are given antibodies to CD11a, CD11b, and ICAM-1 or antisense oligonucleotides to ICAM-1; ICAM-1-deficient mice are also protected. Activation of adenosine A2 receptors on endothelial cells reduces adherence factors and, ultimately, neutrophil accumulation. Hence neutrophil adherence to endothelial cells plays an important role in the pathogenesis of ischemic reperfusion injury.

Besides neutrophils, other inflammatory cells participate in ischemia/reperfusion injury. Biopsies of human kidneys with

acute tubular necrosis reveal the presence of lymphocytes, but whether these cells directly participate in organ injury or whether macrophages and T cells appear only in the recovery phase of ARF is controversial. Indirect evidence for a role for T lymphocytes in ischemic ARF includes studies showing that lymphocyte-related cytokines are upregulated in the postischemic kidney. Moreover, CD4/CD8 knockout mice are protected from ischemia/reperfusion injury. In addition, administration of a selectin ligand resulted in attenuated postischemic renal dysfunction and decreased mortality. In contrast to these reports, mice that are deficient in the recombination-activating gene, RAG-1, have no T- or B-cells and do not produce immunoglobulins or T-cell proteins, but still experience tubular necrosis and neutrophil infiltration when subjected to ischemia-reperfusion.

Taken together, the studies in humans or rodent models of ARF support the idea that endothelial cell injury is accompanied by increased leukocyte and perhaps T-cell-endothelial cell interactions that compromise blood flow to the corticomedullary junction.

MECHANISMS OF TUBULAR CELL INJURY

SUBLETHAL CELL INJURY The apical brush border of the proximal tubule is a site of early morphological change, with patchy loss of apical microvilli that occurs within minutes of acute renal ischemia. Subsequently, there is complete loss of the apical microvilli that are shed into the tubular lumen. These same morphological alterations of the proximal tubule brush border occur in the postischemic renal allografts of patients.

Alterations in the actin cytoskeleton are dramatic. In in vivo as well as in vitro models, there is a disassociation of the heterodimeric capping protein from the actin cytoskeleton during renal ischemia. Dephosphorylation of ezrin and actin depolimerizing factor have been observed in hypoxic tubules and could account for the loss of the cytoskeletal support of the microvillar surface membrane with subsequent microvillar collapse following acute ischemic injury. In addition to the microvillar actin disruption, there is loss of the cortical actin cytoskeleton response to ischemia in vivo or ATP depletion in vitro. Investigators also found conversion of G-actin to F-actin and aggregation of F-actin molecules in the cytoplasm of the cell; redistribution of ankyrin and fodrin, two proteins that anchor NaK-ATPase; redistribution of NaK-ATPase to the apical domain; and inactivation of Rho-GTPase with disruption of the tight junction complex during ATP depletion in vitro. Following ATF depletion, plasma membrane protrusions or blebs containing cytosol and endoplasmic reticulum are formed, reflecting disruption of volume regulation mechanisms and cytoskeleton organization.

The multiple alterations in renal epithelial cell cytoskeletal structure and its surface membrane polarity may contribute to the decrease in the glomerular filtration rate of ARF. Increased paracellular permeability could be the result of changes in tight junctions whereas loss of the integrity of the epithelial cell layer from sloughing of viable cells may contribute to back-leak of the glomerular filtrate. Finally, the loss of cell polarity and the redistribution of β_1 integrin impairs cell adhesion, resulting in clumping of sloughed and nonsloughed cells within the tubular lumen, leading to tubular obstruction.

LETHAL INJURY: APOPTOTIC AND NECROTIC PATHWAYS In ARF induced by ischemia, endotoxemia, nephrotoxins, or other causes, renal tubular epithelial cells die during a catastrophic breakdown of regulated cellular homeostasis known as necrosis. In freshly isolated proximal tubules subjected to hypoxia/reoxygenation, investigators described the formation of pathological plasma membrane pores, or so-called "death channels," these pores can be blocked by glycine at physiological levels. Late in hypoxic stress, an irreversible state of proximal tubule cell injury develops, signified by lysosomal disruption, bleb coalescence and subsequent bleb rupture, followed by loss of membrane permeability. The abrupt failure of the plasma membrane permeability barrier releases cytosolic contents and a collapse of all of the plasmalemmal and electrical and ionic gradients. In this form of cell death, cells swell and there is loss of plasma membrane integrity and rupture of cells releasing a variety of inflammatory mediators.

The modern era of cell death began with the landmark publication by Kerr, Wyllie, and Currie in which they coined the term *apoptosis* and made a distinction between necrosis and apoptosis based on morphological criteria. In apoptosis, cells shrink, lose their microvilli and cell junctions, and explode into a series of membrane-bound, condensed apoptotic bodies. These bodies are phagocytosed by adjacent viable cells with minimal leakage of the contents of the dead cell, thereby invoking no inflammation. Because apoptosis does not evoke inflammation, it is an important mechanism in embryogenesis and normal tissue turnover.

One of the major advances in understanding cell death has been the recognition that the pathways traditionally associated with apoptosis can be critical in determining the type of cell injury associated with necrosis; the same insult may result in mild injury resulting in apoptosis or severe injury, producing necrosis. Thus, the pathway is determined by both the nature and severity of insults. It appears likely that the pathways that lead to apoptotic or necrotic cell death are activated almost simultaneously but there are some common pathways.

The important role that apoptosis plays in renal function during ischemic ARF was highlighted by an infusion of GTP before inducing ischemic reperfusion injury. There was substantial functional protection and amelioration of apoptosis but not necrosis. Administration of guanosine also prevented the expression of p53, whereas a p53 inhibitor, pifithrin, selectively modified apoptosis and ameliorated renal function if it was given within 14 h of the initial insult. These results suggest that amelioration of apoptosis rather than necrosis will account for the major mechanism that protects renal function during ischemic ARF.

DNA FRAGMENTATION AND ENDONUCLEASES IN RENAL TUBULAR EPITHELIAL CELL INJURY

Several reports have demonstrated chromatin condensation, the morphological hallmark of apoptosis, in models of ARF including ischemia/reperfusion injury. However, much of the evidence for the activation of apoptotic mechanisms in cell injury is based on the demonstration of endonuclease activation resulting in oligonucleosome-length DNA fragmentation (approx 200 bp) as one of the biochemical hallmarks of apoptosis. For example, DNA fragmentation in the kidney cortex, or the typical ladder pattern of DNA, has been detected within 12 h after beginning reperfusion.

Key questions are whether endonuclease activation is related to cell death and whether an attempt to halt this process would prevent cell death. The 200 bp ladder, commonly used because of its simplicity, actually measures very late events and only approx 40 double-strand DNA breaks per cell have been shown to be lethal. The role of endonucleases in kidney epithelial cell injury is linked to the biochemical and cellular mechanisms of oxidant injury. For example, hydrogen peroxide in the presence of iron contained in

DNA yields site-specific generation of hydroxyl radicals that damage DNA. In hydrogen peroxide-induced injury, endonuclease activation is an early event leading to DNA fragmentation, and endonuclease inhibitors can prevent hydrogen peroxide-induced DNA strand breaks, DNA fragmentation, and cell death. Endonuclease activation may be important in reactive oxygen mechanisms leading to tubular cell injury.

Subsequently, it was demonstrated that hypoxia/reoxygenation injury of freshly isolated rat proximal tubules results in DNA strand breaks and nuclear DNA fragmentation that precedes cell death. This injury increased DNA degrading activity and this new activity was found in molecules with an apparent molecular mass of 15 kDa. Endonuclease inhibitors protected against DNA damage induced by hypoxia/reoxygenation injury and provided significant protection against cell death. There also is a role of endonuclease in a model of chemical hypoxia. Taken together, endonuclease activation resulting in DNA damage and cell death is an integral part of hypoxia/reoxygenation injury. Despite unequivocal evidence of endonuclease activation, the morphologic features of apoptosis including chromatin condensation were not observed. This result is consistent with studies indicating that chromatin condensation and DNA fragmentation may be triggered through separate metabolic pathways. Cells with morphological features of either apoptosis or necrosis will have evidence of endonuclease activity.

ENDONUCLEASES IN THE KIDNEY Limited information is available regarding the identity of the endonuclease(s) responsible for DNA fragmentation in the kidney. Evidence for two major endonucleases exists in kidneys and kidney cells, a 15 kDa endonuclease just discussed and a 30–34 kDa DNase I-like endonuclease. The 30 kDa is mainly a cytoplasmic enzyme, whereas the 15 kDa endonuclease is located in the nuclei. Because the 30 kDa enzyme is similar to a DNase I by its biochemical characteristics, the role of DNase I in renal injury is being examined. The activity of 30 kDa endonuclease is increased during ischemia/reperfusion injury in the rat kidney and at least in vitro renal tubular epithelial cells that had been transfected with a phosphorothioated DNase I antisense construct were protected against DNA damage and cell death.

CASPASES IN RENAL TUBULAR EPITHELIAL CELL INJURY

A specific class of proteases, the "caspases" (cysteine aspartate-specific proteases), were found to be involved in apoptosis in genetic studies of the nematode *Caenorrhabditis elegans*. Caspases are a family of structurally related cysteine proteases that play a central role in the execution of apoptosis. When cells are subjected to a pro-apoptotic stimulus, the procaspases are proteolytically processed to the active forms; at least fourteen caspases encoded by distinct genes have been cloned and sequenced in mammals, caspase-2, -8, -9, and -10 have large prodomains and initiate the activation of downstream caspases. Caspase-3, -6, and -7 contain smaller domains that have been identified as effecter or executioner caspases. The executioner caspases are the major active caspases detected in apoptotic cells and are widely regarded as mediators of apoptosis by cleaving and inactivating intracellular proteins that are essential for cell survival and proliferation. The specificity of downstream executioner caspases to cleave cellular proteins is unique. For example, following activation, caspase-3 primarily recognizes DEVD or DMQD tetrapeptide sequences whereas caspase-6 recognizes and cleaves the VEID tetrapeptide sequence after the aspartate residue in the target proteins.

There is increasing evidence for a role for caspases in hypoxic renal tubular cell injury. Exposure of freshly isolated renal tubular epithelial cells to hypoxia results in caspase activation, cell membrane damage, and necrotic cell death. A pan-caspase inhibitor attenuates the hypoxia-induced increase in caspase activity in these cells and provides protection against hypoxia-induced cell membrane damage, as determined by release of lactic dehydrogenase from the cells. Chemical hypoxia induced by treatment with antimycin A increases caspase activity that precedes DNA damage and cell death. Caspase inhibitors prevent hypoxia-induced DNA fragmentation as measured either by agarose gel electrophoresis or by *in situ* labeling of cell nuclei. Partial ATP depletion results in marked increase in activation of caspase-8 and the caspase inhibitors provide marked protection against cell death. Activation of caspase-3 by hypoxia or ATP depletion was accompanied by the translocation of Bax, a member of the Bcl-2 family, from the cytosol to the mitochondria and the release of cytochrome-*c* from mitochondria to the cytosol.

There is differential regulation of caspase activities in kidneys subjected to ischemia/reperfusion injury. Caspase-3 activity was significantly increased in the rat and murine models of renal ischemia/reperfusion injury whereas administration of the pan-caspase inhibitor, Z-VAD-FMK, at the time of reperfusion significantly prevented caspase-1 and -3 activities and provided marked protection against ischemic ARF. A rat model of ischemia/reperfusion injury indicated that prolonged ischemia induces proapoptotic mechanisms, including increases in the Bax/Bcl-2 ratio, caspase-3 expression, poly(ADP-ribose) polymerase cleavage, DNA fragmentation, and apoptotic cell number in renal proximal and distal tubules. Besides caspase-3, the proinflammatory caspase-1 is involved; it participates in the proteolytic cleavage of the precursor forms of the proinflammatory cytokines, IL-I β and -18, resulting in the active forms of these cytokines. Because caspase-1 mediated formation of IL-1β and -18 is associated with inflammation in renal ischemia/reperfusion, caspase-1 may play an important role in this form of injury. Results from caspase-$1^{-/-}$ mice have been inconsistent.

MITOCHONDRIA: CENTRAL COORDINATORS OF CELL DEATH

Mitochondria can play a key role in the decision of cells to undergo apoptosis or necrosis by regulating the apoptotic process (Fig. 63-2). When mitochondrial ATP formation by oxidative phosphorylation ceases, anoxic and ischemic injury result. In the case of the proximal tubule, glycolytic capacity is limited and the lack of hexokinase further limits the cell's potential to generate ATP from sources other than fatty acids. Uncoupled respiration has been postulated as a potential mechanism contributing to cell death because it represents a more severe form of metabolic disruption to mitochondria than the inhibition of ATP production.

Uncoupling causes collapse of pH and electrical gradients across the mitochondrial inner membrane and activates the mitochondrial F1F0 ATPase. Indirect evidence for the presence of uncoupling during ischemic ARF includes the presence of an increased expression of uncoupling protein-2 detected in a microarray analysis of ischemic kidney cortex tissue. Profound inhibition of fatty acid oxidation and increased accumulation of long-chain fatty acids and long-chain acylcarnitines have been demonstrated in ischemic ARF in vivo and in freshly isolated tubules responding to hypoxic injury. Accumulation of long-chain fatty acid metabolites is likely to be toxic and contribute to mitochondrial dysfunction during ischemic ARF.

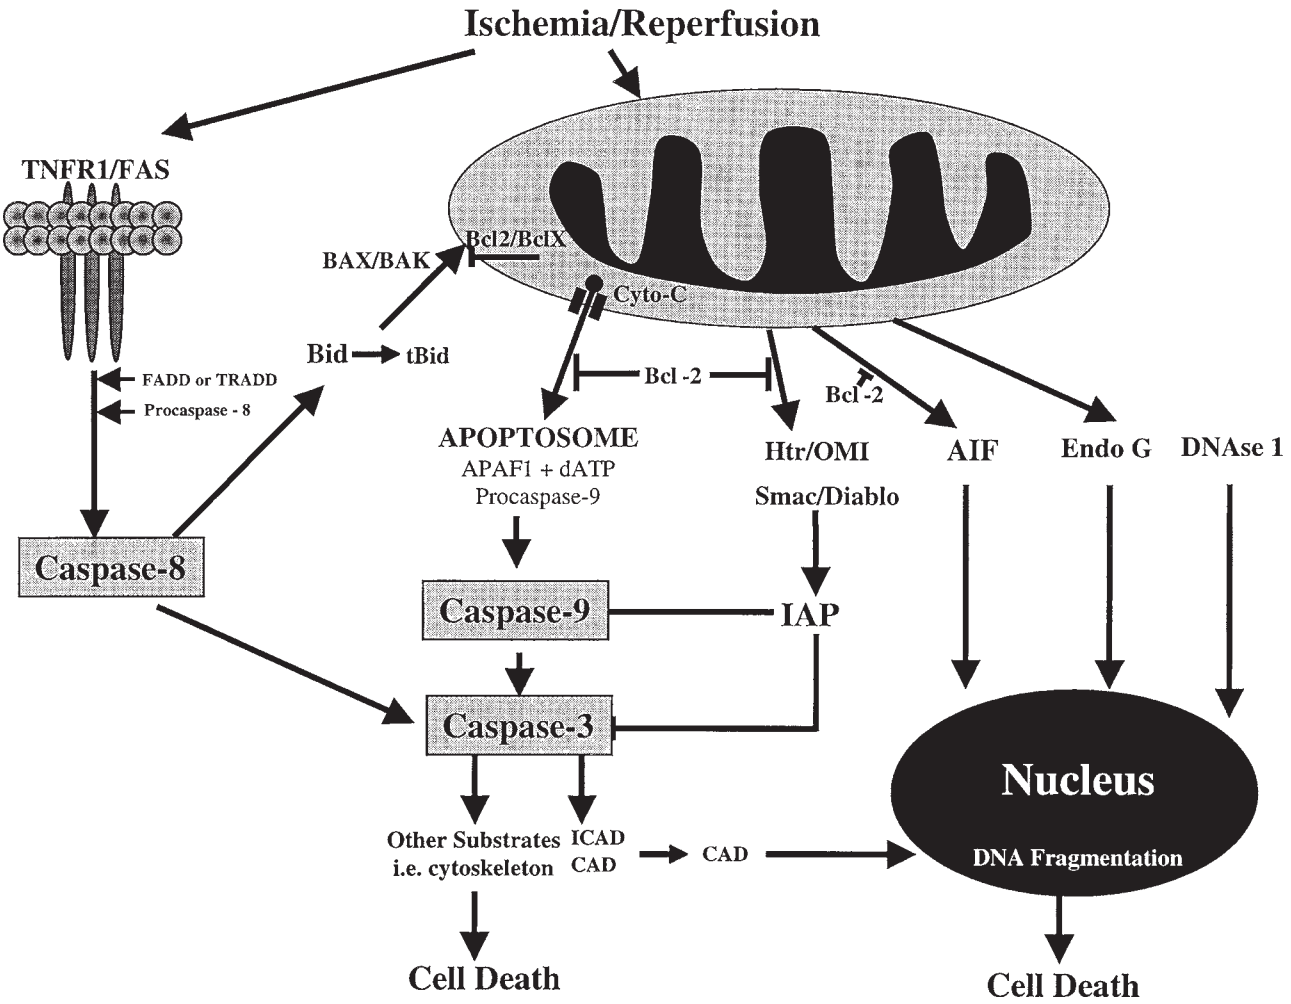

Figure 63-2 Receptor-mediated and mitochondrial-dependent pathways of cell death. TRADD, TNF receptor-associated death domain protein; ICAD, inhibitors of caspase activity DNase; CAD, caspase activity DNase; AIF, apoptosis-inducing factor.

Evidence suggests that mitochondria act as central coordinators of the downstream execution phase of cell death in the apoptotic pathway. Several proapoptotic signal transduction and damage pathways converge on mitochondria to induce mitochondrial membrane permeabilization; this response is under the control of Bcl-2-related proteins. The inner membrane is characterized by a transmembrane potential $\Delta\psi_{m,}$ which is generated through the activity of proton pumps of the respiratory chain. When cells are induced to die and the outer mitochondrial membrane becomes permeable to proteins, $\Delta\psi_{m,}$ dissipates, resulting in the leakage of toxic mitochondrial intermembrane proteins into the cytoplasm. These cytochromes orchestrate the degradation phase of cell death. There is conflicting evidence about the formation of the permeability transition pore. It is made up of a complex of proteins including the adenine nucleotide translocator protein in the inner mitochondrial membrane, the voltage-dependent anion channel in the outer membrane, the cyclosporin A binding protein, cyclophyllin D, in the mitochondrial matrix, and the pro-apoptotic protein, Bax. Although permeability transition pores are assumed to be a normal constituent of mitochondrial membranes, induction of the mitochondrial permeability typically requires damage to the mitochondrial membrane, attack from oxygen radicals, and protein disulfide cross-linking agents. Evidence for a mitochondrial permeability transition pore is found in freshly isolated proximal tubule cells that are subjected to hypoxia/reoxygenation injury.

Two relatively well-characterized cell death pathways activate the downstream executioner, caspase-3. One is receptor mediated and the other is mitochondrial dependent. The receptor-dependent pathway is initiated by activation of cell death receptors (Fas or tumor necrosis factor-α) leading to activation of procaspase-8, which in turn cleaves procaspase-3 to activate caspase-3. The mitochondrial-dependent pathway is triggered by cytochrome-*c* release from the mitochondria. Surprisingly, the holo-cytochrome-*c* (but not the apo-cytochrome-*c*) is required for the activation of caspase-3 in a cell-free system. Cytochrome-*c*, once present in the cytosol, drives the assembly of a high-molecular-weight, caspase-activating complex termed the *apoptosome*. Cytochrome-*c* binds to apoptotic protease-activating factor-1 (Apaf-1), within its C-terminal region rich in WD motifs. Initially believed to be required only transiently for caspase-9 activation, the Apaf-1/caspase-9 complex is thought to represent the active form of caspase-9. Thus, Apaf-1 must be viewed not simply as a caspase-9 activator, but rather as an essential regulatory subunit of a caspase-9 holoenzyme. This holoenzyme—often referred to as the apoptosome—is a very large complex and it could contain additional proteins.

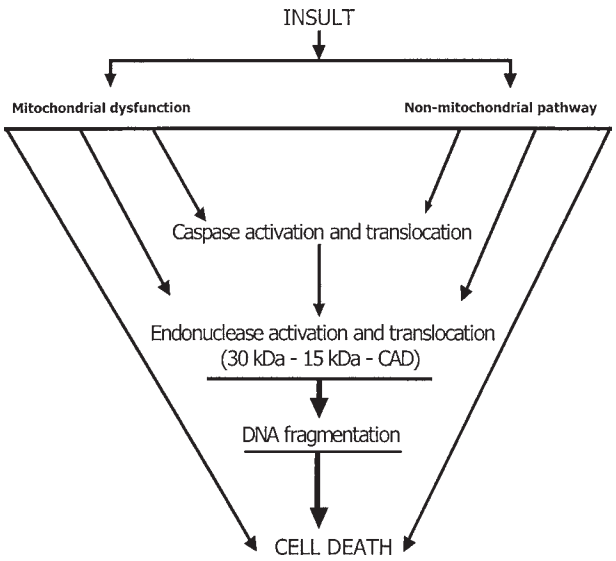

Figure 63-3 Potential pathways for cellular injury. CAD, caspase activity DNase.

A new protein with the dual name Smac/DIABLO is also released from mitochondria and promotes caspase activation by associating with the apoptosome whereas inhibiting inhibitors of apoptosis proteins (IAPs), the naturally occurring inhibitor of caspase-3. Besides these pathways, there is a mitochondrial protein named apoptosis-inducing factor (AIF) that induces apoptosis independently of caspases. Another mitochcondrial factor translocating to the nucleus has also been isolated: endonuclease G (Endo G). After reaching the cytosol, Endo G translocates toward the nucleus in which it generates oligonucleosomal DNA fragmentation, even in the presence of caspase inhibitors. Endo G can catalyse both high-molecular-weight DNA cleavage and oligonucleosomal DNA breakdown in a sequential fashion; it also cooperates with exonuclease and DNase I to facilitate DNA processing.

On induction of apoptosis pathways, mitochondria release several potentially lethal proteins that either participate in caspase activation (cytochrome-*c*, Smac/DIABLO) and/or induce cell death in a caspase-independent fashion (AIF, Endo G). It is difficult to weigh the relative contribution of each of these factors to apoptosis (Fig. 63-3).

REGULATORY MECHANISMS In living cells, mitochondrial changes are predominantly prevented by antiapoptotic members of the Bcl-2 family of proteins. Bcl-2 was first discovered as a proto-oncogene in follicular B-cell lymphoma. Subsequently, it was identified as a mammalian homolog to the apoptosis repressor, ced-9, in *Caenorhabditis elegans*. Since then, at least 19 Bcl-2 family members have been identified in mammalian cells and these members possess at least one of four conserved motifs known as Bcl-2 homology domains (BH1–BH4). The Bcl-2 family members can be subdivided into three categories according to their function and structure: antiapoptotic members, such as Bcl-2, Bcl-XL, Bcl-2, Mcl-1, and A1 (Bfl-1); proapoptotic molecules, such as Bax, Bak, and Bok (Mtd); and the BH3-only proteins, Bid, Bad, and Bim (these are called BH3-only proteins because of 4 Bcl-2 homology regions, they share only the third).

Studies from several laboratories have recognized the phosphatidylinositor-3 kinase pathway, PI-3 kinase/Akt phosphorylation, as one of the signaling pathways that blocks apoptosis and promotes cell survival in response to diverse apoptotic stimuli in different cell types. Akt (also known as protein kinase B) was originally identified as the cellular homolog of the transforming oncogene of the Akt8 retrovirus. Akt is a serine/threonine kinase and is one of the downstream targets of PI-3 kinase because it phosphorylates Akt to activate it.

Several pathways downstream of PI-3/Akt phosphorylation have been proposed to account for survival of the cell. One of the well-studied molecules that mediates cell survival by Akt phosphorylation is the proapoptotic Bcl-2 family member, Bad. Bad has the ability to interact and bind directly to antiapoptotic Bcl-2 and Bcl-XL and block their survival function. Phosphorylated Akt can directly phosphorylate Bad both in vitro and in vivo and may render Bad incapable of binding to Bcl-XL. This response would restore the antiapoptotic function of Bcl-2. Sequestering phosphorylated Bad by 14-3-3 proteins may also participate in the Akt survival pathway by making Bad unavailable to bind to Bcl-2 or prevent it from damaging the mitochondria.

Evidence has been presented that PI-3 kinase-mediated Akt phosphorylation is associated with Bad phosphorylation and suppression of caspase-9 and caspase-3 activation in cisplatin-induced injury to renal tubular epithelial cells. Similar results on the activation of caspase-3 and caspase-9 were obtained by inhibiting PI-3 kinase activity following hypoxia-induced injury to renal tubular epithelial cells. One study has shown that Akt can also phosphorylate human caspase-9 resulting in reduction of caspase-9 activity. Based on these studies, the inhibition of Akt phosphorylation and Bad phosphorylation in cisplatin-induced injury contributes to enhanced activation of mitochondrial-dependent caspase-3 and caspase-9 but not receptor-mediated activation of caspase-8 or proinflammatory caspase-1.

CHANGES IN GENE EXPRESSION IN ISCHEMIC ARF

During the course and induction of ARF many intrarenal alterations occur including changes in the microvascular endothelium, changes in cell polarity, increased levels of inflammatory molecules, expression of adhesion molecules, changes in cellular metabolism, and changes in the patterns of apoptosis and necrosis. DNA microarray technology has been applied to search for other responses. The goal is to analyze the expression of genes during ischemic/reperfusion injury in order to uncover new mechanisms of pathogenesis. Using this technique, changes in the expression of 18 genes were identified during ischemia/reperfusion of the rat kidney and these responses were confirmed by RT-PCR analysis. There were increased mRNA levels of potential "protective genes" such as clusterin, fibronectin, and hemoxygenase-1, similar to previously described changes. There was decreased expression of uromodulin (Tamm-Horsfall protein), an abundant protein exclusively localized to the thick ascending limb of Henle, also previously reported. Analysis of the gene array uncovered novel responses including increased expression of a disintegrin domain and metalloproteinase (ADAM-2), which mediates cell–cell communication. ADAM-2 likely plays a role in repair after ischemic injury. In addition, there were increased mRNA levels of thymosin B4, a member of the family of actin-monomer sequestering proteins that can enhance wound healing, suggesting that this molecule plays a role in repair of the cell cytoskeleton and in the repolarization of renal tubular epithelial cells after ischemic ARF.

Increased expression of uncoupled protein 2, a gene involved in mitochondrial hydrogen peroxide generation and in mitochondrial biogenesis, was also found. Finally, the gene array data revealed downregulation of PPAR-γ during ischemic reperfusion injury.

PPAR-γ belongs to the family of nuclear receptors that serves as a transcription factor and regulates several physiologic pathways associated with lipid metabolism and inflammation. Several fatty acid oxidation target genes of PPAR-α have been identified that are downregulated by ischemic ARF. That another PPAR target gene such as stromyelisin is also downregulated underscores the potential role that PPARs might play in cell repair following ischemic injury.

The cDNA microarray technique has also been used to study the responses to ischemic injury in a mouse model of ARF. Hierarchical clustering revealed several temporal patterns of gene expression. Early changes (at 3 h) during ischemic reperfusion injury included increased expression of transcription factors such as Egr-1 and c-*fos*, repair genes such as heat shock protein 70, growth factors such as hepatocyte growth factor, and Bcl-2. Genes that were upregulated at later periods (12–24 h) of reflow included heparin-binding epidermal growth factor, insulin-like growth factor, transforming growth factor, the cell-cycle protein p21, and cyto-protective factors such as heme-oxygenase 1 and α crystalline. The array confirmed downregulation of the sodium hydrogen exchanger-3, α albumin, and members of the cytochrome-p450 family after 24 h of reflow. Regarding apoptosis, there was persistent increased expression of FADD, DAXX, p53, and Bad at 3, 12, and 24 h of reperfusion. The changes in proapoptotic mRNA transcripts were confirmed at the protein level by immunohistochemistry demonstrating staining for FADD, Bak, Bad, and DAXX localized predominantly to the distal tubule. Changes in gene expression likely represent a multifaceted response to an ischemic insult that includes cell death, dedifferentiation of viable cells, proliferation, differentiation, and restitution of a normal epithelium.

CONCLUSION

The study of cell injury has emerged as one of most intensively investigated areas of research in life sciences. These studies have led to a better understanding of the complexity of the cell death process including the intricacies of the various paths with their complex, interweaving redundancies. There has been little progress in preventing and treating ARF, but with a better understanding of cell injury mechanisms and by carefully defining populations at risk for developing ARF, treatment strategies could be developed. In addition, understanding the pathophysiologic mechanism may allow identification of biomarkers, which may be utilized for early treatment and/or prevention of acute renal failure.

64 Loss of Lean Body Mass in Uremia

S. Russ Price and William E. Mitch

SUMMARY

The pathophysiological consequences of kidney failure and other catabolic conditions such as diabetes, burn injury, cancer, sepsis, muscle denervation and starvation, include loss of protein stores. This chapter will describe the impressive concordance between studies performed with cultured muscle cells and studies involving experimental animals and patients suggests that there is strong evolutionary pressure to maintain these "stress"-related responses. Understanding the mechanisms leading to activation of transcription could lead to improved methods of preventing the loss of muscle protein.

Key Words: Body mass; catabolic signals; glucocorticoids; ubiquitin-proteasome; *UbC*.

INTRODUCTION

The pathophysiological consequences of kidney failure and other catabolic conditions (e.g., diabetes, burn injury, cancer, sepsis, muscle denervation, starvation, and so on) include loss of protein stores. Available information suggests a common pathway is responsible for the loss of protein in all of these conditions. Fundamental questions are why the rate of protein loss varies so widely and what signals or mechanisms can explain why protein mass declines. In healthy adults, muscle proteins turn over at a high rate, the protein equivalent of approx 1–1.5 kg of muscle mass per day. This rate of turnover in muscle is necessary to replace proteins that are incorrectly translated, that become damaged or modified, or that require rapid degradation because they regulate critical cellular functions. However, because the rate of turnover is so high, even a small but persistent decrease in protein synthesis or an increase in protein degradation or both of these changes occurring simultaneously results in substantial muscle atrophy. This is important to clinical medicine because loss of lean body mass is associated with increased morbidity and mortality.

ACTIVATION OF THE UBIQUITIN-PROTEASOME SYSTEM IN MUSCLE

In most conditions associated with loss of muscle mass, a decrease in protein synthesis is not the principal defect causing loss of muscle protein. Instead, there is overwhelming evidence that protein degradation is accelerated. Regarding specific proteolytic pathways that degrade proteins, in muscle, like most tissues, there are several systems. The major systems are lysosomal proteases (e.g., cathepsins), calcium-activated proteases (e.g., calpains), and proteasome-mediated proteolysis (including protein degradation involving ATP and ubiquitin). In experimental animal models of conditions causing muscle atrophy, studies directed at identifying the specific proteolytic pathways that are activated to degrade muscle protein have repeatedly demonstrated involvement of the ATP-dependent ubiquitin-proteasome pathway. Protein substrates of this proteolytic system must be marked for degradation. Thus, the substrates undergo a series of reactions that covalently link ubiquitin to form a polyubiquitin chain, which serves to target proteins for degradation in the proteasome. Ubiquitin is a small protein member of the heat-shock protein family that is present in all cells. Figure 64-1 summarizes the general ubiquitin conjugation and degradation process. Subunits in the 19S regulatory "cap" complexes of the 26S proteasome recognize the polyubiquitin chain and in an ATP-dependent process, unfold the substrate protein. It is then inserted into the proteasome where other subunits remove and perhaps disassemble the polyubiquitin chains for recycling of ubiquitin. In the central chamber of the barrel-shaped proteasome, there are protease activities that utilize the hydroxyl group of threonine to perform nucleophilic attacks on the peptide bonds. The proteolytic sites recognize different amino acid motifs in the substrate protein; hence, there is trypsin-like activity, chymotrypsin-like activity, and so on. The result is a breakdown of the substrate protein into short peptide fragments that are released into the cytoplasm. Subsequently, cytoplasmic endo- and exo-peptidases complete the degradation process. Thus, the ubiquitin-proteasome system is a tightly controlled mechanism for degrading proteins; the substrate protein must first be marked by a ubiquitin chain through a complex series of conjugation reactions and the protein is degraded only after removal of the ubiquitin chain and insertion into the proteasome. A remarkable property of this system is its ability to recognize the different proteins that are destined for degradation. This is owing to the specificity of the myriad of combinations of E2 ubiquitin conjugating enzymes and E3 ubiquitin-protein ligases. The mechanisms by which these enzymes achieve specificity are under intensive investigation. One mechanism of muscle proteolysis has been shown to utilize a specific E3 enzyme, E3α. This enzyme recognizes proteins with distinct amino terminal amino acids and is known as the N-end rule pathway. However, even this process is complex because many proteins are initially modified to change the amino terminal amino acid and hence, the rate of degradation.

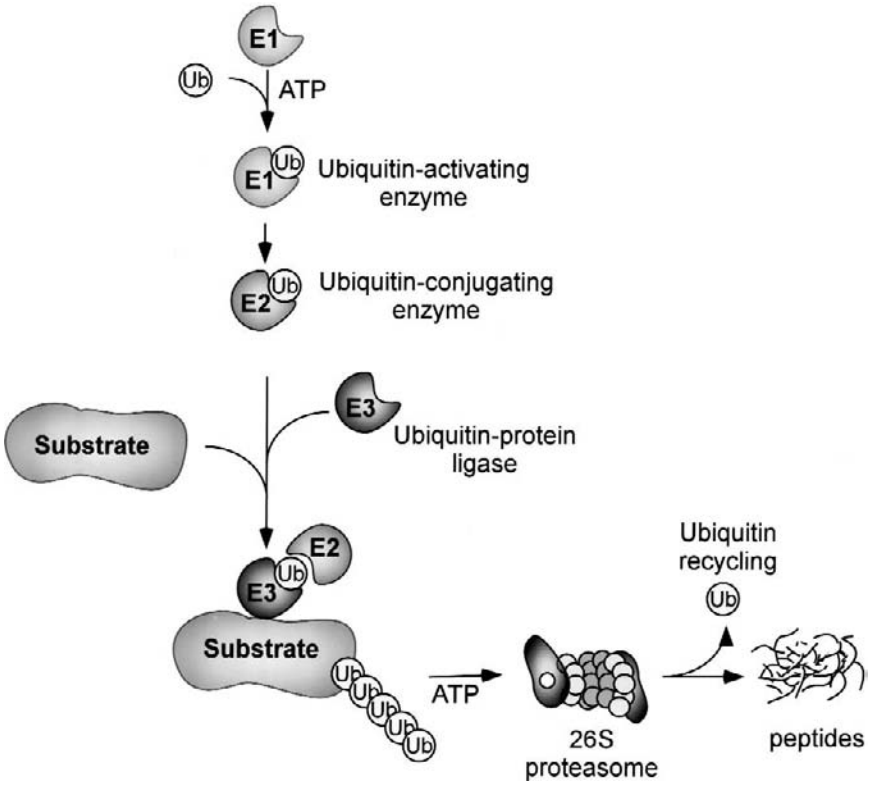

Figure 64-1 General scheme of protein degradation by the ubiquitin-proteasome system. Substrates that are degraded by the ubiquitin-proteasome system first undergo covalent addition of a polyubiquitin chain by a series of reactions that involve (1) ATP-dependent activation of ubiquitin by an E1 ubiquitin activating enzyme; (2) transfer of activated ubiquitin to the ε-NH_2 group of a lysine residue in the substrate and subsequent polyubiquitin chain formation by combinations of E2 ubiquitin conjugating enzymes and E3 ubiquitin protein ligase complexes (E3s can be monomeric or multimeric complexes). Substrate specificity is conferred by the various combinations of E2s and E3s; (3) recognition of the polyubiquitin chain by subunits of the 19*S* regulatory complex, which attaches to the end of a 20*S* core proteasome to form the 26S proteasome; and (4) unfolding, insertion and degradation of the substrate by the 26S proteasome (a process that requires ATP) to yield small peptides that are further degraded by peptidases. Ubiquitin chains are released from the protein and recycled.

Evidence that the ubiquitin-proteasome system is activated to break down muscle protein in kidney failure and other catabolic conditions comes from studies involving measurements of rates of protein degradation in isolated muscles incubated with inhibitors of the different proteolytic pathways. For example, muscles isolated from rats with chronic renal failure were incubated with inhibitors of calcium-dependent and lysosomal proteases and the rate of protein degradation was measured. With these inhibitors, there was a small and parallel decrease in the rates of protein degradation in muscles of both the chronically uremic rats and the sham-operated, pair-fed rats. However, these inhibitors did not block the accelerated rate of proteolysis stimulated by kidney failure. In contrast, when an inhibitor of the proteasome (i.e., MG132) was added or when ATP generation was blocked, the accelerated rate of protein degradation was eliminated and this occurred even in the presence of inhibitors of the calcium-activated and lysosomal proteases. Notably, the rate of protein degradation in muscles of the control rats was also suppressed to a low rate, indicating that the ubiquitin-proteasome system is responsible for the degradation of the bulk of protein in muscle. Additional evidence that the ubiquitin-proteasome system is activated in muscle of rats with various wasting conditions includes:

1. Increased conjugation of ubiquitin to muscle proteins.
2. Increased levels of the proteins that are components of the system.
3. Increased levels of mRNAs that encode ubiquitin and other component proteins of the system.
4. Return of these responses to control levels or lower when the condition causing accelerated muscle proteolysis is attenuated.

Two genes encoding ubiquitin protein ligases (i.e., E3s) have been identified in experiments based on microarray or differential display analyses of muscles undergoing atrophy. One of these proteins, muscle ring finger 1 (MuRF1 or atrogin-1), is a ring finger protein that interacts with titin, a large myofibrillar protein that has several functions. The other newly identified protein, atrogin-1 (also called muscle atrophy F-box [MAFbx]), belongs to the F-box (SCF) family of proteins that includes components of the multi-subunit skp-cullin-F box E3 ligases. Consistent with the role of the ubiquitin-proteasome system as the principal mechanism degrading muscle protein, the mRNA for atrogin-1 is specifically expressed in skeletal and cardiac muscle and its expression is increased >10-fold in muscles undergoing atrophy. Moreover, overexpression of atrogin-1 in C2C12 muscle cells resulted in thinner myotubes, reminiscent of muscle atrophy whereas muscles of mice with null alleles for either MuRF1/atrogin-1 do undergo atrophy in response to muscle denervation, but the degree of muscle wasting was attentuated in comparison with that in wild-type mice. Given the complexity of the pool of muscle proteins, it is likely that multiple ubiquitin conjugation systems are involved when the proteolytic process is accelerated.

The mechanisms leading to activation of the ubiquitin-proteasome system in conditions leading to muscle atrophy are poorly understood. For example, the "rate-limiting" step in muscle proteolysis has not been identified. Potentially important steps include:

1. Availability of muscle protein substrates because actomyosin and myofibrils are not degraded by the system, so the substrates actin and myosin must be liberated before they are degraded by the ubiquitin-proteasome system.
2. Recognition and polyubiquitination of substrate proteins by combinations of E2 and E3 enzymes acting in concert.
3. The proteolytic capacity of the cell related to changes in the levels of the many components of the system.

There are clues or insights into how catabolic signals activate this proteolytic system.

One potential clue is the frequent observation that mRNAs encoding various components of the system (e.g., ubiquitin, ubiquitin-conjugating enzymes, subunits of the 26S proteasome) are increased in each model of different conditions causing accelerated loss of muscle protein. This finding has been extended to patients with catabolic conditions (e.g., head trauma and sepsis) and includes patients with chronic renal failure. These subjects not only have evidence of muscle protein losses but also have higher levels of pathway mRNAs in muscle. At least in chronic kidney failure, removal of the catabolic stimulus, metabolic acidosis, was associated with a coordinated decrease in mRNA level for ubiquitin and muscle proteolysis suggesting the two responses are linked. Specifically, patients with end-stage renal disease receiving chronic ambulatory peritoneal dialysis were treated to remove the metabolic acidosis associated with kidney failure over 1 mo. This treatment yielded an increase in body weight and a simultaneous reduction in the level of ubiquitin mRNA in their muscle.

Several extracellular signals could accelerate proteolysis through the ubiquitin-proteasome system in muscle. In kidney failure, metabolic acidosis, and diabetes (or possibly insulin resistance), cytokines are potential signals acting directly or indirectly to stimulate muscle proteolysis and increase pathway mRNAs. Besides these mechanisms, glucocorticoids play a role because they can regulate the ubiquitin-proteasome system in muscle but their role varies depending on their level in animals. For example, when glucocorticoids are present in the high physiologic range, they are necessary for the activation of proteolysis plus the increase in pathway mRNAs in muscle, but their role is permissive because glucocorticoids require the presence of an additional catabolic signal (e.g., acidosis, cytokines, or a low level of insulin). In contrast, if rats are given pharmacologic doses of glucocorticoids, muscle atrophy does occur and levels of mRNAs encoding components of the ubiquitin-proteasome system in muscle are higher, at least transiently. The clinical relevance of glucocorticoids derives from reports that catabolic conditions upregulate the glucocorticoid signaling system in muscle; the number of glucocorticoid receptors is increased in muscle of rats with experimental sepsis following cecal ligation and puncture. Moreover, the proteolytic response in muscles was blocked by giving septic rats the glucocorticoid receptor antagonist, RU486, suggesting that a positive feedback system is activated in the muscle.

In addition to glucocorticoids, factors that stimulate expression of the components of the ubiquitin-proteasome pathway and enhance muscle protein degradation could include a decrease in muscle cell pH (or some other ion change linked to a fall in extracellular pH) or impairment of insulin signaling. There is evidence in kidney cells that acidification can activate gene transcription via specific signaling pathways. The impact of intracellular acidification in stimulating the ubiquitin-proteasome pathway was investigated by examining chronically uremic rats with the same characteristics as rats expressing accelerated muscle proteolysis and higher levels of mRNAs for the components of the ubiquitin-proteasome system in muscle. Using nuclear magnetic resonance (NMR), pH measurements were taken in the intact muscle of these rats and the pair-fed, sham-operated control rats. It was neither subnormal nor was there a delay in recovery of cell pH when the muscle was stimulated to tetany in order to drop muscle cell pH acutely. Although there could be a change in pH in some compartment of muscle that was not measured, these results do not support a direct role for changes in pH causing stimulation of the ubiquitin-proteasome pathway or transcription of genes.

It has been shown that both acidosis and kidney failure can impair insulin signaling. The latter is important because an acute decrease in insulin markedly stimulates protein degradation and the expression of mRNAs encoding components of the ubiquitin-proteasome pathway in muscle. Furthermore, studying the signals that activate muscle protein loss in acute diabetes shows that stimulation of the ubiquitin-proteasome pathway, including the increase in muscle levels of mRNAs for components of the system, was not blocked when the development of metabolic acidosis was prevented by feeding acutely diabetic rats $NaHCO_3$. The stimulation of the ubiquitin-proteasome system in acutely diabetic rats, like those with metabolic acidosis, required glucocorticoids to activate the system.

CATABOLIC SIGNALS INITIATE A PROGRAM OF TRANSCRIPTIONAL RESPONSES IN MUSCLE

Whether greater amounts of ubiquitin-proteasome pathway mRNAs arise from increased message stabilization or transcriptional activation was revealed from evaluation of nuclear run-off assays using nuclei isolated from the hindquarter muscle of rats with acute diabetes or chronic renal failure. In both cases, there was increased transcription of the ubiquitin and the proteasome C3 subunit genes in comparison with rates measured in muscles of pair-fed control rats. In L6 muscle cells, dexamethasone, a potent glucocorticoid, was found to increase the transcription of the ubiquitin (*UbC*) and proteasome C3 subunit genes, leading to increased levels of these proteins. It has also been reported that there is no difference in the rate of disappearance of ubiquitin mRNA when extensor digitorum longus muscles from septic and sham-operated control rats are incubated in the presence of actinomycin to inhibit transcription. This finding indicates that the increase in mRNA is not attributable to message stabilization or post-transcriptional events. Thus, muscle atrophying conditions activate a program of specific transcriptional responses in muscle.

Genes encoding several components of the ubiquitin-proteasome system in rodents and humans have been characterized (e.g., proteasome C3 and C5 subunits, *UbC*). Surveys of their promoter regions reveal cis-acting elements with the potential for responding to inflammatory or stress-related signals. It has also been reported that CCAAT enhancer binding proteins, (C/EBP)-β and -δ, and activator protein-1, are activated in muscle of rats with sepsis; these are the same transcription factors that mediate inflammatory responses. The role of glucocorticoids in the activation of these factors was examined by giving septic rats an oral dose of RU486, a glucocorticoid receptor antagonist. RU486 blocked the

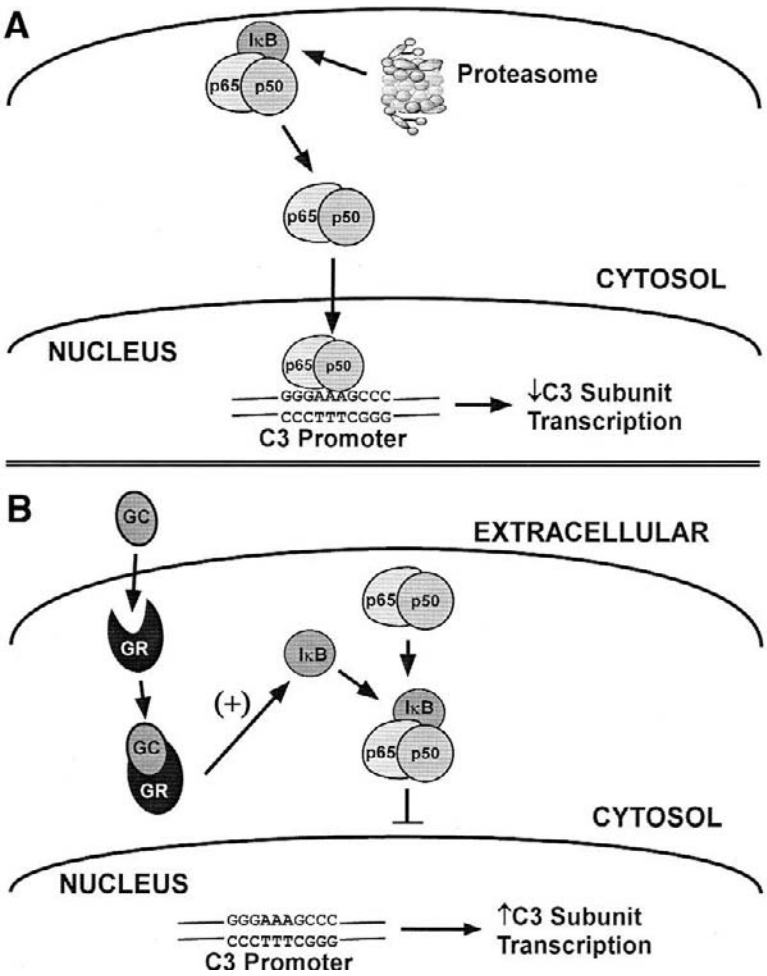

Figure 64-2 Mechanism of proteasome C3 subunit transactivation by glucocorticoids. **(A)** In muscle, NF-κB is activated by proteasome-mediated degradation of IκB, a cytosolic inhibitor protein. NF-κB then translocates to the nucleus in which it binds to sites in the C3 subunit promoter and suppresses transcription. **(B)** Glucocorticoids prevent the proteasome-mediated degradation of IκB, thus inhibiting NF-κB nuclear translocation. Sequestration of NF-κB in the cytosol results in stimulation of proteasome C3 subunit expression.

activation of C/EBP-β and -δ but did not block the activation of activator protein-1. These findings suggest that stress-related mediators play a part in activating the program of transcriptional responses in muscle occurring in response to cachectic signals.

NF-κB IS A NEGATIVE REGULATOR OF THE PROTEASOME C3 SUBUNIT EXPRESSION Glucocorticoids are potent regulators of gene expression and can influence transcription by multiple mechanisms. Investigations of the role of glucocorticoids in the transcriptional responses of the ubiquitin-proteasome system in muscle included studying the influence of glucocorticoids on the regulation of the proteasome C3 subunit in L6 muscle cells. Inspection of the human C3 proteasome subunit promoter region did not identify a classic glucocorticoid response element despite the fact that glucocorticoids-induced expression of this subunit in L6 muscle cells. However, there was a region of the C3 subunit promoter between –400 and –256 bp (+1 = transcription start site) that was essential for stimulation by dexamethasone. This region contains several nuclear factor (NF)-κB-like binding sites, notable because glucocorticoid receptors and NF-κB can exert mutually antagonistic effects to repress or activate gene transcription. Further examination of a binding site at –322/–313 using mobility shift assays revealed that incubating cells to dexamethasone for only 20 min decreased the formation of a DNA–NF-κB complex. This antagonism of NF-κB binding to the promoter region persisted for at least 24 h. Because glucocorticoids act to stimulate the transcription of the proteasome C3 subunit, these findings indicate that NF-κB must act as a repressor of C3 subunit transcription (Fig. 64-2A). Thus, glucocorticoids act to stimulate transcription by antagonizing the transrepression by NF-κB of the C3 subunit of the proteasome. This mechanism was confirmed by demonstrating that overexpressing NF-κB subunits or activating cellular production of NF-κB with cytokines reduced transcription of the C3 proteasome subunit. In contrast, blocking NF-κB activity stimulated transcription of this gene.

How do glucocorticoids antagonize NF-κB transactivation? No evidence exists for a direct interaction between the glucocorticoid receptor and NF-κB subunits nor did dexamethasone increase the transcription of inhibitor of κB (IκB). However, glucocorticoids increased the amount of IκB protein in the cytosol with a concurrent increase in the amount of cytosolic NF-κB p65 subunit, leading to the conclusion that glucocorticoids enhance proteasome C3 subunit transcription by causing a sequestration of inactive NF-κB in the cytosol (Fig. 64-2B). Subsequent studies of muscle from septic and control rats recapitulated the findings with L6 muscle

cells and confirmed that NF-κB serves as a suppressor of proteasome C3 subunit transcription in muscle of intact animals.

GLUCOCORTICOIDS INCREASE UBC TRANSCRIPTION BY A SP1-DEPENDENT MECHANISM Three independent genes (i.e., *UbA*, *UbB*, and *UbC*) encode protein products that are processed to yield "free" ubiquitin protein. Among these genes, *UbC* mRNA has typically increased the most in response to conditions causing muscle atrophy. The human *UbC* promoter region has been characterized, including a number of potential binding sites for factors that could regulate transcription. By cloning the rat *UbC* promoter, conservation of a number of the potential response elements was found, including multiple sites for NF-κB, other inflammatory class transcription factors, and specificity factor 1 (Sp1). As in the case of the proteasome C3 subunit, however, there was a conspicuous absence of consensus glucocorticoid response elements in the rat or human *UbC* promoter even though dexamethasone stimulated transcription of the *UbC* gene in L6 muscle cells. These findings prompted investigation of the cis-acting elements that confers glucocorticoid responsiveness. Initially, in vivo genomic footprinting assays were performed in L6 muscle cells to identify regions of the *UbC* promoter that undergo structural changes in response to dexamethasone. Surprisingly, these bases were located in a potential Sp1 binding site. This location suggested that dexamethasone induces a change in the binding of Sp1 and results of promoter deletion and mutational analysis coupled with mobility shift assays did show that dexamethasone increases the in vitro binding of Sp1 to a *UbC*-specific DNA probe. The importance of Sp1 in mediating the transactivation of the *UbC* promoter was confirmed when an inhibitor of Sp1 binding, mithramycin, was shown to prevent the dexamethasone-induced increase in *UbC* gene activity. Mithramycin also decreased the levels of free ubiquitin protein and ubiquitin conjugated to endogenous muscle cell proteins. Thus, it is clear that a mechanism for increased *UbC* expression by dexamethasone involves Sp1.

Sp1 has traditionally been considered a ubiquitous transcription factor involved in the basal transcription of many genes. To determine how glucocorticoids increase Sp1 binding to the *UbC* promoter, the total cellular content of Sp1 was measured and the distribution of Sp1 between the cytosol and nucleus was examined. Dexamethasone did not change the amount or distribution of Sp1 in L6 cells, suggesting that glucocorticoids do not simply augment the level of Sp1 in the nucleus. There are reports that Sp1 binding activity is modulated by phosphorylation. Moreover, activation of the p42/44 mitogen-activated protein (MAP) kinase (i.e., extracellular signal regulated kinase [ERK] 1/2) signaling pathway has been linked to increased Sp1-mediated transcription and glucocorticoids can stimulate ERK activity. Examination of the role of MAP kinase/ERK kinase (MEK)1/2, the kinases upstream of ERK, using a MEK1/2 inhibitor, U0126 revealed that treating L6 muscle cells with U0126 blocked the induction of *UbC*-driven luciferase activity by dexamethasone. In contrast, transfecting L6 cells to express constitutively active MEK1 mimicked dexamethasone by inducing *UbC* transcription. These findings demonstrate that glucocorticoids stimulate *UbC* transcription by a mechanism involving both Sp1 and MEK1. A potential signaling scheme for this response is shown in Fig. 64-3.

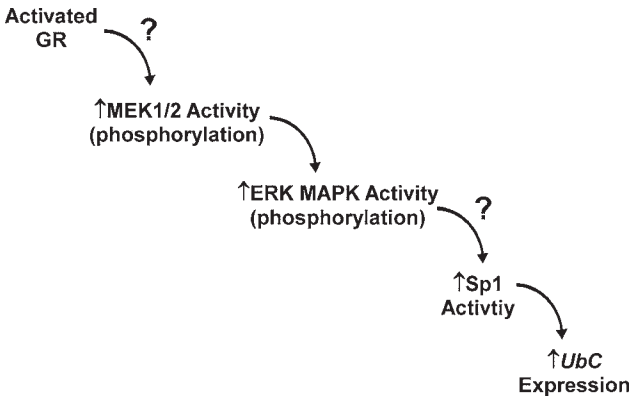

Figure 64-3 Potential mechanism of Ubiquitin C (*UbC*) transactivation by glucocorticoids. Glucocorticoids increase Sp1 binding to the *UbC* promoter. MEK1/2 is involved in the transactivation process but the mechanism is unknown. In the potential scheme shown, glucocorticoids bind to their receptor, which indirectly stimulates MEK1/2, which activates ERK1/2, resulting in the phosphorylation of Sp1. Phosphorylation of Sp1 increases its ability to bind to the *UbC* promoter, thus enhancing its transcription.

CONCLUSIONS

Studies involving a variety of models of pathological states consistently indicate that catabolic conditions causing loss of muscle protein induce a concomitant program of transcriptional responses that result in higher levels of the mRNAs that encode components of the ubiquitin-proteasome system. The transactivation mechanisms for many of these conditions have not been defined and are likely to be complex. The mechanism by which glucocorticoids induce the *UbC* and proteasome C3 subunit genes differ substantially. In the case of the proteasome C3 subunit, glucocorticoids act by antagonizing NF-κB, a suppressor of subunit transcription. Conversely, glucocorticoids induce *UbC* by increasing the binding of Sp1 and the mechanism requires components of a MAP kinase pathway linked to cell growth and survival. Although the importance of the increase in mRNAs encoding components of the ubiquitin-proteasome system in terms of proteolysis is debated, the majority of evidence indicates that catabolic signals that accelerate protein degradation via the ubiquitin-proteasome pathway initiate a program of selective transcriptional responses in muscle. The impressive concordance between studies performed with cultured muscle cells and studies involving experimental animals and patients suggests that there is strong evolutionary pressure to maintain these "stress"-related responses. Understanding the mechanisms leading to activation of transcription could lead to improved methods of preventing the loss of muscle protein.

65 Mechanisms of Renal Allograft Rejection

Daniel R. Goldstein, Anirban Bose, and Fadi G. Lakkis

SUMMARY

The immune response to donor antigens leads to the rejection of transplanted organs. The earliest event in this response is the activation of the innate immune system. Innate activation culminates in the migration of antigen presenting cells to the recipient's secondary lymphoid tissues where they trigger the adaptive immune response. The principal events of this response are the activation of T and B lymphocytes, which generate effector cells that inflict immediate damage. Adaptive immunity also produces long-lived memory lymphocytes that cause either acute or chronic rejection. Here, we will summarize the cellular and molecular mechanisms of the innate and adaptive responses that lead to graft rejection.

Key Words: Adaptive immunity; antigen presenting cells; B cells; cytokines; innate immunity; lymphocytes; memory; natural killer cells; rejection; T cells; transplantation.

INTRODUCTION

Transplanting an organ from one member of a species into a nonidentical member of the same species results in a donor-specific immune response referred to as alloimmunity. If left untreated, alloimmune responses lead to the rejection of the transplanted organ (the allograft). The central mediator of the alloimmune response is the T lymphocyte. On activation by donor antigens (alloantigens) presented on antigen-presenting cells (APCs), allospecific T lymphocytes proliferate and differentiate into effector cells or provide help to other cells that inflict damage on the allograft. This chapter provides an overview of the cellular and molecular mechanisms underlying the immune response that leads to allograft rejection.

OVERVIEW OF THE ALLOIMMUNE RESPONSE

The alloimmune response, like any other immune response to a foreign antigen, occurs in two broad phases: the innate and adaptive phases (Fig. 65-1). In the innate phase, inflammation in the transplanted organ activates APCs and induces their maturation and migration to secondary lymphoid organs (the spleen and lymph nodes). The adaptive immune response is initiated when APCs activate antigen-specific T cells within secondary lymphoid organs leading to effector cell generation and their migration to the allograft where they mediate rejection. The majority of effector T cells eventually undergoes apoptosis and the few that survive become long-lived memory T cells that endanger the survival of a subsequent organ transplant.

Before describing the molecular and cellular mechanisms of the innate and adaptive immune responses to a transplanted organ, it is important to define "alloantigen." The principal non-self-antigens responsible for initiating alloimmune responses are the major histocompatibility complex (MHC) proteins, known as human leukocyte antigens (HLAs) in man. MHC proteins are encoded by a family of highly polymorphic genes and are divided into two classes. MHC class-I antigens are expressed on the vast majority of nucleated cells whereas MHC class-II antigens are expressed primarily on APCs such as dendritic cells (DCs), macrophages, and B-lymphocytes. MHC class-II expression is also induced on activated T cells and, in humans, on endothelial cells. The physiologic function of MHC molecules is to bind antigenic peptides and present them to T lymphocytes. In fact, the T-cell receptor for antigen (TCR) does not interact with whole antigens but instead recognizes small antigenic peptides bound to the grooves of MHC molecules present on APCs. In general, exogenous antigens (e.g., circulating foreign proteins) are taken up by APCs, degraded within endocytic vesicles, and presented by class-II molecules, whereas endogenous antigens (e.g., viral proteins produced within the cell cytosol) are presented by class-I molecules. The highly polymorphic MHC ensures that humans mount immune responses against a wide array of pathogens. Unfortunately, the same polymorphism forms the basis of tissue incompatibility between members of the same species. T cells of one individual recognize the non-self-MHC present on another individual's tissues as foreign, leading to the phenomenon of transplant rejection. In addition to MHC, non-MHC polymorphic molecules, known as minor histocompatibility antigens, also initiate alloimmune responses. Single or multiple minor histocompatibility differences between the donor and the recipient lead to the rejection of MHC-matched organs. A classic example of minor histocompatibility antigens is the HY antigen expressed on male but not female cells.

THE INNATE IMMUNE RESPONSE TO A TRANSPLANTED ORGAN

CELLULAR AND MOLECULAR COMPONENTS OF INNATE IMMUNITY The innate immune system acts as "the first line of defense" against foreign antigens, whether an allograft or an invading microbial pathogen. The cellular components of this phase of the immune system consist of APCs such as DCs and macrophages, natural killer (NK) cells, and neutrophils. These cells reside in

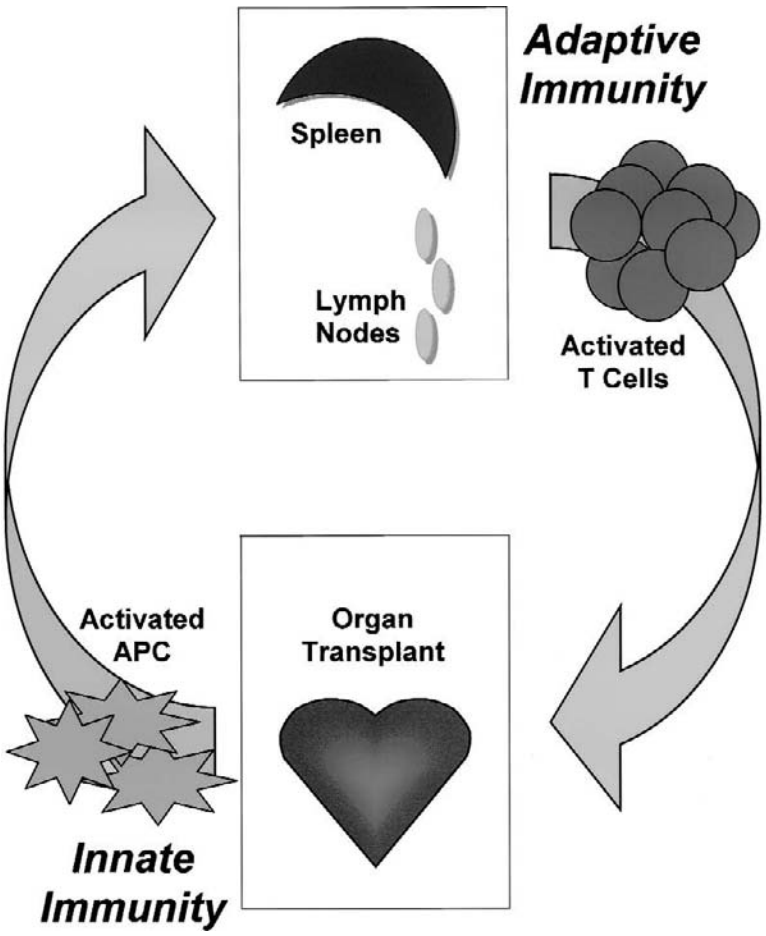

Figure 65-1 Innate and adaptive immune mechanisms lead to allograft rejection. Ischemia-reperfusion injury and inflammation in a newly transplanted organ activates APC, which then migrate to secondary lymphoid organs (the spleen and lymph nodes). In the secondary lymphoid organs, APC activate antigen-specific T cells, which then differentiate into effector cells that migrate to the allograft and cause its rejection.

tissues and are activated, in an antigen-nonspecific manner, by local inflammation that is induced by infections and other noxious stimuli. A set of innate immune receptors, toll-like receptors (TLRs), plays a central role in innate immunity. These receptors are germline-encoded, transmembrane, and intracellular receptors that are critical for the detection of microbial pathogen products, often referred to as pathogen-associated molecular patterns (PAMPS). PAMPS include bacterial lipopolysaccharide, lipoproteins, peptidoglycans, flagellin, and unmethylated cytosine-guanine (cPG) nucleic acids. TLRs are a form of pathogen recognition receptors that are expressed by APCs. To date, at least 10 TLRs have been identified with individual specificity for different microbial products. Once ligated by PAMPS, TLRs initiate a signaling pathway via the universal signal adaptor protein, MyD88, which induces the translocation of nuclear factor-κB and the expression of proinflammatory cytokines (tumor necrosis factor-α, IL-1, 6, 8, and 12). These cytokines induce DCs to mature, migrate to the draining secondary lymphoid tissues, and express surface proteins essential for T-cell costimulation (such as CD40, CD80, and CD86). In secondary lymphoid organs, DCs activate naïve T cells, thus initiating the adaptive phase of the immune response.

INNATE IMMUNITY IN TRANSPLANTATION Evidence supports the concept that TLRs can be activated by pathogen-unrelated, endogenous signals such as heat-shock proteins, heparan sulfate, surfactant, and the contents of necrotic cells. Therefore, it is possible that TLRs may play a role in initiating the immune response to a transplanted organ. Consistent with this hypothesis, investigators have demonstrated that rejection of minor mismatched (HY antigen-mismatched) skin allografts is critically dependent on signaling via MyD88, the adaptor protein required for TLR signaling. Specifically, they demonstrated that female mice that had no MyD88 were not able to reject male allografts from MyD88-deficient donors. Furthermore, the inability to reject these allografts was owing to reduced accumulation of mature DCs in draining lymph nodes and impaired expansion of antigraft-reactive T cells. Thus, the initiation of the alloimmune response to minor mismatched transplant antigens is dependent on innate immune mechanisms that trigger the maturation and migration of APCs. It is not clear whether the rejection of fully MHC-mismatched allografts also depends on TLR signaling via Myd88. In addition, the nature of the ligands that stimulates TLRs in the transplant setting is not known.

The role of other cellular components of the innate immune response (monocyte/macrophages, neutrophils and NK cells) has also been investigated in murine transplantation models. None of these cellular components has been found to be indispensable for the rejection of either allografts or xenografts. However, studies have shown that graft infiltration with these cell types precedes T-cell infiltration, consistent with the idea that they may orchestrate effector T-cell migration and function. For example, NK cells activated

by non-self-antigens secrete interferon (IFN)-γ, which stimulates local production of chemokines that recruit APCs and effector T cells to the site of inflammation.

Soluble components of innate immunity have also been investigated in the rejection of vascularized allografts. The complement system, a set of plasma proteins used to attack extracellular pathogens, has been shown to be critical for the rejection of renal allografts in mice. Specifically, donor allografts that were deficient in C3, a critical protein for complement activation, underwent significantly delayed allograft rejection compared to wild-type donor allografts. If the recipients were C3-deficient, wild-type allografts were rejected in a normal tempo demonstrating that local expression of complement within the graft is important for the rejection process. However, it is not clear whether complement activation plays a role in initiating the immune response (e.g., by activating and mobilizing APCs) or in the effector phase of rejection (e.g., by enhancing the recruitment of effector T cells). The complement cascade is also critical in hyperacute rejection of vascularized allografts and xenografts. In this case, recipients have preformed antibodies against donor transplant antigens. A classic example is the hyperacute rejection of ABO-incompatible allografts, whereby preformed antibodies deposit on the donor endothelium and initiate the complement cascade leading to platelet activation, thrombin deposition, and hemorrhagic infarction of the organ.

THE ADAPTIVE IMMUNE RESPONSE TO A TRANSPLANTED ORGAN

The first stage in the adaptive phase of the alloimmune response is the activation of alloreactive T cells by APCs. This process occurs within the organized structures of secondary lymphoid organs (the spleen, lymph nodes, and mucosal lymphoid tissues). On activation, antigen-specific T cells begin to expand in a logarithmic fashion (the expansion phase) and acquire effector functions that allow them, with the help of B-lymphocytes and other mononuclear cells, to eliminate the foreign antigen (the effector phase). T-cell expansion, however, does not continue indefinitely but quickly halts as autoregulatory mechanisms to ensure that most effector T cells generated during the immune response are eliminated by apoptosis (the regulatory phase). The few T cells that survive the death phase become long-lived memory T cells that confer life-long protection against the foreign antigen (the memory phase). There are cellular and molecular mechanisms underlying the stages of the adaptive immune response to a transplanted organ.

THE EXPANSION PHASE OF THE ALLOIMMUNE RESPONSE

Allorecognition Foreign transplant antigens (alloantigens) are recognized by and activate recipient T lymphocytes via two pathways (Fig. 65-2). In the direct pathway, the recipient's T lymphocytes are triggered by alloantigens expressed on *donor* APCs, commonly referred to as passenger leukocytes, which migrate out of the transplanted organ to the host's secondary lymphoid tissues. These alloantigens are intact allo-MHC molecules complexed to endogenous peptides derived from either histocompatibility antigens or from conserved proteins common to all members of the same species (self-peptides). It is the polymporphic MHC in the latter case that confers "foreignness" to the MHC-peptide complex and leads to the activation of alloreactive T cells. In the indirect pathway, alloantigens are shed by donor cells, taken up and processed by *recipient* APCs, and presented to recipient T lymphocytes in the groove of self-MHC molecules. Although the direct pathway appears to mount a more vigorous immune response, either pathway of allorecognition is sufficient for graft rejection.

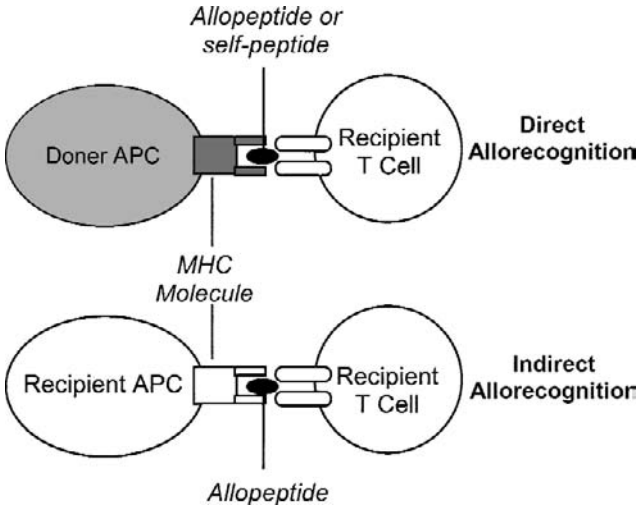

Figure 65-2 The direct and indirect pathways of allorecognition. Both pathways contribute to the initiation of the alloimmune response. However, the direct pathway leads to a more robust immune response by activating a larger number of T cells.

The prevailing view had been that T-cell activation occurs within the transplanted organ and does not require the presence of secondary lymphoid organs. However, studies have challenged this point. Investigators found that mice that lacked all secondary lymphoid organs (splenectomized alymphoplastic mice) did not reject fully vascularized heart allografts but ignored them as if they were self. Using different mutant strains of mice (splenectomized, lymphotoxin-α ($LT\alpha^{-/-}$), and lymphotoxin-β receptor ($LT\beta R^{-/-}$)-deficient mice), other investigators found that allograft rejection was severely delayed in the absence of secondary lymphoid organs although it did eventually occur. The discrepancy between these two studies may be owing to the differences in the mutations present in the recipient mice. Both the $LT\alpha^{-/-}$ and the $LT\beta R^{-/-}$ mice have accumulations of CD4 T cells that may be already activated and thus not require the presence of secondary lymphoid organs to initiate allograft rejection. Nonetheless, both studies demonstrate that secondary lymphoid organs are important for initiating the adapting alloimmune response. Homing of activated APCs to the spleen and draining lymph nodes following transplantation is guided by the chemokine receptor CCR7 and its ligand, secondary lymphoid chemokine. SLC is expressed on the endothelium of the afferent lymphatic system, including high endothelial venules in lymph nodes, where it directs the entry of both activated APCs and naïve T cells. APC–T cell interaction within the T cells' zones of secondary lymphoid organs then initiates the alloimmune response.

T Lymphocyte Activation The first event in APC–T cell interaction that leads to T-cell activation is the binding of the TCR to the MHC–peptide complex on the APC (Fig. 65-3). The ability of the TCR to trigger intracellular signaling in T lymphocytes is dependent on the TCR 2 (TCRz) chain and on noncovalent interactions with the membrane molecule CD3 (Fig. 65-3). The intracellular signaling pathways initiated by the TCRz chain and CD3 include protein kinases, phospholipases, and calcineurin, which is a calcium-dependent protein phosphatase. The clinically important immunosuppressive agents, cyclosporine and tacrolimus, exert their immunosuppressive effects by inhibiting calcineurin

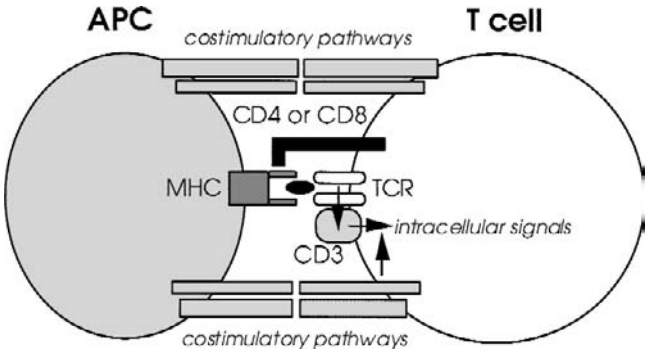

Figure 65-3 T cell activation. Recognition of the foreign MHC–peptide complex by the TCR is the first step in T-cell activation, often referred to as signal 1. The TCR is dependent on the accessory molecule CD3 to deliver intracellular signals that are necessary but not sufficient for triggering T cell proliferation. Additional stimulation, often referred to as signal 2, is required for T-cell proliferation and is delivered by costimulatory molecules present on T cells. Costimulatory molecules are engaged by counter-receptors expressed on activated APCs.

action. The CD4 and CD8 molecules, expressed on the surface of distinct T cell types, often referred to as CD4 helper (Th) and CD8 cytotoxic T lymphocytes (CTL), bind to nonpolymorphic regions of MHC class-II and -I molecules, respectively, and enhance signaling via the TCR-CD3 complex (Fig. 65-3).

TCR-CD3 interaction with the foreign MHC-peptide complex, however, is not sufficient for T-cell proliferation and differentiation into helper or cytotoxic cells. Additional help has to be provided by costimulatory molecules expressed on T lymphocytes (Fig. 65-3). The ligands for costimulatory molecules are present on professional APCs. These costimulatory pathways contribute to the formation of a tight "immunological synapse" between APCs and T lymphocytes. The synapse guarantees that TCR engagement by the MHC-peptide complex is sustained long enough to induce T-cell proliferation. Others have argued that costimulatory molecules provide intracellular signals that are distinct from those delivered by the TCR.

Although many costimulatory molecules have been identified, the ones that are well studied and proven to be critical for the induction of alloimmunity are CD28 and the CD40 ligand (CD40L or CD154). During APC-T cell interaction, B7-1 (CD80) and B7-2 (CD86) on APCs bind to CD28 on the surface of resting T lymphocytes. CD28 crosslinking facilitates T-cell activation by recruiting membrane and intracellular kinase-rich raft microdomains to the site of TCR engagement, resulting in enhanced and sustained TCR-CD3 signaling followed by increased IL-2 production and T-cell proliferation. Proof that the CD28-B7 costimulatory pathway is critical for allograft rejection derives from studies showing markedly prolonged allograft survival in experimental animals treated with CTLA4Ig, a recombinant fusion protein that binds B7-1 and B7-2 with high affinity and prevents their interaction with CD28. Unlike CD28, the costimulatory molecule CD40L is expressed only on activated T lymphocytes. Its counter-receptor, CD40, is a glycoprotein present on the surface of professional APCs and endothelial cells. Studies indicate that the crosslinking of CD40 by CD40L mediates the immunologic functions of this costimulatory pathway. First, CD40 engagement on DCs upregulates B7-1 and B7-2 expression and induces IL-12 production. These activation steps enhance the ability of DCs to induce the proliferation of CD4+ T cells and the differentiation of CD8+ T cells into CTL. Second, CD40 ligation on B-lymphocytes by T cells is essential for the generation of adaptive humoral immune responses characterized by immunoglobulin isotype switching from IgM to IgG. Third, CD40 ligation on monocytes or macrophages by T cells augments their pro-inflammatory activities, and CD40 engagement on endothelial cells by T cells upregulates cell adhesion molecules, which are essential for the migration of leukocytes into sites of inflammation. That the CD40L–CD40 costimulatory pathway plays a crucial role in allograft rejection is demonstrated by studies showing that monoclonal antibodies, which block CD40L–CD40 interaction, significantly prolong allograft survival in rodents and nonhuman primates. CD28 and CD40L are not the only costimulatory molecules present on T lymphocytes. Other membrane proteins such as 4-1BB, ICOS, OX40L, and CD70L provide costimulation for T cells, and murine studies indicate that allograft survival can be prolonged by blocking the binding of these molecules to their ligands on APCs.

Cytokines Cytokines produced by APCs and activated alloreactive T lymphocytes act in an autocrine or paracrine fashion to enhance APC functions, T-cell proliferation, and T-cell differentiation into effector cells. The role of cytokines in allograft rejection has been largely inferred from their in vitro functions and from in vivo experiments in which cytokine expression is correlated with acute rejection. These studies however have led to contradictory results owing to the complexity of cytokine cascades triggered after transplantation. In vivo experiments using cytokine gene-knockout mice and cytokine-neutralizing antibodies point to two main conclusions: (1) cytokine actions are highly redundant; and (2) a single cytokine may have multiple actions and thus, influence the activation, effector, and regulatory phases of the alloimmune response. The redundancy phenomenon is supported by data showing that cytokine gene-knockout mice that lack IL-2, IL-4, or IFN-γ reject allografts vigorously, despite the fact these cytokines have indispensable immunostimulatory functions in vitro. One important exception to cytokine redundancy is that IFN-γ is necessary for the acute rejection of MHC class-II-incompatible allografts. This unique requirement for IFN-γ in the rejection process can be attributed to its essential role in inducing or upregulating MHC class-II expression on APCs and endothelial cells. The observation that a single cytokine could have multiple and sometimes opposing actions derives from experiments showing that immunostimulatory cytokines such as IFN-γ and IL-2 also have essential immunoregulatory roles in vivo. For example, IL-2 is a T-cell mitogen that also programs T lymphocytes for apoptosis. The absence of IL-2 in vivo does not lead to immunodeficiency but, instead, results in the accumulation of activated T lymphocytes, autoimmunity, and failure to accept allografts longterm.

THE EFFECTOR PHASE OF THE ALLOIMMUNE RESPONSE

The effector pathways that lead to allograft rejection involve a multiplicity of mechanisms, classified here according to the principal cell type that is responsible for tissue destruction.

Cytotoxic T Cells CD8+ CTL recognize their targets in a MHC-restricted, antigen-specific manner. The end-result of the interaction between a CTL and an allograft is the apoptosis of target cells. Two pathways of apoptosis have been described. In the first, activated CD8+ T cells synthesize perforin and granzymes that are then stored in intracellular granules. This transformation is assisted by IFN-γ and IL-2 secreted by CD4+ Th cells. On contact with alloantigen presented in the context of MHC class-I molecules, the granules release their contents, and perforin forms pores in the target cell membrane. In addition to their ability to cause

osmotic lysis of target cells, perforin-induced pores allow granzymes, a family of proteases released simultaneously with perforin from CTL granules, to enter the cytoplasm where they cause the release of cytochrome c from the mitochondria and trigger target cell apoptosis. In the second pathway, CTL induce target cell apoptosis via the FasL-Fas pathway. Fas, a member of the tumor necrosis factor (TNF) family of death receptors, is constitutively expressed on most cells whereas FasL is expressed on T cells following their activation. The binding of FasL on the CTL to Fas on the target cell leads to apoptosis via caspase-dependent pathways.

Although perforin, granzymes, and FasL appear to be necessary components of the killing machinery in vitro, their role in acute allograft rejection in vivo is not obligatory. Mice that lack either perforin or FasL reject allografts at the same rate as their wildtype counterparts. The nonobligatory roles of these cytotoxic molecules point to the redundancy of the system. This may occur because of the presence of other cytotoxic molecules, for example TNF-related apoptosis inducing ligand (TRAIL), or because other cell types mediate allograft rejection in the absence of CTL-mediated cytotoxicity.

Monocytes and Macrophages Monocytes that infiltrate an organ transplant differentiate into macrophages that participate in graft rejection. They form an integral part of the infiltrate that characterizes delayed type hypersensitivity (DTH) responses. DTH responses are orchestrated by CD4+ T cells. Activated CD4+ T lymphocytes stimulate macrophages via the CD40L-CD40 pathway and by secreting IFN-γ and lymphotoxin. Macrophages then release a host of mediators that include cytokines (TNF, IL-1, 6, 10, 12, and 15), chemokines, reactive oxygen species, nitric oxide, proteolytic enzymes, and extracellular matrix proteins that lead to fibrosis. Nitric oxide can be cytotoxic by itself at sufficiently high local concentrations. TNF induces expression of adhesion molecules on endothelial cells, enhances intravascular thrombosis, and activates neutrophils, eosinophils, and macrophages. Like TNF, IL-1 mediates local tissue inflammation. IL-6 stimulates the growth of activated B-cells at a late stage in their differentiation into plasma cells. IL-12 induces IFN-γ production by NK and T cells and enhances the generation of CTLs. IL-15 serves as a mitogen to NK and T cells, particularly CD8+ memory T cells.

Natural Killer Cells NK cells are a lymphocyte subset, which expresses neither T- nor B-lymphocyte markers. They are activated by IL-2, IL-15 and type-1 IFNs. They release IFNγ on stimulation by IL-12. IFN-γ in turn induces chemokine secretion by cells of the graft, particularly endothelial cells, leading to the recruitment of more activated T cells. Inflammatory chemokines shown to play a significant role in allograft rejection include CXCR3 ligands (IP-10, MIG, and I-TAC) and to some extent CCR5 ligands (the MIP-1 family of chemokines). Like CTLs, NK cells kill target cells by releasing perforins and granzymes. In addition, they secrete TNF, which induces apoptosis of cells expressing the TNF receptor. NK cells recognize their target cells in two different ways. First, by expressing low affinity receptor for the constant (Fc) portion of IgG, they bind to and kill antibody-coated target cells (antibody-dependent cell-mediated cytotoxicity or ADCC). Second, NK cells also express receptors that recognize MHC class-I molecules complexed to self peptides. Many of these receptors, however, are inhibitory such that NK cells are shut down when they engage self MHC proteins. This implies that NK cells react to non-self by recognizing the absence of self-peptides in the grooves of MHC class-I molecules. Although NK cell depletion does not significantly alter acute rejection, they may play a subtle role in chronic rejection.

B Cells and Alloantibodies Antibodies directed against donor HLA molecules (alloantibodies) pose the greatest threat to a transplanted organ. Alloantibody generation is generally the consequence of sensitization. Sensitization occurs in patients who have been previously exposed to human HLA proteins in the form of transfusions, pregnancy or prior organ transplants. B cells that recognize specific HLA molecules via their B-cell receptor for antigen (membrane-bound immunoglobulins), internalize the HLA-antibody complex, cleave it into allopeptides, and present it in the context of MHC class-II molecules to CD4+ T cells. The production of IL-2, IL-4, and IL-5 by activated CD4+ T cells and T–B interactions via CD40–CD40L leads to B-cell maturation, proliferation, isotype switching, and the production of harmful alloantibodies. The most dramatic example of antibody-mediated allograft damage is hyperacute rejection, initiated by preformed donor-specific antibodies present in the recipient at the time of transplantation. Preformed antibodies that cause hyperacute rejection include anti-ABO and anti-HLA IgG antibodies, particularly those targeted against class-I HLA. Complement and coagulation cascades are activated leading to widespread endothelial damage, intravascular thrombosis, and graft necrosis. Alloantibodies cause tissue damage by activating the complement cascade or by mediating ADCC. In nonsensitized recipients, humoral rejection has been described as a cause of both acute and chronic rejection, but their relative importance is not known. B-cell-deficient mice, for example, are capable of vigorous acute allograft rejection. Chronic transplant arteriosclerosis, on the other hand, does not develop in B-cell-deficient mice, suggesting that alloantibodies play an important role in chronic rejection. In humans, humoral renal allograft rejection is diagnosed by staining for the complement component C4d in biopsy specimens.

Eosinophils Eosinophils are recruited into the allograft by the cytokines IL-4, 5, and 13, which are produced by Th2-type CD4+ T cells. Th2-mediated cellular rejection can occur in experimental models in the absence of CD8+ or CD4+ Th1 cells and is characterized by an eosinophilic infiltrate. The clinical significance of this finding is not known, but hypereosinophilia has been reported to precede acute rejection, and activated eosinophils and IL-5 expression have been observed in acutely rejecting allografts.

THE REGULATORY PHASE OF THE ALLOIMMUNE RESPONSE Expansion of antigen-specific lymphocytes and their differentiation into effectors in response to foreign antigen is followed by rapid clonal contraction. Deletion of the majority of activated/effector lymphocytes ensures that collateral damage to the host does not occur during immune responses. Elimination of the antigen that initially triggered lymphocyte stimulation is the ultimate means by which primary immune responses are terminated. Several down-regulatory mechanisms, however, participate in cases of large or persistent antigen loads such as a transplanted organ. These mechanisms include cell surface molecules and cytokines, which regulate proliferation and survival of activated T lymphocytes. There is also evidence that regulatory T cells that suppress immune responses may exist.

Activation-Induced Cell Death Apoptosis of activated and effector T cells is perhaps the most conspicuous means by which immune responses are regulated. Repeated stimulation of T lymphocytes by antigen results in the apoptosis of activated T cells instead of their continued proliferation. This phenomenon is known as antigen- or activation-induced cell death (AICD). AICD is in large part mediated by interaction between the cell surface

molecule Fas (CD95), a "death" receptor, and its ligand (FasL). Antigenic stimulation upregulates Fas expression and induces *de novo* FasL expression on T lymphocytes. FasL-Fas binding then leads to apoptosis of activated T lymphocytes. Other membrane molecules that trigger T cell apoptosis include members of the TNF receptor (TNFR) family such as CD30, TNF receptor-related apopotosis-mediating protein, and the TRAIL receptor (DR4).

Among cytokines that act on T cells, IL-2 is essential for AICD, a function not shared by other T cell mitogenic cytokines such as IL-4, 7, 9, and 15, which also engage the common cytokine receptor γ-chain (γc). Although IL-2 is a potent mitogen to resting CD4+ and CD8+ T lymphocytes, it programs these cells to undergo apoptosis when restimulated with antigen. It does so by upregulating death-transducing receptors such as Fas and TNFR and by downregulating death-inhibiting molecules such as FLIP and γc. IL-2-deficient mice are not capable of long-term allograft acceptance because of impaired alloantigen-induced apoptosis of activated T cells. Similarly, allograft acceptance cannot be achieved in IFN-γ-deficient mice because of exaggerated T-cell expansion in response to alloantigen. It is still debated whether IFN-γ regulates immune responses by promoting alloantigen-induced apoptosis of activated T cells, by limiting their proliferation, or both. The cytotoxic molecule perforin also contributes to the apoptosis of activated T cells by effecting the suicide or fratricide of both CD8+ and CD4+ T cells. Perforin gene-knockout mice have dysregulated immune responses and are unable to accept allografts even with potent immunosuppression.

Inhibition of T-Cell Proliferation and Differentiation Another mechanism by which immune responses are regulated is the inhibition of T-cell proliferation. The T-cell surface molecule CTL antigen-4 (CTLA4 or CD152) has emerged as an important inhibitor of activated T-cell proliferation. CTLA4 is homologous to CD28 and shares the same ligands, B7-1 and B7-2. Unlike CD28, CTLA4 is expressed on the plasma membrane only on activated T cells, has a much higher affinity to B7 proteins, and delivers a negative signal that turns off the proliferation of activated T cells. Thus, early in the immune response B7-1 and B7-2 interact with CD28 receptors on naïve T cells to effect costimulation, whereas later the high-affinity interaction between B7 proteins and CTLA4 on activated T cells leads to inhibition of cell cycling. The CTLA4-B7-negative feedback pathway is essential for the optimal induction of peripheral tolerance to protein antigens and to transplanted organs. A regulatory cytokine of paramount importance, TGFβ, is a potent inhibitor of activated T-cell differentiation into effector cells. TGFβ has been shown to downregulate alloimmune responses in several murine transplantation models.

Suppressor T Cells There has been an explosive resurgence of the concept that regulatory/suppressor T cells that modulate immune responses exist. The most commonly described suppressor phenotype is the CD4+ T cell constitutively expressing CD25+ on its surface, often referred to as Treg. Other regulatory populations have also been described, including Tr1 cells that seem to suppress immune responses by secreting TGF-β and IL-10. In addition, CD8+ regulatory/suppressor T cells may exist. CD4+CD25+ Treg cells appear to mediate their suppressive effects by direct cell–cell interaction but the exact mechanism by which they inhibit the proliferation of other T cells is not known. An increasing body of evidence suggests that Treg have a role in maintaining self-tolerance, neonatal tolerance, and long-term allograft acceptance. A transcriptional regulator, Foxp3, which is uniquely associated with Treg has been identified. Genetic deletion of Foxp3 leads to absence of Treg and massive expansion of autoreactive, pathogenic T cells. The generation of suppressor T-cell clones may be the result of interaction of naïve T cells with immature DCs or the elusive plasmacytoid DC, DC2.

Table 65-1
Advantages of Memory T Cells Over Naïve T Cells

Characteristic	*Naïve T cell*	*Memory T cell*
Survival	Months to years Dependent on TCR interaction with MHC/antigen	Years to lifetime Not dependent on TCR interaction with MHC/antigen
Migration	Secondary lymphoid tissues	Both lymphoid and nonlymphoid tissues
Response and effector function	Requires stimulation with antigen	Requires restimulation with antigen but is faster and larger in magnitude than naïve T cells
In vivo protection against foreign antigen	Long-lived but relatively inefficient	Long-lived and efficient

AICD, activation-induced cell death; MHC, major histocompatibility complex; TCR, T-cell receptor for antigen.

THE MEMORY PHASE OF THE ALLOIMMUNE RESPONSE

A cardinal feature of the adaptive immune response is the generation of memory lymphocytes. Although the vast majority of effector T cells undergoes apoptosis as the primary immune response dissipates, few lymphocytes survive to become long-lived memory T cells. Memory T cells that recognize microbial antigens provide the organism with long-lasting protection against potentially fatal infections. Conversely, memory T cells that recognize donor alloantigens jeopardize the survival of life-saving organ transplants by mediating both acute and chronic rejection.

Memory T cells have several inherent advantages over their naïve counterparts that endow them with the ability to clear a foreign antigen, whether a microbial pathogen or an allograft, in a vigorous fashion (Table 65-1). The first advantage is that their response to a foreign antigen (recall response) is greater in magnitude and faster than the naïve T-cell response. Memory T cells generate a considerable number of effector T cells, capable of cytokine secretion cytolytic activity, or both, within hours of antigenic restimulation, whereas naïve T cells generate a smaller number of effectors at a much slower pace (days). Second, memory T cells have a survival advantage over their naïve counterparts. Antigen-specific memory T-cell populations persist for years to lifetime in humans and their survival appears to be antigen- and MHC-independent. Mature naïve T-cell populations also persist for a relatively long period of time (months to few years in humans) but their survival is dependent on constant, low-grade stimulation with MHC–self-peptide complexes. Third, the circulation of naïve T cells is restricted to secondary lymphoid tissues, the site where they are activated by foreign antigens presented by APC; memory T cells circulate through both secondary lymphoid tissues and peripheral nonlymphoid tissues. Unlike naïve T cells, memory T cells can directly encounter foreign antigen and mount a productive immune response within nonlymphoid tissues. The migratory advantage of memory T cells, therefore, allows them to detect and eliminate a foreign intruder substantially before it reaches secondary lymphoid tissues. The activation, survival, and migration advantages of memory T cells

confer the organism with enhanced protection against foreign antigens long after the primary immune response has dissipated.

The same advantages of memory T cells that make them efficient at eliminating microbial pathogens enable them to rapidly reject foreign tissues. Unlike inbred mice, outbred animals including humans, harbor a significant number of memory T cells that are alloreactive. These memory T cells generally arise if an individual is exposed to alloantigens via pregnancy, blood transfusion, or a previous organ transplant. However, alloreactive memory T cells also exist in individuals who have never been exposed to foreign tissues. It is proposed that such alloreactivity in the T-cell memory pool is caused largely by cross-reactivity; repeated exposure to viral and bacterial antigens over time leads to the development of memory T cells that also recognize alloantigens. This phenomenon, commonly referred to as heterologous immunity, has been demonstrated in murine infection models, and is supported by experimental findings in humans. Alloreactive memory T cells, whether generated by previous exposure to alloantigens or microbial infection, can cause acute and chronic rejection and interfere with the induction of immunologic tolerance (donor-specific unresponsiveness).

CONCLUSIONS

Despite advances in understanding the cellular and molecular mechanisms of allograft acceptance, long-term survival of transplanted organs remains an important clinical challenge. Moreover, transplantation tolerance and allograft acceptance in the absence of continuous immunosuppression have been elusive clinical goals. The reason for these seemingly insurmountable challenges stems from the properties of the alloimmune response. These properties include the large number of alloreactive T cells present in a given individual, the limitations of immunoregulatory mechanisms responsible for turning off the alloimmune responses, and the fact that immune responses to foreign antigens, by virtue of evolutionary design, are destined to generate immunologic memory. The latter property is perhaps the most formidable obstacle to long-term allograft acceptance and transplantation tolerance. Therefore, an important but unmet challenge in clinical transplantation is whether selective deletion or suppression of alloreactive memory T cells can be accomplished without globally compromising the host's immune system.

66 Muscle Development and Differentiation

Eric N. Olson

SUMMARY

Skeletal muscle is formed through the differentiation and fusion of myoblasts into a multinucleated syncytium. Advances in molecular biology techniques and the generation of transgenic mouse models have contributed to the identification of the molecular pathways involved in skeletal muscle growth and differentiation. During embryogenesis, the specification and development of the myogenic lineage is determined by the spatiotemporal expression of a family of muscle-specific transcription factors. Understanding the molecular mechanism controlling skeletal muscle development may lead to new insights into therapeutic strategies that may alleviate some of the pathological conditions associated with muscular diseases.

Key Words: bHLH proteins; growth factors; MEF2 proteins; MRF4; Myf5; myoblast; MyoD; myogenin; myogenesis; skeletal muscle; somites.

INTRODUCTION

Vertebrate species contain dozens of different skeletal muscles, each with unique positions, sizes, shapes, contractile properties, and patterns of innervation. Dramatic progress has been made toward understanding the genetic pathways that control the formation and patterning of skeletal muscle during embryogenesis. The discovery of several families of genes that act at different steps in the developmental pathway leading to skeletal muscle formation has provided a framework for understanding the complexity of this tissue and will undoubtedly yield insight into the causes of several neuromuscular disorders, as well as provide the potential for therapeutic intervention into such diseases.

REGULATION OF MUSCLE DIFFERENTIATION IN VITRO

Much of the progress in understanding muscle development is attributable to the fact that many of the events associated with muscle differentiation in vivo can be recapitulated in tissue culture. Immortalized muscle cell lines or skeletal myoblasts isolated from embryos proliferate in vitro in the presence of fetal bovine serum and other mitogens such as fibroblast growth factor. Myoblasts are committed to the myogenic lineage, but they do not express muscle structural genes until they are forced to exit the cell cycle. Myoblast differentiation is accompanied by irreversible withdrawal from the cell cycle, fusion to form multinucleate myotubes, and expression of a large array of muscle-specific genes whose products are required for the specialized contractile, excitable, and metabolic properties of the differentiated muscle fiber.

Several studies suggested the existence of myogenic regulatory factors with the potential to activate muscle gene expression. Experiments in which heterokaryons were formed between skeletal muscle cells and various nonmuscle cells demonstrated that muscle genes became activated in nonmuscle cell nuclei and suggested the existence of *trans*-acting factors in muscle cells, which could activate muscle gene expression. Genetic evidence for such myogenic factors was provided by experiments in which the fibroblast cell line 10T1/2 was shown to form skeletal muscle following treatment with the demethylating agent 5′-azacytidine. The frequency of conversion of 10T1/2 cells to muscle (up to 50%) suggested that one gene was responsible for establishing the myogenic phenotype following its activation by demethylation. This hypothesis was confirmed by DNA transfection experiments in which genomic DNA from myoblasts or 5′-azacytidine-treated 10T1/2 cells was shown to convert 10T1/2 cells to myoblasts with a frequency consistent with a single regulatory gene.

THE MYOD FAMILY OF MUSCLE-SPECIFIC TRANSCRIPTION FACTORS

The first myogenic regulatory gene to be cloned was MyoD, which was isolated by cloning mRNAs that were expressed in myoblasts, but not 10T1/2 fibroblasts. When a cDNA clone encoding MyoD was expressed ectopically in fibroblasts, it was found to activate skeletal muscle gene expression (Fig. 66-1). Subsequently three related genes, *myogenin*, *Myf5*, and *MRF4* (also called Myf6 and herculin) were discovered. These genes, which are referred to as the MyoD family, are expressed exclusively in skeletal muscle; there is no detectable expression in cardiac or smooth muscle, even though the three muscle cell types express many of the same muscle-specific genes.

Members of the MyoD family exhibit distinct expression patterns during differentiation of muscle cells in culture. Most established muscle cell lines express either MyoD or Myf5 when they are proliferating as undifferentiated myoblasts. When induced to differentiate by exposure to growth factor-deficient medium, myogenin is rapidly upregulated immediately before activation of muscle structural genes. MyoD and Myf5 also continue to be expressed in differentiated myotubes. MRF4 is not expressed until late in the differentiation program.

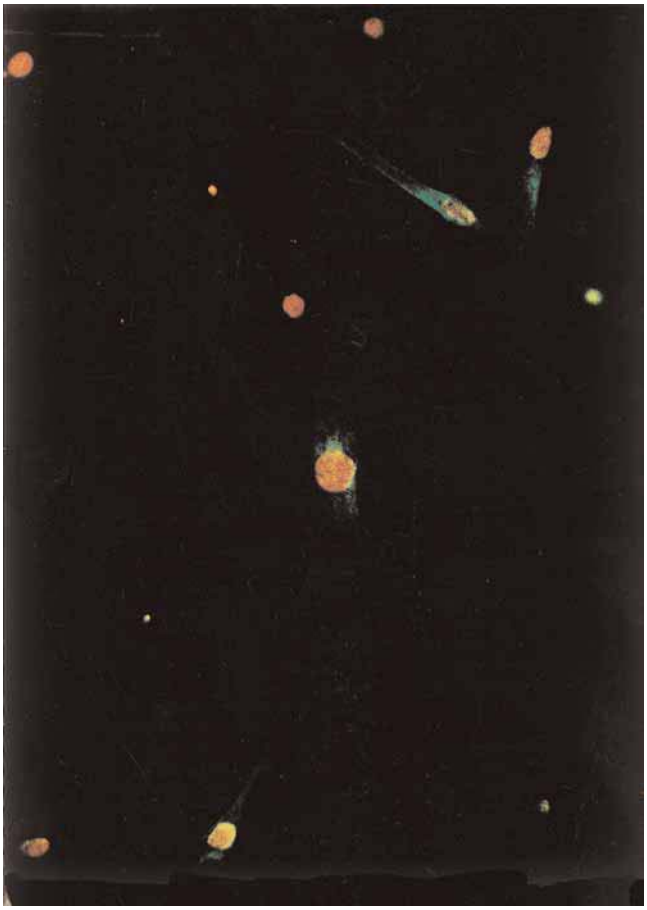

Figure 66-1 Activation of MHC expression in fibroblasts expressing exogenous MyoD. 10T1/2 fibroblasts were transfected with a MyoD expression vector. Cells were then stained using antibodies specific for MyoD (red) and myosin heavy chain (green). MyoD can be seen within the nuclei of transfected cells and myosin is expressed only in the cells that express MyoD. Figure provided by S. Tapscott, Fred Hutchinson Cancer Research Center. (Please *see* color insert.)

Members of the MyoD family can induce skeletal muscle gene expression when they are introduced into a wide variety of cell types including fibroblasts, melanoblasts, chondroblasts, smooth and cardiac muscle cells, and osteoblasts. In some cell types, these factors activate the entire myogenic program, resulting in formation of multinucleate myotubes and expression of the full array of muscle-specific genes, whereas in other cell types, only a subset of muscle genes is expressed. In some cell types, such as adipocytes, forced expression of the myogenic factors represses the endogenous program of cell-specific gene expression, whereas in other cell types the skeletal muscle program is coexpressed with the endogenous program. There are also cell types, such as hepatocytes and several types of transformed cells, in which the myogenic factors are unable to activate muscle gene expression. The failure of the myogenic factors to activate muscle gene expression in these cell types suggests that they lack certain cofactors required by the myogenic factors, that they contain inhibitors of muscle gene expression, or both.

In addition to activating the expression of muscle structural genes, members of the MyoD family regulate each others' expression. For example, if MyoD is introduced into fibroblasts, it activates the endogenous *MyoD* gene as well as the *myogenin* and *MRF4* genes. These autoregulatory interactions have been proposed as a mechanism whereby these factors amplify and maintain their expression and thereby commit cells to a myogenic fate.

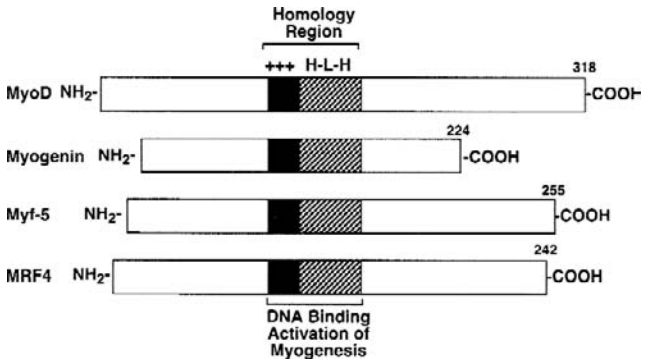

Figure 66-2 Diagrammatic representation of the four myogenic bHLH proteins. A linear representation of each myogenic regulatory factor is shown. The basic (+++) and HLH regions are indicated. The number of amino acids in each protein is shown at the end of each box.

THE BASIC HELIX–LOOP–HELIX FAMILY OF TRANSCRIPTION FACTORS

Members of the MyoD family share about 80% amino acid identity within a 70-amino acid segment that encompasses a region rich in basic amino acids, followed by a region postulated to adopt a helix–loop–helix (HLH) conformation in which two amphipathic α-helices are separated by an intervening loop (Fig. 66-2). Related, but more divergent, basic-HLH (bHLH) motifs are found in members of a superfamily of proteins that regulate cell proliferation and differentiation in species ranging from yeast to humans. Among these are members of the c-myc family of oncoproteins and the products of several *Drosophila* genes that regulate embryonic cell fates, including the *achaete-scute* gene products, which regulate neurogenesis, and twist, which regulates mesoderm formation.

The HLH motif mediates protein dimerization and brings together the basic regions of bHLH proteins to form a bipartite DNA binding domain that recognizes the consensus sequence CANNTG (*N* = any nucleotide), known as an E-box (Fig. 66-3). This DNA sequence motif is found in the control regions of numerous muscle-specific genes, in which it binds the myogenic factors and mediates transcriptional activation.

The myogenic bHLH factors homodimerize inefficiently, but they readily form heterodimers with members of a family of ubiquitous bHLH proteins, known as E-box-binding proteins. There are also HLH proteins that lack basic regions and inhibit the activity of bHLH proteins by forming heterodimers incapable of binding DNA. Among this class of HLH proteins are members of the inhibitor of differentiation (Id) family.

Mutagenesis studies have revealed several functional domains in the myogenic bHLH proteins (Fig. 66-4). These factors contain transcription activation domains in their amino- and carboxyl termini that are important for efficient activation of muscle-specific transcription. The basic regions of the myogenic factors play a dual role in the control of muscle gene expression by mediating DNA binding and by conferring muscle specificity to transcriptional activation. Fine mapping of individual amino acids in the DNA-binding domains of the myogenic factors has shown that two clusters of basic amino acids are required for binding to the E-box consensus sequence (Fig. 66-4). In addition, two adjacent

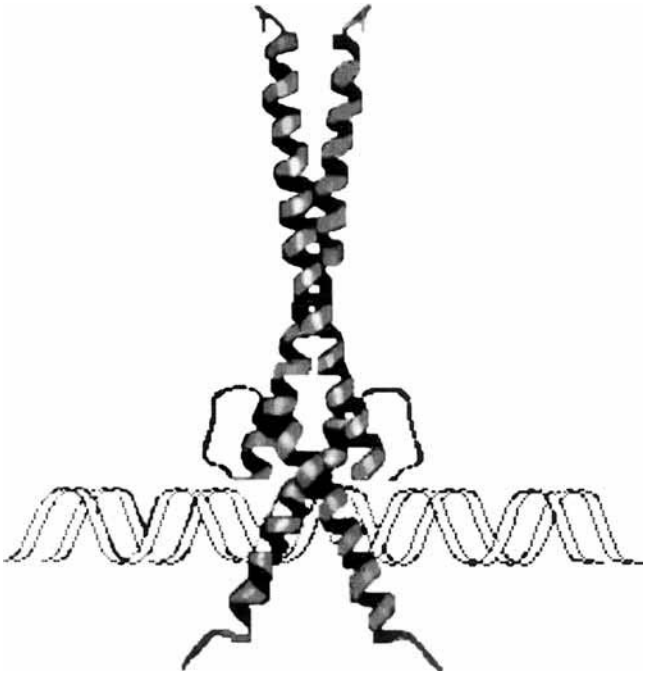

Figure 66-3 Schematic representation of a MyoD/E12 heterodimer is shown. The basic region and helix-1 form a contiguous α-helix separated from helix-2 by an intervening loop. Each basic region recognizes half of the palindromic sequence CANNTG.

amino acids, alanine–threonine, in the center of the DNA-binding domains, are required for activation of muscle gene expression. These residues are conserved in the basic regions of all known myogenic bHLH proteins in species ranging from *Drosophila* and sea urchins to humans, and they are absent from the basic regions of the more than 40 other bHLH proteins described. The specificity and conservation of these residues suggest that they represent part of an ancient mechanism for activation of muscle gene expression.

If the alanine–threonine residues in the basic region of a myogenic bHLH protein are replaced with the amino acids found at that position in the basic regions of E proteins, the resulting mutant protein will bind DNA normally, but is unable to activate muscle gene expression. Conversely, if these residues in addition to a third amino acid between the basic region and helix-1 of the myogenic factors are introduced in the corresponding positions in E proteins, they confer on the E proteins the ability to activate muscle gene expression.

The exact mechanism whereby amino acids in the basic region direct muscle-specific transcription is unclear. However, one possibility is that these amino acids induce an allosteric change in the myogenic factors following DNA binding, which might expose a protein interface that can interact with accessory factors required for the activation of muscle gene expression. In this regard, the crystal structure of a MyoD homodimer binding to an E-box DNA sequence has been deduced. The structure of the complex confirms that the basic region and first helix of the HLH region form a continuous α-helix. Alanine–threonine in the MyoD basic region lie within the major groove of the DNA binding site and are, therefore, inaccessible to other proteins. However, the interaction of these residues with the DNA appears to induce a conformational change in the protein, which may influence the proteins with which it can interact.

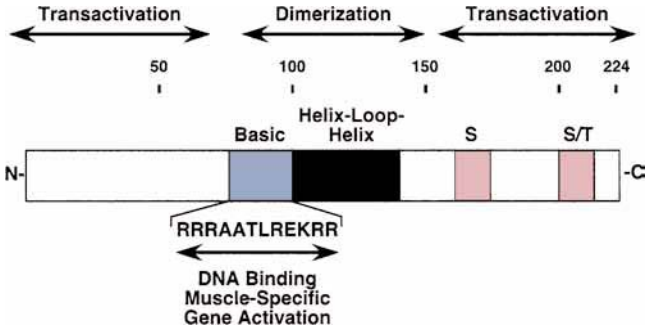

Figure 66-4 Schematic representation of the myogenin protein. Myogenin is a 224-amino acid protein with the bHLH motif near the center. The 12 amino acids within the basic region are required for sequence-specific DNA binding in conjunction with bHLH motif. The alanine–threonine in the center of the basic region is conserved in and specific to all members of the MyoD family and are important for activation of muscle-specific transcription. The threonine is also a PKC phosphorylation site, which inhibits DNA binding when phosphorylated. S, S/T, serine- and serine/threonine-rich regions, respectively.

GROWTH FACTOR CONTROL OF MYOGENESIS

As in many cell types, differentiation of myoblasts is coupled to withdrawal from the cell cycle. Whereas many cell types can re-enter the cell cycle when stimulated with mitogens, skeletal muscle cells lose the ability to reinitiate DNA synthesis when they differentiate and, therefore, become irreversibly committed to the postmitotic state. Because myoblasts express MyoD or Myf5 (these factors are unable to induce muscle gene expression when cells are exposed to growth factors, however), there must be post-translational mechanisms that inhibit their activities. There appear to be multiple mechanisms whereby growth factors prevent myogenic bHLH proteins from activating muscle-specific genes. For example, Id proteins are expressed at high levels in proliferating undifferentiated myoblasts and are downregulated when myoblasts are induced to differentiate. Because Id proteins dimerize preferentially with E proteins, they sequester the dimerization partners for myogenic bHLH proteins in myoblasts. The downregulation of Id has been proposed to release E proteins so that they can dimerize with myogenic bHLH proteins and activate muscle-specific genes. Consistent with this model, forced expression of Id from an expression plasmid is sufficient to prevent myoblast differentiation under conditions that would normally promote differentiation. In the embryo, Id expression is also downregulated in regions of skeletal muscle differentiation.

The nuclear oncogene products Fos and Jun, which are upregulated by mitogens, can also block muscle differentiation by interfering with the activities of myogenic bHLH proteins. The inhibitory activities of Fos and Jun appear to be mediated by competition with the myogenic factors for interaction with a common cofactor required for myogenesis and by direct interactions with the myogenic factors.

Members of the MyoD family have also been shown to be targets for several protein kinases. Protein kinase C (PKC), which is activated by growth factors, can substitute for growth factors and block myoblast differentiation. The threonine residue in the center of the DNA-binding domains of the myogenic factors, which mediates muscle-specific gene activation, has been shown to be efficiently phosphorylated by PKC in vitro and in vivo. In the case of myogenin, this phosphorylation prevents DNA

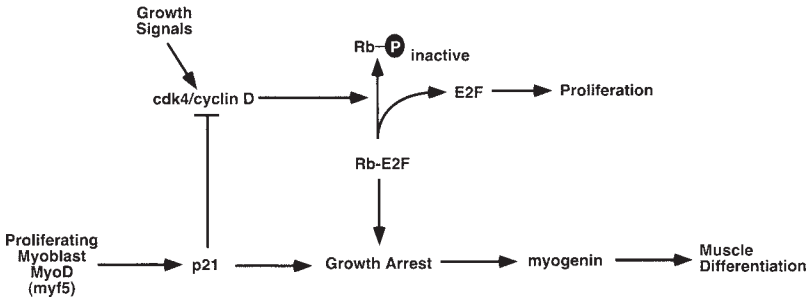

Figure 66-5 Model depicting the interaction between the cell cycle machinery and the myogenic regulatory pathway. MyoD or Myf5 are expressed in myoblasts and induce the expression of the CDK inhibitor p21 in the absence of growth factors. p21 induces growth arrest, which results in myogenin expression. Myogenin in turn activates muscle differentiation. Growth factor signals induce cyclin D1, which activates CDK4, resulting in phosphorylation of the Rb pocket, as well as inhibition of MyoD function. Phosphorylated Rb is unable to bind E2F and is, therefore, inactive as a growth suppressor. In the absence of growth factor signals, Rb is dephosphorylated and binds to E2F. E2F normally activates expression of genes required for cell proliferation, but it is in activated when bound to Rb. Rb, retinoblastoma protein.

binding, presumably because it introduces a negative charge into the center of the DNA-binding domain, resulting in electrostatic repulsion from the DNA. Fibroblast growth factor can induce phosphorylation of this threonine in cultured cells, resulting in repression of myogenin's ability to activate muscle gene expression. The ability of this threonine to serve as a target for growth factor-dependent phosphorylation pathways that block myogenesis demonstrates that this single amino acid plays a dual role in the control of muscle development; it is structurally important for transcriptional activation, and it serves as a target for growth factor signal transduction pathways under control of PKC.

Type-β transforming growth factor (TGF)-β also inhibits muscle differentiation by blocking the activities of the myogenic factors. In myoblasts exposed to TGF-β, myogenic bHLH proteins are expressed, and they can bind to their target DNA sequences associated with muscle-specific genes but are unable to activate expression of those genes. It has been proposed that TGF-β interferes with the expression or activity of a cofactor required by the myogenic factors to activate myogenesis.

The linkage of muscle differentiation to cell cycle withdrawal suggests that the cell cycle machinery interfaces with the mechanism for muscle gene activation. The retinoblastoma protein (Rb) has been shown to be an important regulator of cell cycle progression. Rb is a nuclear phosphoprotein that is phosphorylated in a cell cycle-dependent manner. In cycling cells, Rb is phosphorylated in a specific domain known as the "pocket," whereas in growth-arrested cells Rb is dephosphorylated. When quiescent cells are stimulated to re-enter S phase, Rb becomes phosphorylated during the G1/S phase transition before initiation of DNA synthesis. The pocket of Rb interacts with a variety of nuclear proteins to control cell cycle progression. Among these is the transcription factor E2F, which activates the expression of several genes involved in cell proliferation. Binding of E2F to dephosphorylated Rb inactivates E2F and results in a block to proliferation (Fig. 66-5). Conversely, phosphorylation of Rb releases E2F so that it can activate cell growth. The oncoproteins encoded by several DNA tumor viruses, such as SV40 large T antigen and adenovirus E1A, also bind to the pocket of Rb, which prevents interaction between Rb and E2F, resulting in uncontrolled proliferation. These oncogenes are potent inhibitors of myogenesis and when expressed in terminally differentiated myotubes can lead to reinitiation of DNA synthesis.

MyoD has also been shown to bind to the pocket of dephosphorylated Rb. This interaction requires the basic region and first helix of MyoD and is dependent on the alanine–threonine residues in the basic region that are required for activation of muscle gene expression. Because MyoD and E2F bind the same region of Rb, they must interact with separate molecules of Rb. Exactly how MyoD binds DNA and Rb simultaneously is unclear. The role of Rb in the MyoD–DNA complex also remains to be determined.

Rb is upregulated during myogenesis and is required for irreversible exit of muscle cells from the cell cycle. Myoblasts lacking Rb are able to form myotubes and express muscle-specific genes, but they do not irreversibly exit the cell cycle and can resynthesize DNA in response to mitogenic stimulation.

The pocket of Rb is phosphorylated by cyclin-dependent protein kinases (CDKs). The CDKs are expressed constitutively throughout the cell cycle but are activated by association with regulatory proteins called cyclins. Cyclin D1 is induced during the G1 to S phase transition and activates CDK4, resulting in phosphorylation of Rb. Forced expression of cyclin D prevents activation of muscle gene expression by MyoD, presumably because it leads to inactivation of Rb, although a more direct role of the cyclin D1/CDK4 complex in phosphorylating MyoD has not been excluded.

There is also a family of CDK inhibitors (CKIs) that act as inhibitors of cell growth by blocking CDK activity. One of these CKIs, called p21/WAF1/CIP1, is upregulated during myogenesis and is likely to play a role in locking cells out of the cell cycle. When CKI is expressed in proliferating myoblasts, it can inhibit growth and induce muscle differentiation even in the presence of high concentrations of mitogens (Fig. 66-5); p21 is also expressed in differentiating muscle cells during embryogenesis. Upregulation of p21 expression is also observed in several differentiated cell types in the embryo, suggesting it may be part of a common mechanism linking cell-cycle withdrawal to activation of cell differentiation.

EMBRYONIC ORIGINS OF SKELETAL MUSCLE

The formation of skeletal muscle during embryogenesis involves the commitment of mesodermal stem cells to the skeletal muscle lineage and the subsequent differentiation of myoblasts to form multinucleate myotubes, which mature into skeletal muscle fibers. Skeletal muscle is derived from the somites, which form in a rostral-to-caudal gradient by segmentation of the paraxial mesoderm along the neural tube (Fig. 66-6). Newly formed somites appear as an epithelial sphere, which subsequently becomes compartmentalized to form the dermamyotome and the sclerotome. The sclerotome gives rise to the ribs and vertebrae. The

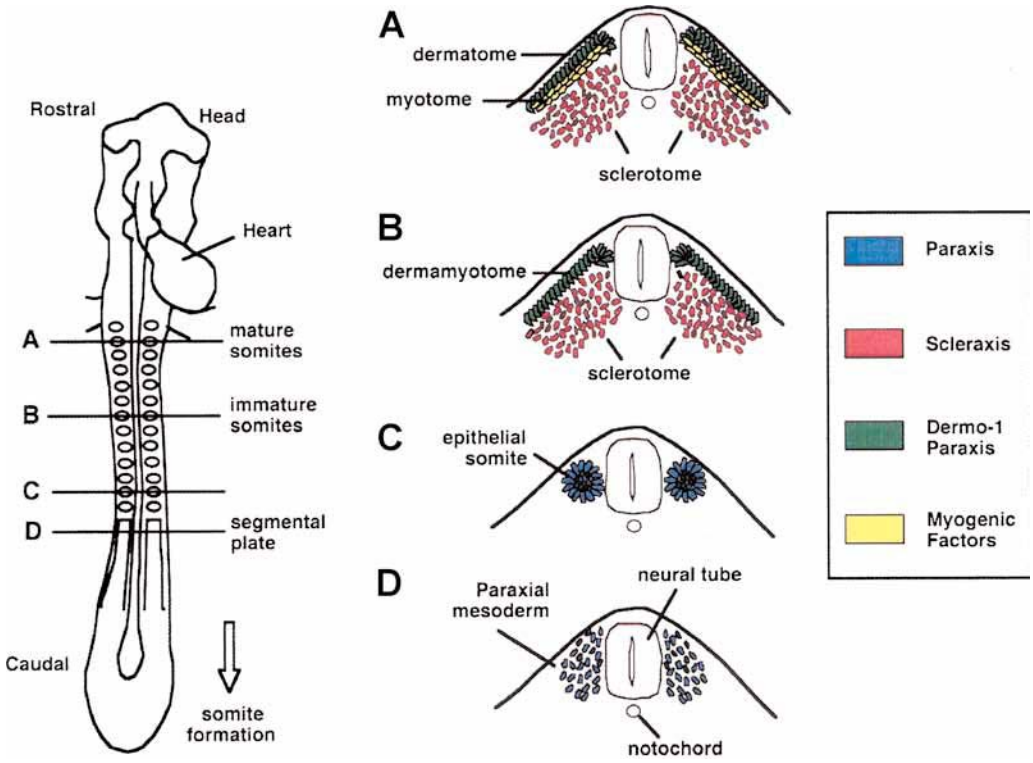

Figure 66-6 Diagrammatic representation of somite maturation. Schematic representation of an early chick embryo is shown on the left. Somites form in a rostral-to-caudal progression by segmentation of the segmental plate mesoderm. *Right*: cross-sections of the embryo at the indicated level. **(A)** Paraxial mesodermal cells in the segmental plates have not yet formed somites. **(B)** Newly formed somites appear as epithelial spheres. **(C)** Immature somites have become compartmentalized to form the dermamyotome and sclerotome. **(D)** Mature somites have formed the dermatome, myotome, and sclerotome. (Please *see* color insert.)

dermamyotome gives rise to the myotome and dermatome, which form axial muscles of the back and the dermis, respectively. Myf5 is the first member of the MyoD family to be expressed during mouse embryogenesis, appearing in the somite at embryonic d 8 (E8). Myogenin transcripts appear in the myotome by E8.5 and MRF4 and MyoD are expressed at E9 and E10.5, respectively.

Muscle cells in the limbs arise from cells that emigrate from the ventrolateral edge of the dermamyotome. These migrating cells are committed to the myogenic lineage, but they do not express the myogenic bHLH factors until they reach the limbs. The homeobox gene *Pax3* is expressed in the migrating myogenic precursor cells. Evidence that *Pax3* is involved in migration or commitment of these cells to the myogenic lineage has been provided by analysis of a mouse mutant called *Splotch*. The *Splotch* mutation maps to the *Pax3* gene and results in the absence of limb muscle. *Pax3* may mediate activation of MyoD and Myf5 in response to muscle-inducing signals from overlaying ectoderm. Interestingly, a chromosomal translocation resulting in structural rearrangement of the human *Pax3* gene has been associated with alveolar rhabdomyosarcoma, a malignant tumor of skeletal muscle (*see* Chapter 71).

Whereas limb muscles are derived from myogenic precursor cells that migrate from the ventrolateral edge of the dermamyotome, the axial muscles of the back are derived from the myotomal compartment of the somites. The neural tube and notochord have been shown to play important roles in somite maturation by serving as a source for signaling molecules that induce patterning of the somites. In the absence of neural tube, the myotome fails to form. In contrast, the formation of limb muscles is independent of the neural tube or notochord.

Relatively little is known about the developmental underlying formation of head skeletal muscles. Head muscles are derived from multiple cell lineages, including prechordal mesoderm anterior to the first somites and paraxial mesodermal precursors that migrate into the branchial arches. Two related bHLH proteins, called MyoR and capsulin, are transiently expressed in migratory paraxial mesodermal cells in the branchial arches. The expression of these bHLH genes precedes that of the MyoD family in head muscles.

Several of the myogenic bHLH genes have been analyzed for *cis*-acting DNA sequences that direct expression in the early somites and subsequently during skeletal muscle formation. The best characterized of these genes is *myogenin*, which is controlled by DNA sequences in the proximal promoter region. When these sequences are linked to the β-*galactosidase* gene as a marker and are introduced into transgenic mice, they direct the expression of β-galactosidase in the exact pattern as the endogenous *myogenin* gene (Fig. 66-7). Within the *myogenin* gene control region is an E-box that binds the myogenic bHLH proteins with high affinity and a binding site for the myocyte enhancer-binding factor-2 (MEF2) family of transcription factors. Together, these two families of regulators control the expression of myogenin in the somites and limb buds.

A GENETIC PATHWAY FOR MUSCLE DEVELOPMENT REVEALED BY GENE TARGETING IN TRANSGENIC MICE

To determine the specific roles of the myogenic bHLH genes in muscle development in vivo, these genes have been deleted from the genome of transgenic mice by homologous recombination.

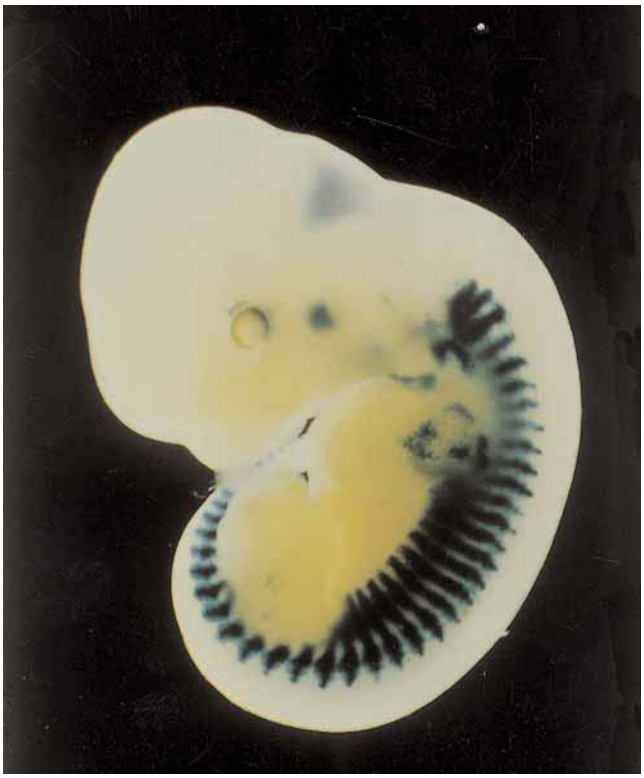

Figure 66-7 Expression pattern of a myogenin-lacZ transgene in an 11.5-d mouse embryo. The myogenin promoter was linked to a β-galactosidase reporter gene and introduced into transgenic mice. The expression of β-galactosidase activity was detected by a colorimetric assay and is shown in blue. The expression pattern of the transgene is identical to that of the endogenous gene. (Please *see* color insert.)

Remarkably, mice lacking MyoD are fully viable and show no obvious muscle abnormalities. The only apparent consequence of MyoD inactivation is a twofold increase in expression of Myf5. Paradoxically, mice homozygous for a null mutation of Myf5 also develop normal skeletal muscle, but die at birth because of the absence of ribs, which results in an inability to breathe. It is unclear why Myf5, which is expressed exclusively in skeletal muscle cells, affects the formation of ribs, which are derived from the somite. One possibility is that Myf5 controls the expression of growth factors or extracellular matrix molecules by muscle cells, which are involved in regulating the behavior of adjacent rib precursor cells in the somite. When both MyoD and Myf5 are inactivated in the same animal, there is a complete absence of skeletal muscle and there are no detectable myoblasts. These findings suggest that MyoD and Myf5 play overlapping roles in the generation of myoblasts. This type of genetic redundancy could occur if MyoD and Myf5 were expressed in the same cells or if they were expressed in separate cells, either of which could support normal muscle development if the other cell population were eliminated. When lacZ expression is driven by the *Myf5* locus in *Myf5* null embryos, muscle progenitor cells migrate aberrantly. Thus, Myf5 protein appears to be necessary for cells to respond correctly to positional cues and to adopt a myogenic fate. The phenotype of mice lacking myogenin suggests that myogenin acts in a genetic pathway downstream of MyoD and Myf5. In *myogenin*-null mice, myoblasts are normally specified and positioned, but there is a near-complete absence of differentiated skeletal muscle fibers. The undifferentiated myoblasts that populate the presumptive muscle forming regions of *myogenin*-null mice express MyoD and Myf5, indicating that these myogenic factors do not require myogenin for their expression and suggesting that they cannot direct the formation of normal skeletal muscle in the absence of myogenin.

During normal muscle development, myogenin is downregulated at birth as MRF4 becomes upregulated to high levels. MRF4 is not expressed above background levels in *myogenin*-null mice, which suggests that it lies downstream of myogenin in the myogenic pathway. *MRF4*-null mice have normal skeletal muscle and are fully viable. However, myogenin is overexpressed in these mice, which suggests that it may compensate for the lack of MRF4. This upregulation of myogenin in the absence of MRF4 also suggests that MRF4 is required for the downregulation of myogenin that normally occurs in postnatal skeletal muscle. Together, the results of gene knockout experiments suggest that muscle cell determination and differentiation are controlled by the type of genetic cascade shown in Fig. 66-8.

The bHLH genes *MyoR* and *capsulin* have also been shown to be essential for development of specific facial skeletal muscles. In mice lacking these two genes, the muscles of mastication are missing and members of the MyoD family are not expressed. The absence of specific head muscles, as well as markers of the corresponding myogenic lineages, in *MyoR/capsulin* double mutant mice resembles the effect of *MyoD/Myf5* double mutations on all skeletal muscles. This phenotype differs from that of *myogenin* mutant mice, in which myoblasts express myogenic bHLH genes but are unable to differentiate. This phenotype demonstrates that *MyoR* and capsulin redundantly regulate an initial step as specification of a subset of facial skeletal muscles. In the absence of these factors, myogenic bHLH genes are not switched on, and the cells from these lineages undergo programmed cell death.

MEF2 FACTORS AND MYOGENESIS

The majority of skeletal muscle genes contains E-boxes in their control regions and are therefore probably directly activated by the myogenic bHLH factors. However, there are also skeletal muscle genes that lack E-boxes. Many of these genes are controlled by the myogenic bHLH factors through a cascade of events in which the myogenic factors induce the expression of intermediate regulators, which in turn activate muscle-specific genes. MEF2 proteins are among these intermediate regulators. MEF2 factors are unable to activate muscle gene expression alone, but they potentiate the transcriptional activity of bHLH proteins. This potentiation appears to be mediated by direct interactions between the DNA-binding domain of these different types of transcription factors. The MEF2 factors belong to the MADS box family of transcription factors, named for MCM1, which regulates mating type-specific genes in yeast, *agamous* and *deficiens*, which act as homeotic genes to control flower development in plants, and serum response factor, which controls several serum-inducible and muscle-specific genes. There are four MEF2 genes in vertebrates: *MEF2A*, *-B*, *-C*, and *-D* (Fig. 66-9). The proteins encoded by these genes are nearly identical within the MADS domain, which is located at their amino termini. The MADS domain mediates homo- and heterodimerization and DNA binding to the sequence CTA(A/T)4TAG, which is found in the control regions of nearly every skeletal as well as cardiac muscle gene. Immediately adjacent to the MADS domain is a region known as the MEF2 domain, in which the

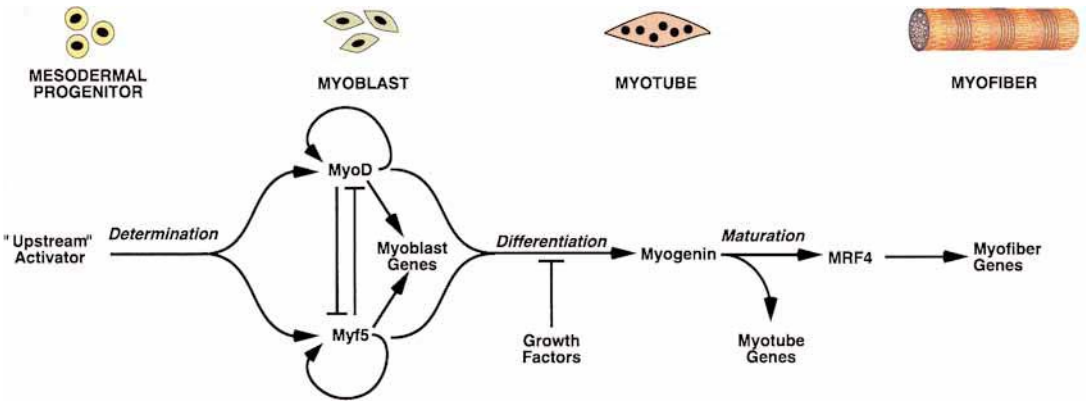

Figure 66-8 The genetic pathway for skeletal muscle development. According to this model, either MyoD or Myf5 become expressed when mesodermal precursor cells from the somite become committed to the myogenic lineage. Myoblast-specific genes are regulated by MyoD and Myf5. When the extracellular concentration of growth factors is reduced, MyoD or Myf5 activate the expression of *myogenin*, which in turn activates myotube-specific genes. *Myogenin* is normally downregulated when *MRF4* is upregulated after birth. In *MRF4*-null mice, myogenin continues to be expressed at a high level, suggesting that MRF4 is normally required for its downregulation.

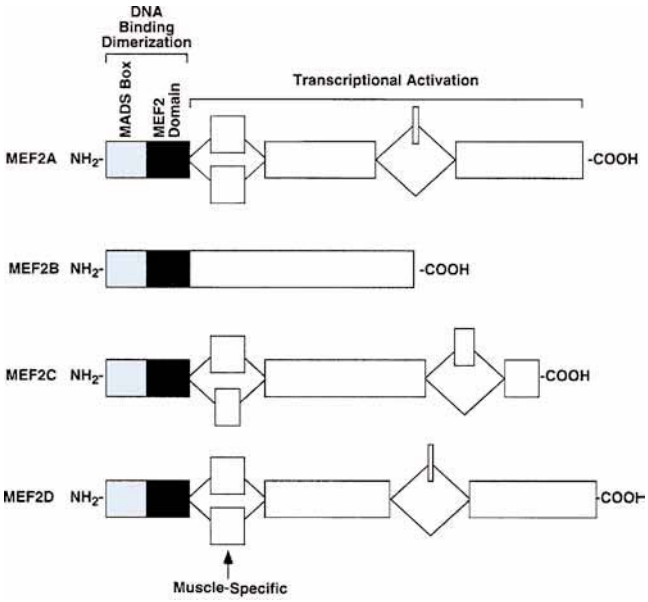

Figure 66-9 Diagrammatic representation of the proteins encoded by the four MEF2 genes. A linear representation of each MEF2 factor is shown. The MADS and MEF2 domains are indicated and alternative exons are shown.

MEF2 factors also share extensive homology. The function of the MEF2 domain has not been determined. The carboxyl termini of the MEF2 factors are required for transcriptional activation and are subject to complex patterns of alternative splicing, which generates enormous complexity of this family.

In addition to regulating muscle structural genes, MEF2 factors have been shown to regulate the myogenic bHLH genes. The promoters of the *myogenin*, *MyoD*, and *MRF4* genes have been shown to contain MEF2 sites that are essential for transcription of these genes in vivo and in vitro. During mouse embryogenesis, the MEF2 factors are expressed in the somite myotome after Myf5 and myogenin, which suggests that they do not play a role in the initial activation of these genes, but they are likely to be required for amplification and maintenance of the expression of these genes once their expression has been initiated.

MEF2 expression can be induced in nonmuscle cells by forced expression of myogenic bHLH proteins, which suggests that the MEF2 genes lie in a genetic pathway downstream of the myogenic bHLH genes. However, forced expression of MEF2 in fibroblasts has been shown to induce the expression of the myogenic bHLH genes and to activate muscle differentiation. This suggests that MEF2 factors and myogenic bHLH proteins function within a complex regulatory network in which members from either family of factors can autoregulate one another and crossregulate the other family members (Fig. 66-10). In this way, these two families of regulators reinforce one another's expression and drive cells toward differentiation.

The four MEF2 genes are also expressed at the earliest stages of heart development, as well as in smooth muscle cells, suggesting that MEF2 factors may regulate muscle gene expression in multiple muscle cell types. The functions of MEF2 have been analyzed genetically in *Drosophila*, which contains only a single MEF2 gene, called *D-mef2*, which encodes a protein that is virtually identical to the vertebrate MEF2 proteins in the MADS and MEF2 domains. The *Drosophila* MEF2 protein also binds the same DNA sequence as the mammalian factors and can activate transcription through the MEF2 site in mammalian cells. Like its vertebrate relatives, *D-mef2* is expressed specifically in myogenic precursors and their descendants during embryogenesis. *Drosophila* embryos lacking *D-mef2* contain myoblasts that are normally specified and positioned, but these cells are unable to differentiate. The severe muscle defect in these mutant flies suggests that MEF2 provides a function required for activation of muscle gene expression in multiple muscle cell types and suggests that the genetic functions of MEF2 have been conserved because flies and humans evolved from a common ancestor over 600 million years ago.

RELATIONSHIP OF SKELETAL MUSCLE TO OTHER TISSUES

There are several reasons to expect that networks of cell type-specific bHLH proteins may control cell determination and differentiation in cell types other than skeletal muscle. The presence of E-boxes in the control regions of numerous tissue-specific genes suggests that these genes are controlled by specific bHLH proteins. The ubiquitous expression of E proteins also suggests the existence of cell type-specific dimerization partners for

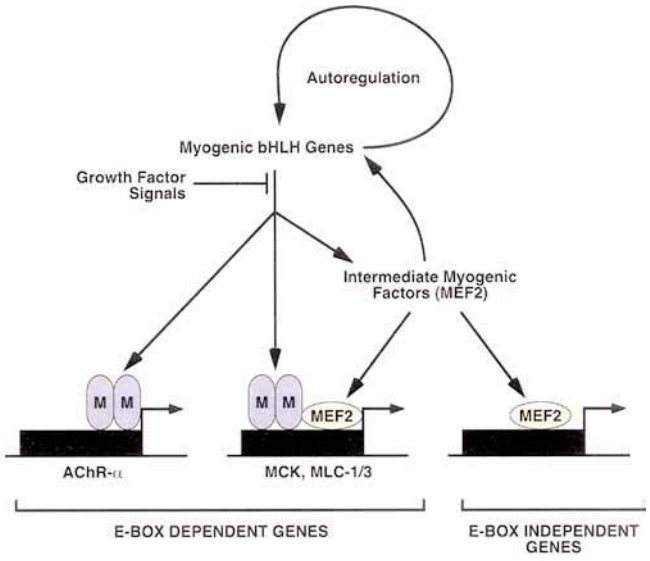

Figure 66-10 Activation of muscle gene expression by myogenic bHLH and MEF2 factors. Members of the MyoD family positively autoregulate their own expression and directly activate transcription of muscle-specific genes containing E-boxes in their control regions. MEF2 factors are induced in response to myogenic bHLH proteins and can in turn activate the expression of muscle-specific genes that lack E-boxes in their control regions. MEF2 proteins also bind the control regions of several myogenic bHLH genes and, therefore, participate in a positive feedback loop that amplifies and maintains the myogenic program. Myogenic bHLH proteins are shown in black, designated M.

these proteins. Id proteins are also expressed in many types of undifferentiated cells. Indeed, several cell type-specific bHLH proteins have been identified in *Drosophila* and vertebrate species. Further investigations into their mechanisms of action may reveal fundamental mechanisms for the control of tissue-specific gene expression during development.

67 Skeletal Muscle Structure and Function

Elizabeth M. McNally, Karen A. Lapidos, and Matthew T. Wheeler

SUMMARY

This chapter summarizes the basic organization of skeletal muscle. Skeletal muscle is responsible for all voluntary movement, and its unique organization is optimized for this function. The sarcomere is the unit of muscle contraction and the sarcomere is linked to the plasma membrane through the Z band. Skeletal muscle is also unique in that mature myofibers are a multinucleate syncytium. Efficient delivery of calcium is necessary for coordinated muscle contraction. Neuronal control is also a key contributor to muscle function. Mutations in the genes encoding many "structural" proteins of muscle lead to muscle weakness and degeneration.

Key Words: Actin; dystrophin glycoprotein complex; myosin; neuromuscular junction; nitric oxide synthase; sarcolemma; sarcomere; sarcoplasmic reticulum; titin; Z bands.

INTRODUCTION

Skeletal muscle is one of the most highly organized structures in the biological world. The importance of responsive movement to the survival of the organism as a whole has contributed to the evolution of highly ordered and near crystalline array of proteins found in the mature skeletal myocytes or myofiber. Muscle is a unique tissue in that it arises from the fusion of mononuclear myoblasts to form a multinucleate syncytium. The syncytial nature of the mature myotube ensures a coordinated response to neural input. Muscle fibers are modified for fast twitch activity or slow tetanic activity. This variation derives from the specific needs of the fibers and is reinforced by fiber type-specific innervation. The major structural components of muscle relate to their function and include:

1. The sarcomere, made up of actin, myosin, and associated proteins. These proteins directly convert chemical energy in the form of ATP to movement and force using molecular motors and a scaffold of networked thin filaments.
2. The membrane that overlies individual myofibers interacts directly with the underlying cortical cytoskeleton, the Z band, and the extracellular matrix to help transmit force.
3. Interwoven through the myofibers is a membrane-bound structure for the efficient delivery of calcium that regulates the timing of muscle contraction.
4. Myocyte nuclei are typically found in the periphery of the myocyte syncytium. Like the plasma membrane, underlying the nuclear membrane is a scaffold of proteins with both structural and signaling roles.

Each of these areas has come into focus with the identification of genetic mutations that alter function and produce muscle disease.

ARCHITECTURE OF MUSCLE AND THE MYOFIBER

Individual muscle cells or myofibers may span the length of an entire muscle. At each end is a myotendinous junction, a unique structure similar to focal adhesions found in nonmuscle cells. Myotendinous junctions transmit force longitudinally along the long axis of the muscle to result in movement. In the resting or uncontracted state, myofibers exert minimal but definitive force because of the opposing nature of many muscle groups. Sarcomeres, the units of muscle contraction, exist in register along the long axis of the myofiber. Myofibrils are made up of contractile proteins and can be isolated from muscle by removing the overlying plasma membrane. Groups of myofibers are encased in an external sheath of dense connective tissue called epimysium. Emanating from the epimysial sheath are septa of perimysia, and surrounding each individual myofiber is an additional layer of connective tissue called the endomysium.

The nuclei are found in the periphery of individual myofibers adjacent to the sarcolemma. Staining for basement membrane proteins such as laminin can clearly distinguish the position of myofiber nuclei from other nuclei that are present in muscle, such as satellite cells. Satellite cells are under the basal lamina, by definition, and are stem cells in muscle with the ability to self-renew and to differentiate into myoblasts. Once a satellite cell has differentiated into a myoblast, it can fuse to a myofiber thereby contributing to myofiber growth. Immediately after regeneration, myofiber nuclei are found in the center, as opposed to the periphery, of myofibers. Central nucleation is thought to arise from myoblast fusion followed by synthesis of sarcomeric proteins to result in cytoplasmic structure surrounding the nucleus. Studies in syncytial cells of the model system *Caenorhabditis elegans* have identified proteins that appear essential for proper nuclear localization. The nuclear-anchoring protein in *C. elegans*, called ANC-1, is an enormously large protein that contains an actin-binding domain and spectrin repeats. Mutations in ANC-1 produce disorganized nuclei in syncytial cells in which normally the nuclei are ordered. Orthologous genes and proteins to ANC-1 are found in the human and mouse, but it is unknown whether these proteins have a similar

Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

function in mammalian cells and specifically whether they have a similar role in the syncytial mammalian muscle fiber.

The connective tissue that surrounds each myofiber is contiguous with the myotendinous junction and ultimately the tendons themselves. Proteins important for attachment to the intracellular matrix are highly concentrated in the myotendinous junction. Integrins are heterodimeric proteins expressed in nearly all cell types. Integrins bind to two major types of proteins in the extracellular matrix, fibronectin, and laminin. In muscle, the most highly expressed integrin isoforms are the laminin receptor $\alpha_7\beta_1$ and fibronectin receptor $\alpha_5\beta_1$. Integrin $\alpha_7\beta_1$ is the major integrin expressed in mature muscle and is highly concentrated at the myotendinous junction in addition to being found at the plasma membrane of muscle. Muscle contraction produces the shortening of individual myofibers, and the connective tissue that surrounds each myofiber is important for force transmission. The register of thin and thick filaments is foreshortened and, thus, redundancy is present in sarcolemma surrounding each myofiber. Because not every myofiber extends the entire length of the muscle, the sheaths that surround each fiber necessarily must function in force transmission. Moreover, the myotendinous junctions transmit force of the entire muscle directly on the tendons and underlying bone.

THE SARCOMERE, THE UNIT OF CONTRACTION H&E staining of longitudinal myofibers shows cross striations that are perpendicular to the long axis of the myofiber (Fig. 67-1). Alternating light and dark bands comprise the cross-striations. The darker bands, or A bands, are so named for their anisotropic properties in that they are birefringent in polarized light. The light bands, called I bands or isotropic, do not polarize light. The Z band, (or Z disk, Z line), is a thin dark band that bisects each I band. Thin filaments are found in the I band, and the Z band is made up of actin binding proteins. Overlying the Z bands at the sarcolemma are specialized structures called costameres. Costameric patterning on the surface of myofibers reflects the underlying Z band structures and provides attachments from the Z band to the surface plasma membrane. In the center of the A band is a lighter area, the H band, which represents thick filaments without any overlapping thin filaments (Fig. 67-1).

Myosin and actin, the components of thick and thin filaments were among the first proteins to be purified and help contribute to the "domain" theory of protein function. Myosin is a hexamer with two heavy chains (220 kDa each) and four light chains (20–25 kDa each). The amino terminus of myosin is globular in nature and the two pairs of light chains bind at the junction between the globular head and the carboxy-terminal rod region. Within the head domain are the sequences required for ATP hydrolysis and actin binding. Proteolysis was used to separate the head region of myosin from the rod region and, using this approach, it was found that the rod region self-assembles with the periodicity of the intact myosin hexamer (143 Å). That is, the 850 amino acids that consist of the head region represent the enzymatically active region of the molecule, whereas the carboxy-terminal 1200 amino acids have an α-helical coiled nature responsible for macromolecular assembly. Thick filaments assemble bidirectionally, so that heads from myosin orient in opposite directions. A typical native thick filament assembles to a length not greater than 1–1.5 μm. Myosin binding protein C, a thick filament binding protein, may help regulate thick filament assembly or may help stabilize thick filaments once they are formed. The role of myosin binding protein C is especially important in the cardiomyocyte in

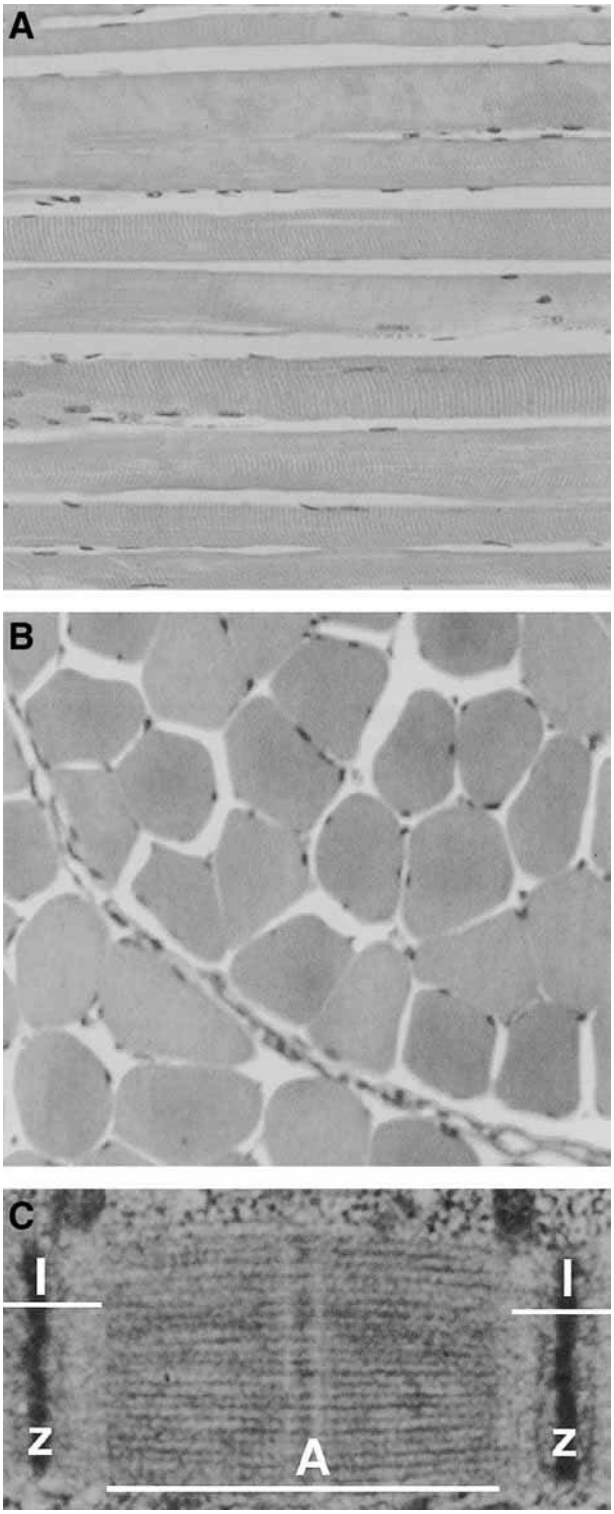

Figure 67-1 Shown are longitudinal **(A)** and transverse **(B)** cross-sections of human skeletal muscle. In the longitudinal section, the cross striations are visible. Each myofiber is a single cell that contains many nuclei located at the periphery of each myofiber. In transverse cross-sections each fiber is uniform in size, and fibers are tightly packed and encased in connective tissue (seen running from the upper left to the lower right of the section). Note the peripheral position of myonuclei. **(C)** shows an electron micrograph of a sarcomere, the unit of contraction. The Z band anchors the thin filaments. The thin filaments interdigitate with the myosin containing thick filaments. The A band represents overlapping thin and thick filaments. The I band is made up of only thin filaments that contain actin, tropomyosin, and the troponins.

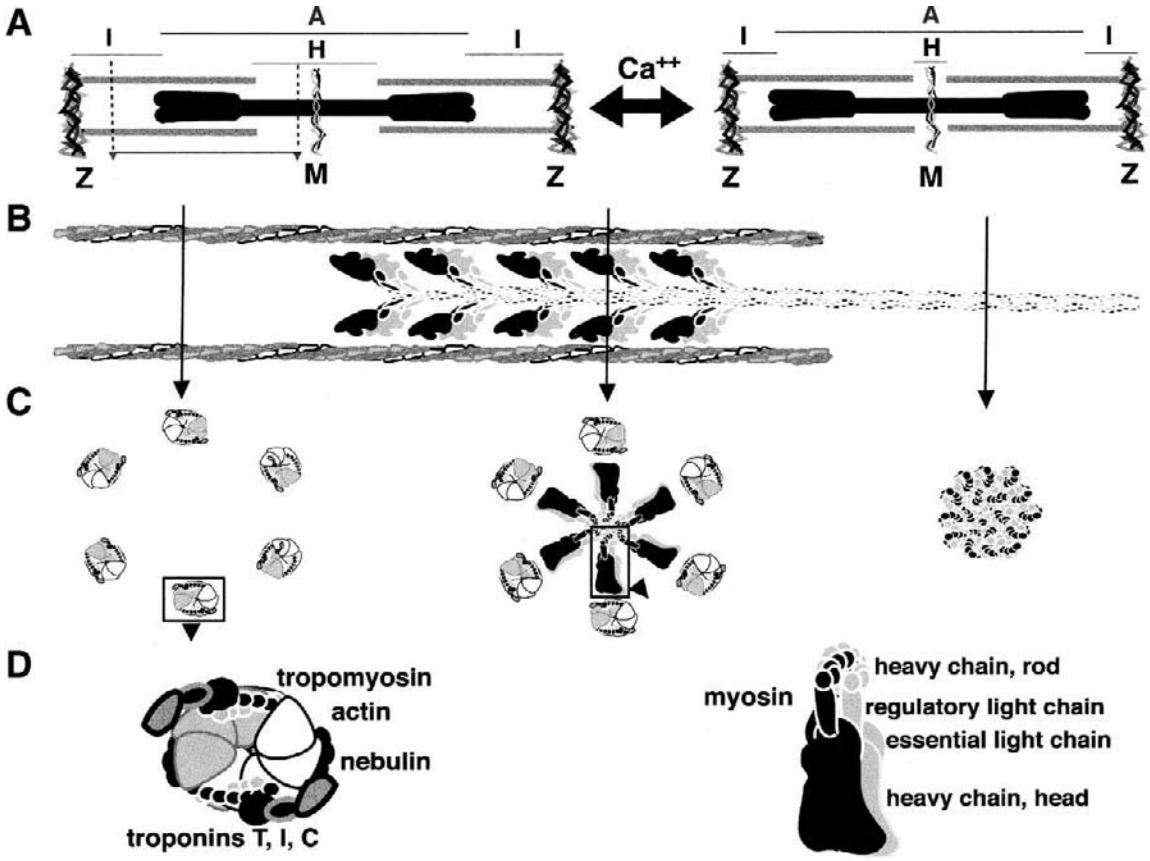

Figure 67-2 **(A)** Shows relaxation (left diagram) and contraction (right diagram) of the sarcomere. In the presence of calcium, a conformation change occurs in the thin filament that allows actin and myosin to interact. Through the myosin power stroke, the overlap between thick and thin filaments increases, and the sarcomere and muscle shorten. **(B)** Shows the myosin heads (gray and black) interacting with actin containing thin filaments. **(C)** Shows a cross-section of thin filaments, further highlighted in **D**. Thin filament regulatory proteins, tropomyosin and the troponins, regulate the actomyosin interface. Large proteins such as nebulin and titin anchor thick filaments. The middle panel of **C** shows a cross-section through a myosin thick filament surrounded by thin filaments. The right panel in **C** shows a cross-section through a myosin thick filament demonstrating the tight packing of myosin rod regions. Myosin is made up of two heavy chains and two each of regulatory and essential light chains. Hexamers of myosin tightly pack to form the thick filament.

which mutations in the cardiac form of myosin binding protein C lead to hypertrophic cardiomyopathy.

Thin filaments are made up of several different proteins, but filamentous actin is the major constituent. Monomeric, or G actin, is 43 kDa. Modulated by ionic strength and actin binding proteins, actin assembles to form a right-handed double helical filament (F actin). The pitch of the actin filament is 36 nm with seven actin monomers per strand. Along the grooves of the actin double helix are the thin filament regulatory proteins, troponins T, C, and I and tropomyosin. Tropomyosin is a rod-like molecule, and troponin T directly interacts with tropomyosin. Troponin C directly binds calcium providing calcium sensitivity to the actomyosin interaction.

From these biochemical observations and the structural observations of muscle, the sliding filament theory was proposed. In this model, the heads of myosin protrude from the thick filaments (Fig. 67-2). Protruding myosin heads directly interact with actin thin filaments to increase the overlap of thick and thin filaments, reducing the I band and effectively shortening the sarcomere and the muscle fiber as a whole. Force is transmitted parallel to the long axis of muscle. As the Z band anchors thin filaments, force is also to some degree transmitted perpendicular to the long axis of myofibers. The Z band also attaches to the plasma membrane at specialized structures called costameres. Further support for the sliding filament model was found by examining the appearance of isolated thick filaments where protruding myosin heads could be seen. In the sliding filament model, the "rowing" movement of myosin protruding heads must occur within the myosin head or neck to be effective in moving the thick filaments along thin filaments. Although electron microscopy of muscle provided anatomic support for the sliding filament theory, demonstrating movement within the myosin head or neck region has been difficult.

A revolution in understanding myosin and actin function occurred with the development of in vitro motility assays that required only purified actin and myosin to visualize the movement of fluorescently labeled actin filaments along myosin fixed to a surface. These assays have provided data on the domains of myosin required for ATP hydrolysis and actin binding, and have allowed the identification of domains required for movement and force production. The crystal structure of the myosin head and structures of myosin heads with actin have been used to identify varying conformational states of the actomyosin interface and have provided support for the sliding filament theory.

One central question in myosin biology is to determine the length of the step that a myosin head can make along the length of actin filament for a hydrolysis of ATP (Fig. 67-3). This calculation, referred to as myosin step size, has been estimated from several

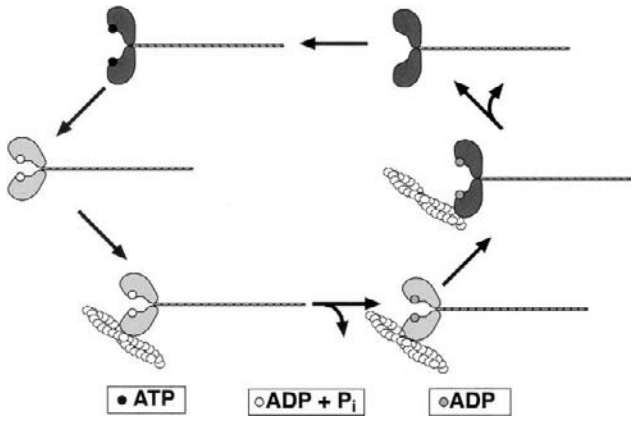

Figure 67-3 Shown is the ATPase cycle of the actomyosin interaction. After hydrolyzing ATP to ADP plus P_i, myosin undergoes a conformational change. The interaction of the myosin head with actin occurs. After release of P_i, myosin is thought to undergo an additional conformational change that moves actin along the actin thin filament. The distance that myosin can move along the actin thin filament per cycle of ATP hydrolysis is referred to as the myosin step size.

approaches. The estimates range from 5 to 15 nm, and this is in the context of a myosin that is approx 20 nm in length itself. There are at least 16 types of myosin molecules defined using electronic database searching and biochemical characterization. Myosins fall into two broad classes. The first, myosin I, are specialized motors for intracellular transport. These myosins have a head region similar to the myosin found in muscle, but have modified tail regions specialized for the cargo and vesicle attachment. The neck regions of myosin are also specialized in that this region may bind light chains or calmodulin to regulate the function of myosin. Muscle myosin, referred to as myosin II, represents the second class. These myosins have the specialized rod region that can form thick filaments. Thus, type-II myosins function as many motors together on a rod whereas type-I myosins may function as single heads or as single molecules with two heads. For example, myosin V has two heads and can take an enormous step of 36 nm. This large step can be accomplished while the second myosin head remains attached. The processivity of this myosin appears to differ from muscle myosin, and this is further supported by kinetic studies that show a slow release of adenosine 5′-diphosphate (ADP) to aid the processive nature of myosin V. Muscle myosin appears to have smaller step size, and a much faster release of ADP. Some estimates calculated the step size of muscle myosin to be as small as 5 nm. Other estimates, which argue that the arrangement of actin filaments influences measurements of myosin head step size, have calculated step sizes as large as 15–30 nm. These investigators reason that to achieve this larger step size, myosin actually takes "substeps" in its interactions with actin. Kinetic studies have not necessarily supported the presence of multiple small "substeps" although further experimentation is required to fully understand the interaction of myosin with actin and the molecular basis of biological movement.

Current structural studies focus on the neck region of myosin, as this appears to have regions capable of serving the lever function for movement. Comparisons of evolutionarily and functionally diverse myosins have revealed myosin VI as a molecule that contains a distinct lever region. In vitro studies of this myosin showed surprisingly that it moves in an opposite orientation relative to all other characterized myosins. Generally myosins move toward the barbed end of actin filaments. In contrast, myosin VI moves toward the pointed end, supporting the idea that not all myosin molecules have the identical unidirectional movement. To date, myosin VI is the only myosin described capable of reverse movement.

ANCHORING THE SARCOMERE, PASSIVE FORCE, ELASTIC RECOIL, AND FORCE TRANSMISSION Titin is giant protein that spans the length of the sarcomere providing attachment from the sarcomere to the Z band and also to the membrane. Titin is alternatively spliced to produce a variety of protein forms that are several megadaltons in size. As an elongated structure, titin can span nearly 1 μm, close to the length of a sarcomere. Titin has a highly repetitive structure thought to impart elastic recoil properties of muscle. Actin-containing thin filaments are anchored to the Z band. A number of Z band-associated proteins have been identified that are important for skeletal muscle and cardiac muscle function. Titin has attachments along the Z band and can interact with proteins such as telethonin (T cap) and subunits of the calcium-activated protease, calpain. Mutations in titin, telethonin, and calpain 3 can lead to muscular dystrophy. Myotilin is a smaller protein that contains several immunoglobulin domains. Genetic mutations in myotilin also are associated with muscular dystrophy. The precise mechanism of how genetic defects in these proteins lead to muscle degeneration is not known, but their convergence on the Z band of muscle implies the importance of this muscular structure.

ANCHORING Z BANDS TO THE PLASMA MEMBRANE Z bands anchor the sarcomere to the plasma membrane. Concentrated over the Z band at the plasma membrane is the dystrophin glycoprotein complex (DGC). The specialized connections of the Z bands to the plasma membrane are referred to as costameres and can be visualized on longitudinal sections of muscle. Dystrophin, the protein product of the Duchenne muscular dystrophy locus, is a 427 kDa protein with an actin-binding domain found at its amino terminus. Within its elongated rod region are 24 spectrin repeats that are interrupted by hinge sites. Hinge sites are defined by breaks in the typical spectrin repeats and are thought to provide flexibility. Spectrin repeats are independently folding domains of roughly 100 amino acids that have a triple-helical bundled structure. Each spectrin repeat has a limited degree of flexibility. Spectrin repeats are named for the prototypical protein spectrin, a protein component of the erythrocyte membrane. Genetic defects in spectrin lead to instability of the erythrocyte membrane and to hemolytic anemia. Similarly, absence or reduction in the dystrophin component of the plasma membrane leads to instability of the muscle membrane producing muscle degeneration and muscular dystrophy. In skeletal muscle, regeneration can occur, but typically in Duchenne muscular dystrophy, regeneration is insufficient to match the ongoing degeneration and therefore, muscle wasting and weakness ensue.

The Dystrophin Glycoprotein Complex and its Role in Membrane Stability The DGC is a macromolecular structure that can be purified from the membrane fraction of muscle (Fig. 67-4). The DGC has cytoplasmic and transmembrane components. A major transmembrane component is the laminin receptor dystroglycan. Dystroglycan is made up of an α- and β-subunit produced by proteolytic cleavage of a single polypeptide. Dystroglycan is broadly expressed, is found in most tissue types and has an essential role in development where it organizes laminin in the extracellular matrix. In addition, in nonmuscle cells dystroglycan serves as a receptor for a number of pathogenic

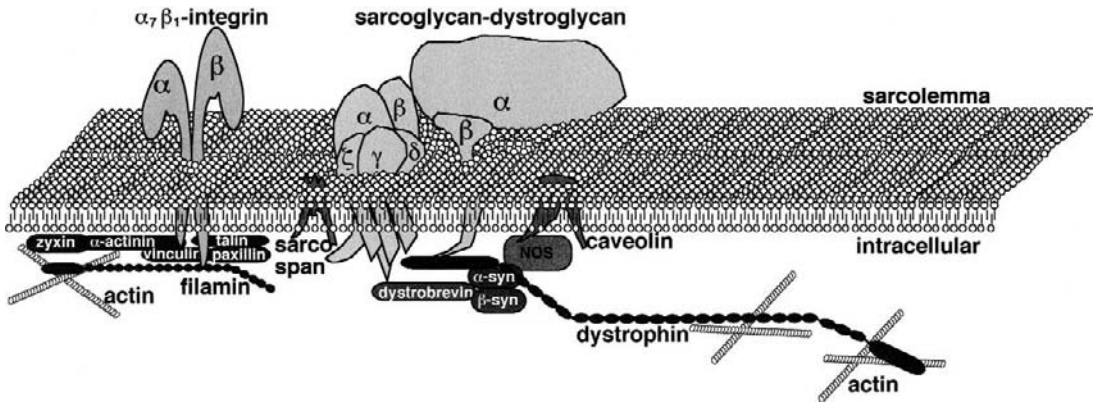

Figure 67-4 Shown is a schematic representation of the dystrophin glycoprotein complex and the integrin complex, two membrane-associated complexes in muscle that serve to connect the extracellular matrix to the membrane and the underlying cytoskeleton. Dystrophin attaches to dystroglycan. The sarcoglycan complex may stabilize the interaction of α and β dystroglycan. The integrin complex is concentrated at Z bands and at the myotendinous junction.

agents. In its intracellular portion, dystroglycan can directly bind to dystrophin. Dystroglycan can also bind Grb2, a protein implicated in Ras. In the central and peripheral nervous systems, α-dystroglycan is 120 kDa, whereas in skeletal muscle, the larger subunit of dystroglycan is 156 kDa, and this difference relates to differential glycosylation.

The sarcoglycan complex is a muscle specific subcomplex within the DGC, and mutations in the genes encoding α-, β-, γ- and δ-sarcoglycan lead to autosomal-recessive limb girdle muscular dystrophy. The precise role of the sarcoglycan complex is not fully understood, but like the entire DGC, the sarcoglycan complex likely has both mechanical and signaling roles for the maintenance and normal function of skeletal muscle membranes. Sarcospan is a four membrane-spanning tetraspanin protein. Other tetraspanin proteins have been demonstrated to interact with integrins. Mice engineered with a null mutation of sarcospan do not develop muscular dystrophy. A number of other tetraspanin proteins are expressed in muscle and compensatory upregulation of other tetraspanins may limit the expression of a phenotype from the loss of sarcospan. Mice have been engineered with null mutations in the sarcoglycan proteins and these mice recapitulate the human phenotypes. The *mdx* mouse is a spontaneously arising mutant that has a nonsense mutation 23 of the dystrophin gene, and, thus, makes no full-length dystrophin. These mice display an identical histopathology to what is seen in Duchenne muscular dystrophy, but do not develop overt muscle weakness, are fertile and have a nearly normal lifespan. Mouse models of dystrophin and sarcoglycan deficiency have proved useful for determining a DGC function in maintaining membrane stability in muscle.

The cytoplasmic face of the DGC includes a number of intracellular proteins including neuronal nitric oxide synthase (NOS or nNOS1), dystrobrevins, and the syntrophins. The syntrophins are PDZ domain containing proteins that can bind directly to nNOS. The dystrobrevins have homology to the carboxy-terminal region of dystrophin and bind directly to dystrophin and each other. The syntrophins bind directly to dystrophin and to dystrobrevin, thus forming a complex that anchors nNOS. Consistent with this, mutations in dystrophin displace nNOS from the plasma membrane. nNOS can also bind to caveolin, a small membrane-bound protein important for the formation of caveolae structures.

Dystrophin, dystroglycan, and laminin are thought to form a mechanical link that stabilizes the plasma membrane through its interaction with the extracellular matrix through the considerable deformation and stress faced through repeated muscle contraction. Mutations that reduce dystrophin result in destabilization of the remainder of the DGC including dystroglycan and sarcoglycan. The loss of the DGC is thought to render the membrane susceptible to contraction-induced damage. Supporting this, muscle lacking dystrophin displays a significant increase in membrane disruption and damage when subjected to eccentric contraction, resulting in a reduction in maximal force production. A common molecular feature between sarcoglycan mutant muscle and dystrophin mutant muscle is the loss of the sarcoglycan complex. Interestingly, in γ-sarcoglycan mutant muscle the sarcoglycan complex is largely destabilized but dystrophin, dystroglycan, and laminin are present. In similar eccentric contraction protocols, γ-sarcoglycan muscle does not demonstrate contraction-induced damage supporting a nonmechanical role for the sarcoglycan complex.

On the cytoplasmic face, muscle lacking for nNOS or the syntrophins does not develop muscular dystrophy. This may relate to compensatory upregulation of related proteins or may indicate that these subunits participate in alternative intracellular functions. Mice engineered to lack α-dystrobrevin develop a mild muscular dystrophy phenotype although the properties of membrane instability may be different than what is seen with sarcoglycan or dystrophin mutations.

At its amino terminus, dystrophin has a classic actin-binding site similar to that seen in α-actinin and other actin-binding proteins. Given the localization of dystrophin at the plasma membrane and especially its concentration overlying Z bands, dystrophin is thought to preferentially interact with γ-actin that forms part of the cytoskeletal network that is under the sarcolemma. Supporting this, when the plasma membrane is mechanically peeled from the underlying myofibrils, the under surface of the plasma membrane has a costameric arrangement of γ-actin (Fig. 67-5). Moreover, when dystrophin is mutant, the pattern of γ-actin is disrupted and is no longer associated with the plasma membrane, remaining instead affiliated with the myofibrillar structure including Z bands. Therefore, dystrophin participates in a mechanically strong linkage that includes γ-actin.

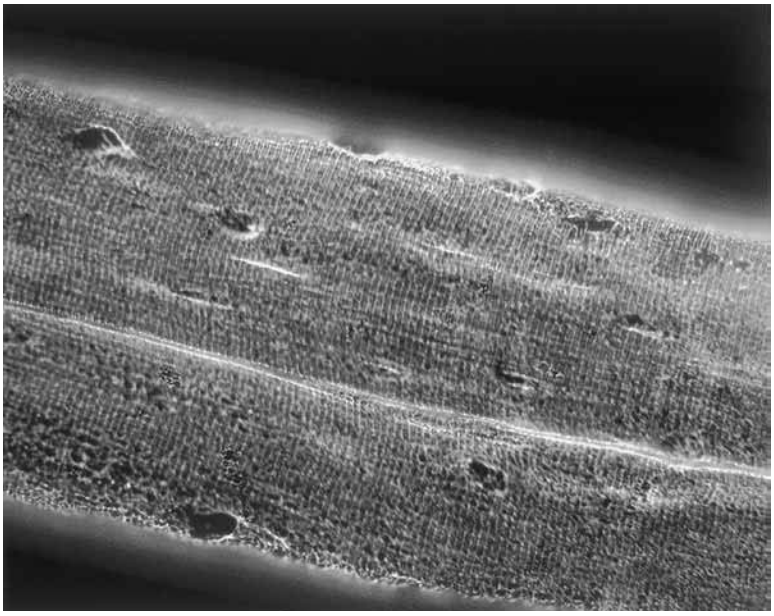

Figure 67-5 Shown is a longitudinal section of mouse muscle immunostained with an antibody for δ-sarcoglycan. The pattern of staining that runs perpendicular to the long axis of the myofiber represents the costameric pattern overlying Z bands. The dystrophin glycoprotein complex is concentrated more highly at costameres.

Dystrophin associates with actin not only through the amino-terminal actin-binding domain, but also through a side-to-side interaction with actin filaments along its rod. Utrophin is a chromosome-6 encoded homolog of dystrophin that is highly expressed in developing muscle and expressed at lower levels in mature muscle. The overall structural similarity between utrophin and dystrophin is substantiated as utrophin can substitute for dystrophin in the *mdx* mouse, a mouse model of muscular dystrophy. Utrophin is also concentrated at neuromuscular junctions (NMJs). The NMJ is a specialization for the organized delivery of neural input to muscle. Utrophin mutant mice have a reduction in the number of folds normally found in the NMJ and concomitant decrease in NMJ function. Moreover, mice doubly mutant for dystrophin and utrophin have a more severe phenotype indicating overlapping roles of dystrophin and utrophin.

NEURONAL CONTROL

Skeletal muscle requires neuronal input from motor neurons and from muscle spindles, receptors required for spatiotemporal proprioception. This input contributes directly to the development and relaxation of muscle groups for coordinated movement. Neural input also provides feedback on a longer time-scale to regulate gene expression and modify fiber typing for the requirements of repeated use. Hypertrophy and fiber recruitment occur in response to training. Muscle fibers fall into two major categories. Type-I fibers are slow twitch muscle with aerobic metabolism. In contrast, type-II fibers are modified for fast twitch function and thereby depend on anaerobic metabolism utilizing glycogenolytic pathways. The program of gene expression varies considerably between these two types of fibers and most human skeletal muscles contain a mixture of fiber types. Some fibers have intermediate properties and certain fiber types may be more susceptible to certain disease processes.

Slow and fast motorneurons provide input to type-I and type-II fibers, respectively. Denervation of muscle leads to atrophy. Gene expression profiling has identified genes and proteins that are uniquely upregulated in atrophic states. Regulation of muscle mass occurs during development and also is constantly regulated in adult states. Myostatin, a member of the type-β transforming growth factor family of proteins, is a negative regulator of muscle mass. Mice engineered that completely lack myostatin have muscle mass nearly 200% of normal. Adult mice treated with inhibitors of myostatin function can increase by muscle mass 20–30%. The ability to inhibit the negative regulation of muscle mass may prove useful in disease states. Myostatin is thought to act directly on muscle itself through paracrine mechanisms although further study is required to fully understand its scope of action.

The NMJ is a highly redundant structure to allow rapid transmission of neuronal input to the muscle. Acetylcholine receptors are the major receptor of this input. Molecules such as agrin participate in acetylcholine receptor clustering and regulation of receptor function. The intracellular surface kinases, such as MuSK, regulate acetylcholine function. The acetylcholine receptor is important in disease states such as myasthenia gravis where defects in receptor function can be induced through immune mediated or inherited mechanisms.

Neural input leads to membrane depolarization that, in turn, must lead to coordinated muscle membrane depolarization and intracellular calcium release. Depolarization of the membrane is directly propagated through membrane invaginations known as transverse (T) tubules. As T tubules contact the sarcoplasmic reticulum (SR) directly, this allows conformational changes in the calcium release channels of the SR.

REGULATION OF MUSCLE CONTRACTION BY CALCIUM

For coordinated activation of actomyosin interaction, intracellular calcium is tightly regulated. Such excitation contraction coupling occurs at regions where the intracellular sarcoplasmic reticulum, an extension of the endoplasmic reticulum, forms

junctions with the sarcolemma. Tubular invaginations of the sarcolemma, T tubules, form a junction with two terminal cisternae regions of the SR forming a triad junction. Within the SR and the T tubule system, there are a number of proteins that regulate calcium sequestration and calcium release. Among these are the intracellular ryanodine receptor, a large >500 kDa protein that forms a tetramer and the dihydropyridine receptor, a voltage gated L-type calcium channel. Together, these proteins are important for the regulation of depolarization-induced calcium release as well as calcium-induced calcium release. Thus, these proteins are essential for coupling excitation and contraction through the release of calcium. Uptake after contraction is equally essential to maintaining tight control on the actomyosin interaction. For this role, the sarcoplasmic reticulum calcium ATPase pump (SERCA) is required. Triadin, junctin, mitsugumin, and junctophilin are proteins that participate in the formation of the triad junction facilitating the interaction of the T-tubular dihydropyridine receptor and the ryanodine receptor. Calsequestrin is a luminal protein that directly binds calcium. Together these proteins each participate in the regulation of the triad junction and play a role in excitation contraction coupling in skeletal muscle.

Highlighting the importance of calcium regulation to disease, mutations in the genes encoding both the ryanodine receptor and SERCA lead to muscle dysfunction and disease. Mutations in the ryanodine receptor lead to malignant hyperthermia in which a sudden increase in intracellular calcium can occur leading to hypercontraction. In Brody's disease, mutations in SERCA lead to abnormal relaxation characterized by painless muscle cramping and exercise-induced impairment of muscle relaxation. Brody patients frequently show an inability to relax skeletal muscle following contracture.

MYOCYTE NUCLEI

As in other eukaryotic cells, the nuclear membrane is made up of two distinct lipid bilayers, the inner and outer nuclear membranes. Facing the nucleus and associated with the inner nuclear membrane is a network of proteins that scaffolds nuclear contents. Lamins A and C are produced from a single gene and form higher order filamentous structures. As in most other terminally differentiated cells, lamins A and C are intermediate filament proteins that provide support to the mature myofiber inner nuclear membrane. Mutations in the gene encoding lamin A/C are a common cause of muscular dystrophy. Recent studies suggest that lamin A/C is important for the mechanical properties of myofiber nuclei. In addition, mutations in the gene encoding the nuclear membrane protein emerin cause an X-linked form of muscular dystrophy. Like lamin A/C, emerin is broadly expressed, yet mutations in this gene lead to a tissue specific phenotype. The identification of lamin A/C and emerin, and their role in muscle degeneration highlights the importance of nucleoskeleton.

CONCLUSIONS

The structure of skeletal muscle is unique and provides the machinery necessary for controlled movement. The cell biological aspects of skeletal muscle have emphasized both structural and nonstructural roles for a variety of proteins in the sarcomere, the Z band, the plasma membrane, and the nuclear membrane. The importance of these proteins to normal skeletal muscle function has been highlighted with the identification of a large number of genetic mutations that lead to skeletal muscle dysfunction and disease. In general, many of these genetic defects have not targeted muscle development, as such mutations may prove too lethal for the organism's survival. However, muscle developmental paradigms are increasingly important with the characterization of pluripotent stem cells in muscle and the role of satellite cells for muscle regeneration. These topics are covered in Chapters 66 and 68.

68 Stem Cells and Muscle Regeneration

CINDY M. MARTIN, THOMAS J. HAWKE, AND DANIEL J. GARRY

SUMMARY

Somatic (adult) stem cell populations are resident in postnatal tissues such as skeletal muscle and function in the maintenance and regeneration of the respective tissues. Use of transgenic and emerging technologies will enhance understanding of the regulation of the somatic stem cell populations and regenerative mechanisms in normal, aging and myopathic states. Furthermore, these studies may promote the use of adult stem cells for cell replacement therapies or for use as vehicles for gene replacement therapy.

Key Words: Aging; embryonic stem (ES); skeletal muscle; somatic; stem cell; regeneration.

INTRODUCTION

The ancient Greeks recognized the potential of tissue regeneration in the legend of Prometheus. As punishment for attempting to steal the secret of fire from the Gods, Prometheus was chained to the side of Mount Caucasus and sentenced to a life of eternal torture as vultures would feed on his liver during the daytime and at night his liver would undergo repair and regeneration. This ability for tissue regeneration remains an area of intense interest and research. Titans or champions of regeneration include the hydra, zebrafish, and the newt, which have the capability of regenerating entire limbs, heart, jaw, retina, and tail. Although a number of common pathways and networks are shared between urodeles (i.e., newts) and mammals, the regenerative capacity of humans and rodents is more limited and dependent on resident stem cell populations, a permissive niche or milieu and molecular networks to promote repair and regeneration of adult tissues such as skeletal muscle.

EMBRYONIC STEM CELLS: PROTOTYPIC STEM CELL POPULATION

Perhaps the most intensely studied stem cell population is the embryonic stem (ES) cell. ES cells are derived from the embryonic blastocyst and are pluripotent. The ES cells have a distinct molecular signature as they express Esg1, Utf1, Oct3/4, Nanog, Rex3, Tex20, and a number of additional factors that promote their unlimited proliferative capacity and multipotentiation. In addition, the ES cells are routinely cultured in the presence of feeder cells (growth arrested or mitotically inactive fibroblasts) to provide growth factors and chemokines, such as leukemia inhibitory factor, which maintain the ES cell population in an undifferentiated and proliferative state. The extensive analyses of murine ES cells ultimately resulted in the isolation of human ES cells. A number of studies have been undertaken to further characterize the culture conditions, proliferative capacity, and the potential of human ES cells to contribute to alternative lineages using in vitro conditions. For example, although human ES cells grow more slowly (double every 36 h) than mouse ES cells (double every 12 h), the human and mouse ES cells are similar in their expression of high levels of telomerase, and their capability of self-renewal and multilineage differentiation in vitro (e.g., muscle, blood, fat, and so on) (Fig. 68-1). In contrast to the ES population, the somatic (adult) stem cell populations are more limited in their proliferative capacity and plasticity.

SOMATIC STEM CELLS FOR THE MAINTENANCE AND REPAIR OF ADULT TISSUES

Tissue-specific adult (somatic) stem cells are important in the growth, maintenance, and regeneration of postnatal and adult tissues. Nearly all adult tissues contain a resident stem cell population including the hematopoietic stem cells and stromal cells (bone marrow), neural stem cells (subventricular zone and hippocampus of the brain), epithelial stem cells (intestinal crypts), oval stem cells (liver), and satellite cells (skeletal muscle) (Fig. 68-1).

Myogenic progenitor cells (satellite cells) are resident in skeletal muscle as small mononuclear cells that occupy a peripheral location with respect to the adjacent multinucleated myotube (Fig. 68-2). The satellite cells can be identified using electron microscopy as they occupy a sublaminar (beneath the basal lamina) position with respect to the adjacent myofiber (Fig. 68-2). In neonatal skeletal muscle, approx 30% of the nuclei are satellite cells that fuse to the growing myofibers and contribute to postnatal growth of skeletal muscle. The satellite cells in adult skeletal muscle are reduced in number, representing approx 2–5% of the nuclei. The quiescent satellite cells are arrested at an early stage of the myogenic program such that they do not express any of the myogenic basic helix-loop-helix (bHLH) regulatory factors of the MyoD family (Myf5, MyoD, Myogenin, and Mrf4). Limited molecular markers for this cell population include Foxk1, m-cadherin, c-met, syndecan-4, Pax7, and CD34. Foxk1 and Pax7 are transcription factors that have important functional roles in the regulation of satellite cells. Using a gene disruption strategy (i.e., gene knockout), mice lacking the *forkhead*/winged helix transcription factor, Foxk1, have a severe growth deficit and impaired muscle regeneration. The impairment in muscle regeneration results from decreased numbers of satellite cells

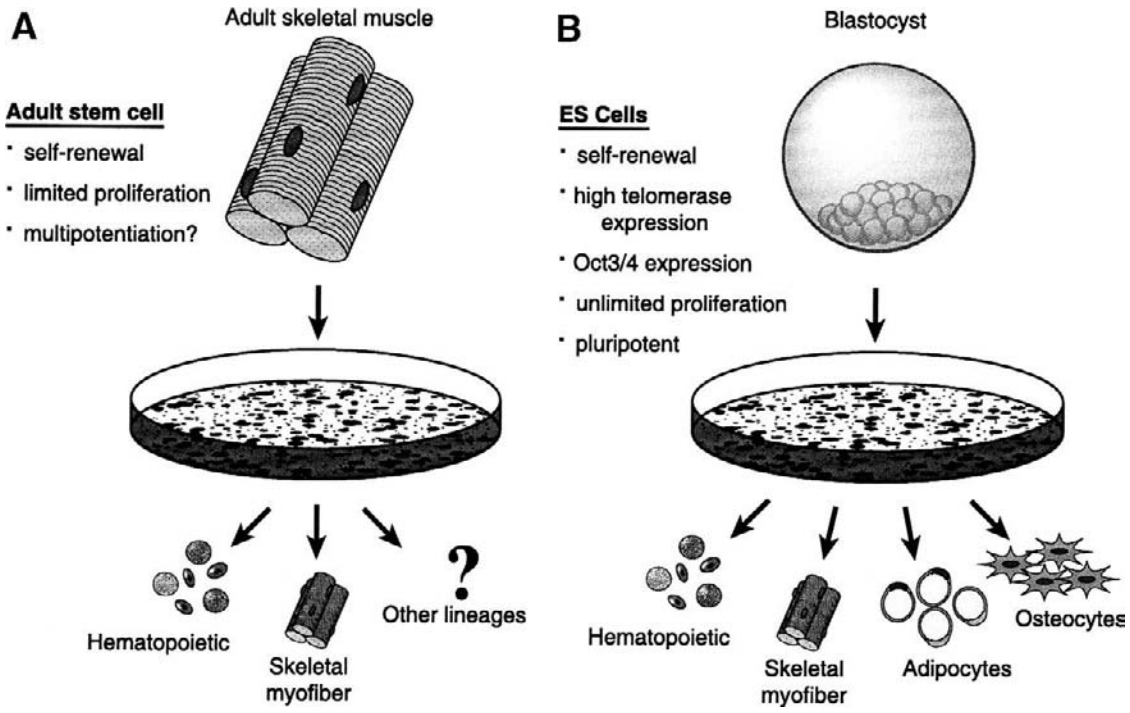

Figure 68-1 Properties of embryonic and adult (somatic) stem cell populations. Schematic representation of similarities and differences of an adult stem cell population such as satellite cells which are resident in adult skeletal muscle and embryonic stem cells.

due to perturbed cell-cycle regulation in Foxk1-deficient satellite cells. The perturbed cell-cycle progression is because of the dysregulation of the cyclin-dependent kinase inhibitor, p21, which is a putative downstream target for Foxk1.

Similarly, mice lacking the paired box transcription factor, Pax7 have an absence of satellite cells in postnatal skeletal muscle. These results suggest that Pax7 is an essential transcription factor for the specification of satellite cells from an undefined precursor cell population. Furthermore, the relative normal skeletal muscle architecture in the absence of satellite cells further suggested the presence of other somatic stem cell populations in Pax7-deficient skeletal muscle.

SIDE POPULATION CELLS ARE ENRICHED IN REPOPULATING CELLS

Dual wavelength flow cytometry and a DNA-binding dye (Hoechst 33342) have been used to identify side population (SP) cells that are enriched in repopulating cells (i.e., stem cells) (Fig. 68-3). These SP cells are resident in adult tissues (i.e., skeletal muscle, bone marrow, heart, liver, brain, and so on) and are able to efflux the Hoechst dye because of the multidrug resistance protein (Abcg2), which is a member of the ATP binding cassette transporter family. SP cell populations are rare but are capable of multipotentiation as they can adopt alternative fates when placed in permissive environments (Fig. 68-3). For example, SP cells isolated from the bone marrow of normal adult mice were able to reconstitute the lethally irradiated *mdx* (a mouse model that lacks dystrophin and is a model of muscular dystrophy) bone marrow; later these cells were recruited from the bone marrow to participate in muscle repair and regeneration. Similarly, SP cells isolated from adult skeletal muscle were able to reconstitute the irradiated bone marrow. These studies provide supportive evidence that SP cells have stem cell capabilities and are able to participate in tissue repair when placed in a permissive environment (Fig. 68-3).

SKELETAL MUSCLE INJURY AND REGENERATION

Adult skeletal muscle has the remarkable capacity for complete repair following severe injury. For example, a chemical-induced muscle injury that destroys more than 70–80% of the muscle will be regenerated with restoration of the anatomical architecture within a 2-wk period. The regenerative capacity of skeletal muscle due to the presence of resident stem cell populations (satellite and SP cells and other potential progenitor cell populations). These resident stem cell pools are quiescent in unperturbed skeletal muscle (Fig. 68-4). In response to a severe injury, the satellite cells are activated and express the bHLH transcription factor, MyoD. These activated satellite cells migrate to sites of injury and enter the cell cycle. The activated satellite cells have an increased proliferative capacity (capable of an estimated 80–150 doublings) and undergo asymmetric cellular division to re-establish a pool of quiescent stem cells. This property of self-renewal is characteristic of stem cell populations and has been shown to involve the Notch signaling pathway. Approximately 5–7 d following injury, the proliferating satellite cells withdraw from the cell cycle and differentiate to form centronucleated myotubes (Fig. 68-4). Over the following 1-wk period the regenerated myotubes increase in size because of fusion of myoblasts and ultimately restore the architecture of the adult skeletal muscle.

These regenerative responses require an orchestrated interactive response between the inflammatory system, growth factors, extracellular matrix (ECM), vascularization, and the stem cell population resident in skeletal muscle. During the initial phase following a severe muscle injury, a prominent neutrophillic infiltrate is observed resulting in the phagocytosis of necrotic myofibers

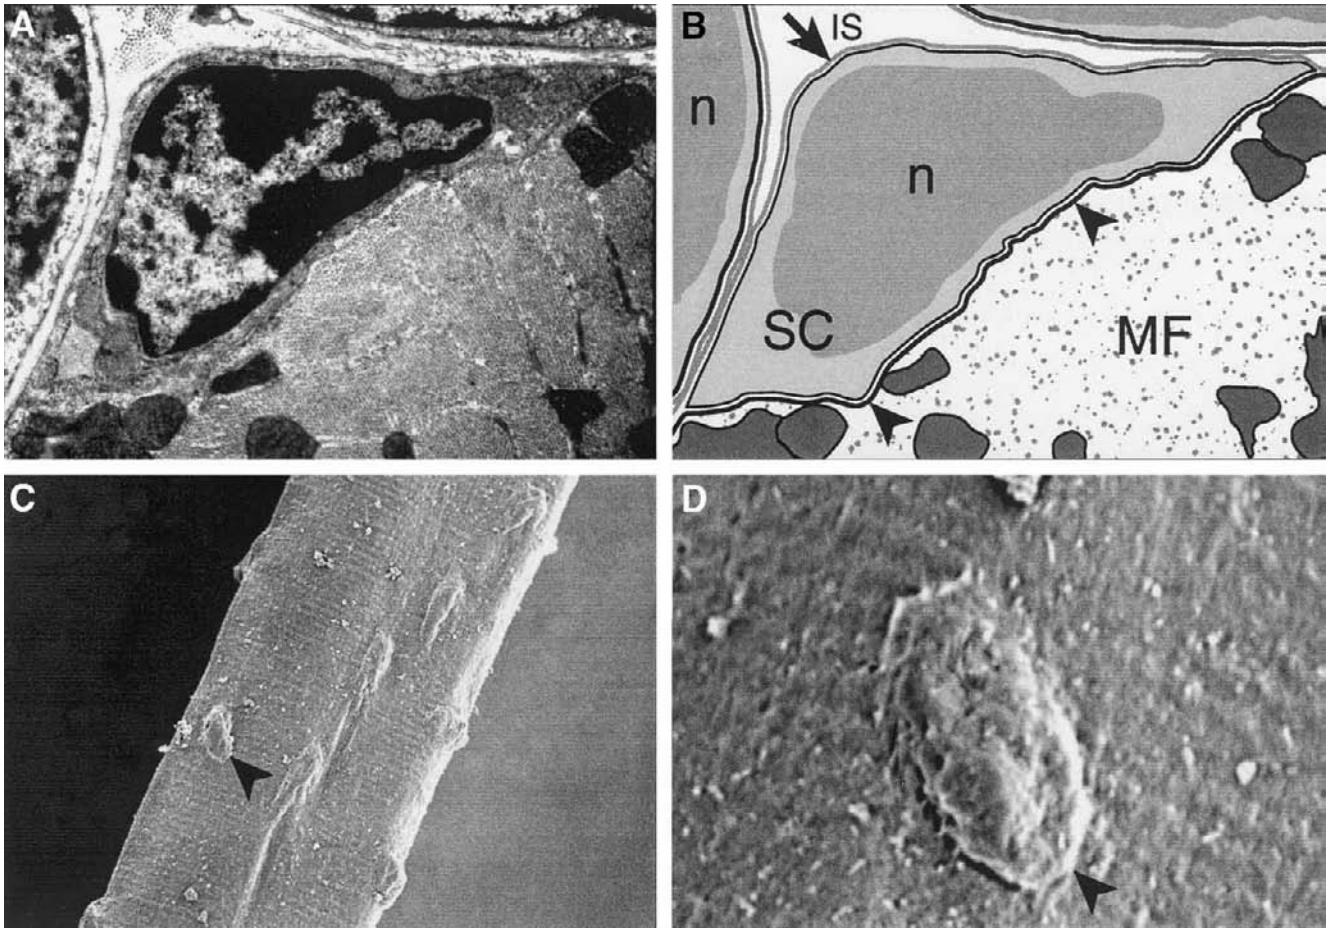

Figure 68-2 Satellite cells are resident in adult skeletal muscle. **(A)** Using transmission electron microscopic techniques, satellite cells are identified as small mononuclear cells that occupy a peripheral location regarding the larger multinucleated myofiber. **(B)** Schematic figure of **A** emphasizing that the mononucleated satellite cell occupies a sublaminar position (beneath the basal lamina marked with an arrow). The arrowheads mark the plasmalemma. **(C)** Satellite cells (arrowhead) are observed on the surface of an isolated myofiber using scanning electron microscopy. **(D)** High magnification of the myofiber in **C** revealing a satellite cell that is active and undergoing chemotaxis. SC, satellite cell; n, myonuclei; and MF, myofiber.

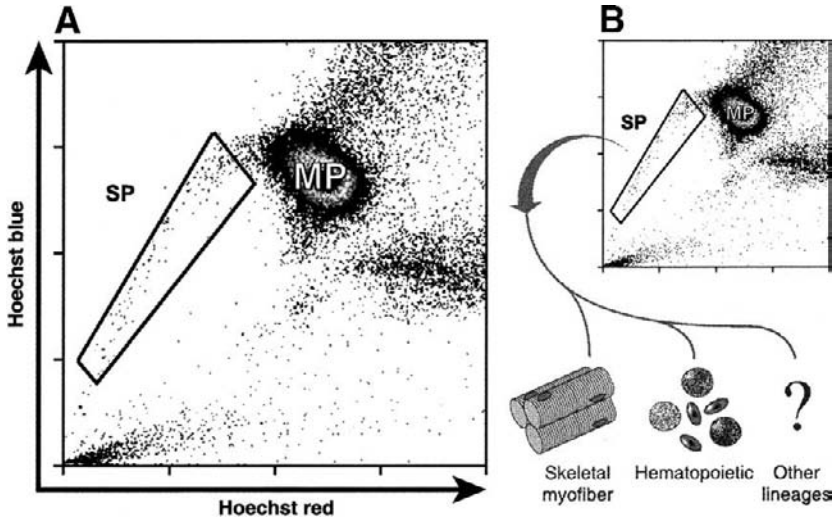

Figure 68-3 SP cells are enriched in repopulating cells. In addition to the satellite cells, adult skeletal muscle has a second population of cells that participate in repair of muscle. **(A)** Using Hoechst 33342 dye and dual wavelength flow cytometry, a cell SP (*see* gated cell population) is identified based on the ability to efflux Hoechst dye in contrast to the main population. **(B)** SP cells isolated from adult skeletal muscle have been shown to contribute to alternative lineages (i.e., hematopoietic) when placed in a permissive environment.

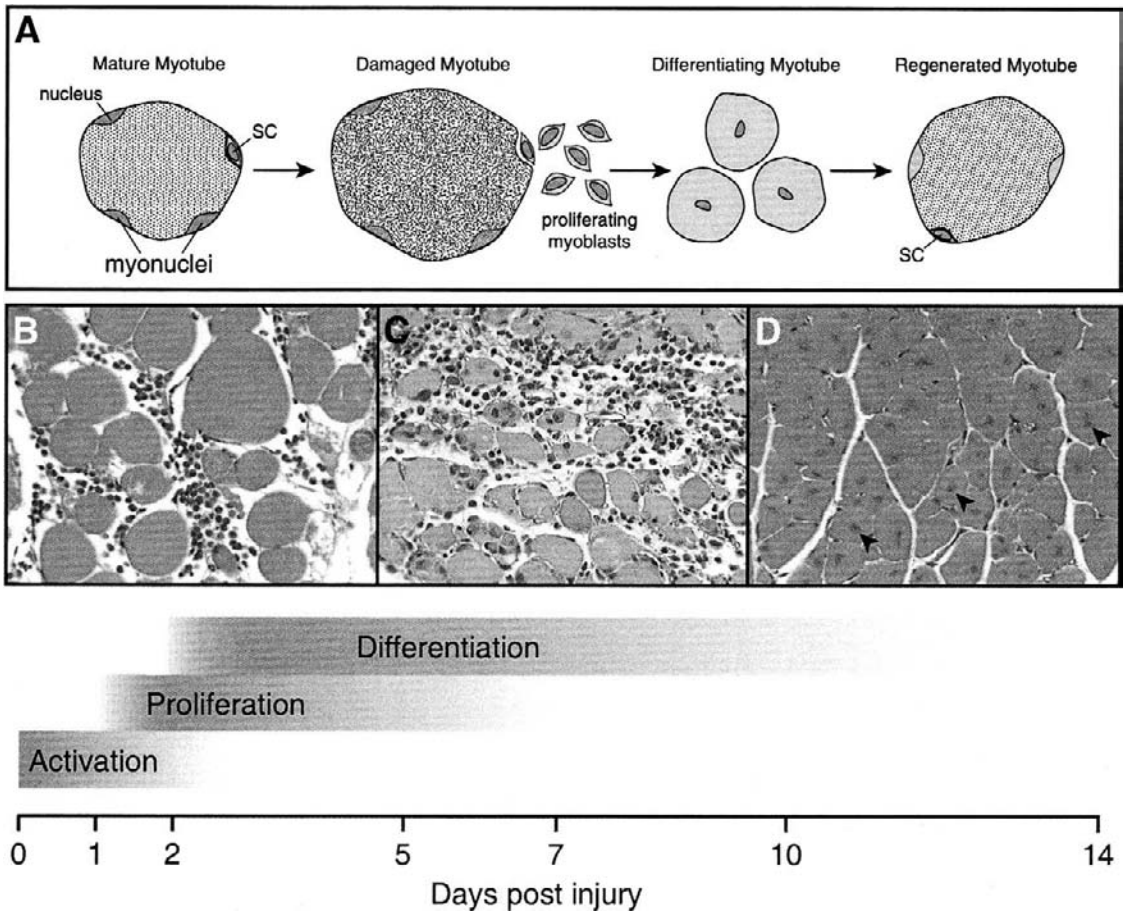

Figure 68-4 Myogenic progenitor cells participate in skeletal muscle regeneration. **(A)** Schematic of one population of progenitor cells (i.e., satellite cells) that are resident in adult skeletal muscle. The quiescent satellite cell occupies a peripheral position with respect to the larger multinucleated myofiber. Following injury the satellite cell is activated (within 2–6 h) and proliferates (d 1–4). These proliferating satellite cells withdraw from the cell cycle and form differentiated central nucleated myofibers. Fusion of additional satellite cells results in an increase in the size of the myofibers and ultimately the nuclei assume a peripheral position in the mature myofiber. Satellite cells are capable of self-renewal to replenish the satellite cell pool. **(B)** Histological analysis of skeletal muscle 1 d following injury reveals increased inflammation (neutrophils and macrophages) and edema. **(C)** Two days following injury there is a marked hypercellular response representing, in part, increased numbers of myogenic progenitor cell populations. **(D)** Restoration of the skeletal muscle architecture is largely complete within 10–14 d. Newly regenerated central nucleated myofibers (arrowhead) are observed at this time period.

(Fig. 68-4). At later stages, macrophages are also associated with the inflammatory response. These inflammatory cell populations liberate a number of interleukins, chemokines, and growth factors that further modulate the stem cell populations and the ECM (Fig. 68-4). A prominent remodeling of the ECM is observed early during the injury/repair process and continues to mature during the final stages of regeneration. The ECM has a number of important functional roles including the regulation of morphogens as well as the establishment of a supportive matrix for the regenerating tissue. Growth factors such as insulin growth factors insulin-like growth factor (IGF)-1 and IGF-2, fibroblast growth factor and transforming growth factor (TGF)-β in concert with cytokines (interleukin-4 and interleukin-13) regulate myogenesis and promote regeneration. Studies have identified the cytokine interleukin-4 as a molecular signal that regulates myoblast fusion with myotubes. Similarly, TGF-β is a multifunctional factor that regulates fibroblasts, ECM maturation, and cellular migration to promote the repair process. Furthermore, the extracellular proteoglycans such as biglycan may bind factors such as TGF-β and thereby modulate the presentation or the sequestration of these factors and impact the remodeling of the muscle and extracellular matrix. This repair process ultimately results in restoration of the skeletal muscle architecture with a lack of any significant fibrosis (i.e., scar). Although this regenerative response is highly efficient, it is not an infinite process as ultimately there is an exhaustion of satellite cells in pathological states such as muscular dystrophy resulting in a failure of regeneration.

DECREASED REGENERATIVE CAPACITY WITH AGING

As age progresses beyond the sixth decade, there is a loss of muscle mass (also known as sarcopenia), a decrease in the size of myofibers and a shift in myofiber composition (i.e., loss of fast twitch glycolytic myofibers), which collectively results in decreased muscle strength. In addition to the loss of muscle strength, aging skeletal muscle is further limited in its ability to undergo efficient regeneration. This impairment in regeneration is multifactorial and highly complex. Although aging muscles are more susceptible to contraction-induced damage, the molecular changes associated with senescent skeletal muscle as well as

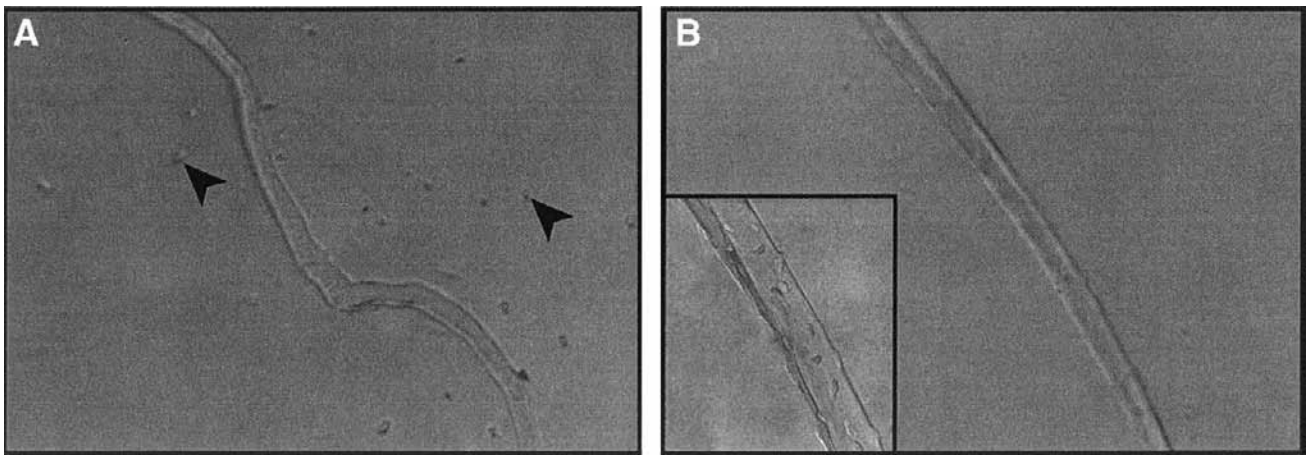

Figure 68-5 Decreased satellite cell activation/proliferation capacity in aging skeletal myofibers. **(A)** Activated satellite cells migrate off of the isolated myofibers obtained from young adult mice and proliferate (arrowheads) in culture. **(B)** Decreased activation/proliferation of satellite cells are observed in myofibers isolated from aged/senescent mice. Inset is a high magnification of the myofiber showing satellite cells that do not become activated and remain associated with the myofiber isolated from aging skeletal muscle.

the host environment further contribute to the impaired regenerative response. Aging skeletal muscle has increased levels of stress proteins (heat shock factors), DNA damaged inducible genes, and oxidative stress inducible genes. The aging immunological system results in decreased phagocytosis of neutrophils and macrophages. In addition, decreased levels of chemokines, hormones (vitamin D, IGF-1, steroid or sex hormones, and so on) and growth factors further contribute to the impaired immunological response. In response to injury of aging skeletal muscle, there is increased fibrosis and adipogenesis resulting in replacement of the myotubes with fat, which negatively impacts the regenerative response and muscle function.

Advancing age is associated with decreased absolute numbers of myogenic progenitor cells, which have a decreased proliferative capacity, in part resulting from impaired activation of the progenitor cells to re-enter the cell cycle (Fig. 68-5). Studies using transgenic technologies to overexpress IGF-1 resulted in improved strength, increased satellite cellular proliferation, and improved regeneration of injured, aging skeletal muscle. These transgenic studies suggest that therapeutic intervention using replacement strategies (i.e., cells or hormones) may be effective in the restoration of muscle strength and regeneration with progressing age.

In addition, many of the defects associated with aging such as muscle atrophy, decreased absolute numbers of myogenic progenitor cells and decreased growth factors may be related to neuromuscular defects. The neuromuscular junction is a source of stimulation (electrical-contractile coupling) and permissive factors resulting in increased numbers of myogenic progenitor cells at this junction. Perturbation of the neuromuscular junction associated with aging results in the loss of these permissive/supportive factors and physiological stimuli that further contribute to the limitations associated with aging.

PARALLEL PATHWAYS FOR THE DEVELOPMENT AND REGENERATION OF SKELETAL MUSCLE

Skeletal myogenesis is a highly coordinated program thought to be initiated in the somite that persists to ultimately contribute to established muscle groups during embryogenesis. Elegant studies utilizing gene disruption strategies have identified bHLH transcription factors including members of the MyoD family that function in the specification (i.e., Myf5 and MyoD) and differentiation/maturation (i.e., Myogenin and Mrf4) of developing myofibers. Biochemical and transgenic studies have further demonstrated that these MyoD family members (i.e., Myf5, MyoD, Myogenin, and Mrf4) interact in combination with other transcription factors (such as the myocyte enhancer factor 2 family members) and cell-cycle regulatory proteins to coordinate myogenesis. A number of shared genetic pathways are observed in developing and regenerating skeletal muscle including the MyoD, MADS box, and T-box transcription factor families. Although a number of parallel pathways are observed, repair/regeneration of skeletal muscle is not simply a recapitulation of ontogeny or embryogenesis. For example, a notable difference is observed in the Pax7 null mice that had relatively normal skeletal muscle development but severely impaired muscle regeneration. Furthermore, the signals and cues from adjacent lineages in the developing somite from the neural tube, notochord and overlying ectoderm are markedly different compared to the adult regenerating skeletal muscle which has adjacent ECM, vasculature, and inflammatory/immunological modulatory influences. These shared and distinct genetic pathways during muscle development and regeneration will be further defined using emerging technologies to comprehensively examine the molecular candidates that regulate skeletal muscle regeneration.

69 Skeletal Muscle Hypertrophy and Response to Training

ZHEN YAN AND R. SANDERS WILLIAMS

SUMMARY

Skeletal muscle of adult mammals retains remarkable plasticity. Hypertrophy is evoked by resistance exercise through increased satellite cell activity and activation of the phosphoinositide 3-kinase pathways involving insulin-like growth factor signaling. Skeletal muscle undergoes fast-to-slow fiber type transformation along with enhanced mitochondrial biogenesis and angiogenesis following endurance exercise. Activation of the Ca^{2+}/calmodulin-dependent kinase and phosphatase signaling pathways and exercise-induced expression of peroxisome proliferator-activated receptor-γ coactivator-1α play important roles in neuromuscular activity-dependent induction and maintenance of slow muscle gene expression.

Key Words: Angiogenesis; calcineurin; Ca^{2+}/calmodulin-dependent protein kinase; exercise; fiber type transformation; gene regulation; glycogen synthase kinase; hepatocyte growth factor/scatter factor; histone deacetylase; hypertrophy; insulin-like growth factor; mammalian target of rapamycin; mitochondrial biogenesis; myocyte enhancer factor-2; nuclear factor of activated T cells; peroxisome proliferator-activated receptor-γ coactivator-1α; phosphoinositide 3-kinase; satellite cell; signal transduction; skeletal muscle.

INTRODUCTION

Skeletal muscles of adult mammalian species, including humans, are the source of power for locomotion and other daily activities essential for survival. Loss of skeletal muscle contractile function is a major cause of falling, morbidity, and mortality, especially in elderly populations. More importantly, skeletal muscles collectively influence total body metabolism of glucose, fat, and protein; abnormalities of these functions are associated with a variety of common diseases. Physical inactivity, a decreased use of the musculoskeletal system, is associated with a modern lifestyle and contributes to an epidemic emergence of modern chronic diseases, such as coronary heart disease, hypertension, obesity, type-II diabetes, certain types of cancer, depression, osteoporosis, and sarcopenia. As a nonpharmacological, efficient, and economical therapy, regular exercise has been shown to have significant positive effects on human health and longevity.

Skeletal muscle of adult mammals, including humans, retains remarkable plasticity such that it regenerates after injury and adapts to changes in functional demand. Depending on the type and duration of exercise training, skeletal muscle exhibits changes in the size and the structural/functional characteristics of the myofiber population. Extensive research has provided much of the understanding of the phenotypic nature and the molecular mechanisms of these adaptations. A better understanding of the cellular and molecular mechanisms of skeletal muscle adaptation will provide information to guide the use of regular exercise for preventing and treating various diseases, and to facilitate the discovery of new drug targets and the design of new therapeutics to enhance human health. This chapter focuses on findings in signal transduction and gene regulation in skeletal muscle adaptation.

SATELLITE CELL ACTIVITY IN SKELETAL MUSCLE HYPERTROPHY

Animal tissue size and shape are, to a certain degree, genetically programmed. However, many of the differentiated, fully functional cells demonstrate changes in size and shape in response to systemic and local stimuli. This adaptability becomes a prerequisite for the survival of animal species. Skeletal muscle hypertrophy (an increase in the volume of individual myofibers) is one of the pronounced responses to high-intensity, weight-bearing exercise interventions, so-called resistance exercise. Experimentally, adult skeletal muscle hypertrophy can be induced by stretch, removal of synergistic muscles, eccentric contraction, or resistance exercise with variations in phenotypic characteristics.

Adult skeletal muscle hypertrophy is mediated mainly by intrinsic mechanisms. Responses in the pre-existing mature myofibers and activity of myogenic stem cells, so called satellite cells, are of importance to skeletal muscle hypertrophy. Quiescent satellite cells are located between the basal lamina and the sarcolemma of mature myofibers. On activation, satellite cells reenter the cell cycle, proliferate, and then exit the cell cycle either to renew the quiescent satellite cell pool or to differentiate into mature myofibers. Satellite cell activity is clearly essential to skeletal muscle hypertrophy in vivo, as sterilization of satellite cell activity by irradiation abolishes adult skeletal muscle hypertrophy. To an extent, the myofibers can only expand with the incorporation of new nuclei, because a constant ratio of nuclei to cytoplasmic volume (nuclear domain) likely is maintained throughout all hypertrophic responses. Therefore,

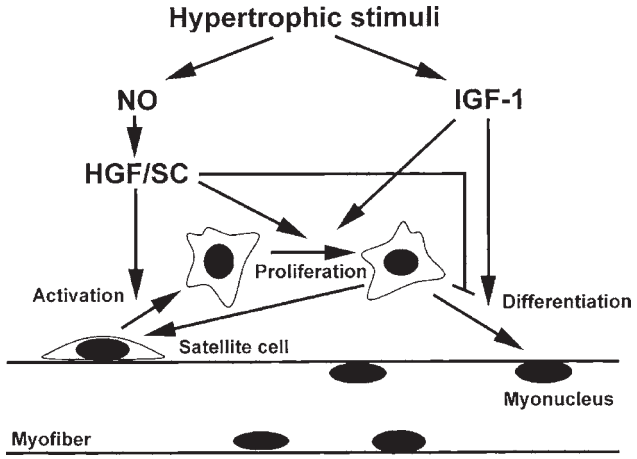

Figure 69-1 Satellite cell activity in adult skeletal muscle hypertrophy. Hypertrophic stimuli induce IGF-1 expression, as well as NO production, which results in subsequent release of HGS/SC. HGS/SC activates quiescent satellite cells, promotes proliferation, and inhibits differentiation. IGF-1, conversely, promotes satellite cell proliferation and differentiation, depending on the stage of the satellite cells.

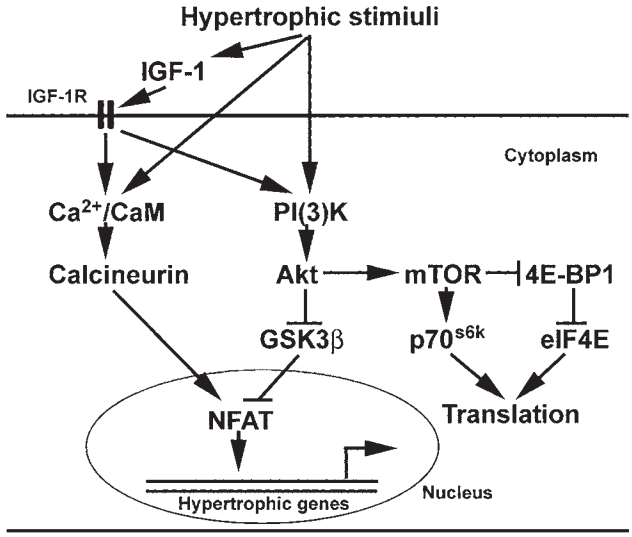

Figure 69-2 Calcineurin- and PI-3K/Akt-dependent pathways for hypertrophic signaling in adult skeletal myofiber. Hypertrophic stimuli activate Ca^{2+}/CaM-dependent calcineurin directly or indirectly through IGF and its receptor, IGF-1 receptor. Activated calcineurin dephosphorylates NFAT cells and promotes its nuclear translocation and transcriptional activation of the hypertrophic genes. Hypertrophic stimuli also activate PI-3K and Akt, resulting in inhibition of GSK-3 and maintenance of NFAT nuclear distribution. Increased protein synthesis that accompanies skeletal muscle hypertrophy is regulated by mammalian target of rapamycin through Akt activation. Mammalian target of rapamycin stimulates initiation of protein translation by the activation of $p70^{s6k}$, which phosphorylates the ribosomal protein S6, and the inactivation of 4E-BP1 protein, an inhibitor of the translation initiation factor eIF4E.

skeletal muscle hypertrophy is dependent on activation, proliferation, differentiation, and fusion of satellite cells with the existing myofibers. Disruption or impairment of any of these processes is likely to block or attenuate hypertrophy.

As an initial step in the multistep process, the activation of satellite cells plays an essential role in skeletal muscle hypertrophy. But the initial signal, timing, and character of activation are still largely unknown. Although many growth factors and cytokines have been shown to have the ability to modulate the proliferative activity of satellite cells, factors such as fibroblast growth factors, insulin-like growth factors (IGFs), platelet-derived growth factor-BB, transforming growth factor β_1 and β_2, and epidermal growth factor do not stimulate quiescent satellite cells to enter the cell cycle. Colocalization of hepatocyte growth factor/scatter factor (HGF/SF) with its receptor c-met is thought to be the earliest indicator of satellite cell activation. It has been shown that HGF/SF is sufficient and necessary for satellite cell activation in vivo and in vitro and plays a dual role in regulating skeletal muscle satellite cell activity, by promoting cell proliferation and inhibiting differentiation. Evidence indicates that satellite cell activation is achieved through HGF/SF release mediated by rapid local production of nitric oxide, which plays an important role in compensatory hypertrophy. The overall process of satellite cell activity in skeletal muscle hypertrophy is illustrated in Fig. 69-1.

IGF-1 AND SKELETAL MUSCLE HYPERTROPHY

Extensive research efforts have also been directed at many other growth factors with potential roles in regulating satellite cell proliferation and differentiation, among which IGF-1 has received the most attention. IGF-1 mRNA expression is induced through either autocrine or paracrine mechanisms in skeletal muscle undergoing compensatory hypertrophy. Many studies demonstrated a similarly close association of induced IGF-1 mRNA and protein expression with skeletal muscle hypertrophy in vivo. Of particular interest is that both IGF-1 and a muscle-specific splice variant of IGF-1, mechano growth factor, are markedly upregulated in response to increased workload with different time-courses, suggesting that IGF-1 and mechano growth factor play distinct biological roles during skeletal muscle hypertrophy. IGF-1, when overexpressed in skeletal muscle in transgenic mice or administrated locally by long-term infusion, is sufficient to induce hypertrophy and to counter the decline in muscle mass of dystrophic or aged mice. Consistent with the idea that different IGF-1 isoforms play distinct biological roles was the finding that muscle-specific IGF-1 overexpression alone was not sufficient to prevent unloading-induced atrophy. It is generally believed that IGF-1 induces muscle hypertrophy via a combination of enhancement of satellite cell activity and stimulation of protein synthesis in differentiated myofibers, as demonstrated from in vitro and in vivo observations.

THE CALCINEURIN PATHWAY

IGF-1 overexpression or treatment in cultured muscle cells results in myotube hypertrophy through a mechanism involving calcineurin-dependent dephosphorylation and nuclear translocation of nuclear factor of activated T cells (NFAT) (Fig. 69-2). The role of this pathway in physiological models of skeletal muscle hypertrophy in vivo has been less certain and the use of pharmacological inhibitor of calcineurin, cyclosporin (CsA), has given different results in different experimental settings. An argument against the role of calcineurin/NFAT pathway in skeletal muscle hypertrophy is based mainly on the findings that muscle-specific overexpression of constitutively active calcineurin in vivo is sufficient to induce slow muscle gene expression without inducing hypertrophy, and calcineurin activity does not increase during hypertrophy. By comparison, a role for calcineurin-NFAT signaling in cardiac hypertrophy has been established by multiple gain-of-function and

loss-of-function experiments. Further research is required to determine whether the calcineurin/NFAT pathway is involved in transducing signals for skeletal muscle hypertrophy.

THE PHOSPHOINOSITIDE 3-KINASE/AKT PATHWAY

Research has clearly demonstrated the importance of the phosphoinositide 3-kinase (PI-3K)/Akt signaling pathway in the control of myocyte size in the heart. Accumulating evidence supports a similar role of this pathway in skeletal muscle hypertrophy (Fig. 69-2). A functional role for Akt in control of adult skeletal myofiber size has been assessed in vivo following transfection of constitutively active form of Akt by direct plasmid injection. There are at least two distinct downstream pathways, both of which are essential for skeletal muscle hypertrophy. First, myofibers transfected with constitutively active Akt showed a significant increase in fiber cross-sectional area in a rapamycin-sensitive manner, acting through the downstream target, mammalian target of rapamycin, and phosphorylation of $p70^{s6k}$ and 4E-BP1. Second, glycogen synthase kinase (GSK)-3β, a downstream target protein of Akt, is phosphorylated during compensatory hypertrophy and has been confirmed to be a negative regulator of skeletal muscle hypertrophy, inhibition of which leads to myotube hypertrophy in vitro. One of the possible downstream targets of GSK-3β is NFAT, and decreased GSK-3β would be predicted to maintain NFAT in the nucleus thereby promoting NFAT-dependent transcription.

MUSCLE CONTRACTILE ACTIVITY AND FIBER-TYPE SPECIALIZATION

Adult mammalian skeletal muscle fibers are heterogeneously specialized as a result of embryonic and postnatal development, varying in contractile properties, metabolic capacities, ultrastructures, and susceptibility to fatigue. Based on the expression of the predominant isoform of myosin heavy chain protein, adult myofibers can be characterized as type I, IIa, IIx, or IIb. Even though terminally differentiated and incapable of proliferation, adult myofibers in rodents remain plastic such that alteration in contractile load, hormonal shifts, or systemic diseases can induce stable, long-term adaptations. Endurance exercise promotes transformation of IIb to IIa myofibers, an increase in mitochondrial density, and an increase in capillary density. A central role of motor nerve activity in determining skeletal muscle fiber-type composition has been revealed by cross-innervation and electric stimulation studies, which demonstrated complete and reversible transformation of preexisting myofibers by changing patterns of neuronal firing. There has been intense interest for several decades in elucidating the mechanism responsible for the reversible fiber-type transformation. Studying the signaling and molecular mechanisms became possible only with advances in molecular genetics.

THE CALCINEURIN PATHWAY IN FIBER-TYPE SPECIALIZATION

Fiber-type specific gene expression in adult skeletal muscles is controlled by signals transduced from the external milieu, which include hormonal, mechanical, and electrical influences, to certain sets of genes in the nuclei of the myofibers. Consistent with a long-hypothesized model, exercise activates multiple signal transduction pathways and transcription factors resulting in genetic reprogramming and ultimate phenotypic changes. Calcineurin/NFAT signaling has been proposed to link neuromuscular activity to expression

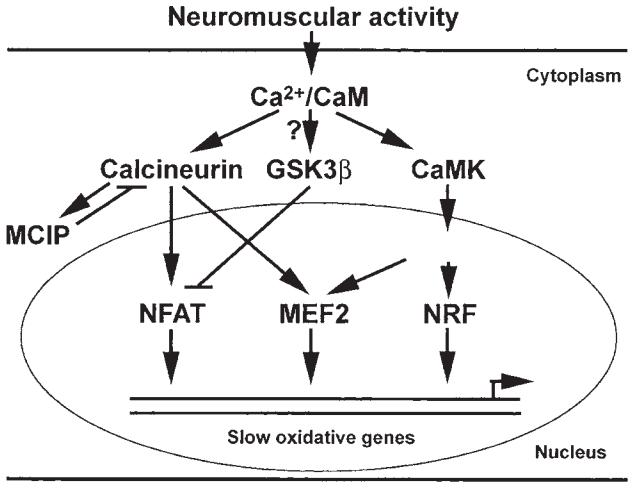

Figure 69-3 Multiple signaling pathways involved in cooperative activation of slow oxidative gene expression in skeletal myocytes. Tonic neuromuscular activity induces low amplitude, sustained elevation of intracellular Ca^{2+} and its binding to CaM. Ca^{2+}/CaM dependent activation of calcineurin promotes NFAT-cells nuclear translocation, whereas Ca^{2+} signal promotes the maintenance of NFAT nuclear distribution by phosphorylation-mediated deactivation of GSK-3β. Ca^{2+}/CaM signal activates Ca^{2+}/CaM-dependent protein kinase and promotes PPAR-γ coactivator-1 expression, facilitating muscle-enriched factor 2 and NRF function in maintenance and regulation of the slow oxidative genes.

of genes characteristic of slow oxidative myofibers (Fig. 69-3). Supporting this central hypothesis were the findings that treatment with the calcineurin inhibitor, cyclosporin A, blocks nuclear localization of NFAT and slow muscle gene expression, and overexpression of constitutively active calcineurin in fast-twitch skeletal muscle increases the percentage of slow myofibers. Other studies suggest different mechanisms of slow muscle gene expression. The positive findings suggest a molecular mechanism in which signals from neuromuscular activity are translated by Ca^{2+}/calmodulin (CaM) to protein kinases and phosphatases that modulate the functions of transcription factors controlling mitochondrial biogenesis and fast-to-slow fiber-type switching. More specifically, tonic neuromuscular activity induces a low-amplitude sustained elevation of intracellular Ca^{2+} concentration and the binding to the intracellular Ca^{2+} sensor protein CaM. Ca^{2+}-bound CaM activates Ca^{2+}/CaM dependent serine/threonine phosphatase, calcineurin, which dephosphorylates NFAT and myocyte enhancer factor-2 (MEF-2) and promotes their transactivation activities on the target genes cooperatively (Fig. 69-3). This notion is supported by findings that nuclear translocation and distribution of NFAT are specifically dependent on slow neuromuscular activity.

This calcineurin-dependent pathway is regulated in the skeletal muscle by means of a negative feedback mechanism conferred by calcineurin-dependent expression of an endogenous calcineurin inhibitor, modular calcineurin inhibitory protein. In addition, endurance exercise has been shown to deactivate GSK-3α and GSK-3β in rats in an Akt-independent manner (Fig. 69-3). Because GSK-3-mediated phosphorylation of NFAT promotes its export from the nucleus, thereby antagonizing NFAT-dependent transcription, it is suggested that exercise-induced GSK-3β phosphorylation plays a synergistic role with calcineurin in promoting the expression of the slow muscle genetic program. Identification of the upstream regulators responsible for the phosphorylation of GSK-3 in skeletal muscle during exercise is anticipated.

MITOCHONDRIAL BIOGENESIS AND SLOW MUSCLE GENE EXPRESSION

Findings in peroxisome proliferator-activated receptor (PPAR)-γ coactivator-1α (PGC-1α) gene regulation and function have led to the consideration of PGC-1α as a key regulator of important features of skeletal muscle adaptation. PGC-1α is a transcriptional coactivator cloned originally by a yeast two-hybrid screen from a differentiated brown fat cell line using PPAR-γ as bait. PGC-1α mRNA and protein are highly expressed in slow, oxidative fibers compared to the fast, glycolytic fibers, consistent with the function of a gene involved in fiber-type specialization. Several different models have suggested the functional importance of PGC-1α in striated muscles. A possible association between polymorphism of the PGC-1α gene and type-II diabetes has also been suggested. PGC-1α protein interacts with many nuclear regulatory proteins, such as thyroid hormone receptor, estrogen receptor α, PPAR-γ, nuclear respiratory factor-1 (NRF-1) and CREB-binding protein. PGC-1α also stimulates the expression of multiple effector genes during various biological processes. The most striking property of PGC-1α function in skeletal muscle is that its overexpression in cultured myoblasts induces mitochondrial biogenesis, and overexpression in transgenic mice causes a remarkable fast-to-slow fiber-type switching and enhanced mitochondrial biogenesis. These findings suggest the possibility that increased expression of PGC-1α in skeletal muscle plays a key role in endurance exercise-induced skeletal muscle adaptation by promoting mitochondrial biogenesis and other genetic and biochemical events. The profound effect of PGC-1α overexpression probably results from the enhancement of the transactivation activities of regulatory proteins, such as NRF-1 and MEF-2, as well as the induction of the genes in encoding these transcription factors.

The importance of PGC-1α function in promoting the acquisition of slow-twitch muscle contractile and metabolic properties also is suggested by the observation that endurance exercise induces PGC-1α mRNA expression in the recruited skeletal muscle through transcriptional control. PGC-1α protein expression along with that of NRF-1 and NRF-2 are also increased in exercised skeletal muscle. Endurance exercise is likely to induce PGC-1α gene expression through a combination of transcriptional activation of the PGC-1α gene and increased protein stability. Studies to elucidate the signal transduction pathways and the molecular mechanism for exercise-induced PGC-1α gene expression in skeletal muscle will yield critically important information.

THE CA^{2+}/CAM-DEPENDENT PROTEIN KINASE PATHWAY

Ca^{2+}/CaM, acting through calcineurin and Ca^{2+}/CaM-dependent protein kinase (CaMK) pathways, stimulates MEF-2 transactivation activity and downstream target genes, such PGC-1α (Fig. 69-3). Relatively little is known about the exact CaMK pathway(s) in exercise-induced skeletal muscle adaptation. A molecular mechanism for CaMK-induced activation of MEF-2 activity has been elucidated in cardiac myocytes. Phosphorylation of histone deacetylase 5 results in its binding with the intracellular chaperone protein 14-3-3 and promotes its nuclear export leading to derepression of MEF-2 activity. This mechanism plays a role in maintenance of mitochondrial biogenesis in the heart. However, the endogenous kinase that is responsible for transducing the signal and catalyzing the dephosphorylation of HDAC remains unknown. Furthermore, it is not known whether the same regulatory mechanism accounts for the adaptation in skeletal muscle in response to exercise training.

The effects of activated CaMKIV in skeletal muscle in inducing PGC-1α gene expression, enhancing mitochondrial biogenesis, and promoting myosin isoform switching in a transgenic mouse model have been described. In this model, a constitutively active form of CaMKIV was expressed in fast-twitch myofibers under the control of the muscle creatine kinase promoter. A significant increase in percentage of slow-twitch fibers in normally fast-twitch muscles and a marked increase in subsarcolemmal mitochondrial density were confirmed along with increases in various genetic and biochemical markers for a slow oxidative muscle phenotype, including a profound induction of PGC-1α mRNA. Another study reported that energy deprivation-induced mitochondrial biogenesis is dependent on an activation of the AMP-activated protein kinase pathway, which was associated with increased CaMKIV protein and PGC-1α mRNA expression. These data suggest a role for CaMK signaling in the acquisition of a slow-twitch muscle phenotype in adults, but do not identify the specific isoforms of CaMK that are relevant to this response.

CONCLUSIONS

Cell size and specialized characteristics of myofibers in adult skeletal muscles are controlled by multiple signaling pathways. Ca^{2+}-dependent activation of calcineurin-NFAT signaling and exercise-induced induction of PGC-1α are both involved in the activity- dependent induction and maintenance of fiber-type-specific gene expression. Satellite cell activity and intracellular signaling activities involving the PI-3K/Akt/mammalian target of rapamycin and PI-3K/ Akt/GSK-3 pathways in mature myofibers appear to mediate skeletal muscle hypertrophy in response to hypertrophic stimuli, such as resistance exercise. The future challenge is to define relationships between these and other signaling pathways that are responsible for neuromuscular activity-mediated adaptations. Such knowledge may foster the development of novel therapeutics and preventive technologies to improve human fitness and health.

70 Muscular Dystrophies

Mechanisms

PETER B. KANG AND LOUIS M. KUNKEL

SUMMARY

Since the cloning of the gene responsible for Duchenne and Becker muscular dystrophy two decades ago, a number of other genes have been associated with various forms of muscular dystrophy. The protein products of these genes display a diversity of cellular localizations and functions, suggesting a complex pathophysiology within this class of disorders. Two recently identified functions of selected proteins include membrane repair and glycosylation, providing important insights into the disease process. A definitive cure remains elusive, but supportive therapies have become increasingly sophisticated, improving the quality of life and lengthening the life expectancy for many affected individuals.

Key Words: Becker; calpain; congenital muscular dystrophy; duchenne; dysferlin; dystroglycan; dystrophin; facioscapulohumeral muscular dystrophy; limb-girdle; merosin; muscular dystrophy; sarcoglycan.

INTRODUCTION

The muscular dystrophies are a group of inherited primary diseases of muscle that are characterized clinically by progressive, chronic weakness, and pathologically by degeneration of muscle fibers with necrosis and connective tissue infiltration. This definition distinguishes muscular dystrophies from other primary diseases of muscle, including the congenital myopathies and inflammatory myopathies, although there are some areas of overlap.

The clinical course of muscular dystrophy varies widely between specific diseases from the rapidly fatal Walker–Warburg disease to the milder Becker muscular dystrophy. There are four major categories of muscular dystrophy: dystrophinopathies, limb-girdle muscular dystrophies (LGMD), congenital muscular dystrophies, and the syndromic muscular dystrophies (Table 70-1). These categories are largely based on the clinical characteristics of the diseases and do not reflect the differences in molecular and biochemical origins. An international collaborative effort in the mid-1980s led to positional cloning of dystrophin, the gene on the X-chromosome responsible for Duchenne muscular dystrophy. Since then, the genes that cause more than a dozen other types of muscular dystrophy have been described (summarized at http://www.dmd.nl/). These proteins, with other associated muscle proteins that have not been shown to play a primary role in human disease, have been extensively studied (Fig. 70-1). The majority of the proteins produced by these genes appear primarily to be structural in function and are linked to each other in the vicinity of the sarcolemma. Some of these proteins may also play a role in cellular signaling and repair. Very few are enzymes.

DYSTROPHINOPATHIES

Duchenne muscular dystrophy is caused by mutations in the *DMD* gene on the X-chromosome. It is the most common muscular dystrophy, occurring in 1 in 3300 live male births. The high incidence is because of the large size of the gene, which has 79 exons and produces a 427-kDa protein called dystrophin. The majority of mutations are deletions that cluster in exons 2–20 and 44–53, areas in which the intronic sequences are unusually long, approaching 200 bp. Polymerase chain reaction amplification techniques concentrating on these exons identify about two-thirds of affected patients. The remainders have point mutations, deletions in other regions, and duplications.

Becker muscular dystrophy, a milder variant, is also associated with mutations in *DMD*. Shifting or preservation of the reading frame is more important than the size of the deletion in determining whether an affected child will have the Duchenne vs Becker phenotype; most children with Duchenne muscular dystrophy have a frameshift mutation, whereas those with Becker muscular dystrophy typically have a preserved translational reading frame.

The dystrophin protein is expressed in a number of organs besides muscle. Brain, Purkinje cells, and muscle produce the full-length 427 kDa protein. Retina, Schwann cells, glial cells, and kidney produce shorter isoforms. In skeletal muscle, dystrophin is located in the subsarcolemmal region and has four major domains: amino terminus, rod domain, cysteine-rich domain, and carboxy terminus. The amino terminus binds to actin, whereas the carboxy terminus binds to a protein complex that extends into the extracellular matrix. Dystrophin's main role appears to be structural, although there is evidence that it, with its associated proteins, may be involved in more dynamic functions such as regulating the perfusion and repair of muscle.

Clinically, Duchenne muscular dystrophy typically presents with gait abnormalities between the ages of 3–5 yr, although in retrospect parents may recall symptoms as early as 1 yr of age. The gait abnormalities may include toe walking, frequent falling

and tripping, waddling gait, and delayed walking. Examination is notable for weakness of the proximal muscles, most marked in the hip girdle in the early stages and more widespread with disease progression. Reflexes are initially normal or reduced and become absent in the later stages. Becker muscular dystrophy has a similar but milder presentation with a typical onset in later childhood or adolescence and a slower progression of weakness.

In suspected cases of Duchenne or Becker muscular dystrophy, initial laboratory evaluation should include measurement of muscle enzymes in the serum: creatine phosphokinase (CPK), aldolase, alanine aminotransferase, aspartate transaminase, and lactate dehydrogenase. The first two are most specific for muscle; the others are also produced in the liver. These enzymes are elevated in both diseases, but more markedly in Duchenne muscular dystrophy. The diagnosis may then be confirmed in about two-thirds of cases by polymerase chain reaction amplification of the most commonly deleted exons on blood leukocytes. When this test is negative, a muscle biopsy with antibody staining for dystrophin confirms or excludes the diagnosis. Routine histochemical staining of muscle tissue reveals muscle necrosis and inflammation with replacement of muscle fibers by connective tissue. On antibody staining, dystrophin is virtually absent in Duchenne muscular dystrophy and present in abnormal size or amount in Becker muscular dystrophy. The need for about one-third of boys with Duchenne muscular dystrophy to undergo muscle biopsy, an invasive procedure that requires general anesthesia in children, is not ideal. Robust DNA sequencing of all 79 exons in children suspected of having Duchenne muscular dystrophy should enable more cases to be confirmed without muscle biopsy.

The course is progressive with Duchenne muscular dystrophy patients often surviving into early adulthood and Becker muscular dystrophy patients surviving well into adulthood. The most common causes of death are respiratory and cardiac complications.

LIMB-GIRDLE MUSCULAR DYSTROPHIES

Clinically and histologically, the LGMDs are similar to the dystrophinopathies, with a progressive course of predominantly proximal weakness and signs of inflammation, necrosis, and connective tissue replacement on biopsy. The severity ranges widely from a mild course similar to Becker muscular dystrophy to a more rapidly progressive one that resembles Duchenne muscular dystrophy. Cardiac complications appear to be common in types 1B, 1D, 2G, and 2I, but the overall frequency is unclear because of the small number of patients reported for a number of subtypes. Intelligence is usually normal. The dystrophinopathies may be regarded as an X-linked recessive category of LGMD, but for historical reasons are usually classified separately. The genes that cause certain LGMDs (1B, 1C, 2B, and 2I) have also been shown to cause other diseases. Certain individual mutations in caveolin and dysferlin are associated with multiple phenotypes, suggesting the involvement of modifying factors.

AUTOSOMAL-DOMINANT LGMD (TYPE 1) Biochemically, the protein products of the identified autosomal-dominant LGMDs do not appear to have much in common. The common thread that runs through these disorders is the inheritance pattern and the generally mild course of disease compared with the autosomal-recessive LGMDs. Type 1 is much rarer than type 2, comprising less than 10% of cases.

LGMD type 1A is caused by mutations in the myotilin gene, whose protein product localizes to the Z-disk of the sarcomere. Myotilin's exact function is unknown, but the protein appears to play a structural role in the Z-disk. Mutations lead to abnormalities in the Z-disk, which may appear under light microscopy as rod-shaped structures similar to the rods found in nemaline myopathy.

Patients with LGMD type 1A have, in addition to muscle weakness, a distinctive dysarthric pattern of speech. The age of onset is usually in early adulthood. In the initial stages, the weakness is mostly proximal, but slowly spreads to involve distal muscles as the disease progresses. CPK levels are significantly elevated.

Mutations in the lamin A/C gene cause LGMD 1B, Emery–Dreifuss muscular dystrophy, cardiomyopathy, and lipodystrophy. A missense mutation in the lamin A portion of the gene has been identified as a cause of Hutchinson–Gilford progeria. The two protein products, lamins A and C, are produced by alternative splicing and localize to the nuclear lamina. The mechanism of disease is unclear, but may be related to impaired interactions with other nuclear proteins or dysfunctional filament assembly.

Cardiac complication rates are high in both LGMD 1B and Emery–Dreifuss muscular dystrophy. The two diseases are distinguished clinically by the absence of early contractures and a proximal pattern of weakness in LGMD 1B.

Mutations in the gene encoding caveolin 3 cause LGMD 1C, rippling muscle disease, distal myopathy, and hyper-CKemia. The same mutation in the caveolin gene has been shown to cause rippling muscle disease with distal myopathy in some individuals, and rippling muscle disease with LGMD in others. Caveolins are the proteins found in caveolae, which are 50–100 nm invaginations of the plasma membrane found in most cell types, including muscle. Caveolae are involved in membrane trafficking, sorting, transport, and signal transduction. Caveolin 3, a muscle-specific caveolin protein, forms a hairpin loop within the sarcolemma, enabling both the amino- and carboxy-terminal ends to face the cytoplasm. The protein coprecipitates with dystrophin, indicating a link to the dystrophin-associated protein complex. This connection is further supported by the development of dystrophin deficiency in mice when caveolin 3 is overexpressed. In mouse models, a deficiency of caveolin 3 leads to a deficiency of caveolae and abnormalities in the T-tubule system.

Onset of proximal muscle weakness in LGMD 1C is typically at 5 yr, with calf hypertrophy, Gowers' sign, and occasional reports of exercise intolerance. CPK levels are significantly elevated.

In LGMD 1D–1F, the genetic loci have been mapped, but the exact genes have not been identified. Genetic linkage has identified the locus responsible for LGMD 1D to a 3-cM region of 6q23. Two nearby laminins have been excluded as causes, but their proximity suggests that a previously unknown laminin may be the gene responsible. The most prominent symptoms are cardiac with dilated cardiomyopathy and cardiac conduction defects the most common manifestations. Sudden death may occur. Onset is typically in early adulthood, sometimes in late adolescence. Mild proximal muscle weakness frequently occurs, and may precede or follow the initial cardiac symptoms. Serum CPK levels are mildly elevated. The phenotype resembles that of LGMD 1B.

The genetic region of interest in LGMD 1E appears to be a 9-cM interval on 7q, although the odds ratio for this region is not ideal. Additional kindreds must be analyzed to confirm this finding and pinpoint the responsible gene. Clinical features in affected individuals include the classic pattern of proximal muscle weakness.

Vocal cord and pharyngeal weakness with autosomal-dominant distal myopathy has been localized to a 12-cM interval on 5q31. Although it is a distal myopathy with little evidence of inflammation on muscle biopsy, it is classified as LGMD 1F. The onset of symptoms is typically in middle adulthood. Clinical manifestations include voice change, finger extensor weakness, peroneal weakness, shoulder girdle weakness, and dysphagia. Serum CPK levels may be mildly elevated.

AUTOSOMAL-RECESSIVE LGMD (TYPE 2) The autosomal-recessive LGMDs (type 2) are more common than the dominant forms, and generally have a more severe clinical course.

The gene encoding calpain 3 is mutated in LGMD 2A. Calpain 3 is a muscle-specific calcium-activated proteolytic enzyme, the first nonstructural protein demonstrated to cause LGMD. Calpain 3 has been shown to cleave filamin 2, but the exact pathogenesis of disease remains obscure; the enzyme is quickly degraded, and is, thus, difficult to study. In human muscle biopsy tissue and mouse models, calpain-3 deficiency is associated with myonuclear apoptosis and abnormal expression of the transcriptional factor nuclear factor-κB and its inhibitor (IκBα). Injection of Evans blue dye, which cannot cross intact membranes, into the mouse model revealed disruption of the sarcolemma, a phenomenon seen commonly in other muscular dystrophies. It is not clear whether the apoptotic cascade or membrane disruption is the more primary event.

LGMD 2A (calpainopathy), thought to be the most common form of LGMD, is characterized by progressive, predominantly proximal weakness, without cardiac or facial involvement. The severity varies widely and does not correlate consistently with the level of expression of calpain 3 in muscle.

Mutations in the gene encoding dysferlin cause LGMD 2B, Miyoshi myopathy, and distal myopathy with anterior tibial onset. Deletion of 1 bp causes both Miyoshi myopathy and distal myopathy with tibial onset in different kindreds, whereas missense mutations cause Miyoshi myopathy and LGMD 2B in different individuals within the same family. The gene is large, consisting of 55 exons and a 6243 bp open reading frame, and is expressed mainly in skeletal and cardiac muscles. The dysferlin protein plays an important role in the calcium-mediated process of membrane resealing, which is crucial for the stability of the muscle membrane.

LGMD 2B has a proximal pattern of weakness; Miyoshi myopathy tends to involve more distal muscles, particularly gastrocnemius. Difficulty standing on the toes is a common initial complaint of patients with Miyoshi myopathy. Onset is typically in childhood or early adulthood. CPK levels are markedly elevated in all the phenotypes. The course is milder than in the other recessive LGMDs; only about 10% of patients lose the ability to ambulate.

The four sarcoglycanopathies are LGMDs 2C–2F and are linked to mutations in the genes encoding γ-, α-, β-, and δ-sarcoglycans, respectively. A fifth sarcoglycan (ε) has been identified. Mutations in ε-sarcoglycan cause a dystonia rather than a muscular dystrophy. The sarcoglycans form a complex that spans the sarcolemma. Because they are physically linked, a mutation in the gene encoding one sarcoglycan often causes a secondary deficiency in one or more of the others, especially when primary mutations in β- and δ-sarcoglycan are present. This frequently makes it difficult to diagnose a sarcoglycanopathy based entirely on antibody staining of muscle tissue, even though antibodies to all four disease-causing sarcoglycans are available. Of the four sarcoglycanopathies, α-sarcoglycanopathy frequently has a mild phenotype; all reported cases of δ-sarcoglycanopathy have been severe.

The telethonin protein localizes to the Z-disk of the sarcomere and is expressed in skeletal and cardiac muscles. Mutations in its gene cause LGMD 2G. Its specific function is unknown, but it interacts with titin, mutations of which cause LGMD 2J. Patients with LGMD 2G typically present in late childhood or adolescence with proximal weakness, sometimes accompanied by distal weakness that may resemble the phenotype of Miyoshi myopathy. A significant minority of patients lose the ability to ambulate independently in the third or fourth decade. Cardiac complications are common.

LGMD 2H is caused by mutations in the gene encoding *TRIM 32*, an E3 ubiquitin ligase expressed in skeletal and cardiac muscle. A deficiency of the enzyme could presumably cause the accumulation of its target protein, but histological examination has not revealed any unusual deposits in muscle fibers. The clinical disease is mild and slowly progressive. Mutations in the gene encoding fukutin-related protein (*FKRP*) cause both LGMD 2I and congenital muscular dystrophy 1C. In contrast to the genotype–phenotype correlations with dysferlin, different mutations in *FKRP* correspond to the two different phenotypes, suggesting that the mutations themselves are the primary determinants of the disease manifestations. Patients with LGMD 2I frequently have a C826A (Leu276Ileu) mutation. In more severely affected patients, the patterns of protein expression may resemble that of the more severe forms of congenital muscular dystrophy, with secondary deficiencies of laminin-α2 and α-dystroglycan observed on muscle tissue immunohistochemistry, Western blots, or both.

In the more severe form of LGMD 2I, children develop hypotonia, motor delays, and muscle hypertrophy (which sometimes causes macroglossia), usually in the first 2 yr of life. Clinically, they resemble patients with Duchenne muscular dystrophy, with cardiac complications and loss of ambulation in early adolescence. The milder form of LGMD 2I has been described in a Tunisian family, having a later onset and a slower progression, with preservation of ambulation in nearly all cases. CPK levels are markedly elevated in both forms.

A sarcomeric protein named titin has been demonstrated to be mutated in LGMD 2J. These patients have proximal weakness with elevated CPK levels. Immunohistochemistry of muscle tissue reveals a secondary deficiency of calpain 3.

A novel form of LGMD, LGMD2K, has recently been described in a small number of Turkish patients. Affected individuals tend to have mild proximal muscle weakness, mild muscle hypertrophy,

and marked elevations in serum CK levels. Onset is between 1 and 3 yr, although this range may be expanded as further patients are identified. Patients remain ambulatory at least until late adolescence. Unusual features include microcephaly and mental retardation. However, brain imaging so far has not revealed any structural abnormalities. Histologically, there is a reduction of α-dystroglycan staining in muscle tissue. A mutation in *O*-mannosyltransferase-1 (*POMT1*) has been identified in this cohort (A200P).

The genetic causes of LGMD have most likely not been fully described. Other genes responsible for this syndrome may yet be identified.

CONGENITAL MUSCULAR DYSTROPHIES

Congenital muscular dystrophies generally share with the other muscular dystrophies the characteristic findings on routine muscle histology. As the name implies, patients typically present at birth with hypotonia and weakness. There are three broad categories of congenital muscular dystrophies, which may be distinguished by the immunohistochemical staining pattern of laminin-α2 on muscle biopsy and by the clinical course. The mild laminin-α2 (merosin)-positive congenital muscular dystrophies are associated with normal MRI findings and normal cognitive development. Patients with the moderately severe congenital muscular dystrophies typically have white matter changes on MRI and normal or slightly impaired cognitive development. This category includes the most common single variant, laminin-α2 (merosin)-negative congenital muscular dystrophy. The severe congenital muscular dystrophies are accompanied by significant structural brain lesions and mental retardation, and often have a rapidly progressive course. Immunohistochemical staining typically demonstrates reduced but not absent laminin-α2.

MILD CONGENITAL MUSCULAR DYSTROPHIES The laminin-α2 (merosin)-positive congenital muscular dystrophies are characterized by normal immunohistochemical staining of laminin-α2 on muscle biopsy. It is rare to have structural brain lesions, and intelligence is normal. Many cases of laminin-α2-positive congenital muscular dystrophy are not further classified, but the genetic origins of two distinct congenital muscular dystrophy syndromes, Ullrich disease, and rigid spine syndrome, have been identified.

Mutations in the collagen-VI α 1, 2, and 3 genes cause some cases of Ullrich disease. These findings correspond to the deficiencies of collagen VI demonstrated on immunohistochemistry of muscle tissue from affected patients. Collagen VI is widely expressed in all connective tissues and anchors collagen I/III fibrils to basement membranes. In contrast, collagen IV expression is upregulated, perhaps as a compensatory mechanism.

Patients with Ullrich disease present in infancy with marked hypotonia, motor delays, and muscle atrophy. The distinguishing clinical features of the disease include distal joint hyperextensibility and proximal joint contractures. Some are able to walk for several years, but all patients eventually are unable to walk. Intelligence is usually normal.

Rigid spine syndrome is caused by a mutation in the gene encoding selenoprotein N (*SEPN1*), which incorporates selenium in the form of selenocysteine. The function of this protein remains obscure, but selenium deficiency is known to cause cardiomyopathy in humans and muscular dystrophy in livestock. Patients affected with rigid spine syndrome generally have a mild degree of weakness, retaining the ability to walk and having little or no elevation in the level of CPK. However, they tend to develop respiratory insufficiency requiring ventilation, perhaps related to selective involvement of the diaphragm. Multiminicore disease has also been linked to mutations in *SEPN1*.

Most children with laminin-α2 (merosin)-positive congenital muscular dystrophy have a mild course and do not have the phenotype of either Ullrich disease or rigid spine syndrome. These patients bear further study; other genetic loci may be identified in the future.

MODERATE CONGENITAL MUSCULAR DYSTROPHIES Primary mutations in the laminin-α2 (merosin) gene cause laminin-α2-negative congenital muscular dystrophy. Laminin-α2 is an extracellular matrix protein that is associated with α-dystroglycan. A deficiency of laminin-α2 on immunohistochemistry of muscle tissue does not necessarily imply a primary laminin-α2-negative congenital muscular dystrophy—this finding only indicates a protein deficiency, which may be caused by either a mutation in laminin-α2 or may be secondary to a mutation in an associated protein, as occurs in the severe forms of congenital muscular dystrophy and LGMD 2I. Many of the published cases of laminin-α2-negative congenital muscular dystrophy do not include mutation analysis. Thus, laminin-α2-negative congenital muscular dystrophy as a disease entity is in flux.

In the classic, severe form of primary laminin-α2-negative congenital muscular dystrophy, affected children present in the first 6 mo of life with hypotonia, muscle weakness, and contractures. The course is moderately severe; most patients never ambulate independently. Serum CPK levels are mildly to moderately elevated. Although these patients have diffuse white matter lesions evident on MRI, gray matter is generally preserved, and intelligence is typically normal, although mental retardation has been reported in some cases. Other less commonly encountered features include seizures, cardiac complications, and neuronal migration defects.

MDC1C with mutations in *FKRP* also spare cognitive function, although the muscular defect is severe and survival past the first decade may only be possible with assisted ventilation.

SEVERE CONGENITAL MUSCULAR DYSTROPHIES The three classic severe congenital muscular dystrophies, Fukuyama congenital muscular dystrophy, muscle-eye-brain disease, and Walker–Warburg syndrome, share in common a more severe course than the other congenital muscular dystrophies, brain abnormalities in both white and gray matter, and mental retardation. The genetic origins of all three have been described, and the protein products all localize to the Golgi apparatus, which is consistent with their putative role in protein glycosylation. Protein glycosylation appears to play a role in cell adhesion, growth, and differentiation. Muscle tissue from affected patients has secondary deficiencies in laminin-α2 and α-dystroglycan on immunohistochemistry.

Mutations in *FCMD*, the gene encoding fukutin on 9q31, cause Fukuyama congenital muscular dystrophy, and have also been associated with the Walker–Warburg phenotype. The most common molecular defect is a 3-kb retrotransposal insertion in the 3′ untranslated region of the gene. Some patients also have point mutations in the coding region. Both defects lead to an absence of protein expression in affected patients. The exact function of fukutin is unknown, although a deficiency of highly glycosylated α-dystroglycan has been noted in the muscle tissue of these patients, suggesting that fukutin may play a role in glycosylation.

Patients with Fukuyama congenital muscular dystrophy have severe hypotonia and weakness, and almost never walk

independently. Cortical and cerebellar dysgenesis (especially micropolygyria), hydrocephalus, and white matter abnormalities are typical. Mental retardation and seizures are common. Patients may survive to early adulthood.

Mutations in the gene encoding *O*-mannose β-1,2-*N*-acetylglucosaminyltransferase (*POMGnT1*) have been demonstrated in patients with muscle-eye-brain disease. This enzyme, a Golgi glycosyltransferase, catalyzes the transfer of *N*-acetylglucosamine from UDP-GlcNAc to *O*-mannosyl glycoproteins, which is the second step in the biosynthesis of *O*-mannosylglycan, a component of α-dystroglycan.

Children with muscle-eye-brain disease have severe hypotonia and weakness, and most are, thus, unable to walk. The eye manifestations include myopia, glaucoma, optic disk pallor, and retinal hypoplasia. MRI commonly reveals lissencephaly, flattened brainstem, cerebellar hypoplasia, and white matter abnormalities. Mental retardation is universal and epilepsy is common. Patients usually survive into early adulthood.

The gene encoding POMT1 has been demonstrated to be mutated in individuals with Walker–Warburg syndrome from at least six different families. A handful of patients with mutations in *FCMD* and *FKRP* also fit the traditional clinical picture of Walker–Warburg syndrome. POMT1, like fukutin and POMGnT1, plays a role in glycosylation, as indicated by the absence of glycosylation of α-dystroglycan in the muscle tissue of affected patients. The amount of α-dystroglycan is also reduced in these muscles. POMT1 is ubiquitously expressed, but peak levels are found in fetal brain, skeletal and cardiac muscle, and adult testis, corresponding to several of the organs most affected.

Walker–Warburg syndrome is the most severe of all muscular dystrophies, with patients rarely surviving infancy. The mothers of affected patients often have a history of miscarriages. These children are born with severe hypotonia and weakness. Brain malformations include cobblestone lissencephaly, agenesis of the corpus callosum, cerebellar hypoplasia, hydrocephalus, and extensive white matter abnormalities. Buphthalmos, glaucoma, and other eye abnormalities are present, as are testicular defects. Serum CPK levels are moderately elevated.

SYNDROMIC MUSCULAR DYSTROPHIES

The syndromic muscular dystrophies do not share genetic or clinical features beyond those common to all the muscular dystrophies. Each one, however, has a distinct clinical presentation, which has traditionally enabled physicians to make the diagnosis before the genetic etiologies were identified.

EMERY–DREIFUSS MUSCULAR DYSTROPHY Defects in two distinct genes have been found to cause Emery–Dreifuss muscular dystrophy: *EMD*, located on Xq28, and *LMNA*. Mutations in *LMNA* are inherited in an autosomal-dominant pattern, and also cause LGMD 1B. EMD is ubiquitously expressed, but is most prevalent in skeletal muscle, heart, colon, testis, ovary, and pancreas.

The clinical presentation of Emery–Dreifuss muscular dystrophy is striking. The three characteristic findings are muscle weakness and atrophy in a humeroperoneal distribution, heart block, and contractures involving the posterior neck, elbows, and heel cords. The contractures are an early finding. Intelligence is preserved.

FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY The genetics and pathogenesis of facioscapulohumeral muscular dystrophy (FSHD) remain largely a mystery. In patients with FSHD, deletions in a D4Z4 tandem repeat sequence on 4q35 have been identified. Each D4Z4 sequence is 3.3-kb long and contains two homeobox domains. Affected individuals have fewer than 11 D4Z4 repeats. The length of the deletion correlates with the severity of disease, and is stably inherited. However, this sequence does not contain a known coding region. The most likely mechanism appears to be position effect variegation, in which a number of genes upstream of the D4Z4 region on 4q35 are upregulated in the disease state. In normal individuals, a multiprotein complex consisting of Yin Yang1, high-mobility box 2, and nucleolin binds to an element within D4Z4 and mediates transcriptional repression of those other genes, including adenine nucleotide transporter 1 and FSHD region genes 1 and 2. When too few copies of D4Z4 exist, the baseline repression of these genes is disrupted, leading to their overexpression and potentially explaining the molecular basis of FSHD.

Patients with FSHD have a distinct pattern of muscle wasting and weakness. As the disease name suggests, the muscles most affected are in the face, shoulder girdle, and humerus. Pelvic girdle, forearm, and peroneal muscles are also affected later in the course. Intelligence is preserved. Sensorineural hearing loss and retinal telangiectasias may occur, requiring periodic hearing tests and ophthalmological evaluations. The majority of patients remain ambulatory. Variants of FSHD that have been linked to the same genetic locus are scapuloperoneal and scapulohumeral dystrophies.

OCULOPHARYGEAL MUSCULAR DYSTROPHY Oculopharyngeal muscular dystrophy is the only muscular dystrophy caused by a triplet repeat expansion. Although myotonic dystrophy is also caused by a triplet repeat expansion and involves muscle wasting and weakness, most muscle samples from these patients do not appear dystrophic on muscle biopsy and it is usually classified as a myotonic disorder. The gene linked to oculopharyngeal muscular dystrophy is poly(A)-binding protein 2, which in control subjects contains a $(GCG)_6$ repeat but in affected patients contains a $(GCG)_{8–13}$ expansion. The expansions are stably inherited and have low copy numbers, in contrast to other triplet repeat expansion diseases. The typical pattern of inheritance is autosomal-dominant, but the $(GCG)_7$ expansion on one allele may modify (worsen) the phenotype typically caused by a higher copy number on the other allele. The $(GCG)_7$ expansion, when present on both alleles, may behave as an autosomal-recessive disease trait.

Patients with oculopharyngeal muscular dystrophy typically present in late adulthood with dysphagia, ptosis, and proximal muscle weakness. The characteristic pathological findings are nuclear filament inclusions in muscle fibers.

CONCLUSION

Since the cloning of the gene encoding dystrophin, 20 other genes causing various forms of muscular dystrophy have been discovered, elucidating the genetic origins of many muscle diseases. Although these genes are in some ways heterogeneous, some interesting patterns emerge. Many are physically connected, either directly or indirectly, to dystrophin, including a large sarcolemmal and subsarcolemmal dystrophin-associated protein complex that appears to stabilize the sarcolemmal membrane and connect the internal cytoskeleton with the extracellular matrix. Many of the dystrophinopathies and LGMDs are linked to components of this complex, and ones that are not may have indirect connections yet to be described. Dysferlin is the first of what may be a number of proteins involved in the process of membrane resealing, which is critical for

maintaining the integrity of the muscle membrane. The congenital muscular dystrophies are more severe and generally related to primary or secondary defects in the extracellular matrix, specifically laminin-α2 (merosin) and the glycosylation of α-dystroglycan.

The genotype–phenotype correlations raise interesting questions for further investigation. Several genes, *LMNA*, *DYSF*, and *FKRP*, cause markedly different phenotypes in different patients, raising the possibility that modifier genes may help determine the actual clinical presentation. The molecular basis of FSHD may be an extreme example of this. Conversely, Emery–Dreifuss muscular dystrophy may be caused by mutations on either of two genes, which are on entirely different chromosomes. Further study of the pathogenesis of these diseases may yield insights into the mechanisms of transcription regulation, as well as potential therapeutic approaches.

71 Rhabdomyosarcomas

STEPHEN J. TAPSCOTT

SUMMARY

Significant progress has been made in understanding the molecular biology of rhabdomyosarcomas and in improving therapeutic regimens for the treatment of these cancers. Alveolar rhabdomyosarcomas are associated with translocations that create a novel fusion protein of either PAX3 or PAX7 with the FKHR transcription factors, whereas, embryonoal rhabdomayosarcomas are associated with a loss of heterozygosity at 11p15.5. In addition, animal models suggest that the combination of factors that induce myogenesis with an abrogation of tumor suppressors such as p53 and Rb can lead to the formation of rhabdomyosarcomas. Historically, treatment stratification has been based on histological criteria, however, the increasing knowledge of distinct molecular phenotypes of rhabdomyosarcomas will likely inform treatment strategies in the future.

Key Words: Alveolar; embryonal; FKHR; muscle differentiation; PAX3; PAX7; rhabdomyosarcoma; tumor suppressors.

INTRODUCTION

Rhabdomyosarcomas are the most common soft tissue sarcomas in childhood, yet they are still a relatively rare tumor, with an incidence in the United States of 1.3–4.5/million children/yr. The histological classification of rhabdomyosarcoma has historically relied on the expression of genes associated with skeletal muscle in some of the tumor cells, giving a subset of cells the appearance of skeletal muscle cells or myoblasts. Several histological subcategories of rhabdomyosarcomas have also been recognized. Embryonal rhabdomyosarcomas occur most frequently during the first 3 yr after birth and account for about 50–60% of rhabdomyosarcomas. Additional distinctions can be made within the group of embryonal rhabdomyosarcomas, for example, there are the botyroid and spindle cell variants. Alveolar rhabdomyosarcomas are distinguished from embryonal rhabdomyosarcomas histologically by characteristic open spaces in pathology sections, reminiscent of alveoli in the lungs. Alveolar rhabdomyosarcomas account for approx 20% of rhabdomyosarcomas and have a bimodal incidence distribution with peaks at approx ages 3 and 15 yr. A third group of pleomorphic or primitive rhabdomyosarcomas is not easily distinguished from other small round cell tumors of childhood, such as neuroblastoma, Ewing's sarcoma, primitive neuroectodermal tumors, and non-Hodgkin's lymphoma based on standard histology. For these primitive tumors, classification as rhabdomyosarcomas can be confirmed using antibodies or other molecular probes to genes characteristically expressed in skeletal muscle, such as desmin, or muscle creatine kinase.

MOLECULAR GENETICS OF ALVEOLAR RHABDOMYOSARCOMAS

Cytogenetic studies identified multiple abnormalities in cells from rhabdomyosarcomas; however, alveolar rhabdomyosarcomas had a characteristic translocation between chromosome 2 and 13, t(2;13)(q35;q14). Fine mapping of the breakpoint identified *PAX3* as a candidate gene on chromosome 2, leading to the demonstration that the rearrangement occurred within the PAX3 gene. Ultimately a novel chimeric transcript was identified, encoding the amino-terminal portion of the PAX3 protein from chromosome 2 and the carboxy-terminal portion of a gene on chromosome 13, with homology to the fork head family of genes.

PAX3 is a transcription factor that is expressed in the neural tube, neural crest derivatives, and in the muscle precursor cells that migrate from the somites into the limb bud. Dominant or semidominant mutations of *PAX3* in mice, the splotch mutant, and humans, the Waartenberg syndrome, are noted for defects in neural crest and neural tube development. Embryos homozygous for some alleles of splotch have deficient limb muscle formation that can be attributed to the inadequate generation or migration of limb muscle precursor cells. This may partly be the basis for limb deformities in human variations of the Waartenberg syndrome that are homozygous for *PAX3* mutations.

The t(2;13) in alveolar rhabdomyosarcomas creates a novel gene with the transcription start site and 5′ coding region of the PAX3 gene and the 3′ region of the fork head homolog rhabdomyosarcoma (*FKHR*) gene, a member of the fork head family of transcription factors, so-called because the prototype gene of the family was described as a mutation in *Drosophila melanogaster* that produced two spiked head structures (*see* Chapter 3). Additional vertebrate members of the fork head family include the hapatocyte nuclear factors (*HNF-3*α, *HNF-3*β, *HNF-3*γ) and brain factor-1. The fusion protein includes two DNA-binding domains in the carboxy-terminal half of the PAX3 protein, a paired box DNA-binding domain and a homeodomain, but disrupts the DNA-binding region of the FKHR protein. The carboxy-terminal portion of FKHR maintained in the fusion protein is rich in prolines and acidic amino acids, attributes consistent with an acidic activation domain, and transfection experiments demonstrate that the fusion protein is more potent than PAX3

as a transcriptional activator of reporter constructs driven by PAX3 binding sites. Further, DNA-binding studies show that the fusion protein binds to PAX3 binding sites, but that it has a mildly altered DNA-binding affinity compared to PAX3. Therefore, the PAX3-FKHR fusion protein may have oncogenic activity based on enhanced activation of genes regulated by PAX3 or through altered binding affinity to specific DNA sequences.

Although PAX3 is apparently expressed in the early migrating muscle progenitor cells, its role in development is not fully understood. Genetic experiments in mice indicate that PAX3 plays a critical role in specifying cells to become myoblasts, in part by regulating the expression of the myogenic basic helix–loop–helix (bHLH) protein MyoD. Although PAX3 plays a positive role in specifying myoblast fate, PAX3 expression inhibits myogenesis in cultured muscle cell lines and inhibits the ability of MyoD to activate the myogenic program in fibroblasts. The PAX3-FKHR fusion protein is a more potent inhibitor of myogenesis and MyoD activity in this system. Based on these observations and the developmental expression of PAX3 in the migrating muscle precursor cells, but not in skeletal muscle, it is possible that the normal function of PAX3 is to initiate and maintain an early phase of myogenesis and the fusion protein either enhances this activity or loses an element necessary to suppress this activity, resulting in an arrested state of development.

Although much less frequent than t(2;13), a t(1;13)(p36;q14) translocation has been described in some alveolar rhabdomyosarcomas. This translocation creates a fusion protein between PAX7 on chromosome 1 and FKHR that is structurally similar to the PAX3-FKHR fusion protein. PAX7 is also expressed in muscle precursor cells and is capable of binding to PAX3 sites either as a homodimer or as a heterodimer with PAX3. Genetic studies in mice revealed that PAX7 is necessary for the formation of muscle satellite cells, the cell population that regenerates skeletal muscle in the adult. Therefore, it appears that PAX3 and PAX7 both have central roles in specifying cells to become skeletal muscle. It is likely that each of the fusion proteins associated with alveolar rhabdomyosarcomas, PAX3-FKHR, and PAX7-FKHR, maintains some ability to initiate the skeletal muscle program but cannot sustain normal differentiation. The role of the FKHR protein is largely unknown, but it promotes myoblast fusion during terminal differentiation and dominant negative mutants of FKHR can prevent fusion. Therefore, the truncated FKHR fusion protein might block specific aspects of the program of terminal differentiation.

MOLECULAR GENETICS OF EMBRYONAL RHABDOMYOSARCOMAS

Most rhabdomyosarcomas are sporadic; however, the appearance of rhabdomyosarcomas in families with the Li-Fraumeni syndrome or the Beckwith-Wiedemann syndrome has provided valuable insights into the genetics of this tumor (*see* Chapter 7). Beckwith-Wiedemann syndrome (*see* Chapter 116) is associated with growth excess and a high incidence of tumors, including Wilms' tumor, hepatoblastoma, adrenal carcinoma, and rhabdomyosarcoma. Because of the association of Wilms' tumor with a locus on chromosome 11p13, this region was analyzed for loss of heterozygosity (LOH) in both rhabdomyosarcomas and in the Beckwith-Wiedemann syndrome. LOH of chromosome 11 was detected in a large portion of rhabdomyosarcomas, but the common region of LOH mapped to 11p15.5 similar to the mapping of the region of LOH for the Beckwith-Wiedemann syndrome. A preferential retention of the paternal allele in both embryonal rhabdomyosarcomas and in the Beckwith-Wiedemann syndrome has led to the suggestion that LOH alters the level of gene expression maintained by an imprinted allele, either decreasing expression of a tumor suppressor gene by loss of the nonimprinted allele or increasing expression of a growth-promoting gene by duplication of the nonimprinted allele.

The presence of a tumor growth suppressor gene at 11p15 has been supported by transfer of subchromosomal fragments to rhabdomyosarcoma cells. Fragments of chromosome 11 that contain 11p15 suppress growth and xenograft tumor formation in embryonal rhabdomyosarcomas, although similar experiments have not been performed in alveolar rhabdomyosarcomas, nor has parental origin of the suppressing allele been analyzed.

The gene relevant to rhabdomyosarcoma formation at 11p15 has not been clearly identified, although some candidates have been studied. Insulin-like growth factor II (*IGF-2*) is a maternally imprinted gene that maps to 11p15, transcriptionally silent on the maternal allele and expressed from the paternal allele. Elevated levels of IGF-2 resulting from paternal disomy associated with LOH may give a growth advantage to cells and have been postulated as the cause of the somatic hypertrophy in the Beckwith-Wiedemann syndrome. IGF-2 has been shown to act as an autocrine growth factor in some rhabdomyosarcomas and loss of imprinting, i.e., expression of IGF-2 from both alleles has been demonstrated in alveolar rhabdomyosarcomas and embryonal rhabdomyosarcomas that do not have LOH at 11p15. The growth-promoting activity of increased IGF-2 levels may play a critical role in the generation of rhabdomyosarcomas; however, this model would not explain the somatic cell genetic experiments that implicate a tumor suppressor gene at 11p15.

A second candidate gene that maps to 11p15, *H19*, is unusual because the H19 transcript does not contain a conserved open reading frame and may function as a regulatory polyadenylated RNA. H19 is imprinted in the opposite manner to IGF-2, expressed from the maternal allele and silent on the paternal allele; therefore, loss of the maternal allele decreases H19 expression. Transfection of H19 into rhabdomyosarcoma cell lines suppresses both growth and tumorigenesis, making it a candidate for the 11p15 tumor suppressor.

Implicating imprinting as a critical factor in the LOH at 11p15 means that the transcription of numerous genes in the region might contribute to the transformed phenotype, and both *H19* and *IGF-2* may contribute to the generation of rhabdomyosarcomas. Many additional genes have been mapped to the 11p15.5 region, including the cyclin-dependent kinase inhibitor $p57^{KIP2}$, the nucleosome assembly protein hNAP2, and the retinoblastoma-associated protein RbAp48. Mutations of the p57 gene have been reported in Beckwith-Wiedemann syndrome and cause developmental abnormalities in mice that are similar to Beckwith-Wiedemann syndrome, indicating that p57 has a critical role in this syndrome. It remains to be determined whether altered expression of p57 or other genes in this region contributes to the generation of rhabdomyosarcomas.

RHABDOMYOSARCOMAS EXPRESS MYOD OR RELATED MYOGENIC FACTORS

Expression of the myogenic regulatory protein, MyoD, or one of the related members of this group of myogenic bHLH proteins, which consists of MyoD, Myf5, Myogenin, and MRF4, can be

used to categorize less differentiated tumors as rhabdomyosarcomas, because almost all rhabdomyosarcomas express one or more of this group of proteins. The myogenic bHLH proteins are transcription factors that orchestrate the expression of genes that characterize skeletal muscle. Gene knockout experiments demonstrate that these genes are necessary for skeletal myogenesis, and the ability to convert nonmyogenic cells to skeletal muscle by expressing one of the myogenic bHLH proteins indicates that in many cell types, they are sufficient to mediate differentiation. In addition to activating expression of muscle structural genes, MyoD has been shown to mediate withdrawal from the cell cycle and induction of p21 expression. The role of these proteins in normal development is discussed in Chapter 92.

Given the ability of the myogenic proteins to activate transcription of skeletal muscle genes, the expression of MyoD in rhabdomyosarcomas can account for the low level of muscle differentiation seen in the tumor. In the tumors that have been analyzed, however, most of the cells in the tumor express MyoD, but do not terminally differentiate into postmitotic muscle cells, indicating that the program of muscle differentiation mediated by the MyoD family of transcription factors has been partially blocked. Analysis of the myogenic bHLH proteins in several tumors has demonstrated that they are not mutant, yet they are inefficient activators of muscle gene expression. Several molecular mechanisms have been identified that can prevent MyoD and related myogenic bHLH transcription factors from functioning. Relevant to the mutations that can cause rhabdomyosarcomas, normal Rb and p53 are necessary for muscle gene expression by MyoD, and amplified MDM2 can prevent MyoD transcriptional activity.

RB, P53, AND ONCOGENES Just as the association of rhabdomyosarcomas with the Beckwith-Wiedemann syndrome focused attention on 11p15, the appearance of rhabdomyosarcomas in families with Li-Fraumeni syndrome suggested that p53 inactivation may be important for tumor formation. Analysis of p53 abnormalities, without respect to alveolar or embryonal histological types, indicated that approximately half of the tumors had abrogated normal p53 function. When histological subtype is considered, it appears that the frequency of p53 mutations is higher in the embryonal rhabdomyosarcomas. Differences between embryonal and alveolar rhabdomyosarcomas are further suggested by a higher frequency of N-myc amplification in alveolar rhabdomyosarcomas, whereas mutation in N-ras and K-ras appear to be more frequent in embryonal rhabdomyosarcomas.

Mouse models have indicated several different regulatory pathways that can contribute to the formation of rhabdomyosarcomas. Mice with a mutation that inactivates the $p16^{INK4a}$ and the $p14^{ARF}$ transcripts, two different transcripts from the same locus that, respectively, regulate pRB and p53 function, mainly develop lymphomas and fibrosarcomas. However, when combined with a transgene that expresses hepatocyte growth factor/scatter factor, the ligand for the c-MET receptor expressed on satellite cells and myoblasts, the INK4a/ARF mutation induces a high rate of rhabdomyosarcomas in mice. In this model, blocking both p53 and pRb activity in the presence of a constitutive myogenic growth factor was sufficient to generate rhabdomyosarcomas. This is similar to the finding that amplified MDM2 can contribute to rhabdomysarcomas by inhibiting the activity of both p53 and Rb when expressed in myoblasts. There are likely many different molecular pathways that can contribute to rhabdomyosarcoma formation, as evidenced by the formation of rhabdomysarcomas in mice deficient in the Patched receptor that inhibits signaling by Sonic Hedgehog. Sonic Hedgehog is necessary to specify skeletal muscle cells in the developing embryo and acts, at least in part, by regulating the expression of the myogenic bHLH transcription factor Myf5, similar to the role of PAX3 in regulating the expression of the related myogenic transcription factor MyoD. One theme that emerges from these different models of rhabdomyosarcomas is the constitutive or aberrant activity of factors that induce myogenesis coupled with conditions that prevent normal terminal differentiation.

CONCLUSIONS

Therapy of rhabdomyosarcomas combines chemotherapy, radiation therapy, and surgery. The Intergroup Rhabdomyosarcoma Studies (IRS) utilized a risk-based design that increased therapeutic intensity in groups with marginally poorer prognosis. In addition to tumor staging based on invasiveness, involvement of lymph nodes, metastasis, and degree of surgical excision, tumor histology is a significant variable in predicting response to treatment. In IRS-II, the 5-yr survival rate was 95% for the favorable category of botyroid, 67% for embryonal, and approx 50% for alveolar and undifferentiated. IRS-III includes therapy intensification of the groups with the less favorable prognosis and has achieved survival rates for alveolar tumors comparable to embryonal ones.

One challenge remaining is to determine if survival can be improved and therapy-related complications minimized by using the available molecular markers to further refine risk-based therapy. An analysis of patients with metastatic alveolar rhabdomyosarcoma enrolled in the IRS-IV study revealed a more favorable outcome for those with a PAX7-FKHR translocation than those with a PAX3-FKHR translocation, whereas the type of translocation did not appear related to outcome in nonmetastatic disease. The availability of molecular methods to accurately identify fusion transcripts, gene amplifications, and gene mutations might permit the identification of other factors associated with response to therapy and survival.

Ideally further understanding of the molecular biology of rhabdomyosarcomas eventually will lead to rationally designed therapies. Perhaps the development of drugs that inhibit PAX3 expression or agents that degrade the PAX3-FKHR fusion transcript would be useful adjuvants to therapy.

2-5A	2′-5′-oligoadenylate
ABL	Abelson
ADH	atypical ductal hyperplasia
ALCL	anaplastic large-cell lymphoma
ALK	anaplastic lymphoma kinase
ALL	acute lymphoblastic leukemia
AMACR	alpha-methylacyl coenzyme A racemase
AML	acute myeloid leukemia
α-MSH	α-melanocyte stimulating hormone
AO	anaplastic oligodendroglioma
AOA	mixed anaplastic oligoastrocytoma
AP-2	activator protein-2
APaf-1	apoptosis protease activating factor
APC	adenomatous polyposis coli
APL	acute promyelocytic leukemia
APO-3	apoptosis antigen 3
AR	androgen receptor
ARF	alternative reading frame
ART	antiretroviral therapy
AT	adenine-thymine
ATM	ataxia-telangectasia mutated
ATRA	all-*trans*-retinoic acid
BCL-2	B-cell leukemia/lymphoma gene
BCR	breakpoint cluster region
bFGF	basic fibroblast growth factor
BH	Bcl2 homology
bHLH	basic helix loop helix
BID	BH3 interacting domain death agonist
BIR	baculovirus inhibitor of apoptosis repeat
BL	Burkitt's lymphoma/leukemia
BM	bone marrow
BMSC	bone marrow stromal cell
BPH	benign prostatic hyperplasia
CAD	caspase-activated DNase
C-ALCL	cutaneous anaplastic large-cell lymphoma
CAMs	cell adhesion molecules
CBF	core binding factor
CCND1	cyclin D-1
CD	cluster designation
CDK	cyclin-dependent kinase
c-FLIP	c-FLICE-like inhibitory protein
CIITA	class II transactivator
CI	chromosomal instability
CIMP	CpG island methylator phenotype
CIN	cervical intraepithelial neoplasia
CIS	carcinoma *in situ*
CKI	CDK-inhibitor
CKI	cyclin-dependent kinase inhibitor
CLL	chronic lymphocytic leukemia
CML	chronic myelogenous leukemia
CMP	common myeloid progenitor
CTL	cytolytic T-cell
Cyt c	cytochrome *c*
DAPK	death-associated protein kinase
DCIS	ductal carcinoma *in situ*
Dex	dexamethasone
DISC	death-induced signaling complex
DLCL	diffuse large-cell lymphoma
DNMT	DNA methyltransferases
DR	death receptor
EB	end-binding protein
EBNA	Epstein-Barr virus nuclear antigen
EBV	Epstein-Barr virus
ECM	extracellular matrix
EGF	epidermal growth factor
EGFR	epidermal growth factor receptor
ER	estrogen receptor
ERE	estrogen response element
ERK	extracellular signal-regulated kinase
ET	endothelin
FAB	French–American–British
FAK	focal adhesion kinase
FAP	familial adenomatous polyposis
FAS.L	Fas ligand
FGF	fibroblast growth factor
FGF-2	fibroblast growth factor-2
FHIT	fragile histidine triad
FISH	fluorescence *in situ* hybridization
FLD	flexible loop domain
FN	fibronectin
FPD/AML	familial platelet defect with propensity to develop AML
FTI	farnesyl transferase inhibitor
G_0	non-proliferative state
G2	Gap2
GBM	glioblastoma multiforme
GC	germinal center
GM-CSF	granulocyte-macrophage colony-stimulating factor
GMP	granulocyte-monocyte progenitor
GPCR	G protein-coupled receptor
GRO	growth-regulated protein
GRP	gastrin-releasing peptide
GSK3β	glycogen synthase-3β kinase

GST	glutathione *S*-transferase
H	*helicobacter*
HAT	histone acetyl transferase
HCV	hepatitis C virus
HDAC	histone deacetylase
HGF	hepatocyte growth factor
HHV-8	human herpesvirus 8
HIF	hypoxia-inducible factor-1
HIV-1	HIV type 1
HNPCC	hereditary nonpolyposis colorectal cancers
HPC	hereditary prostate cancer
HPC1	hereditary prostate cancer 1
HPV	human papilloma virus
HSC	hematopoietic stem cell
Hsp90	heat shock protein 90
HTLV	human T-cell leukemia viruses
IAP	inhibitors of apoptosis
ICC	invasive cervical carcinoma
ICE	interleukin-Iβ-converting enzyme
IFN	interferon
IGF	insulin-like growth factor
IGF-1	insulin-like growth factor-1
IGH	immunoglobulin H
IgH	immunoglobulin heavy chain
IgL	immunoglobulin light chain
IKK	IκB kinase
IL	interleukin
ITAM	immunoreceptor-tyrosine-based activation motif
ITD	internal tandem duplications
Jak	Janus tyrosine kinase
JMML	juvenile myelomonocytic leukemia
JPS	juvenile polyposis syndrome
k-NN	nearest neighbor prediction model
KS	Kaposi's sarcoma
LC	light chain
LCIS	lobular carcinoma *in situ*

72 Apoptosis

W. Stratford May, Jr. and Xingming Deng

SUMMARY

Cell growth represents the net effect of cell proliferation balanced by attrition from terminal differentiation and/or apoptotic cell death. Apoptosis is a genetically and biochemically regulated process known as programmed cell death. Successful execution of apoptosis is required for normal embryonic development, regulation of the immune response, control of cell numbers, the process of aging and senescence and the cell's ability to compensate for otherwise damaging stresses. This chapter focuses on mechanisms responsible for regulating apoptosis in the context of cancer and other pathology.

Key Words: Anoikis; apoptosis; autophagy; BCL-2; caspase; cell growth; cytolytic T-cells; natural killer; necrosis.

INTRODUCTION

Cell growth represents the net effect of cell proliferation balanced by attrition from terminal differentiation and/or apoptotic cell death. Apoptosis is a genetically and biochemically regulated process known as programmed cell death. Successful execution of apoptosis is required for normal embryonic development, regulation of the immune response, control of cell numbers (e.g., in rapidly turning over cells in the GI tract, bone marrow, skin, and uterus), the process of aging and senescence and the cell's ability to compensate for otherwise damaging stresses (e.g., nutrient deprivation, or toxicant drug exposure and DNA damage). Indeed, dysregulation of apoptosis (i.e., too little or too much) can lead to disease pathology including developmental defects, chronic degenerative, and autoimmune diseases and malignancy. Specifically with respect to malignancy, disabling apoptosis affords the cancer cell not only a selective growth advantage but also resistance to chemoradiation treatment. This feature not only helps to ensure survival when the cancer cell finds itself in an otherwise inhospitable microenvironment, for example following metastases, but also when evading attack by the body's immune system. This chapter focuses on mechanisms responsible for regulating apoptosis in the context of cancer and other pathology.

CELL DEATH

NECROSIS AND APOPTOSIS Cell death can result by two distinct processes, necrosis and apoptosis (Table 72-1). Necrosis is a functionally passive process, which occurs when cells are exposed to extreme physical and chemical environmental imbalances (e.g., hyperthermia, hypoxia) or as a result of forceful physical trauma (e.g., blunt trauma) that directly damages membranes and tissues. Such damage leads to an osmotic-type shock that results in the rapid influx of water and extracellular ions through damaged membranes including those of the organelles, which produces cell swelling and rupture with extrusion of cytoplasmic contents, including lysosomal enzymes, into the microenvironment. This triggers a secondary, local inflammatory response that may lead to the destruction of undamaged bystander cells. By contrast, apoptosis is an energy-dependent, active process that is highly regulated and not easily triggered. However, when activated its biochemical consequences lead to the cell's proteolytic destruction from within, primarily through the action of a specific set of proteases, the caspases. This type of cell suicide results from the destruction of key regulatory and structural proteins necessary for the maintenance of cell integrity and viability. The classic morphological features of apoptosis, which contrast with those of necrosis, include cell shrinkage, membrane blebbing, partitioning of nuclear and cytoplasm components into membrane bound apoptotic bodies (containing nuclear-ribosomal or organellar remnants), and specific internucleosomal degradation of cellular DNA, which is the classic molecular "hallmark" of this process. Because the apoptotic cell undergoes volume loss associated with nuclear and cytoplasmic condensation, this process has also been called "shrinkage necrosis." Ultimately the process leads to classic DNA degradation that yields a regular "ladder pattern" of fragmented genetic material that can be diagnostically recognized following gel electrophoresis of DNA as regularly separated, 180-bp fragments. Such DNA "laddering" is caused by the action of a specific class of endonucleases, the caspase-activated DNases (CADs), which are primarily activated by caspases but can also apparently be activated in a caspase-independent manner consistent with a caspase-independent form of apoptosis. Caspase-independent apoptosis is also initiated by leakage of mitochondrial proteins, including endonuclease G and apoptosis-inducing factor. However, rather than activate caspases these apoptogenic factors are translocated to the nucleus in which they can act to mediate characteristic DNA degradation. Therefore, unlike necrosis, apoptosis is a quiet process with respect to a lack of inflammation and damage to surrounding cells. Instead, the neighbor cells are actively recruited into this morbid process by specific "eat me" phospholipid signals displayed on the surface of the dying cell. Neighbor cells respond by engulfing and phagocytosing the corpse, resulting in its elimination without inflammatory fanfare or collateral injury.

Table 72-1
Types of Cell Death

Necrosis
"Explosive" but passive process
Cell swelling and lysis
DNA intact
Inflammation
Anoikis
Apoptosis following loss of cell–cell contact
Autophagy
Golgi, mitochondrial, endoplasmic reticulum membrane degradation
Autophagic vacuoles formed
May "blend" with apoptosis
Apoptosis
Cell directed "suicide"
Volume loss
Membrane blebbing
Chromatin condensation
DNA fragmentation
Apoptotic bodies
Noninflammatory process
Neighborhood cell engulfment

Table 72-2
Physiological Relevance of Apoptosis

Embryonic development
Regulation of immune system
Immune cell development
Cytolytic T-cell killing (e.g., immune surveillance, viral infections)
Terminating active immune response
Tight regulation/renewal of cell numbers (e.g., bone marrow, gastrointestinal, uterus, skin)
Compensatory response to cell stress
Intrinsic pathway (e.g., Growth factor removal, external radiation therapy, chemotherapy)
Extrinsic pathway (e.g., FAS.Ag, TNF-R activation)
Senescence/aging

Table 72-3
Apoptosis and Pathology

Insufficient (too little)
Cancer
Developmental defects
Excessive (too much)
Neurodegenerative
Autoimmune
Cardiovascular
Developmental defects
AIDS (T4 cells)

ANOIKIS AND AUTOPHAGY Two other types of apoptotic-like cell death occur. Anoikis occurs in adherent cells (e.g., fibroblasts and some epithelial cells) that have lost their cell–cell or cell–matrix contact necessary for providing survival signals via integrin binding and "inside-out" survival signaling. Following loss of contact with its environmental substratum, the detached cell undergoes apoptosis. By contrast, autophagy was initially described in yeast and later found to operate in mammalian cells. Autophagy is a process whereby yeast cells are forced to engulf their own organelles in response to amino acid/nutrient starvation. Such recycling occurs in a unique "double-membrane" vesicle, the autophagosome, which surrounds and degrades organellar proteins in an attempt to replenish the depleted intracellular pool of amino acids/nutrients. This provides the affected cell with a means to survive, at least short term, until a more hospitable microenvironment becomes available. However, if uncompensated, by improved nutritional conditions, ongoing autophagy apparently will evolve into cell death indistinguishable from apoptosis.

CYTOLYTIC T CELLS AND NATURAL KILLER CELLS INDUCE APOPTOSIS Cytolytic T-cells (CTLs) and natural killer (NK) lymphocytes utilize a granule-mediated exocytosis pathway to destroy their target, including virally-infected and malignant cells, by inducing apoptosis. For example, after targeting a cell for immune destruction, CTLs and NK cells release their cytotoxic granules that contain perforin and serine proteases known as granzymes. Perforin, a pore forming protein, permeates the membrane of target cell to facilitate the entrance of the injected granzymes. Once inside the cell, granzyme B, for example, can cleave and activate procaspase-3, BH3 interacting domain (BID) death agonist and inhibitor of the CAD nuclease to initiate apoptosis. Other granzymes (i.e., granzymes A and C) can apparently induce a caspase-independent type of cell death.

PHYSIOLOGICAL RELEVANCE

Apoptosis is essential for the regulation of normal embryonic development as well as the maintenance of cellular and tissue homoeostasis in the adult organism (Table 72-2). Unbalancing apoptosis by either inappropriate activation or a failure to activate apoptosis pathways can lead to either a shortening or lengthening, respectively, of cell survival. This can result in various pathological consequences, including developmental defects, chronic degenerative and autoimmune disorders, and tumor development (Table 72-3). For example, accelerated or excessive apoptosis has been causally linked to autoimmune disorders including rheumatoid arthritis, systemic lupus erythematosus, as well as the chronic neurodegenerative disorders including Alzheimer's, Parkinson's, and Huntington's disease (*see* BCL-2 Family Members Regulate Apoptosis Pathway). In addition, primary or secondary immunodeficiency diseases (e.g., HIV), infertility, as well as congenital developmental defects (e.g., limb bud malformation) may result. Furthermore, failure to execute apoptosis following appropriate cues, including developmental or injurious stress, is a characteristic feature of cancer cells that facilitates their prolonged survival and drug-resistant phenotype.

APOPTOSIS PATHWAYS

Accounting for its ancient importance, apoptosis is conserved in metazoans from worms to man. Apoptosis is triggered in response to developmental cues or environmental stresses (e.g., viral infections, toxicant treatment, and so on) that activate a compensatory elimination response. In addition, the mitochondrion has emerged as the principle organelle that assumes the functional role of master "sensor" organ that responds to cell stress. Indeed, it is the mitochondria that act as a clearinghouse for stress injuries that trigger the intrinsic pathway. As such, this organelle pulls "double duty" for the cell by functioning as the cell's major source of energy production and its potential death arsenal. Although the mitochondrion functions during normal, unperturbed cell growth to generate life-sustaining chemical energy in the form of ATP that results from

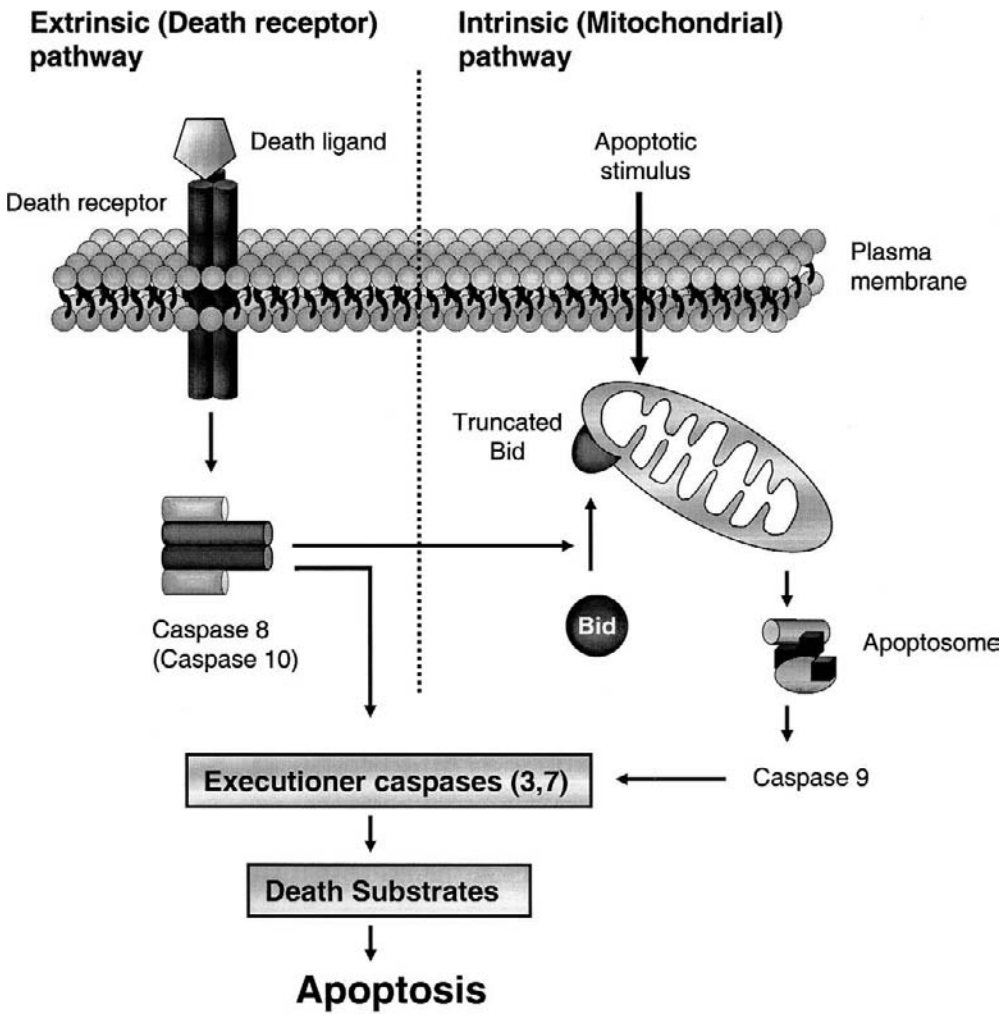

Figure 72-1 Apoptotic pathways. The extrinsic pathway is activated by binding of a death ligand (e.g., TNF-α, FAS.L, TRAIL) to its receptor, which sequentially triggers activation of the initiator caspase 8 followed by an executioner/effector caspase. The intrinsic pathway is activated following a death stimulus resulting from chemotherapy, irradiation or growth factor withdrawal that induces mitochondrial dysfunction characterized by leakage of apoptogenic factors, including cytochrome C, that lead to activation of initiator caspase 9 and effector caspase. Executioner caspases degrade specific substrates to bring about cell death. Cross talk between the extrinsic and intrinsic pathways can occur when caspase 8 cleaves cytosolic BID to truncated BID that is able to translocate to the mitochondria and trigger the intrinsic pathway. This serves to amplify the extrinsic pathway.

electron transfer and oxidative phosphorylation, it also sequesters and can release on cell injury factors that act as potent proapoptotic regulators. Perhaps surprisingly, such apoptogenic factors include the electron carrier cytochrome-C that not only serves as a major transducer of cellular energy but also as the key activator of procaspases when released into the cytosol. It is, therefore, critical to maintain mitochondrial integrity in order to protect cell survival. Apoptotic cell death proceeds through the highly regulated and coordinated signaling of two main pathways, the extrinsic and intrinsic pathways (Fig. 72-1). Although the net result of activation of either pathway will lead to cellular suicide via caspase activation, the regulatory components involved in the two pathways and their mechanism(s) of regulation are both varied and overlapping.

EXTRINSIC APOPTOTIC PATHWAY The extrinsic pathway is triggered by the binding of either soluble cytokines (tumor necrosis factor [TNF]-α, TNF-related apoptosis-inducing ligand [TRAIL]) or cell-bound death ligands (FAS.L) to their cognate surface receptors on target cells (*see* Fig. 72-1). TNF-α, and the FAS.L represent immune mediators produced by inflammatory cells that are necessary for an appropriate immune response because they work with the effector immune cells that facilitate the removal of infected, neoplastic, aged or otherwise unwanted cells. Interestingly, the same cytokines also work to limit the immune attack by inducing the CTL to undergo apoptosis once its target is destroyed.

INTRINSIC APOPTOTIC PATHWAY By contrast, the intrinsic pathway is activated following either damage to an intracellular organelle (e.g., endoplasmic reticulum), DNA or the cytoskeleton following toxicant treatment or from the loss of growth factor–mediated survival signals. Mechanistically, the mitochondrion is able to "sense" cellular stress induced by damage to DNA, intracellular organelles (e.g., endoplasmic reticulum, Golgi, liposomes) or the cytoskeleton. This damage/stress results in the generation of an activated B-cell lymphoma (BCL)-2 homology (BH)-3-only proapoptotic member, (e.g., BID, BIM, and BAD), that translocates to the mitochondria to facilitate a BAX (or BAK) conformational change with oligomerization to form the "death pore" in the outer mitochondrial membrane (OMM). This

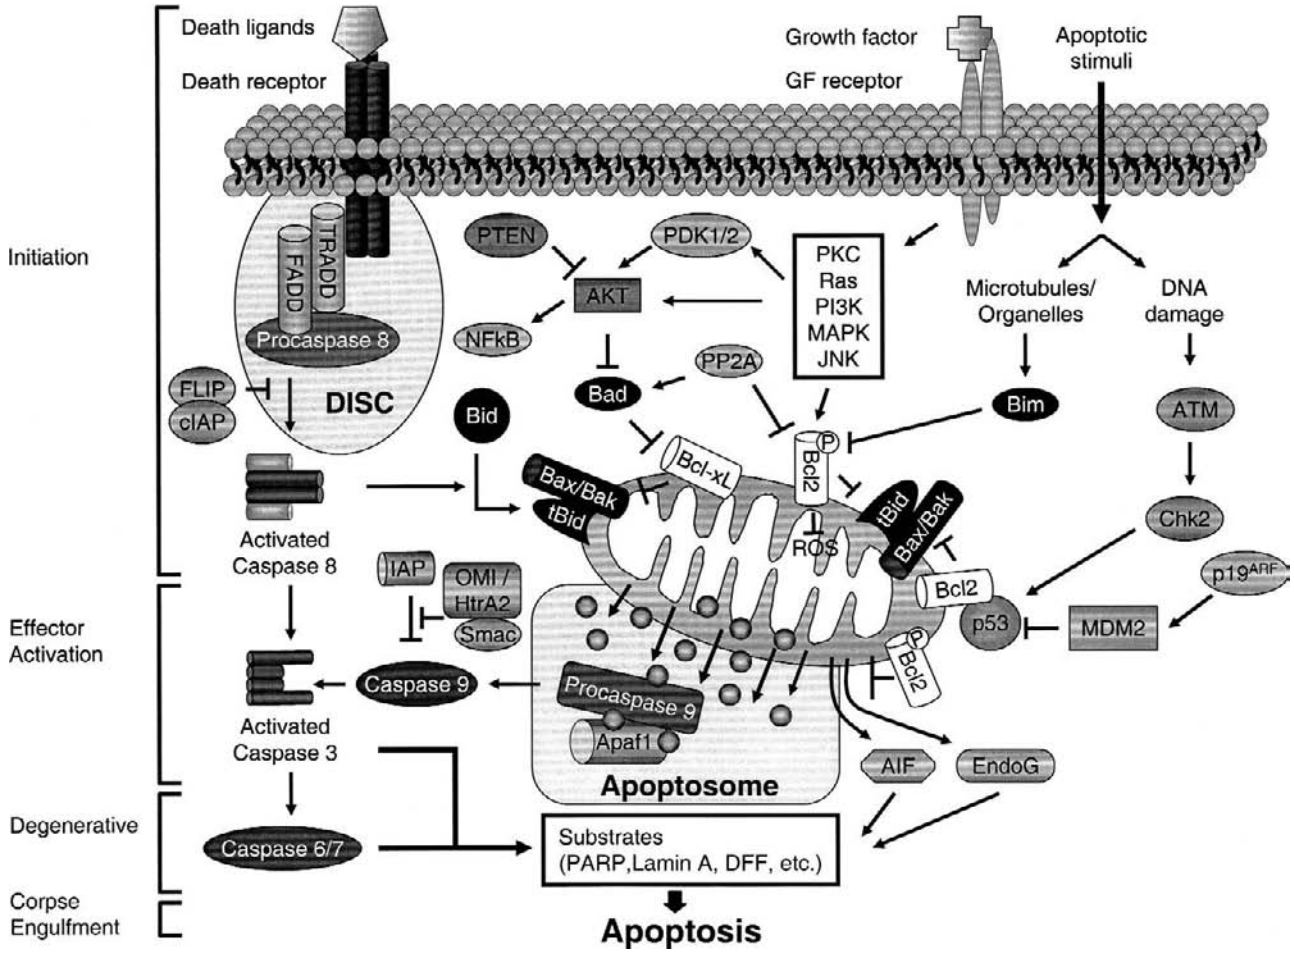

Figure 72-2 Cell signaling and apoptosis pathways are integrated. A schematic demonstrating interactions between growth and apoptotic signaling. Arrows (→) indicate stimulation and crosses (⊥) indicate inhibitory effects. The DISC and apoptosome platforms that enable activation of initiator caspases in extrinsic and intrinsic pathways, respectively, are indicated by light shading. Refer to text and other figures for details. Bcl2, B-cell lymphoma gene 2; GF, growth factor.

leads to leakage of intramembranous contents including cytochrome C and other apoptogenic factors that mediate activation of caspases. In this manner, the intrinsic pathway functions as the cell's compensatory response to overwhelming, nonrepairable damage and/or the prolonged depletion or loss of survival signals. The result is inducing its own death while sparing the undamaged neighbor cells the same fate.

To regulate mitochondrial integrity, the BCL-2 gene family has evolved as the principle guardians of the mitochondrion (Fig. 72-2). Interestingly, some of the members of this large gene family are antiapoptotic and function to maintain mitochondrial integrity by inhibiting the proapoptotic members that function to facilitate the release of apoptogenic mitochondrial intramembranous contents. Formation of a mitochondrial "death pore" with leakage of apoptogenic factors requires one of two proapoptotic members, BAX or BAK (*see* Caspase Proteases Mediate Apoptosis). Thus, although either BAX or BAK null mice are more resistant to toxicant treatment than wild type mice, BAX and BAK double knockout mice are highly resistant. The antiapoptotic BCL-2 family members of which BCL-2 is the prototype function to block mitochondrial dysfunction by binding to and inhibiting pore formation by BH3-only proapoptotic proteins interacting with BAX or BAK. In addition, BCL-2 can also function to block Ca^{2+} release from the endoplasmic reticulum that can trigger apoptosis but the mechanism is not clear. Thus, the direct addition of proapoptotic BAX and BAK to isolated mitochondria induces cytochrome-C leakage in vitro, whereas overexpression of BCL-2 (or Bcl_{XL}, Mcl1, and so on) can block BAX or BAK induced cytochrome C release.

CASPASE PROTEASES MEDIATE APOPTOSIS

The intrinsic and extrinsic proteolytic doom that is created by apoptosis is mediated by a unique class of substrate-specific cysteine proteases known as caspases (i.e., c-terminal aspartate site cleaving proteases; *see* Fig. 72-1). Caspases are synthesized as inactive proenzymes that reside in the cytosol and can be activated by autoproteolysis. The identification and characterization of the caspases began with studies of one of the *C. elegans* death genes, Ced-3. Subsequent studies in mammalian cells led to the identification of the first human caspase, IL-Iβ-converting enzyme, now called Caspase 1. Iβ-converting enzyme is activated by autoproteolysis of its C terminus at a specific aspartate residue and the resulting heterodimer then specifically cleaves pro-IL-1β into the active, proinflammatory cytokine, IL-1β. More than 16 caspases have been identified, which cleave their substrates, which are either critical regulatory or structural proteins necessary for cell integrity. For example, cleavage of the nuclear lamins, PARP and DFF will lead to disruption of the

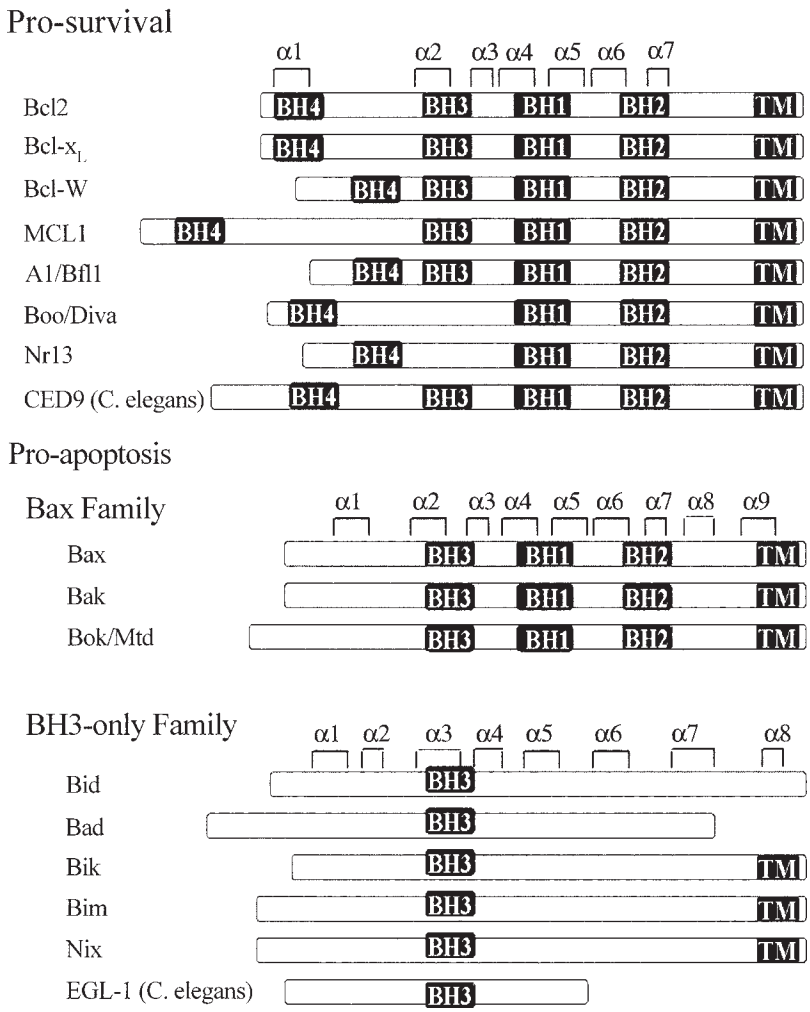

Figure 72-3 BCL-2 family. Anti- and proapoptotic BCL-2 members are shown. BCL-2 homology (BH) regions transmembrane domain and alpha helical structures are indicated.

nuclear envelope with classic DNA "ladder" degradation, whereas cleavage of α-Fodrin, MEKK, or FAK will affect growth signals that regulate and maintain cell shape. By degrading such substrates, caspases mediate intracellular liquefaction.

TWO CLASSES OF CASPASES Caspases are divided into initiators (e.g., caspases 8 and 10) and effectors (e.g., caspases 3, 6, and 7) based on their role in either initiating or executing apoptosis. In addition, different caspases have preferred aspartate cleavage sites, represented by a minimal putative tetrapeptide sequence (e.g., IETD for caspase 3; VETD for caspase 8), which is found in specific substrates. Activated caspases cleave their substrates on the C-terminal side of such aspartate residues. Once activated, the effector caspases target and degrade/inactivate key regulatory and structural polypeptides necessary for the maintenance of cell integrity. In addition to proteolysis of selected substrates and to ensure inactivation of the dying cell's genetic capabilities, effector caspase activation also results in activation of specific endonucleases, the CADs, which degrade cellular DNA to produce the "hallmark" molecular signature of apoptosis, DNA laddering.

CASPASE ACTIVATION Caspases are synthesized and remain in their inactive, proenzyme state during unstressed cell growth. However, developmental cues or noxious, toxicant stresses can trigger their activation. Procaspases are made up of an N-terminal prodomain (long in length in case of initiator caspases and short for effector caspases) that is cleaved to yield a p20 and a p10 kDa domain molecule that heterodimerize. Autocleavage of the procaspases occurs at a specific internal aspartate site to yield the p20/p10 dimer that then forms a tetramer, which represents the mature form of the activated protease (Fig. 72-3). Initially, an initiator procaspase becomes activated, which cleaves and activates a downstream effector caspase. This serial activation is referred to as the "caspase cascade." Initiator caspase activation occurs on one of two different bioplatforms, the death-inducing signaling complex (DISC) in the extrinsic and the apoptosome in the intrinsic apoptotic pathway.

Death-mediating ligands including TNF-α, FAS ligand or TRAIL bind to their cognate surface receptors and induce aggregation of receptor-associated molecules. This creates an intracellular "platform," called the DISC, for the assembly of specific adapter and regulatory molecules (i.e., TRADD or FADD) necessary to achieve activation of procaspase 8 (Fig. 72-4). The DISC functions like a sponge to increase the local concentration of procaspase 8 or 10 and regulatory molecules and facilitate autocleavage and activation of the initiator caspases (i.e., induced proximity model). Once an initiator caspase is activated, it targets and cleaves cytosolic procaspase 3. Activated effector

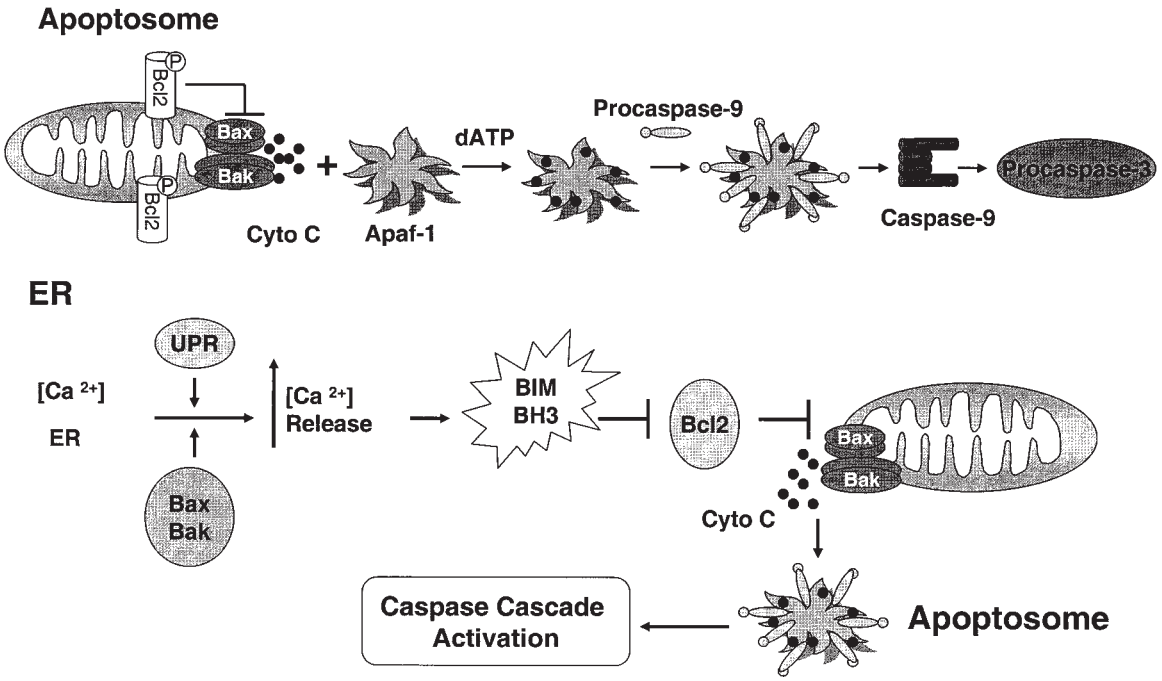

Figure 72-4 Apoptosome and endoplasmic reticulum. Dysregulation of the mitochondria or endoplasmic reticulum can lead to activation of the intrinsic apoptotic pathway. Bcl2, B-cell lymphoma gene 2; BH3, BCL-2 homology 3.

caspase 3 then proceeds to wreak intracellular proteolytic doom. Receptor-mediated activation of apoptosis occurs independently of the mitochondria in some cells called type-I cells (e.g., Thymocytes). Alternately, caspase 8 activation may lead to "recruitment" of the intrinsic/mitochondrial pathway in cells referred to as type-II cells (e.g., hepatocytes). This "recruitment" serves to amplify the extrinsic pathway and results from caspase 8 being able to directly activate caspase 3 and also being able to target and cleave the cytosolic BH-3 only proapoptotic molecule, BID, into its truncated, activated form, tBID. Activated tBID then is able to translocate from the cytosol to the mitochondrion where it binds and disrupts the interaction between BCL-2 (or other antiapoptotic members like Bcl_{XL}) and directly activates BAX (or BAK) (*see* Fig. 72-2). As a result, BAX (or BAK) becomes "functionally" released from inhibition and undergoes a structural conformational change that apparently facilitates its integral insertion into the OMM via its transmembrane domain. Insertion and oligomerization create the "death pore" through which the intramembranous contents are leaked into the cytosol to trigger activation of initiator procaspase 9.

For the intrinsic pathway, initiator and effector caspases are activated following a nonreceptor mediated stress event (e.g., toxicant treatment or withdrawal of growth factor survival signals) that results in mitochondrial dysfunction with release of cytochrome C and other apoptogenic factors. Release induces formation of the apoptosome complex that consists of apoptosis protease activating factor (APaf-1), cytochrome C, dATP, and procaspase 9. Following release from mitochondria, cytochrome-C, and Apaf-1 bind, allowing procaspase 9 to also bind Apaf-1 via its caspase activation and recruitment domain, a feature of all caspases. The "mature" apoptosome then facilitates the efficient autocleavage of procaspase 9, which in turn activates cytosolic procaspase 3 in a postmitochondrial mechanism.

INHIBITION OF CASPASES As a safeguard against chance activation of caspases, normal cellular (and some viral) proteins known as inhibitors of apoptosis (IAP; e.g., including cFLIP, cIAP, and survivin) or the baculovirus p35 protein can inhibit caspases. Interestingly, IAP activity was initially recognized in a baculovirus gene product, p35, which inhibits the proteolytic activity of caspases following viral infection of insect cells. Caspase inhibition allows the virus to maximally replicate by overcoming this host-antiviral mechanism. Later, mammalian cells were also found to express a related activity, cIAP. The IAP contain common tandem repeats known as baculovirus inhibitory repeats that enable their binding to and inactivation of caspases (*see* Fig. 72-2). Cellular IAP may function by either directly inhibiting caspases or by targeting the caspase for ubiquitination and degradation by the proteosome. However, to ensure success of activated caspases, IAP activity can also be inhibited by mitochondrial factors also released along with apoptogenic factors, including SMAC/DIABLO and OMI/HtrA2. These inhibitors function to either directly block cIAP from binding to the activation site of a caspase or by competing with the cIAP once bound to an activated caspase. Because SMAC/DIABLO and OMI/HtrA2 are also sequestered in the mitochondria and released along with cytochrome-C (and other caspase activators), they help to ensure a feedforward functioning of the death pathway once activated.

DEATH RECEPTORS MAY ALSO BE ASSOCIATED WITH SURVIVAL SIGNALING In addition to TNF-α and FAS.L, death ligand-induced apoptosis may also be triggered by TRAIL and apoptosis antigen 3 binding to their receptors, DR 4/5 or DR3. TRAIL or apoptosis antigen 3 binding also sequentially induces caspases 8 and 3 activation and can activate BID to "recruit" the intrinsic death pathway. Because some cancer cells are reported to maintain sensitivity to TRAIL-induced killing, exploitation of this vulnerability as a potential cancer treatment is being studied.

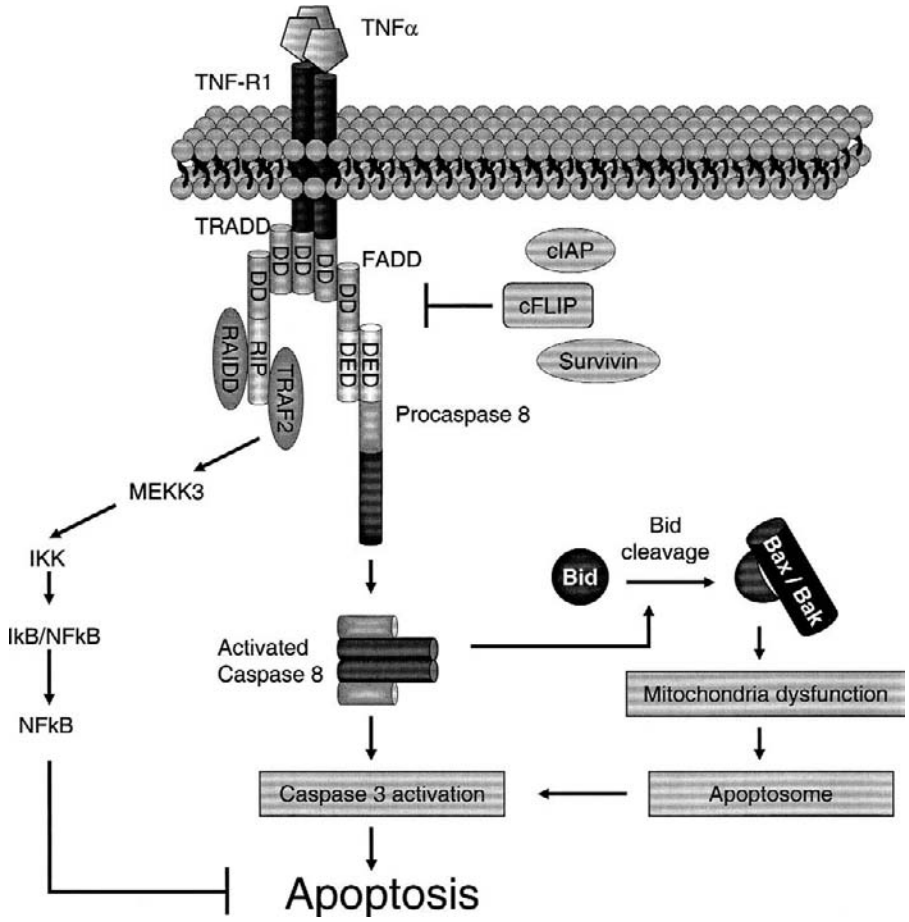

Figure 72-5 Apoptosis signaling through extrinsic death receptors. Binding of the death ligand TNF-α (or FAS.L or TRAIL) to the TNF receptor leads to the formation of the DISC. Made up of adapter molecules, TRADD or FADD bind to the death domain of the receptor and bind to procaspase 8 via its death effector domain (DED-DED). This leads to activation of initiator caspase 8 and triggering of the extrinsic pathway. In some cells, TNF-α binding to its receptor, TNF-R1, and TRADD may recruit RIP, RAIDD and TRAF2, which can result in NF-κβ activation and cell survival signaling that results in upregulation of NF-κβ genes including IAP and cFLIP that inhibit caspases.

However, although FAS.L and TRAIL or APO3L signaling induce apoptosis, TNF-α binding does not always induce cell death. Under certain circumstances, TNF-α can promote cell growth. The mechanism(s) by which TNF-α decides on death or growth appears to result from a cell-type specific type of differential signaling. Thus, while binding of the TRADD and FADD adapter protein to the intracytoplasmic portion of the TNF receptor will induce caspase 8 activation, TRADD binding to RIP and RAIDD may affect other regulators including TRAF2, that can stimulate nuclear factor (NF)-κβ and inhibitor of NF-κβ (Iκβ) kinase. Thus when activated, Iκβ kinase phosphorylates and releases Iκβ, inhibitor of NF-κβ, resulting in its transcriptional activation. This induces NF-κβ-responsive genes, including cFLIP and other IAP, whose activities help prevent procaspase 8 from being activated and results in blocking the TNF-α death signal (Fig. 72-5). However, when the NF-κβ signal falters or becomes weak, the preassembled TRADD-procaspase 8 complex can now activate caspase 8 to engage the extrinsic pathway. Such differential signaling by TNF-α indicates the delicate balance between life and death in certain cells. It also suggests a novel antitumor strategy whereby blocking TNF-α-mediated NF-κβ survival signaling in certain tumors could trip the activation of the extrinsic death pathway. When combined with the effects of chemo- or radiation therapy, this could potentially enhance their cytotoxicity.

BCL-2 FAMILY MEMBERS REGULATE APOPTOSIS PATHWAY

BCL-2 is the prototype and founding member of this large family of regulators of apoptosis (*see* Fig. 72-3). BCL-2 was discovered as the product of translocation of chromosome 14 and 18, t (14; 18) that characteristically occurs in up to 85% of human follicular BCLs. The resulting chromosomal fusion conjoins BCL-2 and the proximal immunoglobulin promoter, which functionally results in overexpression of BCL-2 in B cells. However, unlike other oncogenes, BCL-2 does not promote cell proliferation, rather it cooperates with oncogenes by enhancing cell survival. This unique property was discovered when it was demonstrated that forced expression of BCL-2 in IL-3 factor-dependent cells significantly delayed cell death following growth factor deprivation or on treatment with cytotoxic agents or irradiation. Because BCL-2 is primarily localized to mitochondria, with some expression in the endoplasmic reticulum and nuclear envelope, this highlighted mitochondria in the cell death process. The discovery of BCL-2 also sparked a new field of biomedical research in the mid 1980s and has led to the identification of a large family of structurally related BCL-2 proteins with both antiapoptotic and proapoptotic functions. For example, BCL-2, Bcl_{XL}, Mcl, and Al contain all four BH domains and are

antiapoptotic and suppress cell death. Other members, including BAX, BAK, BAD, BID, and BIM that contain BH 1-3 or BH-3 only domains are proapoptotic and can induce cell death (*see* Figs. 72-2 and 72-3). Consistent with its oncogenic role in tumorigenesis, mice whose B cells overexpress the BCL-2 transgene develop a polyclonal follicular hyperplasia, and some even develop a monoclonal BCL that recapitulates the human lymphoproliferative disease. By contrast, BCL-2 null mice display early and massive apoptosis of their lymphocytes as well as other developmental defects including renal insufficiency and a deficiency in pigmentation of the melanocyte. Interestingly and of particular relevance to tumor biology, in addition to follicular lymphomas, many or even most human cancers including breast, lung, colon, prostate, melanoma, and leukemia also express high levels of BCL-2 (or other antiapoptotic members such as Bcl_{XL} or Mcll) albeit not as the result of a t(14;18) chromosomal translocation. Interestingly, in addition to functioning to suppress apoptosis, BCL-2 has two other properties: it can retard cell-cycle entry from G1 and has an antioxidant function such that its expression in cells is associated with decreased reactive oxygen species (ROS) levels.

ANTI- AND PROAPOPTOTIC FUNCTION OF BCL-2 MEMBERS BCL-2 family members are classified based on their sharing of conserved BH domains, BH1-4 (*see* Fig. 72-3). Although antiapoptotic members contain all four BH domains, proapoptotic members contain either BH1-3 or a BH-3-only domain. The BH-3 domain is necessary for the proapoptotic function. Indeed, removing BCL-2's BH4 domain and leaving its BH3 domain unopposed, can convert BCL-2 into a proapoptotic BH1-3 containing molecule (like BAX or BAK). Solution and crystal structure of Bcl_{XL} and BCL-2 have revealed that the BH1, 2, and 3 domains fold to create a hydrophobic pocket that will accommodate the BH-3 domain of another proapoptotic family member such as BAX (or BAK), which results in the effective neutralization of its killing potential. Furthermore, it is the BH3-domain that apparently must be so shielded because synthetic BH-3-only containing peptides, or small organic molecules that can block BCL-2 (or Bcl_{XL}) and BAX (or BAK) heterodimerization, can also bring about apoptosis. This appears to result in the exposure of the α-helical BH-3 domain of BAX (or BAK) with subsequent integral insertion into the OMM to form the "death pore." Although BAX (or BAK) is required for mitochondrial disruption and apoptosis, simply overexpressing BAX or BAK in most cells is not sufficient to trigger apoptosis without a concurrent stress signal. This indicates that some type of post-transcriptional regulation is generally required for their activation.

BH-3 only proapoptotic members include BID, BAD, BIM, NOXA, and PUMA. When activated following stress, these proapoptotic members act as messengers to convey the death signal generated by a damaged organelle or DNA to the mitochondria. Functionally, when BAX (or BAK) becomes "activated" as a result of a conformational change in its structure triggered either by stress or binding to a BH-3-only containing molecule like tBID, BAX (or BAK) undergoes insertion and oligomerization within the OMM to create a "death" pore-like gateway through which mitochondrial contents, including cytochrome C and other apoptogenic factors, may leak to trigger caspase activation. Mechanistically, an accepted model holds that in viable, unstressed cells, BAX exists primarily in the cytosol or is only peripherally associated in monomeric form but not yet integrated into the OMM. Following a death stimulus, BAX undergoes a conformational change leading to exposure of its transmembrane domain that facilitates insertion into the OMM in which it also may bind a BH3-only member like tBID to facilitate the oligomerization that produces pore formation. Because of the similarity between the α-helical structures of bacterial pore-forming toxic proteins and BAX, one general model holds that oligomerized BAX/BAK may form death pores large enough to release cytochrome C. This is considered a viable hypothesis because BAX forms pores in artificial lipid membranes that are capable of releasing cytochrome C. Another model implicates the well described mitochondrial permeability transition pore that forms between the inner and OMMs as a result of complexing between the voltage dependent anion channel, the adenine nucleotide transporter and cyclophilin D. This channel will leak ions and dissipate ion gradients and result in the collapse of the mitochondrial membrane potential ($\Delta\Psi_m$) that leads to mitochondrial swelling and rupture, with release of cytochrome-C along and apoptogenic activators. However, because cytochrome-C release precedes both permeability transition pore formation and loss of $\Delta\Psi_m$ that occurs during apoptosis, this is a less attractive mechanism to explain how cytochrome C is released and caspases are activated in apoptosis.

REGULATION OF BCL-2 MEMBERS BY PHOSPHORYLATION Antiapoptotic BCL-2 (and MCL-1 and Bcl_{XL}) as well as proapoptotic BAD are regulated by phosphorylation (Fig. 72-6). For BCL-2, serum and growth factors such as IL-3 mediate its phosphorylation on serine 70, a site located within the flexible loop domain (FLD) that positively regulates its antiapoptotic function. The "regulatory" FLD domain lies between BH4 and BH3 regions in BCL-2 (*see* Fig. 72-4). Phosphorylation can be mediated by several growth factor-activated protein kinases, including the MAP kinases, ERK 1 and 2 and JNK1 and 2, as well as PKC and the CDC2 kinase. Multisite phosphorylation of BCL-2 in the FLD at serine 70, threonine 69 and serine 87 can also occur when cells are treated with microtubule disrupting agents such as paclitaxel and vincristine. As revealed by phosphomimetic or nonphosphorylatable BCL-2 mutants, phosphorylation at any of these sites can significantly enhance its antiapoptotic function. Mechanistically, phosphorylation appears to stabilize the BCL-2/BAX interaction as well as protect BCL-2 from degradation that can occur during apoptosis.

The majority of BCL-2 expressed in the cell is localized in the mitochondria with some in the endoplasmic reticulum and nuclear envelope. Interestingly, the majority of cellular ROS are generated (at least in nonphagocytic cells) in the mitochondria. In addition, although the mechanism is not clear, BCL-2 phosphorylation also regulates its antioxidant and cell cycle entry functions. That is, expression of wt and phosphomimetic but not nonphosphorylatable BCL-2 mutants in cells results in a significantly reduced level of cellular ROS and slower cell growth. Furthermore, slower growth results from BCL-2's ability to retard cell cycle entry from G1 and is closely associated with upregulation of the cyclin inhibitor p27 and downregulation of CdK2 activity. Increasing ROS levels in such slowly cycling cells by adding low concentrations of hydrogen peroxide directly to them can reverse the effect, suggesting that BCL-2's antioxidant function may play a role in regulating cell-cycle entry. This apparent functional linkage between BCL-2's antiapoptotic, cell-cycle retardation and antioxidant properties seem to underscore BCL-2's central role in managing cell stress and apoptosis. That is, cells can generally withstand the effects of an apoptotic-inducing stress better when they are not cycling and ROS levels are lower, as compared to cells undergoing DNA replication and/or cell mitotic division when ROS levels are elevated.

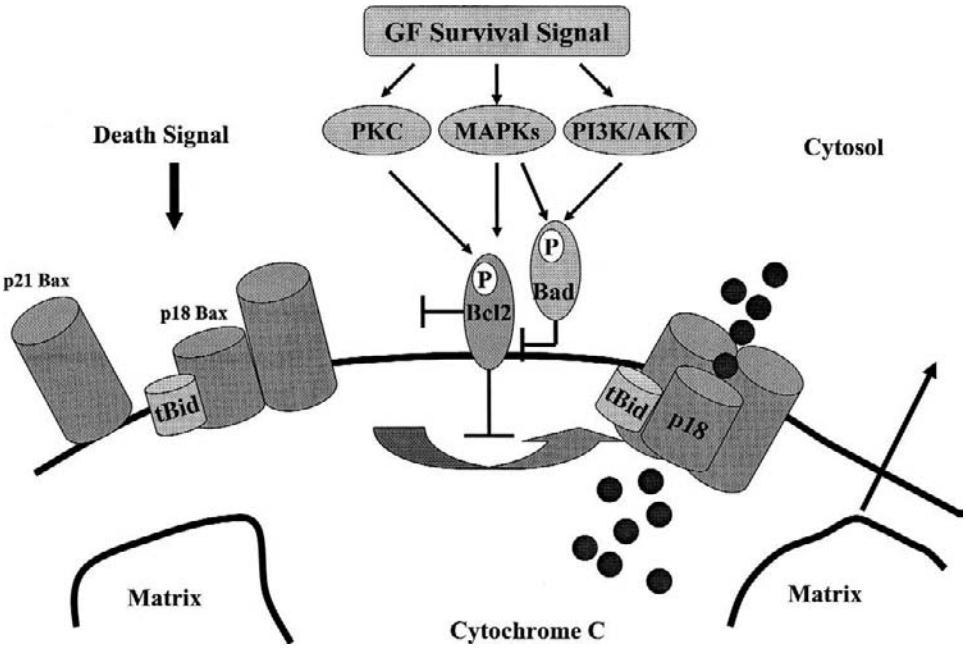

Figure 72-6 Regulation of BCL-2 and BAD by phosphorylation. Growth factors such as IL-3 can activate protein kinases to directly phosphorylate BCL-2 and BAD. BCL-2 phosphorylation blocks BAX oligomerzation and "death pore" formation mediated by tBID that leads to cytochrome C release. BCL-2 also can block cleavage of full length p21 BAX to p18 BAX by a cathepsin-like protease. Phosphorylated BAD is inactive and sequestered in the cytosol. Following a death signal, BAD becomes dephosphorylated and can translocate to the mitochondria and bind and inhibit BCL-2's antiapoptotic function. BCL-2, B-cell lymphoma gene 2.

Whether other antiapoptotic BCL-2 members also may regulate the cell cycle and possess antioxidant effects is not clear.

BAX is the first proapoptotic member of the BCL-2 family to be identified as the heterodimeric binding partner of BCL-2. One popular model holds that BCL-2 binds and neutralizes BAX's proapoptotic activity. The ratio of anti- to proapoptotic activity blocking binding of BH3-only proapoptotic molecules (i.e., BCL-2/BAX) is thought to act like a survival "biorheostat" and set the threshold of cell susceptibility to activation of the intrinsic pathway. Growth factors cannot only provide survival signals to activate antiapoptotic and suppress proapoptotic members but also can transcriptionally increase expression of Bcl_{XL} (and BCL-2 and Mcl1) to facilitate survival. By contrast, stress-induced activation of p53 can induce upregulation of p53 responsive genes including the proapoptotic molecules BAX/PUMA and NOXA that can induce cell death. This outcome alters the BCL-2/BAX ratio such that increased BCL-2 (or Bcl_{XL}) or reduced BAX or (BAK) levels favor survival whereas reduced BCL-2 (or Bcl_{XL}) or increased BAX or (BAK) expression favor increased sensitivity to cytotoxic treatments. In the former case, tumor cells would potentially gain both a survival advantage and a drug-resistance phenotype advantage that could provide a selective growth advantage.

As mentioned, regulating the function of BH-3-only proapoptotic members can occur by several mechanisms including phosphorylation and sequestration away from the mitochondria or proteolytic activation with translocation to the mitochondria. For example, IL-3 addition to factor dependent cells induces multisite phosphorylation of BAD, which then bind to protein 14-3-3 in the cytosol away from the mitochondria. However, following growth factor withdrawal, a BAD PP2A-like phosphatase is activated that mediates dephosphorylation, which interrupts its binding to 14-3-3. That leads to BAD's translocation to mitochondria in which it can directly bind BCL-2 (or Bcl_{XL}) to disrupt the BCL-2:BAX interaction and lead to BAX activation. This causes "death pore" formation and mitochondrial dysfunction with activation of the intrinsic pathway as discussed.

Another BH-3-only molecule, BIM, can also be sequestered from the mitochondria by localizing to the myotubule-associated dynin light chain (LC8) that is part of the motor complex. Following drug treatment, the BIM-LC8 complex is released and BIM is translocated to the mitochondria in which it can now bind and inhibit BCL-2 (or Bcl_{XL}) interaction with to gain access to BAX (or BAK). Thus, activation and translocation of BH3-only proapoptotic molecules to mitochondria represents a common regulatory theme for BH-3 only proapoptotic molecules. Although antiapoptotic BCL-2 and Bcl_{XL} members potentially function to bind and neutralize BAX (or BAK), their activity can be overcome by a barrage of such activated BH-3-only molecules. This has prompted investigators to design novel agents that might target and block the BCL-2/ BAX interaction. Various strategies including antisense technology (e.g., BCL-2 antisense) and design and synthesis of cell permeable small molecule inhibitors of BCL-2 (or Bcl_{XL}) that bind to the BH-3 domain are being developed as potential cancer treatments. Additionally, stabilizing the BCL-2/ BAX interaction or inhibiting caspase activation may potentially preserve the vulnerable tissues in degenerative diseases where the intrinsic pathway is overactive.

p53 AND APOPTOSIS Independent of its transcriptional role in mediating cell-cycle arrest and apoptosis, p53 apparently can also stimulate apoptosis when localized in the cytosol. This can occur by directly binding to BCL-2 (or BCL-2_{XL}) to promote the disassociation of BCL-2/BAX, which results in enhanced BAX proapoptotic activity (*see* Fig. 72-2). p53 not only resides in the nucleus where it functions as a transactivator but also surprisingly may accumulate in the cytosol. Even when deficient in

transactivation function, p53 can directly bind BCL-2 (or $BCL\text{-}2_{XL}$) and lead to BAX activation and engagement of the intrinsic apoptotic program. Although the mechanism is not clear, p53 may facilitate binding of a BH-3 only proapoptotic molecule to Bcl_{XL} (or BCL-2). Thus, the p53 tumor suppressor may pull "double duty" in regulating cellular responses to stress: first, by functioning in the nucleus as a transcriptioned regulator of genes involved in cell-cycle arrest, and DNA repair and apoptosis, second by working also in the cytosol as a proapoptotic regulator of the intrinsic death pathway.

APOPTOSIS AND DISEASE

GROWTH FACTOR SIGNALING AND APOPTOTIC PATHWAYS IN MALIGNANT DISEASE Tumorigenesis is a multistep process resulting from a spontaneous or hereditary mutation or epigenetic alteration of cellular protoonocogenes or tumor suppressor genes. Mutations confer the transformed phenotype of the cancer cell that results from the cell having acquired at least two of the following properties:

1. Replicate in the absence of growth signals.
2. Overcome growth-inhibitory signals.
3. Avoid the host immune surveillance.
4. Maintain an adequate oxygen and nutrient supply necessary for invasion and metastases to unfamiliar microenvironments.
5. Avoid apoptotic cell death.

However, without thwarting apoptosis, the tumor cell would be unable to survive to exhibit its abnormal growth. Furthermore, because malignant cells can both multiply and survive under the most inhospitable of metabolic and microenvironmental conditions (e.g., hypoxia, nutrient depletion) and must be able to successfully defend themselves against or avoid the host antitumor immune response, it is not surprising that mutational or epigenetic alterations of these same genes may affect both proliferation and cell survival. In addition, because chemotherapy and irradiation mediate toxicity by triggering the intrinsic apoptotic pathway, blocking or inhibiting apoptosis in cancer cells may not only cooperate in oncogenicity but also confer a drug resistant phenotype. This linkage seems teleological because it results in conservation of energy and functional simplicity. However, with such interdependence comes the potential risk that mutation of a common component may substantially affect both processes.

Indeed, as discussed, either inactivating mutations or downregulation of proapoptotic genes, including BAX, have been identified in some cancers, which would result in a weakening of the cell's ability to efficiently undergo apoptosis following chemoradiation therapy. In addition, increased expression or an activating mutation of an antiapoptotic gene product like BCL-2 or Mcl-1 may potentially facilitate the development of the malignant phenotype by enhancing cell survival. Interestingly, in addition to lymphomas, BCL-2 is reported to be over/highly expressed in many other cancers, indicating that altered expression of BCL-2 or other antiapoptotic BCL-2 members is a common target in malignancies. Other antiapoptotic regulators may be involved in tumor cells. For example, the cIAP, including c-FLIP, are overexposed in some cancers and implicated in the resistance of tumor cells to chemotherapy-induced activation of caspases. Already well described mutations in critical oncogenes such as RAS, AKT, Myc, PI3K, NF-κβ, and MDM2, clearly lead to enhanced mitogenesis and to enhanced survival as a result of the downregulation of the intrinsic death pathway.
