Foreword

The concept of molecular medicine dates back to Linus Pauling, who in the late 1940s and early 1950s generalized from the ideas that came from the study of the sickle cell hemoglobin molecule. With the first cloning of human genes about 1976, molecular genetics took the molecular perspective on disease to the level of DNA. The term molecular medicine achieved wide currency in the 1980s with the assignment of this designation to journals, at least one society, institutes, and academic divisions of departments of internal medicine. Undoubtedly, molecular medicine has been abetted by the Human Genome Project, which has aided greatly in the molecular characterization of disease. Map-based gene discovery, as in positional cloning of previously unknown genes responsible for "mystery diseases," could be now replaced by sequence-based gene discovery.

What is molecular medicine? In the first edition of *Principles of Molecular Medicine*, Francis Collins seems to define it as "molecular genetics and medicine"—the last four words of his Foreword. He was referring to the pervasive relevance of genetics and genomics to all of medicine. In essence, molecular medicine is genetic medicine.

Since the publication of the first edition *Principles of Molecular Medicine* in 1998, the Human Genome Project has provided a "complete" sequence of the human genome with several surprising revelations relevant to molecular medicine.

As indicated in the Preface of the first edition, the total count of genes was thought to be 50,000 to 80,000. Scrutiny of the complete human sequence leads to a count only half that, perhaps fewer than 30,000. It has come to be realized that each gene can give rise to multiple protein gene products through alternative splicing of pre-messenger RNA, as well as through different posttranscriptional modification of the gene products. Each gene may on the average have as many as 10 different protein products. Mutations in different ones of these can cause quite different clinical disorders. Thus the focus has shifted to the transcriptome and to the proteins that constitute the proteome—a shift from genomics to proteomics.

Compilation of the rapidly expanded topic of molecular medicine since the edition of some 8 years ago is a daunting task. The rate at which new discoveries have been made means that there are many new opportunities and challenges for clinical medicine. One of the effects of the completion of the Human Genome Project is the increasing application of the fields of molecular biology and genetics to the understanding and management of common diseases. Assimilation of the new developments since the first edition has been ably accomplished by Drs. Runge and Patterson with the help of their many knowledgeable authors.

As was evident in the first edition, molecular genetics is involved in every specialty of medicine. A recurrent theme in that edition, perhaps even more striking in the present one, is that information gleaned and research methods designed in one specialty have been highly influential on researchers and physicians in other fields—often in ways that could not have been foreseen. The editors have succeeded in considering all the disciplines while searching for connections and correlations that might otherwise be missed.

The organization selected by the editors allows for the molecular bases of disease, as well as the constantly evolving areas of ethical issues and counseling that affect all disciplines, to be covered in the opening section. Specifics in the several medical disciplines are then handled splendidly in the sections that follow. Each chapter resounds with the amazing detail of what is known and simultaneously probes the many unanswered questions that provide new avenues for research in the 21st century. The state-of-the-art focus in each specialty will be much appreciated by the reader, whether practitioner, researcher or student.

The authors and section editors that participated in this text are recognized leaders in their fields from around the globe. They and Drs. Runge and Patterson, who have led and coordinated this extraordinary effort, deserve commendation. The product is a text that will be useful for all interested in the molecular pathogenesis of disease.

***Victor A. McKusick,* MD**

Foreword to the First Edition

Until recently, medical genetics and molecular medicine were considered the exclusive province of academic specialists in tertiary-care medical centers. Queried about their familiarity with molecular genetic aspects of clinical medicine, most primary-care providers only a few years ago would have responded that such matters were irrelevant to their daily practice.

Yet few could say that today. Few internists or general practitioners have not prescribed recombinant insulin, tPA, or erythropoietin; few pediatricians have not gone through the molecular evaluation of a child with dysmorphology or learning disability; few obstetricians have not performed amniocentesis or CVS for couples at increased genetic risk; and few general surgeons have not faced penetrating questions about the role of genetic testing or prophylactic surgery from women with a strong family history of breast or ovarian cancer.

This level of emergence of molecular genetics into clinical medicine is still quite modest, however, compared to what is coming. As the human genome project hurtles toward completion of the sequence of a reference human genome, and the identification of all human genes, by 2005, the pace of revelations about human illness will continue to accelerate. Until recently, most disease-gene discoveries have related to single-gene disorders (cystic fibrosis, fragile X syndrome, and so on) or to Mendelian subsets of more common illnesses (BRCA1 and BRCA2, the hereditary nonpolyposis colon cancer syndromes, and so on). But with the initiation in 1998 of an aggressive new genome project goal, cataloging all common human sequence variations, it is expected that the weaker polygenic contributors to virtually all diseases will begin to be discerned. Many consequences will result. Individualized preventive medicine strategies, rooted in the gene-based determination of future risk of illness, will become part of the regular practice of medicine. New designer drugs, based not on empiricism but on a detailed understanding of the molecular pathogenesis of disease, will appear. Pharmacogenomics, wherein the efficacy and toxicity of a particular drug regimen can be predicted based on patient genotype, will become a standard component of designing optimum therapy for the individual. And gene therapy, fed by a wealth of disease-gene discoveries, will mature into a significant part of the physician's armamentarium against disease.

As we watch this train coming down the track, this is an ideal time to collect information about molecular medicine into one authoritative text. *Principles of Molecular Medicine* aims to do just that, bridging the current gap between basic science and the bedside. It will thus be useful to researchers and clinicians alike. With more than 100 chapters covering a wide variety of topics, its distinguished cohort of section editors, and its abundant tables and illustrations, it provides an accessible and much needed manual to the present and the future of molecular genetics and medicine.

Francis S. Collins

Preface

Since publication of the first edition of *Principles of Molecular Medicine*, dramatic discoveries in molecular medicine along with concomitant rapid technological advances have revolutionized the diagnosis and treatment of a broad range of human diseases. Given the pace of new discovery, genetic- and cell-based therapies may well become a common part of the physicians' armamentarium in the near future. Direct links between genetic mutations and diseases are being mapped almost routinely. Genomic approaches to diseases such as breast cancer have led to identification of previously unrecognized malignancies and the ability to prognosticate outcomes to therapy. The delicate interplay between adipocytes and regulation of insulin sensitivity, the roles of bone morphogenetic proteins in pulmonary hypertension, and the discovery of mutations involved in an array of cardiomyopathies are but a few of the important recent advances that have direct implications for patient care.

It is virtually impossible to keep track of the breadth of discovery that has led to these biomedical advances. The goal of the many authors and editors of this second edition of the *Principles of Molecular Medicine* has been to present the voluminous discoveries of the past decade in a format that captures the essence of scientific discovery but allows rapid assimilation in each particular area.

This second edition again includes chapters describing advances in fields paralleling traditional medical texts, and will be especially useful to specialists who are updating their education, practicing physicians interested in keeping abreast of new developments, and students appropriately curious about what is known and what lies ahead. Although only 8 years have passed since the first edition was published, we have made every effort to comprehensively update chapters with recent advances and have added chapters for disease entities and areas in which discovery has accelerated during the past five years.

As we have participated in the assembly of this volume, we have had the good fortune to review in depth the molecular discoveries that are transforming medical practice. For example, in the interval since the first edition of this text, stem cell populations have been discovered that regenerate muscle, heart, and neural cell populations, and that have the potential to serve as cell-based therapies in chronic and degenerative diseases. New cell growth and cell death mechanisms that are dysregulated in neoplasia and that may serve as new anticancer targets have been elucidated. Advances have been made in understanding the biology of previously untreatable neurodegenerative diseases such as Huntington's disease. These and many other important advances in our understanding of human diseases are elucidated in this edition.

In addition, we have been able to note the new epistemologies in the genetic basis of human disease that are rapidly emerging. For instance, characterization of candidate genes for human diseases has expanded well beyond monogenic diseases, the study of late-onset diabetes being a notable example. Molecular alterations can have far-reaching effects on many systems. The identification of genes for epithelial sodium channels has led to a deeper understanding of their role in disorders of total body Na+ homeostasis, blood volume, and blood pressure. As a result of advances like these, views that had been held for much of the 20th century are being reconsidered. For example, hereditary hemochromatosis, a familial disease characterized by excess tissue deposits of iron leading to end-organ damage, has traditionally been thought to result from mutations in a single gene. Very recently, the identification of similar phenotypes associated with mutations of at least four different iron-metabolism genes has expanded our understanding of the pathophysiology of this relatively common genetic disease.

One common theme repeated in the chapters in this text is that the pathophysiology of disease is often a succession of genetic alterations, not just a single mutation. Although understanding these genetic relationships is never simple, their role in human diseases is all the more fascinating to consider. Human health often appears tenuous, but the discovery that a series of genetic missteps is often required to produce many disease states can be reassuring. The presence of several genetic steps in a disease process also suggests that multiple therapeutic targets may exist to modulate the course of these diseases. Less exhilarating is the knowledge that numerous diseases result not just from a complex succession of genetic missteps, but also from an individual's

interaction with the environment. Abundant examples of this principle are present throughout clinical medicine, and are described in detail in this edition of *Principles of Molecular Medicine.*

Paradoxically, as new discoveries are made, new mysteries appear. The many advances described in this volume often raise as many new questions as they answer. On the one hand, this indicates that biomedical discovery and medical practice will continue to evolve. On the other hand, the changes in medical care described in the chapters of this text are an indication that the unresolved questions of today may be harbingers of new therapeutic approaches in years to come.

It has been our pleasure to bring together in-depth expositions of the most recent advances in molecular medicine. We invite you to enjoy this magnificent point in biomedical history, as genetics and molecular medicine continue to merge with clinical practice. The compendium of information in *Principles of Molecular Medicine: Second Edition,* has been made possible by the tireless efforts of our section editors. Without their expertise and commitment to this project, this textbook would not be possible. In addition, we thank the individual authors for sharing their expertise with all of us.

In addition to the phenomenal work of the editors and contributors, we would like to extend special thanks to Ms. Katie O'Brien for her commitment to this project; to Ms. Angela Clotfelter-Rego, whose tireless efforts despite numerous obstacles made this project possible; and to Ms. Carolyn Kruse, who synthesized the work of numerous authors to create a blazingly readable text. The editors thank our families, who have tolerated yet another joint effort. Finally, we would like to dedicate this volume to the first chairmen of medicine we had the privilege to serve under, Juha P. Kokko, MD, PhD, and Victor McKusick, MD. As physicians and scientists, these gentlemen nurtured many of the contributors to this edition, and their own work as scientists is frequently cited directly and indirectly in these chapters. It is on the shoulders of men like these that the principles of molecular medicine have been determined.

Deepak M. Sampathu and Virginia M.-Y. Lee

118 Genetics and Neurobiology of Alzheimer's Disease and Frontotemporal Dementias **1130**
Peter H. St. George-Hyslop

119 Prion Diseases **1142**
Adriano Aguzzi

120 Narcolepsy and Other Neurological Sleep Disorders **1153**
Thomas E. Scammell

121 Neurofibromatosis 1 and 2 ..... **1160**
Gregory J. Esper and David H. Gutmann

122 Axonal Regeneration and Recovery From Chronic Central Nervous System Injury **1165**
Stephen M. Strittmatter

XIV. PSYCHIATRY

KERRY J. RESSLER AND CHARLES B. NEMEROFF

123 Molecular Mechanisms Regulating Behavior: *Focus on Genetic and Environmental Influences* **1175**
Kerry J. Ressler and Charles B. Nemeroff

124 The Complex Genetics of Psychiatric Disorders **1184**
Ming T. Tsuang, Stephen J. Glatt, and Stephen V. Faraone

125 Treating Depression: *Antidepressant-Activated Signaling Pathways as a Source for Novel Drug Targets* **1191**
Marcelo Páez-Pereda and Florian Holsboer

126 Anxiety Disorders **1197**
Gregory M. Sullivan and Jack M. Gorman

127 Trauma Spectrum Disorders **1203**
Christine Heim, J. Douglas Bremner, and Charles B. Nemeroff

128 Schizophrenia **1211**
Carol A. Tamminga, Deborah C. Medoff, and Gunvant Thaker

129 Disorders of Substance Abuse and Dependence **1220**
Eric J. Nestler and Jennifer Chao

130 Autism and Related Disorders **1228**
Linmarie Sikich, Thomas H. Wassink, Kevin A. Pelphrey, and Joseph Piven

1 Mendelian Inheritance

Bruce R. Korf

SUMMARY

The basic patterns of genetic transmission in humans have been known for about a century, but are now coming to be understood at the molecular level. In addition to classical dominant, recessive, and sex-linked inheritance, more complex patterns have also been identified. These include maternal transmission of traits encoded in the mitochondrial genome, digenic traits determined by two distinct genes, and genomic imprinting. It is becoming clear that both rare and common genetic traits are determined by a complex interaction of multiple genetic and nongenetic factors.

Key Words: Digenic; dominant; expressivity; imprinting; Mendelian; mitochondrial inheritance; penetrance; recessive; X-linked.

INTRODUCTION

The existence of human traits that are transmitted from generation to generation in accordance with Mendel's laws was first recognized early in the 20th century. Understanding the mechanisms that underlie Mendelian inheritance has unfolded over the ensuing decades, and forms the basis for knowledge of human genetics. With increasing sophistication it has become clear that the seemingly straightforward rules of inheritance—for example, dominance and recessiveness—are in fact complex. With more nuanced understanding, however, comes recognition of genetic principles that have a critical role in diagnosis and counseling. This chapter reviews the basics of Mendelian inheritance and explores how insights in molecular genetics are both explicating and changing views of these fundamental principles.

PATTERNS OF GENETIC TRANSMISSION

The patterns of Mendelian transmission ensue from the fact that humans are diploid organisms, inheriting a complete set of genes from each parent. The two individual copies of a specific gene are referred to as *alleles*. The alleles on homologous chromosomes segregate at meiosis and new combinations are paired together on fertilization. The specific alleles at a locus comprise the genotype; the physical characteristic that results from action of the alleles is the phenotype.

DOMINANT AND RECESSIVE INHERITANCE The first instance of Mendelian transmission in humans was recognized by Archibald Garrod, working in the early years of the 20th century. He originated the term "inborn errors of metabolism" to describe a set of disorders in which specific biochemical pathways were deranged, leading to accumulation of toxic substrates or deficiency of end products. He recognized that these conditions are familial and behave as Mendelian recessive traits. A recessive trait is only expressed in a homozygous individual who inherits a mutant allele from both parents (Fig. 1-1A). The parents are heterozygous carriers, who are asymptomatic because of the action of the dominant allele. A couple consisting of two carriers faces a 25% risk of transmission of homozygosity to any offspring.

The basis of recessive inheritance of inborn errors of metabolism is that the responsible genes encode enzymes required to catalyze specific biochemical reactions. Enzymes function in a catalytic manner, so the 50% level of activity that may occur in a heterozygote is sufficient to complete the reaction and thereby avoid the phenotype. Only a homozygote will lack sufficient activity to manifest the disorder. An example is the disorder phenylketonuria, which is because of mutation in the gene that encodes the enzyme phenylalanine hydroxylase, required to convert phenylalanine to tyrosine. Homozygotes accumulate phenylalanine to toxic levels, and also have a deficiency of phenylalanine metabolites such as dopamine and melanin. Children with this disorder detected by newborn screening can be spared the severe developmental impairment of this disorder by treatment with a low-phenylalanine diet. Carrier parents are asymptomatic, but have a 25% risk of additional affected children.

Dominant traits are expressed in both homozygous and heterozygous individuals (Fig. 1-1B). If the trait is rare, most affected individuals will be heterozygous. Moreover, many dominantly inherited medical conditions are lethal in the homozygous state, technically indicating that they are not "true" dominants. An individual who is heterozygous for a dominant trait has a 50% chance of passing either allele to any offspring.

A prototypical autosomal-dominant disorder is Marfan syndrome, resulting from mutation in the connective tissue protein fibrillin. Affected individuals are tall, lanky, and experience complications such as joint dislocation, lens subluxation, and aortic aneurysms because of weakness of connective tissue. The disorder is compatible with survival to reproductive age, and affected individuals have a 50% risk of transmitting the mutant allele to any offspring. The molecular basis for dominance is reviewed later.

SEX LINKAGE Sex determination occurs by inheritance of two X chromosomes in females or an X and a Y in males. The Y carries a limited repertoire of genes, including those involved

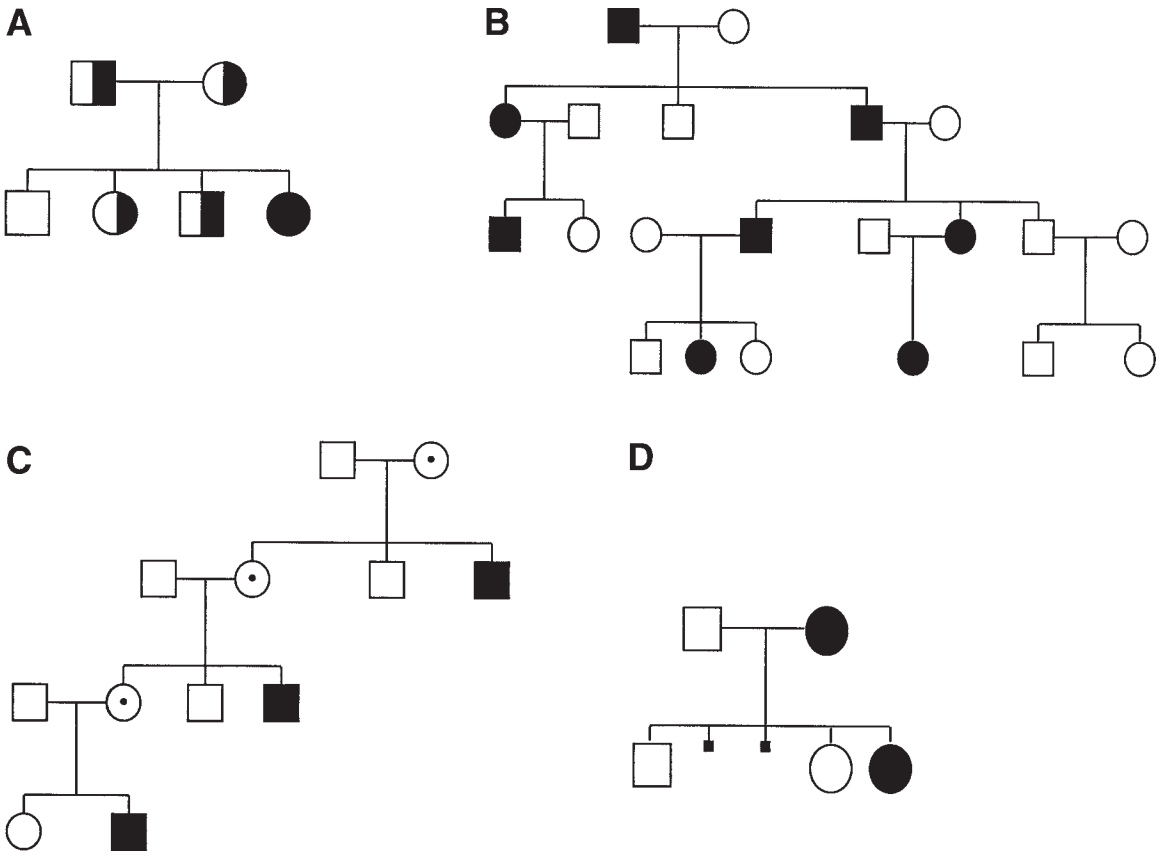

Figure 1-1 Pedigrees depicting autosomal-recessive **(A)**, autosomal-dominant **(B)**, X-linked-recessive **(C)**, and X-linked-dominant with male lethality **(D)**. By convention, squares denote males, circles females, and filled-in symbols are individuals who manifest a phenotype. Half-filled symbols in the recessive pedigree are carriers, and females with dots in the X-linked recessive pedigree are heterozygotes.

in testes determination and spermatogenesis. The X carries a larger set, most of which lack counterparts on the Y. Therefore, for these genes, females have two alleles, but males only one. There are regions at the two ends of the X chromosome where homologous loci exist on the Y. These are referred to as *pseudoautosomal*. For the other loci found only on the X males are said to be *hemizygous*.

Gene dosage is finely controlled, and, therefore, a mechanism exists to compensate for the dosage differences in males and females for X-linked genes. Most genes on the X chromosome are inactivated on one of the two X's in female cells early in development. The choice of X to be inactivated is random, but once an X is "turned off," that chromosome remains off in all descendents of a particular cell. Some genes, especially those in the pseudoautosomal regions escape inactivation. The molecular basis for X chromosome inactivation is becoming understood. It includes selection of the chromosome to be inactivated by an RNA molecule encoded by an X-linked gene called *Xist* and subsequent methylation of DNA on the inactive chromosome.

There are few Y-linked traits of medical significance. A Y-linked gene is transmitted from a male to all his sons and none of his daughters. X-linked traits are transmitted by a heterozygous female to half her offspring; a hemizygous male passes the gene to all his daughters and none of his sons (Fig. 1-1C). The concepts of dominance and recessiveness are meaningless when applied to genes on the X chromosome, which are subject to inactivation, because only one allele is expressed in any cell in either a male or a female. Whether or not a trait is expressed in a heterozygous female depends on whether expression of the mutant gene in approx 50% of cells is sufficient to cause the phenotype, or whether expression of the wild-type allele in 50% is insufficient. Classic "X-linked-recessive" traits such as Duchenne muscular dystrophy and hemophilia A tends not to lead to a phenotype in heterozygous females, unless X chromosome inactivation has somehow been skewed toward inactivation of the wild-type allele. "X-linked-dominant" traits, such as hypophosphatemic rickets, are expressed in both sexes. X-linked traits such as Rett syndrome or incontinentia pigmenti are lethal in hemizygous males and, therefore, only are seen in heterozygous females (Fig. 1-1D).

MATERNAL TRANSMISSION Although not a "Mendelian" pattern, maternal inheritance is another form of single gene transmission. Maternal inheritance applies to a set of genes found on the 16.5-kb circular double-stranded DNA molecules found within mitochondria. These encode 13 peptides involved in mitochondrial oxidative phosphorylation, as well as a set of transfer RNAs and ribosomal RNAs. There are thousands of DNA molecules within mitochondria in every cell. If there is a mutation in some, the cell is said to be heteroplasmic (Fig. 1-2A). Because mitochondrial DNA molecules segregate at random during cell division, the proportion of mutant and wild-type DNA molecules can vary widely between cells. Mitochondrial DNA mutations tend to interfere with cellular energy production. Because of heteroplasmy there can be a wide range of phenotypic effects, depending on the proportion of mutant mitochondria in different tissues.

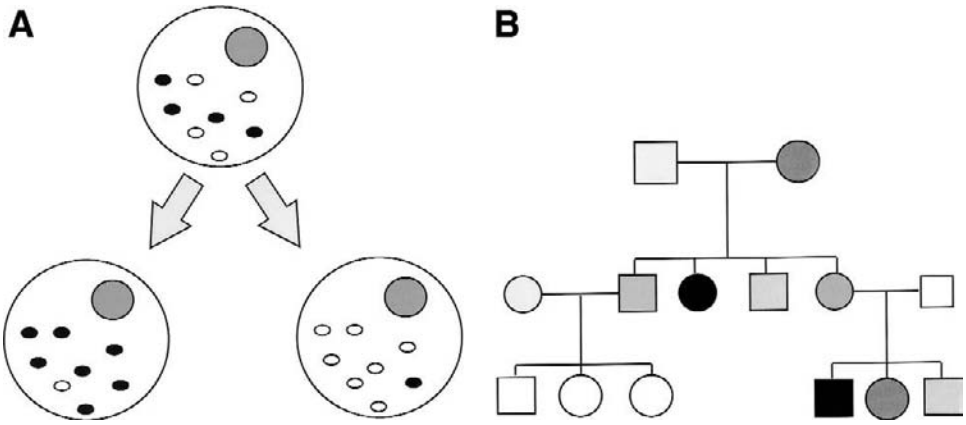

Figure 1-2 **(A)** Mutant and wild-type mitochondrial DNA may coexist in a cell, referred to as heteroplasmy. Mitochondrial DNA molecules segregate passively when a cell divides, so daughter cells may differ in their proportions of mutant and wild-type mitochondrial DNA. **(B)** Essentially, all the mitochondrial DNA is maternally transmitted. Hence, a female with a mitochondrial disorder will transmit it to all her offspring, whereas a male will not transmit the trait. Offspring may differ in their degree of expression of the phenotype because of heteroplasmy.

Most, if not all, mitochondria are transmitted through the oocyte. As a result, a female with a mitochondrial mutation will pass it to all of her offspring, whereas a male will not transmit it at all (Fig. 1-2B). Once again, however, heteroplasmy will account for variability, in this case among members of a sibship. This creates a challenge in recurrence risk counseling for mitochondrial disorders, because the likelihood that an offspring will inherit sufficient mutant DNA molecules to produce a phenotype cannot be predicted.

COMPLEXITIES OF MENDELIAN TRAITS

Although single gene traits are transmitted in accordance with Mendel's laws, a number of phenomena may lead to deviation from the expected segregation ratios. These include nonpenetrance, new mutation, mosaicism, anticipation, imprinting, and digenic inheritance.

PENETRANCE AND EXPRESSIVITY Individuals who have the genotype associated with a particular phenotype yet do not display the phenotype are said to be nonpenetrant. For a dominant trait this may lead to a skipped generation (i.e., a trait is seen in a child and a grandparent, but the parent is not affected). Some phenotypes display age-dependent penetrance, so the probability of phenotypic expression increases with age. This is typical of disorders such as Huntington disease or adult polycystic kidney disease. Penetrance is an all-or-none phenomenon for an individual; the phenotype is either present or not at a particular time. Penetrance should not be confused with expressivity, which refers to the degree of phenotypic expression from individual to individual. The possibility of nonpenetrance or of age-dependent penetrance needs to be considered when counseling an individual at risk of a dominant trait. The lack of phenotype does not necessarily preclude one from occurring at a later age or exclude the possibility of transmission of the trait to an offspring.

MUTATION AND MOSAICISM Sporadically affected individuals with a dominant or an X-linked trait may occur because of a new mutation in the sperm or egg cell. Neither parent will be found to carry the trait, and the affected child will be the first affected member of the family. That child, however, will be at risk of transmitting the trait to his or her offspring. Mutation rates vary among different loci, usually hovering in the range of 10^{-4} to 10^{-6}/gamete/generation. Few distinct risk factors have been identified, although there is a slight increase in the risk of mutation with advancing paternal age.

Mutation may occur in somatic cells as well as in the germline. Somatic mutation during early development results in somatic mosaicism, in which an individual has a mixture of mutant and nonmutant cells. This may manifest as milder expression of a phenotype, or as expression of the phenotype in a limited region of the body. A dramatic example is segmental neurofibromatosis, where *café-au-lait* spots and neurofibromas may be restricted to part of the body. Germline mosaicism results in multiple sperm or egg cells carrying a new mutation. A parent with germline mosaicism can have multiple affected children despite not carrying the mutation in somatic cells.

ANTICIPATION It has long been noted that in some families with particular dominant traits, severity increases, and age of onset decreases, from generation to generation. This phenomenon is referred to as anticipation. Although initially thought to be an artifact owing to bias of ascertainment, it is now known to be a real event that is the signature of a specific type of mutation, the triplet repeat expansion (Fig. 1-3). A number of genes include repeated triplets of bases, such as CAGCAGCAG. The exact number of repeats is a heritable polymorphism, as there is no phenotypic impact regardless of the number, up to a point. Individuals with mutations, however, have expanded numbers of repeats that lead to aberrant gene expression. Anticipation results from two characteristics of repeat expansion mutations. First, the larger the number of repeats, the more severe and earlier is the onset of the disorder. Second, the larger the repeat size, the more unstable it is, creating risk of further expansion in the next generation. The expansion, therefore, increases from generation to generation, leading to anticipation. Disorders associated with triplet repeat expansion tend to affect the nervous system, and include Huntington disease, fragile X syndrome, myotonic dystrophy, spinocerebellar ataxia, and others.

IMPRINTING A subset of genes is expressed only from the maternal or paternal allele, but not both, and is referred to as imprinting. The "imprint" that identifies an allele as being of maternal or paternal origin is "erased" each generation. For example, if it is the maternally derived allele that is expressed, a maternally inherited allele will be turned on in a male, but will be turned off when he transmits it to the next generation. It appears that only

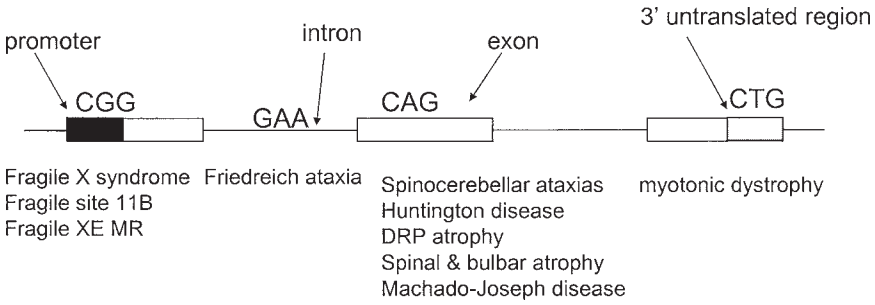

Figure 1-3 A prototypical gene, showing sites of triplet repeats that are prone to expansion, and examples of resultant disorders.

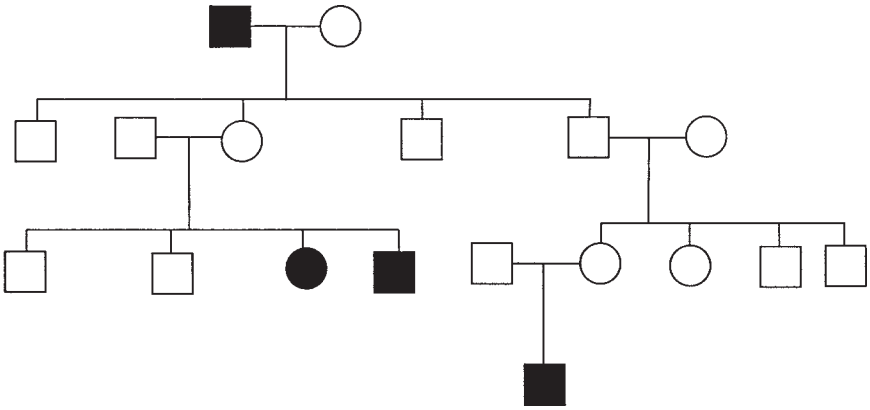

Figure 1-4 In this autosomal-dominant trait, an imprinted gene is only expressed when inherited from a female. Hence, only females can have affected offspring. Individuals who inherit the mutation from their fathers will not express the phenotype, but their daughters who carry the mutation can have affected children.

a relatively small number of genes are subject to imprinting, but these account for some distinct phenotypes and unusual patterns of transmission. A dominant trait because of an imprinted gene will only result in a phenotype when the transmitting parent is the one who transmits the expressed allele (Fig. 1-4). This gives rise to multiple examples of nonpenetrance. For example, this is the case in familial glomus tumors. Prader–Willi and Angelman syndromes result from deletions on chromosome 15 from a region that contains imprinted genes. The gene involved in Angelman syndrome is expressed from the maternal allele, so deletion of this allele results in the disorder. In contrast, paternal deletion of the same region produces Prader–Willi syndrome, reflecting the presence of one or more paternally expressed genes in the region. The same phenotypes can result from the inheritance of both copies of chromosome 15 from the same parent, referred to as uniparental disomy. In this case there will be absence of either maternally or paternally expressed genes, depending on whether there are two copies of mother's or father's chromosomes. Uniparental disomy results when a trisomic zygote produces an embryo in which disomy is restored by a second nondisjunction event. If the chromosomes that remain are from the parent in whom nondisjunction occurred, uniparental disomy will result. Aside from accounting for some cases of Prader–Willi or Angelman syndromes, uniparental disomy for several other chromosomes has been associated with a phenotype.

DIGENIC INHERITANCE In rare instances, it has been found that individuals who are doubly heterozygous for two recessive alleles may manifest a phenotype (Fig. 1-5). This has been found, for example, in some cases of the eye disorder retinitis pigmentosum. Parents who are heterozygous for two different genes can have doubly heterozygous offspring. If the genes are on different chromosomes, an affected child can transmit both mutant alleles to an offspring, producing apparent dominant transmission. Genes that are subject to digenic inheritance tend to encode proteins that interact with one another in the same pathway.

MOLECULAR BASIS OF MENDELIAN INHERITANCE

The patterns of single gene transmission have been known for a long time, but only recently the phenomena have begun to be understood at the molecular level. The bases for the Mendelian patterns as well as the complexities noted in the previous section are gradually emerging.

RECESSIVE VS DOMINANT ALLELES Recessive alleles, by definition, only exert a phenotypic effect in a homozygous state. In general, this implies that a mutation has resulted in loss of function of the gene product, and that partial loss of function is not sufficient to result in a phenotype. As noted, this is the case for most enzyme deficiencies. The mutations responsible for such disorders tend to be those that cause premature termination of translation, such as frame shifts or stop mutations, nonsense mutations, deletions, or splicing mutations, which significantly disrupt the coding sequence. Missense mutations may also cause a phenotype if they significantly disrupt the function of the gene product.

The basis for dominance can be a diverse set of genetic changes. Some mutations lead to gain of function, for example,

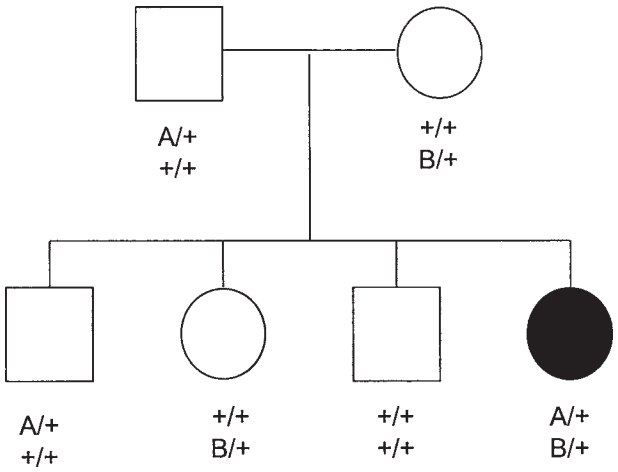

Figure 1-5 Pedigree illustrating digenic inheritance. Each parent is heterozygous for a different gene. The child who is heterozygous for both expresses the phenotype.

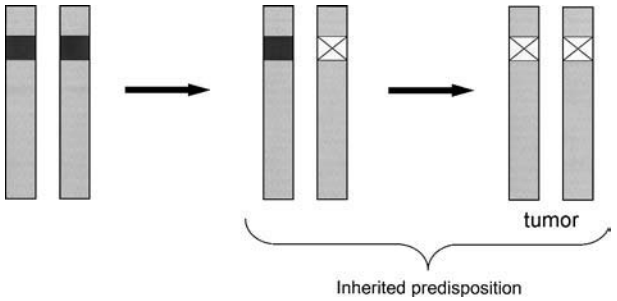

Figure 1-6 Tumor suppressor concept. A tumor suppressor gene is homozygously mutated in a tumor cell. Those who inherit a heterozygous mutation as a dominant trait are at increased risk of cancer if the remaining wild-type allele is mutated.

constitutive activation of a cell membrane receptor as occurs in the *FGFR3* gene in achondroplasia. Activation of just one allele is sufficient to alter the behavior of a cell. Another mechanism is referred to as dominant negative. Here, a single mutant allele produces sufficient abnormal product to disrupt cellular function. This is the hallmark of mutations in genes that encode products of multimeric proteins. Although only 50% of the protein may be abnormal, abnormal subunits may contribute to a higher proportion of proteins, resulting in a heterozygous phenotype. This is the case for some types of collagen mutations responsible for osteogenesis imperfecta. Dominant transmission may also occur with loss-of-function mutations if 50% levels of gene product are insufficient for normal function. This occurs in mild forms of Marfan syndrome because of loss-of-function fibrillin gene mutations. Interestingly, dominant negative mutations in this gene cause more severe disease, because the presence of abnormal fibrillin molecules has a more pervasive effect on connective tissue integrity than does 50% reduction of quantity.

A special case of dominant inheritance is accounted for by tumor suppressor genes. These genes account for familial susceptibility to cancers such as retinoblastoma, colon cancer, and breast or ovarian cancer. In families with an inherited susceptibility, the risk is transmitted as a dominant trait. Within a tumor cell, however, both alleles of the tumor suppressor are mutated, usually with a loss of function type mutation (Fig. 1-6). The mutation of one allele in such families is transmitted from generation to generation. An individual with heterozygous mutation faces an increased risk of cancer because somatic mutation of the remaining wild-type allele is all that is required to start a cell on the path to malignancy.

GENETIC HETEROGENEITY There is a wide diversity of different mutation types, with a range of effects on gene function, including mutations that increase or decrease levels of gene product expression, or change the functional properties of the protein. Different mutations in the same gene may have differing impacts on phenotype. The consequence is that different individuals with a dominant trait may have distinct mutations. Furthermore, the two mutant alleles in an individual who is homozygous for a recessive mutation may differ. There are exceptions; in some cases only a very specific mutation will cause a specified phenotype. This is true for the *FGFR3* mutation in achondroplasia. In other instances, a specific mutation may have arisen in an isolated population and remain relatively common there. This is called the founder effect, and accounts, for example, for the high prevalence of specific mutations responsible for Tay-Sachs disease in the Ashkenazi Jewish population.

Other than these instances, allelic heterogeneity is more a rule than an exception. In some cases, variable expressivity is explained by the occurrence of different mutations causing slightly different phenotypes. Study of genotype–phenotype correlations can sometimes provide information predictive of disease severity useful in genetic counseling. The difference between severe Duchenne muscular dystrophy and the milder Becker form can be predicted from whether the mutation causes complete loss of the gene product, dystrophin (Duchenne), or production of an aberrant protein (Becker). In still other cases, the different mutations result in phenotypes that would not have been regarded as the same disease. For example, different mutations in the *CFTR* gene can cause cystic fibrosis, chronic sinusitis, or male infertility resulting from congenital bilateral absence of the vas deferens.

Genetic heterogeneity extends not only to different alleles, but also to different loci. Studies to identify genes responsible for disease often reveal multiple distinct genes that are associated with the same phenotype in different individuals. In some instances, such as congenital deafness, this locus heterogeneity reflects that a large number of genes contribute to normal hearing. Many of these genes can be disrupted by mutation, all leading to deafness. In other cases, genes that encode proteins that interact with one another in the same pathway result in an indistinguishable phenotype when mutated. This is the case in tuberous sclerosis, associated with mutation in either the *TSC1* or *TSC2* genes. The protein products, hamartin and tuberin, interact with one another to form a complex that is involved in the control of cell growth. Locus heterogeneity is important in clinical genetics, because testing of the incorrect gene will fail to reveal an underlying mutation and could lead to incorrect exclusion of a diagnosis. For a recessive disorder, locus heterogeneity explains why two affected parents may have unaffected children. This is a common occurrence in hereditary deafness.

MODIFYING GENES Although some phenotypes are reliably associated with specific genotypes, such as sickle cell anemia with the substitution of valine for glutain acid at position 6 β-globin mutation, mutations should not be thought of as totally deterministic of any specific phenotype. All mutations act within a context that is specified by factors including genetic background and the

environment. Although a distinction is often made between monogenic and multilateral phenotypes, in a sense all phenotypes are multifactorial. In some instances, a single gene exerts a major effect and in others many genes exert a more modest effect, but in virtually all cases genetic background and environment play some role.

Modifying loci may be intragenic or may occur as interactions between different gene loci. The poly T polymorphism with the *CFTR* gene exerts a modifying effect in the expression of mutations within this gene. Individuals may have an allele with 5, 7, or 9T's with this polymorphic site, which resides within the interval between exons 7 and 8. The 5T allele is associated with skipping of exon 9, whereas the 9T allele leads to normal splicing. Genotype at the poly T site influences phenotype associated with another *CFTR* mutation, R117H. This mutation is associated with CBAVD when in *cis* with 9T and opposite another *CFTR* mutation, but with mild cystic fibrosis if in *cis* with a 5T allele.

A dramatic example of gene–gene interaction is the phenomenon of epitasis, wherein the phenotype of one gene masks that of another. Individuals will only secrete A or B blood group antigens into saliva if they have at least one dominant Se alleles at the secretor locus. Someone with the se/se genotype will not have A or B antigen in saliva regardless of ABO genotype. Modifier loci with more subtle effects are likely to play a role in a large number of phenotypes. At least some degree of variable expression is probably the consequence of interactions between genes. Any single locus can be visualized as a node in a network. Changing the state of a single node will influence, and be influenced by, a large number of other nodes. In rare and common disorders, expression of a phenotype is a consequence of a complex web of interactions, and genetic analysis will increasingly require such complex systems.

CONCLUSIONS

The rules of Mendelian inheritance have provided the basis for the study of human genetics for a century. Studies at the molecular level have provided an understanding of the basis for single gene inheritance and have uncovered some unexpected mechanisms. With new tools of genomics, exploration is beginning of the complexities of gene interactions as they relate to rare and common phenotypes, and knowledge of the elements of genetics is being integrated into a broader picture of biology.

2 Nontraditional Inheritance

Shawn E. McCandless and Suzanne B. Cassidy

SUMMARY

The "rules" of segregation of alleles originally defined by Gregor Mendel explained much of the phenomena associated with inheritance and have been dogmatically applied in the field of genetics. However, there are situations in which the rules of Mendelian inheritance cannot explain observed phenomena. A variety of molecular mechanisms have been identified that explain certain phenomena that are not easily explained by traditional Mendelian patterns of inheritance. These non-Mendelian mechanisms differ on a molecular basis, but can be described as a group by the term "nontraditional mechanisms of inheritance" or "nontraditional inheritance." Stated simply, nontraditional inheritance refers to the pattern of inheritance of a trait or phenotype that occurs predictably, recurrently, and in some cases familially, but does not follow the rules of typical Mendelian autosomal or sex chromosome inheritance. Examples discussed in this chapter are the triplet repeat expansion mutations, and genomic disorders including genetic imprinting, mitochondrial inheritance, and multi-allelic inheritance.

Key Words: Angelman syndrome (AS); fragile X; Mendelian; mitochondrial inheritance; multifactorial inheritance; non-Mendelian; Prader–Willi syndrome (PWS).

INTRODUCTION

The "rules" of segregation of alleles originally defined by Gregor Mendel explained much of the phenomena associated with inheritance and have been dogmatically applied in the field of genetics. However, there are situations in which the rules of Mendelian inheritance cannot explain observed phenomena. A variety of concepts have been suggested to explain such phenomena, including the idea that individual genes may function in cooperation with each other and with environmental factors to produce a given phenotype. This concept of multifactorial inheritance is well accepted; however, specific examples for which the various factors can be well defined have been difficult to identify. Other natural phenomena, such as anticipation, in which genetic traits or disorders become more severe or pronounced in successive generations, or genetically determined conditions that appear to depend on the sex of the parent of origin of the involved chromosome, have been difficult to explain, even using concepts of multifactorial inheritance.

A variety of molecular mechanisms have been identified, which explain certain phenomena that are not easily explained by traditional Mendelian patterns of inheritance. These non-Mendelian mechanisms differ on a molecular basis, but can be described as a group by the term "nontraditional mechanisms of inheritance" or "nontraditional inheritance." Stated simply, nontraditional inheritance refers to the pattern of inheritance of a trait or phenotype that occurs predictably, recurrently, and in some cases familially, but does not follow the rules of typical Mendelian autosomal or sex chromosome inheritance. Examples discussed in this chapter are the triplet repeat expansion mutations and genomic disorders including genetic imprinting, mitochondrial inheritance, and multi-allelic inheritance.

TRIPLET REPEAT EXPANSION

The first disorder identified as resulting from this form of nontraditional inheritance is fragile X syndrome (FRAXA). FRAXA is a well-recognized disorder that causes mental retardation, autistic-like behaviors, and a subtle, but characteristic, external phenotype in all males and many females possessing the mutation. Early studies confirmed that the locus of interest was on the X chromosome, and that in some cases the trait was associated with a cytogenetically visible fragile site on the X chromosome, seen only when cells were grown in a folic acid-deficient medium. The mental retardation syndrome was inherited in a classic pattern of X-linked inheritance, with carrier mothers who might have affected brothers or uncles passing the trait on to half of their male offspring. However, some unusual families caused confusion because of a pedigree pattern demonstrating what came to be known as the Sherman paradox. Specifically, there were families identified in which a male appeared to have passed the trait on to his daughters, but he himself was not affected, even though he might have affected brothers or uncles. This pattern could not be explained by typical X-linked inheritance.

The solution to the Sherman paradox became apparent when the molecular basis of the FRAXA was found to be a unique type of mutation that occurs in a region of repeated nucleotides in the genetic sequence. Specifically, in the FMR1 gene (*Xq27.3*) there is a repeated sequence of CGG nucleotides, a "triplet repeat" (Fig. 2-1). In normal individuals this sequence is repeated 5–44 times, but in an affected individual the sequence is repeated more than 200 times. Even more interesting, the mothers of the affected individuals were found to have triplet repeats with 60–200 copies. The normal allele is stably copied during the process of meiosis,

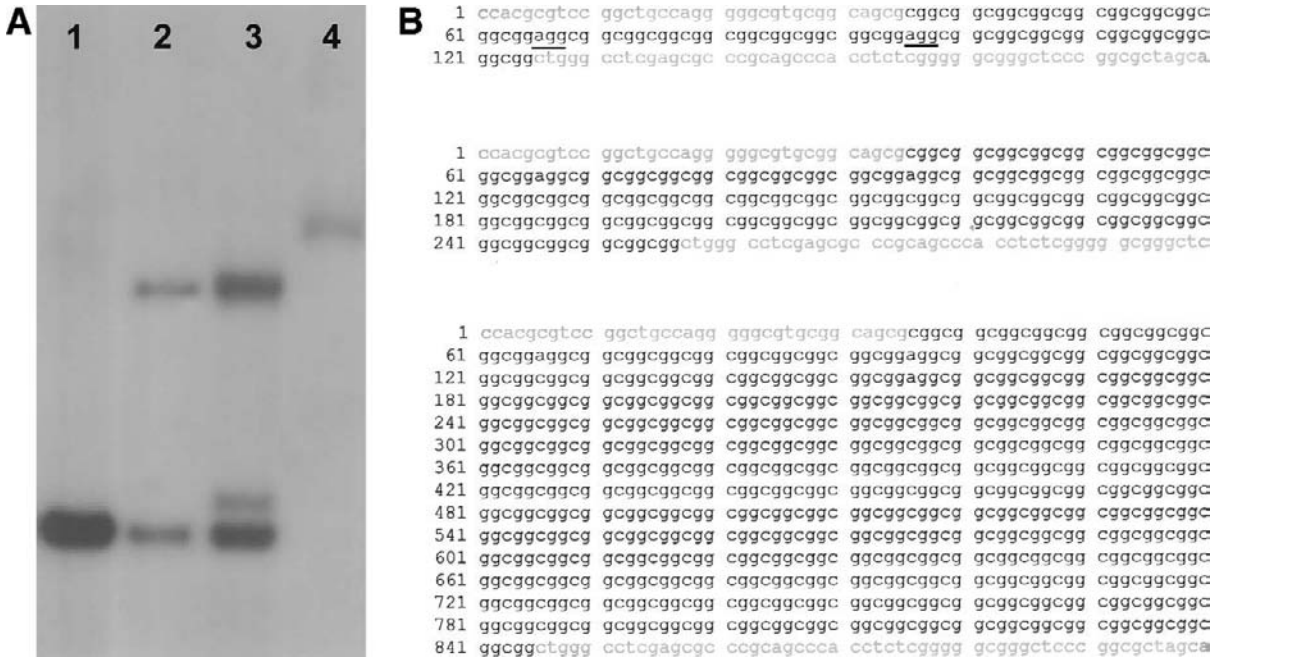

Figure 2-1 Triplet repeat expansion in fragile X syndrome. The gel **(A)** shows Southern blot-based testing for several individuals including a normal male—lane 1, a normal female—lane 2, a female premutation carrier—lane 3, and an affected male—lane 4. DNA is double digested with *Eco*RI, a restriction enzyme that cuts on either side of the triplet repeat, and *Eag*I, a methylation-sensitive enzyme that only cuts unmethylated DNA (including one site near the Fragile X triplet repeat). DNA is loaded from the top of the gel and separated by electrophoresis. A radioactively labeled probe, which binds near the triplet repeat, is used to visualize the bands of interest. Because *Eag*I only cuts unmethylated DNA, the methylated (inactive) allele is not cut and is seen as a 5.2-kb fragment (containing the triplet repeat). The unmethylated (active) allele is cut by *Eag*I and is seen as a 2.8-kb fragment (also containing the triplet repeat). Normal males have only the 2.8-kb fragment, representing the unmethylated allele from the active X chromosome, as seen in lane 1. Because they have two X chromosomes, normal females have both a 2.8-kb fragment and a 5.2-kb fragment, representing the methylated (inactive) and the unmethylated (active) alleles (lane 2). The female premutation carrier (lane 3) has two bands around 2.8 kb, one slightly larger because of the triplet repeat expansion of about 70 repeats (210 nucleotides). These additional 210 nucleotides represent approx 8% of the 2.8-kb fragment, so two lower bands are seen. The upper, methylated, fragment also has two bands, but because the 210 extra nucleotides only account for approx 4% of the whole fragment, the two bands do not separate enough to be visualized. The affected male in lane 4 has only one allele, seen as a fragment larger (above) than the 5.2-kb alleles in the female premutation carrier (lane 3) because of the increased size of the triplet repeat region of the fragment (estimated to be 330–530 repeats). Because males have only one X chromosome, this band represents a full-size expansion of the triplet repeat, which leads to methylation (inactivation) of the gene, resulting in Fragile X syndrome. Examples of the sequence **(B)** are shown for normal, a pre-expansion carrier and an affected allele, with the expansion shown in black and flanking sequence shown in gray. The normal allele in this figure has 30 CGG repeats, the premutation 74, and the full expansion 270. (Fig. 2-1A is courtesy of Stuart Schwartz and Linda Jeng.)

but alleles that are somewhat larger than normal, called "premutations," are prone to further expansion (increase in the number of repeats), leading in some cases to the full mutation. For reasons that are not well understood, the triplet repeat expansion in FRAXA appears to be much more likely to expand during female meioses than during male meioses. Occasionally, a female carrier of a premutation may pass on to her son an allele that has not undergone further expansion. He will not be affected, but can pass on the premutation to his daughters, who then will have a high risk of having an affected child by passing on a further expanded allele. It should be noted that FRAXA is caused by loss of function of the FMR1 protein and can also be caused by other inactivating mutations or deletion of the FMR1 gene.

Another interesting observation about FRAXA is that, contrary to Mendelian expectations for an X-linked recessive disorder, carrier females are often affected. In fact, as many as 50% of females who carry a full expansion will have measurable cognitive defects. This is not because of variation in the triplet repeat expansion, but is instead a result of intraindividual variation in X-chromosome inactivation. In every female cell, one or the other of the two X chromosomes is inactivated to compensate for the fact that women have double the number of X chromosomes as men. This X-inactivation is thought to occur randomly at an early stage of development when there are only 64–128 cells in the blastocyst. On average, half of the cells would be expected to maintain one of the X chromosomes as the active one, and the other half of the cells will maintain the other X. In an individual, however, merely by chance, the ratio may be skewed toward one or the other of the X chromosomes being active. This has been well documented, so that in a population of women there is a normal distribution, with a significant minority of women having one or the other X chromosome much more often inactivated. There are also likely to be different ratios of X-inactivation in a single individual when examining different tissues, with the tissue of interest for the cognitive defects (the brain) being generally unavailable for diagnostic molecular evaluation. These and other examples of the effect of X-inactivation on expression of X-linked disorders have led some to suggest that it is inaccurate to use the distinction of X-linked-recessive or X-linked-dominant. Rather, all of these disorders should be simply called "X-linked."

A number of genetic disorders caused by triplet repeat expansions have now been described. Table 2-1 shows several examples, along with the mode of apparent Mendelian inheritance, the

Table 2-1
Examples of Other Triplet Repeat Expansion Disorders

Disorder	*Inheritance*	*Triplet sequence*	*Normal number of repeats*	*Number of repeats associated with disorder*
Myotonic dystrophy	AD	CTG	5–27	>50 to >1000
Huntington disease	AD	CAG	9–37	>37
Spinocerebellar ataxia type I	AD	CAG	19–38	40 to >80
Friedreich ataxia	AR	GAA	7–20	>200
Fragile X syndrome	XLR	CGG	6–52	>200
X-linked spinobulbar atrophy	XLR	CAG	19–25	>40

AD, autosomal-dominant; AR, autosomal-recessive; XLR, X-linked-recessive.

repeated triplet of bases, and the number of repeats associated with the disease state. The molecular mechanism that causes disease is likely different, because some triplet repeat expansions are in coding regions of the gene (exons), some are in noncoding regions (introns), and others are completely outside of the gene, apparently affecting transcriptional regulation. In some cases, the triplet repeat expansion causes disease because it leads to the loss of function of the normal protein product. The triplet repeat expansion may also cause some new function or interaction, which has been shown to be the case in Huntington disease. Interestingly, the vast majority of disorders known to result from triplet repeat expansion are disorders of the neurological system, especially ataxias and other movement disorders.

This mechanistic heterogeneity extends also to the meiotic instability of the triplet repeat expansions. Some triplet repeats are more prone to expansion during female meiosis (e.g., fragile X and myotonic dystrophy) whereas others are more likely to expand when inherited from the father (e.g., Huntington disease). The FMR1 gene also has mitotic instability, so that there may be variation in the size of expansion in different cells and different tissues in the same individual. This is not a generalized trait of triplet repeat expansions, though, as it does not occur with the Huntington disease gene, Huntingtin (*4p16.3*).

Anticipation refers to an observed phenomenon where a genetic disorder appears to become more severe in successive generations, a condition not easily explained by simple Mendelian inheritance. For many years there was a controversy as to whether this observation was true, or was a result of ascertainment bias because mildly affected parents may only be identified if they have a more severely affected child. It is now known that anticipation does occur, at least in many triplet repeat expansion disorders, because of increasing size of the triplet repeat expansion in successive generations. In Huntington disease, the child of an affected father may present at a significantly earlier age than the father because of further expansion of the abnormal allele during male meiosis. A similar situation occurs with myotonic dystrophy, a disorder characterized by progressive weakness, especially in the distal extremities, associated with myotonia (difficulty relaxing a contracted muscle), cataracts, and frontal hair loss. A mildly affected mother, who may not know she has the disorder, can give birth to an infant with severe hypotonia and weakness causing respiratory compromise and often death in the neonatal period. The mother may have few symptoms, which can be as subtle as difficulty releasing a handshake. A similar pattern of a severely affected infant born to a mildly affected parent has been described with massive triplet repeat expansions occurring in genes associated with some forms of spinocerebellar ataxia.

GENOMIC DISORDERS AND IMPRINTING

Prader–Willi syndrome (PWS) and Angelman syndrome (AS) exemplify several aspects of nontraditional inheritance. In the case of PWS and AS, the parent of origin of chromosome 15 affects the expression of some genes. The discredited hypothesis of Lamarck suggested that the parental factor of inheritance is somehow "imprinted," and that acquired traits can be passed on to the offspring. Although Lamarck was incorrect, the concept of imprinting has survived, in this case meaning that expression of certain genes is determined by the sex of the parent who passed on that chromosome.

These imprinted genes, which reside on autosomes, exist in two copies, as do all autosomal genes. The inactivation of one copy of these genes resulting from imprinting makes the genes dosage dependent. Stated another way, some autosomal genes are normally expressed only from one member of the gene pair even though both genes in the pair have normal base sequence because one allele has been inactivated. This exposes at least three different, and fascinating, causes of nontraditional inheritance not because of variation in the DNA sequence of the genes involved, but instead because of changes affecting the way the genes are transcribed and expressed. "Genomic disorders" are those disorders resulting from the loss of function of a dosage-dependant gene as a result of loss, duplication, or disruption of the region of the genome in which the genes reside. Often, these events are mediated by deletions or duplications caused by aberrant recombination resulting from closely spaced low copy number repeats flanking the critical region. Points in the DNA that break are more susceptible to breakage because of intrinsic characteristics of the DNA sequence that predispose to abnormal DNA looping at the time of meiosis. The following discussion uses PWS and concerning to demonstrate these mechanisms of nontraditional inheritance.

PWS is characterized by two distinct clinical phases, both of which are seen in essentially all individuals with the disorder. The first phase, marked by profound hypotonia, can be noted prenatally with decreased fetal movement and breech position in the uterus. After birth the infant is profoundly hypotonic, sleeps excessively and has difficulty with feeding and weight gain. There is a global developmental delay, often accompanied by hypoplastic genitalia and cryptorchidism (in boys), strabismus, and evidence of growth hormone deficiency. By the end of 1 yr the feeding difficulty is generally resolved, and behavioral issues are mild.

The second phase typically begins around the age of 2–4 yr. The child is noted to have an apparently insatiable appetite leading to profound obesity if not carefully monitored. There is a typical,

Figure 2-2 Gene map of Prader-Willi syndrome/Angelman syndrome region of chromosome 15. This represents approx 4–5 Mb of chromosome 15 just below the centromere. The common breakpoints of the recurrent deletions are shown. Open circles represent maternally imprinted (expressed only from the paternally inherited chromosome) genes. Gray squares are paternally imprinted genes, and black diamonds represent nonimprinted genes. The open ovals represent clusters of small nucleolar RNAs (SnoRNAs) that have been identified. The function of these RNAs is not known, but they are distributed in intronic regions between the 144 purported exons of SNURF/SNRPN. Arrows show the direction of transcription of genes, with the long, dashed arrow showing the direction and extent of the SNRPN exons. Any of the maternally imprinted genes potentially could contribute to the PWS phenotype, although evidence does not suggest a role for MKRN3 or IPW. The imprinting center is shown as two pieces, with the open rectangle representing the region controlling paternal imprinting (AS), and the filled portion representing the maternal imprint control (PWS) region.

but subtle, facial appearance. There is mild mental retardation or low normal intelligence and a characteristic behavioral profile with temper tantrums, obsessive behaviors, verbal perseveration, skin picking, and a variety of other traits. Management includes avoidance of obesity by careful dietary control and exercise, avoiding exposure to food except at mealtime, use of supplemental growth hormone, and an array of behavioral interventions. Without intervention, the life expectancy is significantly shortened because of complications of obesity such as obstructive sleep apnea, right-sided heart failure, and diabetes.

AS is characterized by more significant mental retardation, severe speech delay or no speech at all, marked gait disturbance with ataxia, and an unusual behavioral profile with a happy demeanor, frequent bursts of laughter for no apparent reason, and rapid escalation of behaviors. There is a characteristic facial appearance, microcephaly, commonly seizures, and there may be a typical EEG pattern.

PWS and AS were delineated clinically in the 1950s and 1960s. In the 1980s, the same recurrent chromosomal deletion was shown to cause both of these disparate clinical syndromes. Further study showed that both result from lack of expression of imprinted genes located near the centromere on the long arm of chromosome 15, but the parental origin of the deletion differed in the two disorders. These two disorders were the first abnormalities resulting from imprinted genes to be recognized in humans. Specifically, at least five different causes of these two disorders have now been delineated, all of which result because genes in the affected region of chromosome 15 are expressed differently when inherited from the mother than when inherited from the father. The known genes in the region are shown in Fig. 2-2, with the sex of the parent in whom the genes are expressed (active) indicated.

Much has been learned about the mechanism by which differential gene expression occurs in imprinted genes. Several genes in the PWS/AS region have an excess of methyl groups attached to cytosine nucleotides. The methylation appears to block the transcriptional machinery from attaching to or acting on these genes, so that no messenger RNA is made from the highly methylated chromosome. Therefore, the only active copies of the genes in this region are those that are unmethylated. This hypermethylation is found in a parent-of-origin-specific distribution. In Fig. 2-2, genes that are hypermethylated (inactive) when inherited from the mother are shown as white circles, whereas those that appear to be inactive when inherited from the father are shown as gray squares. Any structural change that leads to loss or disruption of the active genes will lead to an absence of the gene product. Several of the genes produce a protein product, although little is known about the function of any of these proteins.

PWS is a result of the loss of genes that are only expressed from the paternally inherited chromosome 15. The most common mechanism leading to PWS is a small interstitial deletion on the chromosome 15 inherited from the father. This recurrent deletion accounts for about 70–75% of all cases of PWS, and occurs with a frequency as high as 1 in 20,000 liveborn infants (the overall incidence of PWS, resulting from all causes, is thought to be 1 in 10,000–15,000). The same deletion accounts for a similar proportion of cases of AS, when it occurs on the chromosome 15 inherited from the mother. The common deletion in both disorders has the same breakpoints, in the vast majority of cases, resulting from small duplicated sections of DNA flanking the region, spanning a distance of about 4 Mb. This type of duplication has been referred to as a "duplicon," and a number of similar situations appear throughout the genome. Several have already been identified as causing aberrant recombination leading to recurrence of other microdeletions (e.g., deletion 22q11 syndrome).

A second mechanism leading to an individual having no active copies of these imprinted genes occurs when both copies of chromosome 15 are inherited from the same parent, called "uniparental disomy" (UPD). PWS and AS were among the first

disorders caused by UPD to be described. Now, several other conditions have been shown to have a similar mechanism because UPD for chromosomes containing imprinted genes results in absent expression of the imprinted genes. Other examples include some cases of Beckwith-Wiedemann syndrome resulting from UPD for chromosome 11, transient neonatal diabetes resulting from UPD of chromosome 6, some cases of Silver-Russell syndrome resulting from UPD of chromosome 7, and a mental retardation syndrome resulting from UPD for chromosome 14.

UPD most often occurs as a result of a trisomy present at fertilization. PWS occurs when there are two copies of the maternally inherited chromosome 15 present. Most often this results from malsegregation during female meiosis, leading to conception with two copies of chromosome 15 from the ovum and one copy from the sperm. This is nonviable unless there is a second postmitotic event, usually loss of one of the chromosome 15s resulting from malsegregation during mitosis (called "trisomy rescue"). This often occurs because of anaphase lag, where one chromosome fails to move along with the others as the mitotic spindles separate during cell division, and the chromosome is lost into the cytoplasm of one of the daughter cells. It is apparent that there are two possible outcomes from this event. One is the loss of one of the two chromosomes that came from the same parent, resulting in a cell that is now back to the normal and appropriate chromosomal complement, having one chromosome 15 from the father and one from the mother. Alternatively, the chromosome lost in the trisomy rescue process may be from the parent who only contributed one chromosome. This rescues the trisomy, and allows the pregnancy to continue, but if there are imprinted genes on the involved chromosome they will have abnormal expression. Specifically, as seen in PWS, although there are two copies of each gene on chromosome 15, both are from the mother so there will be no gene expression from the imprinted genes.

The point in meiosis where nondisjunction occurs is another important factor concerning UPD. Meiosis I nondisjunction is a failure of separation of the homologous chromosomes, but the sister chromatids divide normally at meiosis II (Fig. 2-3). This results in two gametes that carry one copy of each original parental chromosome (heterodisomy) and two gametes with no copies of the parental chromosome involved. The alternative is that the nondisjunction occurs in meiosis II, after the homologues have successfully separated. Meiosis II defects result in one gamete with two identical copies of the same chromosome (isodisomy), one gamete with no copy of the chromosome and two normal gametes (Fig. 2-3D). Both types of meiotic errors can lead to a trisomic fertilization that is then rescued by loss of one of the chromosomes. Isodisomy can also occur when a gamete that is missing a chromosome (nullisomic) is involved in fertilization. That fertilization results in a monosomic pregnancy, most of which are not viable, unless a mitotic segregation defect occurs that leads to a duplication of the chromosome in question. This mechanism always leads to isodisomy. In AS, the majority of UPD cases have paternal isodisomy, suggesting that the mitotic mechanism is more common. In PWS, both heterodisomy and isodisomy have been seen, making it difficult to determine the mechanism.

Heterodisomy and isodisomy cause a phenotype if there are imprinted genes in the region. Even when the two copies of the chromosome are different (heterodisomy), both carry the identical imprint (i.e., maternally derived or paternally derived) so that the imprinted genes are not expressed. Isodisomy, on the other hand, can also cause a phenotype because nonimprinted recessive disease-causing genes on the duplicated chromosome will be present on both copies of the chromosome. The very first documented case of UPD was in a child with cystic fibrosis (CF) who was homozygous for the common ΔF508 mutation, a mutation that was only found in one of her parents. She also had short stature. Additional studies demonstrated that both copies of her chromosome 7 were inherited from the parent who carried the CF mutation. This situation has been described for other autosomal-recessive conditions. Furthermore, maternal UPD for chromosome 7 has been shown to be associated with poor growth of prenatal onset, and appears to cause some cases of the primordial dwarfing condition Silver-Russell syndrome.

Several possible evolutionary advantages of imprinting have been put forward. One hypothesis suggests a relative survival advantage to males of being physically large (the idea of the "strapping" boy) weighed against the survival advantage to the female, in this case the mother, of surviving the delivery to reproduce again by having a relatively smaller baby. Supportive evidence for this comes from the fact that pregnancies resulting from duplication of the male genome form a mass of trophoblastic tissue (placentation) with little or no recognizable embryonic tissue, the so-called "hydatidiform mole." Likewise, the parental contribution of the extra set of chromosomes in triploid pregnancies correlates with the clinical findings. Triploidy with the paternal genome duplicated is usually associated with a very small fetus and large placenta, whereas maternal genomic duplication is associated with a small placenta and an early spontaneous miscarriage. Many of the earliest imprinted genes identified were found to be associated with growth, although that generalization has not held up entirely as more imprinted genes have been found. Other hypotheses purporting an evolutionary advantage for imprinted genes suggest a role either in protection from inappropriate timing of expression of certain genes, or a role in protecting mammalian females from malignant trophoblastic disease because of parthenogenic reproduction, so that paternally contributed genes are required for normal placentation. It has been suggested that there are only 100–200 imprinted genes out of the total estimated less than 30,000 genes in the human genome.

The third mechanism for development of PWS and AS, accounting for less than 5% of cases of each, also results from an imprinting abnormality. During the normal process of gamete production, an individual must change the imprinting pattern of chromosomes inherited from their own opposite sex parent. For example, the chromosome 15 that a man inherits from his mother will be maternally imprinted, and the imprinted genes will not be expressed during that man's embryonic development. When he passes on that chromosome 15 to his children he must be able to switch the imprint and turn those genes back on. If this does not happen, his offspring will inherit a normal maternally imprinted chromosome 15 from their mother, and an abnormal maternally imprinted chromosome 15 from their father. In this case, there is biparental inheritance of chromosome 15, but both copies are maternally imprinted. When molecular testing is performed there will be no deletion of chromosome 15, nor will there be molecular evidence, usually identified by microsatellite-polymorphism analysis, of UPD. Specific analysis of the methylation pattern in the PWS/AS region of chromosome 15 will be abnormal, though. This "methylation assay" relies on the use of a methylation-sensitive method of evaluating the region, either by use of a methylation-sensitive restriction enzyme, or by use of a specialized methylation-sensitive polymerase chain reaction protocol. In either test, the result will be production of different-sized DNA fragments from

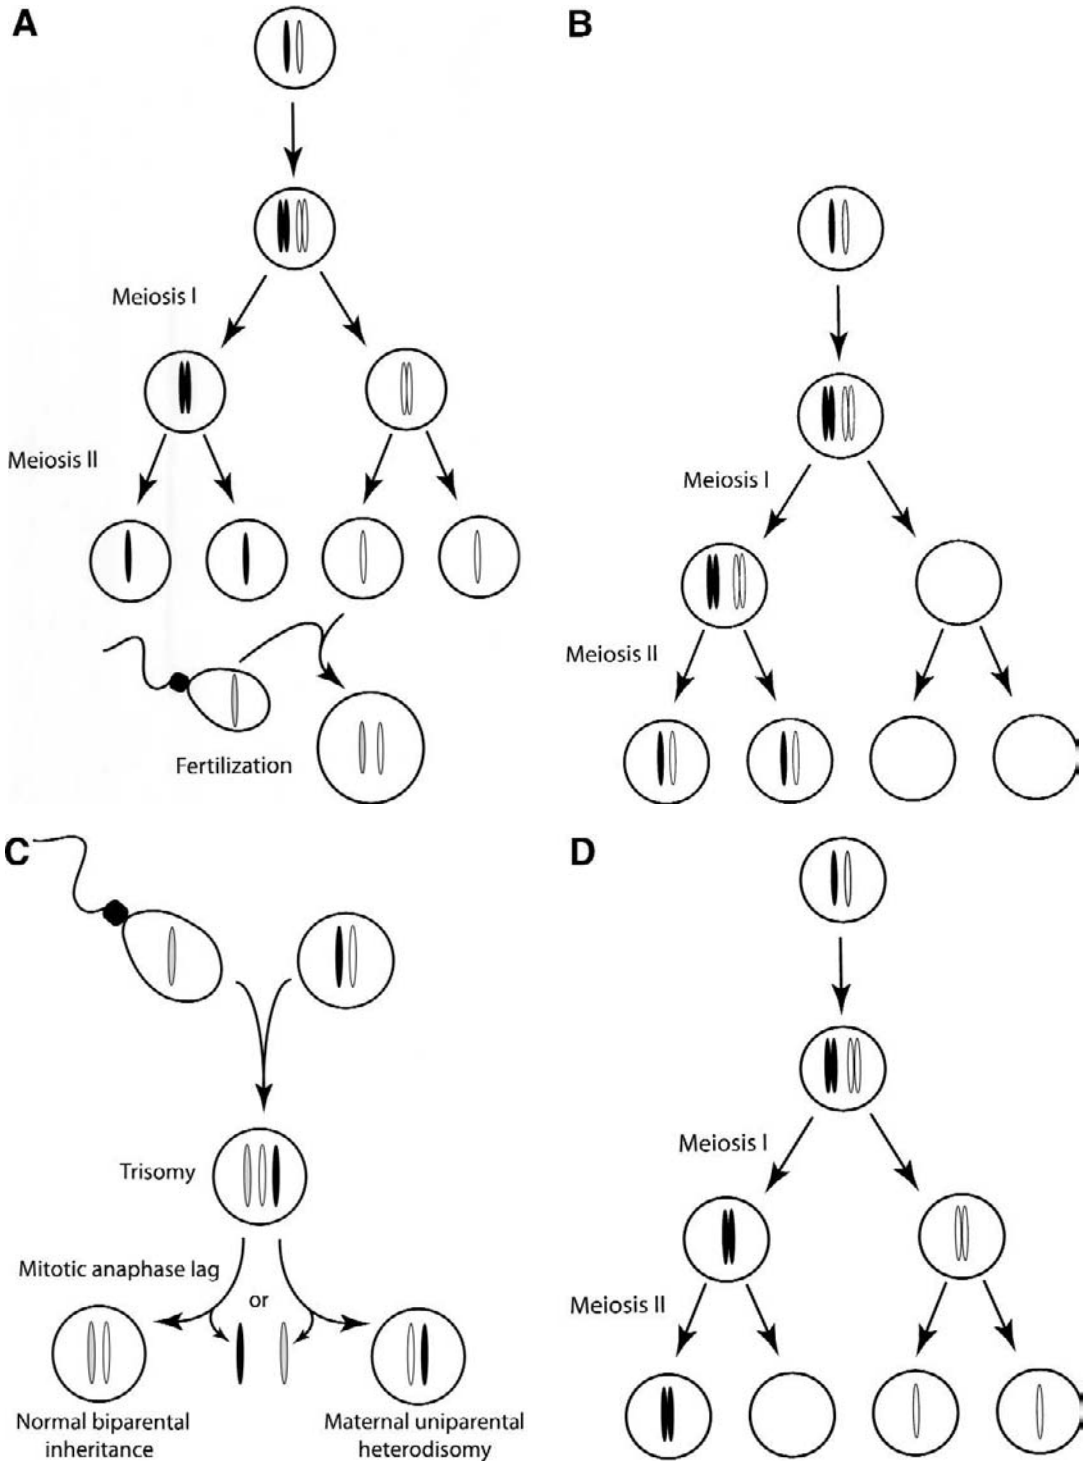

Figure 2-3 ***(Continued)***

maternally and paternally imprinted DNA, demonstrating the presence (or absence) of maternally and paternally imprinted genes. This test will identify all cases of PWS and AS resulting from deletion, UPD, or imprinting defects.

The specific mechanism by which the parent of origin imprint is switched has not been elucidated. The region of chromosome 15 involved, the "imprinting center," has been defined through examination of a series of chromosome rearrangements and progressively smaller deletions. There appear to be distinct, slightly separated, regions responsible for initiating the imprint for the maternally silenced genes and the paternally silenced genes. Unlike deletions and UPD, which occur sporadically, some imprinting defects result from imprinting mutations (mostly very small deletions of sequence around the imprinting center) that may be familial. Imprinting mutations cause a unique situation in which the first individual in a family to acquire the defect will be normal, but half of the chromosomes that they pass on will be abnormal because the imprint will not be properly switched on

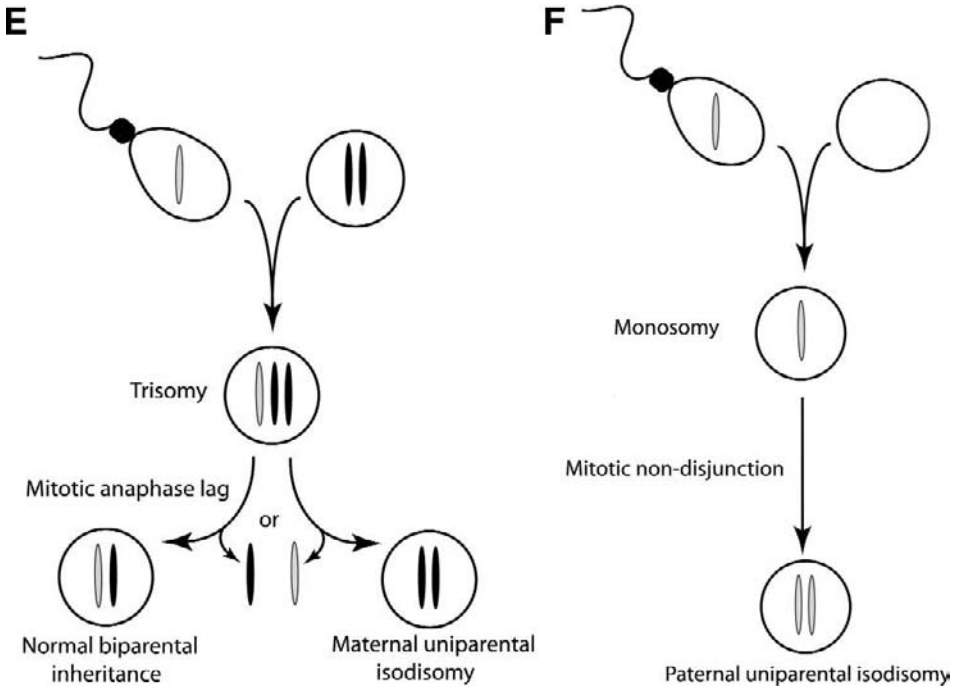

Figure 2-3 Uniparental disomy. This figure follows a single pair of chromosomes through a variety of meiotic and mitotic outcomes to demonstrate how UPD occurs. The chromosomes are shaded differently so that parent of origin for individual chromosomes can be followed easily. All of the meioses are shown in ova, but the process is similar in spermatogenesis. **(A)** Normal female meiotic gametogenesis. After duplication, the homologues separate during the first meiotic division so that each cell contains two identical chromosomes (sister chromatids). During the second meiotic division the sister chromatids separate so that each gamete contains one copy of each chromosome. **(B)** In meiosis I, errors the homologues fail to separate, but the sister chromatids do separate normally during the second meiotic division. Thus there are two potential types of gametes, those that contain one copy of each of the parental chromosomes, and those that contain no copy of the chromosome. The first produces a trisomic fertilization **(C)** that is not viable unless a second error occurs. Mitotic anaphase lag rescues the pregnancy by loss of one of the chromosomes. Depending on which chromosome is lost the result may be either normal biparental inheritance (left side) or uniparental heterodisomy (right side). **(D)** Meiosis II errors occur after the normal separation of the homologues, but with failure of separation of the sister chromatids during the second meiotic division. In this case, there are three potential chromosomal complements for the gametes, isodisomy, nullisomy, and normal. Fertilization of the disomic gamete **(E)** leads to a trisomy that can be rescued by loss of one chromosome. This results either in normal biparental inheritance (left side) or in uniparental isodisomy (right side). Note that in meiosis II errors two of the gametes are normal, whereas in meiosis I defects all of the gametes are abnormal. **(F)** Fertilization of the nullisomic gamete resulting from either type of meiotic error leads to monosomy, which can then be rescued by a mitotic nondisjunction event leading to duplication of the single chromosome. This always results in uniparental isodisomy.

one of their chromosomes. For example, if a woman acquires a new imprinting mutation she will be normal. If that mutation arose on the chromosome 15 that she inherited from her mother, there will be no problem in her offspring because the imprinting pattern does not need to switch. Likewise, each of her daughters who inherit this mutated chromosome will also be fine, as will all of their offspring. However, the son of a mother with a maternally inherited imprinting mutation will be unable to switch the imprint when he passes on that chromosome 15, so that half of his offspring will inherit a maternally imprinted chromosome 15 from their father and will have PWS. This fact makes it important that every child with PWS have the cause thoroughly investigated to rule out this 50% recurrence risk for offspring of the father who carries an imprinting mutation. When analyzing the pedigree of this family it will appear that the trait may skip generations, leading to what has been called a "grandmatrilineal" inheritance pattern for PWS. Similarly, if the original imprinting mutation arises in a male, the eventual result will be females with a 50% risk of having children with AS.

Both PWS and AS have been caused by apparently balanced translocations that either disrupt specific genes, or, more likely, interfere with imprinting in the region. AS can also be caused by mutations in a single gene in the region, UBE3A, possibly accounting for 10% of cases. This gene is unusual in that it appears to be expressed from both alleles in most tissues, but only from the maternal allele in certain regions of the brain. This tissue-specific imprinting pattern is not typical of the genes in the region and the mechanism is poorly understood. It does not appear to be resulting from hypermethylation of CpG islands at the 5′ end of the gene, the most common silencing mechanism for imprinted genes, but may be a result of expression of an antisense transcript of UBE3A. This antisense transcript is in the area of the imprinting region, upstream of UBE3A. It is speculated that on the paternal chromosome the imprinting center allows transcription of the paternally active genes as well as allowing transcription of the paternal copies of the UBE3A antisense region. This antisense transcript, through unknown mechanisms, may interfere with expression of the UBE3A from the same chromosome. The result is that when the imprinting center is "off," the paternally expressed genes are transcribed, as is an antisense transcript that stops expression of UBE3A from that chromosome. Alternatively, when the imprinting center is "on," the maternally expressed genes are

silenced, and the UBE3A antisense transcript is not expressed, thus allowing normal expression of UBE3A from that chromosome.

No mutation in a single gene has been shown to cause PWS, and the abnormal methylation pattern is almost always seen in individuals with typical PWS. This supports the idea that PWS is a true contiguous gene syndrome, meaning that the full phenotype is the result of a combination of effects from several genes that are not properly expressed. There is also support for this idea from the various mouse models of PWS as well, none of which fully recapitulate the complete PWS phenotype.

The recurrent nature of the common deletion in PWS and AS is a result of the genomic structure around the region, which is flanked by highly homologous stretches of DNA that predispose to aberrant recombination and deletion or duplication. Such areas can be found throughout the genome, and are thought to explain several recurrent deletion syndromes. It is important to note that one or more of the genes included in the deleted region must be dosage sensitive, so that the loss of a single copy can lead to disease. Developmental abnormalities resulting from this phenomenon of genomic architecture leading directly to a mechanism of disease that does not involve a traditional type of mutation, or traditional inheritance, have been called "genomic disorders." There are other examples of genomic disorders. Smith–Magenis syndrome, a recognizable mental retardation syndrome, is caused by a recurrent microdeletion on chromosome 17p11.2. Charcot-Marie-Tooth disease type 1A results from a recurrent duplication nearby on 17p11.2, involving the peripheral myelin protein 22 gene, which, when deleted instead of duplicated, causes a different disorder, a hereditary neuropathy with liability to pressure palsy. These genomic rearrangements, once they occur, segregate following Mendelian principles, as can be seen with Charcot-Marie-Tooth, long known to be inherited in an autosomal-dominant fashion. There is some evidence that this particular aspect of genomic architecture, whereas in some instances predisposing to genomic disorders, is actually part of the process of primate evolution, as some of these regions appear to be associated with new genes developing as part of gene families resulting from genomic duplication.

MITOCHONDRIAL INHERITANCE

The idea of nontraditional inheritance developed in response to contradictions between Mendel's laws and observed biological facts and was initially used to describe imprinting defects. The concept, though, can be further extended to include a variety of other interesting phenomena that lead to situations in which inheritance is not easily explained by Mendel's laws. A well-recognized example of this is the condition of mitochondrial inheritance, which appears in a matrilineal pattern. This means that the disorder can be seen in males or females, but can only be transmitted from an affected female to her children. Affected males do not transmit the disorder (although this, like most biological "rules" has not been shown to be 100% true). The cause of this inheritance pattern is now well understood, because the mitochondria contain their own small genome. Mitochondrial DNA (mtDNA) is a small, circular DNA containing only 16,569 bp, encoding 13 proteins, each of which is a part of one of the subunits of the mitochondrial electron transport chain. The mitochondrial genome also encodes a unique set of transfer RNAs (tRNAs), as well as two ribosomal RNAs. Mutations throughout the intronless genes on the mtDNA can cause disease, all of which are manifest by disturbances in energy metabolism, as would be expected by the roles of the known proteins.

During the process of gametogenesis the ovum accumulates a large number of mitochondria, each of which contains multiple copies of the mitochondrial genome. The nucleotide sequence of these mitochondrial genomes is not identical, so that in any particular ovum there may be a variety of mutations, none of which are present in every copy of the mtDNA. The sperm compartmentalizes its mitochondria to the motor unit of the tail, so that none of the mitochondria are delivered into the fertilized egg. Therefore, the mother, explaining the matrilineal inheritance pattern, supplies all of the mitochondria in the fertilized egg.

Another hallmark of mtDNA diseases is that there can be tremendous clinical variation. Different mutations may predispose to different phenotypes, but even with the same mutation the phenotype may vary. One of the reasons for this becomes clear from the fact that multiple different copies of the mtDNA exist in each egg. After fertilization, mitochondria, and their mtDNA component, replicate and segregate during cell division. In this way, different developing tissues may acquire different complements of mtDNA mutations, and, depending on the effect of the mutation and the energy requirements of the tissue in question, there may be selection for one mtDNA genome over another, leading to accumulation or loss of a particular mutation in a particular tissue type. This variation of mitochondrial complement in different tissues is referred to as heteroplasmy.

MELAS, or mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes, is a recurrent mtDNA phenotype most often resulting from a point mutation in the mitochondrial leucine tRNA (nucleotide 3243). There is often an accumulation of mutant mtDNA in successive generations, leading to increased severity with earlier onset in the younger generations. Affected individuals may present with poor growth, lactic acidosis, seizures and ataxia, severe headaches, recurrent strokes or stroke-like episodes, cortical blindness, or muscle weakness. The symptoms tend to progress, with death resulting from respiratory complications, infections, or bowel obstruction. Affected individuals may be identified across many generations and branches of the family, always inherited through females.

Kearn-Sayre syndrome is a progressive disorder consisting of peripheral weakness, pigmentary retinopathy, progressive external ophthalmoplegia (because of weakness of the extraocular muscles), heart block or cardiomyopathy, and, occasionally, diabetes mellitus. Most cases of Kearn-Sayre are associated with large deletions of the mitochondrial genome, but some cases have been reported with point mutations in the same leucine tRNA associated with MELAS. The fact that two distinct phenotypes may result from defects in the same tRNA may be a result of tissue heteroplasmy, but it also points to the difficulty in predicting phenotype from genotype in mitochondrial diseases.

Many other phenotypes have been described with mtDNA mutations, some more predictable than others, but it is important for the clinician to remember that defects of the oxidative phosphorylation process may produce almost any symptom in almost any tissue at almost any time of life. Also, although this section discusses defects resulting from mtDNA changes, many more nuclear-encoded genes are involved in the production of electron transport protein subunits and the formation and maintenance of the mitochondrial membranes, transporters and oxidative phosphorylation complexes, defects of which are most often inherited as traditional autosomal-recessive traits.

MULTI-ALLELIC INHERITANCE

In the later 19th and early 20th century, as Mendel's ideas about the independent segregation of traits were being re-evaluated, it was understood that some traits were clearly not the result of single genes. Sir Francis Galton established that height was a trait that could not be explained by Mendelian arguments, and Ronald A. Fisher, a statistician, later showed how multiple genes, each contributing more or less to the final outcome, could explain Galton's findings on height and other quantitative traits. The concept of polygenic inheritance followed, and along with that the idea that genetic factors may interact with environmental factors to produce a trait in a multifactorial way. Multifactorial inheritance, then, can be invoked to mathematically model empirically observed incidences of a variety of traits, and the concept is now fully accepted in genetic thinking and counseling. This multifactorial model requires several assumptions, including that the genes involved all contribute something to the phenotype, without being dominant or recessive, and that they act together in an additive fashion. The number of genes and environmental factors involved in a multifactorial trait is not infinite, and may vary from just a few to a great many (as has been suggested for the development of hypertension).

Findings now point to a form of nontraditional inheritance that is neither fully Mendelian nor fully multifactorial. Three specific examples are digenic inheritance, synergistic heterozygosity, and triallelic inheritance. None of these are completely unique and independent concepts, but all serve to illustrate the complexity of genetic and biological interactions. Retinitis pigmentosa (RP) is a genetically heterogeneous condition of progressive vision loss because of degeneration of the retina associated with increased retinal pigment deposition. It can be isolated or associated with a variety of genetic syndromes, and at least 26 loci have been described in the genome that cause isolated RP, some as X-linked, others as autosomal-dominant and -recessive traits. All of them, though, result from mutations in a single gene. A unique inheritance pattern was identified when a form of RP was found in several different families because of the combination of heterozygosity for mutations in two different genes, ROM1 and RDS. Homozygosity for mutations in the RDS gene can also cause RP, but heterozygosity for a mutation in either, by itself, does not. This finding, that heterozygosity at two different unlinked loci is a requirement for the development of the phenotype, represents a newly recognized form of inheritance that is neither Mendelian nor multifactorial, but is instead digenic. Specifically, it cannot be said to be multifactorial or polygenic inheritance because it is not an additive effect of the two genes, but a synergistic effect. Similar findings have now been shown for several conditions, including one form of hereditary deafness, some cases of Hirschsprung disease, and severe insulin resistance. It is interesting to note, though, that pedigree analysis of affected families might be suggestive of autosomal-recessive inheritance, because the recurrence risk for the parents of an affected child would be 25% with each pregnancy.

In some cases digenic inheritance could result from mutations in two genes that interact in a developmental pathway, or that both contribute to the same developmental pathway although they may not physically interact with each other. An analogous situation has been described in several individuals presenting with metabolic myopathies. Investigation into the usual causes of disruption in fatty acid oxidation or electron transport pathways led to the observation that in some cases, heterozygosity for mutations in two different genes involved in cellular energy metabolism may cause myopathy. Specific genes involved include those for carnitine palmitoyl transferase II, very long chain acyl-CoA dehydrogenase gene, and some of the nuclear-encoded subunits of the electron transport chain. Each, by itself, will be considered a recessive allele, not expected to cause disease if the other partner of the gene pair were normal. It appears that in the heterozygous state the reduction in flux through a particular pathway may be tolerated, but if there is a mild (heterozygous) defect in a different part of the same pathway, the sum of the reductions in flux through the pathway may lead to insufficiency of energy production during periods of metabolic stress. This condition has been referred to as synergistic heterozygosity, but the parallel to digenic inheritance is obvious.

Although both of these forms of inheritance would lead to Mendelian (recessive) proportions of affected individuals on pedigree analysis, triallelic inheritance would not. This fascinating example of nontraditional inheritance has been described in an isolated population with a high rate of an unusual disorder called Bardet-Biedl syndrome (BBS). Individuals with BBS present with pigmentary retinal dystrophy, polydactyly, obesity, reduced cognitive function, and renal abnormalities. There is genetic heterogeneity for the disorder, with eight loci having been identified. In studying several families it was found that some affected individuals were homozygous for mutations in a previously identified BBS gene, whereas there were unaffected family members that were also homozygous for the same mutations. Further investigation revealed that the difference between the affected and the unaffected individuals was that those affected also had heterozygous mutations of another gene known to be associated with BBS. Therefore, in this population, homozygosity for mutation in the first locus was not sufficient to cause the phenotype, but required a third abnormal allele in a different gene, thus triallelic inheritance. There are different ways to interpret these findings, and debate continues whether these may really represent modifier effects; nonetheless, the complexity of inheritance is much greater than was previously imagined.

Similar arguments could be made for some complex traits. A good example is in the risk of blood clotting resulting from inherited thrombophilia. This is one area in which genetic dissection of a complex, multifactorial trait has led to the recognition of a variety of more or less common genetic factors predisposing to thrombosis. The identification of certain of these factors, including the Leiden mutation in the gene for clotting factor V and the prothrombin 20210G > A mutation, along with certain environmental factors, such as cigaret use and oral contraceptive use, allows, at least partially, for the determination of broad categories of risk of abnormal thrombosis and of the relative contribution of individual factors to that risk.

New technologies for exploring the human genome, the Human Genome Project, and the dedicated work of thousands of researchers are beginning to unravel the complexities of human inheritance in ways that could not have been imagined by Mendel, Galton, or other pioneers of genetics. This chapter has reviewed some of the complexities of non-Mendelian, nontraditional inheritance and discussed new ways of understanding old paradoxes. It is likely that more complexities will be discovered, giving new insight into genetic disorders both rare and common, and informing new therapeutic approaches. At the least, it seems likely that these new genetic findings will lead to more personalized medical

information and risk assessments. The immediate impact, unfortunately, is to make the job of the physician much more complicated. Patient demands for genetic information will make it impossible to ignore these advances, so physicians need to find tools and resources to keep up to date, and to find approaches to share this information with patients in ways that will be beneficial without raising inappropriate expectations or fears.

3 Identifying Causal Genetic Factors

Christopher I. Amos, John S. Witte, and William G. Newman

SUMMARY

The study of a complex disease requires careful characterization of the clinical phenotypes for study. Linkage studies, which can detect relative risks of four or greater, apply stringent diagnostic criteria and restrictive rules for family selection to assure a maximally informative collection of subjects. Clinical characterizations that are adopted for association studies must be precise and should be widely accepted to facilitate large studies. The presence of linkage disequilibrium among tightly linked loci provides a basis for genome-wide association studies. A subset of "tagging" markers that maximally characterize interindividual variability can be sought to minimize genotyping costs. Association studies can detect lower relative risks than linkage methods provided there are a limited number of causal variants at each locus and linkage disequilibrium is present (or one directly studies the causal variant). For some complex diseases there may be multiple disease variants and only moderate risks from any single locus. For these complex diseases alternative strategies using comparative genomics and animal models may be required. Admixture linkage mapping may also permit the study of larger collections of patients than is feasible using traditional linkage methods. Finally, once causal loci are identified, further genotype–phenotype studies will allow the disease to be further delineated. Such studies may also identify subsets of patients with varying responsiveness to treatments.

Key Words: Association; comparative genomics; disequilibrium; genetic linkage; genotype–phenotype correlations; linkage haplotypes.

INTRODUCTION

Identifying genetic factors that increase an individual's risk of disease is a major goal of genetic epidemiology. In this chapter, we provide an overview of the primary approaches that use information from families and individuals to discover disease-causing genes. For illustrative purposes, the chapter integrates examples from studies that are successfully deciphering the complex etiology of inflammatory bowel disease (IBD), identifying genetic factors, and providing potential new targets for therapy. The chapter concludes with a summary of clinical observations relevant to the findings from these studies of IBD. We have decided to use the success in understanding the complex etiology of IBD as an example for which genetic studies have been particularly successful, both in identifying genetic factors as well as in providing potential new targets for therapy. We integrate examples from the study of IBD throughout the chapter and then provide a few clinical observations relevant to the findings from these studies as a summary to the chapter.

A common disease has been defined as affecting 1 or more individuals per 1000 population. A number of factors may suggest that a common disease (or related clinical traits) is inherited. Clustering of affected individuals within families often provides the initial evidence of an inherited susceptibility to disease. Such findings can be supported by studies of twins; greater disease concordance between monozygotic (identical) compared with dizygotic (nonidentical) twins suggests a genetic susceptibility as it presumes similar environmental exposures among twins. Further evidence of genetic predisposition to common disease may be indicated by studies of migrant populations who retain the level of risk for a particular disease from their area of origin rather than that of the indigenous population. Higher prevalence levels of the disease in specific ethnic populations may be accounted for by a genetic variant in an ancestor (founder effect). Occasionally, common diseases can occur as manifestations of rare single gene disorders. However, further analysis often identifies minor differences between these rare, segregating forms of common disease, and the more prevalent form. For example, segregation of mutations in BRCA1 predispose to breast cancer, but the onset is usually early and there are often distinct pathological changes that can identify cancers arising in individuals with BRCA1 mutations from those with sporadic breast cancers.

IBD is an excellent paradigm for a common disease with a significant heritable component. IBD encompasses two major inflammatory diseases of the bowel, Crohn's disease (CD, MIM 266600) and ulcerative colitis (UC, MIM 191390). The heritable nature of IBD was first described over 40 yr ago by Kirsner who noted that individuals with CD and UC were more likely to have relatives affected by these diseases compared to unaffected individuals. Such familial clustering in itself does not provide conclusive evidence for the genetic basis of a disease. However, studies of disease concordance in twins revealed that both CD and UC are present more commonly in both members of monozygotic compared with dizygotic twins. Additional evidence emerged from Asian migrants to the United Kingdom who maintained a lower level of CD risk than the indigenous population. Finally, a higher prevalence of IBD has been reported in the Ashkenazi Jewish population and IBD is a

characteristic feature of rare single gene disorders including Wiskott-Aldrich and Hermansky-Pudlak syndromes.

DEFINING THE PHENOTYPE

CLINICAL CLASSIFICATION In order to identify genetic loci predisposing for disease, studies often adopt stringent criteria for designating an individual as affected. These strict criteria are used in family studies because affected individuals provide the most information about their underlying genotype, especially when studying infrequent diseases for which the penetrance, or probability to be affected given that one has inherited a risk-increasing genotype, is decreased. Often in family studies we are interested in tracking the inheritance of disease susceptibility, and the underlying genotypes can be most effectively deduced from the affected individuals. We use strict criteria in the initial family studies to avoid misclassification of genotypes. Once genetic loci influencing disease susceptibility are identified, then interest turns to evaluating the impact that disease-increasing genotypes have on the broader spectrum of disease. Figure 3-1 displays designs for identifying genetic factors influencing risk for complex diseases. As shown, for diseases in which the risk conferred by a single factor is high (i.e., exceeding a fourfold increased risk), linkage studies are highly effective for disease localization. However, if the risk associated with a mutation is lower, then alternate strategies employing association-based approaches are more likely to be successful.

Precise diagnostic classification of phenotypes is vital to maximize one's ability to identify causal genetic variants. IBD illustrates the importance of collecting complete clinical data. Individuals with CD are 30 times more likely to have a sibling affected with CD and 16 times more likely to have a sibling with UC than a healthy individual. Patients with UC have similarly raised familial risks. This suggests that there are genes that increase the risk of CD and UC specifically and IBD generally. Genetic studies to date in IBD have supported this suggestion (Table 3-1). To dissect these different genes precise classification of CD and UC is imperative. Individuals with IBD can generally be defined as having CD or UC based on endoscopic, histological, and/or radiological criteria. However, in about 10% of patients a differentiation is not apparent and the term indeterminate colitis is applied. International diagnostic guidelines such as the Vienna Classification for the diagnosis of CD can aid consistency among studies.

Table 3-1
Chromosomal Loci Containing Potential or Confirmed Susceptibility Genes for CD, UC, or Both (IBD), as Identified by Genome-Wide Scans or Subsequent Association Studies

	Chromosome locus	*Gene identified*	*Association with CD, UC, or IBD*
IBD1	16q13	CARD15	CD
IBD2	12q14	–	UC
IBD3	6p	–	CD
IBD4	14q11–q12	–	CD
IBD5	5q31–33	OCTN cluster variants	CD
IBD6	19p13	–	IBD
IBD7	1p36	–	IBD
IBD8	16p12	–	CD
IBD9	3p26	–	IBD
	3p21	–	IBD
	10q23	DLG5	IBD
	Xq21.3	–	IBD

Phenotypic expression of common diseases as well as susceptibility may also be inherited. These clinical characteristics may be influenced by disease susceptibility genes or by disease modifier genes, which do not alter risk of the disease itself just the expression. In IBD, epidemiological studies have demonstrated that a number of clinical characteristics may be inherited, including early age of disease onset, disease involving a specific part of the bowel, and more severe disease. Therefore, clinical and demographic data including ethnicity, gender, age of disease onset, and disease severity should all be collected. Ethnicity data are particularly important to ensure that the frequency of a particular genotype in affected individuals is matched to that in an appropriate control population. This is evidenced by variants in the CARD15 gene that have been associated with CD in North American and European but not Japanese populations. In addition, some of the extraintestinal manifestations of IBD including psoriasis and ankylosing spondylitis have a significant heritable component. Genotype–phenotype correlations for mutations in CARD15 have shown associations with the site of bowel disease and earlier age at disease onset among CD patients and with psoriatic arthropathy.

QUANTITATIVE PHENOTYPES An alternative to employing stringent criteria for identifying those families most likely to be segregating a simple cause for a genetic disease is to seek phenotypes that are correlated with the disease of interest but which show a more clear genetic component. For example, in the study of cardiovascular disease, identifying genetic causes of myocardial infarction is difficult, although identifying genetic factors influencing low- and high-density lipoprotein cholesterol levels has been more straightforward. Myocardial infarction as an end point is hard to study because it is caused by many different factors. Aberrant cholesterol levels can be strong risk factors for myocardial infarction, and the genetic causes influencing cholesterol levels are simpler to identify than the many factors influencing myocardial infarction as an endpoint. In addition, because cholesterol levels are measured and variable among subjects, each individual provides more statistical information than is provided by the dichotomous information provided by presence or absence of myocardial infarction. The simpler genetic causation influencing cholesterol levels is indicated by the higher heritability (i.e.,

increased similarity among closely related individuals) of these traits compared with myocardial infarction as an end point. However, heritability alone does not necessarily indicate that a trait has a genetically simple architecture because even traits that are highly heritable can be influenced by multiple genetic factors. In addition to having high heritability, traits that are known from biological studies to have biochemically or physiologically simple causes would be good candidates for genetic studies.

Although quantitative traits can provide more information than dichotomous traits, there are often sampling advantages in studying discrete traits. Individuals who have a disease may become "affected" because they are extreme for an underlying quantitative trait. Identifying individuals with a disease may provide a mechanism for identifying individuals who are extreme for an underlying quantitative phenotype. Families that include some individuals with extreme values may provide the most information in a linkage study because there are underlying genetic variants increasing the trait levels of these subjects.

GENETIC LINKAGE ANALYSIS Genetic linkage analysis has been an extremely powerful tool for identifying specific genetic factors for diseases. Linkage analysis has typically been applied for identifying novel genetic factors, by using a genome-wide analysis of the coinheritance of disease with genetic markers. Evidence in favor of linkage is typically expressed by the LOD score which is the $\log_{10}$ ratio of the likelihood of the data assuming linkage between a modeled disease susceptibility locus and a genetic marker to the likelihood of the data assuming no linkage of the disease susceptibility and genetic marker. To allow for the large number of tests that are indicated in a genome-wide analysis, several testing paradigms have been developed. If a Bayesian approach is adopted then a LOD score of about 3 leads to a 5% posterior probability of linkage assuming the existence of a single disease locus, even when many markers are genotyped over the entire genome. Morton developed an approach for sequentially combining data from multiple studies by adding LOD scores across studies that has been highly effective. From Bayesian and sequential analytical approaches, a LOD score of 3.0 was proposed as providing a meaningful critical value for declaring strong evidence for linkage. More recently, approaches to control the overall significance of genetic studies when studying multiple markers have been adopted. These criteria have been criticized for being excessively conservative particularly when candidate regions are of primary interest, for example, when prior studies indicated evidence for linkage to an area. The significance testing paradigm requires the slightly higher LOD score of 3.3 to declare that a significant result has been obtained while providing a genome-wide significance of 5%.

If a simple genetic mechanism explains inheritance of disease, then a genetic model can be specified and tested for coinheritance of disease susceptibility with genetic markers. In order for linkage studies to be informative, the families chosen for study must be able to show inheritance of a genetic factor. For uncommon diseases for which the penetrance is reduced, the affected individuals provide the majority of information about the segregation or inheritance of genetic mutations predisposing to disease. For quantitative traits, sampling through individuals with extreme phenotypes can increase the probability of sampling a genetic variant influencing the trait of interest. Sampling through extreme individuals is an effective strategy for increasing the power of a linkage study, but may only be practical if the quantitative phenotype can be assayed inexpensively. Some studies of quantitative phenotypes study many phenotypes. Sampling through extreme individuals only increases power for a single or a few correlated phenotypes.

Currently available microsatellite-based mapping platforms usually study the genome at approx 10-cM intervals, and investigators usually follow-up positive signals with denser maps. Evidence for genetic linkage in a region would often be followed by finer scale mapping to (1) improve the information for detecting linkage and to identify any recombinant individuals, and (2) using much finer maps, to search for associations between the disease or trait and particular marker alleles. Standard finer mapping panels for microsatellites provide a 5-cM interval spacing, and microsatellite sequences and technologies for approx 0.2-cM interval mapping are routinely available from DeCode genetics (www.decodegenetics.com) or by custom request for even finer mapping (e.g., by request to Invitrogen genetics). Routine genotyping platforms for the purposes of genetic linkage analysis are available from Affymetrix and Illumina and provide results from genotyping of about 11,000 and 6000 genome-wide single-nucleotide polymorphisms (SNPs), respectively. These much finer mapping panels can improve the power to detect linkages and may provide narrower intervals for positional cloning.

A wide range of genetic linkage methods is available. The diversity of methods reflects, in part, the considerable success that linkage methods have had in identifying genetic causes of disease, and the consequent value and interest in using the methods by the scientific community. Computing statistics over a large number of genetic markers in families for diseases that do not show simple inheritance patterns is computationally demanding and there are three basic approaches that are taken for the analysis of the genetic marker data. The Elston–Stewart algorithm resummarizes information about haplotypes (the set of alleles on a chromosome) sequentially in a pedigree and is, therefore, efficient for statistical analysis of large families, but limited in the number of markers that can be jointly modeled; usually fewer than five markers can be considered jointly. The Lander-Green-Kruglyak (LGK) method adopts a different approach that facilitates the analysis of multiple markers. The LGK model first identifies the possible inheritance patterns of genotypes within families and stores this information as inheritance vectors. Because the number of inheritance vectors increases rapidly according to the number of individuals in a family, this approach is only suitable for small- or medium-sized families, usually allowing at most 25 individuals in a family to be studied. In addition, because the method stores all possible inheritance vectors in memory, the approach requires considerable RAM to be efficient. The major advantage of the LGK approach is that computational speed increases only linearly in the number of markers so that it is highly efficient for genome-wide analyses.

Analyses including many markers on large pedigrees or analyses of pedigrees that include more than a few inbred individuals may not be effectively performed using the Elston–Stewart of LGK algorithms. In this case, Monte-Carlo Markov Chain (MCMC) algorithms are used to approximate the likelihood of the data. MCMC methods provide tools for sampling the haplotype configurations in data. The MCMC procedure samples possible haplotypes according to the underlying probability distribution that generated the data and provides an accurate approximation to the likelihood. A major advantage of MCMC procedures is a decreased need for memory, because they do not require summing over all possible genotypes as in the Elston–Stewart algorithm, or over all possible inheritance vectors as in the LGK. One disadvantage may include the complexity in storing output from analysis, because

results from large numbers of realizations from the sampling of genotype configurations are often stored. MCMC methods infer the genotypes for all individuals that are specified as a part of the analytical file. Individuals with known genotypes have a limited number of potential haplotypes, but individuals who have not been genotyped can have a large number of potential genotypes and haplotypes. The probability distribution from which MCMC methods must sample can become quite large if many individuals who have not been genotyped are included in the analytical file. Therefore, it is often beneficial to remove the ungenotyped individuals from MCMC analyses, particularly those who are not affected, because they contribute little in most linkage analyses.

An issue in performing genetic analysis is whether to use model-dependent or model-free methods for linkage analysis. Model-dependent methods have higher power for linkage analysis if an approximately valid genetic model can be specified to describe the manner in which disease susceptibility at a given locus is expressed. One approach for estimating penetrance to be used in a linkage study is to first perform a segregation analysis of families that have been ascertained according to a specified sampling scheme. The approach estimates parameters for models describing the inheritance of genetic and environmental factors that most closely fit the dependence in family data. For uncommon conditions, random sampling of families would not result in an informative family, and a sampling scheme is usually followed in which relatives of cases with a disease are preferentially sampled. When the families are not randomly sampled, an ascertainment correction for nonrandom sampling is required in order to obtain parameter estimates that reflect the more general population of families. In order to correct for the nonrandom sampling approach that is typically used, a clearly defined sampling scheme must typically be followed. Using only a binary phenotype (e.g., affection or nonaffection) one may not be able to estimate all the parameters that are necessary to describe the penetrance of the genotypes of the loci influencing disease susceptibility, unless restrictive assumptions about the interactions among the loci are made.

Sampling families and collecting information for segregation analysis can be an arduous task and may not be fully informative about the parameters that describe the penetrance and disease allele frequencies. Therefore, investigators studying complex diseases may postulate genetic models from assumptions about the relative risks for disease that are observed from epidemiological studies. It has been shown that postulating an inaccurate genetic model for genetic linkage studies does not lead to false-positive results, in a model-based linkage study. However, if multiple models are tested, then there can be an inflation in the overall number of false-positive results from linkage studies because of the inherent multiple testing problem that is so introduced. A powerful approach for studying complex diseases is to evaluate the evidence for linkage assuming simple recessive and dominant models of disease and then to adjust the required critical value for the LOD score upward by about 0.3 for the small multiple testing problem so engendered.

If the genetic model influencing disease susceptibility cannot be inferred with any confidence, either because the genetic model appears too complex or because there is a lack of epidemiological data from which to postulate penetrance, then model-free methods are typically adopted. One approach is to set the penetrance to an artificially low level, thus restricting analysis to include only the affected subjects: with very low penetrance, unaffected individuals provide no information about their possible genotypes and so do not contribute in the linkage analysis, but this approach still makes some modeling assumptions about disease expression. An alternative approach is to evaluate the similarity in alleles that have been inherited by common parentage (identity by descent) and test whether or not there is evidence that affected relatives share more alleles than expected identical by descent. In some cases this approach may provide a more powerful test for linkage than a model-dependent approach, particularly when multiple independent loci additively increase disease risk. Because pedigrees are usually variable in size and contain different numbers of affected relatives, a variety of different tests have been proposed and are available for testing for linkage. These tests are optimal for varying disease penetrances (which are typically unknown). As a compromise, the pairs statistic, which includes all affected relatives in a pedigree and gives only moderately higher weight to families that include multiple affected relatives is often used.

The joint analysis of covariates along with genetic markers in family studies usually has limited utility. Typically collecting covariate information in families is difficult because data cannot be directly collected from deceased or otherwise unavailable individuals. In addition, the genetic risks that are sought in linkage analyses are often large. Some nongenetic factors such as smoking and reproductive behaviors can be reliably collected through proxies (when needed) are inexpensive to collect and may have a strong effect on risk for some diseases.

One of the first major investigations to identify genes/chromosomal loci for a common disease was performed by John Todd's group at Oxford University in 1994 in families with type 1 diabetes mellitus. Siblings have a 50% chance of inheriting the same allele from a parent. A wide range of statistical methods have been developed to identify regions showing excess sharing of inherited alleles in relatives. This theory has provided the basis for numerous further investigations in a range of common diseases where panels of evenly spaced microsatellite markers are used in genome-wide linkage studies. In IBD there has been consistency between linkage study results with replication of six loci (Table 3-1).

For complex diseases, a large number of families may be needed to obtain adequate power to detect linkages. Meta-analysis combining multiple studies can assist in overcoming power limitations from a single study. However, in order for meaningful results to be obtained in meta-analysis, investigators must be studying comparable classifications of the same disease. Coordination of studies becomes necessary for the study of complex diseases.

Genetic linkage analyses of IBD have identified numerous genomic regions harboring susceptibility factors. Because of the apparent genetic complexity of these diseases, simple Mendelian models have typically not been applied. Instead, model-free methods using primarily nuclear families have been the preferred method for identifying genetic factors. Genetic linkage analysis followed by positional cloning has been effective in identifying CARD15 and OCTN1/OCTN2 causal mutations for CD. The identification of CARD15 mutations as causal resulted when genetic linkage analysis indicated the chromosome 16q region as likely to contain a genetic susceptibility factor. The CARD15 locus had previously been identified by homology to a similar locus in mice and it was an excellent candidate locus for IBD because mice homozygous for CARD15 deletions showed an IBD-like phenotype. In contrast, genetic linkage analysis identified a region of chromosome 5 encompassing the cytokine cluster on 5q. Haplotype studies, discussed below showed that a single extended haplotype was often present in CD patients. However, causal variants in OCTN1

and OCTN2 were only found after extensive sequencing of all the genes in an extended region.

ASSOCIATION STUDIES Although parametric and nonparametric linkage analysis approaches have proved successful for mapping many disease and trait genes, in some gene mapping investigations, the limited number of meioses occurring within pedigrees limit one's ability to detect by linkage the recombination events between closely spaced (~ <1 cM) loci. One might instead map more closely spaced disease genes by using association studies. These studies generally have a case–control design, where cases are recruited from a disease registry or hospital-based populations. Controls can range from the cases' family members (e.g., parents or siblings) or unrelated individuals. Genetic variants observed in cases are contrasted with those observed among controls to determine an "association" exists between genes and disease.

Association studies may allow one to get closer to the disease-causing gene than allowed by linkage studies (i.e., more recombinant events over evolutionary time). This type of study can also be used to look directly at genetic variants in known candidate genes. That is, association studies can be used either in an "indirect" manner as a tool for mapping genes using linkage disequilibrium or in a "direct" manner for evaluating associations with postulated causal ("candidate") genes.

The growing use of association studies is driven in part by how quickly and easily they can be undertaken, and the availability of high-density SNP genotyping technology. The SNP consortium (http://snp.cshl.org) has provided sequences for 1.8 million SNPs, and at least 250,000 of these have been verified as polymorphic by Perlegen (alone), whereas polymorphisms in hundreds of thousands of additional SNPs have also been verified by the SNP consortium, Applera, and by many investigators and companies.

LINKAGE DISEQUILIBRIUM AND HAPLOTYPES The genetic variants that cause disease arise through, for example, novel mutations or immigration of mutation carriers into a population. When a mutation initially arises, it has a particular chromosomal location and specific neighboring marker alleles. At this incipient point in time, the mutation is completely associated with the adjacent alleles: it is only observed when the marker alleles are also present. Marker alleles that were in the neighborhood of the disease gene when its mutation was introduced into the population will generally remain associated over numerous generations (i.e., in linkage disequilibrium). If specific marker allele frequencies are higher among cases vs controls, this suggests linkage disequilibrium between the corresponding loci and a disease gene. The extent of this disequilibrium depends on the number of subsequent generations because the mutation was introduced into the population, the recombination between the disease and marker alleles, mutation rates, and selective values.

Alleles in linkage disequilibrium may be parts of haplotypes, and recent work indicates that there may exist discrete chromosomal regions with low haplotype diversity, termed "haplotype blocks," which are separated by recombination hotspots. Information from some polymorphisms within each block may be redundant; in other words, having information on one SNP provides all the information about another if they are in strong linkage disequilibrium. The majority of the haplotypes within a block can thus be distinguished using a much smaller number of SNPs, known as "haplotype tagging" SNPs or htSNPs (Fig. 3-2). Using such SNPs can drastically reduce the effort required to undertake large-scale association studies. Instead of saturating an entire chromosomal region with genotypes in all study samples, an investigator can first screen for SNPs within a subsample of study subjects to determine the htSNPs. Then only these tagging SNPs (and possibly other promising SNPs) can be genotyped in the entire study population. Several approaches have been suggested for identifying optimal htSNPs. These include simple visual inspection of haplotypes and analytic approaches.

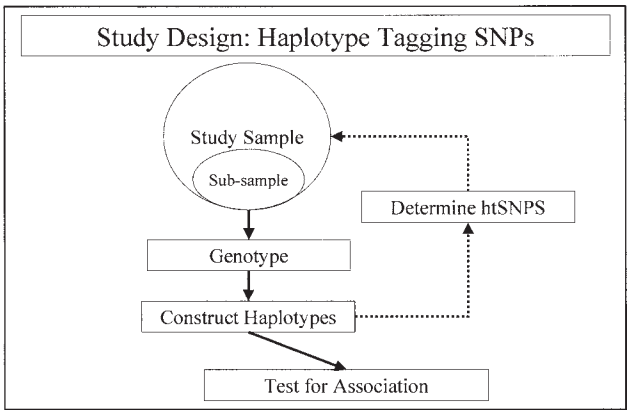

Figure 3-2 Two-phase study design based on haplotype tagging SNPs. First, one screens for SNPs within a subsample of study subjects to determine the htSNPs. Then these htSNPs, and possibly other promising SNPs, are genotyped in the entire study population.

FAMILY-BASED ASSOCIATION STUDIES The most common familial case–control designs use parents or siblings as controls (Fig. 3-3). In the former, the parents themselves are not the controls, but the set of genotypes the parents could have transmitted to the case, given their own genotypes (the case's "pseudosibs"). For example, the Transmission/Disequilibrium Test (TDT) compares alleles transmitted from parents to diseased offspring with those alleles that are not transmitted (i.e., the "nondiseased alleles"). The TDT provides a joint test of linkage and association (i.e., linkage in the presence of association or vice versa). In doing so, when there is disequilibrium between marker and disease alleles, incorporating the additional information that the same alleles are associated across families with the TDT can provide increased power in comparison with linkage analysis. Furthermore, the use of pseudosib controls has better statistical efficiency than sibling or cousin controls (even more than population controls for a recessive gene), but the requirement that parents be available for genotyping limits its usefulness for late-onset diseases.

As with pseudosib controls, siblings are derived from the same gene pool as the cases, and, thus, provide another attractive source of controls for family-based studies. However, using siblings as controls can pose other difficulties. A major issue is that not every case will have an available sibling. If sibship size or other determinants of availability are associated with genotype, selection bias may result, possibly leading to false-negative or -positive results. Another issue is that controls should generally be selected from siblings who have already survived to the age at diagnosis of the case free of the disease. In practice, this will tend to limit control eligibility to older siblings, which can lead to confounding by factors related to year of birth, family size, or birth order. Siblings are also more likely to have the same genotype as the case than are unrelated controls, thereby leading to some loss of statistical efficiency (i.e., larger sample sizes required to attain the same statistical precision).

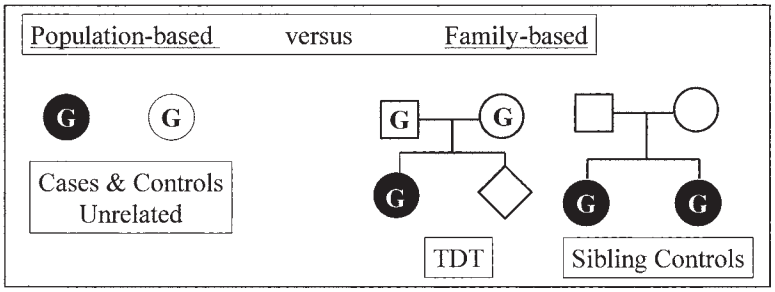

Figure 3-3 Population- and family-based association study designs.

POPULATION-BASED ASSOCIATION STUDIES The use of unrelated controls is susceptible to a form of confounding known as "population stratification" if the gene under study shows marked variation in allele frequency across subgroups of the population and if these subgroups also differ in their baseline risk of the disease. A number of authors have proposed using genomic information to help address the problem of bias resulting from population stratification, and overdispersion owing to cryptic relatedness (Fig. 3-4). In particular, with a panel of polymorphic markers that are not linked to the candidate gene under study, one can attempt to address the issue population stratification by (1) using an overdispersion model to determine a test statistic's appropriate empirical distribution; (2) evaluating whether stratification exists; and (3) using a latent-class model to distinguish homogeneous subpopulations. Witte et al. (1999) further explore the theoretical, statistical, and practical considerations in choosing between family and unrelated population controls.

The ability to identify genetic loci through an association-based technique depends very heavily on the degree of association between the disease-causing variants and genetic markers. Many of the power calculations that have been presented suggest outstanding power to detect disease-causing loci through an association-based approach. However, the earlier, optimistic power studies make highly optimistic assumptions that one is studying the causal SNP, that there is a single disease-causing variant, and/or that the population being studied is homogeneous with respect to the association between the marker(s) being studied. Less optimistic power calculations that do not assume complete disequilibrium of the study of a causal variant lead to far more pessimistic conclusions about the power of an association study to detect genetic variants. Similarly, the presence of multiple alleles influencing trait variability or disease susceptibility leads to a dramatic loss of power. Slager et al. shows that if there are multiple disease-susceptibility alleles and one is studying a tightly linked locus but not the causal locus, then the required sample sizes for detecting association can easily become unattainable. Despite these concerns, many groups are proceeding with very large-scale association genotyping projects with the hope that at least some disease-susceptibility loci will be identified.

Although it is highly likely that this approach will identify some loci for which the underlying genetic architecture is straightforward (i.e., a single common-disease-causing variant in strong linkage disequilibrium with disease), it is also likely that some disease-causing variants will be missed because the genetic architecture is too complex (several disease-causing variants in the same locus and/or low levels of linkage disequilibrium with SNPs or extensive locus heterogeneity with multiple loci causing the same phenotype). Alternative approaches can be used to identify genetic regions harboring some causal loci. One novel approach seeks to identify loci by evaluating ancestrally shared regions of the genome. This approach can identify evidence for genetic effects even when there are multiple distinct mutations predisposing to disease. This mapping scheme requires the study of admixed populations and the availability of genetic markers that can discriminate among ancestral founding populations. Another approach that has been effective in identifying genetic factors predisposing to mental retardation, schizophrenia, and autism searches for small regions of segmental aneusomy (i.e., duplicated or deleted segments of DNA) in affected individuals.

COMPARATIVE GENOMICS

Animal models of complex disease have provided additional information to direct the identification of gene variants relevant to human disease. Animal models and in particular, mice, have a number of advantages when trying to identify human disease genes. Breeding can be planned with the generation of large numbers of affected progeny and environmental influences can be controlled. Comparative genomics has become increasingly relevant as a number of genomes have been mapped, linkage maps created and information about SNP variation has become available. This has facilitated an explosion in linkage and association studies for both disease and quantitative trait loci.

A number of techniques and strategies have informed comparative genomics. Congenic strains allow refinement of a disease associated locus through the isolation of a chromosomal region known to predispose to a particular disease or disease parameter and through its insertion into the genome of a rodent strain that is not predisposed to the disease under study. Chromosomal synteny is the conservation of whole chromosomal segments between species. Such that the identification of a susceptibility locus in a rat model of rheumatoid arthritis on chromosome 10 led to the investigation and confirmation of an RA susceptibility locus in the syntenic region on the long arm of human chromosome 17. In addition, transgenic and knockout mice can be used to study the effects of specific gene variants on phenotype. Animal models of human disease may arise spontaneously or be induced either by mutagenesis by radiation or by chemical means using *N*-ethyl-*N*-nitrosourea or another insult, for example, injection of collagen into rodent footpads to effect arthritis.

Animal models of single gene disorders have also provided insight into pathways important in common diseases. The *ob/ob* mouse is characterized by gross obesity. Mutations in leptin have been identified to underlie this phenotype and a very rare recessive form of obesity in humans, but the study of the leptin pathway has provided significant insights in the control of body weight.

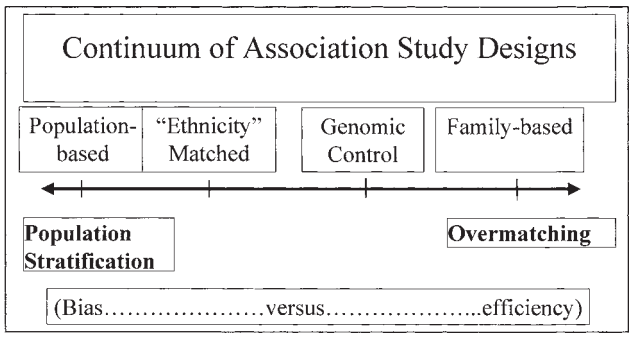

Figure 3-4 Identifying genetic regions for further positional cloning efforts. The designs range from population-based without matching to family-based, which are completely matched on ethnicity. Many forms of matching decrease efficiency, but provide increasing protection from false-positive results from population substructure.

A number of animal models of IBD have been identified including mice administered dextran sulfate and the spontaneously occurring C3H/HeJBir mouse strain. No model completely replicates the disease process in humans, but each may provide important clues to direct human gene and disease pathway identification. Multiple pathways lead to and protect against bowel inflammation. The IL-10 knockout mouse is illustrative in that one strain develops IBD, whereas another strain is resistant, demonstrating the importance of genetic background in animal models.

Linkage studies have identified loci which are syntenic to loci identified in genome-wide scans of IBD in humans, for example, the D5Mit216 locus is syntenic to the human 5q31 locus recently shown to harbor a high-risk haplotype across SLC22A4 and SLC22A5 genes for CD. Furthermore, animal models of IBD have shown the impact of nongenetic factors with disease only manifesting in animals once they are removed from a germ-free environment.

CONCLUSIONS

The search for genes that predispose to IBD has been successful. Variants in CARD15 are associated with CD in many populations and more recently variants in the OCTN gene cluster at chromosome 5q31 and DLG5 on chromosome 10 have been identified. Both positional cloning and candidate gene analysis have been successfully employed to identify these variants and the use of linkage disequilibrium mapping has been a powerful aid to refine the critical regions containing the susceptibility variants. Subsequent work has started to define the phenotypic consequences of these disease associated gene variants, for example, both CARD15 and OCTN variants increase the risk of ileal disease. In addition, the functional effects of these variants have been explored, especially in CARD15, which appears to act as a host defense mechanism to clear intracellular bacteria.

It is interesting to speculate on whether the genes identified to be associated with CD also predispose to other inflammatory diseases, for example, an intronic variant in SLC22A4 (OCTN1) has been associated with rheumatoid arthritis. This would support a proposed theory that common gene variants predispose to multiple diseases. This is compatible with the common disease: common variant hypothesis underpinning the genetic study of common diseases. This theory provides part of the justification for the HapMap project to identify SNPs and the relationships between these SNPs and is hoped that it will lead to the rapid identification of common disease associated variants. In IBD research, the discovery of variants in the OCTN gene cluster and DLG5 support this approach and provide hope for further significant advances in common disease genetics. Major challenges still lie ahead to determine the function relevance of disease associated variants and how this information may be translated into advances in clinical practice.

4 Cancer Genetics and Molecular Oncology

Sharon E. Plon

SUMMARY

Cancer is a genetic disease, but there are many different types of genetic changes found within a cancer cell. The study of relatively rare cancer predisposition disorders has provided crucial insights into basic mechanisms of cellular physiology and tumorigenesis. In this chapter, we review different mechanisms that result in an inherited predisposition to cancer, including chromosomal disorders, defects in imprinted genes, mutations in tumor suppressor genes, activation of oncogenes, and mutations in DNA repair genes. This research is now being accelerated through the Human Genome Project and high throughput analysis of the genetic changes found in cancer cells.

Key Words: Autosomal-dominant; autosomal-recessive; cancer susceptibility; deletions; DNA repair; imprinting; mutations; oncogenes; translocations; tumor suppressor genes.

INTRODUCTION

Overwhelming evidence demonstrates that cancer is the result of genetic changes in the DNA of the tumor cell. The mechanism of mutation and the impact of these somatic alterations on the growth of cancer cells make up the field of molecular oncology. In addition to mutational changes, a number of genes are deregulated in the cancer cell by epigenetic mechanisms including DNA methylation. Overall, the percentage of human cancers that is caused by a major inherited predisposition is low. That percentage varies with individual tumor types and is a composite of several different genetic factors. Despite their lower frequency, the ability to identify the genes mutated in these families has provided significant insight into the etiology of cancer in the general population. Our understanding of somatic mutations in cancer cells has relied heavily on identification of important genes through study of familial cases with subsequent research focused on mutations in these genes in sporadic cases (*see* Fig. 4-1). Key examples of the different forms of inherited predisposition to cancer will be reviewed.

Hereditary predisposition may include either genetic alterations that have been passed on to the individual from a parent or new mutations that occurred in the oocyte or sperm before fertilization. Therefore, hereditary predisposition to cancer is not always associated with a family history of the disease. For example, a *de novo* mutation in a cancer predisposing gene such as *RB1* can result in healthy parents having a child with the hereditary form of retinoblastoma. In the case of new dominant mutations in genes that result in highly lethal tumors, there may not be a family history because the children with cancer do not live to reproduce. In these cases, the process of gene discovery can work in reverse (*see* Fig. 4-1). For example, in atypical rhabdoid tumors, it was found that the tumors frequently carry a cytogenetically visible deletion at chromosome 22q11.2. This harbors the *hSNF5/INI-1* gene. Subsequently, children who carry a point mutation in this gene in their tumor were found to actually carry the mutation in all the cells in their body. These new dominant mutations presumably occur during the production of the egg or sperm before fertilization. This results in children with a cancer predisposition syndrome without an obvious family history. The identification of the gene by tumor cytogenetics allowed the uncovering of this syndrome. Thus, there may be other apparently sporadic cancers that could be the result of *de novo* constitutional mutations.

There are a variety of mechanisms that result in inheritance of cancer susceptibility. In this chapter, we will review examples of the major types including, constitutional chromosomal abnormality, Mendelian autosomal-dominant and autosomal-recessive patterns, and non-Mendelian inheritance. Non-Mendelian patterns include multigenic disorders, mutations in mitochondrial DNA, and imprinting errors. Imprinting refers to the fact that gene expression from a given gene may differ if the gene is on a chromosome inherited from the mother or father. Conversely, for any given tumor type there may be more than one mechanism that results in an inherited predisposition to that disorder. The most commonly cited example is Wilm's tumor, a malignant cancer of the kidney frequently diagnosed in very young children. An increased risk of Wilm's tumor can be the result of a chromosomal deletion, an autosomal-dominant disorder or a disorder of imprinting.

CONSTITUTIONAL CHROMOSOMAL ABNORMALITIES

Children with constitutional chromosomal abnormalities often present with many different medical problems including abnormalities in growth, multiple congenital anomalies (birth defects), and learning abnormalities. Constitutional chromosomal abnormalities are the result of abnormal number (i.e., aneuploidy) or structural rearrangements of chromosomes. Cells normally contain 46 chromosomes (i.e., 22 pairs of autosomes and the sex chromosome pair). In addition to their other medical problems, individuals with a constitutional chromosome problem may have an increased predisposition to cancer.

On the right is an interphase cell. Hybridization is also performed with a probe from the short arm of chromosome 5 as a control. (Photograph courtesy of R. Naeem.) (Please *see* color insert.)

DOWN SYNDROME Down syndrome (DS) is one of the most common chromosomal abnormalities in humans. It is the result of a child having three copies of chromosome 21 (trisomy 21). This increase in chromosome number typically results from an error in chromosome segregation during oogenesis. Thus, the child is usually the only person in the family with trisomy 21 and there is no structural abnormality in the three chromosome 21s present in the child. In addition to particular facial features and learning disabilities, it was noted quite early that children with DS have a strikingly increased predisposition to leukemia. By 5 yr of age approx 2% of children with DS will be diagnosed with leukemia. This is in contrast to approx 5/100,000 in the general population. Despite the fact that this association has been known for many years, we are still not certain which genes on chromosome 21 result in the increased leukemia risk. The completion of the sequencing of the entire chromosome 21 as part of the human genome project and large-scale expression studies of leukemia cells using microarray technology is facilitating this search. Children with DS also demonstrate another common feature of cancer predisposition syndromes, which is that they are increased risk for only certain cancer types, in spite of the fact that all cells of their body contain the extra chromosome 21. It is often the case that in inherited syndromes there are specific subtypes of cancer that show an increased predisposition. Again, scientists often do not have a molecular mechanism to explain this specificity. In the case of children with DS, they are particularly predisposed to an otherwise less common form of leukemia termed acute megakaryocytic leukemia (AMKL). AMKL is the result of malignant transformation of the megakaryocyte cell that provides platelets in the bloodstream. Outside of DS, AMKL is a very rare form of leukemia with a 400-fold increase of AMKL in children with DS. Clearly, the megakaryocyte is particularly sensitive to an extra copy of chromosome 21. Also, children with DS and AMKL show a different pattern of mutations in other genes within the cancer cell compared with other children with AMKL. In particular, the characteristic translocation between chromosomes 1 and 22 (t[1;22][p13;q13]) is absent in children with DS and AMKL.

As we will discuss for other malignancies, the leukemogenic effect of trisomy 21 is also seen in children without DS. If one looks at the pattern of chromosomes from leukemia cells in children without DS, one frequently finds that the leukemia cell has acquired a third chromosome 21. Thus, if we can understand why children with DS have an increased risk of leukemia it may help us better understand leukemogenesis in the general population.

Despite the well-documented increase in the risk of leukemia in children with DS, several large-scale population studies have not found an increased risk of other cancers in children with DS. In particular, many common cancers, including breast cancer, were less frequent in the population of adults with DS. Again we see a specific relationship between trisomy 21 and leukemia risk even though all cells in the body contain an extra chromosome 21. The reason why mutations in certain genes result in the development of cancer in only specific cell types is one of the remaining challenges in the field of cancer genetics.

STRUCTURAL CHROMOSOMAL ABNORMALITIES

Detection and Impact The ability to detect the number and, subsequently, the overall shape of human chromosomes improved through the 1960s and 1970s. As these techniques improved it became possible to identify that deletions of certain portions of chromosomes were a frequent occurrence in human cancers. In a smaller number of patients, this deletion or chromosome loss is an inherited event and again may be associated with a specific pattern of birth defects. Over the last 20 yr, the technology has continued to improve. In particular, the development of fluorescently labeled DNA probes allowed researchers to identify chromosomes that appear normal in the microscope but are deleted for sequences that bind to the fluorescent probe. This technique is termed fluorescent *in situ* hybridization (FISH) and is in regular use in both clinical and research laboratories. Figure 4-2 demonstrates FISH analysis of leukemia cells demonstrating deletion of part of chromosome 5 that results in loss of the *EGR1* gene. Over the last several years, even newer methodologies are being developed to allow scientists to screen the entire genome of a normal or cancer cell for small areas of loss or gain. These methods combine the power of microchip arrays and fluorescent probes. Thus, we expect that our ability to detect clinically important deletions will increase exponentially in the next decade.

Deletions of a portion of a chromosome can result in the loss of several neighboring genes. The size of the deletion impacts how many of these genes are lost and how many different medical problems a patient may manifest. Chromosomal deletions may be *de novo* events or inherited from either parent.

WAGR: Wilm's Tumor, Aniridia, Genital Abnormalities, and Mental Retardation The WAGR syndrome is named after an acronym that represents the most common medical problems seen in the condition including: *W*ilm's tumor, *a*niridia, *g*enital-urinary abnormalities, and mental *r*etardation. Two early cytogeneticists noticed that children with this group of medical problems had a microscopically visible deletion of the short arm of chromosome 11 (named 11p13).

When techniques were first developed to map the location of DNA fragments onto specific chromosomes, members of the Housman laboratory laboriously defined the minimal amount of DNA that had to be deleted to result in the WAGR syndrome, termed the "critical region." They then searched for the genes contained in this region and were able to identify that a specific gene, named *WT1* for Wilm's tumor 1, was deleted in the children with WAGR and Wilm's tumor. They also found that this gene is normally expressed in the developing kidney. *WT1* was one of the first genes identified that encodes a member of the family of transcription factors called zinc finger proteins. We have subsequently learned that many different tumor types result from mutations in this class of genes. All or part of *WT1* is deleted in children with WAGR and Wilm's tumor. In contrast, mutations of a single amino acid in the *WT1* gene are the cause of another genetic condition, Denys–Drash syndrome, which also results in an increased risk of Wilm's tumor. This latter finding was the final proof that mutations in *WT1* are the cause of an increased predisposition to Wilm's tumor.

The results of identification of the genetic mechanism underlying these syndromes have lead to development of specific screening regimens for young children with these disorders. For example, all children with aniridia who are found to carry a deletion in the *WT1* gene are screened every 3–4 mo by renal ultrasound in order to detect any Wilm's tumor at an early stage, thus decreasing the intensity and potential toxicity of their cancer treatment and increasing the likelihood of a cure.

OVERGROWTH DISORDERS AND IMPRINTING ERRORS

BECKWITH–WEIDEMANN SYNDROME Not surprisingly, there has long been a recognized relation between disorders of increased growth and predisposition to cancer. Certain genetic conditions result in abnormal growth profiles and an increased risk of cancer. In particular, Beckwith–Wiedemann syndrome (BWS) and hemihyperplasia (HH) are linked to a significantly increased risk of developing abdominal tumors, including Wilm's tumor and hepatoblastoma. It is estimated that approx 3–5% of children with BWS develop one of these tumor types compared with less than 1/10,000 in the general population. BWS is characterized by excessive intrauterine and postnatal growth, organomegaly, and several specific congenital anomalies. HH (HH—also sometimes referred to as hemihypertrophy) in a child is defined as asymmetric growth owing to overgrowth of one side relative to the other. It can be limited to a limb or the face or include the whole side. Several studies have demonstrated that children with both BWS and HH had a higher risk of Wilm's tumor, than either condition alone.

The genetic basis of BWS and HH is complex but a common theme is that there are differences in development of BWS depending on the parent it is inherited from. In rare children with BWS (and no family history) part of chromosome 11p15 (distinct from where *WT1* resides) is duplicated. This duplication always occurs on the chromosome they inherited from their father.

The dependence on whether the abnormality is inherited from the father or mother is the result of imprinting. Imprinting refers to the fact that certain genes are expressed differently, depending on whether they were inherited on the maternal or paternal chromosome. An extreme example is that some children with BWS have two normal chromosomes 11 but they inherited both copies of chromosome 11 from their father, termed uniparental disomy and none from their mother.

Extensive research efforts have identified multiple imprinted genes in this region of chromosome 11 which when deregulated result in BWS. These include a growth factor, IGF-2, a cell-cycle inhibitor, $p57^{KIP1}$, and RNAs, *H19* and *LIT1*. For example, *IGF-2* is expressed from the paternal chromosome and $p57^{KIP1}$ is only expressed from the maternal chromosome. Thus, the study of rare disorders has shed light on a hitherto unsuspected but fundamental aspect of inheritance, that there are distinct differences in expression from the maternal and paternal chromosome. When this balance is disrupted congenital anomalies can develop as well an increased risk of cancer. Cancer biologists are now trying to understand how loss of imprinting may play a role in cancers in the general population.

MENDELIAN INHERITANCE OF A PREDISPOSITION TO CANCER

There are many families that show a Mendelian inheritance pattern of cancer predisposition consistent with inheritance of either a dominant or recessive mutation in a single gene. In the following sections, we discuss examples of both autosomal-dominant and autosomal-recessive disorders that results in family members with an increased risk of developing cancer.

AUTOSOMAL-DOMINANT DISORDERS The majority of syndromes that result in an increased susceptibility to cancer are owing to autosomal-dominant mutations. The autosomal name refers to the fact that the mutations are on an autosome as demonstrated by the mutation being equally transmitted from either the father or mother to a son or daughter. Dominant refers to the finding that cancer predisposition results from inheritance of a mutation from only one parent. Thus, one sees a multigenerational pattern of cancer risk in one lineage. However, as we also see in other autosomal-dominant conditions, the degree of cancer risk varies within the family and there may be members of the family who inherit the cancer-predisposing mutation but never develop cancer (termed incomplete penetrance). Thus, we emphasize to patients and their physicians that these are cancer predisposition or susceptibility disorders, and that simple inheritance of such a mutation does not guarantee that an individual will develop cancer. The risk of developing cancer varies with the specific syndrome from over 95% for colon cancer in familial adenomatous polyposis to 15% for ovarian cancer in women who inherit a *BRCA2* mutation.

Retinoblastoma The study of genetic predisposition to a rare pediatric eye tumor, retinoblastoma, was a turning point in our general understanding of the pathogenesis of cancer. Alfred Knudson and his colleague Louise Strong published a series of articles in the early 1970s that were based on the statistical analysis of children with retinoblastoma and other pediatric malignancies. By modeling the age of onset of retinoblastoma in children with bilateral disease in comparison with unilateral disease,

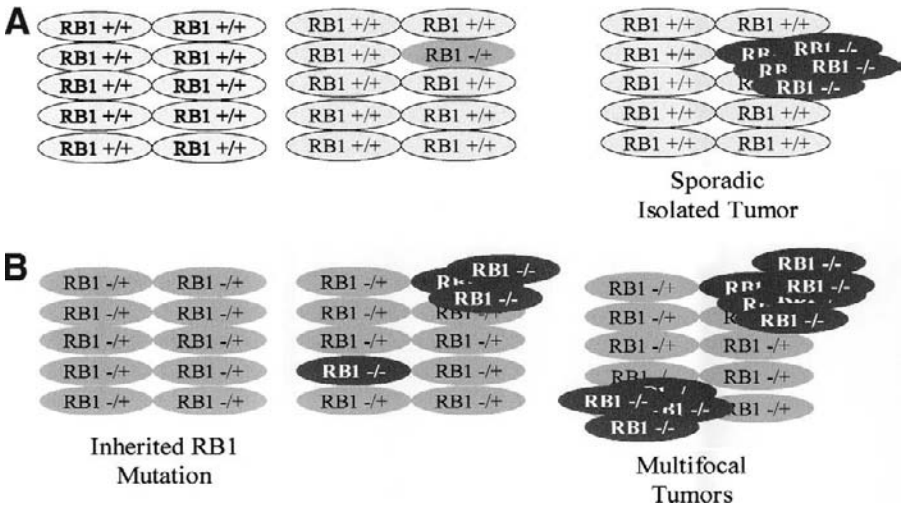

Figure 4-3 Model of the two-hit hypothesis. **(A)** illustrates the events in the retina of a child born with two normal copies of the *RB1* gene. A rare retinal cell may develop a single *RB1* mutation and eventually lose the second copy of *RB1* and become a tumor. **(B)** illustrates the events in the retina of a child born with a constitutional *RB1* mutation. All retinal cells carry this mutation and there is an increased frequency of tumors developing when the second copy of the *RB1* gene is lost.

Knudson tested the hypothesis that bilateral retinoblastoma represented the inherited form of the disorder with those patients inheriting the first event, presumably a mutation. His data were most consistent with a model that posited that the bilateral form required only one additional event or "hit" but that the unilateral form required two hits. Knudson recognized that in unilateral or sporadic forms of the disease the same two events must occur in a somatic cell, a relatively rare event (Fig. 4-3). In the inherited cases, all cells in the body contain the first hit and thus the frequency of a second hit in a somatic cell is high leading to bilateral or multifocal disease with an earlier age of onset.

The two-hit hypothesis is consistent with the finding that inherited forms of retinoblastoma present earlier and with a greatly increased percentage of bilateral and multiple primary tumors. Importantly, some patients (~15%) with unilateral disease also carry a constitutional mutation as well; presumably having only a single cell that incurred a second hit. Overall, approx 10% of people with a constitutional mutation in *RB1* do not develop retinoblastoma, yielding a "penetrance" for retinal tumors of 90%. These features of early age of onset, multifocal or bilateral disease, and incomplete penetrance are found in many different cancer predisposition syndromes that are the result of mutations in tumor suppressor genes (Table 4-1). Tumor suppressor gene is the term used to describe genes that normally function to prevent tumor development by controlling proliferation, maintaining genomic stability, or DNA repair and are inactivated in tumors.

An additional phenotype common to the autosomal-dominant conditions was also found for retinoblastoma families by long-term follow-up of childhood survivors. Individuals carrying germline mutations in the *RB1* gene are at increased risk for development of other primary tumors. In particular, there is an increased risk of osteosarcoma and malignant melanoma. This clustering of a specific subset of tumor types is found in a number of other cancer predisposition syndromes including breast and ovarian cancer in the same families.

Rare children with bilateral retinoblastoma who were found to carry a cytogenetically visible deletion of chromosome 13q14 led to the cloning of the *RB1* gene. Molecular studies of this gene in both inherited and sporadic cases of retinoblastoma provided a physical confirmation of the two-hit hypothesis. Retinoblastoma requires loss or inactivation of both functional copies (i.e., two hits) of the *RB1* gene for a tumor to develop (Fig. 4-3). The *RB1* gene is a prototypical "tumor suppressor gene," whose normal function is to negatively regulate the cell division cycle. The loss of this function, called tumor suppression, is consistent with loss of cell cycle control when both copies are inactivated. In the familial form, a mutation in one *RB1* gene is inherited, and therefore all the cells in the body have only one normal allele. If during development of the eye, the remaining normal copy is mutated or lost then there is no residual *RB1* function and cell cycle control is disrupted. Many different mechanisms can lead to loss of the second copy of the *RB1* gene, such as deletion of a portion of the chromosome, loss of the whole chromosome, loss and duplication of the mutant chromosome, or smaller events within the *RB1* gene. In the sporadic form, mutation or loss of both *RB1* genes must occur in the same retinal cell for retinoblastoma to develop.

Table 4-1
Clinical Features Associated With Autosomal-Dominant Cancer Susceptibility

Feature
Increased cancer risk seen in multiple generations in one lineage
Transmission of cancer risk through both men and women
Earlier onset of cancer diagnosis compared with general population
Bilateral or multifocal cancers
An individual diagnosed with more than one type of cancer
Clustering of specific cancer types within a family, for example, breast and ovarian cancer

Implications Several themes first identified in the study of retinoblastoma have been found to be true of a number of autosomal-dominant cancer predisposition syndromes. Specifically, important molecular events may be shared between the cancers that arise in those rare individuals with an inherited predisposition and the much

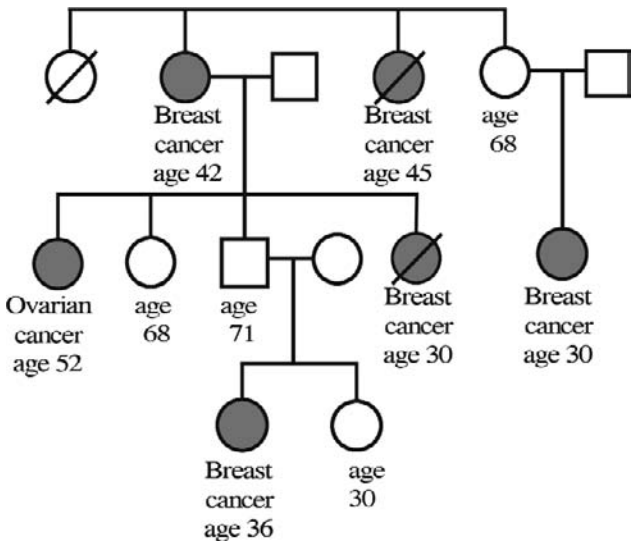

Figure 4-4 Pedigree of a family carrying a mutation in the *BRCA1* gene. Note the increased number of women diagnosed with breast cancer at young ages, the occurrence of ovarian cancer and the transmission of the risk of cancer through both men and women.

more common sporadic cancers. For example, the same genes that are mutated in inherited syndromes has also been found to be inactivated in significant percentages of kidney cancers, sarcomas, colon cancers, and skin cancers. This inactivation can be due to mutation or to epigenetic changes that silence the gene. For example, rare inherited mutations in the mismatch repair gene, *MLH1*, result in hereditary nonpolyposis colon cancer. In contrast, in about 15% of colon cancers in the general population, the *MLH1* gene is silenced by methylation. Exceptions to this relationship between inherited and sporadic cancers will be summarized in the section on breast cancer susceptibility.

A fundamental result of mutation of the *RB1* gene is inactivation or loss of function leading to cancer development. Genes that share this feature have been termed tumor suppressor genes because when present they result in decreased cancer development. The identification of tumor suppressor genes was in stark contrast to the earlier discovery of oncogenes and the genetic mechanisms that result in activation of the oncogene in human tumors including amplification, point mutation, and translocation. The majority of syndromes that result in inherited susceptibility to cancer are due to inactivating mutations in tumor suppressor genes. However, as described in the section on multiple endocrine neoplasia, there are rare syndromes that result from the inheritance of a mutation that activates a protooncogene.

***BRCA1*: DISCORDANCE BETWEEN INHERITED AND SPORADIC BREAST CANCER** A woman's risk of developing breast or ovarian cancer is a combination of personal risk factors (age of menarche, number of children, hormonal exposure, history of breast disease), and genetic predisposition. Statistically, one of the most significant risk factors for these cancers is family history of these cancers. *BRCA1* was the first major breast and ovarian cancer predisposition gene identified. Its chromosome location was identified as 17q21 by classic linkage analysis of a large number of families characterized by multiple cases of early onset breast cancer, ovarian cancer, and bilateral breast cancer (Fig. 4-4). Much of the impetus for identifying the *BRCA1* gene came from the expectation that mutations in this gene would also be found in sporadic breast cancers in the general population. This idea was supported by studies of breast tumors themselves, which suggested that the 17q21 region was rearranged or lost in sporadic breast cancers.

BRCA1 is a large gene containing 24 exons and encodes a protein of 1863 amino acids. Studies of tumors from women, found to have inherited a *BRCA1* mutation, were consistent with the Knudson two-hit hypothesis. The tumors showed loss or inactivation of the remaining wild-type gene in both breast and ovarian cancers in these women. Surprisingly, studies of breast cancers from women who do not carry a constitutional mutation revealed no evidence for somatic mutations in the *BRCA1* gene. Thus, the *BRCA1* gene functions primarily as a tumor suppressor gene in women who inherit one mutation. Why mutations do not occur in sporadic breast cancer is unknown. Some studies have suggested that the BRCA1 protein may be regulated differently in sporadic cancers, although that remains unclear. Thus, one cannot predict *a priori* whether the same gene will be mutated in both inherited syndromes and sporadic cancers. As each new tumor suppressor gene is found, it is important to directly determine the frequency of mutations in both situations. In some cases, it may be that different genes in the same cellular pathway are mutated in inherited vs sporadic cancers.

Recent studies have demonstrated that the normal function of the BRCA1 protein is in recognition of DNA damage and transduction of that signal to downstream proteins that mediate cell cycle arrest (termed checkpoints) and DNA repair. Loss of *BRCA1* function results in somatic cells having an increased number of mutations and genomic instability with subsequent tumorigenesis. Other proteins encoded by tumor suppressor genes, including p53, ATM, and CHEK2 also function in the same pathway. Mutations in each of these genes have been found in women with an inherited predisposition to breast cancer and *p53* mutations are also found in sporadic breast cancers. Thus, one can generalize our understanding of breast cancer to say that women who inherit defects in the DNA damage checkpoint pathway have a significantly increased risk of breast cancer. The susceptibility of mammary tissue to DNA damage can also be demonstrated by the very high rate of breast cancer in women who were treated as adolescents with radiation therapy to the chest for Hodgkin lymphoma.

MULTIPLE ENDOCRINE NEOPLASIA: INHERITANCE OF A MUTATION IN AN ONCOGENE Thus far we have emphasized autosomal-dominant cancer predisposition disorders that are the result of inheriting a mutation in one copy of a tumor suppressor gene with tumors resulting from the somatic loss or inactivation of the remaining copy. Like all good rules there are exceptions and multiple endocrine neoplasia (MEN) type 2 represents such an exception. The MEN disorders represent at least three different diseases, which all result in an increased risk of tumors in endocrine organs. MEN1 is characterized by parathyroid, pancreatic islet cell, and pituitary gland involvement and is due to mutations in the *MEN1* gene on chromosome 11.

MEN type 2 is divided into subtypes MEN2A and MEN2B. Both MEN2A and MEN2B syndromes present in childhood but have a different pattern of onset and tumors types. MEN2A is more common and is associated with medullary thyroid carcinoma, parathyroid adenomas, and pheochromocytomas beginning in childhood and young adults. MEN2B is a related

disorder but with the onset of tumors in infancy and associated with other medical problems.

The gene for MEN2A was initially mapped using standard genetic techniques to a small region on human chromosome 10q11.2. It was assumed that mutation in a tumor suppressor gene was responsible. However, researchers noted that the *RET* protooncogene, a receptor tyrosine kinase gene, mapped in this region. *RET* had been found to be activated in papillary thyroid cancer due to a translocation. Thus, it had many features of a classic oncogene. Surprisingly, analysis of constitutional DNA from multiple MEN2A families revealed a set of highly consistent mutations in the *RET* gene. The MEN2A mutations found in these families appeared to replace one of four cysteines with another amino acid in the extracellular domain of the protein encoded by exons 10 and 11. There was also some correlation between the types of cancers seen in the families and the specific cysteine mutation. For example, a mutation in cysteine 634 results in a high risk of pheochromocytomas in the family. Patients with MEN2B did not have cysteine mutations but subsequent studies demonstrated two specific missense mutations in the highly conserved tyrosine kinase domain of the *RET* gene in over 95% of MEN2B patients.

What we see in MEN2 families is in contradiction to the two-hit hypothesis. These missense mutations do not inactivate the Ret protein and the remaining copy of the gene remains intact in the tumor cell. Laboratory tests directly demonstrated that the cysteine mutations result in constitutional activation of the Ret protein and transforming activity. Thus, the predisposition to endocrine cancers is the result of inheritance of a mutation that activates an oncogene in contrast to inactivating a tumor suppressor gene.

Clinically, the screening and treatment of MEN2A and MEN2B families have been significantly improved by these genetic discoveries. In comparison to older hormonal studies to identify which family member was at increased risk for a cancer, there is greatly improved accuracy in DNA testing, particularly for young children. The DNA test need only be performed once, and it decreases the cost and potential health risks of the older techniques. Those children found to have inherited the mutation are recommended to have removal of the thyroid gland in early childhood in order to prevent the development of medullary thyroid cancer.

AUTOSOMAL-RECESSIVE DISORDERS

Recessive disorders that predispose to cancer have distinct characteristics when compared with the autosomal-dominant disorders. Individually, these are very rare disorders. There may be specific ethnic groups with an increased risk of a specific autosomal-recessive disorder owing to a high rate of carriers for a recessive trait. Clinically, recessive disorders result when a person carries two mutant alleles, one inherited from each parent. Thus, these disorders normally occur in sibships and are not evident in multiple generations. Generally, the parents who carry a single copy of the mutation are asymptomatic without an increased cancer risk, but have a one in four chance of having a subsequent child with the same disorder.

The symptoms of autosomal-recessive disorders are often more severe than in autosomal-dominant disorders and are typically diagnosed in childhood. Many of the autosomal-recessive cancer syndromes are caused by mutations in genes that encode DNA repair enzymes or proteins that monitor the presence of DNA damage. The lack of these functions results in increased mutation rates or genomic instability. The loss of a specific enzyme or surveillance function results in cells from these patients showing increased sensitivity to spontaneous and exogenous DNA damage and increased risk of specific cancer types.

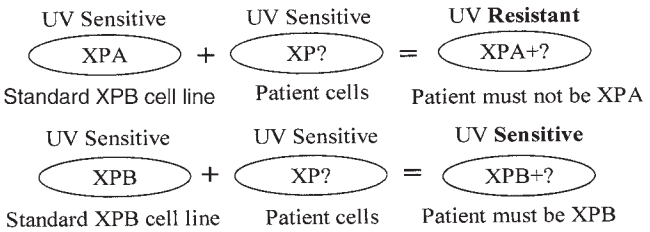

Figure 4-5 Complementation assay using UV sensitivity for cells from patients with xeroderma pigmentosum (XP). The patient sample is fused to standard cell lines from each XP subtype. If the fusion restores UV resistance then the patient must carry a mutation in another subtype. If the fusion does not restore UV resistance then the patient carries mutations in the same subtype genes.

XERODERMA PIGMENTOSUM Xeroderma pigmentosum (XP) represents the classic DNA repair defect syndrome. Patients demonstrate extreme photosensitivity to even very modest sun exposure and present within the first few years of life with burns, telangiectasias, and freckling of the skin. Ocular abnormalities are common and are found in UV light-exposed areas of the cornea, lids, and conjunctivae, including corneal clouding and ocular malignancies. There is a several thousandfold increased risk of basal and squamous cell skin carcinomas and melanomas beginning in childhood in sun-exposed areas including the neck, face, and tip of the tongue.

The clinical finding of photosensitivity led investigators to test the response of cells from patients with XP to UV light. XP cells demonstrate increased UV sensitivity in vitro. More detailed analyses of the repair of UV-induced DNA damage demonstrated that in cells from different XP patients there were different defects. The determination that multiple genes caused the same clinical disorder was based on complementation assays in which fibroblasts from different patients are fused together in the laboratory (Fig. 4-5). The cell resulting from the fusion (heterokaryon) is then tested to determine if the cells remain sensitive to UV light. If the heterokaryon is sensitive that implies that both patients carry mutations in the same gene. If the heterokaryon becomes resistant to UV light (complementation) then that implies that different genes must be mutated in the two cells. It became apparent from these types of complementation assays that XP can result from mutations in at least seven different genes.

Once the different complementation groups were identified, biochemical assays revealed the specific step in repair of a UV-induced DNA lesion, which was defective in each group. One could then use this biochemical defect to identify which normal human gene could restore repair of the UV-induced lesion to the cell. Analysis of these gene products demonstrates that many of them encode proteins that are highly conserved. Similar proteins that perform similar functions can be found in prokaryotes (*Escherichia coli*) and many simpler eukaryotic organisms. It appears that developing defense mechanisms against UV-induced DNA damage is important for all organisms. This

similarity between human and bacterial proteins has been found for other causes of inherited cancer. For example, mutations in mismatch repair genes cause an increased risk of colon cancer. There are similar proteins in bacteria and humans for performing this form of DNA repair. The similarity also allows scientists trying to understand the function of these cancer-suppressing proteins to carry out much of their research using simple bacterial or yeast organisms in the laboratory.

CONCLUSION

In this chapter, we have reviewed different mechanisms that result in an inherited predisposition to cancer, including chromosomal disorders, defects in imprinted genes, mutations in tumor suppressor genes, activation of oncogenes, and mutations in DNA repair genes. In each case, the analysis of a relatively rare disorder has provided crucial insights to basic mechanisms of cellular physiology and tumorigenesis. The recent development of large-scale highly automated methods including genome sequencing, microarray analysis and sophisticated hybridization techniques is aiding investigators to further apply what has been learned from these inherited disorders to cancers in the general population.

5 Pharmacogenetics

Renee E. Edkins and Dennis J. Cheek

SUMMARY

The clinical implications of pharmacogenetics are vast and many more are becoming apparent as research continues. Health-care providers will increasingly need to take pharmacogenetics into consideration when prescribing medications. Each patient's history, physical condition, gender, and ethnicity must be considered when prescribing drugs. Specific genotypic testing of patients for polymorphisms that influence drug metabolism and action will become a clinical reality. Silicone chip technology utilizing single-nucleotide polymorphisms will be able to provide a practitioner with reliable and timely information in an office setting to guide practice. Genetics and pharmacology are no longer separate sciences.

Key Words: Adverse drug event (ADE); drug development; extensive metabolizers (EM); pharmacogenetics; safety.

INTRODUCTION

Pharmacogenetics is targeted to the understanding of how genetic variation contributes to an individual's response when exposed to pharmacological agents. Pharmacogenomics takes entire populations into consideration when designing and evaluating disease and drug development. Variation or polymorphism, present in all genes, results in different forms of a protein. Such differences are especially important from the pharmacological standpoint for those proteins that are involved in the metabolism of many different medications. In addition to metabolism, receptor affinity to pharmacological agents is subject to variations. These variations can result in toxicity or loss of efficacy. As more becomes clear about the human genome, medications will be tailored to individuals, avoiding many adverse events and drug–drug interactions. Genes that code for the proteins that modulate drug targets vary. For example, genes that code for the cholesteryl ester transfer protein influence a patient's response to pravastatin (Fig. 5-1). Mutations in this protein can result in a patient's cholesterol remaining high in spite of the use of cholesterol-lowering drugs. Initial doses of pravastatin in these patients may show no effect, but this lack of response is because of genetics, not poor compliance. Increasing the dose may show no efficacy, but instead result in adverse reactions. This chapter reviews this fascinating interplay of genetics and pharmacology.

HISTORICAL OVERVIEW

The actual start of the field of pharmacogenetics is debatable. It is clear that a difference in the tolerance of certain people to the growing number of chemicals, both natural and pollutants, food toxins, and medications (collectively referred to as xenobiotics) in their environment had been observed long before the elucidation of the double helix in 1953. Pythagoras, as early as 510 BC, identified individuals who could not tolerate eating fava beans whereas others could. Those not tolerating fava beans developed hemolytic anemia because of a deficiency in glucose-6-phosphate dehydrogenase, a deficiency that has been well defined since 1956. In 1902, Archibald Garrod identified enzymes playing a key role in the detoxification of foreign substances. This work was expanded by Guthrie, who developed a simple blood test to identify newborns with phenylketonuria, a condition resulting from an inborn error of metabolism.

The 1950s were a defining decade for pharmacogenetics. It was becoming clear that inheritance might explain many individual differences in the efficacy of drugs and in the occurrence of adverse drug event (ADEs). In 1953, individuals were noted to experience neurological side effects from the antituberculosis drug isoniazid. Later biochemical analysis revealed that these subjects were poor metabolizers (PM) of isoniazid resulting from a deficiency in the enzyme *N*-acetyltransferase. Initial trials for the drug suxamethonium, a muscle relaxant used for surgery, evidenced no complications or adverse events. Thought to be safe, this drug was released into the larger population. Soon thereafter, prolonged and dangerous muscle relaxation was noted in an alarming number of individuals. It was found that variances in plasma cholinesterase levels left many individuals unable to clear the drug from their systems resulting in prolonged muscle relaxation.

In 1977 research on the antihypertensive agents bethanidine and debrisoquin revealed that bethanidine acted within a relatively narrow range of dosing. Debrisoquin, however, evidenced a wide effective dose range. It was discovered that bethanidine was rapidly absorbed and excreted unchanged. No metabolic transformation was required, thus the narrow range of dosage. Debrisoquin was also rapidly absorbed, but was excreted as metabolites. One subject excreted few metabolites, but mostly active parent compound. This individual evidenced a profound hypotensive response to the same dosage that caused no response in other individuals. Further work in this area led to the discovery of the first polymorphism of drug oxidation in man. The terms extensive metabolizers (EM) and PM, discussed later in this chapter, were first introduced in this research.

Pharmacogenetics is not a new discipline. Although the term pharmacogenetics entered the lexicon in 1959 when coined by Fredreich Vogel, the effects of polymorphisms on metabolism in humans have been observed as early as the sixth century. With the mapping of the human genome, pharmacogenetics will play an increasingly important role in clinical medicine. Health-care providers will need to take variation and genetics into account when prescribing medications.

CLINICAL DEVELOPMENT AND APPROVAL

Medications are essentially prescribed through a process of trial and error. Federal law in the United States mandates that medications are approved only after going through clinical trials to prove their worth. However, clinical trial populations are of relatively small size compared to the general population. It is only after a drug has been approved for use in the general population and many more exposures have occurred that its true safety and efficacy profile becomes clear.

The development of a drug can be a long and arduous process. Basic research by chemists, pharmacologists, and molecular biologists seeks to determine if a desired chemical effect can be obtained with minimal toxicity. Hundreds of thousands of chemical compounds are screened for candidates. Likely candidate compounds that show promise move into a pipeline for development. Whether a compound has been chosen specifically to treat a disease or has simply evidenced unique properties, it must undergo a long process of research to become a new drug.

The traditional path of drug development can take 6–14 yr. At any time in this path a potential drug can be pulled from the pipeline for failing proof of concept. Thousands are rejected, but in the future the problem evidenced by these compounds may no longer present an obstacle and they will be reinvestigated. For those that succeed, the average time to market, according to the Food and Drug Administration (FDA) is 8.5 yr.

The classic clinical trial paradigm occurs in four phases following an initial preclinical stage (Table 5-1). Once a compound has cleared preclinical testing in the laboratory, it moves into Phase 1 trials. These trials consist of the initial human studies and usually involve healthy volunteers. Small populations are enrolled, averaging 20–80 subjects. At this phase study end points consist of safety, tolerability, and pharmacokinetic data. For a compound to enter this phase an investigational new drug (IND) application must be filed and approved by the FDA. The IND reference number will be linked to all future studies.

Phase 2 trials represent the start of testing in select affected populations and last 1–2 yr. These are small pilot studies, consisting of about 100–300 subjects. Safety and pharmacokinetic data continue to be evaluated, but with the addition of two new end points: dose escalation and efficacy.

Phase 3 clinical trials are the studies that attract the most public attention. These trials are large, by industry standards, and can enroll from 1000 to 10,000 affected subjects. As the exposed population grows, a profile of the investigational drug's-related adverse effects and therapeutic ranges emerges. An investigational drug remains in this phase for 2–3 yr. Even at the largest and most expensive enrollment of 10,000, this represents only a scant percentage of the total population for which a drug is usually intended.

In the last of these three phases, a new drug application is completed and submitted to the FDA for review. This review process can take up to 2 yr. If the data are positive, the investigational drug receives approval and becomes available by prescription to the general population. Approval, though, does not mean the end of evaluation. After approval, a fourth phase of evaluation is entered. Phase 4 consists of postmarketing surveillance by the pharmaceutical company. The FDA continues to monitor approved drugs for safety. Additionally, the pharmaceutical company studies pharmacoeconomic data and clinical reports to elucidate additional indications. For example, the drug minoxidil, approved for hypertension as Loniten®, was found to increase hair growth in men. After further research the drug was approved for a new indication, alopecia, and appears as Rogaine®.

SAFETY As indicated by the paradigm discussed earlier, most drugs approved by the FDA have had only a limited exposure in humans for only a short period of time. Some drugs can cause serious ADEs at very low frequencies and thus require more exposures to detect such reactions. In 1997 bromfenac sodium (Duract®), a nonsteroidal anti-inflammatory agent developed for short-term management of acute pain was approved for short-term use. Although clinical trials had revealed some elevation of liver functions, no incidences of overt liver failure occurred and the drug was approved. Because some liver enzyme elevation had occurred, a warning was included in the packaging to only prescribe the product for short-term use. Within 1 yr of approval the FDA had received 20 reports of serious hepatotoxic events. Of these 20 reports, four patients died of liver failure and eight required liver transplant. In 1998, 1 yr after approval, Wyeth-Ayerst Laboratories withdrew Duract from the market. Duract caused serious hepatotoxicity in only 1 in 20,000 patients taking the drug for longer than

Table 5-1
Drug Development and Approval

Phase	*Number of patients*	*Focus*	*Length of trials*	*Regulatory*
Preclinical	Laboratory and animal models (no humans)	Safety, pharmacokinetics	Indeterminate	Investigational new drug application filed IND approval must be received to enter Phase 1 trials
Phase 1	Healthy human volunteers or special populations of intent (up to one hundred)	Safety, tolerability pharmacokinetics	1–2 yr	Continuing updates to IND
Phase 2	Population of intent (up to several hundreds)	Safety, dosing, efficacy, pharmacokinetics	1–2 yr	Continuing updates to IND
Phase 3	Population of intent (up to several thousands)	Safety, efficacy, pharmacoeconomic	2–3 yr	New drug application (NDA) filed
Phase 4	General population	Safety, pharmacoeconomic	Ongoing	NDA approved prior to marketing, followed by a 120 d review Continuing updates and monitoring through FDA MedWatch Program

10 d. To have reliably predicted the hepatotoxicity during clinical trials, roughly 100,000 human exposures to Duract would have had to occur. Only 2400 exposures to this drug occurred before approval. Knowing which patients were at risk for hepatic toxicity could have resulted in their exposure being limited.

The Institute of Medicine reported in January of 2000 that from 44,000 to 98,000 deaths occur annually from medical errors. Of this total, an estimated 7000 deaths occur because of ADEs. An analysis of multiple hospitalized populations has placed much higher estimates on the overall incidence of serious ADEs. This study estimates that 6.7% of hospitalized patients have a serious ADE with a fatality rate of 0.32%. These results lead to an estimate of more than 2,216,000 serious ADEs in hospitalized patients and over 106,000 deaths annually. These results do not address ADEs in the ambulatory setting, and additionally, an estimated 350,000 ADEs occur in US nursing homes each year. The exact number of ADEs is unknown, but ADEs represent a significant public health threat that can be potentially preventable.

VARIABILITY

What causes this range of response in individuals when they are exposed to the same dose of the exact same drug? Human beings are approx 99.9% identical at the genetic level, 100% in the case of monozygotic twins. Yet it is these small individual differences in the sequence of DNA that result in clinically significant variation between individuals. The issue of interindividual variability is central to pharmacogenetics. Individuals who metabolize drugs rapidly may require dosages many times larger than what is recommended in initial research performed on relatively small numbers of subjects. PM may experience toxicity at the recommended dose. If metabolism is required to transform the compound from prodrug to active metabolite, no efficacy may be seen at all. Enzymes responsible for activation and/or transformation of drugs and prodrugs show substantial individual variation.

In addition to metabolism there is also the issue of drug targets. Drugs are designed to function with specific targets such as enzymes or substrates. Because gene expression can be variable, target structures may be mutated. Polymorphisms can cause loss of function, decreased function, or in the case of multiple copies, rapid function. In such cases, drugs administered to an individual may show no benefit and actually increase the risk of ADEs. Multiple agents may be tried in this scenario with the hope that side effects may be tolerable. Time and money are lost with this method of drug use, whereas the risk to the patient increases because of disease progression and potential ADEs.

Health-care providers must be aware of host factors that can affect how drugs react within the human system. Variability in host factors can play as important a role as metabolism and drug targets in pharmacogenetics. Each of these three areas—variability in metabolism, drug targets, and host factors—is critical in pharmacogenetics.

METABOLISM Of the two phases of metabolism (Phase I and Phase II), Phase II typically results in conjugation of a drug to a water soluble group like a sugar, peptide, or sulfur group and does not usually present the obstacles which Phase I metabolism presents. However, in ill patients Phase II metabolism can be an issue. Many drugs are bound to intracellular proteins such as albumin. In a chronically ill individual albumin levels can be low and result in dangerously high free serum levels of drugs such as phenytoin. Because there are usually an excess of peptide, sugar, and sulfur groups in a well-nourished cell, these reactions are rarely rate limiting and may be best discussed under host factors. Thus for the purposes of discussion, this chapter focuses on Phase I metabolism.

Drugs are metabolized during Phase I by oxidation or reduction reactions. Most drugs are lipophilic in composition allowing for easy movement into cellular membranes. Enzymes are responsible for the biotransformation of very lipophilic molecules in preparation for Phase II metabolism, often accomplished by adding a hydroxyl group resulting in a conjugation site. Most medications require Phase I biotransformation into water-soluble moieties. This action ultimately facilitates excretion. Biotransformation is performed primarily by the cytochrome P450 mono-oxygenase system. These heme-containing proteins are located in the smooth endoplasmic reticulum of many tissues. However, the liver is the main repository of these proteins, and so has a critical role in drug metabolism. This system has broad substrate specificity. It is induced by hundreds of different compounds including steroids and is responsible for the metabolism of up to 50% of all drugs.

In 1962, an unknown pigment was identified as a heme-containing protein. It had a unique 450-nm optical peak in its reduced carbon monoxide form. This led to the term cytochrome-P450 and a designation of "CYP." There are many cytochrome-P450 isoforms; indeed the growing number of identified isoforms led to confusion.

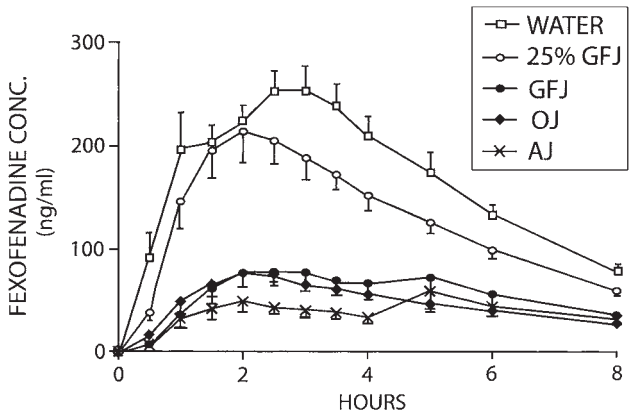

Figure 5-2 Mean plasma fexofenadine concentration–time profiles for persons (n = 10) orally administered fexofenadine (120 mg) with 300 mL water, grapefruit juice at 25% of regular strength (25% GFJ), grapefruit juice, orange juice, or apple juice followed by 150 mL of the same fluid every 0.5–3 h (total volume, 1.2 L). (Reprinted from Dresser GK, Bailey DG, Leake BF, et al. Fruit juices inhibit organic anion transporting polypeptide-mediated drug uptake to decrease the oral availability of fexofenadine. Clin Pharmacol Ther 2002;71:11–20, with permission from American Society for Clinical Pharmacology and Therapeutics.)

To rectify this, a classification system is in use. Twelve main cytochrome-P450 gene families have been identified in humans and are designated by a number. To increase specificity, each family is then divided further into a subfamily designated by a letter. Last, the specific location of the gene responsible for the production of that isoform is listed. Thus, CYP2D6 is a cytochrome-P450 protein located in a genetic family with at least 40% similar amino acids and is designated by the number "2." The family is further categorized to amino acids with similar sequences. This is designated by the letter "D." The gene responsible for this particular isoform can be found on chromosome 6. Nine cytochrome-P450 enzymes metabolize most medications but it is CYP3A4 that is responsible for the vast majority of this activity. Following CYP3A4 in importance is CYP2D6.

As an example of the variability in the CYP450 family, consider CYP2D6. This isoform is absent in 7% of Caucasians and 1–2% of non-Caucasians. Extra copies of the isoform are common in East Africans; up to 30% of this population evidences hyperactivity. CYP2D6 is responsible for the primary metabolism of such drugs as codeine, many β-blockers, and tricyclic antidepressants. It is inhibited by drugs such as fluoxetine, haloperidol, paroxetine, and quinidine. Keeping these factors in mind, consider a patient who presents to the emergency department after an automobile accident.

The subject is a healthy young woman, admitted for observation and prescribed codeine for pain. After receiving several doses of codeine through the night, she becomes nauseated and complains of continued unrelieved pain. In evaluating this patient would it be prudent to increase the dose of codeine and add an antiemetic? Or is it possible that she abuses narcotics and thus has developed a tolerance? In this particular case neither explanation is correct. In completing an admission history it should be noted that the patient is also taking paroxetine for depression associated with premenstrual syndrome, and this is an important clue to her lack of response to codeine.

Codeine is a prodrug which requires biotransformation by CYP2D6 to its active metabolite, morphine sulfate. Paroxetine inhibits CYP2D6. Thus, repeated doses of codeine do not relieve this patient's pain and increase the adverse reaction of nausea. Paroxetine requires a 14 d wash-out period before it is totally eliminated from the body, so its inhibitor effects will be seen in this patient for some time. There are many such drug–drug interactions resulting from issues with the CYP450 system that should be considered. If the individual was of East African descent it would be possible that codeine would never be effective as many individuals in this population lack the required catalysts. This is a perfect example of genetic variability and the role that CYP450 plays in drug efficacy and ADEs. Even something as innocuous as fruit juices can inhibit these enzymes and leave patients to appear as if they are totally lacking the necessary proteins for drug metabolism (Fig. 5-2).

Genetic differences in individuals' ability to metabolize a drug through a given pathway are important contributors to the large interindividual differences in biotransformation within a population. There are PM, EM, and ultra rapid metabolizers, each with progressively more metabolic capacity. Genetic polymorphisms are often responsible for this variability but xenobiotics can also cause changes in the ability to metabolize a drug. For example, CYP1A2 is induced by smoking tobacco and catalyzes the primary metabolism of drugs such as theophylline. Prolonged exposure to tobacco smoke frequently results in chronic obstructive pulmonary disease, often treated with theophylline. Yet the cause of the disease may result in the treatment being ineffective.

A hypothetical example serves to illustrate the potential clinical impact of variability in drug metabolism among individuals. After drug X was tested and approved within a population and becomes commonplace, exposures increase and various patterns become evident. EMs in this population evidence normal enzyme activity. They would represent 75–85% of the hypothetical population. The EMs are homozygous (+/+) or heterozygous (+/–) for the genetic alleles most prevalent in the population and therefore would possess the enzymatic potential to safely metabolize drug X.

Ultra rapid metabolizers would constitute 1–10% of the target population. These individuals would have high-activity alleles that code for the necessary metabolic enzymes leading to very rapid metabolism of the drug. Thus, drug X will never have a chance to reach therapeutic levels. Efficacy would likely never be seen because of increased drug clearance. ADEs may occur as drug X metabolizes rapidly resulting in high metabolite concentrations.

The remaining percentage of the population would fall into the classification of PM. Genetic mutations resulting in loss of function or total absence of the alleles coding for the necessary metabolic enzymes would result in high blood level of a drug. This group would be particularly prone to ADEs as the drug reaches toxic levels.

TRANSPORTERS, TARGETS, AND RECEPTORS The journey is not finished once a drug gets past the cytochrome-P450 system. As stated, drugs must traverse other obstacles to reach their targeted sites. A key ATP-dependent drug efflux transporter (P-glycoprotein), encoded by the multidrug resistance gene (*MDR1*), can play a large role in the availability of protease inhibitors in vitro. Disrupting the function of the P-glycoprotein gene in mice caused the plasma concentration of indinavir, nelfinavir, and saquinqvir to rise dramatically. A compound that would effectively target this P-glycoprotein would result in much higher concentrations of protease inhibitors and thereby more effective HIV treatment.

The *MDR* gene results in the transport out of the cell of a variety of compounds such as cyclosporine A and fexofenadine. In addition its overexpression in a malignancy is associated with

resistance to chemotherapeutic agents such as adriamycin and paclitaxel. A broad family of transporter mediators including multiple variants of the *MDR* gene is being studied for their role in drug uptake in the brain, intestine, liver, and kidneys.

Designing drugs to interact with proteins directly involved with the disease process results in more effective treatment. A prominent example of this is the drug trastuzumab (Herceptin®). Herceptin is a recombinant DNA-derived humanized monoclonal antibody that selectively binds with high affinity to the extracellular domain of the human epidermal receptor 2 (HER2). HER2, one of the members of the family of epidermal growth factor receptors, is overexpressed in about 25% of breast tumors. This overexpression portends a poor prognosis. Herceptin® has proven to be highly effective in this population. However, because the drug target is HER2, tumors that do not overexpress this receptor will not be affected by the drug. For this reason genetic testing of tumor tissue by means of fluorescent *in situ* hybridization or immunohistochemical assessment is routinely conducted to determine the value of adding Herceptin to a treatment regimen.

Another example from oncology is the chemotherapeutic agent fluorouracil. A large percentage of this agent is catabolized by the enzyme dihydropyrimidine dehydrogenase (DPD). DPD enzyme deficiency can result in the shunting of fluorouracil into an alternate pathway leading to profound cytotoxicity. This is an instance where testing for the DPD genotype would profoundly increase patient safety.

Oncology is not the only area where progress is being made in the field of pharmacogenetics. Mutations have been identified in the gene *MDR1* that can result in increased plasma concentrations of digoxin, an agent with a notoriously narrow therapeutic index. Function of the β_2 adrenergic receptor gene is a major determinant of an individual's response to albuterol, a common bronchodilator. Such clinically important genetic polymorphisms of the CYP450 system, drug targets, and transporters are being identified through continuing research.

HOST FACTORS Last is the issue of host factors. Common single gene disorders such as Factor V Leiden need to be considered when medications are prescribed. The prescribing of oral contraceptives to individuals with this prothrombin gene variant greatly increases a woman's risk for deep vein thrombosis. Although mass screening of women for this mutation would prevent the inappropriate exposure of susceptible individuals to oral contraceptives, it would not be cost-effective and would present other problems such as an increase in unwanted pregnancies and the attendant health impacts that would follow. The best alternative is a thorough discussion between patients and practitioners to reveal any family history of thrombosis. This approach would increase patient satisfaction as well as safety.

Fetal alcohol syndrome may occur when a fetus is exposed to elevated alcohol levels although being carried by a mother with polymorphisms in alcohol dehydrogenase. Individuals with the 677C-T polymorphism in the *MTHFR* gene have reduced enzyme activity, which results in elevated plasma homocysteine levels. This inborn error of folic acid production can easily be corrected with supplemental folic acid and may also provide some explanation for the observed prevention of neural tube defects by folic acid.

6 Hemophilia as a Model Disease for Gene Therapy of Genetic Disorders

JAY LOZIER

SUMMARY

Gene therapy offers the potential for cure of hemophilia, a sex-linked genetic bleeding disorder caused by deficiency of either coagulation factor VIII or coagulation factor IX. The features of hemophilia that make it a leading candidate for gene therapy include the fact that the factor VIII and factor IX genes have been identified and cloned, therapeutic benefit would result from achieving expression at plasma levels as low as 1% of normal, and a wide variety of gene transfer vectors and cell target types could be useful. The challenge is to obtain long-term gene expression at levels sufficient to prevent spontaneous bleeding, while avoiding unwanted toxicity or immune responses to the expressed clotting factor.

Key Words: Adenovirus; AAV; factor VIII; factor IX; gene therapy; gene transfer; hemophilia; lentivirus; retrovirus; vector.

INTRODUCTION

Hemophilia is a model disease for gene therapy of genetic disorders and has attracted tremendous attention from investigators interested in its cure as opposed to its treatment by protein replacement therapy. Hemophilia is actually two diseases, hemophilia A and hemophilia B, resulting from deficiency of factor VIII and factor IX, respectively (Fig. 6-1). The salient features of hemophilia that are attractive for gene transfer are as follows: each is a single-gene disorder, both the factor VIII and factor IX cDNAs have been cloned; active protein may be expressed from either gene in various cell types as long as the correct post-translational modifications are made. Additionally, as little as 1% of normal protein levels could moderate the bleeding phenotype significantly. Overexpression should not be a problem owing to regulation of the factor VIII/factor IX enzyme complex by other downstream enzyme reactions of the blood coagulation "cascade" such as protein C, protein S, and antithrombin III anticoagulant proteins. Although epidemiological studies suggest elevated factor VIII or factor IX levels are associated with thrombotic diseases, it is unlikely that these superphysiological levels of factor VIII or factor IX would be achieved and sustained for the long periods of time described in these studies (years). Preclinical hemophilia gene transfer testing is facilitated by various small and large animal models such as factor VIII and factor IX knockout mice and spontaneous hemophilia A and B dog colonies. It also is possible to detect epitope-tagged human factor VIII or normal human factor IX in normal monkeys after gene transfer with various vectors, thus permitting assessment of vector safety as well as gene expression in vivo in nonhuman primates.

GENETICS OF HEMOPHILIA

Hemophilia A and B are both X-linked diseases. Thus, they are more common than bleeding disorders resulting from a deficiency of other (autosomal) coagulation factors because any male inheriting a mutation in either the factor VIII or factor IX genes will manifest disease. Inbreeding to produce two defective alleles in an affected individual is therefore not required and *de novo* disease resulting from new mutations is frequently seen. Hemophilia A is more common than hemophilia B for two reasons. First, the factor VIII gene is approx 186,000 bp long, five times the size of the factor IX gene, which is approx 34,000 bp in length. More DNA is therefore "at risk" for mutation by any mechanism in the factor VIII gene than in the factor IX gene. Second, there is a common unique inversion of the factor VIII gene that involves homologous recombination between a transcribed gene in intron 22 of the factor VIII gene and one or the other of two nontranscribed copies of this "factor VIII-associated" gene found outside the factor VIII gene. The resulting inversion puts the first 22 exons of the factor VIII gene in the opposite orientation to the last four exons, and no functional protein is produced in such affected individuals.

MOLECULAR BIOLOGY OF FACTOR VIII AND FACTOR IX

The molecular biology and physiology of factors VIII and IX are important to understand when considering gene therapy of hemophilia A or B. Factor VIII mRNA (approx 9.2 kb) is transcribed from the 186-kb gene in hepatocytes and endothelial cells of the liver and various other organs. Factor IX mRNA (approx 3 kb, half of which is untranslated) appears to be transcribed from the 34-kb gene in hepatocytes exclusively. Factor VIII circulates in trace amounts (approx 100–200 ng/mL) in plasma and has a half-life of 8–12 h in the circulation. Factor IX is found in plasma at levels of approx 5 µg/mL and has a half-life of 18–24 h. Unlike factor VIII, which remains in the circulation and does not normally enter the extravascular space, factor IX traverses blood vessels in equilibrium with the extravascular space. Both factor VIII

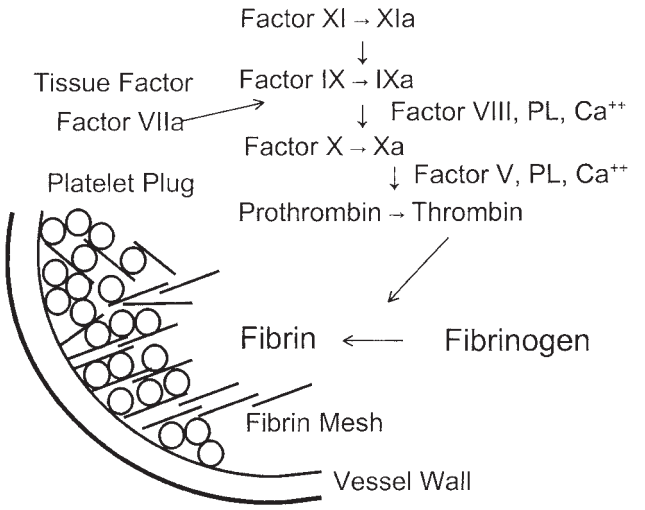

Figure 6-1 Blood coagulation and the coagulation cascade. Blood coagulation is a dynamic process in which the platelet initially forms a friable hemostatic plug at the site of damage to blood vessels; the temporary plug is reinforced by the deposition of a rigid protein mesh that consists of fibrin. Fibrin is produced by the polymerization of its precursor, fibrinogen, which is converted to fibrin through enzymatic cleavage by the enzyme thrombin. Thrombin is generated in small amounts by a series of tightly regulated enzymatic reactions (the coagulation "cascade") in which a series of serine proteases cleave one another so as to amplify an initiating signal leading to blood clotting. The physiological signal initiating blood coagulation is the subject of much debate but would seem to be mediated by the interaction of platelets with exposed vascular subendothelium followed by interactions between tissue factor (a ubiquitous, cell surface apolipoprotein) and coagulation factor VIIa, one of the coagulation enzymes that circulates in blood. A recurring theme of the coagulation cascade is the interaction of a serine protease with phospholipids in the presence of a large cofactor protein to form an enzyme complex that cleaves and thereby activates another serine protease, which in turn continues the chain of activation events until thrombin is produced. One of these complexes contains the serine protease enzyme factor IX and its cofactor protein, factor VIII. Deficiency of either factor VIII or factor IX results in the clinically indistinguishable bleeding disorders hemophilia A or hemophilia B, respectively. PL, platelets.

and factor IX undergo posttranslational modifications that include attachment of N-linked and O-linked oligosaccharide groups, phosphorylation and sulfation of certain amino acids, and, in the case of factor IX additional carboxylation of γ-carbons of certain glutamic acid residues and β-hydroxylation of a single aspartic acid residue. These properties of the factor VIII and factor IX proteins must be taken into account when designing gene therapy strategies for hemophilia A or hemophilia B.

GENERAL PRINCIPLES OF GENE TRANSFER

Gene therapy may be defined as introduction of a nucleic acid into cells or tissues of a patient with a disease in order to replace the missing function of the defective or absent gene. The process of introducing DNA or RNA into cells (gene transfer) can be accomplished using viruses that have been engineered to contain a gene (or expression cassette) in place of certain viral genes that are normally associated with virulence. This process of producing a viral vector serves the dual purpose of placing a desired gene into the vector for introduction into host cells and removing the viral genes that are required for its replication (and virulence) in the host. Two differing strategies, termed "in vivo" and "ex vivo" have been the primary strategies employed for gene transfer therapy experiments. In the in vivo approach, a DNA vector containing the desired corrective gene is infused into the living organism in hopes that cells will take up the vector and synthesize the desired product. This strategy is simple and convenient, but suffers from low efficiency of gene transfer. The ex vivo approach consists of removing the target cells from the organism (e.g., fibroblasts from skin, hepatocytes from liver, or hematopoietic cells from the bone marrow), growing them in the laboratory, and introducing the desired vector into the cells at this stage. The altered cells are then replaced back into the organism. This approach results in far more efficient gene transfer but is obviously much more cumbersome.

Typically retroviruses, adenoviruses, and adeno-associated viruses (AAVs) have been used as vectors for gene transfer; each has intrinsic properties that confer certain advantages and disadvantages for the purposes of gene transfer (Table 6-1). For instance, retroviruses have the ability to transfer nucleic acid fragments on the order of about 7 kb in size, adenoviruses can be modified to transfer nucleic acid fragments on the order of up to 34 kb in size, but AAV can only transfer fragments of about 5 kb in length. Titers of adenovirus vectors are typically on the order of 10^{12}–10^{13} vector particles/mL and are exceptionally efficient at in vivo gene transfer into cells of epithelial origin (e.g., lung, liver, and intestinal epithelium), whereas retrovirus vectors are not typically produced in titers of more than 10^8 vector particles/mL without special concentration procedures and are much less efficient at in vivo gene transfer. Accordingly, adenoviruses have been utilized mainly for in vivo gene transfer and retroviruses have been utilized most commonly for ex vivo gene transfer, particularly into hematopoietic cells. Unfortunately, most adenovirus vectors do not have the ability to mediate integration of nucleic acids into host chromosomal DNA to effect long-term gene expression, and furthermore have been associated with significant toxicity at high doses. Therefore, adenovirus vector-mediated gene transfer for long-term correction of a genetic defect is now considered less promising than other vector systems. AAV vectors have been proposed as gene transfer agents with the theoretical ability to mediate integration of nucleic acids, but lack the efficiency of retroviruses, especially the lentiviruses under study. Production of AAV vectors requires either the use of adenovirus as a helper virus, or multiple transfections of nucleic acid constructs into producer cells, which can be problematic because of the need to remove the adenovirus or the lower efficiency of nucleic acid transfections. Potential targets for gene transfer that have been addressed in preclinical studies in vivo include cells from skin, muscle, liver, and bone marrow.

GENE TRANSFER STUDIES IN HEMOPHILIA A AND B

Skin fibroblasts or keratinocytes are easily grown and transduced by a wide variety of gene transfer vectors that may contain selectable markers (e.g., neomycin resistance). Transduced cells can then be reintroduced to the host in which the desired protein will be produced and secreted into the bloodstream. Studies of factor VIII or factor IX transduced fibroblasts or keratinocytes in rodents have shown that significant levels of factor IX or factor VIII can be achieved using retroviral vectors. However, lack of sustained factor VIII or factor IX expression has been a recurring problem and may be owing to loss of transduced cells from cell-mediated immunity or promoter shutdown in the cells that remain

Table 6-1
Properties of Gene Transfer Vectors Used for Gene Therapy

Vector/system	*Category*	*Gene transfer capacity*	*Vector titer*	*In vivo tissue tropism/efficiency*	*Comments*
Retrovirus (Moloney murine leukemia virus)	ssRNA virus, enveloped	approx 8.8 kb	$>10^8$ transducing particles/mL	No clear in vivo tropism	Requires cell division for integration into cellular DNA
Retrovirus (lentivirus)	ssRNA virus, enveloped	approx 9.6 kb	$>10^8$ transducing particles/mL	No clear in vivo tropism	Can integrate into cellular DNA of nondividing cells
Adenovirus	dsDNA virus, nonenveloped	up to 34 kb	$>10^{11}$ pfu/mL	Epithelial cells (liver, lung, intestine)	Adenovirus serotype 5 most commonly used as vector
Adeno-associated virus (AAV)	ssDNA virus, nonenveloped	approx 4.5–5.0 kb	10^{13} vector genomes/mL	In vivo tropism varies with serotype	AAV serotype 2 most commonly used as vector; capacity varies with serotype
Herpesvirus (HSV)-1	dsDNA virus, enveloped	approx 30 kb	Not determined	Epithelial and neural cells	HSV-1 most commonly used as vector
Molecular conjugates	"Hybrid of viral/nonviral"	Unlimited	Not applicable	Tropism may be conferred by ligands in conjugate	Adenovirus capsids linked to DNA facilitate gene transfer
Liposomes	Nonviral	Unlimited	Not applicable	No clear in vivo tropism	Low efficiency of gene transfer in vivo; direct application to mucosal surface has been performed in vivo
Naked DNA	Nonviral	Unlimited	Not applicable	No clear in vivo tropism	Typically delivered by injection (e.g., "gene gun")

viable. One clinical trial has been performed in which factor VIII-transfected skin fibroblasts were reimplanted in the omentum. The peak factor VIII levels achieved were only marginally therapeutic, however, and were not sustained. The need to make autologous transduced cells for each individual patient's treatment could be approached by the use of standardized cell lines expressing factor VIII or factor IX contained in an immunoisolation device as protected allografts; however, this has not been tried in humans.

Gene transfer to muscle can be performed using appropriate promoters to direct tissue-specific gene expression. Engineered cells can be implanted in the host, and factor IX has been expressed in mice using muscle cells transduced before reimplantation. Alternatively, muscle cells have been encapsulated in alginate compounds before implantation to protect the modified cells in vivo, permitting them to express human factor IX in immunocompetent mice. Immunodeficient (nude) hemophilia B mice have developed tumors of myoblast origin after implantation of encapsulated cells, which raises the possibility that muscle cell therapies may be tumorigenic in humans under some circumstances. It would be much more practical to transduce myocytes in vivo because there are no human myoblast/myotube cell lines suitable for use in humans.

In vivo gene transfer to muscle by intramuscular injection would be more appealing than ex vivo approaches because the methodology is simpler; one vector could be used for all patients, and there would be no need for in vitro cultivation of patient myocytes. The most extensively studied application of this approach utilizes AAV vectors. AAV vectors can only transfer DNA of total length less than 4.5 kb, which can accommodate factor IX gene transfer, but not factor VIII gene transfer. Preclinical studies with AAV vectors in hemophilia B knockout mice and hemophilia B dogs have achieved sustained, clinically relevant plasma levels of factor IX using this approach. Poor delivery of recombinant factor IX by muscle into plasma is the key problem directly related to the use of muscle as an in vivo target for gene transfer. This has been attributed to binding of factor IX by type-IV collagen, and seems to be mediated by epidermal growth factor-like domains on factor IX. It also appears that AAV gene transfer is significantly more efficient in type-X (slow-twitch) fibers as compared with type-Y (fast-twitch) fibers, perhaps as a consequence of more AAV receptors on the cell surface for the former muscle fiber type. Clinical trials of AAV-factor IX gene transfer targeting muscle have demonstrated therapeutically significant plasma factor IX levels approaching 1% of normal in patients given 2×10^{11} vector genomes/kg. Patients reported fewer joint bleeds and administered fewer doses of factor IX after treatment as compared with the period before treatment. A placebo effect cannot be ruled out because this was an open label study, however. Hopes for greater factor IX plasma levels were not realized when higher doses of AAV-factor IX vector were given to other patients, and the factor IX levels seen in the early trials gradually disappeared. It is not clear whether the loss of factor IX was because of loss of vector, adsorption of factor IX by type-IV collagen, methylation of promoter DNA, or other epigenetic events; inhibitor

antibodies to human factor IX were not seen in any of these patients, however.

Nonviral gene transfer by electroporation of plasmid DNA has been studied. Using in vivo electroporation of plasmid DNA into muscle of mice and dogs it has been possible to demonstrate transient factor IX expression at levels of about 1% of normal, which was followed by an antibody response to foreign (human) factor IX. This technique requires confirmation of factor IX activity in hemophilia B animals to confirm its utility.

Factor VIII expression in muscle has not been shown to deliver active factor VIII to the circulation. The amount of factor VIII that can be expressed by muscle cells and secreted in active form into the circulation may be the chief limiting factor to this approach.

Liver hepatocytes synthesize many plasma proteins including coagulation factors VIII and IX, and make some proteins, such as albumin, in tremendous quantities. For these reasons, in vivo gene transfer to liver is one avenue being investigated for hemophilia gene therapy. Hepatocytes cannot be easily propagated in tissue culture, but in vivo gene transfer has been demonstrated in animals using adenovirus, AAV, and retrovirus vectors. Adenovirus vectors can mediate quantitative in vivo gene transfer to hepatocytes when administered intravenously. Thus, it is not surprising that adenovirus vectors have been used for in vivo gene transfer of factor VIII or factor IX to liver cells of mice, monkeys, and hemophilic dogs. Unfortunately, adenovirus-mediated gene transfer is typically characterized by a gradual decrease in gene expression. Moreover, adenovirus vector proteins in immune-competent animals induce numerous cytokines and have powerful adjuvant effects that may cause antibodies to the gene product to be formed. Efforts to create and test vectors with most of the adenovirus genes removed have been pursued, based on the observation that deletion of adenovirus vector genes may result in longer periods of gene expression and a decreased immune response. Problems with production of large quantities of these highly deleted vectors have impeded the translation to clinical trials. At least one clinical trial is testing an extensively deleted adenovirus vector for in vivo factor VIII gene transfer. Use of adenovirus vectors may be limited by neutralizing antibodies to the common serotypes, which commonly infect humans; however, the sequential use of different serotypes of adenovirus vector might be employed to circumvent this problem.

Although AAV-mediated factor VIII gene transfer to liver in vivo has been reported, gene transfer to liver hepatocytes using AAV vectors has focused largely on factor IX, because of the size constraints of vector DNA packaging. Gene transfer of factor IX DNA by intravenous, portal vein, or hepatic artery injection of AAV vectors has resulted in expression of factor IX in mice, dogs, and nonhuman primates. The results of these studies have justified clinical trials, one of which is underway in patients with hemophilia B. This trial was temporarily put on hold because of vector shedding in the semen of the first subject enrolled. After showing that the AAV vector was not incorporated in germline DNA, the trial has resumed but data on factor IX gene transfer and expression are not yet available.

In the field of AAV vector development it has sometimes been difficult to predict the effectiveness of in vivo gene transfer from the results of in vitro experiments. Accordingly, many new approaches are being evaluated. It has been shown recently that different AAV vector serotypes (e.g., AAV 1, AAV 5, AAV 7, AAV 8, and so on) may have advantages for gene transfer regarding DNA capacity or efficiency of gene transfer in particular cell types or animal species, as compared with the AAV 2 vectors that have been more commonly utilized. Some of the "new" AAV serotypes have been identified as pathogens in nonhuman primates, and their utility in human gene therapy has yet to be proven.

Although retroviral vectors based on Moloney murine leukemia viruses are not suitable for in vivo gene transfer to hepatocytes owing to the low rate of cell division in this cell type, lentivirus vectors (which can transfer genes into nondividing cells) may be useful for hemophilia gene therapy. Pseudotyped lentiviral vectors have been used to transfer the factor VIII cDNA into liver more efficiently than nonpseudotyped vectors.

Hematopoietic cells are logical targets for gene transfer because they could be transduced ex vivo and returned to the donor by marrow transplantation, after which progeny cells would circulate in the bloodstream. In the case of platelets, an additional advantage might be realized because they would be concentrated at the site of vascular injury where factor VIII or factor IX is needed most. Such hematopoietic cell gene transfer has been attempted as an experimental approach to both hemophilia A and B. Retroviral gene transfer of the (B domain-deleted) human factor VIII gene into hemophilia A knockout mouse bone marrow did not result in detectable plasma levels of human factor VIII after transplantation with concomitant myeloablation, but immune tolerance to human factor VIII in recipients of transduced bone marrow was conferred. A nonspecific viral (long terminal repeat) promoter was used to drive expression of factor VIII, thus the vector could in theory direct expression in any progeny cell type, including many nonhematopoietic cell lineages. It is possible that expression of factor VIII in either hematopoietic or nonhematopoietic progeny cells could mediate the immune tolerance response that was seen after gene transfer in these experiments. Similar experiments using a lentiviral vector that expressed factor VIII in hematopoietic cells resulted in antibodies to human factor VIII in mice that were transplanted with transduced bone marrow; it is suggested that the immunogenic (rather than "toleragenic") effect might be owing to higher expression levels seen in lentivirus-transduced cells and/or more efficient transduction of antigen-presenting cells.

Erythroid and megakaryocytic cell lines secrete significantly higher levels of factor VIII than do B- or T-cell lines in vitro when transduced with lentivirus vectors containing factor VIII expression cassettes. Cytokine stimulators had little effect on factor VIII expression, but differentiating agents such as phorbol myristic acid, which activates protein kinase C, induce approx two- to threefold greater factor VIII expression.

Human myeloid leukemia (HL)-60, cells can express factor IX in vitro when transduced by Moloney retroviral vectors; expression from the CMV promoter is increased with phorbol myristic acid (a monocytic differentiating agent) or dimethylsulfoxide (a granulocytic differentiating agent). Human erythroleukemia cells can express factor IX in vitro when expressed under control of a megakaryocyte-specific (glycoprotein IIb) promoter, suggesting that platelets could store the expressed protein in granules that would be available for release at the site of platelet aggregation in vivo. Induction of differentiation resulted in increased levels of factor IX expression in vitro as was seen in previous work with myelomonocytic leukemia cells. However, factor IX has not been expressed at clinically significant levels in vivo by hematopoietic cells.

Stromal fibroblasts are cells from bone marrow, which can be obtained by modestly invasive methods (marrow aspiration) and can be grown easily in tissue culture and transduced by retroviral vectors in vitro. Human marrow stromal cells transduced ex vivo

with a gibbon ape leukemia virus-pseudotyped Moloney retroviral vector containing a factor VIII expression cassette showed clinically significant (6% of normal) factor VIII levels after reimplantion of cells in the spleen of NOD-SCID mice. Expression of human factor VIII ceased after approx 4 mo owing to promoter inactivation, however. Reinfusion of factor IX-expressing bone marrow stromal cells in canines after irradiation of marrow (to facilitate growth of infused cells in the marrow) led to detectable levels of factor IX in plasma; it is unlikely that such a procedure would be practical in humans, however.

Under appropriate culture conditions cells that have the properties of endothelial cells can be induced to grow from nucleated peripheral blood cells. These so-called blood outgrowth endothelial cells (or BOECs) have been isolated from humans, transduced with factor VIII vectors, and infused into immunodeficient mice in which they have expressed significant amounts of factor VIII. The BOECs have been shown to persist with endothelial cell properties in the spleen and bone marrow of treated mice. Use of autologous BOECs transduced with factor VIII or factor IX vectors may be another relatively noninvasive avenue for gene therapy of hemophilia in humans.

FUTURE DIRECTIONS

Future issues to be addressed in the field of gene therapy include minimization of the risk for immune response and antibody formation, development of vectors that can sustain high levels of protein expression, and avoidance of germline transmission of vector nucleic acid sequences. It will be instructive to see whether inhibitor antibodies to factor VIII or factor IX in hemophilia gene therapy patients will be observed once the technology is applied to patients who have not had extensive exposure to clotting factor proteins. Novel viral vectors are rapidly being developed and their suitability for gene transfer is being assessed. Novel strategies for expression of relatively large genes such as factor VIII cDNA are required and so-called split vectors may someday permit hemophilia A gene therapy with AAV vectors. Another potential avenue for the introduction of large genes such as hemophilia A is the use of vectors that mediate splicing of normal mRNA in place of defective or missing 3′ mRNA in the message. This method has resulted in transient therapeutic factor VIII levels in hemophilia A knockout mice, and in principle would be an attractive approach to the problem in the common intron 22 inversion of the factor VIII gene in which the last 4 of 26 exons are missing. The hemophilia A dogs in which the same inversion mechanism occurs would be a good model in which to test this approach before clinical trials in patients.

Concerns for the safety of retroviral gene transfer to bone marrow cells have been raised by the finding of clonal T-cell proliferation in two young patients with X-linked severe combined immunodeficiency (SCID)-X1 treated with retroviral gene transfer; in both cases the vector was shown to be integrated into genomic DNA of T cells near the *LMO2* proto-oncogene promoter. It remains to be seen whether this event is specific to patients with SCID-X1, the vector construct used in the trial, or retroviral vectors in general. The lack of similar adverse events in extensive preclinical and clinical experience with retroviral vectors in other trials suggests that the problem is not generic to retroviral vectors. The problem of T-cell leukemogenesis may be related to the selective advantage that T cells gain in SCID patients after transduction with the γ-subunit of the IL-2 receptor (IL2Rγc), compared with nontransduced T cells. Further, the IL2Rγc gene sequence may preferentially integrate in the *LMO2* genomic DNA sequence.

Vector constructs that mediate integration by novel methods have also been described. Novel targets, such as intestinal epithelial cells that have been transduced in vitro by viral and/or nonviral vectors, need to be studied in vivo. These areas are being addressed by investigators throughout the world.

7 Genetic Counseling

Robin L. Bennett

"Genetic counseling is the process of helping people understand and adapt to the medical, psychological and familial implications of genetic contributions to disease. This process integrates:

— Interpretation of family and medical histories to assess the chance of disease occurrence or recurrence.

— Education about inheritance, testing, management, prevention, resources and research.

— Counseling to promote informed choices and adaptation to the risk of condition."

—National Society of Genetic Counselors, 2006

SUMMARY

Genetic counseling is an expanding field in the age of genomic medicine. Genetic counselors provide services to clients across the lifespan, from preconception counseling to prenatal diagnosis, the diagnosis of newborns or pediatric genetic disorders, and the diagnosis of adults with inherited predisposition to diseases such as cancer, presenile dementia, psychiatric disorders, and heart disease. The approach to genetic counseling involves assessing family, medical, and environmental history to determine disease risk; assisting in genetic testing, diagnosis, and disease prevention and management; and offering psychosocial and ethical guidance to help patients make informed, autonomous health care and reproductive decisions. Genetic counseling focuses on complex issues related to the value of genetic testing, and on medical interventions and health care practices that have varying degrees of efficacy and success. The traditional dogma that genetic counseling must be nondirective is being challenged in favor of a psychosocial approach that emphasizes shared deliberation and decision making between the counselor and the client.

Key Words: Cancer genetics; genetic counseling; genetic testing; neurogenetics; prenatal genetics.

INTRODUCTION

Historically, the practice of genetic "counseling" focused on providing information about recurrence risks for particular conditions within a family. The first clinics providing information on disease inheritance were established in the early 1900s in Cold Spring Harbor, New York and the University College, London, where scientists collected data on human traits and sometimes provided information to affected families, with the primary purpose of "…accumulating and studying records of physical and mental characteristics of human families to the end that the people may be better advised as to reproduce fit and unfit marriages, and in order to establish the potentialities of an individual."

The horrendous excesses of Nazi Germany and the eugenics movement in the first half of the 20th century led to a retreat from advising families about potential hereditary conditions to a more neutral educational model. Risk information was provided to couples and families with the main options being to "take their chances" by becoming pregnant or to refrain from pregnancy. Sheldon Reed is credited with introducing the term "genetic counseling" in 1947. In the 1940s, genetics clinics were staffed by physicians and doctoral geneticists, using a medical/prevention model that primarily involved providing "facts" (risk figures, natural history, and treatment information) so that couples and families could make informed reproductive decisions.

With the advent of carrier testing and prenatal diagnosis in the 1960s and 1970s, couples and families were faced with a new range of choices. The educational model of providing genetic information did not facilitate patient decision-making. In 1969, Melissa Richter had the foresight to initiate the development of a master's degree program in genetic counseling. The provision of genetic information shifted to a more client-centered approach with information being presented within a psychological and cultural context so clients could make informed decisions regarding genetic testing and reproductive options. A tenet of nondirectiveness, particularly regarding reproductive choices, was held firmly in this genetic counseling model, to demonstrate respect for patient's autonomy and to clearly distance the genetic counselors of this era from the earlier eugenics movement.

Genetic counseling is an expanding field in the age of genomic medicine. Genetic counselors provide services to clients across the lifespan, from preconception counseling to prenatal diagnosis, the diagnosis of newborns or pediatric genetic disorders, and the diagnosis of adults with inherited predisposition to diseases such as cancer, presenile dementia, psychiatric disorders, and heart disease. The approach to genetic counseling involves assessing family and environmental history to determine disease risk; assisting in genetic testing, diagnosis, and disease prevention and management; and offering psychosocial and ethical guidance to help patients make informed, autonomous health care and reproductive

decisions. Genetic counseling focuses on complex issues related to the value of genetic testing, and on medical interventions and health care practices that have varying degrees of efficacy and success. The traditional dogma that genetic counseling must be nondirective is being challenged in favor of a psychosocial approach that emphasizes shared deliberation and decision-making between the counselor and the client. As genetic counselor Beth Fine noted in 1998, "Genetic counselors function within the health care system as patient advocates who aim to empower patients and families to find solutions to problems and ways of coping that are optimal for them."

WHAT IS UNIQUE ABOUT GENETIC INFORMATION?

As more tests are developed that identify a hereditary component to common chronic disorders such as cancer, heart disease and presenile dementia, genetic disorders are no longer categorized in the exclusive realm of rare, mostly pediatric diseases. Competency in genomic medicine is important for all health professionals, and an idea of "genetics exceptionalism" may no longer apply. But there are still several features of genetic information that present unique personal, family, and social consequences that distinguish genetic disorders from other nonhereditary medical conditions.

Obviously, genetic disorders are familial. A genetic diagnosis may embrace multiple generations and members of a family. Often, to provide comprehensive risk assessment to relatives, molecular testing must first be performed on an affected relative to identify the specific gene mutation. When a client seeks an opinion of a surgeon for knee surgery, no other relatives are involved; the consultation remains a private conversation between the consultant and the health provider. In contrast, a healthy woman with a strong family history of breast cancer seeking an opinion regarding her options for breast cancer risk reduction and surveillance may need to obtain medical records and death certificates on multiple affected relatives. Testing the client's affected mother or sister to identify a gene mutation may be important to provide the consultant with critical information regarding whether she has a high lifetime risk to develop breast and possibly other cancers. In medical genetics, a whole extended family often becomes the client unit, raising unique issues of confidentiality and privacy of health and personal information.

Knowledge of familial disease risks might have profound effects (both positive and negative) on interpersonal relationships among family members. Parental guilt is a common experience of the parents of affected offspring. Children might blame a parent for passing on the genetic disorder in the family, or partners may blame each other for the birth of an affected child. Survivor guilt is another common problem that is experienced by unaffected individuals in a family who have "escaped" the genetic disease in the family. The healthy individuals may wonder why they are unaffected whereas other relatives have been less fortunate. The "survivor" may feel on the outskirts of the "family team" despite knowing it is irrational to desire ill health.

The familial nature of genetic disorders may alter reproductive plans of many relatives. The parental role is often threatened by learning genetic carrier status. There may be challenges to religious and ethical belief systems between couples and their extended family as couples wrestle with core values of biological parenting and views on adoption, assistive reproductive technologies (including donor gametes and preimplantation diagnosis), prenatal diagnosis, and potential abortion.

Although remarkable advances are continuing to be made in the general understanding of the mechanism of many genetic disorders, unfortunately, durable cures such as gene therapy have been slow to become reality. The permanent nature of genetic disease may bring a sense of fatalism or hopelessness with the diagnosis or results of genetic testing.

Genetic disorders are chronic, thus there is often a continual array of new health and physical challenges over a person's lifetime. Individuals with a genetic disorder often experience increasing medical problems as they age. The individual and the family may experience "chronic sorrow" for the "healthy person who will never be."

Genetic disorders are complex, usually affecting multiple organ systems. Frequently, a multidisciplinary team approach is needed to provide comprehensive care to persons with inherited disorders. Individuals with rare genetic disorders often face continual frustration attempting to locate health professionals with experience in their condition. They may feel extremely isolated, with a sense that no one else is quite like them. Linking these individuals through disease specific support networks (such as the Genetic Alliance) can be instrumental in providing clients with the emotional and medical support they require. Genetic disorders often demonstrate enormous variability of disease expression, with some individuals having few manifestations and others have multiple disabling features of the condition. This clinical variability further confounds the understanding of appropriate management for individuals with genetic disorders and makes prognostic predictions close to impossible.

Unfortunately, genetic disorders continue to be labeling. As Francis Galton observed, "Most men and women shrink from having their hereditary worth recorded. There may be family diseases of which they hardly dare to speak, except on rare occasions, and then in whispered hints, or obscure phrases as though timidity of utterance could hush thoughts…." A genetic diagnosis still carries the potential for social stigma. A person may be considered less desirable as a mate or employee. The family may feel their heritage is "tainted." Fear of genetic discrimination (insurance, employment, and societal) may hinder the willingness of individuals and their families to participate in genetic testing and research.

The ability to test a healthy person for possible future health status provides new challenges to traditional definitions of "healthy" and "diseased." Not long ago, the usual appointment with a health professional centered on the client's specific medical symptoms. Now, a healthy person can be tested for a growing list of potential inherited diseases. Yet, the spectrum of disorders for which there is effective medical therapy remains relatively small compared with the burgeoning number of available genetic tests. None of these genetic tests predict the exact age a person will develop the genetic condition nor do they predict the specific manifestations and severity of the disease. Jonsen and colleagues coined the term the "unpatient" for this group of "genetically unwell" but outwardly healthy individuals who have inherited a gene mutation predisposing to disease. An individual with diagnostic results that are opposite of his or her preconceived affected status may be at higher risk for adverse psychological consequences. Results of genetic testing may alter the person's self-concept and self-esteem, as well as his or her perceptions of wellness and genetic or social identity.

WHO ARE GENETIC COUNSELORS?

Genetic counseling is a distinct medical specialty with the role of providing clinical health care, education and emotional support to individuals and families challenged by congenital and inherited diseases. The field of genetic counseling developed from a

Table 7-1

International Federation of Human Genetics Societies	www.ifhgs.org/genetics/ifhgs/members.htm

need to educate, manage, and counsel individuals and families diagnosed with, or at risk for genetic diseases, with respect to how these conditions affect the psychological, medical, financial, and social aspects of life.

The term "genetic counselor" is generally reserved for masters-level health professionals with extensive training in human genetics and counseling skills. The first group of ten genetic counselors graduated from Sarah Lawrence College in 1971. There are 30 programs in the United States and Canada accredited by the American Board of Genetics Counseling (ABGC) with similar programs in place in the United Kingdom, South Africa, Australia, Cuba, Norway, the Netherlands, Taiwan, Spain, Sweden, Saudi Arabia, Japan, France, Israel, and China. As of 2004, there were more than 2300 members of the professional society of genetic counselors, the National Society of Genetic Counselors.

Graduates from genetic counseling programs accredited by the ABGC demonstrate competencies in 27 areas within four critical domains: communication, critical-thinking, interpersonal counseling, and psychosocial assessment, and professional ethics and values. Didactic coursework in genetic counseling training programs involves human and medical genetics, cytogenetics, developmental biology and embryology, teratology, statistics, qualitative and quantitative research, counseling theory, communication skills, interviewing techniques, and public health. Clinical skills are obtained by a combination of role-playing and >800 h of comprehensive supervised fieldwork in a variety of practice settings. Teaching experience and completion of a thesis or other scholarly enterprise are ABGC accreditation requirements. Program lengths are approx 2 academic years.

Adopted in 1993 and revised in 2006, The Code of Ethics of the National Society of Genetic Counselors is an "ethic of care," because this approach emphasizes the interdependence of individuals and reflects the values, principles and beliefs of genetic counselors. The relationships are genetic counselors themselves; genetic counselors and their clients; genetic counselors and their colleagues; and genetic counselors and society. A primary focus is respect for client autonomy and patient advocacy.

Most genetic counselors work in university medical centers, private and public hospitals, or large medical facilities. Genetic counselors work independently or as a member of a multispecialty team. An increasing number of genetic counselors work with diagnostic laboratories and pharmaceutical companies as well as in positions related to the development of government and public policy. Genetic counselors are also uniquely trained to work as research coordinators for genetic research studies. Most genetic counselors are involved in education, including providing education to a variety of health professionals and community organizations, as well as students at all levels, from elementary schools to postgraduate programs.

Other health professionals that are specifically trained to provide genetic counseling services include physician (medical) geneticists and clinical nurse specialists in genetics. Medical geneticists attend a fellowship or residency program through a program accredited by the American Board of Medical Genetics or the Canadian College of Medical Genetics. Clinical geneticists often have particular areas of interest such as oncology, pediatrics, dysmorphology, prenatal diagnosis, neurogenetics, or metabolic disorders. Advance Practice Genetic Nurses meet genetic competencies through a portfolio process established by the International Society of Nurses in Genetics and the Genetic Nurses Credentialing Committee.

All health care professionals need to develop basic aptitude in human genetics as genomic medicine becomes incorporated into all fields of medicine. The National Coalition of Health Care Provider Education in Genetics has developed a set of core competencies that can be adapted to various health specialties. Recognizing the need for genetic counseling and referral to a genetics specialist is an important component of these competencies. Table 7-1 includes a list of resources for locating health professionals with expertise in genetic counseling and medical genetics; many of these listings include specialty areas of practice (such as cancer genetics, neurogenetics, prenatal genetics, and so on).

THE PROCESS OF GENETIC COUNSELING

Genetic counseling sessions with clients and their families may involve a one-time crisis intervention dealing with a new genetic diagnosis, or may develop into a relationship over many years if the client is treated in a specialty clinic for diseases such as hemophilia, neurofibromatosis, fragile X syndrome, or Huntington disease. The genetic counseling intervention is designed to reduce the client's anxiety, enhance the client's sense of control, and mastery over life circumstances, increase the client's understanding of the genetic disorder and options for testing and disease management, and provide the individual and family with the tools required to adjust to potential outcomes. A major paradigm of genetic counseling is that it is noncoercive. The information provided during genetic counseling helps the individual and family personalize often threatening information in order to clarify their values and strengthen their coping mechanisms.

Whether a genetic counseling session is a one-time visit or over many years, there are three broad areas that are covered in each session, assessment, education, and counseling.

ASSESSMENT The process of genetic counseling begins with "contracting"—the merging of the counselor's and client's expectations. Why is the client here? What are their concerns? What are the mutual expectations and goals of the session? Gathering information during the phone intake or early in the visit assists in developing patient rapport and realistic expectations of the visit as well as appropriate triage to other health professionals. Explaining what will happen and who is involved in the visit can help alleviate client anxiety. What are the client's preconceived notions about patterns of inheritance, chances of testing positive or developing the family disorder? What is the perceived burden of the disease (financial, emotional, and social)? If the genetic counseling information is divergent from a client's perceptions, the client may have difficulty incorporating the information or implementing disease-management recommendations. Throughout the process of genetic counseling,

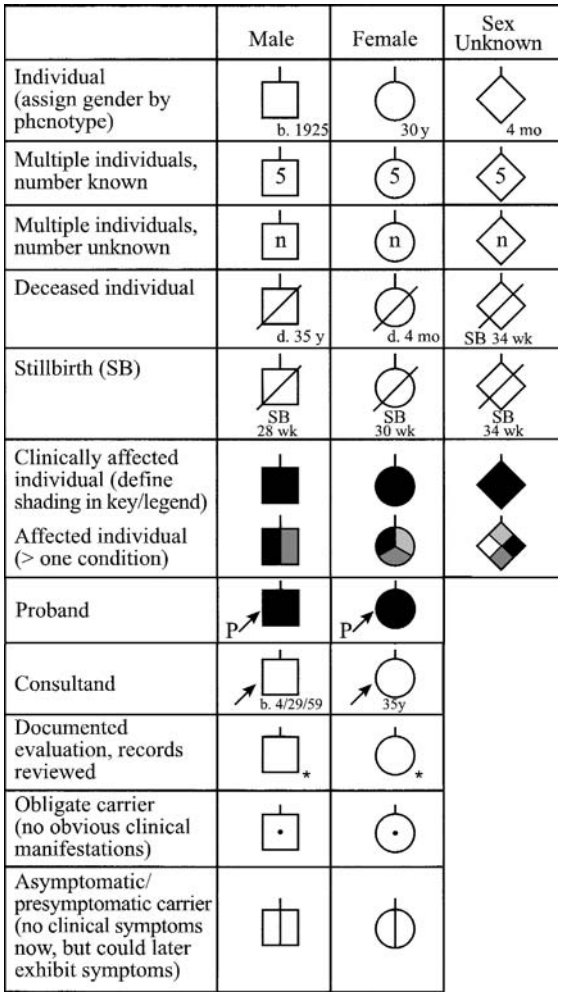

Figure 7-1 Pedigree symbols. Reproduced with permission from the University of Chicago, from Bennett RL, Steinhaus KA, Uhrich SB, et al. Recommendations for standardized human pedigree nomenclature. Am J Hum Genet 1995;56:745–752.

there is continual appraisal of family beliefs about causation, and of emotional, experiential, social, educational, and cultural issues that may affect the client's incorporation of information and coping patterns.

Early in the session a medical family history is recorded using standard pedigree symbols (Figs. 7-1–7-3). Usually a pedigree includes two generations of ascent from the consultant (the person seeking information) or proband (the first affected relative who brings the family to medical attention), and two generations of descent. For example, pedigree assessment for a 60-yr-old man with a family history of colorectal cancer would include information about his parents, grandparents, aunts and uncles, and possibly his cousins, as well as information regarding his siblings, children, and likely his grandchildren. A pedigree is an important method of establishing patient rapport and serves as a visual demonstration for providing patient education on variation in disease expression in the family, as well as identifying other relatives at risk for disease.

Statistical risk assessment based on pedigree analysis, epidemiology (such as Hardy-Weinberg equilibrium), various risk models (such as Bayes theorem), and the sensitivity and specificity of various genetic tests is central to genetic counseling. Genetic counseling involves explaining risks in multiple ways, such as distinguishing absolute from relative risks (e.g., a 10% absolute risk but a threefold increased relative risk), and using percentages to frame the magnitude of risks from different perspectives. For example, if an autosomal-recessive pattern is the mode of inheritance, the chance of having an affected child would be framed in terms of a 25% or one in four chance of occurrence or recurrence, as well as a 75% chance or three in four chance that a son or daughter would be unaffected.

Has a diagnosis been established? Confirmation of family medical information through review of medical records and death certificates or even obtaining family photographs can be essential to ensure that the pedigree, and thus the risk assessment provided to the client, is based on accurate information. A client's recall of information about second- and third-degree relatives (e.g., aunts and uncles, grandparents, and cousins) is much less likely to be accurate than information about more closely related relatives (e.g., siblings, parents, and children).

EDUCATION AND HEALTH PROMOTION Knowledge is more than information. Genetic counselor Ann C. M. Smith noted, "Individuals and families affected by genetic diseases face a plethora of high tech information from which they seek to gain true knowledge about their genetic circumstances. What is said and how information is communicated can have a significant impact on their ability to process the information, and to their understanding and assimilation into personal life circumstances. To place more power into the hands of individuals and their families affected by genetic disease is to be sure that they have adequate knowledge—not just information—about their genetic circumstance…the genetic counselor seeks to effectively "communicate" such highly technical genetic information in a way that is compassionate, empathic, and sensitive to the ethnocultural values of the client. In this way, the genetic encounter moves from basic patient education to the multifaceted practice of genetic counseling."

Genetic education and health promotion usually involves communication about the following areas:

- Discussing options for available genetic testing or diagnostic procedures (including testing costs, sensitivity, and specificity), and arranging for testing as appropriate.

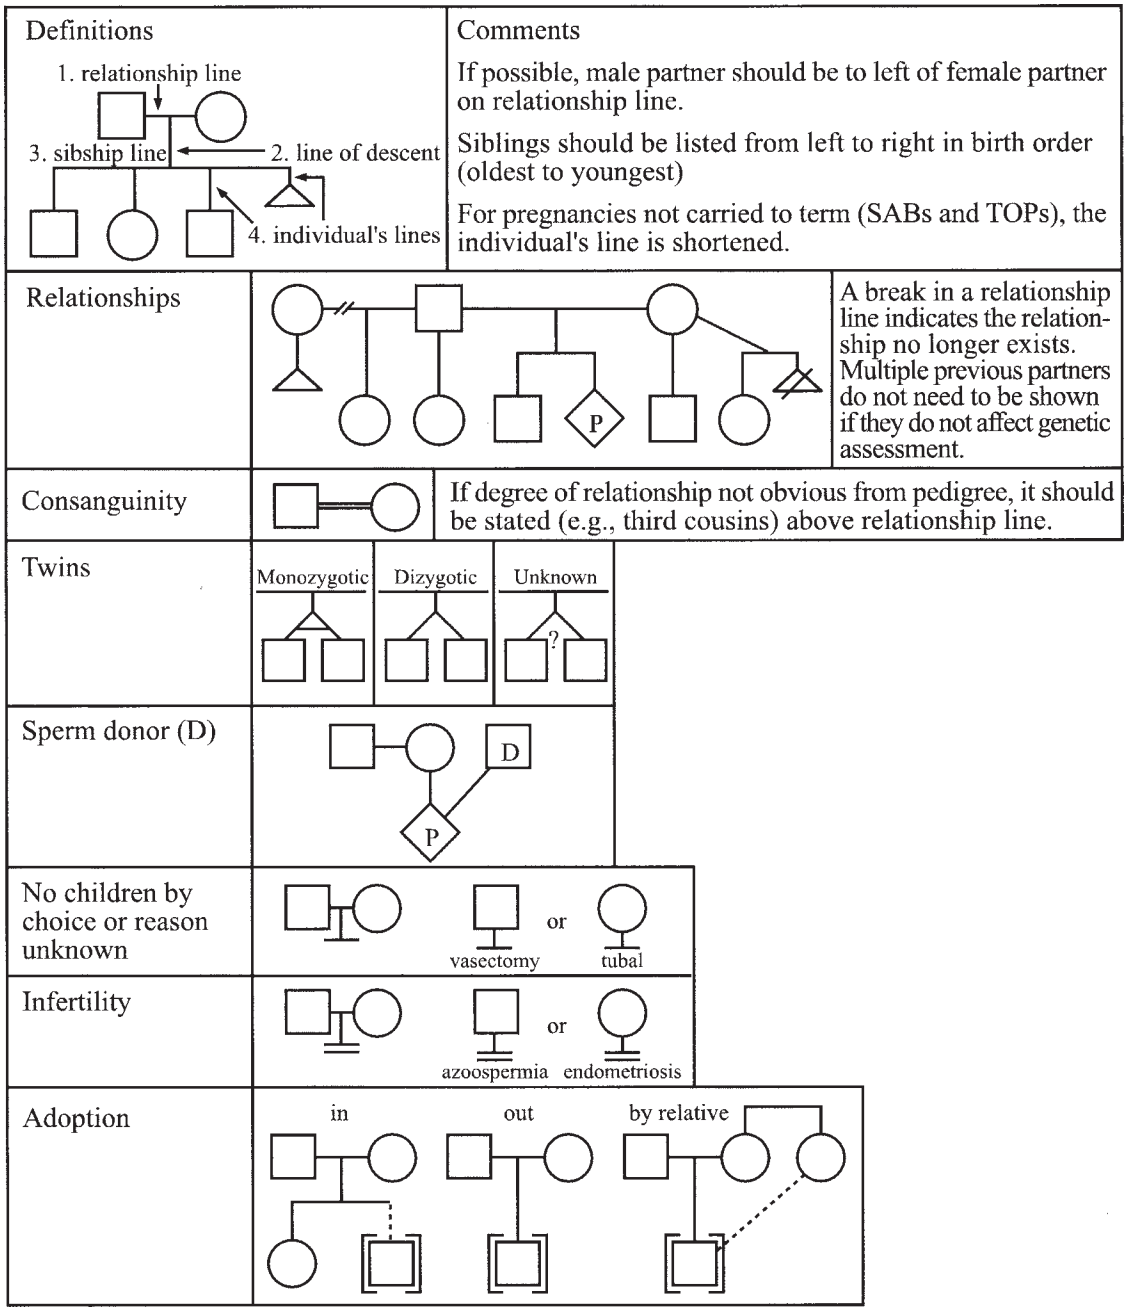

Figure 7-3 Pedigree relationships. Reproduced with permission from the University of Chicago, from Bennett RL, Steinhaus KA, Uhrich SB, et al. Recommendations for standardized human pedigree nomenclature. Am J Hum Genet 1995;56:745–752.

- Review of the inheritance pattern(s) and natural history of the condition, disease monitoring and management, available preventive measures, and reproductive options.
- Options for prenatal diagnosis and availability of assistive reproductive technologies (e.g., gamete donation, preimplantation diagnosis).
- Provision of contact information for disease specific support groups (*see* www.geneticalliance.org).
- Referral to community resources and health specialists, as needed.
- Recommendations for genetic evaluation of other relatives with information about local resources for relatives that live in other communities.

Because of the potentially profound effect that a genetic diagnosis may have on the life of the individual being evaluated, genetic test results are usually relayed in person. A support person is encouraged to attend most genetic counseling visits, especially when tests results are disclosed. A follow-up visit or phone call to discuss the client and family's reaction to the results is advisable.

Patients are likely to remember only about half of the information presented during a clinical visit. Focusing on areas of client concern that were ascertained in the initial assessment helps make the information meaningful to the client. Patients also remember best what they are told first; therefore concentrating on the most important issues in the beginning of the session aids client recall. Providing opportunity for questions and for clients to restate the

Table 7-2
Pros and Cons of Genetic Testing of an Asymptomatic Minor

Potential adverse consequences of testing (focus on positive test results)	*Potential benefits of testing*
Damage to the minor's self esteem	Resolution of the parent's (and possibly the child's) concerns about mutation status
Distortion of the family's perception of the child. Siblings may be treated differently depending on their genetic status	Allow child and family time to adjust to status if test is positive. No anticipation of developing disease if result is negative
Child may identify with severely affected relatives	Affected relatives can be positive role models for child
Loss of future adult autonomy and confidentiality for the tested child	Anticipatory guidance such as choosing physical activities and occupation for possibly affected child
Adverse effects on the child's capacity to form future relationships	Health status is normalized and perception of disease becomes part of the child's sense of self
Fear of rejection in forming long-term relationships. Fear/guilt if person wants biological children	Ability to make informed reproductive decisions
Fear/guilt if person wants biological children. Chronic sadness for "planned" family.	Anticipatory guidance regarding reproductive decisions (e.g., discussions of alternative forms of parenting such as adoption and donor gametes)
Discrimination (insurance, employment, education, choice of mate)	Decreased premiums for insurance because risk factor eliminated if test result is negative
Increased medical surveillance for "healthy" child. Child feels labeled	Available at earliest opportunity for medical intervention (if available)

From Bennett RL, Hart KA, O'Rourke E, et al. Fabry disease in genetic counseling practice: recommendations of the National Society of Genetic Counselors. J Genet Couns 2002;11:121–146. With kind permission of Springer Science and Business Media.

information in their own terms also allows the health professional to estimate how much of the information is understood by the patient. Providing information in several ways to accommodate different learning styles (e.g., verbal, audiovisual, written, and websites) is useful. A patient follow-up letter (that can also be sent to relevant health professionals) provides a resource after the clinic visit that may be referred to even years later, and also assists with coordination of patient care and as a resource for informing at-risk relatives.

COUNSELING Genetic counseling is multifaceted; it includes assessing personal, social, religious, and ethnocultural views on how a genetic diagnosis, genetic testing, and test results affect the client's life. Assessing possible ethical concerns such as confidentiality, disparate paternity, concerns about insurability, views on discrimination, employment issues, feeling about reproduction, and prenatal diagnosis, and testing minor individuals for adult onset conditions are some of the many areas that are explored in genetic counseling. Understanding the client's perception of risk is more important than the actual risk number. Did the client have a preconceived notion of whether the "chances" were high? What percentage risk does the client consider acceptable or too high? Is the information presented different from what the client expected? Patient decisions are supported in the context of individual values, beliefs and goals. There are several excellent books that review the many counseling issues and process of genetic counseling.

THE FUTURE OF GENETIC COUNSELING

The demands for genetic counseling will increase as new genetic tests continually become available. Pharmacogenetics and susceptibility counseling pose novel challenges to the system of genetic counseling that has traditionally concentrated on rare genetic disorders with clear patterns of Mendelian inheritance. Models of genetic counseling must continue to evolve. Can the health care system afford the time intensive previsit preparation, interviewing, assessment, and counseling intervention that the present genetic counseling model embraces? It can be argued that the subject matter at the core of genetic counseling sessions—heart-wrenching reproductive choices or decisions centering on extreme prevention measures such as prophylactic mastectomy or oophorectomy—deserve more time than what has become the usual 10-min health encounter.

Genetic advances will challenge ethics of care. For example, it is generally thought that healthy minors should not be tested for adult-onset conditions in which there are no treatments, yet there may be benefits to testing children under certain circumstances (Table 7-2). With the advent of high-throughput genetic technologies such as tandem mass spectrometry, a growing number of disorders with limited treatments are being added to the diseases that are available for newborn screening—the potential is there for simultaneous screening for hundreds of diseases. How can parents truly be educated and counseled about the implications of so many disorders? Is there significant natural history data on these diseases to know the age that a medical intervention should be implemented? Will parents have a choice regarding which screening tests are given to their newborns?

Finally, the atrocities that were committed in the spirit of genetic research and "ethnic cleansing" in the Eugenics era must never be forgotten. By 1926, laws mandating sterilization of the "mentally defective" were implemented by 23 of the 48 United States. Federal immigration quotas limited immigration by "inferior" ethnic groups. Euthanasia was a legal program in Nazi Germany, where the lives of over 70,000 people with hereditary disorders were extinguished, in addition to the six million Jews and others who were murdered. With the clarity of hindsight modern human geneticists shudder at these early biases and abuses. Yet, genetic counselor Robert Resta notes that genetic research as all scientific research may be "influenced by the political and social beliefs of all-too-human geneticists. Those beliefs may be so ingrained that we mistake them for biological laws. It is, I suspect, beyond our ability to know which of our personal biases we are disguising as scientific truths. The whispers and hints of our biases may be heard only by future generations of geneticists." The voluntary nature of genetic testing

and the availability of genetic counseling by skilled health professionals must continue.

8 Animal Models in Biomedical Research

Ethics, Challenges, and Opportunities

ROBERT W. WILLIAMS

> We are all conscious today that we are drowning in a sea of data and starving for knowledge.
>
> —Sydney Brenner (2002)

SUMMARY

Diagnostic power needs to be matched to prognostic accuracy. To accomplish this, we need robust animal models that incorporate the same level of genetic and genomic variation as highly diverse human populations. A key goal of biomedical research is to provide clinicians with sufficient knowledge to predict disease risk and choose effective treatment. We are on the cusp of having complete genome data for each patient. However, our current understanding of complex biological systems and individual differences does not allow us to predict effects of novel interventions and drugs. Animal models provide precise genetic and experimental control, and they also provide a route to more rapid discovery and validation of disease prevention and treatment. But the successful application of experimental results to diverse humans requires that models accurately represent both the underlying disease process and the impact of human genetic variation on treatment and outcome.

Key Words: Animal model; biomedical research; humanizing mice; inbred; molecular medicine.

INTRODUCTION

It has been just over 50 yr since Linus Pauling introduced the term *molecular medicine* in the context of groundbreaking work on sickle cell anemia, and since Roger Williams wrote *Biochemical Individuality*—a prescient introduction to what we now call individualized medicine. Progress in genetics and molecular biology has been relentless over these fifty years, and thanks to new technologies that range from microarrays to magnetic resonance imaging, we are acquiring information at an accelerating pace. In the next decade, patients are likely to have their individual genomes and transcriptomes stored as part of their medical records. Fine-tuning treatment on a case-by-case basis will become the norm, and we can hope that this process will involve more science than art.

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

Despite this upbeat assessment and the impressive size of *Principles of Molecular Medicine*, biomedical research is only now beginning to move from relatively simple qualitative analysis of single factors to well-designed studies of multiple interacting factors and a multitude of genes. In his *Foreword*, Victor McKusik points out that we still do not have an accurate inventory of the number of genes, mRNAs, or proteins that make up a human. We know even less about the interactions among these complex molecules. We have just begun to explore the intricate molecular networks that mediate between our genomes, our environment, and our health. We know comparatively little about the linkage between gene variants and the most common and pervasive diseases.

Animal models are essential for this transition to a more global and integrative approach to medical care. These models have a vital role as fast and secure routes to improving our understanding of the vocabulary and syntax of the genome and of the complex relations between gene variants and disease. Only research with animals allows us the precise experimental and genetic control required to confirm causality. Animals are also essential when cellular assays fail to provide a relevant biological context, for example, to study the regulation of blood pressure or the systemic effects of drugs or pathogens. As a result, we can expect to rely more heavily on animal models as we transition from simple approaches to more sophisticated and realistic studies that account for human genetic diversity and differences in environmental exposure. Animal models will remain a permanent part of any experimentally validated research program, and will be even more crucial to converting the sea of data alluded to by Sydney Brenner in the opening quotation into effective knowledge that will have a positive impact on human health.

USING ANIMALS IN RESEARCH: RATIONALE AND ETHICAL CONTEXT

A wide variety of unusual species have been valuable in specific areas of research. Several examples highlight serendipitous discoveries and unique animal models that are making important contributions.

- The common nine-banded armadillo has an unusually low average body temperature (approx 32°C), which makes it a unique nonhuman host for the leprosy bacillus, Mycobacterium

leprae. In nature, prevalence of infection reaches 30% in some coastal parts of Louisiana. For three decades, armadillos have, therefore, been the pre-eminent model used to study leprosy and to develop and test vaccines. Female armadillos also give birth to litters of monozygotic quadruplets, a unique pattern of reproduction that makes armadillos an intriguing model for the developmental biology of twinning and the limits of genetic control.

- Groundhogs have a high endogenous incidence of hepatitis B virus that leads to liver cancer virtually indistinguishable from that of humans infected with the same virus. This species is used to evaluate environmental and toxicological factors such as aflatoxin that affect susceptibility to liver pathology and cancer progression in humans.
- Two closely related species of voles provide insight into variation in neuroendocrine modulation of reproduction and social structure. Montaine voles are monogamous, whereas meadow voles are polygamous. The activity of neuroactive peptide hormone systems—vasopressin in particular—has a strong impact on pair bonding and social structure. This work continues to lead to mechanistically sound information into how neuroactive peptides modulate aspects of reproduction and behavior.

Most biomedical research, however, relies on familiar domesticated subspecies of mice, rats, hamsters, rabbits, ferrets, cats, dogs, and pigs. Although the size of these species is often confounded with their complexity and similarity to humans, mammals are not arrayed from simple to complex, from primitive to modern, or from stupid to smart. From the standpoint of evolutionary refinement or biochemical complexity, mice, rats, dogs, pigs, chimpanzees, and humans are peers—all are the latest products of roughly 200 million yr of mammalian evolution.

ANTHROPOMORPHIC LEGAL THEORY Old-world monkeys and apes (macaques, baboons, chimpanzees, and so on) belong to a special category of genuinely wild species that share evolutionary history and biological affinity with humans. They are not more complex than mice or more deeply thoughtful than dogs or pigs, but they are incontrovertibly more similar biologically to humans. This in itself is a reason for using these species in research despite the cost and emotional qualms their use engenders.

A vocal wing of the legal community, led by Steven Wise, Laurence Tribe, and Alan Dershowitz, is exploring the idea that "humanity quotients" can be assigned to life forms as diverse as honeybees and chimpanzees, arguing that each species should be provided with scaled legal protection. For example, according to Wise's scale, the humanity quotient of parrots ranks them somewhere between elephants and dolphins. This fractional anthropomorphic legal theory clearly remains outside the scope of scientific discourse. Misapplying the results of cognitive neuroscience to scale species and perhaps even individuals will produce unintended consequences and a cascade of legal ambiguities. Being human is not an honorary degree that scientists or lawyers are poised to confer. Yet these misframed ideas have begun to exert a subtle but serious impact on scientists themselves, many of whom are willing to concede or even to formally endorse the inverted proposition that similarity to humans makes the use of an animal model inappropriate.

This is precisely wrong. The more closely an animal is related to humans, the more potential value it has as a model. Given that animal research is ethically well grounded and is not abusive, biomedical research is a more meaningful use of animals than their alternative uses as pets, food, transport, or articles of clothing. Their contributions become a permanent part of a knowledge base. Only biological Luddites will deny the long-term positive impact animal models are having on medical care. In this context, the intrinsic barrier to using chimpanzees in research becomes clear: their use is limited by their wild origin and endangered status, their size, and their high cost.

Classification schemes based on scales of intelligence and levels of consciousness will falter because the sensory and cognitive capacity of each species is unique and of roughly equal sophistication from a neurobiological perspective. The biological quirks of human brains and the self-reported complexity of human thought are not the qualities that make humans special. Yes, humans have a slight cognitive edge, but what distinguishes humans is our highly complex cultures and unique ability to accumulate and pass knowledge from generation to generation. A sound understanding of human biology is a priceless scientific heirloom bequeathed to the next generation.

Animal rights activists exert almost continuous pressure to reduce or eliminate the use of nonhuman mammals in biomedical research. It is relatively easy and effective for this advocacy group to shift the focus away from the unequivocal benefits that have already accrued from animal research onto ethical ambiguities and the difficulties of generating effective animal models. Exploiting the emotional bonds that most humans have with domestic animals and pets, opponents of animal research paint a bleak picture of the state of biomedical research and the need for animal models.

The term "sacrifice" is used to refer to killing animals as part of research projects. This is not a euphemism; this word choice is an acknowledgment of their death and our intent to use them for common good. As individuals and as groups, humans constantly make active and passive decisions about the value of human lives compared with those of other species with which we have natural affinity and even sympathy. Animal research is an explicit and honest example of one of these decisions.

LIMITS OF USING HUMANS IN BIOMEDICAL RESEARCH Several prominent commentators, researchers, and organizations have stressed the need for more widespread and effective use of humans to study human disease. Their point is that with appropriate safeguards, new informatic methods can be harnessed to effectively mine vast clinical resources within patient records, tissue samples, and images. Massive clinical resources can in principle be merged with data on DNA sequence variants and gene expression differences to generate deep insights into disease vulnerability and environmental modulators. The systematic efforts of deCode in Iceland and the United Kingdom BioBank in Britain are beginning to provide compelling examples of the effective integration of clinical, genetic, and molecular analyses of large populations of humans. The limitation of these massive studies is that they often cannot directly test relations between cause and effect.

The critical advantage of animal models is that they can be used to directly test causal relations and mechanisms of action under well-defined experimental conditions and perturbations. The ponderous effort by the US Surgeon General to prove the causal connection between cigarette smoking and cancers in the 1950s is a compelling example of precisely why good animal models are needed. How can human association studies be expected to disprove the alternative hypotheses that a common genetic

factor causes both cancer and a yearning for nicotine, or perhaps a tumor suppressor gene variant is tightly linked with a nicotinergic acetylcholine receptor gene variant? Animal models can unequivocally resolve these types of ambiguity.

The need for unequivocal mechanistically sound explanations cannot usually be circumvented by use of humans or cell lines. The effects of thalidomide, ethanol, or heavy metals on human embryonic development cannot be studied, and even unintended toxicological "experiments" of these types are unacceptable. Even voluntary participation in biomedical research by humans must be tightly constrained for ethical reasons. For example, for what period of time is it permissible to temporarily blind human volunteers to study brain reorganization and subsequent recovery—a day, a week, a month, or a year? —and what is the appropriate compensation for participation in such a project?

THE PROBLEM OF TRANSLATION Most common diseases are inherently complex and multifactorial. Elias Zerhouni stated this point clearly: "Solving the puzzle of complex diseases, from obesity to cancer, will require a holistic understanding of the interplay between factors such as genetics, infectious agents, environment, behavior, and social structures." Molecular medicine is not something usually considered holistic, but oddly enough, this direction seems likely with high throughput genomic tools that will soon provide many humans with their personal genome sequence. This advance in medicine will produce exceedingly well-informed patients who will expect customized care.

Molecular processes and organismal responses will often not extrapolate directly across individuals, strains, and species. The supposed failure to make rapid progress in research and clinical delivery—for instance, in the war on cancer initiated in 1971—often reflects a misunderstanding of the complexity of biology (a single cell can be thought of as having greater organizational complexity than the stock exchange), the current depth of ignorance of these complex systems, and the disappointment that follows from overly optimistic media reports on the latest results and potential cures. Unjustified high expectations and incautious headlines are followed by disappointment and denunciation of the models on which they are based.

Nonetheless, there are reasons to constructively critique animal models. A general problem is that the majority of models are designed to reduce genetic and environmental complexity—an unrealistic setting that fails to account for, let alone embrace, the inherent complexity of human populations. Several generations of biologists have been trained to adhere to reductionist methods in which single variables and subsystems of subsystems are studied in isolation. Although this approach is highly productive when access is limited to statistical resources and when questions and answers are focused on fundamental qualitative processes such as basic mechanisms of transcription or enzymatic pathways, it is no longer adequate.

The closer that research gets to clinical treatment—the major purpose of animal models—the greater the need for more complex models that can handle multifactorial perturbations. The computational and collaborative tools are now available to retain the power of reductionist methods while encompassing the power of complex multifactorial experimental designs. A solution to this puzzle requires new types of animal models that more accurately mimic the complex structure of human populations simultaneously allowing control of genomes and environments.

Research involves long-range vision, gradual progress, and delayed gratification, and it is difficult to quantify the many losses that would be the consequence of failure to make discoveries through the use of animal models. Hence, these compromises are made between costs and benefits. It is usually faster, more efficient, and less costly to conduct studies using animal models rather than humans.

BUILDING MODELS AS A KEY TO PROGRESS

The phrase "animal model," first used widely in the 1960s, implicitly acknowledges the many fundamental differences between animals such as mice and our peculiar human species. Often human diseases cannot be fully replicated using other species, even chimpanzee. If a disease is hard to define in humans—autism, for example, slides across several diagnostic subcategories—then it will be hard to model in macaques or chimpanzees, let alone mice. Nonetheless, there are profound and compelling reasons to develop and refine animal models for as wide a variety of human diseases as possible, even those that might initially generate a cynical smile, such as mouse models for macular degeneration (mice have no macula or fovea) or developmental dyslexia (a subtle and uniquely human disorder affecting the ability to process and interpret text).

The phrase "animal model" is also used to indicate that the production of models is often an active process that involves an intense effort in selecting or modifying the genetics of a species or in devising treatments, which consistently produce valuable information and knowledge. Building a good animal model typically involve cycles of testing, modification, and refinement. The process may take years to refine. In the 20th century, technical advances were episodic, and animal models were introduced at a leisurely pace. For example, inbred strains of mice were initially generated by Clarence Little and colleagues in the late 1920s to demonstrate that differences in cancer susceptibility had a genetic basis. Little's first inbred strain was spontaneously prone to several types of cancer, whereas his second strain was not. The use of inbred strains diffused over a period of decades into other fields, in particular, immunology, developmental biology, neurology, behavioral genetics, and toxicology, but the underlying resources and models were not modified significantly.

NEW METHODS TO MAKE NEW MODELS New methods to generate models are being introduced at a rapid rate. The successful integration of exogenous genes into the oocytes of several inbred strains of mice in the early 1980s by Palmiter and Brinster dramatically accelerated the pace with which engineered mice could be generated. Hundreds of transgenic lines of mice are now available, including lines in which human genes are overexpressed. The Huntington's disease gene, *HTT*, and the β-amyloid precursor protein, *APP*, are two prominent examples of human genes that have been moved into mice to explore mechanisms of neurodegeneration.

Transgenic models were followed in the 1990s by the first wave of knockout mice, in which single genes were inactivated in all cells throughout life—what could be called the absolute knockout. The current trend, ca. the year 2000, is to introduce subtle and specific alterations in the expression of genes and their derivative proteins—what are called conditional knockouts. The effect of the knockout may be limited to a particular organ, tissue, cell type, or the knockout may be restricted to a particular stage of development.

It is now possible to imagine adding the equivalent of an expression "volume control" to each gene and to selectively control

the settings of those controls on a cell-by-cell and stage-by-stage basis. This possibility is only a few years behind science fiction. Every year, researchers generate not only new models but also new methods to make models. Even the most active research groups find it challenging to track, let alone exploit, the profusion of molecular and cellular techniques. Technical advances in making models sometimes outpace the basic and clinical research they are intended to produce and serve. The technologies that are used to produce models now have an impact that is equivalent to major advances in instrumentation.

ALL MODELS ARE IMPERFECT Humans are a particularly difficult species to model. This fact leads to failures and misapplications, but it should spur further efforts rather than resignation. Human populations have uniquely human problems; the high prevalence of myopia, Alzheimer's disease, obesity, diabetes, asthma, and cancer is just a few unfortunate examples. Most of these problems are produced by a combination of genetic susceptibility factors and the effects of highly variable demographics, environments, and lifestyles.

Because of human diversity and environmental flexibility, some humans are not even particularly good models for other humans. Consider the well-known differences in alcohol metabolism and tolerance associated with aldehyde dehydrogenase gene variants (Han Chinese, for example, typically have low activity alleles and low ethanol tolerance), whose effects extend to social customs and population health. Dramatic individual differences in drug metabolism are associated with several cytochrome p450 gene variants. In some cases, genetic and environmentally induced variation makes the notion of the standard dose or treatment untenable. Recognition of this fact, coupled with advanced technology, drives an intense interest in individualized medicine. The difficulty of generating a good model or generalizing results from an animal to a human, or from one human to another, does not diminish the vital need for models—it simply emphasizes that multiple models are needed and that only a well-considered review of several animal models can provide sufficient grounds to begin the arduous, costly, and inherently risky process of testing new treatments in clinical trials.

Models rely on biological commonality. The fundamental basis for using animal models is that virtually all human disease is partly modulated by molecular and cellular interactions that are reasonably well conserved across a broad swath of the animal kingdom. There are of course species-specific exceptions, but this biological and genetic conservation often extends through the entire chordate phylum through to model organisms in other phylae and kingdoms, including *Drosophila*, nematode, plants, yeast, and bacteria.

Having full gene sequence data for many species has greatly enhanced the long-term ability to discover and exploit this biological commonality. New genomic data allow systematically testing the functions of genes, in isolation and in networks. With these rich comparative data, extrapolations can be made more confidently across species boundaries. The ocular disease aniridia type 2 is caused by mutations in the *PAX6* gene. A feature that has been highlighted by research in *Drosophila*, cephalopods, rodents, and humans is the general conservation of this transcription factor in modulating key aspects of eye development. Other aspects of *PAX6* are more variable, and the phenotypes naturally differ depending on the particular mutant allele of this gene and on the substantial variation between and within species.

Building up and outward from the genomic level to complex and contingent cellular networks that are closer to the disease process will remain challenging work for many years, but at least a list of the mammalian genetic vocabulary is being formed. Converting this list into a dictionary and encyclopedia of the mammalian genome is the next crucial phase that will make animal models much more powerful and useful.

CONSIDERATIONS OF COST, EFFICIENCY, AND NUMBERS OF ANIMALS Investigators attempt to maximize the impact of their research within the limits imposed by budget and expertise. Maximizing impact usually means conducting and interpreting a series of experiments that often require the use of many animals. The cost of acquiring, treating, and analyzing each case therefore is a significant part of the expense.

A key issue is the number of cases needed to give a compelling answer or an accurate estimate of the effect of treatment. One obvious and effective way to improve statistical power (the ability to detect a genuine biological signal) is to increase the number of cases that are studied within each group. The standard error of the sample mean is roughly proportional to the square root of the number of animals per group. A twofold reduction in experimental error requires approximately a fourfold increase in sample size.

Assuming that equally precise and equally relevant measurements can be obtained from a mouse, rat, rabbit, or dog, the statistical advantages of using a larger number of mice rather than a smaller number of dogs will be substantial (the cost ratio is roughly 1/30). Both assumptions will often be wrong—more accurate measurements can often be obtained from larger species. This is precisely why dogs have been the pre-eminent model used to study heart function, cardiovascular disease, and hypertension. It is not that dogs are inherently more like humans than mice or rats are, but that instrumentation used to study heart, kidney, and cardiovascular systems in humans was readily adaptable for use in animals of comparable size. This equipment was, therefore, relatively easy to modify to yield accurate data at a modest cost.

Guidelines of many scientific societies and funding agencies require that investigators use the "minimum number required to obtain *valid* results." This is a key statement formalized in the influential guide for the care and use of laboratory animals. The statement presupposes that researchers know in advance the effect size that they want to detect and that the variance structure and stability of the traits being measured is understood. A minimum number, however, is a recipe for truncated experimental design. ("Appropriate number" would be a wiser term than "minimum number.") By truncating a study to only include male rats at exactly 90 d of age, for example, numbers can effectively be minimized and investigators may be able to show a significant effect of a treatment with an α error rate of $p < 0.05$ with only two per group. To generate this significant result all that is needed is a lucky draw, a genuinely large effect, or an unintended confound (perhaps caging conditions varied). Should that information be published with an n of 4? Not at all. A statistically *significant* result is not necessarily a *valid* result. The actual trend in practice is to increase n to obtain better power, more precise estimates of effects, and better generality of conclusions.

Instead of striving for a minimum number, researchers should use a more complex and somewhat *ad hoc* procedure to determine the number of animals required to obtain valid results. The intended goal is usually to obtain results that have broad utility and some applicability to humans. To claim to have discovered a potentially important therapeutic effect of an estrogen treatment on the aging process in one inbred strain of mouse, for example, it should be almost mandatory to verify that difference in several

other inbred and even outbred strains of mice. Differences that do not generalize across different strains of mice may interest mouse geneticists, but they are unlikely to interest a clinician treating patients. Ideally, similar results would also be demonstrated in another species before moving to clinical trials.

MOUSE MODELS IN BIOMEDICAL RESEARCH

Studies that exploit mice, many of which are referenced in other chapters and on an almost daily basis in the press, are designed ultimately to improve the diagnosis and treatment of human disease. There are inevitable limitations in relying on a single species that differs so much from humans in size, ecological niche, and reproductive strategy. However, mouse models have reached a high level of molecular and genetic sophistication.

Mice presage the achievements that can be expected with other species of mammals—and perhaps of the human species—over the next several decades. For example, the ability to inactivate a gene by homologous recombination (knockout technology) was introduced in mice in the early 1990s by Mario Cappechi and Oliver Smithies and successfully adapted to rats with a 12-yr lag. Many thousands of knockout lines are now in widespread use as models of human diseases and as test beds of gene function. This chapter does not review the burgeoning technical repertoire used to generate genetically engineered strains of mice, but focuses on several concepts and strategies surrounding the generation and use of mouse models.

SIZE AS A FACTOR IN ANIMAL MODELS Mice are the smallest mammals commonly used in biomedical research. Adult body weight of various species and subspecies ranges from 10 to 30 g, roughly 1/3000 the size of humans. This scaling applies even to an organ such as brain that is considered unusually large in humans; the brains of both mice and humans comprise roughly 2% of total body mass, and in terms of neuron numbers mice are actually proportionally brainier than humans (approx 75 million vs 100 billion neurons). Like humans, mice have significant body size sexual dimorphism; males typically weigh 30–50% more than females.

The main advantage of small size is that a set of 8–10 animals can be maintained in good health in a shoebox-sized cage. Current practice is to maintain 4–5 adults/cage (an anthropomorphic standard for which there is no scientific support). Small size is also associated with particularly rapid development and rapid aging. Gestation in mice is typically 19 d. Mice do not open their eyes until 8–10 d of age, but they develop rapidly and can be weaned after 3 wk of age. Females often produce their first litters at 60–70 d. A full generation therefore typically requires about 3 mo, and up to four generations can be produced per year. Mice are usually fertile for a year or less, and life-span typically ranges from 600 to 800 d. Thus, the biomedical research community has easy access to a mammal in which size, length of the life cycle, and breeding costs are already optimized. These factors have contributed to rapid progress in generating useful mouse models for human disease.

Methods initially perfected in large species such as cats and dogs have been miniaturized to the point that it is now practical in many cases to exploit smaller species such as mice. This shift is driven not by ambiguous ethical gradations that may distinguish small from large mammals, but primarily by greatly improved prospects of generating useful results at a lower cost using instruments and methods specifically geared for studying small mammals. Almost equally accurate results will often be generated from mice as from humans and other large mammals. The main inducement to use mice is not always lower animal costs and higher numbers of research subjects (the mouse/rat cost ratio is only 1/2) but rather the enormous variety of genetically engineered and selected lines of mice.

In some cases there are hard limits to measurement precision that can be obtained using small animals. A case in point is the resolution limits of structural and functional MRI data sets. MRI imaging resolution in any species is not expected of much less than 10 μ because of water diffusion. The proportional in-plane resolution in the mouse brain will be roughly 1/15 that of humans (the cube root of the weight ratio), and a 50-μ resolution in mouse is equivalent in anatomical terms to a 700-μ resolution in human. This resolution limit is counterbalanced, however, by the ability to image many more mice that have been subjected to well-defined manipulations. Again, the inevitable tradeoff is evident between increased measurement precision in large animals vs increased precision and generality made possible using larger numbers of small animals.

INBREEDING AND ITS CONSEQUENCES A hallmark of most mouse models is that they usually rely on a particular inbred stock or strain. Most transgenic mice, knockouts, and spontaneous mutations are bred onto inbred stocks such as C57BL/6, FVB, and 129 strains. Inbred strains make it possible to perpetuate a mouse model essentially as a permanent clone. An inbred strain can be considered a sexually reproducing "clone" of a single genome in which the only residual variation is that required to perpetuate both males and females.

An important distinction needs to be made between isogenic and monozygotic human twins and two inbred mice of the same sex. Identical twins have the same allelic diversity of other humans—they will often have two different alleles (the maternal and paternal allele) at genes and markers distributed across their entire genome. In contrast, inbred mice have been generated in a way that has eliminated nearly all allelic variation.

The problem with using inbred strains as models or as genetic "hosts" for specific engineered gene variants is that inbred strains are very odd types of mammals. There is almost nothing like an inbred strain in the wild (cheetahs and other species that have gone through severe population bottlenecks may come close). Human populations are not inbred to any significant extent; the inbreeding coefficients even in human populations such as Hutterites are low (<0.04) by the standards of mouse genetics (>0.5).

Production of an inbred strain requires just over 20 generations of consecutive matings between sibling males and females. Generating an inbred strain of mouse is therefore a 7–8 yr effort that is often not successful. Inbreeding greatly diminishes reproductive fitness; the deleterious effects of recessive alleles are exposed fully, and natural selection often expresses its disapproval. But in the relatively mild laboratory environment, 50–80% of incipient inbred strains reach the finish line, each permanently archiving a unique combination of gene variants inherited from the original source population as well as a small load of spontaneous mutations acquired and fixed during inbreeding itself.

The complete lack of heterozygous loci in inbred strains has the advantage of making perpetuation of a defined genome and strain feasible almost indefinitely, but the cost is that these strains are idiosyncratic and highly variable in how they respond to all kinds of exogenous factors. This fact can be viewed in a positive light—variation among strains is a great source material for genetic studies—but it also means that the effects of knockouts and mutations will typically be highly dependent on the genetic

background (strain of mouse) on which a mutation is placed by breeding. The effects of a mutation when present on a C57BL/6J background cannot be generalized with much confidence to be similar to those of the same mutation on a 129X1/SvJ background.

There is really nothing like a "normal" mouse; wild-type means that a single gene is in its putative normal or wild-type state. In other words, the mouse happens to be wild type at a single one of approx 25,000 genes. C57BL/6J is not a wild-type mouse—it is an inbred strain that contains hundreds of recessive alleles and frank mutations that have been locked into its genome. Even nominally "wild-type" strains such as CD-1 that are bred with specific avoidance of sibling matings are clearly not wild type; these mice are albinos and are often completely blind.

When a pair of different inbred strains is bred to each other, they produce a filial 1 (F1) generation of offspring. The F1 progeny are still isogenic; males and females are genetically identical, just like their inbred parents. Unlike their parents, however, these F1 mice are heterozygous at all genes that differ between the original pair of parental strains. F1 animals, therefore, retain the advantage of being isogenic but also have the advantage of being much more similar to truly wild populations of mammals, including humans. A study of a knockout on a single F1 hybrid background is analogous to a study of a disease in a single human, and there is a compelling need to evaluate gene function in a broad sense and in the context of diverse genomes and environments.

STRATEGIES FOR MAKING MOUSE MODELS From a genetic perspective, human populations are inherently complex, an outcrossed population in which millions of common polymorphisms are simultaneously segregating and assorting according to Mendel's laws. Humans are also complex in terms of the highly variable environmental factors to which we are subjected, beginning with the formation of oocytes several decades before our own conception.

Mouse geneticists have intentionally constructed mice with simple genomes (fully inbred), and researchers retain tight control over most key environmental factors (diet, pathogen exposure, social structure, temperature, and so on). The reason to make mouse models with a structure diametrically opposite to the human condition is that this structure allows powerful experimental advantages. For example, a single point mutation or a single gene knockout can be introduced onto the fixed genetic "background" of an inbred strain. Similarly, the genome can be untouched and one facet of the environment be varied. Differences in phenotypes between control mice and experimental mice can therefore be confidently attributed to effects of genetic or environmental factors.

The reductionist approach using such models has been effective in revealing causes and effects. The statistics of single-factor experiments are simple, and a conventional *t*-test will usually give nearly optimal power to reject the null hypothesis. But the downside of reductionist models is precisely that they do not attempt to model the real-world genetic and environmental complexity of human populations. This problem has led to a serious critique not just of individual animal models (e.g., those used in cancer biology) but of the whole effort to generate animal models, even to study drug toxicology.

GENERAL MODELS AND INTEGRATING ACROSS SCALES Biomedical researchers are beginning to face major challenges in integrating data across scales, from single base pairs to social structure. It is also important to integrate data across systems, departments, and institutional boundaries—for example, to consider complex interactions between the immune system, neuroendocrine responses, metabolic networks, and cardiovascular performance. Integration across scale and systems is difficult and inefficient because of the inherently fractured and specialized nature of biomedical research. Few researchers gain mastery in a single field, let alone two or more, and generalists lose in the funding and publication competition with specialists. Most models necessarily reflect the highly honed specialty of researchers and are often of use only in a narrow field of application.

There are solutions to this problem, but they are unfortunately more latent than real. The foremost solution is the common use of reference panels of inbred or isogenic mice that have broad utility in many areas of research. Usually a model is considered to be a single entity—a single genetically modified mouse, such as a particular knockout line or a single inbred strain with a tendency to develop lymphomas. But a whole panel of inbred strains of mice, rather than an individual strain, can also be considered a model with which to systematically explore variation in many traits and in many environments. In this case, researchers rely on the range of variation that has been intentionally or inadvertently captured in the reference panel. Human populations in clinical research often consists of what are essentially reference panels—for example, the Framingham cohort and the very well studied panel of 60 large families that form the core of the CEPH Family Panel used throughout the 1990s in gene mapping experiments.

To clarify this distinction between single strain-single gene models and panels of strains, consider two contrasting approaches to studying the genetics of obesity using single mouse models or a reference population.

Approach 1 To analyze phenotypes associated with a spontaneous or induced mutation in a specific gene that leads to marked obesity in mice, a single line on a single genetic background (e.g., a new mutant allele of the leptin receptor on the background of strain DBA/2J) is generated, optimized, and studied. The homozygous knockout is compared with the heterozygote and the wild-type strain (–/–, –/+, and +/+). The phenotypic differences across these three classes may provide exquisite biochemical detail and high power. However, results may not be easily generalizable to other strains of mice such as C57BL/6 or 129X1/Sv, let alone to other species and to human populations. Because the model is unique, data generated are not easily aggregated and integrated using this novel line with data from other experiments and models. Integration will be at a comparatively high level: do the overall conclusions agree or not with those of other studies? The simple solution to the first problem of generality is to make a habit of studying monogenic manipulations on a set of different genetic backgrounds. This is quite easy in mice, because changing the background may simply involve one or two generation breeding experiment (an outcross of the mutation to a different wild-type strain).

Approach 2 The interest in the genetics of obesity continues, but now an entire reference panel of 30 or more genetically and phenotypically diverse strains of mice rather than the three classes of a Mendelian mutation is used. For example, variation in fat pad mass or leptin receptor protein level in hypothalamus across this panel could be assayed. Variation in this measurement across the panel is the "experimental" signal used for two types of subsequent analyses: (1) gene mapping studies of the chromosomal regions that contribute some fraction of the variation detected across the strains, and (2) association studies of variation in fat pad mass with hundreds of other phenotypes that have already

been acquired in this same panel under similar and different conditions. Results of hundreds of experiments can be pooled and integrated for the simple reason that the same genetic individuals—members of the reference panel—are being used by multiple research communities. For example, data on fat pad mass could be compared with pre-existing data for the same strains on variation in blood pressure or activity levels. Networks of phenotypes can readily be explored that covary in the same way that clinical researchers search for patterns of comorbidity among diseases. The price for this integrated approach is obvious: there is more phenotyping to contend with, and the variation of interest does not have an immediate genetic cause. The mapping studies may suggest that three or more different chromosomal regions contribute to differences in phenotypes. Getting to the point of understanding the biochemical basis of a variant phenotype is still comparatively difficult.

There are several types of reference panels that share the attribute that their constituent strains are a stable resource. A major project of this type, the Collaborative Cross, involves interbreeding eight mouse strains to produce a set of about 1000 derivative strains, each with a unique but fixed set of allelic variants, phenotypes, and disease susceptibilities. Several smaller reference panels of this type typically consist of 8–80 strains of mice. For example, the BXD panel of recombinant inbred strains was made 30 yr ago by combining the genomes of two strains (C57BL/6J and DBA/2J) that have both been almost fully sequenced. A multiplicity of phenotype and genotype data from these BXD strains can be exploited in genetic mapping studies and can also be used in phenotype association studies to test the consistency, strength, specificity, and coherence of associations between an amazing variety of traits (*see* www.genenetwork.org for an example of this integrative approach).

HUMANIZING MICE Imagine a line of mice genetically engineered to biochemically resemble a human (as much as possible, given the massive scaling differences and biometric consequences). Transgenic mice in which human genes are inserted into the mouse genome represent the first step in this direction; it is now possible to extend this idea to groups of genes or even whole organs.

There has been substantial progress in generating new types of mice in which the endogenous immune system has been genetically extirpated. These mice can be engrafted with human hematopoietic stem cells that mature into lymphocytes and T- and B-cell subpopulations. Such humanized mice will be especially valuable in studying host–pathogen interactions in ways that would not otherwise be possible. Similar techniques are being developed to make mice that incorporate human liver and breast tissues, and this trend is expected to continue as more control is gained over tissue differentiation in vivo and in vitro. This process will inevitably have its own set of problems, but there will be inexorable progress in generating more faithful and useful models that can be used to study basic mechanisms and test the safety and efficacy of new treatments.

There is a risk (highlighted by Clifton Leaf) that researchers enamored with their sophisticated animal models may fail to promptly consider clinical applications or may be sidetracked into marginally relevant areas with little short-term payoff. Yet, strong counterbalancing incentives provided by funding agencies, pharmaceutical companies, and research institutions drive researchers to translate their results into effective clinical practice. In fact, these incentives can be so compelling that investigators may leap from research results to clinical tests without the delay imposed by an intermediate analysis of other model organisms to test generality and species specificity.

CONCLUSION

In light of costs and benefits and the urgent need for rapid advances, animal models are an essential component of biomedical research. Computer simulations, cell-based assays, and human association studies are all critical components of research, but they cannot substitute for the rigorous mechanistic insight into cause and effects that can be gained from expanded use of more sophisticated and general animal models. A failure to exploit these models to improve quality of life and to provide effective compassionate care would be negligent.

There will be a constant tension between what is regarded as uniquely human characteristics vs common denominators shared with other species. The major challenge in using animal models is to generalize results with reasonable fidelity to humans. To get to this point will often require higher numbers of cases because more variables need to be includeed—both sexes, several ages, several genotypes, and perhaps even several environmental conditions and several species. Achieving such goals may involve a balanced analysis of several model organisms, each with its own unique experimental and practical advantages.

9 Ethical, Legal, and Social Implications

MARCIA VAN RIPER

SUMMARY

This chapter provides an overview of some of the complex ethical, legal, and social issues associated with advances in genomics and molecular medicine, such as equity in access to genetic information and services, use of genetic information in nonhealth-related settings, and genetic discrimination. It is hoped that this discussion will stimulate future discussions about these and other issues that are just beginning to emerge in the exciting, ever-changing world of genomic health care. Discussions such as these are critical to the development of appropriate policies and legislation.

Key Words: Discrimination; ethics; genetics; genetic information; genome; pharmacogenomics.

INTRODUCTION

Clinical practice has been dramatically altered by advances in genomics and molecular medicine, such as the sequencing of the human genome. Although it will probably be at least 10 yr before one's entire genome will be sequenced for $1000 or less, there have been important advances in the application of genomic information to the prevention, diagnosis, and treatment of human disease. Some of these advances include the use of preimplantation genetic diagnosis to help families affected by devastating genetic conditions have unaffected children; the use of genotyping to stratify patients according to their risk of specific diseases, such as long-QT syndrome; the use of gene-expression profiling to assess prognosis and guide treatment decisions for women with breast cancer; and the use of pharmacogenomics to tailor medications and dosages for individual genotypes.

Although advances such as these are promising and may ultimately transform the model of population-based risk assessment and empirical treatment into a predictive individualized model based on the molecular classification of disease and targeted treatment, they also have the potential to complicate the web of ethical, legal, and social issues already associated with advances in genomics and molecular medicine. This chapter provides an overview of the ethical, legal, and social issues connected with advances in genomics and molecular medicine.

GENETIC INFORMATION: CHANGES IN ACCESS AND USE

The term "genetic information" has been used in a variety of ways. Commonly used to indicate the information obtained from a specific genetic test, it may also be used to refer to information about a specific genetic condition, or information about a person's entire genome. Regardless of which definition is used, the term genetic information tends to elicit a wide variety of emotions, including excitement, wonder, relief, fear, sadness, and anger.

CHANGES IN ACCESS

Access to Genetic Information Through Genetic Professionals Previously, the primary way to gain access to genetic information was through interactions with genetic professionals (geneticists, genetic counselors, and nurses with expertise in genetics). Typically, genetic professionals follow a genetic services paradigm that includes the construction of a family pedigree, a risk assessment, education about the genetic component of specific conditions, psychosocial assessment and counseling, a discussion of testing and management options, and support with decision making. For many conditions, no treatments exist, so management options may be limited to surveillance and risk-reducing strategies. If genetic testing is available, genetic professionals usually provide both pre- and post-test counseling to give the individual or family who is considering genetic testing a chance to discuss possible ethical, legal, and social implications (ELSI) of testing. It also gives the genetic professional a chance to anticipate possible negative consequences of testing. If it appears that the individual or family might have difficulty dealing with the test results, additional counseling, and support can be provided.

Access to Genetic Information Through Other Sources There are a variety of ways to gain access to genetic information. Genetic services, especially genetic testing, are becoming increasingly available in mainstream health care. In addition, advances in technology and mass communication have made it possible for many people to access genetic information in their homes. The Internet is rapidly becoming a major source of genetic information. Although many individuals are using web-based resources to expand their understanding of specific genetic conditions, others are using Internet chat rooms and discussion boards to help in their decision making about genetic testing and management options, and some are receiving ongoing information and support through websites devoted to specific conditions. Moreover, some individuals and families are becoming aware of and gaining access to genetic testing through companies that offer direct-to-consumer marketing.

Ethical, Legal, and Social Issues Associated With Changes in Access Changes in access to genetic information increase the possibility that individuals and families from diverse backgrounds will be able to gain access to genetic information, but these changes also increase the possibility of ethical, legal, and social issues. For example, if an African-American woman with a strong family history of breast cancer is offered BRCA1/2 testing, she can give informed consent only after (1) she receives full disclosure of pertinent information concerning the test and (2) she fully understands the risks, benefits, and limitations of the test. If she undergoes the testing in mainstream health care, this is less likely to occur because many physicians in mainstream health care lack the time and expertise necessary to adequately counsel their patients about BRCA1/2 testing. In addition, the information she receives may not be clearly understandable or culturally sensitive. Also, depending on her socioeconomic status, she may not have the financial resources or insurance coverage needed to undergo testing. Concerns about cost, confidentiality, and insurance discrimination may prevent her from being tested.

In a study about BRCA1/2 testing in the community setting, 82% of the 646 women who underwent testing recalled discussing and reviewing the consent with their primary care provider. However, the time spent on this (median time spent on counseling and informed consent was 30 min, range was from 1 to 240 min) was much less than is usually devoted to this activity in specialty clinics and research programs. Almost 13% of the women did not recall discussing the consent form. Concerning how they became aware of their test results, 57% received their results during an office visit, 39% received them by telephone, 3% got their results in the mail, and 2% did not answer the question. Three of those who received their results in the mail had variants of uncertain significance. Whereas most of the women (67%) reported that the testing was paid for by their health insurance or through research funds, 25% paid for it themselves. The remaining women either had insurance claims pending or they did not report a source of payment. None of the women reported increased premiums or loss of health or life insurance because of undergoing the testing. These findings need to be viewed with caution because it had been less than 2 mo since they received their test results.

As with access to genetic information through physicians in mainstream health care, a number of ethical, legal, and social issues are associated with access to genetic information through the Internet. The first concern is that the information provided on these websites may be incorrect or misleading. Next, there are concerns about privacy and confidentiality, especially if the sharing of personal information is a prerequisite to gaining access to a website. Also certain websites can be used to purchase medications, dietary supplements, and genetic tests without the supervision of a health-care provider.

Findings from a study about direct-to-consumer sales of genetic services on the Internet suggest that most of the websites offered genetics services such as paternity testing, identity testing, and DNA banking. Only 14 out the 105 websites reviewed offered health-related tests. Although some of these tests were conventional genetic tests (hemochromotosis and cystic fibrosis), others related to nutrition, behavior, and aging. The authors of this study concluded that the availability of direct-to-consumer health-related genetics tests creates the potential for inadequate decision making prior to testing, a misunderstanding of test results, and access to genetic tests of questionable clinical value.

GeneWatch UK, a nonprofit group that monitors developments in genetic technologies noted a number of problems with the approach taken by one company that offers to provide products (lotions and other skin-care products) and services (guidance on training methods and nutrition requirements) that are designed to match an individual's genetic profile. According to GeneWatch UK, (1) the company's claims are misleading, (2) the company does not adequately inform their customers about possible risks associated with the testing, (3) the company plans to keep the DNA samples and link them to personal genetic information and lifestyle information as long as the customer continues to be a subscriber, (4) the customer's genetic information may ultimately be patented without their knowledge, and (5) the customer may experience negative consequences, such as financial burden because of the high cost of products that may not be necessary. Their analysis would suggest that individuals who use this source to gain access to their genetic information may experience a lack of informed consent, a violation of their right not to know, loss of privacy, workplace and insurance discrimination, confidentiality issues, and unnecessary financial burden.

CHANGES IN USE

Use of Genetic Information to Improve Health and Well-Being Initially, the primary use of genetic information was to help individuals and families affected by genetic conditions face the associated ongoing challenges. Once genetic testing became available for select conditions, possible uses for genetic information increased dramatically. For example, expectant couples can use the genetic information that they acquire through pre- and postaminocentesis counseling to help them prepare for the birth of a child with Down syndrome or the termination of an affected pregnancy. New parents can use the genetic information they receive following their child's positive newborn screen for phenylketonuria to start their child on a special formula known to prevent the mental retardation commonly associated with phenylketonuria. Individuals found to carry the gene for Huntington disease (HD) can use genetic information in their decision making about reproduction, as well as their decision making about how and where they want to live the rest of their life. Before the availability of genetic testing for familial adenomatous polyposis, children in families with a history of familial adenomatous polyposis were usually started on close surveillance, which comprised annual sigmoidoscopies, starting at around age 10. Because genetic testing is available, results of the test can be used to determine which children need this type of close surveillance.

With the development of risk-reducing strategies and treatments for select genetic conditions, possible uses of genetic information to improve health and well-being have increased again. For example, as data came to light indicating that an individual's short-term risk of developing a second breast cancer is substantially affected by whether she carries one of the BRCA mutations associated with hereditary breast and ovarian cancer, newly diagnosed breast cancer patients are increasingly being asked to consider undergoing BRCA1/2 testing before they make decisions about their treatment options. This way, they can use the results of their genetic test to help in decision making about possible treatment options. Women who test positive and choose to undergo a bilateral mastectomy rather than a breast-conserving procedure can avoid radiation treatment and possibly a second surgery. For some, an even more important use of their test results is to help their offspring, by making them aware of any increased risk.

The ability to test for a specific gene mutation far exceeds the ability to treat the genetic condition associated with this mutation. In the early 1990s there was a great deal of optimism about the possibility of using genetic information to provide quick solutions to a long list of health problems. Unfortunately, the field of gene therapy, also known as gene transfer, has sustained a number of major disappointments. One of the most upsetting events was the death of an 18-yr-old volunteer, Jesse Gelsinger, in a gene therapy trial in the fall of 1999. The death of Jesse Gelsinger drew particular attention to the safety of gene therapy because unlike most other volunteers in gene therapy trials, Jesse was not seriously ill. He had a less severe form of an inborn error of metabolism called ornithine transcarbamylase deficiency. He chose to volunteer for the experiment because he wanted to try to help the children who die of the condition. Jesse died 4 d after receiving the gene therapy.

Although the early optimism about gene therapy was probably never fully justified, it is likely that the development of safer and more effective methods for gene delivery will ensure a significant role for gene therapy in the treatment of some diseases. Major challenges include targeting the right gene to the right location in the right cells; expressing the transferred gene at the right time; and minimizing adverse reactions.

One use of genetic information that has received a great deal of attention during the past decade is pharmacogenomics. There has been speculation that pharmacogenomics may become part of standard practice for a large number of disorders and drugs by 2020. The expectation is that by identifying common variants in genes that are associated with the likelihood of a good or bad response to a specific drug, drug prescriptions can be individualized based on the individual's unique genetic make-up. A primary benefit of pharmacogenomics is the potential to reduce adverse drug reactions. Considering that adverse drug reactions result in significant morbidity, mortality, and excess medical costs, pharmacogenomics could prove to be important.

Use of Genetic Information in Nonhealth-Care Setting Genetic information is being used or has been considered for use in a wide variety of settings other than health care, such as insurance, employment, education, adoption, and civil litigation. Insurers argue that they need access to genetic information so they can stop individuals with known mutations from "loading up" on insurance at the regular rates. Employers argue that they need access to genetic information so that they can prevent unnecessary injury or death. For example, a trucking company does not want one of their employees to be symptomatic for HD or Alzheimer's disease.

One place in which genetic information is being used extensively is in the criminal justice system. DNA profiling is routinely used to find and convict criminals. In 1995, the first national DNA database was established in the United Kingdom. This database holds about 2.1 million DNA samples from individuals and 215,000 profiles from crime scenes. In a typical month, matches are found linking suspects to 30 murders, 45 rapes, and 3200 other crimes. Genetic information is also being used to establish the innocence of individuals believed to be wrongly convicted. Two states, Illinois and Maryland, implemented a death penalty moratorium because of growing concern about the execution of wrongly convicted individuals. However, the moratorium has since been lifted in Maryland. At least eight states have enacted laws to guarantee that inmates have access to DNA testing to help establish their innocence.

Ethical, Legal, and Social Issues Associated With Changes in Use Use of the over 1000 available genetic tests is much less than was anticipated. When genetic testing for HD first became available, it was anticipated that demand for testing would be high (approx 60–70%). Actual use has been 5–25% of the people at risk for HD. A variety of reasons have been given for nonparticipation in genetic testing, such as lack of interest, taboos about the disease in the family, family conflicts, lack of information about the testing, and an inability to cope with the results, but the most commonly expressed reason for nonparticipation is fear of genetic discrimination.

Despite limited empirical evidence demonstrating the existence of genetic discrimination, many people continue to fear that genetic information will be used in ways that could harm them. That is, they fear genetic information will be used to deny them access to insurance, employment, and education. In addition, there is concern that adoption agencies may refuse to accept a couples' adoption request if they learn that one of the prospective parents has tested positive for certain genetic mutations.

People who are concerned about genetic discrimination may avoid seeking reimbursement from their health insurer for testing, or they may seek reimbursement only if the test result is favorable. Some people chose to undergo anonymous testing. The people who are at greatest risk for health insurance discrimination are those who purchase health insurance on their own. These people have to undergo the greatest scrutiny. For people who are covered by government programs (Medicare, Medicaid, Military) or employers who have greater than 20 employees, there is actually little or no risk of genetic discrimination.

The most widely publicized example of genetic discrimination in the workplace is a case involving Burlington Northern Santa Fe Railroad (BNSF). Employees of BNSF who had developed carpal tunnel syndrome and were seeking disability compensation were tested for a genetic mutation associated with hereditary neuropathy. Allegedly the testing was done based on the advice of the company's physician, who supposedly had relied on information he received from the diagnostic company who performed the test. Employees who were tested were not aware of what they were being tested for. Although the company's motive for doing the testing was never made explicit, it was hypothesized that BNSF planned to deny disability benefits to any employee who had the specific genetic mutation. Soon after this practice came to light, it was stopped and shortly thereafter the company settled employee claims for an undisclosed amount of money.

The use of genetic information is shaped, and in many instances constrained, by factors such as social norms, where care is received, and socioeconomic status. Most pregnant women in the United States have at least one ultrasound, many undergo some type of multiple marker screening, and a growing number undergo other types of prenatal testing. The range of prenatal testing options available to a pregnant woman and her family varies significantly based on where she receives prenatal care and her socioeconomic status. Certain types of prenatal testing may not be available in smaller communities and rural settings (e.g., chorionic villus sampling; fluorescent *in situ* hybridization analysis). In addition, certain types of genetic testing may not be offered in conservative medical communities (e.g., preimplantation diagnosis). Concerning socioeconomic status, some types of genetics testing are expensive and typically not covered by health insurance. Because of this, these tests may only be available to a relatively small number of individuals and families, people who can

afford to pay for them. This issue needs to be addressed; ideally, there should be equity in access to care.

Equity in access to care is also an issue in pharmacogenomics. The idea of tailor-making medications for individual genotypes goes against the model of mass-producing medications that are suitable and safe for the widest possible range of people at competitive prices. Inequalities are likely to develop between those individuals who have adequate resources and those who do not. Individuals who have adequate resources may be the only ones who can afford the tailor-made "designer drugs." The potential for insurance discrimination is another possible ethical issue with pharmacogenomics. Insurers may try to use the results of tests for drug reactions to exclude or charge higher premiums for those individuals who need the more expensive medications. Pharmaceutical companies may need to include additional warnings on their labels if they want to avoid class action suits from individuals who have genotypes that increase their susceptibility to adverse reactions. Critics of pharmacogenomics say it represents a misallocation of scarce resources. They argue that rather than wasting a country's scarce resources on pharmacogenomics, these resources should be devoted to solving more urgent problems facing humanity such as global famine and accessibility to clean water.

EFFORTS TO ADDRESS ETHICAL, LEGAL, AND SOCIAL ISSUES

ETHICAL, LEGAL, AND SOCIAL IMPLICATIONS PROGRAMS AT THE NATIONAL HUMAN GENOME RESEARCH INSTITUTE AND THE DEPARTMENT OF ENERGY Before the beginning of the Human Genome Project (HGP), widespread concern about misuse of the genetic information gained through the HGP resulted in 3–5% of the HGP budget being designated for the study of ELSI of human genome research. Two large ELSI programs were created to identify, analyze, and address ELSI of human genome research at the same time while the basic science issues were being studied. One ELSI program was established in the National Human Genome Research Institute at the National Institutes of Health and another was established in the Office of Biological and Environmental Research at the Department of Energy. The two ELSI programs are separate, but complementary. High priority issues for these programs are those surrounding the completion of the human DNA sequence and the study of human genetic variation; issues raised by the integration of genetic technologies and information into healthcare and public health activities; issues raised by the integration of knowledge about genomics and gene environment interactions into nonclinical settings; ways in which new genetic knowledge may interact with a variety of philosophical, theological, and ethical perspectives; and how socioeconomic factors and concepts of race and ethnicity influence the use and interpretation of genetic information, the utilization of genetic services, and the development of policy. In 2004, the ELSI program at the National Human Genome Research Institute provided funding for four Centers of Excellence in ELSI Research, as well as a number of planning grants for Centers of Excellence in ELSI Research. It also called for research proposals on intellectual property rights in genetics and genomics research and development, and the effect of such laws and policies on progress in these fields and on commercialization, drug development, health-care delivery, and the public health.

LEGISLATION ON GENETIC DISCRIMINATION Although many states have enacted antidiscrimination laws, the need for federal legislation has grown as the Supreme Court has consistently narrowed the protection provided under the Americans with Disabilities Act. There have been a number of attempts to draft federal legislation on the issue of genetic discrimination in the United States, but this is likely to be an ongoing process. For example, S. 1053, "A bill to prohibit discrimination on the basis of genetic information with respect to health insurance and employment," passed the US Senate by a vote of 95 to 0 on October 14, 2003. Then, in February 2005, the US Senate passed the Genetic Information Nondiscrimination Act of 2005 (S. 306). The two bills (S. 1053 and S. 306) are identical. In March 2005, a bipartisan group of over 100 members of Congress introduced a bill, "Genetic Information Nondiscrimination Act of 2005," HR 1227, in Congress. Again this bill is identical to S. 1053. As of October 2005, this bill has yet to be passed in Congress.

CONCLUSION

The ethical, legal, and social issues discussed in this chapter are only some of the complex issues associated with advances in genomics and molecular medicine. It is hoped that this discussion will stimulate future discussions about these and other issues that are just beginning to emerge in the exciting, ever-changing world of genomic health care. Discussions such as these are critical to the development of appropriate policies and legislation.

CARDIOLOGY II

SECTION EDITOR:
ANTHONY ROSENZWEIG

Abbreviations

II. CARDIOLOGY

4E-BP1	4E-binding protein 1
AAA	abdominal aortic aneurysms
ABCA1	ATP binding cassette transporter A1
AC	adenylate cyclase
ACE	angiotensin-converting enzyme
ACS	acute coronary syndrome
ACTH	adrenocorticotropic hormone
ADP	adenosine diphosphate
AGT	angiotensinogen
Ang-I	angiotensin I
Ang-II	angiotensin II
APA	aldosterone-producing adrenocortical adenoma
Apo A-I	apolipoprotein A-I
Apo B	apolipoprotein B
ARH	autosomal-recessive hypercholesterolemia
ARVD	arrhythmogenic right ventricular dysplasia
ATPase	adenosine triphosphatase
β-MHC	β-myosin heavy chain
CABG	coronary artery bypass surgery
CAD	coronary artery disease
cAMP	w/e (cyclic adenosine monophosphate)
cbEGF	calcium-binding epidermal growth factor-like
CETP	cholesterol ester transfer protein
cGMP	cyclic guanosine monophosphate
CGRP	calcitonin gene-related peptide
CHD	coronary heart disease
CK	creatine kinase
cMyBPC	cardiac myosin binding protein C
CRP	C-reactive protein
CsA	cyclosporine A
cTnT	cardiac troponin T
CVD	cardiovascular disease
DCM	dilated cardiomyopathy
DGS	DiGeorge syndrome
DMD	Duchenne muscular dystrophy
EAD	early after depolarization
E-C	excitation-contraction
ECM	extracellular matrix
eEF2K	eukaryotic elongation factor-2 kinase
EGF	epidermal growth factor
eIF	eukaryotic initiation factor
ENaC	epithelial sodium channels
eNOS	endothelial nitric oxide synthase
EP	electrophysiology
EPCs	endothelial progenitor cells
ERK	extracellular signal-regulated kinase
ET-1	endothelin-1
FBN1	fibrillin-1 gene
FDB	familial defective apolipoprotein B
FH	familial hypercholesterolemia
FISH	fluorescence *in situ* hybridization
Gi	G inhibitory
GPCR	guanine nucleotide protein coupled receptor
GRA	glucocorticoid-remediable hyperaldosteronism
GSK-3	glycogen synthase kinase-3
HCM	hypertrophic cardiomyopathy
HDL	high-density lipoprotein
HMG CoA	3-Hydroxy-3-methyl-glutaryl coenzyme A
ICAM-1	intercellular adhesion molecule-1
ICD	implantable cardiac defibrillator
IDL	intermediate density lipoproteins
IGF-1	insulin-like growth factor-1
ISA	intrinsic sympathomimetic activity
JNKs	c-Jun N-terminal kinases
KO	knockout
LCAT	lecithin cholesterol acyl transferase
LDL	low-density lipoprotein
LDLR-/-	low-density lipoprotein receptor deficient
LMWH	low-molecular-weight heparin
LV	left ventricular
LVAD	left-ventricular assist device
LVH	left-ventricular hypertrophy
MAP	mitogen-activated protein
MAPK	mitogen-activated protein kinase
MAS	marker-assisted selection
MCIP	muscle-enriched calcineurin inhibitory protein
MCP-1	monocyte chemotactic protein-1
MEK	mitogen-activated protein and extracellular signal-regulated kinases
MEN-2	multiple endocrine neoplasia 2
MFS	Marfan syndrome
MHC	myosin heavy chain
MI	myocardial infarction
MLP	muscle LIM protein
MMP	matrix metalloproteases
mTOR	mammalian target of rapamycin
NBD	nucleotide binding domains
NCEP	National Cholesterol Education Program
NFAT	nuclear factor of activated T cells
NHANES III	Third National Health and Nutrition Examination Survey
NO	nitric oxide
NOS	nitric oxide synthase
PAI-1	plasminogen-activator inhibitor

PCI	percutaneous coronary intervention
PDK1	phosphoinositide-dependent protein kinase-1
PI3-K	phosphoinositide 3-kinase
PKA	protein kinase A
PKB	protein kinase B
PKC	protein kinase C
PRKAG2	γ-2 regulatory subunit of AMP-activated protein kinase
PTEN	phosphatase and tensin homolog
PTX	pertussis toxin
QTL	quantitative trait loci
RyR	ryanodine receptor
SCD	sudden cardiac death
SDH	succinate dehydrogenase
SHR	spontaneously hypertensive rat
SIDS	sudden infant death syndrome
SMC	smooth muscle cells
SNP	single-nucleotide polymorphism
SNPs	single-nucleotide polymorphisms
SP	substance P
SR	sarcoplasmic reticulum
SSRE	shear stress response element
STAT	signal transducer and activator of transcription
STE	ST elevation
SVAS	supravalvar aortic stenosis
TIMP	tissue inhibitors of MMP
TOF	Tetralogy of Fallot
t-PA	tissue plasminogen activator
u-PA	urokinase-type plasminogen activator
VCAM-1	vascular cell adhesion molecule-1
VCFS	Velo-cardio-facial syndrome
VEGF	vascular endothelial growth factor
VHL	von Hippel-Lindau syndrome
VLDL	very low-density lipoproteins

10 Congenital Heart Disease

Lazaros K. Kochilas and Alvin J. Chin

SUMMARY

Cardiogenesis is a complex process involving different cell types, such as muscle, endothelial, neural crest, and matrix cells. These cells follow a "protocol" that emerges through changes in gene expression induced by developmental and mechanical cues. Data from human genetics and animal mutants suggest that most congenital heart malformations are arise from gene alterations. The next challenge will be to unravel the sequence of molecular decisions that result in the formation of heart and blood vessels from the first embryonic tissue layers. This knowledge is expected to result in novel strategies for diagnosis, treatment or prevention of heart diseases.

Key Words: Cardiac development; congenital heart defects; endocardium; genes; mutations; myocardial cells; neural crest cells; transcription factors.

INTRODUCTION

The heart is the first organ to form and function during mammalian organogenesis. The formation of the heart and vasculature is an extremely complex process because of its multicomponent constituency, with the heart at its center and the vascular network at its periphery. A diversity of cell types including muscle, endothelial, neural crest, and matrix secretory cells have to follow a strictly coordinated "protocol" to build the normal system. Underlying the complexity at the macroscopic level is corresponding complexity at the molecular level. In the human cardiovascular system, thousands of genes are expressed in any given single cell. Although a significant proportion of these genes are devoted to maintenance of basic cellular function, a subset of them has more restricted expression (spatial and temporal) and contributes to the cardiovascular system's diversity of cell types. The development of the cardiovascular system as a whole is the end product of the changes in gene expression in response to developmental and mechanical cues that drive growth, pattern formation and differentiation. Cardiac malformations occur in 5–8 of 1000 live births, and worldwide approx 1 million infants are born annually with heart defects (20,000/yr in the United States). Sufficient progress has occurred in identifying, characterizing, and surgically repairing physiologically important congenital cardiac defects so that 85% of these infants can expect to survive to adulthood. However, congenital heart defects are the leading cause of death during the first 5 yr of life and are associated with significant morbidity in neonatal life and beyond. Because only the most severe structural malformations thwart management schemes, prevention and early *in utero* detection are the remaining strategies to reduce the impact of heart malformation on the health of infants and children; however, any preventive approach would depend largely on knowing the percentage of congenital heart defects that are genetic. For example, if most congenital heart anomalies result from intrauterine insults (infectious agents, toxins, nutritional factors, mechanical stress, and so on) to the embryo during the first 30 d of gestation, then a prevention strategy would be ineffective, and improving fetal imaging skills should be a focus of effort; because most pregnancies are already monitored by ultrasound at least once for accurate dating, perhaps adding a "cardiac surveillance" portion to the imaging protocol would suffice to increase the chance of prenatal identification. However, evidence suggests that most congenital heart malformations result from gene alterations.

Therefore, the scientific challenge is to unravel the sequence of molecular decisions that result in the construction of the heart and blood vessels from the first embryonic tissue layers. Understanding the development of the cardiovascular system in more detail will allow exploration of novel interventional strategies for treatment or prevention of disease. In vertebrates studied, the heterogeneity of phenotypes associated with even single-gene null mutations points to the importance of modifier genes, environmental factors, and genetic polymorphisms in determining the severity and type of congenital heart disease. It will be important to identify these "modifier genes" because they may partially explain the variability of defects in human conditions such as the DiGeorge syndrome (DGS), usually associated with a multigene deletion. Much of the variability in diseases caused by point mutations occurs from the generation of hypomorphic alleles of different strengths. It is also important to study the effects of environmental factors like toxins, nutrients, and alcohol that are similarly implicated in cardiac development.

More than 150 genes are involved in cardiovascular morphogenesis (Table 10-1), but how they function to form the heart and great vessels remains obscure. Both forward and reverse genetic approaches are being investigated, and a variety of organisms are being scrutinized because the underlying mechanisms of patterning appear to be widely shared among vertebrates. Among these the mouse has been the classic model for cardiac genetic studies because

Table 10-1
Genes Involved in Cardiovascular Development

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
1. Gene/protein expression				
Transcription factors				
NK	*Nkx2.5*	Human: Heterozygous mutations: ostium secundum type ASD, TOF, Ebstein's anomaly, AV conduction defects and "left ventricular noncompaction" Mouse: *Nkx2.5*$^{+/-}$: ostium secundum type ASD, AV conduction defects and vulnerability to arrhythmia *Nkx2.5*$^{-/-}$: embryonic lethal at E10-E11 from cardiac insufficiency; cardiac developmental arrest at the stage of looping; poor chamber differentiation and trabeculation pattern *Drosophila:*	*Nkx2.5* is expressed in myocardial precursors (mouse, *Xenopus*, zebrafish) and is required for completion of cardiac looping morphogenesis.	*Nkx2.3*, *Nkx2.6*, *Nkx2.7*, and *Nkx2.8* (various species) *Bagpipe (Drosophila)* *Bax: Nkx3.1* (mouse)
	Tinman	*tinman* mutant embryos lack heart or visceral muscles		
GATA	*GATA-4*	Human: Heterozygous *GATA-4* missense mutations are associated with familial VSDs Mouse: *GATA-4*$^{-/-}$: embryonic lethal at E8.5-E10.5 with cardiac bifida and absent pericardial cavity	*GATA-4* is expressed in endocardium, endocardial cushions and myocardium except distal outflow tract (mouse) and is required for ventral migration and fusion of cardiac primordia.	*GATA-5*, *GATA-6* (mouse): display overlapping but distinct spatio-temporal expression patterns during cardiogenesis. *GATA6* is dispensable for early cardiac development but may play a role in later cardiomyocyte differentiation.
	Pannier (pnr)	*Drosophila:* *Pnr* mutant embryos have excess pericardial cells and deficient development of cardioblasts	*pannier* is expressed in the dorsal mesoderm and required for cardial cell formation, while repressing a pericardial cell fate.	
	GATA-5	Zebrafish**:** *Fau (GATA-5 mutants)*: cardiac bifida		
FOG	*Fog2*	Human: Heterozygous *FOG2* missense mutations were reported to be associated with congenital diapharagmatic hernia and lung hypoplasia, but no cardiac defects Mouse: *Fog2*$^{-/-}$: embryonic lethal at midgestation with various cardiac defects characterized by thin ventricular myocardium, endocardial cushion defects (common atrioventricular canal), conotruncal abnormalities and hypoplastic coronary arteries	Expressed throughout the myocardium and is important for the normal looping and septation of the heart (mouse).	

		Drosophila:		
	U-shaped (ush)	*Ush* mutants lack heart formation.	*U-shaped* promotes heart development, by maintaining *tinman* expression in the cardiogenic region. *zfh-1* is expressed in the early mesoderm and later in the forming heart.	
	zfh-1	*Zfh-1* mutants form a heart tube that is specifically missing the even-skipped (eve) –expressing subset of pericardial cells		
T-BOX	*T/Brachyury/ntl/ Xbra*	Mouse: *T*$^{-/-}$*:* randomization of cardiac looping and orientation Zebrafish: *no tail*$^{-/-}$ mutants have randomization of cardiac orientation Xenopus: *Xbra* overexpression or inactivation causes randomization of heart looping	*Brachyury* is not expressed in the vertebrate heart.	*Tbx2/3* (human, mouse, chicken), *Tbx4* (mouse) *xEomes* (*Xenopus*) *Tbx18* (mouse, zebrafish)
	Dorsocross (Doc 1/2/3)	*Drosophila:* Combined mutants for *Doc1-3* lack cardioblasts	*Doc1-3* are expressed in distinct areas of the cardiogenic mesoderm and the dorsal vessel in *Drosophila*.	
	Tbx1	Human: *TBX1* is included in the DGCR, whose haploinsufficiency is associated with DiGeorge syndrome (DGS) Mouse: *Tbx1*$^{+/-}$: truncus arteriosus, IAA, RAA, aberrant RSCA and other aortic arch defects *Tbx1*$^{-/-}$: perinatally lethal and occasionally embryonic lethal at E13.5-E14.5; DGS-like features with a range of conotruncal and aortic arch defects including truncus arteriosus, IAA, aberrant RSCA, VSD, TOF, TOF/Pulmonary atresia and branch pulmonary stenosis *Tbx1* transgenics with *Tbx1* overexpression display also conotruncal and arch anomalies Zebrafish: *vgo/tbx1*$^{-/-}$: bilateral arch anomalies	*Tbx1* is expressed in cardiac crescent, cardiac outflow tract, mesodermal core of pharyngeal arches (mouse). In zebrafish *tbx1* expression is found in sinus venosus, atrium, ventricle and outflow tract.	
	Tbx5	Human: *HOS-1 (Tbx5)*: Heterozygous mutations are associated with Holt–Oram syndrome (limb defects and range of cardiac abnormalities: AV block, failure of septa formation and HLHS, aortic stenosis, mitral valve prolapse, and TOF) Mouse: *Tbx5*$^{+/-}$: 50–80% perinatal lethality; ASD, VSD, limb defects	*Tbx5* is expressed in embryonic epicardium, myocardium, and atrioventricular tissue; endocardial expression is restricted only in left ventricle in mouse but bilaterally in human; it can act as cellular arrest signal during cardiogenesis and thereby modulates cardiac growth and development.	

(Continued)

Table 10-1 ***(Continued)***

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
		Tbx5$^{-/-}$: embryonic lethal at E10.5; severely hypoplastic posterior cardiac segments, delayed looping, absent atrial septum, and atrioventricular cushions Zebrafish: *Heartstrings* (*tbx5*) mutants have hearts that initially form and function normally but later fail to loop and display progressive hypoplasia of ventricle and atrium		
	hr-T/tbx20	Zebrafish: *hr-T morphants*: have dysmorphic hearts	*tbx20* is expressed in cardiac precursors at the anterior lateral plate and later throughout the myocardium (zebrafish).	The *Tbx20 Drosophila* orthologs, *mid*, and *H-15*, are required for the functional diversification of cardioblasts and the expression of *tinman*-dependent terminal differentiation genes within the dorsal vessel.
	spt/tbx16/ XvegT	Zebrafish/Xenopus: *spt*$^{-/-}$: randomization of left–right development and heart looping situs	*tbx16* is expressed in mesoderm (zebrafish).	
NFAT	*NFATc1/CNB1, NFATc2, NFATc3, NFATc4*	Mouse: *NFATc1–/–*: Embryologically lethal at E13.5-E17.5; cardiac failure secondary to abnormal semilunar valve formation.	Calcineurin/NFAT signaling functions sequentially from myocardium to endocardium and is required for repression of *VEGF* in the endocardium (mouse). This repression allows endocardial cells to transform into mesenchymal cells and initiate valve formation in vertebrates.	
FOX	*Foxc1, Foxc2*	Mouse: *Foxc1*$^{-/-}$, *Foxc2*$^{-/-}$, and *Foxc1*$^{+/-}$; *Foxc2*$^{+/-}$: perinatally lethal, various aortic arch defects (mostly fourth arch derivatives), and VSD.	*Foxc1* is expressed in the endothelial cells and mesenchyme of the branchial arches (mouse). *Foxc2* is also expressed in the valves and cardiac outflow tract (mouse). *FoxH1* is expressed initially in the lateral plate mesoderm and then is restricted to the heart (mouse). FoxH1 functionally interacts with Nkx2-5 and is essential for development of the anterior heart field and its derivatives.	
	FoxH1	*FoxH1*$^{-/-}$: embryonic lethal between E8.5-E10.5. Primitive heart tube is formed but fails to develop outflow tract and right ventricle, development arrests at looping stage, and cardiac failure occurs Zebrafish: *schmalspur (sur)* mutants have severe defects in all axial structures and randomization of heart looping		
	Foxp1	Mouse: *Foxp1*$^{-/-}$: embryonically lethal at E14.5; thin myocardium and severe cardiac outflow tract, septation and cushion defects	*Foxp1* is expressed in myocardium and endocardium (early stages up to E14.5).	
	Foxp4	*Foxp4*$^{-/-}$: embryonically lethal at E12.5; cardiac bifida	*Foxp4* is expressed in ciliated epithelial cells.	
	Foxj1(Hfh4)	*Hfh4*$^{-/-}$: perinatally lethal, failure to grow, situs inversus or heterotaxy with randomization of heart position		

Homeotic *genes*	*Hoxa-3*$^{-/-}$	Mouse: *Hoxa-3*$^{-/-}$: die around the time of birth with various conotruncal anomalies, thymic and parathyroid agenesis reminiscent of the human DGS	Expressed in the mesenchyme and endothelial cells of the third and fourth pharyngeal arches	*hoxd-3*, *hoxa-4*, and *hoxd-4*: expressed at the early stages of heart formation in the chicken.
	Gax	Mouse: Forced expression of *Gax* inhibits cardiomyocyte proliferation and causes thin myocardium phenotype	Gax has a biphasic pattern of expression in cardiomyocytes (an early one from begin of cardiogenesis up to E12.5 and a late one within compact layer at E15.5)	*Mtsh 1*, *Mtsh2* (mouse) are expressed in mesenchyme of branchial arches. *tsh* (*Drosophila*)
SOX	*Sox4*	Mouse: *Sox4*$^{-/-}$: embryonic lethal at E14; die of heart failure; abnormal formation of semilunar valves and persistent truncus arteriosus	Expressed in endocardial ridges	*Sox7/8/9/10/17/18* (Human, mouse, chick, *Drosophila*)
Myc	*c-myc* *N-myc*	Mouse: *c-myc*$^{-/-}$: embryonic lethal between E9.5-E10.5; heart failure. *N-myc*$^{-/-}$: embryonic lethal at E10.5-12.5; poorly developed ventricular myocardium, VSD	*c-myc* is expressed in myocardial cells. *N-myc* is expressed only in compact myocardium.	
Jun proto-oncogenes (components of AP-1 transcription factors)	*c-Jun*	Mouse: *c-jun*$^{-/-}$: embryonic lethal at E13 with TA, RAA, aortic arch anomalies, and thin right ventricle	The different AP-1 components including Jun proteins are expressed in a development- and tissue-specific manner in multiple tissues including the heart.	c-*jun* and *junD* are genetically redundant. Mice lacking both *jun* genes display cardiovascular and angiogenic defects during embryonic development.
Iroquois	*Irx4*	Mouse: *Irx4*$^{-/-}$: Hypertrophic cardiomyopathy in the adult mouse	Expressed in ventricular myocardium and plays a critical role in establishing chamber-specific gene expression in the developing heart	*Irx1*, *Irx2*, and *Irx5* may partially compensate for loss of *Irx4* function in the heart
Prh Homeobox *(Hex)*	*Prh/Hhex (Hex)*	Mouse: *Hhex*$^{-/-}$: right ventricular hypoplasia, thin myocardium Zebrafish: *Hhex* knock-down causes randomization of gastrointestinal chirality	Expressed in the anterior tip of the primitive streak in the mouse embryo, as well as also in the endothelium throughout the developing vascular network and in the third pharyngeal pouch	
ras-GTPase-activating proteins (ras-GAPs).	*Nf1*	Human: Patients with neurofibromatosis 1 have increased incidence of certain congenital heart defects like pulmonic stenosis and coarctation. Also a case with multiple coronary aneurysms has been reported in a child with neurofibromatosis Mouse: *Nf1*$^{-/-}$: embryonic lethal at E14; poor development of ventricular myocardium, VSD, PTA, abnormal atrioventricular valves	Neurofibromin (Nf)-1 modulates epithelial-mesenchymal transformation and proliferation in the developing heart by down-regulating ras activity. It is expressed in human atrial and ventricular tissue. In the mouse, *Nf1* is expressed ubiquitously but is developmentally regulated in the heart and neural crest derivatives.	Mutations in the related genes *TSC1*, *TSC2* are associated with tuberous sclerosis and cardiac rhabdomyomas in humans
Pax (Paired domain homeoboxes)	*Pax3*	Human: Heterozygous mutations are associated with Waardenburg's syndromes 1 and 3 (no cardiac defects); homozygous mutations are presumed to be early embryonic lethal.	Expressed in migratory neural crest cells	

(Continued)

Table 10-1 ***(Continued)***

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
		Mouse: *Pax3*$^{+/-}$*(Splotch*$^{+/-}$*)*: no cardiac defects, only skin pigmentation defects *Pax3*$^{-/-}$: embryonic lethal at E13.5, persistent truncus arteriosus, thin ventricular myocardium, VSD		
bHLH	*dHAND (Hand2)*	Mouse: *dHand*$^{-/-}$: embryonic lethal at E10.5; absence of heart looping, absent right ventricle	*dHAND* is predominantly expressed in the morphologically right ventricle and *eHAND* in the left ventricle (mouse).	*Xenopus dHAND* and *eHAND* are also expressed bilaterally in the lateral mesoderm but without any left-right asymmetry. No *eHAND* homologue was found in zebrafish.
	eHAND (Hand1)	*eHAND*$^{-/-}$: embryonic lethal at E8.5-9.5; heart development arrests at late cardiac crescent stage showing incomplete heart tube fusion and no observable contractions		
	Hey1/Hesr1 *Hesr2 (hairy and enhancer of split2)/Hey2/ HRT2/grl*	Mouse: *Hey1*$^{-/-}$;*Hey2*$^{-/-}$: embryonic lethal at E11.5 with hypoplastic trabeculae, single ventricle, impaired EMT in atrioventricular cushions and defects in blood vessel development *Hey2*$^{-/-}$: die perinatally from cardiac failure and display various cardiac malformations including ventricular septal defects, tetralogy of Fallot, dysplastic atrio-ventricular valves and cardiac hypertrophy Zebrafish: *grl*$^{-/-}$: abnormal arterial development with variable disruption of aorta segments that resembles coarctation of the aorta	The *Hesr* genes are expressed in the cardiac crescent. At later stages *Hesr1* is expressed in the atria, while *Hesr2* is also expressed in the atria, but predominantly in the ventricles, aortic and pharyngeal arches.	*Hesr1/Hey-1/HRT-1/CHF-1* and *hesr2* are redundantly required to mediate Notch signaling in the developing cardiovascular system (mouse). The *bHLH* transcriptional repressor *mSharp-1/mDEC2* is expressed in the mouse heart at E8.5 and remains active until at least E16.5
	MesP1 *MesP2*	Mouse: *MesP1*$^{-/-}$: embryonic lethal at E10.5 with cardiac bifida *MesP1*$^{-/-}$;*MesP2*$^{-/-}$: embryonic lethal at E9.5 with absent mesodermal layer and heart formation *MesP2*$^{-/-}$: perinatally lethal with skeletal anomalies but no heart defects	*MesP1* is expressed in cardiac precursors in the primitive streak (mouse). *MesP2* is expressed in early mesoderm but its expression is down-regulated after E7.0 (mouse).	
Bicoid-related homeobox genes	*Pitx2a,b,c,d*	Human: Rieger syndrome (*RIEG*/*Pit2a* heterozygous mutants): occular, dental, umbilical cord abnormalities Mouse: *Pitx2*$^{-/-}$: deletion of all Pitx2 isoforms is embryologically lethal at E14.5 with multiple developmental abnormalities (ASD, complete AV canal, abnormal arterio-ventricular	*Pitx2* isoforms are expressed initially in the left lateral plate mesoderm at E8-9; later are expressed bilaterally in the derivatives of the lateral plate mesoderm and only Pitx2c is expressed asymmetrically in the left side of most organ primordia (heart, lungs and gut). Pitx2c is also expressed asymmetrically in the ventral part of branchial arches and at the junction with the aortic sac	

		connections, abnormal cardiac positioning [but normal cardiac d-looping], hypoplastic RV, right lung isomerism, open ventral wall, eye abnormalities) *Pitx2c*$^{-/-}$: lethal in neonatal age with abnormalities of the aortic arch patterning and the outflow tract		
nieuwkoid/ dharma homeobox	*nieuwkoid/ dharma*	Zebrafish: *bozozok/dharma* mutants display independent randomization of heart and gut chirality	*dharma* is expressed in the dorsal blastoderm and is required at the blastula stages for formation of the embryonic shield and expression of multiple organizer-specific genes.	
SAP domain nuclear proteins	*Myocardin* *Myocardin-related t*^{t}*ranscription factor B (MRTF)-B*	Mouse: *Myocardin*$^{-/-}$: embryonically lethal at 10.5 with severely impaired embryonic vasculogenesis but no evidence of cardiac defects *MRTF-B*$^{-/-}$: homozygous mutant mice die between embryonic day (E)17.5 and postnatal day 1 from cardiac failure and display cardiac outflow tract defects (TA, Double outlet right ventricle, IAA and large VSDs)	Master gene regulator of many cardiac specific genes, which is diffusely expressed in myocardial tissue. *MRTF-B* is expressed in the premigratory neural crest, in rhombomeres 3 and 5, and in the neural crest-derived mesenchyme surrounding the aortic arch arteries.	Myocardin and MRTFs physically associate with SRF and activate SMC-restricted transcription. *MRTF-A* is expressed by multiple cell lineages and is a potent transcriptional coactivator of some SRF-dependent genes.
Hop homeobox	*Hop*	Mouse: *Hop*$^{-/-}$: two phenotypic classes characterized by an excess (hypertrophic myocardium in adult age) or deficiency of cardiac myocytes (thin myocardium and embryonic death during midgestation from heart failure). *Hop*$^{-/-}$ mutants display also conduction defects below the level of the AV node Zebrafish: Inhibition of Hop activity in zebrafish embryos likewise disrupts cardiac development and results in severely impaired cardiac function	Expressed in cardiac precursors and cardiac myocytes (mouse). Balances growth vs differentiation of ventricular myocytes.	
Cited nuclear proteins (CBP/p300 -interacting transactivator with ED-rich tail)	*Cited2*	Mouse: *Cited2*$^{-/-}$: embryonic lethal at E13.5-E16.5 with cardiac outflow tract defects (TOF, DORV, truncus arteriosus, right aortic arch), adrenal agenesis, abnormal cranial ganglia and exencephaly	Expressed in primitive streak in areas fated to become heart tissue and in the presomitic and lateral plate mesoderm.	
ZFHX	*ZFHX1B/SIP1*	Human: *SIP1* mutations are associated with Hirshprung's disease and PDA	Expressed ubiquitously	
SMAD	*SMAD1-8*	Mouse: *Smad4*$^{-/-}$: display cardiac hypertrophy *Smad5*$^{-/-}$: embryonic lethality between E9.5 and E11.5 with defects in heart looping and embryonic turning	*Smad4* is expressed specifically in cardiomyocytes. *Smad5* is ubiquitously expressed in the mouse and zebrafish embryo.	*Smads* act as BMP receptors by transducing their signaling effects.

(Continued)

Table 10-1 ***(Continued)***

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
MADS	*Mef2c*	Mouse: *Mef2c*$^{-/-}$: Embryonic lethal at E9.5-10.5; absence of heart looping, lack of OFT and right ventricle, single LV fused directly to atrial chamber, lacking trabeculae and dissociated cardiomyocytes. *Drosophila*: *D-mef-2* mutants fail to express contractile protein genes in all muscle lineages (heart, visceral and somatic muscles)	Essential for differentiation of muscle cell lineages (mouse, *Drosophila*)	*Mef2α, Mef2b, Mef2d* (mouse). *SRF* is expressed in cardiac and skeletal muscle cells and is implicated in the control of cardiac muscle gene expression (mouse)
ETS	*Ets1, Ets2*	Chicken: Targeting *Ets1/2* mRNA by antisense oligonucleotides causes abnormal coronary vessels	*ETS* are important for the epithelial-mesenchymal transformation in the primary and secondary heart fields (chicken)	*XI-fli, Xsap 1* (*Xenopus*): Expressed in heart and branchial arches
	pointed	*Drosophila*: *Pnt* mutants have excess cardioblasts	*Pnt* is a key regulator of cardioblast and pericardial cell fates in the posterior segments of the heart, by promoting pericardial cell development and opposing cardioblast development (*Drosophila*).	
GLI superfamily	*ZIC3*	Human: *ZIC3* mutations are associated with X-linked heterotaxy (HTX1) Mouse: *Zic3*$^{-/-}$: embryonic lethal, heterotaxy	Expressed in mesoderm (mouse)	
	Gli1/2/3	Human: *Gli3* mutations are associated with skeletal malformations syndromes (mostly polydactuly) and cancer Mouse: *Gli2*$^{-/-}$*;Gli3*$^{+/-}$: VACTER-like phenotype, PTA and heart looping defects	Expression of *Gli1* is more restricted and transcriptionally regulated by *Shh*, *Gli2/3* expression is broader and less dependent from Shh signaling (mouse).	
TEA domain *(TEAD)* family	*Transcriptional enhancer factor (TEF-1/TEAD1)*	Mouse: *TEF-1*$^{-/-}$: embryonic lethal at E12; noncompaction, VSD	Expressed in myocardium	
AP-2	*TFAP-2B*	Human: Missense mutations cause Char syndrome with persistence of ductus arteriosus	Expressed in third, fourth, and sixth pharyngeal arches and later in ductus arteriosus	
LIM	*Isl1*	Mouse: *Isl1*$^{-/-}$: display cardiac malformations with absent outflow tract and most of the atria	Expressed in cardiomyocytes in the secondary (anterior) cardiac field.	
ladybird (lb)	*lbe (early)* *lbl (late)*	*Drosophila:* *lb–/–*: display hypoplasia of cardiac precursors. Overexpression of both *lbe* and *lbl* reveals hyperplasia of heart progenitors	*lb* genes are expressed in clusters of about four cells per hemisegment in the developing heart region.	
Protein synthesis/modification				
Subtilisin-like	*SPC1/Furin*	Mouse:	*Spcs* induce endoproteolytic maturation of TGF-β-related molecules. *Spc1* is expressed in the visceral endoderm	

proprotein Convertases (SPCs)		*Fur*$^{-/-}$: embryonic lethal at E10.5 with failure of cardiac primordial to fuse in the ventral midline or with formation of a short unlooped heart with reduced number of cardiomyocytes	and the cardiogenic mesoderm. *Spc4* is expressed in the definite endoderm and the left lateral plate.	
	SPC4/ PACE4	*Spc4*$^{-/-}$: embryological lethal at E13.5-E15.5 with situs ambiguous, congenital heart defects (PTA, VSD, common atrium, DORV), combined with left pulmonary isomerism or complex craniofacial malformations including cyclopia		
SPT translation elongation factors	*Spt5*	Zebrafish: s*k8/s30* (*Spt5*) mutants have similar phenotype with pandora	Spt5 and 6 are both transcriptional elongation factors that interact with each other.	
	Spt6	*Pandora (Spt6)* mutants have dysmorphic hearts, decreased number of ventricular myocytes and pericardial effusion		
Chromatin modification				
HDACs	*Hdac1*	Mouse: *Hdac1*$^{-/-}$: embryonic lethal at E10.5. The mutant embryos are severely dysmorphic and growth restricted, so that the cardiac phenotype could not be assessed. Zebrafish: *hdac1* mutants have dysmorphic and hypoplastic hearts with absent atrio-ventricular valve	Several class II HDAC members (in particular HDAC5 and 9) are very strongly expressed in cardiomyocytes and postulated to inhibit post-mitotic cardiac growth and repress cardiac hypertrophy (human, mouse).	Several class I HDAC members (1, 2, 3, 8) are also expressed in cardiac tissue (mouse, zebrafish) but their particular role in cardiac development is still unknown.
	Hdac5, Hdac9	Mouse: *Hdac5*$^{-/-}$ and *Hdac9*$^{-/-}$: sensitize animals to hypertrophic stimuli		
CREB-binding protein	*CREBBP*	Human: Haploinsufficiency of the *CREBBP* gene (16p13.3 deletion) has been associated with a severe form of Rubinstein-Taybi syndrome that includes mental retardation, skeletal abnormalities, accessory spleens, lung laterality defects and congenital cardiac defects (hypoplastic left heart, VSD).	*CREBBP* and its paralog *EP300* are ubiquitously expressed transcriptional coactivators and act as histone acetyl transferases (HATs).	*EP 300*
p300/CBP transcriptional activators	*p300*	Mouse: *p300*$^{-/-}$: mutant mice die between E9.5-E11.5 from cardiac failure associated with defects of cardiac muscle differentiation	Expressed ubiquitously from early developmental stages.	*p300* and *CBP* play a critical role in cardiac hypertrophy that is dependent on their histone acetyltransferase activity.
Polycomb genes	*rae28*	Mouse: *rae28*$^{-/-}$: die around the time of birth with conotruncal anomalies (tetralogy of Fallot and aortic stenosis), asplenia and abnormalities in the eyes, hard palate, and parathyroid glands	The gene contains DNA binding domains that belong in the chromatin-associated group of proteins.	

(Continued)

Table 10-1 ***(Continued)***

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
2. Intercellular signaling and signal transduction (signals, ligands and receptors)				
a. Secreted factors				
Hedgehog	*Shh/syu*	Mouse: *Shh*$^{-/-}$: alterations in cardiac looping, tetralogy of Fallot with pulmonary atresia Zebrafish: *syu*$^{-/-}$: absent dorsal aorta and axial vein	Expressed in endoderm of pharyngeal arches	
	Ihh	Mouse: *Shh*$^{-/-}$;*Ihh*$^{-/-}$: developmental arrest at somitogenesis with small, linear heart tube, open gut and cyclopia (identical phenotype with *Smo*$^{-/-}$)		
TGF-β	*TGF*-β*2*	Mouse: *TGF*-β*2*$^{-/-}$: die in perinatal period with malformations of the cardiac outflow tract, the AV canal region, the aortic arches and the semilunar valves	*TGF*-β-related signals (like *Nodal, lefty, southpaw, Gdf1*) specify in vertebrates the anteroposterior and left-right axes. *TGF*-β*2* is expressed in the endocardium and the myocardium adjacent to the endocardial cushion tissue.	*TGF*-β*1* is expressed in endothelial cells. *TGF*-β*3* is expressed in endocardial cushions
	BMP-1/Tolloid like proteases (Tld): Tolloid-like 1 (Tll-1)	Mouse: *Tll-1*$^{-/-}$: embryonic lethal during midegestation with AV-canal type of VSD and abnormal semilunar valves	*Tll-1* is expressed specifically in precardiac tissue and endocardium at E7.5-8.5 mouse embryos.	
	Bmp2	Mouse: *Bmp2*$^{-/-}$: Early embryonic lethal with amnion and chorion malformations and abnormal development of the heart in the exocoelomic cavity. No cardiac defects in heterozygotes Zebrafish: *Swirl/bmp2b* mutants display dorsoventral patterning defects but no cardiac abnormalities	*Bmp2* is expressed in the AV junctional myocardium and valve tissue and interacts with *TGF*-α*3* for the formation of endocardial cushions.	
	Bmp4	Mouse: *Bmp4*$^{+/-}$: No cardiac defects in heterozygotes. *Bmp4*$^{-/-}$: Early embryonic lethal. Cardiac specific ablation of *Bmp4* is embryonic lethal at E13.5 with outflow tract defects including truncus arteriosus, and in combination with a hypomorphic allele causes common atrioventricular canal *Drosophila:* *Dpp* mutant embryos: heart and visceral mesoderm formation is abolished (as in *tinman*)	*Bmp4* is expressed in the cardiac outflow tract (incl. truncus arteriosus) and the endocardial cushion ridges (mouse). It has also a developmentally regulated expression in zebrafish.	*Dpp* (decapentaplegic) is required along with the secreted signaling molecule, wingless (wg) to specify the heart in Drosophila.

	Bmp5/6/7	Mouse: *Bmp5*$^{-/-}$*;Bmp7*$^{-/-}$: embryos die at E10.5 with absent endocardial cushions *Bmp6*$^{-/-}$*;Bmp7*$^{-/-}$: embryos die between E10.5 and E15.5 due to cardiac failure with delayed formation of the outflow tract endocardial cushions, defects in valve morphogenesis and chamber septation	*Bmp5* is expressed in the developing myocardium; *Bmp6* is expressed in the outflow tract and the atrioventricular cushions; *Bmp7* is expressed in overlapping and adjacent sites with *Bmp6*, including the endocardial cushions. It is also expressed diffusely in axial and lateral mesoderm, gut endoderm and allantois. *BMP-10* expression is restricted initially in the trabeculated part of the common ventricular chamber and the bulbus cordis, but after E12.5, additional expression is seen in the atrial wall (mouse)	
	Bmp10	*Bmp10*$^{-/-}$: embryologically lethal at E10.5 with hypoplastic ventricular wall		*BMP-10* is important for the trabeculation and ventricular growth of the embryonic heart.
	Nodal	Mouse: *Nodal*$^{-/-}$: die in gastrulation but compound heterozygotes between hypomorphic and null alleles (*Nodal*$^{fl1/}$) die at E14.5 and display abnormal cardiac looping, dextrocardia or mesocardia, TGA and VSDs. *HNF3*-β$^{+/-}$*; nodal*$^{lacZ/+}$ double-heterozygous embryos display randomization of heart looping and left pulmonary isomerism.	*Nodal* is expressed in left lateral plate mesoderm and is required for formation of the primitive streak. It is indirectly implicated in laterality defects in human, mouse, chicken, and frog.	Mutations of the zebrafish nodal related gene *cyclops* (*ndr2*) does not cause laterality defects.
	southpaw nodal related gene	Zebrafish: *southpaw* morphants display severe disruption of early (cardiac jogging) and late (cardiac looping) aspects of cardiac left-right asymmetry.		
	LEFTA / lefty 1(Ebaf)	Human: Mutations identified in patients with laterality defects similar to mouse *lefty 1*$^{-/-}$.	*Lefty1* is expressed asymmetrically in the left lateral plate in the mouse embryo.	*Lefty2* (*LEFTB*) is also asymmetrically expressed in the left lateral plate in the mouse embryo and seems to be controlled by *lefty1*.
	Gdf-1/Vg-1	Mouse: *lefty 1*$^{-/-}$: laterality defects described as left thoracic isomerism. Mouse: *Gdf1*$^{-/-}$: spectrum of laterality defects, including visceral situs inversus, right pulmonary isomerism, and a range of cardiac anomalies incl. abnormalities of cardiac looping, transposition of great arteries, VSD, and atrio-ventricular canal.	*Gdf-1* is expressed bilaterally in intermediate and lateral plate mesoderm. *Vg1* cell-signaling pathway plays a central role in left–right coordinator function in *Xenopus*.	
TGF-β *antagonists*	*Chordin(Chrd)*	Mouse *Chrd*$^{-/-}$: die during mid-gestation or at time of birth with DGS phenotype incl. Truncus arteriosus, right aortic arch and aortic arch branching abnormalities. Zebrafish/*Xenopus*. *Chordino(dino)* mutants display randomization of heart looping	*Chrd* is a secreted Bmp-binding protein that is expressed in the mouse node and its derivatives, notochord and pharyngeal endoderm (mouse). *Chordin gene* is first expressed on the dorsal side of the embryo (starting before gastrulation) (Zebrafish, *Xenopus*).	The role of other *bmp* inhibitors like *noggin*, *follistatin*, and *Sog* on cardiac development is unknown

Table 10-1 *(Continued)*

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
Early response gene growth factor	*SIL*	Mouse: *SIL*$^{-/-}$: embryonic lethal around E10.5 with axial midline defects and randomized cardiac looping	Ubiquitously expressed	
Neurotrophin growth factors	*Nt3*	Mouse: *Nt3*$^{-/-}$: perinatally lethal with severe cardiovascular abnormalities including atrial and ventricular septal defects, and tetralogy of Fallot	Essential for the survival and/or migration of cardiac neural crest	
Vegf	*Vegf*	Human: Certain *VEGF* haplotypes are associated with increased risk for cardiovascular defects in *del22q11* individuals Mouse: *VEGF* isoforms associated with decreased *VEGF* expression display various aortic arch abnormalities. Transgenics overexpressing *VEGF* die at E12-E14 and display conotruncal anomalies (TOF, pulmonary hypoplasia), VSD and thin myocardium	Expressed in the endoderm of the pharyngeal arches, the aortic sac, cardiac outflow tract, and ventricular septum	
Erythropoietin	*Epo*	Mouse: *Epo*$^{-/-}$: embryonic lethal during midgestation from failure of erythropoiesis. The mutants display also ventricular hypoplasia, detachment of epicardium and abnormalities of the vascular network	Erythropoietin affects cardiomyocyte proliferation in a cell non-autonomous manner.	Similar results were found also in the erythropoietin receptor knockout mice.
Wnt/Wingless	*Dvl2(Dsh2)*	Mouse: *Dvl2*$^{-/-}$: 50% perinatally lethal (predominantly the males) DORV, TGA, PTA	Widely expressed in embryonic and adult tissues. Important for cardiac neural crest development	*Wnt1/Wingless*: *Wnt* antagonism initiates cardiogenesis in *Drosophila*, *Xenopus laevis* and chick. *Wnt1* is expressed in subset of cardiac neural crest cells
EGF-CFC	*CFC1/Cryptic*	Human: Loss-of-function mutations are associated with heterotaxic phenotypes with a variety of congenital heart defects (d-TGA, DORV, Pulmonary atresia, complete AV canal, HLHS, ASD, VSD, PDA) Mouse: *cryptic*$^{-/-}$: right pulmonary isomerism, dextrocardia, malposition or transposition of the great arteries and DORV	Expressed at E7.5 in the precardiac and lateral plate mesoderm in the mouse; later is expressed in the cardiac inflow and outflow tract.	*Cripto* and *oep* act as co-receptors or presenting molecules in *nodal* signaling pathway.
Adapter proteins	*CRKL*	Human: Included within the DGCR Mouse:	Expressed in dorsal neural tube, dorsal root ganglia, some clearly defined some of the branchial arches and the front nasal mass.	

		Crkol$^{-/-}$: abnormalities of the cardiac outflow tract and the aortic arch arteries		
Semaphorins	*Sema3A*	Mouse: *Sema3A*$^{-/-}$: perinatally lethal with selective hypertrophy of the right ventricle and right atrial dilation	*Sema3A* is expressed in cardiac tissue (rat)	
	Sema3C	*Sema3C*$^{-/-}$: perinatally lethal, interrupted aortic arch, and PTA.	*Sema3C* is expressed in migratory and postmigratory neural crest cells in the myocardium surrounding the outflow tract. Important for the migration of cardiac neural crest cells to the outflow tract	
Ephrins	*ephrinB2*	Mouse: *ephrinB2*$^{-/-}$: embryonic lethal before E11.5 with poorly organized vessels, deficient myocardial trabeculation, pericardial effusion and no cardiac looping Endocardiac-specific *ephrinB2* inactivation leads to similarly defective cardiac morphogenesis	*EphrinB2* is expressed in arterial endothelial cells.	
EGF Neuregulin and EGFR signaling	*NRG1*	Mouse: *NRG1*$^{-/-}$: embryonic lethal during midgestation due to the aborted development of myocardial trabeculae in ventricular muscle (Long 2003)	*NRG1* is expressed by pluripotent neural crest cells and endocardium.	
	HRG	*HRG*$^{-/-}$: embryonic lethal at E10.5 with thin myocardium, irregular heart beat	Heparin-binding epidermal growth factor (HB-EGF) and betacellulin (BTC) are activating ligands for EGF receptor (EGFR/ErbB1) and ErbB4. HB-EGF is expressed by endocardial cells lining the margins of cardiac valves. Tumor necrosis factor-alpha converting enzyme (TACE) activates EGFR by deriving soluble HB-EGF. Proper cardiac valvulogenesis is dependent on EGFR activation that is required to regulate BMP signaling in endocardial cushions.	Although BTC and TACE do not belong to the same family of genes they all act through activation of the EGFR signaling pathway and are bundled together in this context.
	HB-EGF	*HB-EGF*$^{-/-}$: die in neonatal age from heart failure secondary malformed semilunar and atrioventricular heart valves, and hypoplastic, poorly differentiated lungs (Meno 1998)		
	Betacellulin (BTC)	*HB-EGF*$^{-/-}$; *BTC*$^{-/-}$: similar defects as described above with more accelerated occurence of cardiac failure and death		
	TACE	*TACE*$^{-/-}$: similar phenotype with defective valvulogenesis as above		
FGF	*Fgf8*	Zebrafish: *acerebellar*: homozygous mutants for *fgf8* have dysmorphic hearts with reduced ventricular mass Mouse: *Fgf8* homozygous hypomorphic alleles display looping abnormalities as well as various aortic arch defects, including outflow tract, intracardiac and aortic arch anomalies	*Fgf8* is expressed in cardiac precursors and later in the ventricular tissue, ectoderm of first pharyngeal arch and core mesenchyme of more caudal pharyngeal arches (mouse) Fgf8 is required for induction and patterning of myocardial precursors Fgf8 is a left determinant in the mouse but in the chicken appears to be a right determinant.	*Fgf1, 2, 4, 7, 12, 13, 16* *Fgf10* is expressed in pharyngeal mesodermal cells that contribute to the arterial pole of the heart.
Endothelins	*ET-1*	Mouse: *ET-1*$^{-/-}$: conotruncal and aortic arch defects	Expressed in the neural crest-derived pharyngeal mesenchyme, as well as endoderm and ectoderm	
Nonmembranous protein tyrosine phosphatases	*PTPN11*	Human: Defects in *PTPN11* account for 50% of patients with Noonan's syndrome (which includes cardiovascular anomalies such as pulmonary	*PTPN11* is widely expressed in both embryonic and adult tissues and encodes the nonmembranous protein tyrosine phosphatases SHP-2, which mediates signal transduction from numerous	

(Continued)

Table 10-1 ***(Continued)***

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
		stenosis and hypertrophic cardiomyopathy) and some cases with Leopard syndrome (multiple lentigines, congenital cardiac abnormalities mostly pulmonic stenosis, ocular hypertelorism, and retardation of growth) Mouse: *Ptpn11*$^{D61G/D61G}$: Homozygous mutants for the D61G mutation in the Ptpn11 gene are embryonic lethal at E13.5 (grossly edematous and hemorrhagic, have diffuse liver necrosis and severe cardiac defects). Heterozygous embryos exhibit cardiac defects (DORV, thin myocardium, thickened atrioventricular and outflow tract valves, growth failure, perturbed craniofacial development and a mild myeloproliferative disease	receptor tyrosine kinases. It is positively associated with pulmonic stenosis but negatively associated with hypertrophic cardiomyopathy, suggestive of a more critical role for *SHP-2* in valvulogenesis than cardiomyocyte proliferation	
MicroRNAs	*microRNA-1-1 (miR-1-1)*	Mouse: Excess *miR-1-1* in the developing heart leads to a decreased pool of proliferating ventricular cardiomyocytes	*miR-1-1* and *miR-1-2* are specifically expressed in cardiac and skeletal muscle precursor cells	During cardiogenesis *miR-1* genes titrate the effects of cardiac regulatory proteins to control the balance between differentiation and proliferation.
b. Receptors and Ligands				
Notch	*Notch1*	Human: *Notch 1* mutations cause a spectrum of developmental aortic valve anomalies and severe valve calcification in non-syndromic autosomal-dominant human pedigrees Mouse: *Notch1*$^{-/-}$: embryonic lethal with severe neuronal and somitic defects. In addition, Notch1$^{-/-}$ mutants show defects in angiogenic vascular remodeling in the embryo, yolk sac, and placenta. Endothelial-specific *Notch1* inactivation recapitulates the *Notch1*$^{-/-}$phenotype	*Notch1* and *Notch2* are expressed in the outflow tracts and the epicardium, in specific cell populations that express *JAG1*. *Notch 1* transcripts are particularly enriched in the aortic valve.	*Notch1* (*Xotch*) and *Serrate1*are expressed in overlapping patterns in the early heart field in *Xenopus. Notch* signaling suppresses cardiomyogenesis through *suppressor hairless, Su(H)* and this is essential for the correct specification of myocardial and nonmyocardial cell fates
	Notch2	*Notch2*$^{del1/del1}$: mutants die perinatally and display myocardial hypoplasia, edema, kidney and ocular vascular defects		
	Notch4	*Notch4*$^{-/-}$: No vascular phenotype *Notch1*$^{-/-}$; *Notch4*$^{-/-}$: More severe vascular phenotype than *Notch1*$^{-/-}$	*Notch4* is restricted to the vascular endothelium	
Dsl proteins	*Dll1*	Mouse: *Dll1*$^{-/-}$: situs ambiguous phenotype, including	*Dll1* encodes one of the four known mammalian DSL	

		randomization of the direction of heart looping and embryonic turning. Human:	proteins and acts as a ligand for the receptor Notch. *Dll1* is expressed in the human embryonic heart (atria, ventricular endocardium, coronary arteries and epicardium).	
	Jagged-1 (JAG-1)	Mutations in *JAG1* are associated with Alagille syndrome (AGS) and cardiac defects (TOF, VSD, ASD, PDA, PTA, pulmonary atresia, hypoplasia of the entire pulmonary vascular tree) Mouse: *Jag1*$^{-/-}$: embryonic lethal at E10.5 from hemorrhage and exhibit defects in remodeling of the embryonic and yolk sac vasculature (Hamblet 2002) *Jag1*$^{+/-}$*; Notch2*$^{+/-}$: Phenotype reminiscent of human Alagille syndrome	In the mouse embryo. *Jag-1* has more global expression but comparable in the heart (atria, ventricles, outflow tracts, valve precursors) and the great arteries (pulmonary arteries, descending aorta and all pharyngeal and their vascular derivatives)	
Receptors of TGF-β-like ligands	*TBRII*	Mouse: *TBRII*$^{null/flox}$*;Wnt1-Cre*$^{+/-}$: Neural crest specific *TBRII* inactivation is perinatally lethal with DGS phenotype including truncus arteriosus and abnormal aortic arch branching	All receptors are expressed diffusely in several issues during embryonic mouse development	*TBRI,TBRII, TBRIII* and ALK2 mediate TGF-β signaling and induce epithelial-mesenchymal transformation in the AV cushions
	Endoglin	*Endoglin*$^{+/-}$: Hereditary hemorrhagic telangiectasia type 1 (HHT1) *Endoglin*$^{-/-}$: embryonic lethal at E10.5 with diffuse vascular abnormalities, absence of cardiac cushions formation and pericardial effusion	Endoglin is expressed at high levels on endothelial cells of capillaries, veins, and arteries (human) as well as on mesenchymal stromal cells in several tissues (mouse)	
	ALK1 (acvrl1)	Human: Heterozygous mutations are associated with primary pulmonary hypertension and hereditary hemorrhagic telangiectasia type 2 (HHT2) Mouse: *ALK1*$^{+/-}$: Hereditary hemorrhagic telangiectasia type 2 (HHT2) Zebrafish: *Vbg(acvrl1)*$^{-/-}$: dilated cranial vessels	*ALK1* is expressed in endocardial cells (mouse, chicken)	
	ALK2 (acvrl2)	Mouse: *ALK2* $^{null/flox}$*;Tie2-Cre*$^{+/-}$: Endothelial-specific *ALK2* inactivation is embryonically lethal and leads to endocardial cushion defects *ALK2;Wnt1-Cre*$^{+/-}$: Neural crest-specific *ALK2* inactivation causes craniofacial anomalies and aortic arch abnormalities reminiscent of human DGS phenotype	*ALK2* is expressed abundantly in endocardial cells of the outflow tract, ventricle, and AV cushion (mouse, chicken)	
	ALK3 (*BMPR1A*)	*ALK3* $^{null/flox}$*;αMHC-Cre*$^{+/-}$: Cardiac-specific deletion of *ALK3* is embryologically lethal around E15.5 with endocardial cushion defects and hypoplastic trabeculae	*ALK3* is expressed ubiquitously in mouse embryonic tissues (with the exception of liver)	*ALK3*(*BMPR1A*) is required for mesodermal formation in vertebrates.

(Continued)

Table 10-1 ***(Continued)***

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
		ALK3 $^{null/flox}$ *cGATA6-Cre*$^{+/-}$: Targeted *Alk3* deletion in cardiomyocytes of the AV canal results in atrio-ventricular valve defects reminiscent of Ebstein's disease and WPW		
	ALK5	α*MHC-ALK5*: Transgenics with cardiac-specific *ALK5* activation display arrest of looping morphogenesis and a linear, dilated and hypoplastic heart tube	*ALK5* is expressed throughout the heart.	*ALK5* is not involved in the endothelial–mesenchymal transformation of the endocardial cushions.
		Human:		
	ACVR2B (ActRIIB)	*ACVR2B* mutations were only rarely found among cases of LR axis malformation		
		Mouse:		
		ActRIIB$^{-/-}$: Lethal at birth; randomized heart position, malposition of the great arteries, atrial and ventricular septal defects; right pulmonary isomerism and splenic abnormalities, recapitulating the clinical features of the human asplenia syndrome.		The ActRIIB-mediated signaling pathway interacts with retinoic acid and plays a critical role in patterning both anteroposterior and left–right axes.
	BmpR2	Human:		
		Mutations in *BMPR2* were found in patients with primary pulmonary hypertension (PPH1)		*BmpR2* is required for primitive streak formation.
		Mouse:		
		BmpR2$^{+/-}$: susceptible to pulmonary vascular obstructive lung disease		
		BmpR2$^{-/-}$: die in utero at gastrulation but homozygous mice for a *BmpR2* hypomorphic allele die at midgestation with cardiovascular defects like truncus arteriosus with interrupted aortic arch and dysmorphic semilunar valves		
EGFR family/	*EGFR*	Mouse:	*EGFR* is ubiquitously expressed during gastrulation, somitogenesis and later stages (zebrafish).	*ErbB4* expressed in cardiomyocytes
		Egfr$^{-/-}$: *EGFR* mutant and null mice have abnormal semilunar valves with thickened leaflets		
Neuregulin receptors		Zebrafish:		
		Inhibition of zebrafish *EGFR* activity in vivo impeded blood flow via the outflow tract into the aorta and impeded circulation in the axial and intersegmental vessels by 80 hpf. Analysis of the heart showed that the heart chambers and pericardial sacs were dilated and the outflow tracts were narrowed		
		Mouse:	*ErbB2* expressed in cardiomyocytes	

	ErbB2	*ErbB2*$^{-/-}$: similar with *HRG*$^{-/-}$; die at midgestation because of heart malformation. Conditional mutation of the *ErbB2* in cardiomyocytes leads to dilated cardiomyopathy		
	Erb3	*ErbB3*$^{-/-}$: embryonic lethal at E13.5 with underdeveloped AV valves and mildly reduced myocardial thickness	*ErbB3* expressed in endocardial cushion mesenchyme	
Cysteine-Rich with EGF-Like Domains	*CRELD1*	Human: *CRELD1* is deleted in the cytogenetic disorder 3p– syndrome that is associated with common atrioventricular canal ASD and VSD	*CRELD1* is ubiquitously expressed in early development but later becomes more markedly expressed in the developing heart and branchial arches (chicken). Expression persists in adulthood in most tissues (human).	
Neurotrophin receptors	*trkC*	Mouse: *trkC*$^{-/-}$: mice lacking all trkC receptor isoforms die in the early postnatal period with severe cardiac defects such as atrial and ventricular septal defects, and valvular defects including pulmonic stenosis	Expressed in the outflow tract, the posterior wall of the aorta and the cardiac ganglia	
Eph receptors tyrosine kinases	*EphB2/B3*	Mouse: *ephB2*$^{-/-}$;*ephB3*$^{-/-}$: similar phenotype with *ephrinB2* mutants but even more severely affected vessel formation *ephB4*$^{-/-}$: similar phenotype as *ephB2*$^{-/-}$.	*ephB2* is expressed in endocardiac cells and mesenchyme. *ephB3* is expressed in all endothelial cells and aortic arches. *ephB4* is specifically expressed in endothelial cells of all major veins.	
Semaphorin A receptors: neuropilins	*Np1*	Mouse: *Np1*$^{-/-}$: embryonic lethal at E12.5 with congenital heart defects like transposed great arteries, truncus arteriosus and arch anomalies most notable absent fourth and sixth aortic arches	*Np1* is a receptor for class 3 s*emaphorins* and for *VEGF* and is preferentially expressed in the endothelial cells of arteries.	*Np2* is similarly a receptor for class 3 s*emaphorins* but is preferentially expressed in the endothelial cells of veins. *Plexin A2* belongs to the *plexins* family of receptors for transmembrane *semaphorins* and is expressed in migratory and postmigratory cardiac neural crest cells.
Integrins	α*4*β*1 integrin*	Mouse: α*4*β*1 integrin*$^{-/-}$: embryonic lethal at E12.5 with absent epicardium and hemorrhagic cardiac disease.	α*4*β*1 integrin* is expressed both in epicardial cells and cardiac outflow tract cells and appears to be essential for epicardium formation and maintenance	
FGFR	*DFGF-R2 (DFGRI)/ Heartless (Htl)*	*Drosophila*: *Htl* mutants lack visceral mesoderm, heart, and the dorsal somatic muscles.	*Htl* is expressed in the embryonic mesoderm and is essential for cell migration and establishment of several mesodermal lineages into primordia for the heart, visceral and somatic muscles.	
*PDGFR*α	*PDGFR*α	Mouse: *PDGFR*α$^{-/-}$: conotruncal defects, thin myocardium, pericardial effusion	Expressed in cardiac neural crest cells	

(Continued)

Table 10-1 ***(Continued)***

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
Ig superfamily	*VCAM-1*	Mouse: *VCAM*$^{-/-}$: most of them embryonic lethal between E10.5 and E12.5 with severe placental defects, absent epicardium, bloody pericardial effusion and reduced compact layer of ventricular myocardium and intraventricular septum.	Expressed in the epicardium and the underlying myocardium, as well as in the intraventricular septum	*Pecam-1* is expressed in the endothelium of the dorsal aorta and the ventricular and outflow tract endocardium (mouse).
Retinoid acid receptors	*RXR*	Mouse: *RXR*α$^{-/-}$: embryonic lethal at E14.5 from heart failure as result of a thin walled myocardium *RAR*α–/– and β–/–: thin walled myocardium	Retinoic acid and its metabolites are signals that trigger and modulate cardiac morphogenesis during vertebrate development. The mediators of response to retinoids are transcription factors and proteins of the nuclear hormone receptor superfamily (*RARs, RXRs*), that bind these ligands. *RXRs* are expressed in neural crest cells (mouse, chicken). *RARs* are expressed in neural crest and its derivatives, in endocardial cells and sites of ectomesodermal interaction.	There is considerable overlap and redundancy among the various RAR receptors, so the exact role of each one is difficult to be determined. Conoventricular and conoseptal hypoplasia type VSDs have been identified in compound heterozygotes for various RAR receptor isoforms in association with excessive cell death in the conoseptum.
	RAR(α1/β2, α/β2, αγ)	*RAR* inhibition of all isoforms (α, β, γ) impairs the formation of third, fourth, and sixth pharyngeal arches and their derivatives and is associated with conotruncal defects (interrupted aortic arch, truncus arteriosus, VSD, DORV).		
Angiopoietin	*Agpt1*	Mouse: *Agpt1*$^{-/-}$: embryonic lethal at E12.5 with severe vascular anomalies reminiscent of those seen in embryos lacking *TIE2*. Mutant mice have abnormal ventricular endocardium with decreased trabeculations and collapsed atrial endothelial lining.	Expressed in myocardium wall surrounding the *TIE2* expressing endocardium	
Erythropoietin receptor	*EpoR*	Mouse: *EpoR*$^{-/-}$: embryonic lethal during midgestation with similar phenotype as the *Epo*$^{-/-}$ mice	*EPOR* is expressed in the developing heart in a subset of cardiac tissues (endocardium, epicardium, pericardium and endocardial cushions) but not myoocardium.	
Endothelin receptors	ET_A	Mouse: $ET_A^{-/-}$: conotruncal and aortic arch defects	Similar expression pattern as *ET-1*	
ECE	*ECE-1*	Mouse: *ECE-1*$^{-/-}$: conotruncal and aortic arch defects (Rebagliati 1998)	Expressed in the pharyngeal ectoderm and the aortic arch endothelium.	
	ECE-2	*ECE-1*$^{-/-}$;*ECE-2*$^{-/-}$: as above plus atrioventricular valve abnormalities	Expressed in the endocardiac cushions	
Orphan nuclear receptors	*COUP-TFII (Nr2f2)*	Mouse: *COUP-TFII*$^{-/-}$: embryonic lethal with defects in angiogenesis and heart development; the atria and sinus venosus fail to develop past the primitive tube stage.	*COUP-TFII* is expressed in mesoderm but only in sinoatrial region of the forming heart.	svp (Drosophila)
Phospatidyl-serine recptor	*Ptdsr*	Mouse: *Ptdsr*$^{-/-}$: Ablation of *Ptdsr* function in knockout mice causes perinatal lethality from cardiac failure associated with cardiac defects such as VSDs, double-outlet right ventricle, and		

		hypoplasia of the pulmonary artery. They also display thymus hypoplasia, ocular lesions, hematopoietic defects, growth retardation as well as delay in terminal differentiation of the kidney, intestine, liver and lungs during embryogenesis	
c. Channels			
Connexins	*Cx40*	Mouse:	Both *Cx40* and *45* are expressed in the His bundles in mice. *Cx43* is expressed in proepicardial and cardiac neural crest cells and is involved in the proper epithelial–mesenchymal transformation of the proepicardial cells and the development of cardiac neural crest cells.
	Cx43	*Cx40*$^{-/-}$: cardiac conduction abnormalities but not complete cardiac block	
	Cx45	*Cx43*$^{-/-}$: lethal in neonatal period, conotruncal defects in the RVOT, coronary artery abnormalities	
		Cx45$^{-/-}$: Embryologically lethal at E10; heart failure, endocardial cushion defect, conduction block	
3. Cell structure and motility			
KIF		Mouse:	
	Kif3A	*Kif3A*$^{-/-}$: embryonic lethal at E10.5; cardiovascular insufficiency, pericardial effusion, randomization of laterality in heart looping	Expressed in nodal cilia and ubiquitously. Important for leftward nodal flow
	Kif3B	*Kif3B*$^{-/-}$: left-right randomization	
Axonemal dynein	*DNAH11/ Lrdynein (lrd)/iv*	Human:	Initially is expressed symmetrically in the node at embryonic day 7.5 but at embryonic day 8, a striking asymmetric expression pattern is observed in all three germ layers, suggesting roles in both the establishment and maintenance of left–right asymmetry.
		Mutation in *DNAH11* has been found in a patient with Kartagener syndrome.	
		Mouse:	
		lrd$^{-/-}$: Homozygous mutants display randomized left-right development but no congenital heart defects (identical with *iv/iv* mutant mice)	
Smoothened	*Smo*	Mouse:	*Smo* acts epistatic to *Ptc1* to mediate *Shh* and *Ihh* signaling in the early mouse embryo.
		Smo–/–: developmental arrest at somitogenesis with small, linear heart tube, open gut, and cyclopia	
Laminin	*Laminin*	*Drosophila*:	Expressed in extracellular mattrix
		laminin A deficient embryos:display twists and breaks of cardioblasts at late embryonic stages as a result of dissociation of the pericardial cells	
		Mouse:	
		laminin–$\alpha 2^{-/-}$: display phenotype equivalent with muscular dystrophy; mutants die prematurely at 5 mo from unidentified cause	
Hyaluronidase synthase	*Has2*	Mouse:	Important for AV cushion transformation
		Has2$^{-/-}$: embryonic lethal at E9.5 with abnormal formation of AV cushions and outflow tract, thin myocardium, pericardial edema	

(Continued)

Table 10-1 ***(Continued)***

Protein family function	*Gene name*	*Organism*	*Expression sites and stages of involvement*	*Other family genes with potential role in cardiac development*
UDP-glucose dehydrogenase	*UDP-GD*	Zebrafish: *jekyll*: zebrafish mutants for *UDP-GD* have thin myocardium and hypoplastic endocardial cushions		
Perlecan (heparin–sulfate proteoglycan)	*Perlecan*	Mouse: *Perlecan*$^{-/-}$: embryonic lethal at E10 or at birth; TGA, hyperplastic semilunar valves	Perlecan is present in the basal surface of myocardium and endocardium, as well as surrounding neural crest cells. It controls production of heparin–sulfate proteoglycan and is important for AV cushion transformation.	
Versican	*Cspg2 (versican)*	Mouse: *Hdf (Cspg2* $^{-/-}$*)*: Embryonic lethal at E10.5; the future right ventricle and conotruncus of the single heart tube fail to form and the endocardial cushions are absent	*Cspg2* gene controls expression of the chondroitin sulfate proteoglycan versican and is required for the successful development of the endocardial cushion swellings and the embryonic heart segments that give rise to the right ventricle and conotruncus.	
Fibulin	*Fibulin-2*	Mouse: *Fibulin-2* $^{-/-}$: No cardiac developmental abnormalities	Expressed in AV cushions	
Fibrillin	*Fbn-1* *Fbn-2*	Human: Heterozygous mutations of *Fbn1* and *Fbn2* are associated with Marfan's phenotype	Expressed in endocardial cells	
Elastin	*Elastin*	Human: Haploinsufficiency of Ch7q11.23 that includes elastin is associated with Williams-Bueren syndrome (supravalvular aortic stenosis, elfin facies, hypercalcemia and mental retardation)		
Collagen	*COL3A1*	Human: Ehlers-Danlos syndrome type IV results from mutations in the *COL3A1* gene, which encodes the polypeptides in type III collagen	Collagen VI genes are expressed in the AV canal tissue of embryonic mouse hearts and are included in the region of the human chromosome 21 that is considered critical for congenital heart defects.	
	Collagen6 α1/α2	Mouse: Specific alleles of the collagen genes associated with atrioventricular canal defects		
Vinculin	*Vinculin*	Mouse: *Vinculin*$^{-/-}$: early embryonic lethal between E8-E10 with severely reduced and akinetic myocardial and endocardial structures	Ubiquitously expressed (mouse)	
4. Metabolism				
Folbp	*Folbp1*	Mouse: *Folbp1*$^{-/-}$: embryonic lethal at E10, growth retardation, neural tube defects and aortic arch defects	*Folbp1* is expressed in the mesenchyme of the pharyngeal arches. Phenotype was rescued by folate rich diet.	
RALDH	*RALDH1,2*	Mouse: *RALDH2*$^{-/-}$: embryonic lethal at E10.5 with formation of an unlooped medial distended cavity and severe impairment of posterior	*RALDH2* is expressed in the mesenchyme and the early heart epicardium	*RALDH1* is coexpressed with *Raldh2* in the early heart epicardium, and is later specifically expressed in developing heart valves.

	chamber (atria and sinus venosus) development. The developing ventricular myocardium consists of a thick layer of loosely attached and prematurely differentiated cardiomyocytes. Mutant mice harboring a hypomorphic allele of *RALDH2* die perinatally and exhibit the features of the human DiGeorge syndrome (DGS) with heart outflow tract septation defects and selective defects of the posterior (third to sixth) branchial arches

ASD, atrial septal defect; VSD, ventricular septal defect; TOF; Tetralogy of Fallot; IAA, interrupted aortic arch; RAA, right aortic arch; TA, truncus arteriosus; AV canal, atrioventricular canal; DORV, Double outlet right ventricle; HLHS, hypoplastic left heart syndrome; DGS, DiGeorge syndrome; DGCR, DiGeorge critical region; RSCA, retroesophageal subclavian artery; bHLH, basic helix-loop-helix; Prh, proline-rich homeobox is the new name for Hex, hematopoietically expressed homeobox; TGF, transforming growth factor; FGF, fibroblast growth factor; EGF, epidermal growth factor; PDGF, platelet-derived growth factor; Bmp, Bone morphogenetic protein; VEGF, vascular endothelial growth factor; RALDH2, retinaldehyde dehydrogenase.

of its close phylogenetic relationship to humans and the similarities between the mouse and the human heart at the anatomic and physiological levels. The completion of sequencing of the mouse genome adds an additional advantage over other species for dissecting genetic pathways associated with congenital malformations.

However, murine cardiac development is difficult to observe in a serial fashion in vivo without new imaging techniques because of the relatively inaccessible embryo, and because most mouse embryos with severe cardiac malfunction die early *in utero*, complicating functional analysis. Systematic screens of the mouse genome for recessive mutations affecting morphogenesis of several organs have been initiated but are decidedly expensive. Experimentation with the chick *Gallus gallus*, whose embryonic material is easily accessible for physical manipulation from the earliest stages, has proven beneficial for some areas like the study of neural crest. The African clawed frog *Xenopus laevis* has been used mostly to study the inductive interactions in the establishment of polarity and tissue differentiation. The drawback of these vertebrates is the long generation time and the inapplicability of classic genetics. The teleost fish *Danio (formerly Brachydanio) rerio* (zebrafish) has emerged as a model system because of its prolific egg production, rapid (90 d) generation time, optically transparent embryo, and extremely rapid heart development (48 h). In addition the sequencing of the zebrafish genome is close to completion. Loss-of-function gene models have been successfully created in zebrafish with the use of morpholino-modified antisense oligonucleotides. In zebrafish embryos the cardiovascular system is functional at 24 h but not essential for survival of the early embryo, which obtains adequate oxygen by simple diffusion, and even mutant embryos with complete lack of circulation can survive for 3 d. This is an important advantage over the mammalian embryos, whose survival is dependent on an intact circulation, and allows the study of zebrafish mutants with cardiovascular defects, whose mammalian embryonic counterparts undergo rapid degeneration and absorption. Despite the advantages of the zebrafish system for mutational analysis, there are some aspects of cardiovascular construction, namely septation and pulmonary artery formation that must be studied in higher vertebrates. Finally, the fruit fly, *Drosophila melanogaster*, completes the panel of experimental models used in cardiogenomics. One of the most remarkable discoveries was of the gene needed in *Drosophila* to produce a heart. Finding this gene, named "*tinman*" after the Wizard of Oz character in need of a heart, led to the identification of the evolutionarily conserved, and previously unknown, class of homeodomain-containing "*NK*" genes, which are critical for cardiac muscle development in all animals. Orthologous relationships between *NK* and other cardiac gene regulatory networks in *Drosophila* and mouse have been identified, showing that control of cardiac formation is likely to have been conserved over 600×10^6 yr.

Information on the genetic and molecular bases of cardiovascular development, function, and disease that has accumulated from the combination of data from animal models and human genetic studies is leading to a redefinition of the pathophysiology of congenital heart diseases, and innovative diagnostic and prognostic tools are emerging. This chapter discusses the anatomic malformations, which comprise the majority of cases of human congenital heart disease, but specifically excludes heritable cardiomyopathies, long QT syndrome and Marfan syndrome, discussed in other chapters.

CLINICAL FEATURES

The majority of human newborns with hemodynamically significant heart defects present in the first 2 wk of life with one out of four physiological arrangements: obstruction to pulmonary arterial circulation, obstruction to systemic arterial circulation, inadequate mixing between pulmonary and systemic circulations, or pulmonary venous obstruction. Because of the two-connected-pumps-working-in-parallel construction of fetal cardiac circulation (Fig. 10-1, left panel), these four types of hemodynamic aberrations are well tolerated for a 40-wk gestation. An obstruction to the pulmonary or aortic outflow is reliably compensated by blood flow shifting to the contralateral side of the heart. Transposition of the great arteries with intact ventricular septum does not have hemodynamic consequences because it merely constitutes a different variety of two-connected-pumps-working-in-parallel configuration. Anomalous pulmonary venous connection with pulmonary venous obstruction does not substantially alter prenatal hemodynamics because minimal blood flows into the lungs *in utero*.

The four physiological derangements described earlier are unmasked when the circulation is acutely changed at birth to a two-unconnected-pumps-working-in-series arrangement, with lungs but without placenta (Fig. 10-1, right panel). The rapidity of presentation is critically dependent on the time-course of foramen closure or ductal closure or both. Impaired pulmonary flow manifests as cyanosis, whereas impaired systemic circulation manifests as "low output syndrome." Inadequate mixing between the pulmonary and systemic circulations also appears as cyanosis. Because of the interstitial edema, pulmonary venous obstruction manifests as tachypnea in addition to cyanosis. Although these four hemodynamic subsets account for virtually all cases of heart defects appearing in the first 2 wk of life, severe cases of the rare malformation "absent pulmonary valve syndrome," whose cardinal feature is ventilatory failure because of airway impingement by adjacent markedly dilated pulmonary arteries, may also present on the first day of life.

A few types of malformation are evident after 2 wk of age. Isolated large septation defects resulting in left-to-right shunt physiology typically do not present in the first 2 wk of age because the magnitude of the left-to-right shunt depends mostly on the pulmonary vascular resistance, the latter parameter falling to its adult value gradually over the first 6 mo. The uncommon condition of anomalous origin of the left coronary artery from the pulmonary artery, which results in gradual-onset myocardial ischemia, also manifests after the neonatal period because the reduction in perfusion of the left ventricle is closely linked to the fall in pulmonary vascular resistance. Finally, in some rare forms of congenital heart defects, a physiologically corrected but inherently abnormal organization of the cardiac segments has no immediate hemodynamic effects (L-TGA). However, at a much later point, the longevity of this arrangement is challenged by the long-term mechanical cues (e.g., pressure or volume overload) normally not destined for these anatomic structures, and heart failure frequently occurs.

DIAGNOSIS

Although the screening protocol includes physical examination, arterial blood gas, electrocardiogram, and chest roentgenogram, the principal tool for detailed characterization of morphology and hemodynamics in the human newborn is ultrasound imaging. With

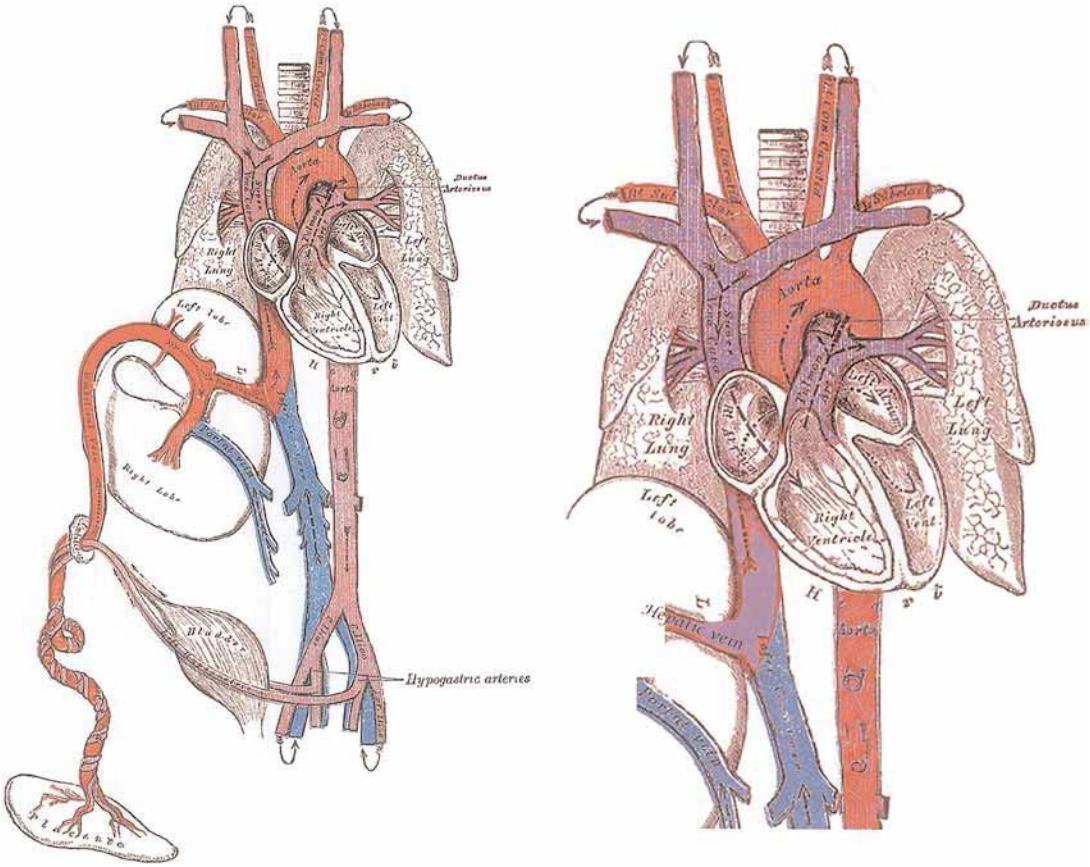

Figure 10-1 (Left) Fetal circulation in the human. Oxygenated blood travels from the placenta to the fetus through the umbilical vein and then the ductus venosus. After combining with deoxygenated inferior vena caval blood, it preferentially streams across the foramen ovale into the left heart and eventually supplies the ascending aorta. Deoxygenated superior vena caval blood preferentially fills the right heart and supplies the descending aorta through the ductus arteriosus. Because they do not function as the gas exchange site, the lungs are not inflated *in utero* and receive very little blood flow. The two sides of the heart function as parallel pumps, communicating at the level of the atria (foramen ovale) and the great arteries (ductus arteriosus). (Right) Neonatal circulation in the human. The lungs inflate, assume their gas exchange function and begin to receive more blood flow. Ductus venosus and ductus arteriosus constrict in the first few days. The two sides of the heart function as pumps-in-series now; any blood passing through the right heart must eventually also pass through the left heart. (Reproduced with permission from Fray H Clemente CD: Gray's Anatomy of the Human Body, 1986, Lea and Febiger, Philadelphia.) (Please *see* color insert.)

progressive refinement over the last 20 yr, its accuracy in assessing anatomy and circulatory physiology in the newborn and young infant now approaches that of cardiac catheterization.

Taking a detailed family history and surveying the patient for subtle extracardiac anomalies will become an increasingly important part of the workup. For example, a prolonged PR interval in patients with ostium secundum atrial septal defect in healthy first-degree relatives can be useful in genetic counseling because it indicates the possibility of mutation in the *CSX/NKX2.5* gene. For the detection of deletions, translocations, or duplications, fluorescence *in situ* hybridization will become standard as probes become widely available. With the advances in detecting underlying genetic defects, it is expected that classification of the patients by phenotype will give way to classification by genotype.

GENETIC BASIS OF DISEASE AND MOLECULAR PATHOPHYSIOLOGY

The prevailing view of the etiology of congenital heart disease had been that 8% of defects were single-gene defects, 2% were teratogens, and 90% were "multifactorial." Three classes of observation argue against this view. First, as the number of adult survivors of congenital heart disease in the United States approaches 1 million, surveys of the F1 generation reveal a much higher incidence of congenital heart malformation than previously reported. Second, an increasing number of genes responsible for syndromes involving the heart are being identified by positional cloning, a technique based on identifying a DNA marker with which a phenotype cosegregates. Third, mutations producing phenotypes similar to human congenital heart disease are being identified in several lower vertebrates (Table 10-2). In mouse, the technique of targeted gene disruption has uncovered models for DGS (*Tbx1, Hoxa-3, RALDH2, CRKL* knockout mice) and subpulmonary stenosis (*connexin 43* knockout). Spontaneous mutations in the *iv* and *pax-3* genes produce models for heterotaxy and truncus arteriosus, respectively. In zebrafish, initial mutagenesis screens have revealed mutants lacking endocardium or valves, manifesting tachyarrhythmias, and demonstrating myocardial hypoplasia or hyperplasia. Besides the growing list of molecules found to affect heart development, epigenetic factors are likely to be also involved in this process. For example, intracardiac hemodynamics and early myocardial function seem to affect the endothelial-mesenchymal transformation that precedes the development of endocardial

cushions and formation of heart valves. In addition, clinical and experimental data suggest that abnormal cardiac function because of alterations of the cardiac contractile and cytoskeletal properties can impair ventricular growth.

Reverse genetics in humans has been successful as exemplified by the mapping of several familial disorders to specific chromosomal loci. Familial supravalvar aortic stenosis (SVAS), an autosomal-dominant disorder affecting many large arteries (particularly the pulmonary arteries and the ascending aorta) was found to be coinherited with a DNA polymorphism at 7q11.23. Analysis of a SVAS family in which a balanced translocation, involving chromosome 7 cosegregated with the phenotype showed that the elastin gene was disrupted. Another SVAS family manifested a large deletion in the elastin gene. In addition, SVAS also occurs as part of Williams syndrome (supravalvar aortic or pulmonary stenosis, stenoses of other systemic arteries, elfin facies, precocious verbal ability, hypersensitivity to sounds, poor visual-motor integration); 95% of Williams syndrome patients have a 1.5 Mb deletion encompassing 28 genes including elastin.

Of patients who have a complete atrioventricular canal, approx 85% exhibit Down syndrome. In the complete form of common atrioventricular canal, the atria and ventricles are incompletely septated; in addition, the atria drain into the ventricles via a single (common) atrioventricular valve with typically five leaflets. Through studies of families with various partial 21 trisomies, a critical region of 9 Mb for atrioventricular canal defects has been identified (21q22.2-21q22.3). However, a specific gene has not yet been identified as responsible for the common atrioventricular canal.

Holt Oram syndrome (an autosomal-dominant condition with forelimb anomalies, ostium secundum atrial septal defects, and

atrioventricular block) is caused by mutations in the gene *TBX5*, which was cloned from the disease locus on human chromosome 12q24. Finally, progress has been made in the search for the etiology of interrupted aortic arch, truncus arteriosus, and Tetralogy of Fallot (TOF) (Tables 10-1 and 10-2). These defects with Velocardio-facial syndrome (VCFS)/DGS are associated with the microdeletion in the region 22q11 (DiGeorge Critical Region). The anomalies in the VCFS/DGS phenotype are in structures to which migrating neural crest cells contribute, so it is understandable that much attention is being focused on genes known to be important in cell–cell signaling and cell movement. Other work centering on transcription factors, which may function as master controls, is also important. *TBX1*, a transcription factor within the deleted region, is emerging as the critical gene for cardiac outflow tract development with a dose dependent function (Fig. 10-2). Intriguingly, human patients with an isolated deletion or mutation of *TBX1* had not been reported until a few patients with DGS in Japan were identified, who harbor nonfunctional *TBX1* mutations. The interaction of *TBX1* with modifier genes is a possible explanation for this paradox, although only a few potential *TBX1* partners have been identified. However, it is likely that *TBX1* has several other partners that contribute to the variable expressivity of the mutant phenotype, and this model could be operational in other congenital heart diseases.

Although the physiologically based schema mentioned in the clinical features section works well for the clinician, a developmentally oriented classification of defects may be more appropriate for the molecular biologist. The important steps of cardiac development as known from different species should be taken into account, starting with the genesis and migration of precardiac cells from the lateral plate mesoderm followed by their ventral migration to form a single beating heart tube and the activation of genes responsible for the subsequent morphogenetic steps of looping, wedging, atrio-ventricular septation, formation of the outflow tracts largely from pharyngeal mesoderm and endocardial cushions, and aortic arch formation and remodeling.

MANAGEMENT/TREATMENT

Today, surgical or catheter-based reconstruction of most congenital heart malformations is virtually always feasible. Even the varieties with hypoplasia of one or the other ventricle can be palliated for approx 20 yr with a modified Fontan operation, in which the systemic venous circulation is rerouted directly into the pulmonary arteries. Assessment of the quality of the surgical repair is no longer done 6 or 12 mo postoperatively but rather in the operating room or shortly before hospital discharge. Long-term follow-up typically uses noninvasive techniques such as ultrasound, MRI, and exercise testing. However, in most cases the treatment is palliative, not curative, and the incidence of residual disease remains relatively high among the exponentially expanding population of adult survivors with "corrected" congenital heart disease. For example, patients with Fontan physiology need a series of "staged" operations and are at risk for developing recurrent effusions, arrhythmias, hepatic dysfunction and protein losing enteropathy. Moreover, the single functional ventricle in these patients gradually decompensates, and they eventually need heart transplantation. Patients with severe forms of Tetralogy of Fallot may need successive surgeries for replacement of their conduits because of recurrent stenosis or for inability to tolerate severe residual pulmonary insufficiency. Lesions repaired through ventriculotomy (such as double-outlet right ventricle and truncus arteriosus) pose increased risk for fatal arrhythmias later in life.

Further medical and surgical advances may address some of these remaining questions; in particular the advent of fetal cardiac surgery may open new perspectives in the management of congenital heart diseases. Alternatively, other ways of further lowering the morbidity of congenital heart defects are prevention (by genotyping, counseling, or some form of early "genetic" intervention), termination *in utero* on phenotype recognition, and better prenatal as well as postnatal screening. Although the second may be practiced in some countries, for religious and ethical reasons it is doubtful whether it will ever be widely implemented in the United States. The third way (improved screening methods) has not proved cost-effective. Hence, efforts will likely be concentrated on the first approach. As a prerequisite, more work is needed to understand the construction of the heart and vessels at the molecular level. Once the specific genetic basis for cardiac defects is identified, it should become possible to establish the basis for genetic counseling and treatment. In particular, genotypic analysis could determine the risk status of the patients' relatives or identify individuals predisposed for specific defects at an early stage; bioengineering technology could allow the delivery of a corrected gene copy or correction of a structural defect. Stem cell biology and tissue engineering could generate parts (valves, vessels, or tissue for patches) to replace or repair defective heart tissue, thereby avoiding the complications associated with the use of artificial prostheses and heart transplantation. It would necessitate technological development in the fields of gene therapy, biopharmaceuticals, organ culture, and fetal surgery. The knowledge that secondary factors affect the ultimate phenotype of genetic mutations predicts that at least some types of congenital heart defects might be prevented by modulating these factors. Hence, it may become possible to choose drugs that would regulate gene expression to overcome a problem. For example, virtually all morphological and molecular abnormalities elicited by dietary or genetic retinoid deficiency can be rescued by systemic (maternal) administration, reminiscent of preventing neural tube defects with folic acid supplementation in women of reproductive age.

FUTURE DIRECTIONS

The following are some of the questions that biologists hope to answer:

How do the myocardial, endocardial, endothelial, and "cardiac neural crest" lineages become specified? How is the heart tube correctly positioned in the embryo and then "patterned?" Do the same families of molecules responsible for body axis patterning get reused in the patterning of organs? What is the role of the endocardium in the development of the heart? How are the cardiac valves formed? How is the "specialized" conduction system formed? (Humans with abnormal lateralization or looping have anomalous conduction systems.) Given that in mammalian hearts two atria and two ventricles function in parallel (and develop in tandem *in utero*), how is the growth of the left heart exquisitely matched to that of the right heart throughout gestation? How are the pulmonary vasculature and coronary vasculature formed? How are myocardial cells maintained in a state of terminal differentiation and how can non-heart or stem cells be reprogrammed toward a cardiogenic fate?

A variety of model organisms will yield answers to these questions. Although laboratories studying the mouse system will continue to create knockouts (including double and triple knockouts,

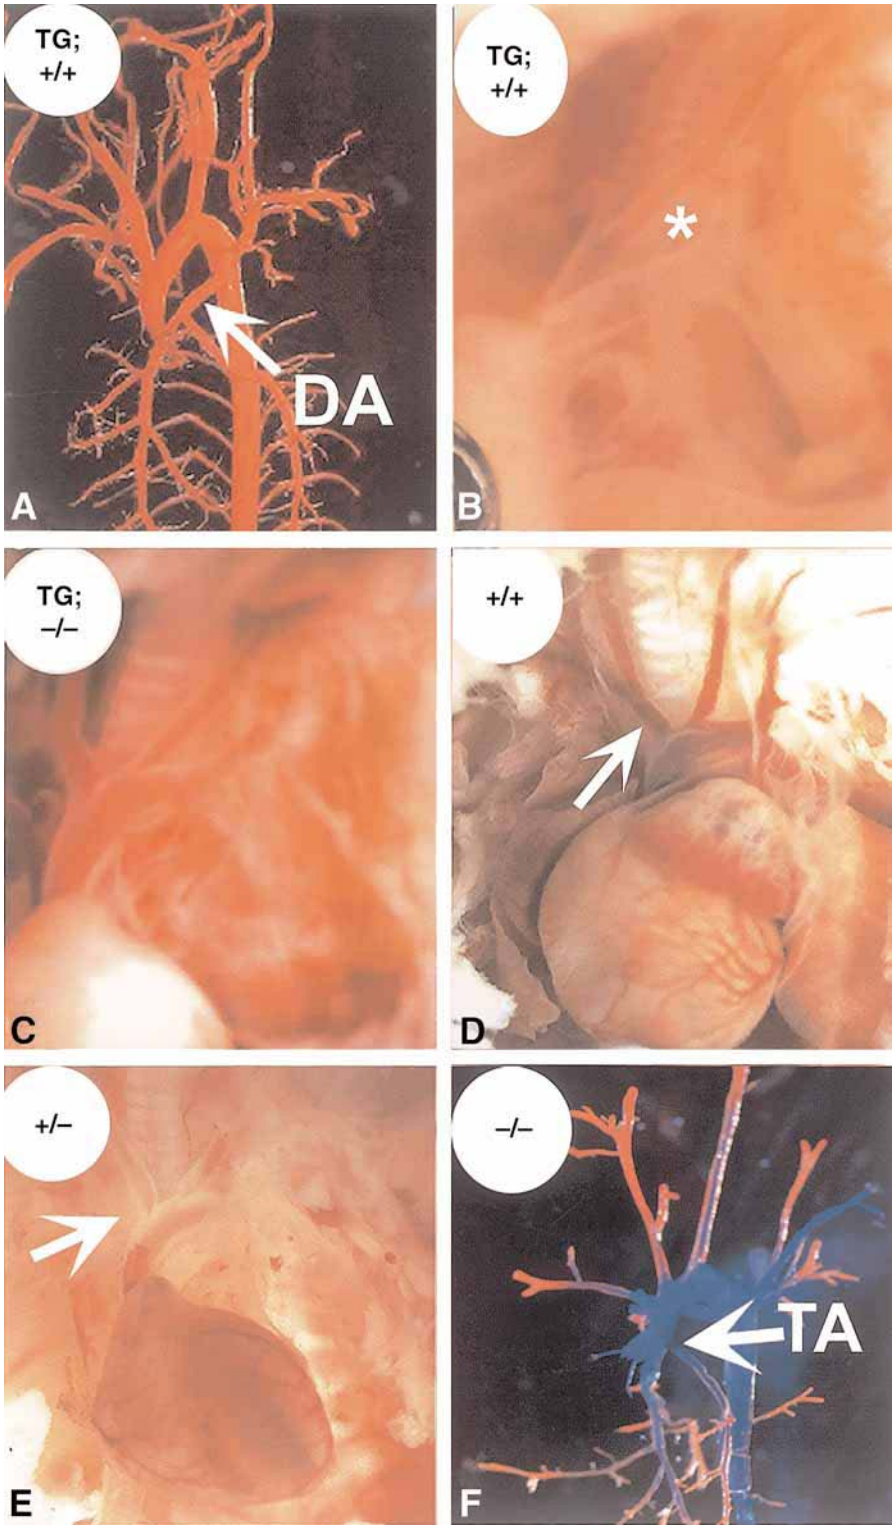

Figure 10-2 Dosage sensitive role of *Tbx1* in the etiology of cardiovascular defects in mice. Aortic arch variations in E18.5 mouse embryos with different Tbx1 dosage as seen by corrosion casts (A, F) or tissue dissection (B–E). Higher than normal *Tbx1* dosage in transgenics overexpressing *Tbx1* on wild type background (TG;+/+) causes several outflow tract and aortic arch abnormalities (A, B). **(A)** Pulmonary atresia with absent main pulmonary artery: the ductus arteriosus supplies the branch pulmonary arteries bilaterally. **(B)** Interrupted aortic arch type B (*indicates the site of interruption). As the *Tbx1* dosage normalizes in mice harboring the overexpressing transgene on $Tbx1^{-/-}$ background (TG;–/–) or in wild mice (+/+) the cardiovascular abnormalities are rescued (C, D). Both **(C)** and **(D)** display normal aortic arch anatomy; the arrow in D indicates the bifurcation of the innominate artery into right subclavian and right carotid artery. Lower than normal Tbx1 dosage as in mice haploinsufficient (+/–) or null for *Tbx1* (–/–) causes similar conotruncal and aortic arch defects as higher than normal Tbx1 dosage (E, F). **(E)** Aberrant right subclavian artery: the arrow points to the right carotid artery originating as a single vessel from the aortic arch because of the aberrant origin of the right subclavian from the descending aorta (the aberrant retroesophageal subclavian artery cannot be seen in this view). **(F)** Truncus arteriosus with the pulmonary arteries originating directly from the common arterial trunk. (Please *see* color insert.)

and so on), mice carrying specific mutations of nonnull, i.e., hypomorphic alleles may be more illuminating, because they may mimic the human conditions more closely. "Conditional," such as tissue- or stage-specific, mutant lines will also become more common. Zebrafish labs will continue to analyze the zygotic recessive mutations affecting cardiovascular development. Cloning the genes affected in these mutants will be facilitated by the completion of sequencing of the organism's genome. However, the construction of additional genetic tools such as transgenic fluorescent-reporter zebrafish lines whose embryos fluoresce green when a structure or tissue of interest is first specified could serve as the starting reagent for large-scale "targeted" mutagenesis screens in this organism. In the current postgenomic era, with the complete genome sequences of several species (including human, mouse, and zebrafish) at hand, the challenge will be to understand the function of genes within the cardiovascular system. One of the most powerful methods available to assign function to a gene is to inactivate the gene by reverse genetic approaches. In this regard loss-of-function gene models have been successfully created in zebrafish with the use of antisense morpholino oligonucleotides that can specifically inhibit the translation of a specific gene. However, this method is suited only for early developmental stages with the additional drawback of nonspecific side effects. Recently, a new reverse genetic approach, hitherto utilized in plants, target induced local lesions in genomes is being applied to zebrafish to generate allelic series in individual genes of interest. In humans, positional cloning will continue to be employed for large families with single-gene disorders. Attempts to correlate particular amino acid substitutions with specific human cardiac malformations will afford further insight into the structure-function relationships of the relevant proteins, whether they are transcription factors, signals, or receptors.

11 Inherited Cardiomyopathies

Carolyn Y. Ho and Christine E. Seidman

SUMMARY

Genetics is an emerging field in cardiovascular medicine. Remarkably, less than 50 yr ago genetics was a nascent field of basic research with little apparent relevance to cardiovascular science or any other medical subspecialty. Yet today cardiovascular genetics is a discipline that fully integrates high technology laboratory investigation and clinical medicine. From this unusual hybrid have emerged discoveries that precisely identify cause in here-to-for "idiopathic" disorders, that provide fundamental insights into disease processes, and that delineate subtypes in well-defined pathologies. Insights from these discoveries uproot traditional anatomic classifications of disease and integrate cell physiology and molecular biochemistry into the study of pathology. For researchers, practitioners, and patients alike, cardiovascular genetics has a growing impact on the definition and diagnosis of disease, on explaining prognosis, and expanding treatments.

Key Words: Dilated cardiomyopathy; DNA; gene; genetic risk; hypertrophic cardiomyopathy; mutation; modes of inheritance; preclinical disease; sequence.

INTRODUCTION

Cardiomyopathies are disorders of the myocardium, which arise from a variety of etiologies and trigger pathways that may culminate in hypertrophic or dilated remodeling of the heart. The details of the cellular and molecular events that lead to compensatory forms of cardiac remodeling in response to a superimposed load remain largely unknown. In contrast, there have been greater advances in the study of primary cardiomyopathies, disorders of cardiac myocytes, which remodel the myocardium in the absence of other underlying pathology. Inherited gene defects are increasingly recognized as the most common cause of hypertrophic cardiomyopathy (HCM) and a frequent cause of dilated cardiomyopathy (DCM). Elucidating the molecular mechanisms leading from genetic mutation to the clinical expression of disease will have profound effects on the understanding of broader issues of basic myocyte structure and function, and influence the approach to disease management.

HYPERTROPHIC CARDIOMYOPATHY

CLINICAL ASPECTS HCM was first described over 100-yr-ago but the modern characterization dates to 1959. It has been traditionally typified by unexplained cardiac hypertrophy in a nondilated ventricle (Fig. 11-1). By definition, this refers to myocardial hypertrophy that occurs in the absence of any systemic or cardiac condition (such as hypertension or aortic stenosis) which may account for an increased load on the heart. The most common pattern of hypertrophy is asymmetric septal hypertrophy, but there is a significant variation in both the location and extent of left-ventricular hypertrophy (LVH) in affected individuals. The histopathological hallmarks of this condition are myocyte hypertrophy with myocardial disarray and fibrosis (Fig. 11-2). Genetic studies have defined HCM to be a disease of the sarcomere, caused by mutations in genes encoding different components of the contractile apparatus.

Clinical manifestations of HCM are diverse and its description has been largely shaped by available diagnostic tools. Traditionally the most obvious and easily characterized features of this condition have been emphasized: outflow tract obstruction and LVH. However, resting outflow tract obstruction occurs in only approx 25% of patients. A provocable gradient may be detected in other patients by administering medications or performing maneuvers that reduce afterload or preload or increase cardiac contractility.

EPIDEMIOLOGY The prevalence of unexplained LVH in the general population is estimated to be 1 in 500. Most of these cases are likely attributable to mutations in genes that encode sarcomere proteins, making HCM the most common genetic cardiovascular disorder. HCM is also the leading cause of sudden death among competitive athletes in the United States.

SYMPTOMS The clinical spectrum of HCM is diverse. Although some individuals experience no or minor symptoms and are diagnosed only in the course of family screening, others develop refractory symptoms of pulmonary congestion, progressing to end-stage heart failure that may require cardiac transplantation. In a small subset, sudden cardiac death (SCD) may be the presenting event.

Shortness of breath, particularly on exertion, is the most common symptom of HCM, occurring in about 90% of patients. Other manifestations include chest pain (approx 30%, often exertional), palpitations, orthostatic lightheadedness, presyncope and syncope (15–25%), orthopnea/paroxysmal nocturnal dyspnea, and fatigue. There is no close correlation between the degree of LVH or outflow tract obstruction and the severity of symptoms. Although often multifactorial in etiology, the occurrence of syncope may be a marker for increased risk of SCD, especially in younger individuals.

(From Science 2003;299:1410–1413.) (Please *see* color insert.)

PHYSICAL EXAMINATION Left ventricular (LV) systolic function is typically preserved; however, abnormal diastolic function has been well documented and may largely account for symptoms of pulmonary congestion and exercise intolerance. Diastolic dysfunction may be a fundamental manifestation of altered sarcomere function. It precedes the development of LVH in preliminary studies of individuals who have inherited a causal sarcomere gene mutation, but have not yet developed other typical features of disease. In addition to impaired contractile function, some individuals with HCM have altered blood pressure response to exercise, possibly related to

abnormal vasomotor tone. This finding may indicate a worse prognosis with a higher risk for sudden death.

Typical findings on physical examination include a prominent LV apical impulse or lift, a fourth heart sound (S4), and a brisk, occasionally bifid carotid upstroke. If obstruction is present, there may be a harsh crescendo-decrescendo systolic murmur typically best heard at the apex and lower left sternal border, radiating to the axilla and base, but usually not to the neck. This murmur may reflect outflow tract obstruction as well as mitral regurgitation.

NATURAL HISTORY The natural history of HCM is highly variable, even among family members who have inherited the same causal mutation. HCM rarely presents in infancy or early childhood; development of LVH typically occurs in adolescence in conjunction with the pubertal growth spurt. The age of onset of hypertrophy may be determined to some extent by the specific nature of the underlying gene defect. Disease caused by mutations in the β-myosin heavy chain (β-MHC) gene is generally associated with phenotypically obvious disease with near-universal development of LVH by the second decade. In contrast, disease caused by mutations in the cardiac myosin binding protein C (cMyBPC) gene may not display clinically evident hypertrophy until the fourth or fifth decade of life. cMyBPC mutations have been associated with elderly onset HCM with initial clinical manifestations developing late in life.

Estimates of the annual mortality of HCM vary. Evaluation of populations drawn from specialized referral centers suggests a significant annual mortality rate of 4–6%. In contrast, community-based studies, which may be less susceptible to selection bias, suggest a more benign outcome with a projected annual mortality rate of 1–2%. HCM-specific causes of morbidity and mortality include SCD, progressive heart failure, atrial fibrillation, and heart failure, and stroke. Sudden death is the most feared complication of HCM and accurate estimation of an individual's risk for sudden death is a challenge. The risk for sudden death in the overall HCM population varies from 1 to 5% with about 10–20% of patients at highest risk. Less than 10–20% of patients progress to the "burnt-out" phase of HCM, marked by worsening symptomatic heart failure, LV systolic dysfunction, regression of LVH, and chamber dilatation. These patients may ultimately require cardiac transplantation for end-stage heart failure.

MANAGEMENT There are two major aspects to HCM management: alleviation of symptoms and assessment of the risk for SCD. Medical therapy is the cornerstone of treatment for symptomatic HCM and typically incorporates agents such as β-adrenergic and calcium channel antagonists to increase diastolic filling time, slow the heart rate, decrease contractility, and help normalize intracardiac filling pressures. For medically refractory patients with obstructive physiology, mechanical intervention to relieve outflow tract obstruction may be considered, including surgical septal myomectomy or catheterization-based alcohol septal ablation.

Clinical indicators of increased risk for sudden death include: a history of cardiac arrest or sustained ventricular tachycardia; significant nonsustained ventricular tachycardia on ambulatory monitoring; recurrent syncope; a hypotensive response to exercise in patients younger than 50 yr; massive LVH (>30–35 mm); and a family history of SCD or identification of a malignant genotype. However, estimation of an individual's risk is imprecise. If two or more risk factors are present, increased risk of SCD is present with an estimated annual mortality of 4–6%. Sudden death may be the initial presenting symptom of HCM or occur in only mildly symptomatic patients. Although sudden death has been associated with vigorous physical activity and HCM is the leading cause of SCD in US competitive athletes, many episodes have occurred in the setting of only mild or no exercise. Implantation of a cardiovertor-defibrillator is effective in decreasing the risk of sudden death from lethal arrhythmias in appropriate individuals.

GENETIC ASPECTS The observation that HCM occurred in families defined it as a genetic cardiovascular disorder with Mendelian autosomal-dominant inheritance. Linkage analysis of large kindreds with HCM identified several disease loci on chromosomes 1, 11, 14, and 15. Positional cloning and candidate gene analysis identified discrete mutations in genes that encode for different elements of the contractile apparatus, including cardiac β-MHC, cardiac troponins T and I, cMyBPC, α-tropomyosin, actin, the essential and regulatory myosin light chains, and titin (Table 11-1). Thus, genetic studies established the paradigm of HCM as a disease of the sarcomere (Fig. 11-3).

The sarcomere is the functional unit of myocyte contraction. Proteins are organized into a latticework of thick (myosin heavy and light chains) and thin (actin, the troponin complex, and α-tropomyosin) filaments that interdigitate during muscle fiber shortening and lengthening. The detachment and attachment of actin and the myosin head serve as the molecular motor of contraction and relaxation. The hydrolysis of ATP provides fuel, and changes in intracellular Ca^{2+} concentration coordinate thick and thin filament interaction.

More than 300 individual mutations have been identified in 11 different components of the contractile apparatus. Types of mutations include missense mutations (resulting in amino acid substitution), nonsense mutations (resulting in premature termination of translation), short insertions and deletions, and alteration of splice donor or acceptor sites (resulting in altered transcripts). There is no significant founder effect in HCM as mutations tend to be "private"—unique from family to family with rare reappearances in unrelated kindreds. *De novo* or sporadic mutations are also well described.

Mutations in cardiac β-MHC, cMyBPC, and cardiac troponins T and I account for approx 80–90% of described HCM cases. Significant diversity exists in the clinical expression of these inherited gene defects. Although a handful of mutations have been described as characteristically "benign" or "malignant," heterogeneity of phenotype is the rule. Further identification of causal mutations and accurate description of genotype–phenotype correlations remain a work in progress, but the wide genetic and clinical spectrum of HCM make this challenging. As the ability to more precisely and sensitively assess phenotype improves, more accurate associations will emerge. Broad, recurring themes are outlined in Table 11-1. It remains unclear why some sarcomere mutations cause more severe disease than others and why individuals with the same mutation have a wide range of clinical features. Description of wider genetic and environmental factors that shape the expression of the underlying mutation is an active area of investigation.

Cardiac β-MHC Mutations Mutations in the cardiac β-MHC gene on chromosome 14 are thought to account for approx 40% of cases of HCM. This protein is organized into two functional domains: an amino terminal globular head that interacts with actin and a carboxyl terminal rod. The force of the power stroke is transduced through a hinge region connecting the rod and head domains. Most HCM-causing mutations are of the missense

Table 11-1
Mutations That Cause Hypertrophic Cardiomyopathy and General Phenotypic Correlations

	Gene	*Designation*	*Chromosome*	*Frequency*	*Number of mutations*	*Phenotypic correlation*
HCM-sarcomere proteins	β-myosin heavy chain	β-MHC	14q1	~30–40%	>80	Typically obvious disease with significant LVH; several severe phenotypes (end-stage heart failure and sudden death)
	Cardiac myosin binding protein C	cMyBPC	11q1	~30–40%	>50	Typically more mild disease, but severe phenotypes have been described; elderly onset HCM
	Cardiac troponin T	cTnT	1q3	approx 5%	>20	Typically mild LVH but increased association with sudden death
	Cardiac troponin I	cTnI	19p1	5%	>10	
	α-tropomyosin	α-TM	15q2	<5%	8	
	Myosin essential light chain	MLC-1	3p	Rare	2	Skeletal myopathy
	Myosin regulatory light chain	MLC-2	12q	Rare	8	Skeletal myopathy
	Actin		11q	Rare	5	
	Titin		2q3	Rare	1	
Inherited left ventricular hypertrophy	γ-subunit AMP kinase	PRKAG2	7q3	?	3	Glucose metabolism; preexcitation and conduction disease; catecholeminergic polymorphic ventricular tachycardia
	Lysosome associated membrane protein 2	LAMP2	X	?		
	Muscle LIM protein	CRP3	11p	?	3

Cell 2001;104;557–567; http://cardiogenomics.med.harvard.edu/project-detail?project_id=230, with permission from Elsevier.

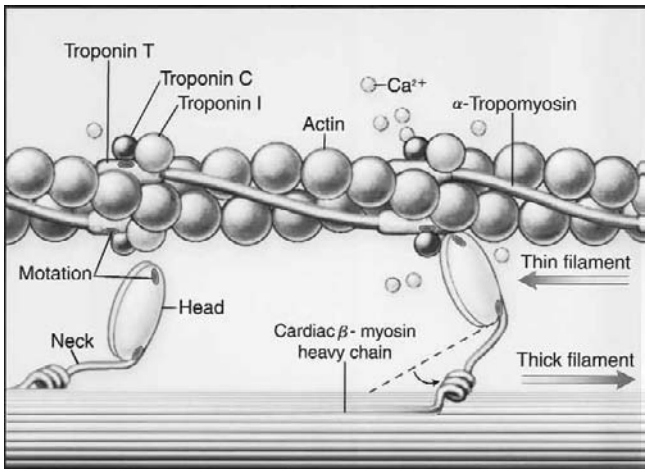

Figure 11-3 Mutations in genes that encode sarcomere proteins form the genetic basis of hypertrophic cardiomyopathy as well as some forms of dilated cardiomyopathy. (Reprinted with permission from N Engl J Med 2000; 343:1688–1696.)

variety and clustered within the globular head. The genetic basis of HCM was first described as missense mutation in this gene in which a single base pair is changed, resulting in the substitution of glutamine for arginine at residue 403.

Over 80 different β-MHC missense mutations have been reported in familial and sporadic disease. The phenotypic expression of these mutations tends to be fairly obvious with significant degrees of LVH apparent by late adolescence. Although heterogeneous, the clinical course of certain MHC mutations has been severe, associated with a striking risk of sudden death or development of end-stage heart failure. The precise determinants of the relationship between prognosis and underlying gene mutation are likely multifactorial and poorly understood. Mutations that result in a change in the charge of the substituted amino acid appear to result in more severe disease, presumably owing to more dramatic effects on protein structure and function.

Cardiac Myosin Binding Protein C Missense, splice site, and deletion/insertion mutations in cMyBPC likely account for approx 30–40% of HCM cases. This large protein (1274 amino acids) is encoded on chromosome 11 and may function to provide structural support to the sarcomere and to modulate myosin ATPase activity in response to sympathetic stimulation. In a significant subset of individuals with cMyBPC mutations, the development of clinically apparent LVH is delayed until age 50 yr or older. Elderly onset HCM is associated with mutations in cMyBPC. Disease course is generally mild and not typically associated with attenuated survival, but there are reports of increased sudden death risk related to cMyBPC mutations.

Cardiac Troponin T Troponin T links the troponin complex to α-tropomyosin and, therefore, plays a central role in regulating contraction. The cardiac-specific isoform is encoded on chromosome 1. Approximately 5% of HCM is thought to be attributable to cardiac troponin T (cTnT) mutations. Traditionally, the clinical phenotype has been characterized by modest degrees of LVH but an increased risk of sudden death, although "benign" cTnT mutations are also described.

EXPERIMENTAL MODELS OF HCM Mutations in sarcomere proteins may alter actin–myosin crossbridge formation, intracellular calcium cycling, the energetics of force generation, or the

transmission of force. However, the heterogeneity of HCM in the human population has challenged the dissection of the precise molecular mechanisms that lead from inherited gene defect to clinical phenotype.

To evaluate the consequences of specific mutations in a more precise and controlled manner, a variety of in vitro and in vivo experimental models of HCM have been developed. In vivo models are based on genetically modified animals in which β-MHC, cTnT, and cMyBPC mutations that cause human disease are introduced. The resultant animals develop a phenotype that recapitulates HCM phenotype, developing myocardial fibrosis, hypertrophy, and disarray in an age-dependent manner. Hemodynamic changes and abnormalities of diastolic function typically precede the development of LVH. Interrogation of these models remains a work in progress, but will allow further investigation into basic questions such as whether LVH is primary or secondary in response to either enhanced or impaired contractility; the influence of genetic background, modifier genes, the environment, and pharmacologic manipulation; and clarification of the early molecular events that lead to myocyte hypertrophy.

NEW PARADIGMS OF INHERITED CARDIAC HYPERTROPHY HCM is caused by mutations in genes that encode elements of the contractile apparatus. Mutations have been described in nonsarcomere proteins that mimic the phenotype of HCM. Genetic studies of families and sporadic cases of unexplained LVH with conduction abnormalities (progressive atrioventricular block, atrial fibrillation, ventricular pre-excitation/Wolff–Parkinson–White syndrome) have identified a novel disease entity caused by mutations either in the γ-2 regulatory subunit (PRKAG2) of adenosine monophosphate-activated protein kinase, or in the lyosome-associated membrane protein 2 (LAMP2) gene both enzymes involved with glucose metabolism. Ventricular pre-excitation typically occurs early in life and is often symptomatic. Progressive conduction disease occurs with increasing age such that permanent pacemaker implantation was necessitated in 30% of affected individuals and helped serve as a discriminating feature from HCM caused by sarcomere mutations. Severe clinical outcomes were noted in a subset of patients with PRKAG2 and LAMP2 mutations, including progression to end-stage heart failure or transplantation and SCD.

Inherited LVH caused by PRKAG2 and LAMP2 mutations is a disease entity distinct from HCM caused by sarcomere protein mutations. Despite superficial similarities, this distinction is illustrated by the different morphologic appearances of these glycogen storage cardiomyopathies as compared with HCM. LVH in mutations caused by LAMP2 mutations is typically striking and concentric. Histopathologically, PRKAG2 and LAMP2 mutations do not display the myocardial disarray characteristic of HCM, but rather a relatively minor amount of fibrosis and prominent nonmembrane bound vacuoles that, if appropriately handled and stained, demonstrate glycogen and amylopectin accumulation. These histologic features are more consistent with other disorders of glycogen storage, such as Danon or Pompe disease. Different molecular signaling pathways are involved and therefore the clinical approach to individuals glycogen storage cardiomyopathies should not be predicated on management tenets of HCM.

Mutations in the muscle LIM protein (MLP) may also cause inherited LVH. This protein plays an essential role as a promoter of myogenesis and may also act as a cofactor in the regulation of muscle-specific gene expression in skeletal and cardiac muscle. Mice with a MLP gene knockout have been described to develop both a dilated and hypertrophic cardiac phenotype. Studies to analyze for mutations in the *CRP3* gene (encoding MLP) in humans with hypertrophic heart disease revealed three novel missense mutations in three unrelated families.

DILATED CARDIOMYOPATHY

CLINICAL ASPECTS Heart failure is an important public health problem affecting 5 million patients in the United States. It is responsible for 1 million hospitalizations and 300,000 deaths annually. Pathologic remodeling of the heart resulting in increased chamber volume is termed DCM. Cardiac mass is increased because of enlargement of the chambers with only modest increase in ventricular wall thickness. Histopathologic changes may be relatively subtle with only minor myocyte hypertrophy, degeneration, and interstitial fibrosis.

DCM is a common cause of heart failure with a worldwide prevalence of about 36.5/100,000. Clinical manifestations may be somewhat protean, particularly in the early stages of disease. Characteristic symptoms include exertional dyspnea, fatigue, orthopnea, and lower extremity edema. Diagnosis is generally based on identifying increased cardiac dimensions and decreased contractile function. Exclusion of disorders that may cause cardiac dilation and dysfunction (coronary artery disease, alcohol abuse, thyroid disease, viral myocarditis, and infiltrative disorders such as hemochromatosis) generally leads to the diagnosis of "idiopathic" DCM; approx 25–30% are thought to have a genetic cause. The genetic basis of DCM is less specifically described than that of HCM. The clinical syndrome of DCM is also less distinctive than HCM, further challenging precise characterization.

There is significant variability in the clinical features of DCM because of single gene mutations. Age of onset ranges from early childhood to late adulthood, although most patients present during the fourth or fifth decades of life. Families may also manifest additional phenotypes that cosegregate with disease, including additional cardiac involvement (mitral valve prolapse and conduction system disease) and extracardiac conditions (sensorineuronal hearing loss and muscular dystrophies). These additional manifestations may be expressed in advance of DCM and therefore serve as supplemental measures to assign phenotypic status.

GENETIC ASPECTS The most common mode of inheritance of familial DCM is autosomal-dominant, but infrequent autosomal-recessive, X-linked, and mitochondrial transmission have been described (Table 11-2). Autosomal-dominant inheritance has been defined for a number of chromosomal loci and several specific genetic mutations have been characterized. Dominant mutations causing DCM may be associated with additional phenotypes as described above. Mutations that result in altered force generation and force transmission have been reported as a cause of autosomal-dominant DCM.

Missense mutations in β-MHC, α-tropomyosin, and an in-frame deletion of a lysine residue in cTnT have been identified as causes of autosomal-dominant DCM. Surprisingly, these mutations occur in sarcomere protein genes traditionally associated with causing HCM. The mechanisms by which mutations in the same gene lead to either a hypertrophic or dilated phenotype remain unclear. One speculation is that mutations associated with HCM may involve areas of the protein that are directly involved with generating energy or initiating the power stroke, resulting in impaired force generation, whereas mutations associated with DCM may result in impaired force transmission with subsequent cardiac enlargement and dysfunction.

Proper cardiac function also requires effective transmission of the force generated by the contractile apparatus to the extracellular

Table 11-2
Mutations That Cause Dilated Cardiomyopathy

	Gene	*Inheritance*	*Chromosomal location*	*Associated phenotypes*
Sarcomere proteins	β-myosin heavy chain	Autosomal-dominant	14q1	None
	Cardiac troponin T	Autosomal-dominant	1q3	None
	α-tropomyosin	Autosomal-dominant	15q22	None
	Actin	Autosomal-dominant	11q	None
Intermediate filament proteins/structural proteins	δ-sarcoglycan	Autosomal-dominant	5q33-34	None
	Desmin	Autosomal-dominant	2q35	Skeletal myopathy
	Desmoplakin	Autosomal-recessive	6p24	Wooly hair and keratoderma
	Plakoglobin	Autosomal-recessive	17q21	Arrhythmogenic right ventricular dysplasia, wooly hair, and keratoderma (Naxos syndrome)
	Dystrophin	X-linked	Xp21	Muscular dystrophy
Miscellaneous genes	Lamin A/C	Autosomal-dominant	1p1-q21	Conduction disease
	Tafazzin	X-linked	Xq28	Short stature and neutropenia (Barth syndrome)

Adapted from Schonberger J, Seidman CE. Many roads lead to a broken heart: the genetics of dilated cardiomyopathy. Am J Hum Genet 2001:69:249–260, with permission of The University of Chicago Press.

matrix. Filamentous proteins linking the sarcomere to the sarcolemma may assist in the propagation of force. Mutations in the portion of actin that participates in actin–cytoskeletal (rather than actin–myosin) interactions and mutations in the giant structural molecule, titin, have been implicated in causing isolated DCM. Intermediate-filament proteins, including desmin, connect actin to the dystrophin–sarcoglycan complex beneath the plasma membrane of all muscle cells. Mutations in desmin, dystrophin, and δ-sarcoglycan cause skeletal myopathies, some associated with myocardial involvement, as well as DCM with subclinical or no skeletal muscle involvement. The basis for the cardiac specificity of these mutations is unclear.

Rare syndromes with autosomal-recessive inheritance have been attributed to mutations in cellular adhesion molecules plakoglobin (associated with arrhythmogenic right ventricular dysplasia with palmoplantar keratosis and wooly hair—Naxos syndrome) and desmoplakin (similar phenotype with more prominent LV involvement). These molecules play critical roles at the junctions of desmosomes and adherens and therefore may participate in cell-to-cell force propagation. Sporadic or maternally inherited mutations in mitochondrial DNA can result in complex, multisystem phenotypes, including cardiac involvement with DCM.

Apart from disruption of the production or transmission of force, a separate paradigm of familial DCM has been suggested by the identification of a missense mutation in phospholamban as a cause of autosomal-dominant DCM. Phospholamban is a transmembrane sarcoplasmic phosphoprotein that regulates the Ca^{2+} ATPase pump, SERCA2a. This mutation may result in constitutive inhibition of SERCA2a via trapping of the phospholamban regulatory protein, protein kinase A. Therefore, alterations in myocyte Ca^{2+} homeostasis may be a primary trigger for the development of DCM.

The mechanisms by which other genetic mutations give rise to a DCM phenotype remain elusive. Mutations in tafazzin, an X chromosome-encoded acetyltransferase protein of unknown function, give rise to Barth syndrome, a triad of DCM, neutropenia, and 3-methylglutaconicaciduria. Dominant mutations in the nuclear envelope proteins, lamin, cause progressive conduction system disease with eventual development of DCM. Of note, distinct lamin A/C mutations can give rise to autosomal-dominant Emery–Dreyfus muscular dystrophy, limb-girdle muscular dystrophy, and to familial partial lipodystrophy. Each of these clinical phenotypes may be associated with cardiac disease, predominantly DCM.

CONCLUSION

Unraveling the molecular and genetic basis of inherited cardiomyopathies will provide further insight into their fundamental pathophysiology, and to the mechanisms underlying more common forms of acquired dilated and hypertrophic heart disease. Screening of family members in DCM kindreds may identify individuals with asymptomatic LV dysfunction or dilatation. Early initiation of medical therapy at this stage improves symptoms, morbidity, and prognosis. More definitive treatment to interrupt the natural history of dilated and hypertrophic cardiomyopathies will be drawn from better mechanistic understanding of how inherited gene defects remodel the heart.

12 Heart Failure

Emerging Concepts in Excitation–Contraction Coupling and β-Adrenoceptor Coupling

Clive J. Lewis, Federica del Monte, Sian E. Harding, and Roger J. Hajjar

SUMMARY

The process that begins contraction in the heart is known as excitation–contraction (E–C) coupling because it couples electrical signals on the membrane of the cardiac cell to activation of the myofilament and cross-bridge cycling. The cardiac action potential is produced by the coordinated interaction of many ion channels, which transduce physiological signals within and between cardiomyocytes. These cardiomyocytes are further regulated by a number of receptors that control the strength of the contraction on a beat-to-beat basis and their morphology in a chronic fashion. In heart failure, a number of steps in E–C coupling become abnormal. In this chapter, we will examine the role of these abnormalities in the development of heart failure.

Key Words: β-receptor kinase; β-receptors; calcium; contractility; excitation contraction coupling; G proteins; L-type calcium channel; myofilaments; phospholamban; sarcoplasmic reticulum; sodium calcium exchanger.

INTRODUCTION

The understanding of cardiac excitation contraction coupling and β-adrenoreceptor signaling continues to evolve. Defects in the steps of excitation contraction coupling and β-adrenergic signaling have been identified in human and experimental models of heart failure. Abnormalities in ionic channels, transporters, kinases, and various signaling pathways collectively contribute to the "failing phenotype." β-adrenoceptors are widely expressed in human tissues and activated by neuronally released and circulating catecholamines. They are important mediators of the sympatho-adrenal axis regulating numerous physiological events, including relaxation of vascular smooth muscle, cardiac inotropy, chronotropy, and lusitropy. The traditional view of signal transduction is changing because of the emergence of concepts in the complexity of guanine nucleotide protein coupled receptor (GPCR)-effector coupling, an intracellular coupling.

EXCITATION–CONTRACTION COUPLING

On a beat-to-beat basis, depolarization of the cell membrane in cardiac myocytes leads to the opening of voltage gated L-type Ca^{2+} channels resulting in the influx of transsarcolemmal influx of Ca^{2+} into the cell (Fig. 12-1). These channels are in close proximity to the ryanodine receptors (RyRs), which are Ca^{2+} release channels located on the sarcoplasmic reticulum (SR). Ca^{2+} entering the cells through a single L-type Ca^{2+} channel induces the opening of one or a cluster of RyRs resulting in the local release of Ca^{2+} from the SR. During membrane depolarization, a large number of L-type Ca^{2+} channels are opened, resulting in a large release of Ca^{2+} from the RyRs, raising cytosolic Ca^{2+} from 0.1–0.2 to 2–10 μ*M*.

A functional Ca^{2+} signaling and releasing unit has been characterized, namely the Ca^{2+} spark. Ca^{2+} sparks were first identified as the "elementary events" of spontaneous increases in intracellular [Ca^{2+}], which were detected by laser scanning confocal microscopy and the fluorescent Ca^{2+} indicator fluo-3. Ca^{2+} sparks also can be produced by the triggering Ca^{2+} entered through the L-type Ca^{2+} channel during the E–C coupling process. Functionally, the Ca^{2+} sparks represent Ca^{2+} releases from the SR through the opening of the SR Ca^{2+} release channels/RyRs. Ca^{2+} sparks are produced by activation of 10–100 RyRs based on the ratio of the Ca^{2+} sparks' current and the single RyR channel current and because the morphology of Ca^{2+} sparks varies even within a single cell. Ca^{2+} sparks are depicted/measured by their morphology and the frequency of occurrence. The morphology information includes the sizes of Ca^{2+} sparks (amplitude, width, and duration), and the kinetics is described by the spark rising and decaying dynamics. The activity of individual RyRs and the number of the RyRs recruited during a spark play an important role in the spark morphology. Thus, the more active the Ca^{2+} release channels, the more Ca^{2+} would be released and consequently, increased size and more frequent occurrence of Ca^{2+} sparks would be observed. Therefore, direct modifications that change the RyRs activity or the modulators that regulate RyR activity will affect the size and frequency of Ca^{2+} sparks. SR Ca^{2+} content also regulates Ca^{2+} sparks because luminal (Ca^{2+}) plays a critical role in regulating RyR by increasing

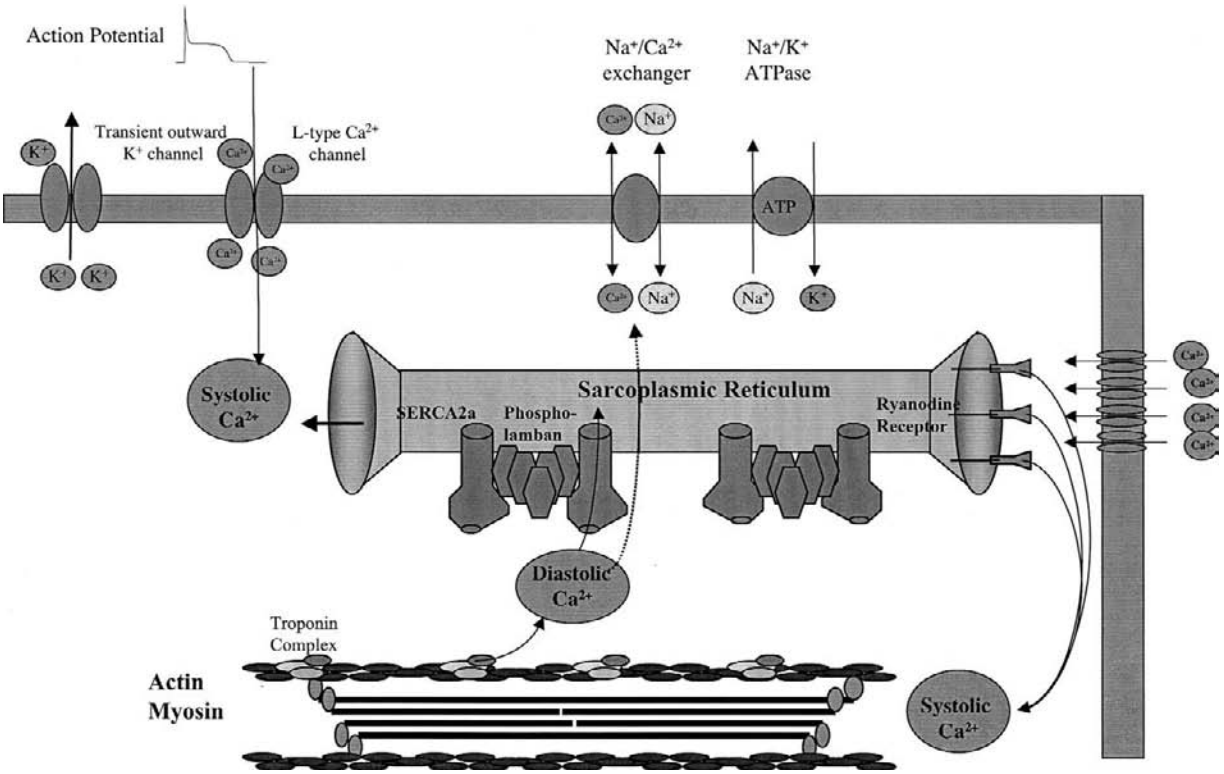

Figure 12-1 Depolarization of the membrane by the action potential leads to the opening of voltage gated L-type Ca^{2+} channels allowing the entry of a small amount of Ca^{2+} into the cell. Through a coupling mechanism between the L-type Ca^{2+} channel and the SR release channels (RyRs), a larger amount of Ca^{2+} is released activating the myofilaments leading to contraction. During relaxation, Ca^{2+} is reaccumulated back into the SR by the SERCA2a and extruded extracellularly by the sarcolemmal Na^+/Ca^{2+} exchanger.

the activity of the RyRs and by sensitizing the threshold of RyR for activation to the stimulus. The signaling between L-type Ca^{2+} channel and RyR Ca^{2+} sparks can be triggered by the Ca^{2+} influx through the L-type Ca^{2+} sparks during voltage pulses. Thus, the kinetics, fidelity, and stoichiometry of coupling between L-type Ca^{2+} channels and RyR play a critical role in determination of the signal transduction during the E–C coupling process. The distance of the cleft between the cell plasma membrane and the SR membrane, roughly 12 nm in normal cardiomyocytes, is critical for such coupling and signal transduction. Extension of the distance between them by pulling the plasma membrane under tight-seal condition decreases/abolishes the signaling reliability.

Relaxation occurs when calcium detaches from troponin C and is reaccumulated back into the SR by the cardiac isoform of the Ca^{2+} adenosine triphosphatase (ATPase) pump (SERCA2a) and extruded extracellularly by the sarcolemmal Na^+/Ca^{2+} exchanger. The contribution of each of these mechanisms for lowering cytosolic Ca^{2+} varies among species. In humans approx 75% of the Ca^{2+} is removed by SERCA2a and approx 25% by the Na^+/Ca^{2+} exchanger. SERCA2a transports Ca^{2+} back to the luminal space of the SR against a Ca^{2+} gradient by an energy dependent mechanism (one molecule of ATP is hydrolyzed for the transport of two molecules of Ca^{2+}), where it binds to a calcium buffering protein, calsequestrin.

The Ca^{2+} pumping activity of SERCA2a is regulated by phospholamban. In its unphosphorylated state, phospholamban inhibits the Ca^{2+} ATPase, whereas phosphorylation of phospholamban by cAMP-dependent protein kinase and by Ca^{2+}-calmodulin dependent protein kinase reverses this inhibition.

CALCIUM HANDLING IN HEART FAILURE

The myopathic heart exhibits abnormalities in the systolic and diastolic phases. Changes in diastolic function often appear earlier than systolic dysfunction. Compensated hypertrophy phenotypically demonstrates impaired relaxation parameters in the presence of normal or increased systolic function. The first report of abnormalities in calcium handling was made when calcium transients, recorded with the calcium indicator aequorin from trabeculae from myopathic human hearts removed at the time of cardiac transplantation, revealed a significantly prolonged calcium transient with an elevated end-diastolic intracellular calcium. This was corroborated by recordings in single isolated cardiomyocytes loaded with the fluorescent indicator Fura-2 from myopathic hearts. The calcium transients were characterized as having elevated diastolic calcium levels, decreased systolic Ca^{2+}, and a prolonged relaxation phase. Studies both in muscle strips and isolated cardiomyoctes found that systolic calcium concentration was decreased in the failing state whereas diastolic calcium concentrations were elevated. These differences were more accentuated at higher stimulation rates. Because intracellular calcium transients and calcium concentrations are regulated by the voltage-dependent Ca^{2+} channel, the SR ryanodine Ca^{2+} release channels, the SERCA2a/phospholamban complex, and the Na/Ca exchanger, several studies have focused on the relative changes in these proteins between myopathic and normal hearts.

Conflicting findings have been reported when calcium channels were measured with radioligand binding assays. One group reported an approx 20–30% reduction in mRNA and Bmax for dihydropyridine binding. However, two other groups found no difference in the

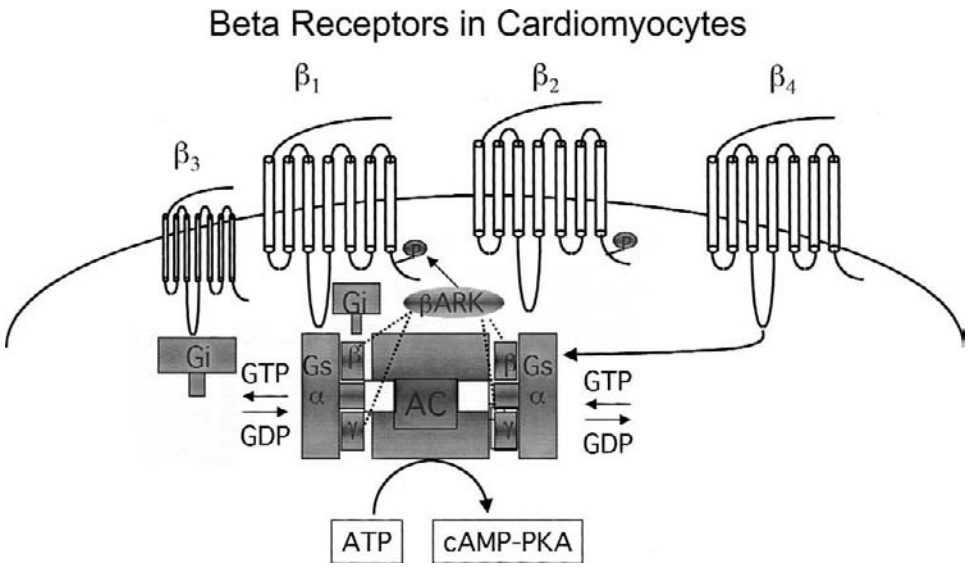

Figure 12-2 There are four β-adrenoceptor subtypes that modulate human myocardial function. β_3-adrenoceptor mediates cardiodepression mediated by the G_i protein. "Putative" β_4-adrenoceptor causes cardiostimulant effects at concentrations 1000 times greater than those required to antagonize the cardiostimulant effects of catecholamines at β_1- and β_2-adreonceptors with high affinity.

number of calcium channels as measured with radioligand binding. Despite these conflicting reports it is appreciated that radioligand-binding assays can detect nascent channels and are only a surrogate marker of the number of active calcium channels.

Altered myocyte calcium handling might play an important role in the development of heart failure in humans. This hypothesis is consistent with alterations found in some of the key proteins involved in the uptake and release of calcium in myopathic hearts. Calcium is released from the SR through a calcium sensitive release channel, the RyR. RyR mRNA is reduced in both myopathic human hearts and animal models. Inconsistent reports on RyR protein levels in myopathic human myocardium have appeared in the literature. Some research has shown altered gating mechanisms and altered responses to ryanodine in myopathic human myocardium, whereas other studies have found normal basic properties. Thus, although gene expression of the RyR receptor might be unchanged, its gating behavior, i.e., activity, might be impaired in failing myocardium. Even though the number of receptors might not be changed in heart failure and hypertrophy, there is a defective coupling between the L-type calcium channel and the RyR. The molecular correlates of this uncoupling seem to be a hyperphosphorylation of the RyR.

HUMAN MYOCARDIAL FUNCTION IS MODULATED THROUGH FOUR β-ADRENOCEPTORS

β_1- and β_2-adrenoceptors coexist in human and rat myocytes with the β_1-adrenoceptor the predominant subtype, even in heart failure when the relative proportion of β_2-adrenoceptors increases (Fig. 12-2). The proportion of β_2-adrenoceptors is greatest in humans of all species studied. β_1- and β_2-adrenoceptors are pharmacologically and genetically distinct entities with only 71% amino acid identity in the transmembrane-spanning domains and 54% identity overall; however, they appear to have the same mechanism of signal transduction through G_s and cAMP. Furthermore, epinephrine and norepinephrine are able to enhance contraction, relaxation, arrhythmia, and protein kinase A (PKA)-dependent phosphorylation of downstream regulatory proteins to a similar extent through human β_1- and β_2-adrenoceptors, respectively, despite the difference in receptor number. To explain this, tighter coupling of the β_2-adrenoceptor to the Gs/adenylate cyclase (AC) pathway was proposed. Evidence suggests that β_1- and β_2-adrenoceptors have distinct physiological actions, coupled to distinct signal transduction pathways, and might occupy different spatial localization within the heart or within single cells (compartmentalization). In addition, β_2-adrenoceptors might exist in two active forms that couple in parallel to G_s and G inhibitory (G_i), respectively.

In addition to β_1- and β_2-adrenoceptors, evidence is consistent with the involvement of four β-adrenoceptor subtypes in the modulation of human myocardial function. A third β-adrenoceptor has been cloned and found to mediate vasodilatation, adipocyte metabolism, and cardiodepression mediated by the G_i protein. Pharmacological data also support existence of an atypical or novel β-adrenoceptor subtype, which mediates cardiostimulant effects including inotropy, chronotropy,and lusitropy and led to the proposal of the fourth cardiac β-adrenoceptor. "Putative" β_4-adrenoceptor pharmacology has been defined using nonconventional partial agonist β-adrenoceptor antagonists that cause cardiostimulant effects at concentrations 1000 times greater than those required to antagonize the cardiostimulant effects of catecholamines at β_1- and β_2-adreonceptors with high affinity. These agents include clinically used β-adrenoceptor antagonists such as pindolol, alprenolol, oxprenolol, and bucindolol as well as the useful experimental agent CGP 12177A. This receptor phenotype differs from the "classic" described function of known GPCRs and might be explained by novel receptor states or conformations or receptor dimerization.

β_1- AND β_2-ADRENOCEPTOR COUPLING The coupling of β_1- and β_2-adrenoceptors to G proteins mediates the beneficial effects of catecholamines and is also involved in the pathophysiology of the heart, thus consideration of the emerging molecular mechanisms that can alter coupling of these subtypes is important. There has been much interest in single-nucleotide polymorphisms (SNPs) of GPCRs because they are thought to affect the responses

to endogenous agonists and/or drugs and therefore alter the pathophysiology of disease states by altering G protein coupling and signaling.

The β_1-adrenoceptor gene is polymorphic with 18 SNPs of which seven lead to amino acid substitutions within the coding exon. Two loci have been studied closely: Glycine49Serine (A for G at nucleotide 145) and Glycine389Arginine (C for G at nucleotide position 1165). Expression studies have demonstrated that despite similar affinities for both agonists and antagonists, the 49Serine receptor variant was relatively resistant to agonist-promoted downregulation compared to the 49Glycine variant. The Glycine389Arginine polymorphism, however, in the cytoplasmic tail G_s coupling domain, affects coupling to AC. In expression studies, the 389Arginine variant demonstrated and approx 30-fold greater ability to couple to AC when activated by isoproterenol and approx twofold for the β_4-adreonceptor agonist CGP 12177A. Several studies have investigated whether any clinical correlate of this pharmacogenetic effect can be demonstrated, but the lack of agreement means that no conclusions can be drawn. The 49Glycine variant does not appear more frequently in patients with heart failure but is associated with a greater mortality. In dilated cardiomyopathy patients, the 389Arginine variant was more frequent in those without ventricular tachycardia. Neither polymorphism appears associated with long QT syndrome or acute coronary syndrome but higher blood pressures were observed in subjects with at least one 389Arginine allele and the 389Arginine genotype in combination with a deletion mutant of the α_{2C}-adrenoceptor significantly increases the risk of heart failure in African Americans. In addition to the β_1-adrenoceptor, the β_2-adrenoceptor has several SNPs, the most interesting of which is Isoleucine164. This amino acid change results in decreased β_2-adrenoceptor activity via decreased G protein/AC coupling. For the Isoleucine164 variant there is a fivefold increased relative risk of mortality in patients with heart failure. Thus SNPs that affect G protein coupling and signaling might have important implications in understanding cardiac physiology, disease, and pharmacological therapy.

NON-CAMP DEPENDENT β_1-ADRENORECEPTOR COUPLING (DIRECT L-TYPE CA^{2+} CHANNEL COUPLING) E–C coupling of the β_1-adrenoceptor via G_s/cAMP is well established, but the possibility of a membrane delimited, non-cAMP dependent mechanism exists involving activated $G_{\alpha s}$ directly interacting with the sarcolemmal L-type Ca^{2+} channel. Evidence for a non-cAMP dependent activation of Ca^{2+} channel comes from five lines of experiments:

1. $G_{\alpha s}$ reactivates Ca^{2+} channels that have run down in excised guinea-pig ventricular patches.
2. $G_{\alpha s}$ stimulates L-type Ca^{2+} channel activity after reconstitution in lipid bilayers.
3. Dihydropyridine and radio-labeled $G_{\alpha s}$ binding suggest that G proteins bind and activate purified Ca^{2+} channels.
4. Isoproterenol stimulated atrial myocytes demonstrate biphasic Ca^{2+} currents with the fast response (~5% total) resistant to phosphodiesterase inhibition by isobutyl methyl xanthine and $G_{\alpha s}$ activation by forskolin.
5. Incomplete blockade of β-AR responses by inhibitors of PKA.

However, there are some inconsistencies and the overall relevance of these findings under physiological conditions has been questioned.

Supportive evidence exists for a non-cAMP dependent activation of Ca^{2+} channel mechanism under physiological conditions in isolated, paced single rat ventricular cardiomyocytes overexpressing human sequence β_1-adrenoceptors. Increased basal, unstimulated myocyte contraction resulting from constitutive activity of overexpressed β_1-adrenoceptors (ability of a receptor to signal through a second messenger pathway and activation of downstream effectors in the absence of agonist) has been observed. The raised basal contraction could be returned to control levels by CGP 20712A acting as an inverse agonist. The constitutive activity appeared non-cAMP dependent because cAMP levels were not increased by β_1-overexpression and neither RpcAMPS (cAMP antagonist) nor carbachol (inhibits cAMP-mediated contraction) had a significant effect on contraction. However, the L-type Ca^{2+} channel current was significantly enhanced by β_1-overexpression supporting a direct membrane-delimited activation by $G_{\alpha s}$ of the constitutively active β_1-adrenoceptor.

Controversy remains over constitutive activity of the β_1-adrenoceptor. cAMP-dependent constitutive activity was observed in atria from transgenic mice and cell lines overexpressing β_1-adrenoceptors. However, no change was found in basal contraction amplitude or basal cAMP in myocytes from β_1/β_2 double knockout (KO) mice overexpressing β_1-adrenoceptors. Constitutive activity of the β_2-adrenoceptor has also been observed. In transgenic mice with approx 200-fold overexpression of the β_2-adrenoceptor, cardiac contractility and AC activity are raised to levels observed with maximal agonist stimulation in control. The constitutive activity could be reduced by the inverse agonist activity of ICI 188,551.

GPCRs are proposed to exist in equilibrium between two conformational states, an inactive form (R) and an active form (R*) that can interact with G proteins. Agonist binds to and stabilizes the R form resulting in a shift to the R* form that involves a conformational change allowing G protein activation by guanosine triphosphate binding. In the β-adrenoceptor overexpressing myocytes, the levels of R + R* are increased and sufficient to produce increased basal contraction (constitutive activity). Inverse agonism is thought to result from the antagonist binding to the inactive R form and shifting the equilibrium away from R* with a corresponding decrease in contraction and AC activity.

DIFFERENCES BETWEEN β_1- AND β_2-ADRENOCEPTOR COUPLING Differences between β_1- and β_2-adrenoceptors emerged by studying chronic heart-specific overexpression of each subtype in transgenic mice. β_1-overexpressing mice have early mortality owing to the development of myocyte hypertrophy and myocardial fibrosis leading to heart failure despite unaltered cardiac function and basal AC activity. Proapoptotic effects mediated by activation of β_1-adrenoceptor signaling pathways might mediate this observation. Transgenic mice overexpressing β_2-adrenoceptors at a similar level did not show increased mortality or heart failure, although the explanation for this was unclear.

As opposed to the selective coupling of the β_2-adrenoceptor to G_s/AC in humans, a non-cAMP E–C mechanism has been suggested for mouse and rat heart. It was based on the observations that isoproterenol produced increases in contraction through β_2-adrenoceptors without changes in the speed of relaxation or phospholamban phosphorylation and that agents reducing cAMP-mediated effects did not affect contraction. The coupling of β_2-adrenoceptors to G_i was observed by the use of pertussis toxin (PTX) when cAMP-dependent E–C coupling was revealed. Interestingly, G_i activation

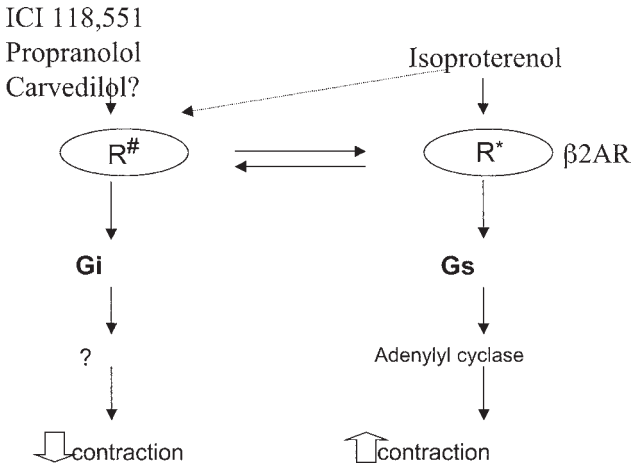

Figure 12-3 Description of stimulus-trafficking in which different effects can be mediated by the same receptor acting though different G proteins, previously described for several GPCRs including β_2-adrenoceptors.

through β_2-adrenoceptors could oppose the proapoptotic effect of β_1-adrenoceptors through G_s. Mitogen-activated protein and phosphatidylinositol 3′-kinase pathways were identified as downstream mediators of β_2-/G_i signaling. The protection from early mortality owing to heart failure in β_2-overexpressing mice as opposed to β_1-overexpressing mice was linked to spontaneous upregulation of Gi (decreasing constitutive activity and hyperresponsiveness to catecholamines) and opposition of proapoptotic pathways. Subsequently β_2-adrenoceptors were observed to couple to both G_s and G_i resulting in activation of opposing signaling pathways.

Coupling of human β_2-adrenoceptors to G_i in failing ventricle has been confirmed. ICI 118,551 (selective β_2-adrenoceptor antagonist), at inverse agonist concentrations, produced a profound reduction of contraction in isolated ventricular myocytes from human heart, which could be prevented by treatment with PTX, indicating the involvement of G_i. The use of specific agonists/antagonists demonstrated G_i coupling to β_2- rather than β_1- or β_3-adrenoceptors. PTX-sensitive inverse agonist effects of ICI 118,551 have been observed in rat and rabbit by overexpressing human β_2-adrenoceptors or $G_{i\alpha 2}$.

In failing human heart, β_2-adrenoceptors do not demonstrate constitutive activity and there is no "spare" β-adrenoceptor capacity, yet G_i is upregulated and there are dampened β_2-adrenoceptor responses. Thus a "stimulus-trafficking" modification has been proposed to the original theory of inverse agonism (Fig. 12-3). Stimulus trafficking describes the mechanism in which different effects can be mediated by the same receptor acting through different G-proteins; it has previously been described for several GPCRs including β_2-adrenoceptors. Binding of the inverse agonist is not to the inactive R form but to another active G_i-coupled form ($R^{\#}$), which occurs in parallel with the usual R*-G_s coupling. In nonfailing heart of mouse, rat or humans, total levels of β_2-adrenoceptor ($R^* + R^{\#}$) and Gi levels are moderate with no effect on basal contraction. In failing heart, when G_i is upregulated, the G_i-$R^{\#}$ form will shift the equilibrium away from R* resulting in the dampened contractile response to catecholamines observed in failing human heart. Inverse agonists bind to $R^{\#}$ but because of the increased amount of G_i-$R^{\#}$ in heart failure, a direct negative inotropic effect of β-adrenoceptor antagonists is observed mediated by the β_2-adrenoceptor. In explaining the findings above, ICI 118,551 is an agonist through the G_i-$R^{\#}$ but not the G_s-R* pathway. However, the downstream G_i linked targets for mediating the negative inotropic effect of ICI 118,551 have not been identified.

This negatively inotropic effect of ICI 118,551 has been observed for other β-adrenoceptor antagonists and is clearly important in human heart failure where they are used therapeutically to reduce mortality. The initial decrease in cardiac output during titration of β-adrenoceptor antagonists may, in addition to the removal of sympathetic tone, be owing to their direct negative inotropic effects.

COMPARTMENTALIZATION OF GPCR SIGNALING A large body of functional data supports the existence of subcellular compartmentalization of the cAMP/AC/PKA signaling pathway in heart. There appears to be a fixed and specific spatial relationship between components of cAMP generation, response mechanisms and degradation. Thus within a cardiac myocyte, not all cAMP gains access to all PKA and its downstream regulators, and only a limited amount of phosphodiesterases might degrade cAMP. Molecular mechanisms contributing to compartmentalization include localization of receptors, G proteins, and AC in caveolae within the sarcolemma; localization of PKA by A-kinase anchoring proteins resulting in scaffolding and inhibition of activity; localization of activated PKC isoforms, their downstream target substrates, and phosphodiesterase isoforms in caveolae; and compartmentalization of cAMP generation and phosphodiesterase degradation in sarcolemmal microdomains.

Evidence has highlighted compartmentalization of cAMP signaling in cardiac myocytes. In neonatal rat cardiac myocytes, specificity of signaling is guaranteed by tight localization of signaling events to the surface membrane. β-adrenoceptor stimulation generates multiple microdomains with increased concentrations of cAMP, but free diffusion of the second messenger is limited by the activity of phosphodiesterases and cannot transmit to nonsarcolemmal proteins. The possibility of compartmentalized cAMP signaling has also been investigated for the β_2-adrenoceptor in adult rat ventricular myocytes where contraction appeared dissociated from cAMP. L-type Ca^{2+} current and contraction to β_2- as well as β_1-adrenoceptor agonists was entirely abolished by the use of PKA inhibitors, suggesting functional compartmentalization of cAMP-dependent signaling.

Direct G protein activation of the L-type Ca^{2+} channel has also been suggested for β_2-adrenoceptor. However, a compartmentalized cAMP/PKA pathway mediating β_2-adrenoceptor signaling to the L-type Ca^{2+} channel seems more likely. In hippocampal neurons, the β_2-adrenoceptor appears to form a macromolecular signaling complex with the L-type Ca^{2+} channel, a G protein, AC, cAMP-dependent PKA and the counterbalancing phosphatase PP2A. This signaling complex ensures specific and rapid signaling. Moreover, β_2-adrenoceptors appear compartmentalized spatially, residing exclusively in caveolae isolated from quiescent rat cardiomyocytes allowing regulation of cAMP signaling in microdomains.

Further specificity of signaling might result from the selective coupling to different isoforms of AC. Nine mammalian isoforms of AC have been identified, of which types 5 and 6 are the predominant isoforms expressed in heart and are inhibited by multiple intracellular signaling pathways including G_i, PKA, PKC, and Ca^{2+}. In myocytes overexpressing AC6, a selective enhancement

of β-adrenoceptor stimulated cAMP formation was observed with colocalization of β-adrenoceptor and AC in caveolar microdomains allowing rapid and specific signal transduction in cardiac myocytes. Whether selective AC isoform coupling occurs with different β-adrenoceptor subtypes is under investigation.

HOMO- AND HETERODIMERIZATION OF β_1- AND β_1-ADRENOCEPTORS

The classic GPCR model predicts that the stoichiometry of receptor, G protein and effector is 1/1/1; however, several studies have demonstrated that GPCRs exist as dimeric or oligomeric complexes. In addition to homodimers, heterodimers between members of the GPCR family exist. Homodimerization of both β_1-adrenoceptors and β_2-adrenoceptors has been observed in vitro and in vivo, and intermolecular interactions between receptors might have functional and structural implications for G protein-mediated signaling. The sixth transmembrane domain of the β_2-adrenoceptor appears to be involved in homodimerization because a peptide derived from this domain inhibits both dimerization and β-adrenoceptor G_s/AC coupling, indicating a functional role for dimerization. Agonist stimulation was also found to stabilize the homodimer, whereas inverse agonists favored the monomeric state, further suggesting that conversion between monomer and dimer forms might play a physiological role.

The coexistence of β_1- and β_2-adrenoceptor subtypes within a single myocyte raises the possibility of heterodimerization between these two receptors giving rise to potential novel pharmacology. Heterodimeriation of β_1- and β_2-adrenoceptors has been observed in cell lines and mouse cardiomyocytes cooverexpressing β_1- and β_2-adrenoceptors. β_1- and β_2-adrenoceptor colocalization has been demonstrated on the cell membrane surface together with novel functional properties. There was approx 1.5 log unit leftward shift in the concentration-response curve to isoproterenol of myocyte contraction when β_1- and β_2-adrenoceptors were coexpressed in myocytes from double β_1-/β_2-adrenoceptor KO mice. In addition, decreased affinity of known ligands was observed (K_d of CGP 20712A decreased approx 10-fold and the K_d of ICI 118,551 decreased approx 70-fold compared with each subtype expressed alone), suggesting that β_1- and β_2-adrenoceptors can form high-affinity heterodimers with a novel binding site and altered ligand binding properties. However, similar efficacy and potency of isoproterenol-stimulated cAMP production has been demonstrated when β_1- and β_2-adrenoceptors were expressed in cell lines alone or together when they were observed to form heterodimers. However, a unique functional property of β_1-/β_2-heterodimers was observed, with complete loss of the isoproterenol stimulation of ERK 1/2 mitogen-activated protein kinase activation, which is usually seen when β_2- (but not β_1-) adrenoceptors are expressed alone. Thus homo- and heterodimerization of β_1- and β_2-adrenoceptors alters G protein coupling and downstream signaling, although the functional basis of these interactions remains to be explored.

β_3-ADRENOCEPTOR COUPLING IN HUMAN HEART

The functional role and coupling mechanism for cardiac β_3-adrenoceptors remains unclear. β_3-adrenoceptors are pharmacologically characterized by four criteria:

1. Low affinity of classic β-adrenoceptor antagonists such as propranolol and nadolol.
2. Activation by selective β_3-adrenoceptor agonists BRL 37344, SR 58611A, and CL 316243.
3. Activation by nonconventional partial agonists CGP 12177A, cyanopindolol, and pindolol.
4. Blockade by selective β_3-adrenoceptors antagonists SR 59230A. Activation of recombinant β_3-adrenoceptors increases adenylyl cyclase activity by signaling via G_s.

β_3-adrenoceptor mRNA has been reported in human atrium and ventricle in addition to gastrointestinal and adipose tissue, and protein expression has been demonstrated in human heart. Nonetheless, little evidence suggests a cardiostimulant role for the β_3-adrenoceptor because cardiostimulant effects of selective β_3-adrenoceptor agonists have not been observed in human ventricle or atrium, or rat or ferret heart. β_3-adrenoceptor selective agonists BRL 37344 and SR 58611 increase L-type Ca^{2+} current 1.7- and 2.2-fold, respectively in human atrial myocytes by a nadolol-resistant mechanism and increased atrial inotropic and chronotropic response, but these effects are most likely mediated by activation of classic β_1- and β_2-adrenoceptors.

However, β_3-adrenoceptors also appear to couple to G_i and produce cardiodepression and action potential shortening in human ventricle with nanomolar potency. In addition, high concentrations of endogenous catecholamines were shown to elicit a nadolol-resistant cardiodepression. The cardiodepressant effect of β_3-adrenoceptor agonists was attenuated by pretreatment by PTX, suggesting mediation by coupling to G_i. The observation that the cardiodepressant effects were reduced by nitric oxide (NO)-antagonists led to the suggestion of a G_i/NO-dependent cyclic guanosine monophosphate signaling pathway mediating β_3-adrenoceptor negative inotropic effects in human ventricle. However, although NO-mediated β_3-adrenoceptor stimulation is present in human atrium, at least in nonfailing heart, it does not directly affect atrial contraction.

β_3-adrenoceptors are more resistant to desensitization than classic β_1- and β_2-adrenoceptors, and β_3-adrenoceptor expression appears increased in failing human ventricle. This suggests that in heart failure, the relative importance of β_3-adrenoceptors might be increased with impairment of contractility mediated by activation of β_3-adrenoceptors by high circulating concentrations of norepinephrine and coupling to a G_i/cyclic guanosine monophosphate/NO signaling pathway.

However, the observation of cardiodepression by β_3-adrenoceptor selective agonists has not been confirmed in isolated human cardiac preparations by others. β_3-adrenoceptor selective agonists failed to cause cardiodepression in human atrium, and in failing ventricle in both whole trabeculae and isolated myocytes. Furthermore, the cardiodepressant effect of BRL 37344 was observed with nanomolar potency, whereas this compound has been observed to have micromolar potency at recombinant and adipocyte β_3-adrenoceptors. As described, negative inotropic effects of β-adrenoceptor antagonists have been demonstrated in failing human ventricle mediated primarily by a G_i-dependent interaction with the β_2-adrenoceptor. BRL 37344 has a similar affinity for the β_2- and β_3-adrenoceptor and produces positive inotropic effects in atrium mediated by β_1- and β_2-adrenoceptors. Thus in failing ventricle, the cardiodepressant effects of BRL 37344 could be mediated by β_2-adrenoceptor coupling to G_i. Clearly, the implication of β_3-adrenoceptor mediated cardiodepression is important, particularly in the context of heart failure, and further elucidation is required to address this controversy.

THE "PUTATIVE" β_4-ADRENOCEPTOR

The β_4-adrenoceptor is of particular interest, because of its potential importance

in cardiac physiology, its implication in arrhythmogenesis and as a target for clinically used β-adrenoceptor antagonists. This apparent novel receptor subtype is an alternate state or conformation of the β_1-adrenoceptor in addition to the "classic" catecholamine activation site. Species homologues of the "putative" β_4-adrenoceptor are present in all mammals studied and are expressed in sinoatrial node, atrium, and ventricle. In common with the activation of "classic" β_1-adrenoceptors, β_4-adrenoceptor agonists produce positive inotropy, chronotropy, and lusitropy and effect signal transduction in human and rat heart through a G_s/AC pathway increasing cAMP and PKA. β_4-adrenoceptor's effects are relatively resistant to those of propranolol yet are antagonized with moderate potency by bupranolol, carvedilol, and a range of β-adrenoceptor antagonists but with approx 100 times lower affinity than at the "classic" β_1-adrenoceptor.

Functional human β_4-adrenoceptor responses have also been found in vivo. Pindolol, in the presence of β_1- and β_2-adrenoceptor blockade by propranolol, induces a 10% increase in heart rate in healthy volunteers, which can be prevented by predosing with carvedilol.

CGP 12177A is more potent than norepinephrine at shortening the ventricular monophasic action potential but does not alter the refractory period, suggesting differential coupling to individual ion channels. CGP 12177A also increases both intracellular Ca^{2+} transient and current through the L-type Ca^{2+} channel, although less than via "classic" β_1-adrenoceptors. In part, the continuing interest in the β_4-adreonceptor's pharmacology is owing to its potential involvement in arrhythmogenesis. CGP 12177A produces ventricular extrasystoles in whole ferret ventricle, arrhythmic Ca^{2+} transients in atrial and ventricular rat myocytes and arrhythmic Ca^{2+} transients in mouse ventricular myocytes with a potency 40 times greater than through the "classic" β_1-adrenoceptor.

The pharmacology of the β_4-adrenoceptor partly resembles that of the β_3-adrenoceptor. However, in rat, mouse and human heart, selective β_3-adrenoceptor agonists do not produce cardiostimulant effects and neither selective β_3-adrenoceptor antagonists nor mice with targeted disruption of the β_3-adrenoceptor gene (β_3 KO mice) alter the effect of CGP 12177A.

A novel low-affinity state or conformation of the β_1-adrenoceptor is responsible for the "putative" β_4-adrenoceptor pharmacology. Thus, the β_1-adrenoceptor might exist in at least two different states, a "high-affinity" state ("classic" β_1-adrenoceptor catecholamine site with high affinity to propranolol) and another "low-affinity" state stabilized by CGP 12177A, responsible for β_4-adrenoceptor pharmacology and with low affinity to propranolol.

CGP 12177A stimulates adenylyl cyclase in cell lines expressing recombinant rat and human β_1-adrenoceptors and its cardiostimulant effects were significantly more resistant to β-adrenoceptor antagonism than catecholamines were. This, therefore, suggests that the β_1-adrenoceptor fulfilled some of the pharmacological criteria for the β_4-adrenoceptor. Adenoviral overexpression of β_1-adrenoceptors in isolated, cultured adult rat ventricular myocytes has been accomplished and a similar increase in the cardiostimulant potency of both isoproterenol and CGP 12177A has been demonstrated, indicating involvement of a propranolol-resistant state of the β_1-adrenoceptor. This concept is supported by the demonstration of agonist specific differences in antagonist affinity revealing two different affinity states of the β_1-adrenoceptor in recombinant β_1-adrenoceptors in cell lines and in ferret heart preparations. Moreover, an obligatory role for β_1-adrenoceptors in the cardiostimulant effect of CGP 12177A was demonstrated in the β_1-/β_2-adrenoceptor double KO mice. CGP 12177A increased sinoatrial rate and left atrial contractile force in heart from wild-type and β_2-adrenoceptor KO mice but were absent in β_1-/β_2-adrenoceptor double KO mouse heart.

β_4-adrenoceptor's involvement in heart failure has been suggested by the parallel desensitization and resensitization of β_1- and β_4-adrenoceptors in a rat model of heart failure. The resensitization induced by PTX suggests that in cardiac failure, both β_1- and β_4-adrenoceptors can couple to G_i as well as G_s because $G_{i\alpha 2}$ mRNA is increased in this model of heart failure. A similar desensitization in cardiostimulant responses (maximal effect and potency of CGP 12177A) through both states of the β_1-adrenoceptor was seen in right atrium of failing human heart. In addition, a parallel decrease in both the high (catecholamine site) and low-affinity (β_4-adrenoceptor site) [^{3}H]-CGP 12177A binding sites was observed in right atrium from failing compared with nonfailing human myocardium. The ability of the low-affinity site of β_1-adrenoceptors to couple to G_i appears to be restricted to heart failure because PTX had no effect on the CGP 12177A response in nonfailing heart in mouse and rat.

In addition to a low-affinity state of the β_1-adrenoceptors mediating the cardiostimulant effects of CGP 12177A, reports suggest that part of the stimulant effect is through β_2-adrenoceptors. If novel states of receptors are common throughout the GPCR super family, then CGP 12177A might be activating a novel site on the β_2-adrenoceptor with low affinity for propranolol and ICI 118,551, similar to the novel state of the β_1-adrenoceptor. The concept that the β_2-adrenoceptor can exist in more than one active conformation has been suggested previously.

A propranolol and ICI 118.551 (selective β_2-adrenoceptor antagonist) resistant enhancement of the positive inotropic effect of CGP 12177A has been demonstrated in isolated rat ventricular myocytes adenovirally overexpressing β_2-adrenoceptors. This is time-dependent, with an early (24 h) enhancement of the positive effect lost by 48 h, paralleling changes in β_2-adrenoceptor stimulation of contraction. The attenuation of the effect with time can be restored by pretreatment with PTX suggesting that the CGP 12177A cardiostimulant site, like the β_2-adrenoceptor, can couple through G_i as well as G_s. Mediation of the cardiostimulant effect of CGP 12177A via β_2-adrenoceptors is consistent with the weak partial agonist activity of CGP 12177A (intrinsic activity only 10–20% of that at expressed β_1-adrenoceptors) on cAMP accumulation in cell lines overexpressing recombinant β_2-adrenoceptors. Alternatively, the possibility that the cardiostimulant effects of CGP 12177A are mediated by an interaction with β_1- and β_2-adrenoceptor homo- or heterodimers, as shown for the effect of isoproterenol, has also been suggested. In support of this possibility, a further approx 10-fold enhanced cardiostimulant effect of CGP 12177A has been observed in isolated rat ventricular myocytes adenovirally coexpressing β_1- and β_2-adrenoceptors compared with myocytes expressing each subtype alone. This suggests that heterodimerization of β_1- and β_2-adrenoceptors creates a novel pharmacological profile to CGP 12177A in addition to isoproterenol. Because native β_1-adrenoceptors are present in rat myocytes, the effect of β_2-adrenoceptor overexpression to enhance effects of CGP12177A might also be mediated by heterodimers. Under normal circumstances, different membrane localization of β_1-adrenoceptors might prevent receptor dimerization by spatial

separation from the caveolar domains where β_2-adrenoceptors are found, but these spatial arrangements could be disrupted after adenovirally mediated overexpression.

CLINICAL IMPLICATIONS

In a meta-analysis of β-adrenoceptor antagonists given after myocardial infarction, those with high intrinsic sympathomimetic activity (ISA) appeared to have worse effects on mortality and a lower level of risk-reduction than those with low ISA. Xamoterol (β_1-selective antagonist) with ISA increased mortality in heart failure, and bucindolol (nonselective β-adrenoceptor antagonist) had no overall benefit on mortality and a worse outcome in severe heart failure. Interestingly, bucindolol has ISA at the low-affinity state of the β_1-adrenoceptor in humans, suggesting that the study outcome was owing to interaction with this novel site. Carvedilol improves mortality in heart failure and has antagonist effects at both the classic and low-affinity site of the β_1-adrenoceptor, suggesting that part of its beneficial effect in heart failure and its superiority over metoprolol may be resulting from an interaction at the low-affinity state of the β_1-adrenoceptor. Alternatively, activation of protective Gi-mediated pathways by an action of carvedilol through β_2/Gi coupling could contribute to recovery.

CONCLUSION

Cardiac β_1- and β_1-adrenoceptors differ in G protein coupling, cAMP signaling, target protein phosphorylation, and alteration of cardiac E–C coupling. The dual coupling of β_2-adrenoceptors to both G_i and G_s explains many of these differences. Additionally, functional localization and spatial compartmentalization of β_2-adrenoceptor cAMP/PKA signaling to membrane microdomains further contributes to specificity of signal. The stimulus-trafficking model of parallel pathway β_2-adrenoceptor G_i and G_s coupling might explain the dampened β-adrenoceptor response in failing human heart and might explain the negative inotropic effects of clinically used β-adrenoceptor antagonists. The concept of novel "low-affinity" sites or state of GPCRs, elucidated for the "putative" β_4-adrenoceptor, requires further investigation, especially because drugs in clinical use interact at the novel site of the β_1-adrenoceptor. In addition, the observation of functional homo- and heterodimers of β- and β_2-adrenoceptors indicates the complexity of β-adrenoceptor signaling and the need to study the impact of β_1- and β_2-adrenoceptors' differences and interactions both in their physiological and pathophysiological roles. Studies are needed to define the molecular, structural and spatial mechanisms underlying differential G protein coupling, downstream signaling and regulation of apoptosis of β_2- vs β_1-adrenoceptors.

13 Aortic Diseases

Saumya Das, James L. Januzzi, Jr., and Eric M. Isselbacher

SUMMARY

Aneurysms are the most important disorder that affects the aorta. Aneurysms involving the abdominal aorta are typically associated with atherosclerosis, whereas those involving the thoracic aorta have many causes, including congenital abnormalities in the structure of the aortic wall. This chapter will discuss thoracic aortic aneurysms, such as Marfan syndrome, bicuspid aortic valve, and familial thoracic aortic aneurysm syndrome, and also abdominal aortic aneurysms.

Key Words: Aneurysm; aorta; bicuspid aortic valve; familial thoracic aortic aneurysm syndrome; Marfan syndrome.

INTRODUCTION

Although diseases of the aorta are significantly less common than those of the heart, because aortic disease can be life threatening, its diagnosis and treatment are clinically relevant. Aneurysms are the most important disorder that affect the aorta. Aneurysms involving the abdominal aorta are typically associated with atherosclerosis, whereas those involving the thoracic aorta have many causes, including congenital abnormalities in the structure of the aortic wall. Because aortic aneurysms typically do not produce symptoms until they are large, the diagnosis is often not made until a rupture or dissection occurs. However, mass population screening is not likely to be practical or cost effective. Therefore, the ability to identify genetic factors that could predict risk for aortic aneurysms would be a valuable guide screening and therapy in clinical practice.

THORACIC AORTIC ANEURYSMS

MARFAN SYNDROME Marfan syndrome (MFS) is the best-studied aortic disease regarding genetic basis and molecular mechanisms. The search for the causes of MFS exemplifies a systematic approach used to identify candidate genes and gain insight into the disorder's biology and pathophysiology.

MFS is a systemic disorder of connective tissue with protean manifestations, with the skeletal, ocular, and cardiovascular systems most often affected. The hallmark of MFS is abnormality of the medial layer of the aortic wall, characterized by fragmentation and disorganization of the elastic fibers, a generalized loss of elastin content, and deposition of amorphous matrix components. The mechanical properties of the aorta are primarily a function of the elastic fibers within the media, so loss or abnormalities of elastin could weaken the tensile strength of the aortic wall. Indeed, the most threatening consequence of MFS is dilatation of the aortic root and the ascending aorta, which, if untreated, can result in potentially fatal aortic dissection or rupture.

The syndrome is relatively uncommon, with a prevalence of one in 5000–10,000. Traditionally, the diagnosis has relied on a series of clinical criteria as outlined in the Ghent nosology, reflecting the pleiotropic manifestation of the disease: the phenotypes of the affected individuals form a continuum from the severe neonatal MFS to milder forms known by the acronym MASS (myopia, mitral valve prolapse, aortic dilatation without dissection, and skin and skeletal muscle abnormalities). The Ghent nosology was designed to account for varying presentations by defining highly specific major criteria with less specific minor criteria. A positive diagnosis requires a combination of major criteria in at least two organ systems and minor criteria in a third organ system.

The clustering of MFS in families is well recognized and classic genetic analysis has shown it to be autosomal-dominant with complete penetrance (but with pleiotropic manifestations). In exploring for the genetic cause of MFS, researchers first excluded certain candidate genes such as elastin. Then, in one affected family, positional cloning indicated that the mutation was localized to chromosome 15q21. Cloning and sequencing of the DNA in that region led to the identification of the *fibrillin (FBN)-1 gene*. Subsequently, FBN1 mutations were linked to the majority of the cases of MFS. In addition, a distinct gene on chromosome 3p24 was linked to another family with MFS.

The identification of the FBN1 prompted investigation into the role of FBN1, the protein product of the FBN1, in the development and homeostasis of the aortic wall. Studies undertaken to elucidate the basic structure of the fibrillin gene progressed on two fronts. Some investigators mapped the various mutations associated with MFS, attempting to correlate genotype and phenotype. Others examined the biology of fibrillin (and they are made up of microfibrils), trying to understand how specific abnormalities in protein structure may alter biology at the cellular, organ, and systemic level. Of the 337 mutations in the FBN1 reported in patients with MFS, 69 have been found in more than one unrelated individual, eight in three or more unrelated individuals, and only three mutations have been found in four of more unrelated individuals. Unfortunately, the difficulty expressing fibrillin and constituting microfibrils in vitro has hampered the correlation of structure and function. Consequently, only a few of these mutations have been tested experimentally.

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

The majority of FBN1 mutations in MFS are missense mutations that lead to substitution of one of six highly conserved cysteines. Cysteines are important in the formation of intramolecular disulfide bonds critical to protein folding, so substitution of any of these amino acids could disrupt fibrillin protein structure and, consequently, have deleterious effects on the global structure of microfibrils. Some of the other missense mutations are in the conserved calcium-binding motif. The binding of calcium by this motif may serve to rigidify the protein and perhaps even stabilize FBN1 against proteolytic degradation. Nevertheless, it remains unclear whether the primary consequence of the alteration in the structure of the fibrillin protein is an increased sensitivity to proteolysis, an altered protein–protein interaction, individual microfibril disarray, or overall disruption of the architecture of polymeric microfibrillin arrays owing to distortion in the individual monomeric fibrillin modules.

Most of the identified mutations do not seem to segregate with particular phenotypes. Indeed, even in classic MFS, there is a striking intrafamily variability. For example, family members sharing the same mutation can have clinical syndromes that vary widely in terms of the age of onset, the organ systems involved, and the severity of disease.

Nevertheless, a minority of mutations do produce more consistent phenotypes. For example, 20% of reported mutations are either nonsense mutations or have a frameshift resulting in a premature stop codon. Messenger RNAs containing these transcripts display a reduced concentration owing to a phenomenon called nonsense-mediated decay, and most of these manifest as a mild clinical phenotype. Indeed, none of these mutations has been reported to cause neonatal MFS, the most serious manifestation of the disease. Conversely, patients with the phenotype of neonatal MFS—who are diagnosed at birth and die primarily of heart failure from severe tricuspid and mitral regurgitation rather than aortic dissection—have mutations that cluster in exons 24–32. Another clinical phenotype, atypically severe MFS, which presents with early-onset cardiovascular complications with aortic dissection or need for aortic surgery before age 16, is also associated with mutations in exons 24–32, although these mutations are typically distinct from mutations found in neonatal and classic MFS.

Nonetheless meaningful conclusions about genotype–phenotype correlations have been difficult to draw. Without further detailed knowledge of the three-dimensional structure of fibrillin, its protein partners, and the biology of microfibrils, it would be hard to correlate mutations with clinical phenotypes. Furthermore, given that most mutations in FBN1 (apart from those seen in classic MFS) have been identified in only one affected individual or family, it would be hard to generalize genotype–phenotype correlations. Finally, MFS is likely only a small percentage of fibrillinopathies, because FBN1 mutations have been reported in Marfan-related aortic syndromes and disorders of skeletal system such as Weill-Marchesani syndrome. Further progress awaits characterization of these disorders and more knowledge of the role of microfibrils.

The histological hallmark of MFS is the disorganization and fragmentation of elastic fibers and a decrease in elastin content in the medial layer of the aorta. No comprehensive theory has emerged that explains how mutations in the FBN1 lead to this pathological hallmark. However, several major hypotheses have emerged. The first proposed mechanism is the dominant-negative model of pathogenesis. Microfibrils consist of polymers of the FBN1 protein. According to the dominant-negative model, mutant FBN1 proteins interfere with the assembly of wild-type FBN1—produced by the normal allele in heterozygotes—into microfibrils. This model is attractive from a theoretical standpoint because large polymers are especially sensitive to defects in monomeric components; in the case of fibrillin, mutations in the cysteine residues might affect not only intramolecular disulfide bonds but also intermolecular bonds that might be essential to the assembly of microfibrils.

Premature truncation codon mutations are associated with lower levels of mutant transcripts leading to decreased numbers of mutant fibrillin monomers. If the dominant-negative model were true, fewer mutant monomers should produce less interference with assembly of the remaining wild-type monomers, and hence a milder phenotype. Indeed, in one study the patient with the lowest proportion of mutant transcript (6%) had a clinically mild MASS phenotype, whereas another patient with higher levels of mutant transcript (16%) had the more severe classic MFS phenotype. However, this model may not alone be sufficient, as in one report patients with 2 and 7% mutant transcript levels both had severe manifestation of MFS.

Studies using cultured fibroblasts from MFS patients also seem to support the dominant-negative hypothesis. Using pulse-chase experiments with radioactive sulfur to label the cysteine-rich fibrillin proteins, the synthesis, secretion and aggregation of fibrillin molecules were studied. Fibroblast cell lines derived from patients with MFS (with a variety of mutations) showed only 35% expected fibrillin deposition (based on normal controls) in the extracellular matrix (ECM). Interestingly, three nonsense mutations with mutant transcripts proportions of 15–25% demonstrated ECM deposition rates of 7–25% of normal, whereas one nonsense mutation with a lower mutant transcript level of 6% showed ECM deposition of 54% normal, supporting a dominant-negative effect. A “threshold effect” may exist in which low levels of mutant transcript may be insufficient to disrupt the assembly of microfibrils from the wild-type fibrillin protein expressed from the wild-type allele, whereas higher levels of mutant proteins are able to exert their dominant-negative effect.

Finally, in a classic experiment, a mutant allele was expressed from an MFS patient in normal human and murine fibroblasts. There was substantially reduced ECM deposition of fibrillin in these cultures. Thus, even in the background of two normal alleles, the expression of the mutant monomer led to disruption of fibrillin deposition in the ECM.

The second proposed mechanism of the pathogenesis of MFS is an altered homeostasis of the microfibril. The elastic fibers within the aortic media consist of an amorphous core comprised primarily of cross-linked tropoelastin monomers surrounded by microfibrils. During development, microfibrils are found at the margins of maturing elastic fibers, leading to the hypothesis that microfibrils and FBN1 may play a crucial role in the deposition of elastic fibers during embryogenesis, and that the distortion in the architecture of elastic fibers seen in MFS thus reflects abnormal elastogenesis.

Mice with targeted mutations in the FBN1 were created to test this hypothesis, leading to a 10-fold reduction in the level of the mutant transcript. Heterozygous mice expressed very low levels of the mutant transcript and were morphologically and histologically indistinguishable from the wild-type mice. Homozygous mutant mice appeared normal at birth, but died shortly thereafter of vascular complications, with histologic analysis revealing thinning of the proximal aortic wall. Immunostaining showed substantial reduction in the amount of extracellular fibrillin, but a normal amount of elastin staining, suggesting that elastogenesis may

proceed in a normal fashion even in the absence of normal development of microfibrils. The investigators hypothesized that microfibrils may be important in the homeostasis of the aortic wall, and in the absence of proper microfibril development, the aortic media is unable to sustain the hemodynamic stress to which it is subjected, eventually leading to aortic dilatation. The disruption of the elastic network may then be a secondary event.

Studies involving another mutant mouse model producing a fivefold reduction in gene expression support the concept. The homozygous mutant mice gradually develop severe kyphoscoliosis and die prematurely of Marfan-like vascular complications. Histological examination of these mice at birth shows normal vascular anatomy with a seemingly normal appearing elastin network in the aortic media. However, by 6 wk of age a sequence of events commences with focal calcification in the aortic elastic lamellae, progressing to intimal hyperplasia, monocytic infiltration, fragmentation of elastic lamellae, and eventually dilatation of the aortic wall.

An increase in fibrillin proteolysis is the third mechanism proposed of the pathogenesis of MFS. It is recognized that calcium binding to the calcium-binding epidermal growth factor-like (cbEGF) domains of fibrillin is essential for the proper assembly and integrity of the microfibrillar aggregates, and that calcium may protect wild-type fibrillin from proteolysis. Because FBN1 mutations reduce the calcium affinity of cbEGF motifs in vitro, investigators have hypothesized that mutations in the cbEGF domains might render the FBN1 aggregates more prone to proteolysis. Studies have been hampered by the difficulty of expressing full-length fibrillin in vitro, so most experiments have used fibrillin fragments. Nonetheless, these experiments have shown that certain FBN1 mutations increase protease susceptibility by exposing enzyme-specific cryptic cleavage sites for particular proteases. The clinical sequelae remain unclear. In one study, however, surgical thoracic aortic aneurysm specimens from patients with MFS did show increased immunofluorescence for certain matrix metalloproteinases (proteolytic enzymes), especially at the border of areas of cystic medial necrosis. Nonetheless, in contrast to the pathogenesis of abdominal aortic aneurysms (AAAs, discussed later), direct evidence linking proteases to the pathogenesis of MFS is lacking.

The pathogenesis of MFS thus remains unclear. It appears that all three mechanisms described may contribute to the ultimate disruption of the cellular and molecular architecture of the aortic wall's tunica media. A unified theory will require a better understanding of the dynamic biology of the microfibril, its interaction with other proteins, and its interaction with adjacent vascular smooth cells. Also unclear is the potential role of modifying genetic elements, which may be responsible for modulating the phenotypic expression of a particular MFS genotype.

BICUSPID AORTIC VALVE Bicuspid aortic valve is the most common congenital cardiac malformation, affecting 1–2% of the population. Bicuspid aortic valve is highly associated with other congenital aorta abnormalities, such as coarctation and patent ductus arteriosis. Bicuspid aortic valve is often associated with dilatation of the aortic root or ascending aorta and may progress to frank thoracic aortic aneurysms and aortic dissection. Consequently, despite its name, bicuspid aortic valve should be considered an abnormality of both the valve and aorta, rather than just the valve. Indeed, over time most individuals with a bicuspid aortic valve will develop complications—either valve dysfunction or aneurysm of the thoracic aorta—requiring surgical treatment.

The pathogenesis of the bicuspid aortic valve is not well understood. However, it seems likely that the abnormal aortic cusp formation during valvulogenesis is the result of a complex developmental process involving the ECM. During development the ECM provides scaffolding and cues that are critical in cellular migration and pattern formation. In the aorta, differentiation of the cushion mesenchymal cells into mature valve cells correlates with the expression of microfibrillar proteins fibrillin and fibulin. Genetic mutations that result in inadequate amounts of such proteins, or that disrupt the timing or function of such proteins, lead to abnormal valvulogenesis early in life, and perhaps a weakened aortic wall later in life, in turn resulting in aortic aneurysms and dissection. Although there does appear to be a familial risk, no single mutation resulting in the bicuspid aortic valve phenotype has been identified.

Research is focusing on transcriptional elements and signaling molecules that may alter the expression of the important ECM proteins. Mice deficient in endothelial nitric oxide synthase (eNOS) have a high incidence of congenital bicuspid aortic valves. In wild-type mice, the expression of endothelial nitric oxide synthase is noted in the myocardium as well as the endothelium during development, but is localized to the endothelium lining the valve at maturity, suggesting a role in valvulogenesis. Conversely, there was no difference in the diameter of the aortic lumen between the two groups.

Research has also concentrated on the etiology of the vascular complications associated with bicuspid aortic valve. The pathology of the aortic wall is likely the result of intrinsic defects in the ECM rather than a secondary consequence of valvular dysfunction. This is supported by the observation that dilatation of the ascending thoracic aorta can be found in young adults with a bicuspid aortic valve but without significant valvular stenosis or regurgitation. Similarly, even those with a bicuspid aortic valve who have undergone aortic valve replacement can develop ascending thoracic aortic aneurysms at a later date.

The thoracic aortic aneurysms associated with bicuspid aortic valve typically demonstrate accelerated degeneration of the aortic media. The histopathology in such cases is similar to that of patients with MFS who also have abnormal FBN1 content in their aortic wall.

FAMILIAL THORACIC AORTIC ANEURYSM SYNDROME In addition to the association of ascending thoracic aortic aneurysms with MFS and bicuspid aortic valve, some patients with such aneurysms and proven cystic medial degeneration have no other identifiable congenital abnormalities. Indeed, evidence suggests that many of these patients also have a genetic mutation that may account for cystic medial degeneration. Moreover, it is recognized that cases of thoracic aortic aneurysms in the absence of overt connective tissue disorders are often familial in nature and reflect a familial thoracic aortic aneurysm syndrome.

In an analysis of a large database of patients with thoracic aortic aneurysms, at least 19% of those without MFS had a family history of a thoracic aortic aneurysm. Most pedigrees suggested an autosomal-dominant mode of inheritance, although some suggested a recessive mode and possibly X-linked inheritance as well. Another series examined the families of 158 patients referred for surgical repair of thoracic aortic aneurysms or dissections and found that first-degree relatives of probands had a higher risk of thoracic aortic aneurysms compared with controls.

Investigation of the genetic basis for this syndrome is still in its infancy. Several genes have been implicated. A mutation on 3p24.2-25 has been identified that can cause both isolated and familial thoracic aortic aneurysms owing to cystic medial

degeneration. However, despite a dominant pattern of inheritance, there is a marked variability in the expression and penetrance of the disorder, with some inheriting the gene but showing no manifestation. Two other studies of familial thoracic aortic aneurysm syndromes have mapped the mutations to at least two different chromosomal loci, but other families mapped to neither of these, suggesting genetic heterogeneity in addition to variable expression and penetrance.

ABDOMINAL AORTIC ANEURYSMS

Unlike the ascending thoracic aortic aneurysms discussed, abdominal aortic aneurysms (AAAs) are typically associated with aging and atherosclerosis. Gender plays a role; men are 10 times more likely than women to have an AAA of 4 cm or greater. However, women with an AAA have a significantly greater risk of rupture than men. It is also recognized that genes influence aneurysm formation. Those having a first-degree relative with an AAA have an increased risk of 13–32% compared with the 2–5% risk in the general population. In addition, those with familial aneurysms tend to be younger and have higher rates of rupture than those with sporadic aneurysms. However, no single gene defects for AAA have been identified, and pedigree analysis suggests that the increased risk is probably polygenic.

To clarify the genetic underpinnings and foster improvements in prevention and therapy, there has been intense investigation to elucidate the pathophysiology of AAA. Examination of human AAA tissue resected at surgery and experiments from explanted AAA tissue maintained in tissue culture have provided important clues. First, the pathologic hallmark seems to be destructive remodeling of the elastic media of the aortic wall, including progressive degradation of the fibrillar matrix proteins. Second, evidence of an infiltration of inflammatory cells exists, including B lymphocytes, T lymphocytes, and macrophages. Third, there is increased immunoreactivity for elastolytic matrix metalloproteases (MMP), particularly MMP-2, MMP-9, and MMP-12. Of these, MMP-9 is the most abundant elastase secreted by AAA human tissue explants in vitro and seems to be actively expressed by macrophages at the site of tissue damage in resected AAA tissue.

Of the animal models developed to study the specific roles of the various MMPs, one of the most durable is the elastase-induced rat or mouse model of AAA. In it, the infrarenal aorta is temporarily ligated proximally (just below the level of the renal artery) and distally at the level of the bifurcation. A catheter is introduced via an aortotomy at the distal site of ligation and the portion of the aorta between the two ligations is perfused with elastase for 5 min. The sutures are then removed and the aortic dimensions can be measured at various time-points. A moderate amount of aortic dilatation appears immediately after the perfusion. There is then no further increase in aortic diameter for the next 7 d. However, at 14 d, the aortas in the elastase infusion group were significantly dilated (compared with a heat-inactivated elastase control group) and reached aneurysmal proportions.

Light microscopy revealed minimal damage to the medial elastic lamellae for up to 7 d in both groups. By 14 d, however, the elastase-perfused aortas exhibited a dense inflammatory infiltrate along with extensive degradation of the elastin framework. In contrast, the aortas infused with inactive elastase appeared normal at 14 d. This supports a model in which the initial elastase infusion serves as an insult that evokes an inflammatory response leading to tissue destruction and elastolysis, and ultimately, aneurysmal dilatation of the aortic wall.

Work has focused on the molecular players immediately upstream of elastolysis, and hence may form reasonable targets for therapeutic intervention. As mentioned, the most obvious candidates were MMP-9, MMP-12, and MMP-2. Using the mouse model of elastase-induced aneurysmal dilatation, investigators found that the development of aneurysms in this model was temporally and spatially correlated with "chronic inflammation." Staining with antibodies seemed to indicate that these macrophages were the likely source of MMP-9. Furthermore, levels of MMP-9 and MMP-12 were both increased during development of elastase-induced AAA, and treatment of these animals with doxycycline, a nonselective MMP-inhibitor, led to a significant reduction in the size of the aneurysms. In a final set of elegant experiments, the authors attempted to uncover the role of various specific MMPs using mice with targeted disruption of the MMP-9 and MMP-12 genes. Elastase infusion resulted in a significantly smaller AAA size in MMP-9 knockout mice and in mice that had been bred to have combined deficiencies in MMP-9 and MMP-12. However, there was no reduction in AAA size in the MMP-12 knockout mice.

Examination of aortic tissue from these mice models revealed no suppression of the elastase-induced inflammatory response. Indeed, the MMP-9 knockout mice continued to display infiltration by macrophages and polymorphonuclear leukocytes, yet at 14 d the elastic lamellae remained well preserved. However, when the bone marrow of the MMP-9 knockout mice was reconstituted with wild-type bone marrow (i.e., not MMP-9 deficient), a significant increase in aortic diameter resulted. These experiments suggest that the signals to recruit the inflammatory response following exposure to elastase are not dependent on the presence of the MMPs examined. The expression of MMP-9 by the infiltrating macrophages appears to be crucial to elastolysis and the subsequent development of aortic aneurysms.

It is unclear what other agents may be involved in the MMP cascades that seem to underlie the development of aneurysms. For example, plasmin and plasminogen activators seem to be involved in the development of aneurysms in some mice models, and the overexpression of plasminogen-activator inhibitor (PAI-1) can suppress aneurysm formation in a rat model. Proteases such as plasmin/PA and elastases may be part of a cascade that leads to progressive activation of other proteases (such as MMP-9 from pro-MMP-9) much like the coagulation and complement cascade. Furthermore, protease inhibitors such as plasminogen-activator inhibitor and tissue inhibitors of MMP might act as checks to prevent rampant activation of the proteases. Disruptions or changes in the "balance of power" could alter the process in favor of proteases and hence elastolysis.

Despite the extensive progress in the understanding of the protease cascades that may be responsible for elastolysis, much less is known about the signals that initiate the inflammatory process in the wall of aortic aneurysms. There is a clear association between atherosclerosis and aneurysm formation, so atherosclerotic plaques (known to contain an inflammatory infiltrate) might be an "insult" to the arterial wall, akin to the exposure of mice aorta to elastase. A model of atherosclerosis and underlying endothelial cell dysfunction has emerged in the form of mice deficient in apo-E, which have accelerated atherosclerotic lesions. However, despite their extensive atherosclerotic lesions these mice do not develop AAA. Hence just the presence of atherosclerosis and the associated inflammation may not be sufficient to induce the formation of aneurysms. One possible explanation is that

compensatory mechanisms in the vascular bed—such as the release of nitric oxide by endothelial cells—counteract some effects of inflammation.

Although endothelial cell-dependent relaxation of the vascular bed is mediated by nitric oxide, it appears that nitric oxide may have multiple other roles, including inhibition of smooth muscle cell proliferation, platelet aggregation/adhesion, and leukocyte activation. Perhaps removing this versatile signaling molecule in the presence of atherosclerotic plaque induces the formation of an aneurysm. This was accomplished experimentally by crossing e-NOS knockout and apo-E knockout mice to create mice deficient in both proteins. The "double knockout" mice were more hypertensive that control wild-type mice, and a significant proportion of these mice developed an AAA. The development of the AAA was not simply owing to hypertension, because lowering the blood pressure to levels seen in the control mice had no effect in reducing aneurysm development, suggesting that there may be a "multihit" mechanism for the development of AAA. Atherosclerotic lesions, such as those seen in the apo-E knockout mice, may serve as the initial insult leading to a chronic inflammatory state; meanwhile, the presence of preserved endothelial function mediated by nitric oxide may protect from the development of AAA. However, the addition of significant endothelial dysfunction (in this case the lack of the critical endothelial regulator nitric oxide) may be the second factor that accelerates the process of AAA formation.

14 Atherosclerotic Coronary Disease

Robert E. Gerszten and Anthony Rosenzweig

SUMMARY

Atherosclerotic coronary artery disease is a complex biological process resulting in narrowing of the arterial vessels that supply the heart muscle with oxygen and nutrients. Despite major advances in the understanding of this process and its clinical management, it remains a major cause of morbidity and mortality throughout the world. In the United States, coronary artery disease accounts for about 500,000 deaths each year, of which about half are sudden. This chapter reviews the clinical presentation and treatment of this condition, focusing on advances and the biological insights they provide. Some of the leading hypotheses regarding the molecular mechanisms underlying this incompletely understood condition are considered.

Key Words: Angina; atherosclerosis; coronary artery disease; endothelial cells; genetic models; infarction; inflammation; ischemia; lipids; platelets; reperfusion; smooth muscle cells.

DEFINITION OF TERMS

The major complication of coronary artery disease (CAD) is myocardial injury and dysfunction from inadequate delivery of essential nutrients. Coronary obstruction can be severe before it limits blood flow, particularly under resting conditions, and thus this process can develop over years while remaining clinically silent. Inadequate blood flow that does not produce permanent myocardial cell damage is termed myocardial ischemia. Reduction or obstruction in flow sufficient in severity and duration to cause irreversible, clinically detectable myocardial damage is termed myocardial infarction (MI). Improved biochemical markers of myocyte injury with greater sensitivity and specificity (such as cardiac troponin isoforms) have made the detection of small amounts of myocardial injury feasible in a clinical setting. Detection of these markers identifies a subset of patients at higher risk for subsequent complications and increases the number of patients with diagnosable infarction who would previously have been considered to have suffered "only" an episode of ischemia. The clinical and biological spectrum from mild ischemia to substantial infarction appears to be a continuum rather than distinct categories.

The clinical symptoms associated with myocardial ischemia are termed angina pectoris. Many patients with coronary disease experience exertional symptoms in a consistent and predictable pattern termed chronic stable angina. A marked acceleration in the frequency, severity, or duration of angina, or a significant decrease in the level of exertion inducing angina, constitutes unstable angina and carries a substantial risk of progression to MI. Together unstable angina and MI comprise the acute or unstable coronary syndromes. The biological basis for the transition from no or chronic stable angina to an unstable coronary syndrome is the subject of intense investigation and has important clinical implications.

CLINICAL FEATURES

Elements contributing to the development of atherosclerotic lesions include genetic predisposition, elevated lipid levels, diabetes, tobacco smoking, and hypertension. Peripheral markers of inflammation such as C-reactive protein may provide independently informative risk stratification. Many of these clinical risk factors generally fit well with the prevailing inflammatory hypothesis of atherogenesis discussed next. However, a precise and comprehensive understanding of the pathophysiological mechanisms responsible remains elusive. Moreover, known factors do not fully account for individual or heritable risk of developing CAD.

Nevertheless, efforts to mitigate these now-established risk factors in combination with improvement in medical and surgical management have led to a significant decline in age-adjusted mortality rates for patients with cardiovascular disease over the past several decades. One of the major advances in management of MI has been the recognition of the importance of rapidly restoring reperfusion to the affected myocardium. The rapidity of reperfusion appears critical whether achieved through thrombolysis or catheter-based intervention. Though studies suggest a clinical advantage to the latter approach, logistical considerations and the availability of experienced interventionalists may sway the decision toward the former. Yet the increase in aggressive management of coronary disease has produced valuable clinical information, and in part through this experience, theories about the pathogenesis of the atherosclerotic plaque have also evolved. For example, serial angiographic studies show that often it is not the most angiographically severe lesions that become unstable clinically. Rather, nonobstructive lesions may progress rapidly to obstruction through plaque rupture and/or thrombosis. Thus the angiographic appearance of a lesion is a poor predictor of its clinical behavior. Lessons learned from clinical trials with lipid lowering agents are consistent with these observations. Although lipid reduction only modestly improves the angiographic severity of high-grade atherosclerotic lesions, it substantially reduces the risk of acute coronary events such as unstable angina or MI. In this sense, CAD is not simply a mechanical problem of luminal obstruction but also

a biological process, which increases the challenges and opportunities of managing such patients.

DIAGNOSIS AND MANAGEMENT

STABLE CORONARY DISEASE The chest discomfort associated with ischemia is termed angina and is classically described as a substernal chest pressure brought on by exertion and relieved by rest. Radiation of this discomfort (to the arm or jaw) and associated symptoms such as dyspnea or diaphoresis are common. Other precipitants include emotional stress, cold weather, or even large meals. Comorbid diseases such as anemia, thyrotoxicosis, or infection should be considered as possible contributors. Angina most frequently results from epicardial coronary stenoses that impair coronary flow reserve. As it is decreased, stress-induced myocardial ischemia typically results in anginal chest discomfort. Angina often correlates with coronary stenoses of 70% of the luminal cross-section, whereas rest angina usually does not develop until stenoses are greater than 90%. Many patients with CAD have documented episodes of ischemia in the absence of anginal symptoms. The full implications and management of silent ischemia remain controversial.

Although the physical examination provides important insights into the status of the patient's cardiovascular system and general health, it can neither establish nor refute a diagnosis of CAD or angina. Further evaluation is useful for diagnosis in patients with suspected CAD and for prognosis in patients with known CAD. As with all clinical testing, a positive or negative result must be interpreted in the context of the prior probability that a diagnosis such as ischemic heart disease exists in the patient or population under study. Further testing is most useful when clinical evaluation places the prior probability of CAD in an intermediate level. If the prior probability of disease is extremely low, a positive test is most likely to be a false-positive and may precipitate a cascade of expensive, otherwise unnecessary and potentially harmful invasive testing. Conversely, if the prior probability is extremely high, a negative test is likely falsely negative and a positive test contributes little to the diagnosis. However, testing can be useful in patients with an intermediate probability of CAD, because a positive test may appropriately tip the balance toward invasive evaluation whereas a negative test may lower the likelihood of CAD sufficiently to obviate the associated risks. In patients with known CAD, exercise testing can provide a useful functional assessment and prognostic information.

Evocative testing is necessary because ischemia connotes a relative deficiency of blood flow that is usually not apparent at rest until stenoses become severe. In general, provocative approaches include exercise and pharmacological manipulations such as IV adenosine, dipyridamole, or dobutamine. The pharmacological approaches do not provide as much functional information as exercise-testing and generally should be reserved for patients who cannot exercise adequately. Clinical status (symptoms, blood pressure, and ECG) is monitored but is generally a more reliable indicator of ischemia with exercise than pharmacologic testing. Noninvasive assessment of myocardial perfusion is most commonly accomplished with radionuclide scintigraphy following the intravenous administration of a radioisotope such as thallium-201 or Technetium-99m. Such radionuclide scintigraphy improves the sensitivity and specificity of evocative testing. In addition, these techniques often allow differentiation between ischemic and infarcted zones. In the former, isotope uptake is reduced during initial stress but normalizes over time with isotope redistribution (thallium) or reinjection (technetium). In contrast, in infarcted tissues, uptake is persistently diminished. Information about coronary flow can also be inferred from dynamic changes in systolic wall movement and thickening most commonly assessed by echocardiography. The sensitivity and specificity of stress echocardiography are similar to that of thallium stress testing. These imaging modalities increase the sensitivity, specificity and expense of evocative testing.

UNSTABLE CORONARY SYNDROMES The hallmark of unstable coronary syndromes is rapidly progressive substernal chest pressure, often radiating to the jaw or left arm. The initial presentation, however, may be symptoms at rest. The discomfort of acute MI is qualitatively similar, though often more severe and prolonged. It is acute in onset and often associated with diaphoresis, dyspnea, and an impending sense of doom. Elderly and diabetic patients often have less typical symptoms. Underlying illnesses such as anemia or infection may precipitate the presentation of CAD. Acute infarction occurs in a minority of patients presenting with chest pain of presumed cardiac origin. Chest discomfort described as "pressure" or "burning" is most associated with acute infarction. Positional or pleuritic pain should prompt consideration of other etiologies. It should be noted that approx 25% of MIs are silent and associated with no or only mild and atypical symptoms. The prognosis of such silent infarctions appears similar to that of more classic presentations.

PHYSICAL EXAMINATION Physical examination neither establishes nor excludes the diagnosis of acute MI or unstable angina. It does, however, provide critical clinical information of practical importance in patient management. Evaluation of the vital signs is particularly important in patients with chest pain. The heart rate is usually normal or slightly elevated, though infarctions involving the diaphragmatic portion of the heart are often accompanied by bradycardia and nausea. An irregular rhythm should raise the suspicion of ventricular ectopy or atrial fibrillation. Hypotension in the setting of chest pain may be secondary to pump failure and is a particularly ominous finding. Mild hypertension is more commonly found with acute onset of symptoms. Tachypnea may be secondary to evolving congestive heart failure.

The jugular venous pulsation is usually normal. An elevated measurement may denote chronically elevated right-sided filling pressures but should raise the possibility of right ventricular involvement. The diagnosis of right ventricular infarction may also be suggested by a paradoxical rise in venous pressure with inspiration, known as Kussmaul's sign.

Evaluation of the arterial pulse amplitude and duration provides important clues to possible valvular disease or associated noncoronary arterial disease. The pulse contour also reflects the patient's cardiac output. This evaluation may be confounded in elderly patients by noncompliant arteries in which the pulse amplitude may appear normal despite a significantly reduced cardiac output. The status of peripheral arteries and the quality of the lower extremity veins should be carefully assessed before consideration of interventions such as cardiac catheterization, angioplasty, intraaortic balloon counterpulsation or bypass surgery.

The possible auscultatory findings in atherosclerotic heart disease are protean. An S4 heart sound is common. A third heart sound, however, reflects significant systolic impairment. Cardiac murmurs may be fixed or transient, emphasizing the importance of serial examination. Both stable and unstable symptoms may be precipitated or exacerbated by underlying valvular heart disease such as aortic stenosis. The murmur of papillary muscle dysfunction is often transient whereas mechanical complications such as

ventricular septal defect may not occur until days into the hospital stay. A pericardial friction rub often occurs several days after infarction. Evaluation of the lungs centers on the presence of rales consistent with congestive heart failure. In the acute coronary syndromes (ACSs), pulmonary rales coupled with an S3 gallop is a poor prognostic sign.

LABORATORY EVALUATION The classic ECG pattern of acute MI includes ST segment elevation in multiple leads reflecting a coronary distribution, followed by evolution of T-wave inversion and significant Q waves in these same leads, reflecting a Q-wave MI. However, patients with infarction can also present with ST segment depression or T-wave inversion alone without evolution of Q waves, termed non-Q wave-MI. The correlation of these ECG findings with pathological findings of transmural or subendocardial infarction is sufficiently imprecise to favor exclusive use of the ECG descriptors in clinical practice.

Serological markers of myocardial necrosis remain the cornerstone in establishing the diagnosis of MI. The serum creatine kinase (CK) and its myocardial-specific isozyme, CK-MB, are widely used. However, as previously noted, cardiac troponin isoforms have improved sensitivity and specificity compared with CK, and generally become abnormal by 6 h after injury facilitating more rapid risk stratification. The degree of elevation in all these markers correlates approximately with the amount of myocardium damaged but is influenced by other factors. Elevated levels of serum transaminase and lactate dehydrogenase with isoform reversal occur later after infarction. Measurement of these levels generally adds little to clinical management and should not be routinely employed in evaluation of acute chest pain. Panels of markers reflecting myocyte necrosis (Troponin), neurohormonal activation (brain natriuretic peptide), and inflammation (CRP) are being evaluated to see if together they provide more precise prognostic information.

MANAGEMENT In approaching an individual patient, several goals must be considered simultaneously: prevention of disease progression, control of symptoms, and optimizing prognosis. Available tools include patient education and risk factor modification, pharmacological therapy, and mechanical interventions including surgical and catheter-based approaches. All these considerations must be integrated into a coherent clinical approach, which in practice is often influenced dramatically by the acuity of the patient's clinical presentation.

Patient education and behavior modification form the cornerstone of primary and secondary prevention. Aggressive risk factor modification, particularly reduction in serum lipids, can have a dramatic clinical impact even within a few years in populations with documented CAD. Randomized trials have documented angiographic regression of plaques, establishing that regression is possible in principle. However, even more intriguing is the observation that although the degree of regression has been modest, the improvement in clinical end points has been more dramatic. Reduction in serum lipids appears to have clinical benefits, which are only imperfectly reflected in the angiographic appearance of lesions. These clinical benefits can be realized during a relatively brief (2–3 yr) period of treatment, which underscores the importance of secondary prevention efforts. Although lifestyle modifications are emphasized as the first step in this process, it is often necessary to move to pharmacological lipid lowering therapies. The particular agent(s) employed is determined by the specifics of the patient's lipid profile.

Other therapies of proven clinical benefit in patients who have a history of MI include aspirin, β-blockade, and angiotensin-converting enzyme inhibitors, particularly in patients with a reduced left ventricular ejection fraction. These agents reduce the incidence of clinical cardiovascular events and mortality. For this reason, they should be considered in all patients after MI, even if they are asymptomatic. Medications that may be useful in the long-term treatment of coronary patients but have not been demonstrated to improve prognosis include calcium channel blockers and nitrates. In fact, in the setting of non-Q-wave infarction, the calcium channel blocker diltiazem had a deleterious effect on 1-yr survival in patients manifesting congestive heart failure during the initial hospitalization. These medications may help control anginal symptoms, hypertension, or arrhythmias, but should not be routinely prescribed independent of a specific indication because of the lack of proven outcome benefit.

Therapy for chronic stable angina includes pharmacological and mechanical interventions. The three classes of pharmacological agents primarily employed are β-blockers, calcium channel blockers, and nitrates. As noted, only the first has documented survival benefit in postinfarction patients but all three have been demonstrated to improve exercise tolerance and can reduce ischemic symptoms, both valid goals. Mechanical interventions encompass a variety of catheter-based approaches such as percutaneous transluminal angioplasty as well as coronary artery bypass surgery graft (CABG). CABG provides a survival benefit over medical therapy alone in patients with significant left main coronary disease or severe three-vessel coronary disease (particularly in the setting of compromised left ventricular function). In patients with one- or two-vessel coronary disease and mild symptoms, CABG does not confer a survival benefit. However, surgery eliminates or reduces anginal symptoms more effectively than medical therapy alone. Catheter-based interventions are also highly effective at reducing ischemic symptoms but have generally not been demonstrated to improve survival. Percutaneous coronary interventions (PCIs) have historically been plagued by a significant rate of restenosis. The advent of mechanical support (stents) has significantly reduced this rate. The development of stents that simultaneously mediate local release of pharmacological agents has had an even more dramatic reduction in restenosis. Although the indications for such interventions are undergoing evaluation, it is likely the number of such procedures will continue to grow.

Basic science findings have best been translated into therapy in relationship to platelet biology and evolving therapies for patients presenting with ACSs. In particular, efforts have centered on the abrogation of signaling triggered by the two major platelet agonists, adenosine diphosphate (ADP) and thrombin. Heparin, an indirect thrombin antagonist, works via activation of antithrombin 3, and is a mainstay of the medical regimen of all patients with ACSs. Comparative trials of the more specific low-molecular-weight heparin have demonstrated its superiority over unfractionated heparin in reducing cardiac events in ACS. Two direct thrombin inhibitors, hirudin, and bivalirudin, show trends toward benefit over heparin therapy alone in patients with ACS. The direct thrombin antagonist bivalirudin has also shown promise as an adjunctive therapy in patients undergoing percutaneous revascularization. However, owing to tremendous cost differences between low-molecular-weight heparin and direct thrombin inhibitors vs unfractionated heparin, these newer therapies have not gained widespread acceptance. Direct thrombin inhibitors are commonly used, though for anticoagulation of patients with heparin induced thrombocytopenia, a growing problem worldwide.

ADP receptor antagonists have become a mainstay of therapies for ACS and PCI. Clopidogrel in combination with aspirin

confers a 20% reduction in cardiovascular death, MI or stroke compared with aspirin alone in both low- and high-risk patients with ACS. The benefit of treatment before PCI has also been seen with greater than 30% reduction in events even at 1 yr. Ongoing studies are also evaluating ADP receptor antagonism in primary prevention.

New strategies for profound inhibition of platelet activity at the injured coronary plaque have also focused on blockade of the platelet surface membrane glycoprotein IIbIIIa receptor, which binds circulating fibrinogen or von Willebrand factor and crosslinks platelets as the final common pathway to aggregation. Four agents directed against this receptor include chimeric monoclonal antibody fragments, peptide inhibitors, and nonpeptide mimetics. Multiple large scale placebo-controlled trials have evaluated approx 50,000 patients. Patients undergoing percutaneous interventions and high-risk patients with ACS appear to derive the greatest benefits. Benefits have been relatively uniform between the various classes of inhibition. Monoclonal antibody fragments may be most efficacious, potentially via their dual effects on platelet integins and the vitronectin receptor on the disrupted endothelium. Efforts to generate oral IIbIIIa antagonists for chronic therapeutic intervention have been unsuccessful likely because of partial agonist effects.

In acute MI, the immediate goal is restoration of adequate coronary flow as quickly as possible to minimize or avoid irreversible myocardial damage. Two general approaches are widely employed to achieve this goal: primary angioplasty and thrombolytic therapy. Additional clinical benefit exists from primary angioplasty if it can be accomplished quickly by experienced interventionalists. However, in many communities this is not practical and immediate administration of thrombolytic agents may be preferable. One study suggested that the benefits of angioplasty outweighed the potential disadvantages of the delays inherent in transferring patients to specialized centers, at least in some settings. Whether this approach is further validated and becomes generally accepted remains to be seen. Thrombolytic agents have not been beneficial in the treatment of unstable angina. However, therapy with heparin and aspirin—alone and in combination—reduces the rate of progression to frank infarction. Patients with unstable symptoms that cannot be controlled by heparin/aspirin and maximal anti-ischemic therapy should undergo early catheterization to define possible options for immediate mechanical intervention. The platelet glycoprotein IIb/IIIa receptor is a pivotal mediator of platelet aggregation as noted earlier. Platelet adhesion, the first step in the process of hemostasis, can be triggered by endothelial dysfunction or injury, resulting in interaction of platelets with the subendothelial matrix. Adhesion molecules of the vessel wall, along with clotting proteins such as fibrinogen, interact with platelet-membrane glycoproteins—of which integrins such as IIb/IIIa play a key role. Although some combination of these approaches appears likely to optimize early reperfusion, additional efforts are directed at determining whether adjunctive therapies can maximize myocardial salvage after reperfusion and lead to additional therapeutic benefit. Animal studies suggest this is, in principle, possible but these concepts have not been validated clinically.

GENETIC BASIS OF DISEASE

Atherosclerosis is a complex phenotype, which most commonly appears modulated by interactions between environmental factors and multiple genetic loci, only some of which have been identified. Genetic dyslipoproteinemias can substantially accelerate disease progression. Assessment of serum lipid levels should be included in the evaluation of all patients with CAD, thereby providing an initial screen for genetic dyslipoproteinemias as well. Similarly, understanding the genetic bases for other recognized clinical risk factors such as diabetes mellitus or hypertension has an important impact on the development and progression of CAD. Some studies have suggested an association between the deletional allele of the angiotensin converting enzyme gene and the risk of MI. However, this was not confirmed in a prospective study of a large cohort of US physicians. Elevated serum levels of homocysteine can result from genetic defects in specific metabolic enzymes and is independently associated with ischemic heart disease. The epidemiological relationship of CAD and markers of thrombosis such as fibrinogen levels are also being investigated. However, the genetic basis of most ischemic heart disease remains elusive. In part, this reflects the nature of most CAD seen clinically as a polygenic, quantitative trait. Experimental and statistical approaches to analysis of such traits have been developed and are being applied to a variety of CAD phenotypes. Ultimately, it is hoped that this approach can identify patients at risk, the likelihood of favorable responses to specific therapies, and unanticipated genes involved in disease pathogenesis. Although this represents an exciting approach to an important clinical problem, the impact of such approaches on clinical management remains to be validated. The conceptual and practical issues associated with such studies are addressed elsewhere in this text.

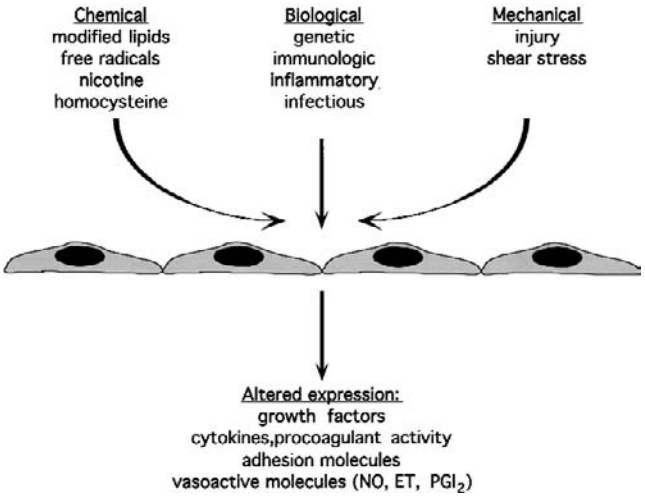

Figure 14-1 The central role of vascular endothelium. Many different stimuli may induce a similar repertoire of dysfunctional endothelial responses that ultimately contribute to clinical atherosclerosis. The endothelium provides a potential pathophysiologic link between well-established clinical risks factors such as hypercholesterolemia, cigarette smoking, or hypertension, and atherogenesis. The role of the endothelial effects of other agents such as homocysteine or viral infection as well as inflammatory cascades, remains more controversial. ET, endothelin-1; NO, nitric oxide; PGI_2, prostaglandin I_2.

PATHOPHYSIOLOGY

MOLECULAR PATHOPHYSIOLOGY Hypotheses concerning the molecular pathogenesis of ischemic heart disease seek to explain two related but distinct phenomena: the gradual development of obstructive atherosclerotic lesions responsible for stable angina and the rapid progression of these lesions to the ACSs.

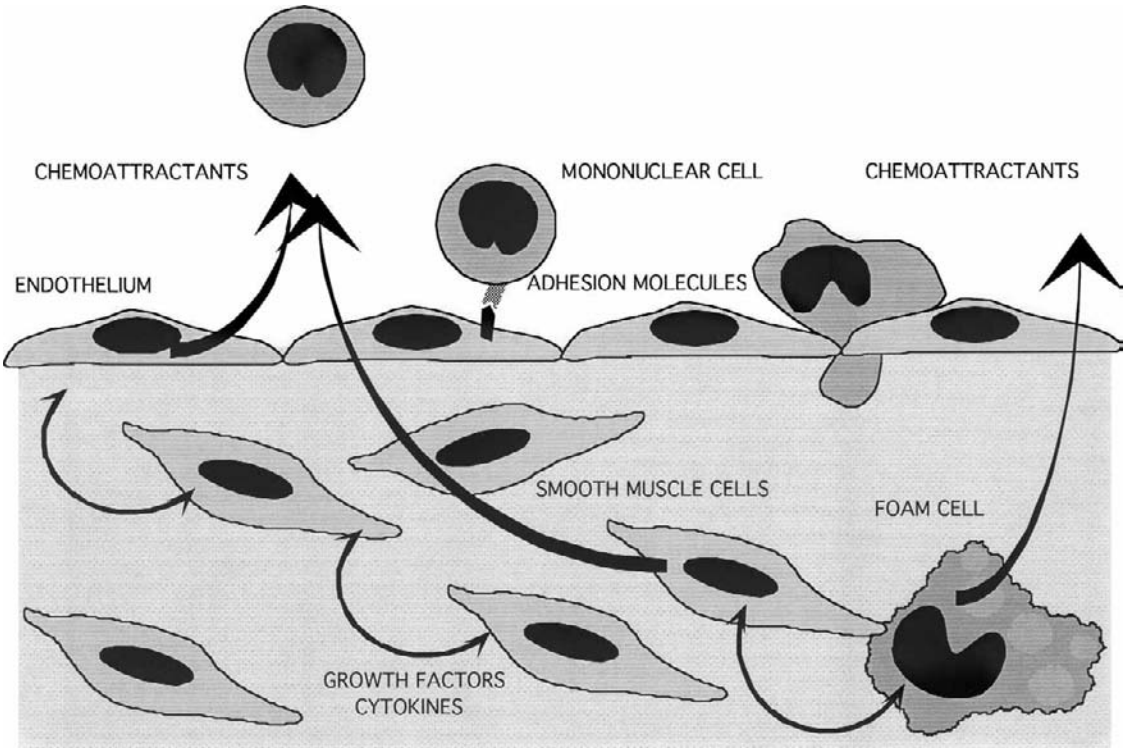

Figure 14-2 Leukocyte interactions with the vessel wall. An activated or dysfunctional endothelium may initiate a cascade of events that augment atherogenesis, including the recruitment of leukocytes through endothelial expression of cytokines and adhesion molecules, as well as alterations in smooth muscle cell function mediated by growth factors, cytokines, and vasoactive substances (indicated by arrows). Mononuclear cells and the foam cells they give rise to, as well as vascular smooth muscle cells, can also release growth factors and cytokines that further perpetuate this cycle.

It was first proposed that atherosclerotic lesions develop as a "response to injury" of the vascular endothelium, and much of the view of atherogenesis arises from these concepts. Subsequently this model has been modified to suggest that atherogenesis may begin with endothelial activation or dysfunction rather than actual injury or loss of the endothelium. Indeed, endothelial dysfunction may represent a common response to a wide variety of clinically relevant factors (Fig. 14-1), and the endothelium may represent a critical interface integrating these stimuli and modulating the behavior of circulating leukocytes and subintimal constituents of the vessel wall, such as smooth muscle cells (SMCs, Fig. 14-2). Activation of vascular endothelium may initiate a cascade of events leading to mononuclear leukocyte recruitment into the vessel wall with subsequent release of cytokines and growth factors contributing to SMC migration and proliferation, as well as abnormalities of extracellular matrix formation. Although this model is intuitively appealing and supported by a wealth of correlative studies, the precise molecular mechanisms involved in vivo are only incompletely understood. Even less well delineated are the mechanisms underlying the abrupt clinical change from stable angina (or no symptoms at all) to the unstable coronary syndromes. The anatomic correlate of this clinical transformation appears to be acute plaque rupture. Exposure of the atherosclerotic fatty core to the blood likely serves as a substrate for the propagation of clot and inflammation. Consistent with this model, pathological studies have emphasized the importance of a central lipid core in the process of plaque fissuring and confirmed the role of thrombosis in unstable angina and MI.

MURINE MODELS OF ATHEROSCLEROSIS The understanding of atherogenesis and the ability to deduce causal relationships has been substantially advanced by the use of inbred murine models. Although most wild-type mouse strains appear resistant to atherosclerosis, certain strains—such as C57BL/6—develop lesions when placed on a high-cholesterol diet (often in combination with cholic acid). Studies in these mice have explored the role of specific mediators in atherogenesis and the genetic differences between atherogenesis-prone and resistant strains. However, lesions in this model do not progress beyond "fatty streaks." The advent of genetically manipulated murine models that recapitulate more of the morphological features of seen in advanced human atheroma has considerably enhanced such investigation.

The two most widely studied murine models of atherosclerosis are ApoE deficient ($ApoE^{-/-}$) and low-density lipoprotein receptor deficient ($LDLR^{-/-}$) mice. $ApoE^{-/-}$ mice fed a "Western" diet (21% fat by weight/40% by calories, 1.25% cholesterol) develop marked hyperlipidemia most consistent with Type III hyperlipidemia (rare in humans). On a standard chow diet, $ApoE^{-/-}$ mice develop fatty streaks lesions after approx 10 wk and these lesions progress, although the process is substantially accelerated on a Western diet. The complex plaques seen in this model are reminiscent of the human disease, although thrombosis is not generally described. $LDLR^{-/-}$ were initially developed as a model of familial hypercholesterolemia. In contrast to $ApoE^{-/-}$ mice, $LDLR^{-/-}$ mice do not develop significant atherosclerotic lesions on a normal chow diet, thus facilitating kinetic studies of atherogenesis. However, complex lesions are less common in $LDLR^{-/-}$ mice fed a Western diet and some investigators use supplemental, dietary cholic acid, which may have confounding pro-inflammatory effects. Both $ApoE^{-/-}$ and $LDLR^{-/-}$ models of atherosclerosis have been extensively characterized and although each has its potential advantages and advocates, results in both models have generally been concordant. Other models (e.g., transgenic overexpression of apoB100) provide important

insights into the role of specific lipoproteins but have been less extensively characterized. In virtually all models of atherosclerosis, atheroma develops, preferentially in specific regions marked by disturbed flow and increased expression of pro-inflammatory endothelial cell effectors. In mice, these regions exhibit enhanced expression and increased activation of the family of transcription factors, nuclear factor-κB (NF-κB), which act as key regulators of the expression of genes modulating inflammation and survival.

The development of these models has enabled investigators to exploit the power of murine germline genetics to analyze the role of specific modifier loci as well as putative effectors in atherogenesis. By breeding atherogenic murine lines (e.g., ApoE$^{-/-}$ and LDLR$^{-/-}$) to different in-bred genetic backgrounds or mice engineered to lack or overexpress specific candidates, many useful insights into the role of these pathways in atherogenesis have been generated. However, these models do not generally recapitulate the biology of plaque rupture associated with unstable human lesions. A tacit hypothesis underlying much work in this field is that interventions that mitigate the overall burden of atherosclerosis also favorably modify the tendency to plaque rupture. This has been true clinically with some therapies such as statin treatment, which improve serum lipid profiles, inhibit lesion progression, and even more dramatically reduce the rate of unstable coronary syndromes. Nevertheless, the development of animal models that accurately reflect these processes—particularly in species amenable to genetic analysis—would further facilitate investigation into the biology of the unstable plaque and the events leading to ACSs.

ROLE OF LIPIDS Autopsy studies have shown that fatty streaks frequently exist in the coronary arteries and aortae of teenagers. These lesions may constitute the earliest recognizable precursor of atherosclerotic plaques, although it is formally possible that they either do not progress or actually regress with time. The major lipid component of these lesions is oxidized LDL. In vitro experiments have shown that oxidized LDL stimulates the adherence of monocytes to vascular endothelium most likely through increased expression of endothelial adhesion molecules. Oxidized LDL also stimulates transcription and secretion of monocyte chemotactic protein (MCP)-1 by human aortic and SMCs in vitro. MCP-1 is a powerful chemoattractant for monocytes and memory T cells in vitro, which are the predominant leukocyte populations in atherosclerotic lesions. Lysophosphatidylcholine, which constitutes a significant fraction of oxidized LDL, is a chemoattractant for monocytes and also induces expression of the endothelial adhesion molecules vascular cell adhesion molecule (VCAM)-1 and intercellular adhesion molecule (ICAM)-1. In addition, oxidized LDL can stimulate platelet aggregation and promote procoagulant activity on the surface of macrophages by an increase in tissue thromboplastin activity and by stimulating the expression and secretion of tissue factor by monocytes or aortic endothelial cells. Finally, oxidized LDL may also contribute to the vasomotor dysfunction that can promote or exacerbate the atherosclerotic lesion. Therefore, in many patients with atherosclerosis, lipids (particularly oxidized lipids) likely constitute an early and persistent precipitant of endothelial activation and dysfunction.

SMOOTH MUSCLE CELLS Abnormal growth of vascular SMCs is prominent in atherosclerosis. At least two phenotypes of the SMCs make up the vascular wall, based on examination of myosin filaments and details of the secretory protein apparatus. When cells are in a contractile phenotype, they respond to elements that promote vasoconstriction or vasodilation such as endothelin, angiotensin II, prostaglandin I2, or nitric oxide. A second synthetic phenotype has also been identified. In this state, SMC synthesize numerous growth factors and their receptors, cytokines, as well as matrix proteins. Multiple factors may be able to stimulate SMC proliferation and migration from the vessel media, through the internal elastic membrane. These activated SMCs, in turn, release substances that act in complex paracrine and autocrine manners, involving vascular endothelial and SMCs, as well as blood-borne elements such as white cells and platelets (Table 14-1 and Fig. 14-2). A particularly dramatic example of this process occurs after mechanical injury of the vessel during angioplasty, but a similar process may contribute to atherogenesis. A central issue in the investigation of atherogenesis is to define the source(s) of the critical factors that initiate and perpetuate the shift in SMC phenotype. Of note, a substantial advance in the management of CAD has been the development of coronary artery stents that release pharmacological agents, providing mechanical support and a local biological intervention, termed drug-eluting stents. Drug-eluting stents appear to dramatically reduce the rate of restenosis after coronary interventions. One of the preliminary successes of this approach has utilized stents that release rapamycin, an inhibitor of the signaling molecule mammalian target of rapamycin (mTOR). mTOR plays an important role transducing signals to growth and proliferation pathways in a wide variety of cell types, including SMCs. However, whether inhibition of mTOR and/or modulation of these signaling pathways underlies the clinical success seen with rapamycin eluting stents has not been demonstrated.

Table 14-1
Cellular and Molecular Mediators of Atherosclerosis

Factor	*Source*	*Target*
Growth factors		
PDGF	EC, WBC	SMC
bFGF	EC, SMC, WBC	EC, SMC
M-CSF	EC	WBC
VEGF	SMC	
Cytokines		
IL-1	EC, SMC, WBC	EC, WBC, SMC
TNF-α	EC, SMC, WBC	EC, WBC, SMC
IFN-γ	WBC	EC, WBC, SMC
Chemokines (MCP-1)	EC, SMC, WBC	WBC
Vasoactive substances		
Nitric oxide	EC	SMC, WBC
Endothelin	EC	SMC
Prostaglandin	EC	SMC

bFGF, basic fibroblast growth factor; EC, endothelial cell; IFN, interferon; IL, interleukin; MCP, monocyte chemotactic protein; M-CSF, monocyte-colony stimulating factor; PDGF, platelet-derived growth factor; SMC, smooth muscle cells; TNF, tumor necrosis factor; VEGF, vascular and endothelial growth factor; WBC, white blood cells.

LEUKOCYTES Because of their early and consistent association with atherosclerotic lesions, mononuclear cells appear to be central to atherogenesis. The mononuclear cells in atherosclerotic lesions are predominantly monocytes and lymphocytes of the memory T-cell phenotype (CD45 RO^{+}). Monocyte-derived foam cells are a major component of atheroma, comprising up to 60% of cells found in the necrotic lipid core, and 10–20% of cells in the fibrous cap. Recruitment of monocytes by activated endothelium marks an early event in atherosclerotic lesion formation. Mononuclear cells serve as the progenitors of foam cells and a

potential source of growth factors and cytokines (Fig. 14-2). These chemical signals in turn may mediate intimal and smooth muscle hyperplasia and amplify recruitment of more leukocytes to the vessel wall. Thus, monocytes also appear to be important participants in the progression of atherosclerosis through effects on inflammation, extracellular matrix remodeling, and coagulation. Monocytes may be important in the plaque instability thought to underlie ACSs. More importantly, correlative studies are supported by evidence from multiple studies that mice genetically engineered to lack specific signals in monocyte recruitment and function are resistant to atherosclerosis.

ENDOTHELIAL PROGENITOR CELLS Work in many fields has prompted a growing realization that adult cells and tissues have substantially greater plasticity and potential for regeneration than previously realized. In the context of vascular biology, circulating endothelial progenitor cells (EPCs) in animal models and humans have been identified. EPCs have the potential to incorporate into vascular endothelium in adult tissues, although little is understood about the molecular signals controlling this process. Intriguingly, the number of circulating EPCs appears to correlate inversely with established risk factors for atherosclerotic vascular disease, and is enhanced by treatment with statins. Moreover, the number of EPCs correlates better with vascular reactivity than did a cumulative index of established risk factors, leading to the hypothesis that reduced EPCs may be mechanistically connected to abnormal vasoreactivity because of a role in ongoing vascular renewal. Although intriguing, this hypothesis remains largely speculative and such correlative findings could simply reflect common underlying pathophysiology. Thus, although much is unknown about the biology of EPCs, it is possible that they play an important role in vascular homeostasis and could influence atherogenesis. Further characterizing this role and exploring the therapeutic potential of these observations is the focus of intense investigation.

MOLECULAR SIGNALS

Adhesion Molecules Based on the discussion earlier, it is understandable that many investigators have explored the mechanisms responsible for recruitment of leukocytes into the vessel wall. Findings have delineated a multistep sequence of events. Leukocyte-endothelial interaction often begins with a relatively weak adhesive interaction manifested as leukocyte rolling. This rolling is largely mediated by the selectin family of adhesion molecules, which appear capable of rapid and reversible, though relatively weak, interactions with their counter-ligands. Conversion of leukocyte rolling to arrest and firm adhesion is likely a critical step in recruitment. The chemokine family of cytokines (discussed earlier) plays an important role in this conversion. Firm adhesion appears mediated predominantly by leukocyte integrins binding to endothelial adherence receptors of the immunoglobulin family, such as ICAM-1 and VCAM-1. Firm adhesion can then be followed by diapedesis and the cascade of pro-atherogenic events previously described. Studies combining atherosclerosis-prone mouse strains (e.g., ApoE$^{-/-}$) and genetically engineered deficiency or mutation of specific adhesion molecules suggest important roles for VCAM-1 in atherosclerosis. Moreover, expression of VCAM-1 correlates well with recognized local and systemic risk factors for atherogenesis (Fig. 14-3). An effect of ICAM-1 ablation has also been noted, though appears less dramatic and consistent. Some studies suggest that P-selectin may individually play a larger role than E-selectin in atherosclerosis but work with doubly deficient mice suggests the two molecules likely act in a coordinate manner contributing to disease progression.

Figure 14-3 Expression of VCAM-1 at sites of atherogenesis. In the left panel, the aorta of a hypercholesterolemic rabbit has been stained with Oil-Red-O to reveal characteristic sites of fat deposition and atherogenesis (darker) involving areas of disturbed flow including the aortic arch and intercostal branch points. In the right panel, an autoradiograph of the same aorta using radiolabeled antibody to rabbit vascular cell adhesion molecule-1 (VCAM-1) demonstrates that these areas of fat deposition and atherogenesis correlate well with surface VCAM-1 expression. (Courtesy of Dr. Myron Cybulsky, Department of Laboratory Medicine and Pathobiology, University of Toronto, Toronto General Research Institute, Toronto, Canada.)

Chemoattractant Cytokines In addition to cell surface expressed adhesion molecules, smaller secreted proteins also appear to play an important role in atherogenesis. The chemoattractant cytokines, called "chemokines," are proinflammatory cytokines postulated to contribute to the recruitment of specific mononuclear leukocyte subpopulations into atherosclerotic plaques. As noted, in addition to acting as chemoattractants, an important additional property of these molecules is their ability to convert leukocyte rolling under laminar flow conditions to arrest, a necessary prelude to diapedesis. Monocyte chemoattractant protein (MCP)-1 is a chemokine that acts specifically on monocytes and memory T cells, the two leukocyte populations most prevalent in atheroma. Expression of MCP-1 by vascular SMCs is induced in vitro by oxidized lipids. Furthermore, *in situ* studies show increased MCP-1 mRNA in vascular SMCs, mesenchymal intimal cells and macrophages in atherosclerotic lesions, as compared with normal vessels. These observational studies were substantially advanced by work in murine models demonstrating that ablation of MCP-1 or its receptor mitigated the development of atherosclerosis. Another compelling candidate

for a role in atherosclerosis signaling is the chemokine receptor CX3CR1, which is expressed on monocytes. Deletion of CXC3CR1 in atherosclerotic murine models severely retards atherogenesis, similar to deletion of MCP-1/CCR2. Equally compelling are data from three human studies, including the Framingham Heart Study, where there is a clear association of a common receptor variant with lower prevalence of atheroscerosis. Importantly, this mutation confers diminished monocyte adhesion in functional studies thus bolstering the epidemiological results.

Nuclear Factor-κB Most of the molecules previously discussed, including chemokines and adhesion molecules, are transcriptionally regulated under the control of the nuclear factor (NF)-κB family of transcription factors (p65 or RelA, p50, p52, BCl-3, c-Rel, and RelB). Interestingly, NF-κB is activated in the early stages of atheroma formation, as well as in advanced lesions. In addition, NF-κB also activates pro-coagulant (e.g., tissue factor) and proliferative targets (Cyclin D1) that could participate in atherogenesis. A striking correlation exists between modulation of local NF-κB-activation and atherosclerotic plaque formation. NF-κB activation in leukocytes from patients with unstable coronary syndromes has also been demonstrated. An intuitively appealing hypothesis is that NF-κB provides a critical master control point linking a variety of biological and mechanical stimuli to the expression of molecules demonstrated to play an important role in atherogenesis by regulating the transcription of these genes. This hypothesis raises the possibility that modulation of NF-κB could provide a therapeutic target in atherosclerosis. However, NF-κB-independent signaling pathways, such as p38 and JNK/SAPK, also appear important in endothelial activation. Moreover, NF-κB promotes a variety of potentially beneficial effects including endothelial survival, as well as expression of specific antioxidants. Finally, NF-κB signaling appears important in many different disease processes from fighting infection to cancer. Thus, the full ramifications of NF-κB signaling are complex, and given that a direct requirement for NF-κB activation in atherogenesis has not been demonstrated, consideration of its therapeutic potential should proceed with caution.

Hemodynamic Forces Certain sites within the vasculature are more prone to develop atherosclerosis. They are often sites of disturbed flow such as vessel branch points. Hemodynamic forces induce various functional changes in vascular endothelium, including morphological changes and alterations in the production of important product such as coagulation factors, fibrinolytic factors, growth factors, and cytokines. One mechanism linking hemodynamic forces and endothelial gene expression likely involves a *cis*-acting DNA element called the shear stress response element (SSRE) found in the promoters of several pathophysiologically relevant genes, including PDGF-A and ICAM-1. The SSRE is a functional NF-κB binding site in vascular endothelial cells under these conditions. This SSRE may represent a common pathway by which mechanical forces influence gene expression. Other adhesion molecules such as VCAM-1 or E-selectin, whose promoters lack this motif, are not upregulated under these conditions. Identification of the molecular basis of VCAM-1 upregulation under more complex hemodynamic conditions may provide insights into the differential regulation of these genes and their role in atherogenesis.

Nitric Oxide and Atherosclerosis Nitric oxide (NO) is produced by three major isoforms of nitric oxide synthase (NOS) and plays a critical role in many physiological processes. In arteries, NO produced by endothelial NOS (eNOS) is a critical determinant of vascular tone. In addition, NO may inhibit atherogenesis through other effects including inhibition of SMC proliferation, platelet aggregation, and leukocyte activation, adhesion, and emigration. NO donors inhibit NF-κB activation, although potentiation of NF-κB-dependent genes has not been seen in mice lacking eNOS.

In a variety of disease states including human and experimental atherosclerosis, effective eNOS activity is reduced, a condition often termed "endothelial dysfunction," which typically develops before advanced anatomic lesions. Multiple mechanisms likely contribute to reduced eNOS activity in atherosclerosis, including relative deficiency of substrate (L-arginine) or cofactor (tetrahydrobiopterin or BH4), decreased eNOS activity and/or protein, enhanced degradation of NO, and increased endogenous inhibitor levels. In human atheroma, there is markedly decreased luminal endothelial eNOS expression, but increased expression in endothelial cells of the vasa vasorum. Endothelial dysfunction (reduced NO) occurs in $ApoE^{-/-}$ and $LDLR^{-/-}$ mice. Interestingly, NOS can produce not only NO but superoxide (O_2^-), which may enhance atherogenesis through increased oxidative stress and inactivation of NO. O_2^- production by eNOS appears primarily regulated by tetrahydrobiopterin levels and signaling through the Lox-1 receptor. Perhaps for these reasons, O_2^- production is increased in hypercholesterolemia and may contribute to endothelial dysfunction in atherosclerotic $ApoE^{-/-}$ mice. However, mice that are doubly deficient for eNOS and ApoE develop substantially more aggressive atherosclerosis, as well as aneurysms. Overall, these studies suggest NO production plays an important modulatory role in atherogenesis. It seems plausible that genetic variations in components in this pathway may well contribute to predisposition (or resistance) to atherosclerosis in humans and may represent therapeutic targets, though these concepts remain to be validated.

FUTURE DIRECTIONS

Further genetic analysis of atherosclerosis as a complex trait will be imperative. Such studies should provide substantial insight into the significant proportion of clinical coronary risk that remains unattributable. Improved assessment of genetic risk for atherosclerosis would focus and facilitate efforts at primary prevention and intervention. Ultimately, the identification of the relative contribution of specific genes will also improve the understanding of the fundamental biology of atherogenesis.

Although germline manipulation of mice has already provided important information, future studies employing high-throughput, unbiased genomic, or proteomic screens for important modulatory pathways could greatly increase the yield of this approach. The development of models recapitulating not only atherogenesis but plaque instability would also provide an important foundation for addressing this clinically important issue. The anatomic degree of stenosis is a poor predictor of biological behavior. Identification of markers of plaque instability and the ability to measure or image these in vivo would greatly improve the management of patients with CAD. Thus, although substantial advances in the understanding of atherogenesis have occurred, it remains to translate most of these to application in the clinical arena.

15 Lipid Metabolism and Coronary Artery Disease

MASON W. FREEMAN

SUMMARY

The treatment of patients with lipid disorders constitutes one of the most common interventions in adult medical practice and remains the centerpiece of strategies aimed at reducing the incidence of coronary heart disease. This chapter examines lipoproteins, the genetic basis of lipid disorders, such as monogenic low-density lipoproteins disorders and monogenic high-density lipoproteins disorders, and the management of coronary heart disease with sections about risk assessment as a guide to selection of therapy and the dietary and drug treatment of lipid disorders.

Key Words: Chylomicrons; coronary heart disease (CHD); high-density lipoproteins (HDL); intermediate-density lipoproteins (IDL); lipid disorders; low-density lipoproteins (LDL); very low-density lipoproteins (VLDL).

INTRODUCTION

The relationship between alterations in serum lipoprotein levels and heart disease risk was recognized more than 50 yr ago. Since then, remarkable expansion has occurred in the knowledge of the genetics, molecular, and cellular biology, and physiology of the lipoprotein metabolism system, leading to large-scale clinical trials of lipid-lowering drugs to test their efficacy in preventing acute coronary syndromes. The value of this approach has been repeatedly affirmed. As a result, the treatment of patients with lipid disorders constitutes one of the most common interventions in adult medical practice and remains the centerpiece of strategies aimed at reducing the incidence of coronary heart disease (CHD).

LIPOPROTEINS

To circulate in the aqueous environment of the blood, highly hydrophobic lipids, such as cholesterol ester and triglyceride, must be packaged so they can be transported from sites of synthesis to sites of utilization. The lipoprotein structure solves this packaging problem by complexing the neutral lipids with both proteins and more polar lipids, such as unesterified cholesterol and phospholipids. The more hydrophobic lipid is sequestered on the inside of the spherical lipoprotein, whereas more polar lipids and proteins decorate the outer surface (Fig. 15-1). The protein components of the lipoproteins, known as apoproteins, play structural and functional roles in the metabolism of lipoprotein particles. They determine the specificity of receptor interactions by lipoproteins and also affect their regulation by enzymes involved in lipid transfer or degradation processes. Mutations in the genes encoding apoproteins are rare, but they can have a profound influence on the circulating levels of lipoproteins and, consequently, on the risk of developing cardiovascular disease.

Lipoprotein particles were originally classified using density gradient separation by ultracentrifugation. In the 1960s and 1970s, attention was focused on the electrophoretic properties of lipoproteins, giving rise to alternative names such as α- and β-lipoproteins, referring to the migration of those particles in an electrophoretic field. Since then, however, the fields have reunified and the older density nomenclature has been retained. Although lipoproteins form a continuous spectrum of density within the plasma, they can be divided into five major classes: chylomicrons, very low-density lipoproteins (VLDL), intermediate-density lipoproteins (IDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL) (*see* Fig. 15-1). Further subdivisions of these major lipoprotein classes have been proposed, especially of HDL, but, these additional complexities have not been widely assimilated in clinical practice. The least dense of the lipoproteins are also the largest in size and the most triglyceride-rich, the chylomicrons and VLDL. IDL contain substantial amounts of triglyceride and cholesterol, whereas the LDL and HDL are predominantly cholesterol-carrying particles.

CHYLOMICRONS Chylomicrons derive from dietary fat and carry triglycerides throughout the body. They have the lowest density of all lipoproteins and will float to the top of a plasma specimen refrigerated overnight. The chylomicron itself is probably not atherogenic, but the atherosclerotic role of the triglyceride-depleted chylomicron remnant remains controversial. Triglyceride makes up most of the chylomicron and is removed by the action of an enzyme that is bound to the surface of endothelial cells, lipoprotein lipase. Patients deficient in this enzyme or its cofactors (insulin and apo C-II) have very high serum triglyceride levels and are at increased risk of acute pancreatitis.

VERY LOW-DENSITY LIPOPROTEINS VLDL are also triglyceride-rich and are acted on by lipoprotein lipase. Their function is to carry triglycerides synthesized in the liver and intestines to capillary beds in adipose tissue and muscle, where they are

Lipoprotein	Density (g/mL)	Sources
Chylomicrons	< 0.98	Intestine
VLDL (Very Low-Density Lipoprotein)	0.98-1.006	Liver
IDL (Intermediate-Density Lipoprotein)	1.006-1.019	Catabolism of VLDL
LDL (Low-Density Lipoprotein)	1.019-1.063	Catabolism of IDL
HDL (High-Density Lipoprotein)	1.063-1.21	Liver, intestine, other

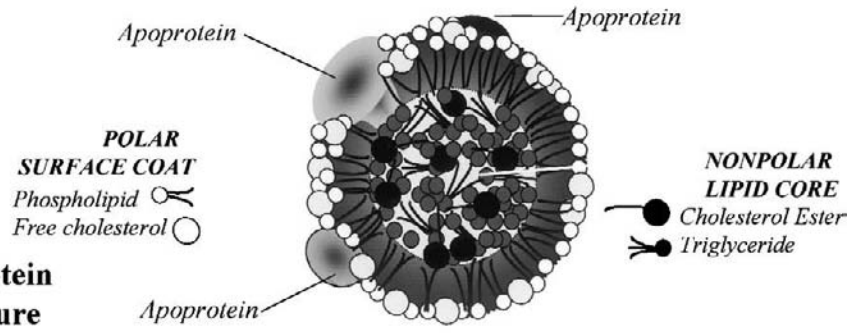

Figure 15-1 Lipoprotein classification and structure. Plasma lipoproteins can be divided into five density classes. The lightest density (chylmicrons and VLDL) are the most triglyceride-rich. LDL and HDL are cholesterol-rich. The general structure of a lipoprotein is shown in the lower half of the figure. More hydrophobic lipids are packaged on the inside of the lipoprotein whereas more polar lipids and the protein constituents are on the outside, where they can interact with the aqueous environments of blood and interstitial fluid.

hydrolyzed. After removal of their triglyceride, VLDL remnants (called IDL) can be further metabolized to LDL. VLDL serve as acceptors of cholesterol transferred from HDL, accounting in part for the inverse relation between HDL cholesterol and VLDL triglyceride. This transfer process is mediated by an enzyme called cholesterol ester transfer protein.

LOW-DENSITY LIPOPROTEINS LDL are the major carriers of cholesterol in humans, responsible for supplying cholesterol to tissues with the highest sterol demands. LDL are also the lipoproteins most clearly implicated in causing atherogenic plaque formation. Circulating LDL levels can be increased in persons who consume large amounts of saturated fat and/or cholesterol. LDL levels are also elevated in those who have genetic defects that affect LDL receptor function (familial hypercholesterolemia [FH] and autosomal-recessive hypercholesterolemia [ARH]), the structure of LDL's apoprotein, apolipoprotein B-100 or who have polygenic disorders affecting LDL metabolism. When serum LDL exceed a threshold concentration, they traverse the endothelial wall and can become trapped in the arterial intima, where they may undergo oxidation or other biochemical modification, be taken up by macrophages, and stimulate atherogenesis. The association of total serum cholesterol with CHD is predominantly a reflection of the role of LDL.

HIGH-DENSITY LIPOPROTEINS HDL are believed to function to protect tissues from the unwanted accumulation of cholesterol. They participate in a reverse cholesterol transport pathway in which peripheral tissues efflux cholesterol back to lipid-poor forms of HDL for return to the liver (Fig. 15-2). There, cholesterol can be secreted into the bile. The unesterified cholesterol from tissues that is transferred to HDL is esterified by the action of lecithin cholesterol acyl transferase (LCAT) and stored in the central core of HDL. This esterified cholesterol can be transferred back to lower density lipoproteins by the action of cholesterol ester transfer protein or it may be removed at the liver by the action of a plasma membrane receptor called scavenger receptor B-1. A particularly effective reverse transport system is thought to explain, at least in part, why elevated HDL levels are associated with a reduced risk of developing CHD. Apolipoprotein (apo)-A-I is the major apoprotein of HDL, and its serum concentration also correlates inversely with the risk of CHD. Women have higher levels of HDL cholesterol than men and this may partly explain the lower incidence of CHD in premenopausal women. Exercise increases HDL levels, whereas obesity, hypertriglyceridemia, and smoking lower them.

CLINICAL FEATURES

In most individuals, alterations in serum lipoproteins produce no clinical manifestations until an atherosclerotic vascular event supervenes (e.g., a myocardial infarct, stroke, or peripheral vascular occlusion). Individuals with extremely elevated levels of serum triglycerides, because of VLDL, or chylomicron accumulation, or both, can develop pancreatitis. Such patients may first come to clinical attention because of an episode of pancreatitis or because their plasma is noted to be milky in appearance when routine blood tests are performed. Individuals with such marked triglyceride elevations (typically plasma triglyceride levels >1000 mg/dL) can also develop eruptive xanthomas, accumulations of lipid in the skin (Fig. 15-3). Individuals whose LDL levels are significantly elevated can also develop xanthomas, though these are typically located in either the Achilles tendon or extensor tendons of the hands. Individuals with accumulations of IDL can also develop xanthomas, which are classically of the tubero-eruptive or palmar type. Xanthelasmas, seen in individuals with elevated serum cholesterol levels, can often be detected in older individuals whose lipid levels are not dramatically increased. Individuals with some of the rare HDL disorders can

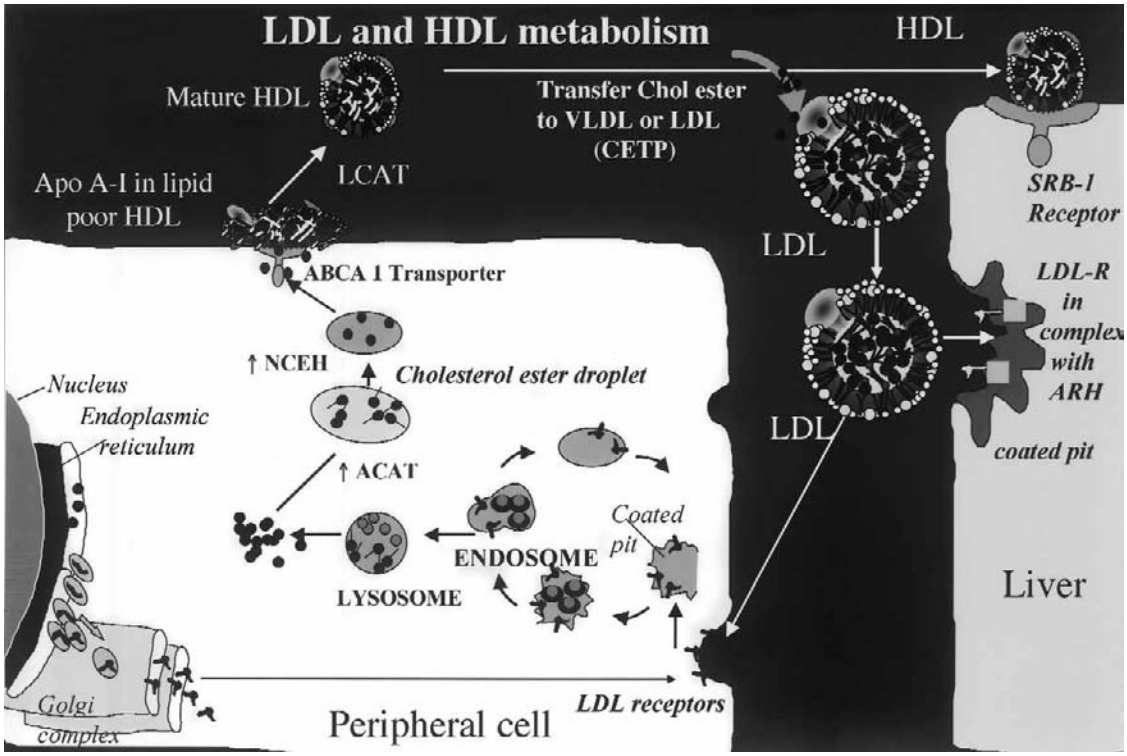

Figure 15-2 LDL and HDL metabolism. A schematized model of HDL and LDL metabolism. Cholesterol in a peripheral tissue cell, such as a macrophage, is initially stored in the cell as cholesterol ester. When stimulated by a lipid-poor HDL apoprotein A-I, the cell hydrolyzes the fatty acid from the cholesterol ester and the unesterified cholesterol is transported to the cell membrane. The action of the ABCA1 transporter results in the transfer of the free cholesterol to the apoprotein. Once bound to the apoprotein, the cholesterol is re-esterified by the action of LCAT creating the spherical HDL lipoprotein via storage of cholesterol ester in the core of the lipoprotein. HDL can then either donate this lipid back to LDL particles it encounters in the blood or travel to the liver in which its cholesterol ester content can be selectively removed by the action of scavenger receptor B-1. The cholesterol can be stored in the liver, reused for new lipoprotein synthesis, or excreted in the bile. Cholesterol that is transferred to LDL can be sent back to the periphery or the liver, in which LDL receptors bind and endocytose the particle. The action of the ARH gene product is important for LDL receptor activity in the liver. LDL originally derived from VLDL is secreted by the liver in a process not depicted in this slide.

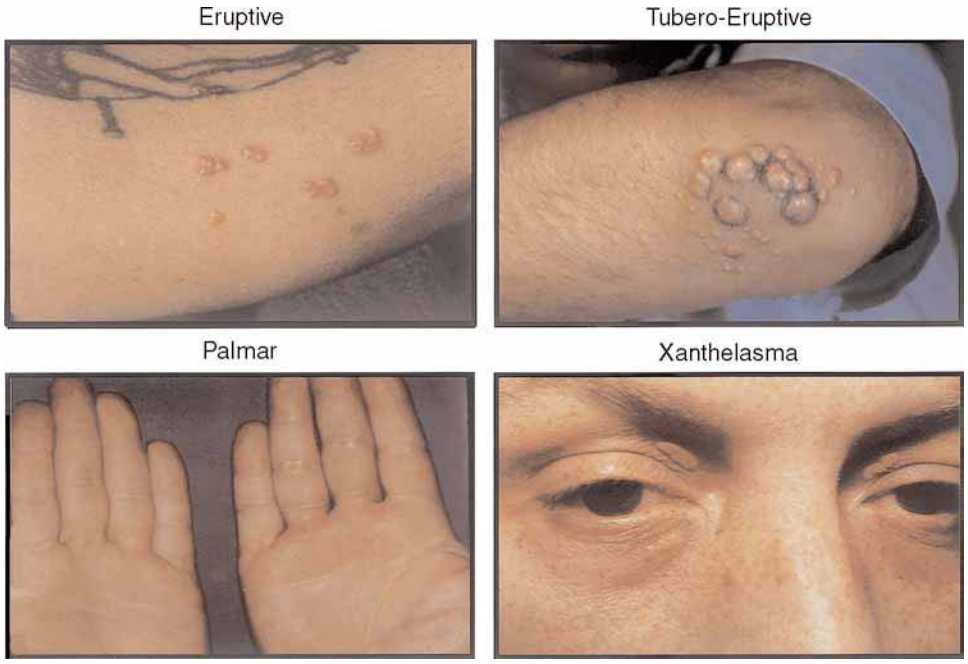

Figure 15-3 Xanthomas. Several different types of xanthomas are shown. The palmar and tubero-eruptive xanthomas are classically seen in patients with increased concentrations of IDL whereas the eruptive xanthomas are typically found in patients with massive serum triglyceride elevations resulting from excess chylomicrons and/or VLDL. (Please *see* color insert.)

present with corneal opacities, tendon xanthomas (deposits typically embedded in extensor tendons), or a peripheral neuropathy. Rarely, a lipid abnormality may be detected because of abnormal liver function tests caused by steatosis of the liver or by lipid accumulation in the eye (corneal arcus). With regular measurement of lipids in adults, standard practice in the United States, lipid disorders are most commonly detected by routine laboratory screening tests.

DIAGNOSIS

The diagnosis of a lipid disorder should be based on more than one measurement of serum lipids, because combined analytic and biologic variations in serum lipids range from 10 to 20%. The technology for measuring LDL levels directly has improved steadily, but in most laboratories, it remains a calculated value. To perform this calculation, the total and HDL cholesterol levels as well as the triglyceride value are measured. The LDL cholesterol concentration is then estimated using the following formula:

$$\text{LDL cholesterol} = \text{total cholesterol} - [\text{HDL cholesterol} + \text{triglyceride}/5]$$

The triglyceride/5 factor represents an estimate of VLDL cholesterol. The validity of this formula for estimating LDL cholesterol has been confirmed by ultracentrifugal measurement of lipoprotein levels and remains reasonably accurate as long as the total triglyceride is less than 400 mg/dL. To obtain an accurate calculation, patients must fast for at least 12 h to clear their blood of any chylomicrons, as these lipoproteins distort the triglyceride ratio on which the formula relies. If the triglyceride level is greater than 400 mg/dL, the LDL cholesterol must be determined by alternative methods. Apo B-100, present in both LDL and VLDL, can be measured directly to get an assessment of lower density lipoprotein particle numbers, but this is not routine in the United States. With increasing evidence for a greater atherogenicity of smaller, denser LDL particles, more sophisticated assessments of LDL number, and composition are being introduced into clinical practice in some regions of the world. Their place in the routine diagnostic evaluation of most patients remains controversial.

Before embarking on a treatment plan, conditions must be excluded that could cause hyperlipidemia secondarily. The most common clinical conditions that influence lipids levels are obesity, diabetes, and hypothyroidism. The latter two are best screened using a serum glucose (or Hgb A1-c) measurement and a thyrotropin stimulating hormone level, respectively. Many medications commonly cause a secondary hyperlipidemia, with antiretroviral therapy, estrogens, and glucocorticoids heading the list.

In the mid-1960s, a classifications scheme for lipid disorders was devised based on the phenotype of lipoprotein abnormalities. Because a better understanding of the genetics of these disorders has emerged that classification is rarely used. However, no unified classification of comparable simplicity has replaced it. Instead, the National Cholesterol Education Program (NCEP), Adult Treatment Panel III has promulgated a set of guidelines that are primarily aimed at targeting therapy in patients with elevated LDL levels or decreased HDL values. Table 15-1 summarizes the LDL-based treatment guidelines. Although the NCEP treatment targets for HDL and serum triglycerides are not as detailed as those for LDL values, HDL levels >40 mg/dL in men and 50 mg/dL in women are considered normal as is a serum triglyceride value <150 mg/dL.

Table 15-1
NCEP ATP III Treatment Guidelines

Risk factors	*LDL treatment threshold*	*LDL treatment goal*
<2 risk factors	>190	<160
>2 risk factors	>160	<130
10-yr risk <20%	10-yr risk <10% >130	
CHD or equivalent 10-yr risk >20%	10-yr risk 10–20% >130[a]	<100[a]

[a]LDL between 100 and 129 is good, but not optimal.
LDL, low density lipoprotein; CHD, coronary heart disease.

GENETIC BASIS OF LIPID DISORDERS

Of the variety of genetic disorders of lipid metabolism, many do not primarily affect CHD risk and are not discussed here. The most important lipid disorders affecting coronary disease risk are those that increase the serum LDL level or reduce the HDL level. The most severely affected individuals often have a single gene defect responsible for their lipid disorder. Most hyperlipidemic patients, however, do not have a monogenic defect. Rather, they are most likely to have a polygenic disorder with a variable contribution from environmental factors (e.g., excessive saturated fat intake for high LDL levels; obesity or smoking for lower HDL levels). The application of the NCEP treatment guidelines does not require that a genetic diagnosis be made, as treatment is based on phenotype (lipid levels) and not genotype. Nevertheless, the identification of the causes of monogenic lipid disorders has been critical to the understanding of normal lipoprotein physiology. Several examples of monogenic LDL and HDL disorders illustrate key concepts in that understanding.

MONOGENIC LDL DISORDERS The molecular basis of four monogenic disorders that primarily affect LDL levels has been characterized: FH, familial defective B (FDB), autosomal-recessive hypercholesterolemia (ARH) and PCSK9 mutations. As these disorders illustrate distinct mechanisms leading to elevated LDL levels, three of them will be described in greater detail.

Familial Hypercholesterolemia FH is one of the most thoroughly studied and common genetic disorders; approx 1 in 500 individuals carry a mutation in one allele encoding the LDL receptor. These mutations results in defective clearance of LDL from the blood and a rise in serum total and LDL cholesterol levels. The elucidation of this defect and its associated cell biology led to insights into the homeostatic control of cholesterol metabolism that transformed the lipid field. Several hundred individual mutations in the LDL receptor have been identified. The gene, located on chromosome 19 and spanning 45 kb, has 18 exons that encode a mature protein of 839 amino acids. The inheritance of the disorder is autosomal-codominant. Heterozygous patients have LDL cholesterol levels in the 200–500 mg/dL range and the rare homozygous FH patient typically has an LDL cholesterol >500 mg/dL. Heterozygous patients commonly have tendon xanthomas and premature coronary artery disease, whereas these are universal in the untreated homozygous individual. Mutations in the LDL receptor have been described that affect multiple aspects of receptor biology, ranging from defective LDL binding to abnormal trafficking of the receptor to the plasma membrane. The effect of all of these mutations is to reduce LDL and IDL clearance from the blood, resulting in an enhanced conversion of IDL to LDL. The net result is markedly elevated LDL cholesterol levels in the plasma and a strong predisposition to early CHD if the disorder is not treated. FH heterozygotes typically respond well

to 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG CoA) reductase inhibitors (statins), though additional therapies may be needed to reach desirable LDL levels. FH homozygotes respond poorly to reductase inhibitors and inevitably develop early atherosclerotic vascular disease if LDL apheresis or liver transplantation is not performed.

Familial Defective Apo B FDB is an autosomal-codominant disorder caused by mutations near the carboxy terminus of apo B. apo B is a 4536 amino acid protein encoded by a gene on chromosome 2 that consists of 29 exons. The most commonly identified mutations in FDB affect an arginine at position 3500 that is either mutated to a glutamine or tryptophan. As most individuals with FDB are heterozygous for their mutation, and there is only one molecule of apo B per LDL particle, the LDL in the serum of these individuals is a mixture of normal LDL and FDB LDL. The LDL containing the defective apo B does not bind normally to the LDL receptor and is therefore cleared more slowly. The explanation for the lower receptor affinity of LDL carrying the FDB mutations is not known with certainty. There is evidence, however, of a molecular interaction between the arginine at 3500 and tryptophan at position 4369 that appears to be necessary for the adoption of an apo B conformation recognized by the LDL receptor. Patients with FDB have elevations in their LDL levels that fall within the range of those seen in FH heterozygotes, but the mean is generally lower than the mean in FH cohorts. There is considerable variability in both genetic populations, however, making generalizations about the diagnostic value of this measurement not very useful. Tendon xanthomas are common but not universal, and premature coronary artery disease is prevalent. Treatment with reductase inhibitors or other standard LDL lowering drugs is typically effective in FDB patients.

Autosomal-Recessive Hypercholesterolemia Studies of families in which LDL levels were inherited in an autosomal-recessive pattern led to a successful genetic linkage analysis that mapped the genetic defect in these families to the short arm of chromosome 1. Candidate gene sequencing led to the identification of mutations in a gene, designated ARH, comprising nine exons and eight introns. Patients diagnosed with ARH have been clinically similar to patients who are homozygous for LDL receptor mutations in that they have markedly elevated LDL cholesterol levels (typically >500 mg/dL), tendon xanthomas, and premature coronary atherosclerosis. The autosomal-recessive mode of inheritance is an important differentiating factor between ARH and FH, as is greater LDL receptor activity, measured in cultured fibroblasts taken from the patients. The defect in ARH patients appears to affect liver cholesterol metabolism disproportionately, and data indicate that the ARH gene product likely serves as an adaptor protein required for LDL receptor internalization via clathrin-coated pits. ARH patients do respond to HMG CoA reductase inhibitors, but this treatment is usually inadequate to control their markedly elevated LDL cholesterol levels, making them candidates for LDL apheresis.

MONOGENIC HDL DISORDERS Three distinct monogenic disorders that cause markedly reduced levels of HDL in the plasma by different mechanism are Tangier disease, LCAT deficiency, and apo A-I mutations.

Tangier Disease Tangier disease was first recognized in 1960 in a sibling pair living on Tangier Island in the Chesapeake Bay in Virginia. The dyad of enlarged, yellow-orange tonsils and little or no circulating HDL cholesterol are the classic findings. Cases have been identified in which the presenting symptom was a peripheral neuropathy. Patients may also have hepatosplenomegaly. Serum LDL and total cholesterol levels are usually low, whereas serum triglyceride values are moderately elevated. Tangier disease is an autosomal-recessive disorder. The cause of Tangier disease was identified by several groups following mapping of the gene defect to chromosome 9. Candidate gene analysis in the appropriate genetic interval identified mutations in an ABC transporter as the cause. The transporter, called ATP binding cassette transporter A1 (ABCA1) is a full-sized ATP-binding cassette-containing protein that is predicted to span the plasma membrane 12 times (Fig. 15-4). ABCA1 is a 2261 amino acid protein encoded by a gene spanning 50 exons. Approx 50 mutations have been identified in the gene. ABCA1 mediates the efflux of cholesterol from cholesterol-enriched cells when stimulated by the major apoprotein of HDL, apo A-I (*see* Fig. 15-2). This activity is lost in Tangier patients and is reduced by approximately half in carriers of one abnormal ABCA1 allele. The mechanism of the movement of cholesterol from inside the cell to outside the cell has not been established. Individuals with Tangier disease and heterozygous carriers of ABCA1 mutations (a disorder called familial hypoalphalipoproteinemia) both appear to have increased risk of premature coronary disease. There is no specific therapy for this disorder.

Lecithin Cholesterol Acyltransferase Deficiency The esterification of free cholesterol in circulating lipoproteins is catalyzed by a plasma enzyme called LCAT. Two clinically separable syndromes result from a deficiency of LCAT. Fish eye disease is from a partial deficiency of LCAT, with patients presenting with dense corneal opacities and very low HDL cholesterol levels. Familial LCAT deficiency arises from a nearly complete absence of LCAT activity and produces a more severe syndrome characterized by corneal opacities, anemia, and proteinuric renal failure. The serum lipid and lipoprotein profile in the more severe disorder is characterized by normal or increased triglyceride levels, reduced LDL cholesterol values, and markedly diminished HDL levels. The gene encoding LCAT is located on chromosome 16 and consists of six exons. Cleavage of a signal peptide of 24 amino acids converts the pro-enzyme from a 440 amino acid precursor to the final 416 amino acid glycoprotein that circulates in the plasma. When unesterified cholesterol from tissues is transferred to HDL by passive diffusion or by ABCA1 mediated lipid transport, LCAT's activity esterifies the transferred cholesterol, trapping it in the HDL core (*see* Fig. 15-2). As cholesterol ester is more hydrophobic than unesterified cholesterol, it is energetically unfavorable for the cholesterol ester to transfer back to the cell of origin. These steps of cholesterol transfer and esterification are the initial events in the reverse cholesterol transport pathway whereby cholesterol is moved from peripheral tissues back to the liver. Apo A-I is the major activator of LCAT activity, accounting for the predominant effect of the enzyme deficiency on HDL levels. LCAT does, however, contribute to the esterification of cholesterol in lower density lipoproteins as well. Despite very low HDL levels, patients with either fish eye disease or familial LCAT deficiency do not seem to have a predilection for early coronary atherosclerosis. The small number of patients with the disease, some of whom have been found to have CHD, make it difficult to determine if the risk of coronary atherosclerosis is substantially altered by the enzyme deficiency. There is no specific treatment for LCAT deficiency. Corneal and kidney transplantation are performed in these patients to ameliorate their major clinical disabilities.

Apo A-I Mutations Apo A-I is the major structural protein of HDL. The gene encoding apo A-I is located on chromosome 11 and comprises four exons. Following cleavage of the signal and

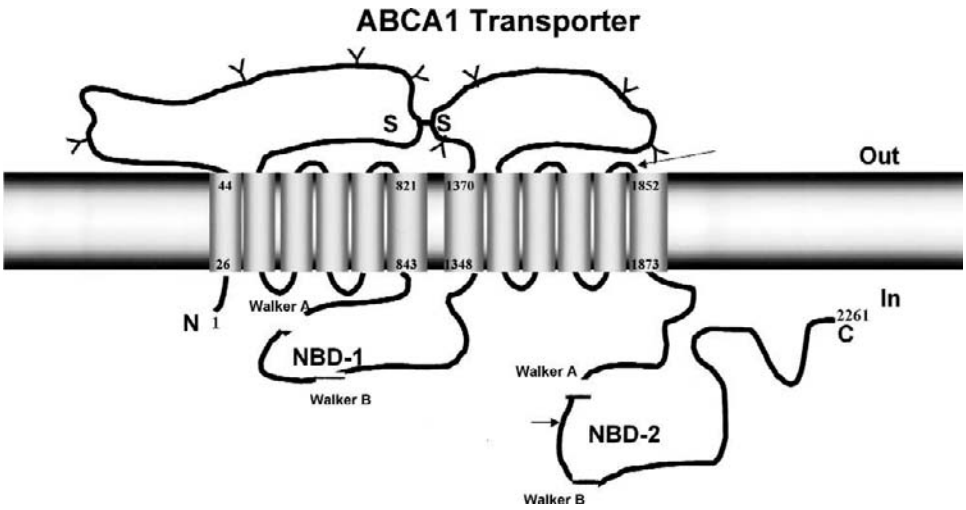

Figure 15-4 The ABCA1 transporter. The ABCA1 transporter is a full-sized 12-membrane spanning ATP-binding cassette protein. It is genetically altered in patients with Tangier disease, resulting in decreased cholesterol efflux from cells in response to apo stimulation. The ABCA1 transporter has two large loops positioned outside of the cell and the defining sequences of an ABC protein (Walker motifs in the nucleotide binding domains [NBD]) inside the cell. Approximately 50 mutations have been identified in the ABCA1 transporter, with most occurring either in the two large extracellular loops or in the NBD regions. The transporter has 2261 amino acids and the numbers on the graph indicate the approximate amino acid residue at each of the positions indicated.

prohormone sequences, a 243 amino acid mature protein is produced. The protein has multiple repeats of an amphipathic helical structure that enables it to interact with both lipid and aqueous environments. Mutations that cause profound alterations in apo A-I structure or expression have been reported, though they are extremely rare. Individuals carrying these mutations have virtually no circulating HDL and develop early CHD. Corneal opacities and xanthomas have been documented in many of these individuals. Most patients harboring these mutations are homozygous for the gene defect, usually as a result of consanguinity. Heterozygotes carrying these mutations commonly have half-normal HDL cholesterol levels, although cases with greater reductions in HDL levels have been reported, suggesting that some mutations may exert a dominant negative effect. As HDL typically contain four apo A molecules per particle (either four apo A-I or two A-I and two apo A-II proteins), a heterozygous individual carrying an expressed apo A-I mutant would have at least one mutant apo A-I on most HDL particles. The atherosclerosis of individuals with structural mutations in apo A-I appears to be more pronounced than that seen in the LCAT deficiency or Tangier disease patients. No specific therapy is available for this disorder, but aggressive LDL lipid-lowering therapy is justified.

SUMMARY OF GENETIC DISORDERS The six LDL and HDL disorders described are illustrative of molecular genetic defects that contribute to abnormal lipid metabolism. These defects include the production of dysfunctional lipid uptake receptors (LDL receptor), post-receptor adaptor proteins (ARH), or lipid efflux transporters (Tangier disease and ABCA1); generation of abnormal apos that either lower (apo A-I mutations) or raise (FDB) lipoprotein levels; and synthesis of nonactive lipid modifying enzymes (LCAT). Many other monogenic disorders in lipid metabolism are due to mutations that affect proteins that fall into one of these classes.

MANAGEMENT

Aside from the rare patient at risk for hypertriglyceridemic pancreatitis, the goal for most hyperlipidemic patients is to reduce the risk of coronary morbidity and mortality. The approach to treatment of hyperlipidemia outlined by the NCEP ATP III treatment panel is guided by an assessment of total CHD risk, not solely the lipid abnormality. For a given degree of LDL cholesterol elevation, the threshold for initiation of therapy decreases and the intensity of therapy increases with increasing CHD risk. Dietary modification, complemented by exercise and weight reduction, are combined with appropriate pharmacological therapy, when needed, to achieve the targets identified in the guidelines.

RISK ASSESSMENT AS A GUIDE TO SELECTION OF THERAPY With benefit from treatment of hypercholesterolemia linked to the degree of pretreatment CHD risk, an assessment of that risk is imperative before deciding whom to treat, when to treat, and how aggressively to treat. The CHD risk assessment should be a comprehensive one, extending beyond lipid levels to include consideration of blood pressure, smoking, diabetes, family history of premature CHD, age, sex, and presence of established CHD or other atherosclerotic disease.

Treatment recommendations follow directly from the degree of estimated CHD risk. Dietary modification is the sole mode of therapy for patients at the lower end of the CHD risk spectrum, whereas pharmacologic measures are reserved for patients at higher risk or for those who fail dietary intervention. Studies showing benefits from HMG CoA reductase inhibitors in patients with LDL cholesterol levels less than 130 mg/dL may shift pharmacological treatment targets further downward.

DIETARY AND DRUG TREATMENT OF LIPID DISORDERS Reductions in total fat, saturated fat, partially hydrogenated unsaturated fatty acids, and dietary cholesterol are recommended for adults with elevated LDL cholesterol levels. Not only is it important to reduce total fat in the diet, but perhaps more critical is substituting foods that provide polyunsaturated and monounsaturated fats for those rich in saturated and trans-saturated fat. For patients with VLDL elevations, carbohydrate intake and alcohol use may be more important dietary factors to address than the cholesterol or saturated fat ingestion.

Weight loss (if obese), aerobic exercise, and smoking cessation can increase HDL and contribute to the dietary lowering of lower

density lipoproteins and CHD risk. They also reduce CHD risk by decreasing blood pressure and glucose intolerance. When drug therapy is added to a lifestyle program, clinical trials have demonstrated significant reductions in the rate of atherosclerotic plaque progression, modest plaque regression, and declines in nonfatal and fatal cardiac events. In several studies, overall mortality has also been reduced.

HMG-Coa Reductase Inhibitors (The Statins) Statins have become the first-line drug therapy for treatment of elevated LDL levels because of their effectiveness, patient acceptability, clinical outcomes data, and favorable safety record. They block the rate-limiting enzyme in cholesterol synthesis, HMG-CoA reductase. Serum LDL levels fall by 20–60%, depending on dose and preparation. HDL levels generally stay the same or increase slightly on statins. Statins also influence thrombotic and inflammatory mechanisms, effects whose importance remains to be elucidated.

Myalgias, with or without creatine kinase elevations, are the most common side effect of the class. Asymptomatic hepatocellular dysfunction manifested by an increase in serum levels of transaminases occur in approx 1% of patients taking the medications. Statins available in the United States and Canada are lovastatin, simvastatin, pravastatin, fluvastatin, atorvastatin, and rosuvastatin.

Niacin Niacin is a B vitamin that must be used in megadoses to lower lipids. The precise mechanism of action is unknown, although a receptor for niacin was recently identified. Niacin, at doses of 1000 mg and higher, typically lowers LDL and VLDL levels, and raises HDL levels. It is the most effective HDL cholesterol-raising drug available. There are sufficient clinical trial data using niacin to conclude it is an effective anti-atherosclerotic agent, though there are no long-term, randomized prospective clinical trials establishing an overall mortality benefit with its use. Niacin's principal disadvantages include a litany of side effects, reflecting the large doses required. Niacin can exacerbate gout and diabetes, elevate liver enzymes, and produce rashes, nausea, and vomiting. It also triggers acute vasodilation that can result in flushing and even postural lightheadedness. Pretreatment with aspirin mitigates this reaction. Niacin is available in prescription and nonprescription formulations.

Cholesterol Absorption Inhibitors Cholesterol absorption inhibitors block intestinal cholesterol absorption. The bulk agents (cholestyramine, colestipol, and colsevelam) interfere with micellar solubilization of cholesterol, whereas ezetimibe blocks an intracellular cholesterol transport pathway. LDL cholestrol reduction is typically 15–20% with these agents. Gastrointestinal side effects such as constipation, bloating, heartburn, and nausea are the major drawbacks to the use of the bulk agents. They are commonly used as an adjunct to statin therapy to achieve greater LDL reductions, or when statins are not tolerated.

Fibrates (Gemfibrozil and Fenofibrate) These agents work by activating the peroxisome proliferation-activating receptor-α nuclear transcription factor, which decreases VLDL synthesis and enhances VLDL clearance. Thus, these drugs are primarily effective in the treatment of elevated triglyceride levels. They can be used in combination with statins to treat patients with combined VLDL and LDL disorders, but this therapy is associated with an increased likelihood of serious muscle breakdown leading to rhabdomyolytic renal failure. Side effects are rare but include abdominal discomfort.

CONCLUSION

Better understanding of the physiology and genetics of lipoprotein metabolism has resulted in better diagnostic and therapeutic interventions for patients with lipid disorders. Most patients with increased levels of LDL can be effectively treated with HMG CoA reductase inhibitors, either alone or in combination with niacin and/or cholesterol absorption inhibitors. Increased levels of VLDL are usually well managed by fibrate therapy, although weight loss and dietary changes are typically required to achieve optimal lipid targets. Disorders resulting in low HDL levels are still refractory to most interventions. Niacin therapy with moderate exercise can increase HDL values. Although this approach can lead to substantial rises in HDL levels, it is usually not effective in individuals who have a severe, monogenic disorder as the cause of their low HDL level. The growing understanding of the pathophysiology of atherosclerosis and progress in polygenic disorders is likely to lead to new therapies directed at nonlipid factors influencing CHD. Appropriate treatment of lipid disorders remains the cornerstone of any treatment program aimed at CHD prevention.

16 Hypertension

KHURSHED A. KATKI AND DONALD J. DIPETTE

SUMMARY

Human hypertension is a complex disease. With the generation of animal models and techniques like genomics and proteomics, therapies for monogenic forms of hypertension are available. Our knowledge of essential hypertension and its therapy is restricted by its polygenic nature and the compounding interaction between genes and the environment. However, successful forays into the genetics of human hypertension should result in early intervention and more clinically and cost-effective therapies limiting the complications of this disease. Development of molecular profiles for essential hypertension and drug response genes to individualize therapy will potentially revolutionize the diagnosis and treatment of hypertension and its associated target organ diseases.

Key Words: Animal models; genetics; pharmacogenomics; rennin–angiotensin; salt sensitivity.

INTRODUCTION

Hypertension is a complex, multifactorial condition defined by a consistently elevated arterial blood pressure. If untreated, hypertension leads to morbidity and mortality primarily secondary to heart disease (congestive heart failure, coronary artery disease, and left-ventricular hypertrophy), renal failure, or stroke. As with many disease states, the molecular etiology of hypertension could originate with one gene (monogenic) or several genes (polygenic). Few cases of hypertension in humans have been shown to be monogenic. Because essential hypertension (i.e., hypertension not caused by a secondary etiology such as renal artery stenosis) is likely a complex, polygenic disease, a major task of hypertension research has been to elucidate its genetic basis. Owing to the complexity of the task, investigators have used multiple genetic strategies in the basic science and clinical research settings. In addition, essential hypertension is a multifactorial state involving interactions between genetic, environmental, and demographic factors. Essential hypertension is likely to result from an elaborate interaction between a network of major and minor genes that mediate the pathophysiological process of elevating blood pressure. In addition, susceptibility genes that modify an individual's response to environment, age, sex, body mass index, and probably other unknown factors compound these genetic interactions. Multiple epistatic effects within and between the causative and susceptibility genes complicate this process. Thus, essential hypertension is a truly complex disease whose treatment and therapy depend not only on identifying candidate genes involved, but also on dissecting their interactions with other factors.

Advances in genomics and proteomics have provided powerful tools to study the genetics of multifactorial diseases like hypertension. However, with the exception of monogenic forms of hypertension such as familial hyperaldosteronism, Liddle's syndrome, and mutations in epithelial sodium channels (ENaC), little progress has been made in identifying the underlying genetics of essential hypertension. Thus, there is great difficulty in studying a pathophysiologically heterogeneous disease like hypertension that varies by renin status and sodium dependency, among other factors. This chapter focuses on some of the attempts to elucidate the underlying genetics and the molecular mechanism(s) that lead to the development and pathogenesis of hypertension.

ANIMAL MODELS USED TO STUDY THE GENETICS OF HYPERTENSION

Genetic animal models have been used to study the etiology of hypertension, mostly in the rat. Rats are used to study the genetics of hypertension because of their ease of handling and breeding and their low associated costs. However, because genetic manipulation is easier in the mouse than the rat, the use of the mouse model for hypertension research has increased. It is routinely possible to mutate, delete (knock-out), or add genes (knock-in) of interest in the mouse genome, and to couple these manipulations to the gain-or loss-of-structure and function. These strategies combined with newer methodologies to measure cardiovascular variables, especially in the mouse, have led to increased use of the mouse model to explore the genetics of hypertension.

IMPORTANCE AND USE OF RAT MODELS IN HYPERTENSION Genetic models of hypertension have been developed primarily in rats, but a number of species including dogs, rabbits, turkeys, and mice have been used. At least 18 genetic models of experimental hypertension exist in inbred rats (Table 16-1). The two most commonly studied strains of hypertensive rats are the spontaneously hypertensive rat (SHR) and the Dahl rats. The SHR and the stroke prone SHR are inbred strains that are mainly renin-independent. Both develop hypertension and target organ damage similar to that in human essential hypertension. The SHR is used to study the target organ complications of hypertension, to screen potential antihypertensive pharmacological agents and to investigate the genetics

Table 16-1
Genetic Models of Experimental Hypertension

Strain	*Sub-strain(s)*	*Name*	*Associated phenotype*	*Blood pressure QTLs*	*Representative candidate genes/loci studied*
CRDH		Cohen rosenthal diabetic hypertensive	NIDDM, high-blood pressure (176 ± 8 mmHg), fibrinoid necrosis in arteries and arterioles, smooth muscle, and vascular hyperplasia.	None	—
DSS/1		Dahl salt-sensitive	Sensitive to salt-induced hypertension	None	—
DSS/2		Dahl salt-sensitive	Sensitive to salt-induced hypertension	None	—
DSS/3		Dahl salt-sensitive	Sensitive to salt-induced hypertension	None	—
F344	F344/Crj F344/ NHsd F344/Pit	Fisher	Hypoxia-induced right-ventricular hypertrophy	Hypoxia-induced right-ventricular hypertrophy-1	Hirvh1
FH		Fawn hooded	Spontaneous hypertension. Altered serotonergic function, glomerular sclerosis and proteinuria	None	Genetic model of depression
FHH		Fawn hooded hypertensive	Systemic hypertension and proteinuria leading to premature renal failure and death.	Blood pressure QTLs 1, 2 and QTL cluster 14, 4255 SSLP markers	Bpfh1, Rf1, and Rf2
FHL/Eur		Fawn hooded low-blood pressure	Does not develop hypertension. Altered renal hemodynamics.	Blood pressure FH QTL2	Bpfh2, Rf3, Rf4, and Rf5
FHR		Fawn hooded hypertensive	Systemic hypertension and proteinuria, renal disease and hypertension under independent genetic control.		
GH		Genetically hypertensive rat	Inherited hypertension. Prevalence of cardiac hypertrophy and vascular disease. Levels of substance P in superior cervical ganglion, spinal cord, iris and trachea are twofold that of normal rats, and substance P containing sensory neurons are also elevated.	Blood pressure QTL7 on chromosome 6.	Renal α_2-adrenoreceptor
MHS		Milan hypertensive strain	High-blood pressure early in life, left-ventricular hypertrophy, renal atrophy, volume expansion and increased water intake, faster sodium transport	Blood Pressure QTLs on chromosomes 1,10,14, and 20	α-Adducin-1 gene, α_{1B}-adrenergic receptor, Na(+)/H(+) exchanger-3 gene.
SD-Tg (Ren2)27		Sprague-Dawley transgenic	Model for low-renin hypertension, susceptible to malignant hypertension, susceptible to cardio-vascular disease and cerebral haemorrhage.		Ren2 gene

Table 16-1 ***(Continued)***

Strain	*Sub-strain(s)*	*Name*	*Associated phenotype*	*Blood pressure QTLs*	*Representative candidate genes/loci studied*
SHR		Spontaneously hypertensive rat	Polygenic hypertension, cardiovascular disease, increased peripheral vascular resistance, cardiac hypertrophy, increased neurogenic tone; environmental and dietary factors influence the degree of hypertension.	Blood pressure QTLs on chromosomes 1-6, 8-10, 11, 13, 16, and 19.	Bp16–23
SHRSP		Stroke prone SHR	Higher blood pressure than SHR, stroke is affected by genetic and environmental factors, excessive salt intake, cerebral hemorrhage or infarction in 82% of 100 d-old males and 58 % of 150 d-old females	Blood pressure QTLs on chromosomes 1–5,10, 18, and X. Sensitivity to stroke QTLs on chromosomes 1, 4, and 5.	Str1–3, Bp1–4, Bp13–15, Bp28, and Bp49.
SR		Sprague-Dawley rapp	No effect of a high-salt diet on development of hypertension, mild hydronephrosis, mutant form of cytochrome P450.	None	
SR/Jr		Salt-resistant rapp	Same as above	Blood pressure QTLs on chromosomes 1,8, 9,10,13, and 18	Bp12,24,25,30, 34,39,41.
SS		Sprague-Dawley	Develop salt-sensitive and fulminant hypertension, vascular and renal lesions.	Blood pressure QTLs on chromosomes 8,13,15,18.	Angiotensin, dopamine-1 and endothelin-3
SS/Jr		Salt-sensitive rapp	Endothelium-independent myogenic activation of gracilis arteries.	Blood pressure QTLs on chromosomes 1–3, 5,7,8–10,13,16–18	Angiotensin converting enzyme 1
WF		Wistar furth	Low-blood pressure, resistant to adrenal regeneration hypertension	None	Mammary carcinoma susceptibility genes 1–4

Bp, blood pressure; Bpfh, blood pressure fawn-hooded; FH, fawn hooded; Hirvh1, hypoxia-induced right-ventricular hypertrophy-1 gene; NIDDM, noninsulin-dependent diabetes mellitus; QTL, quantitative trait loci; Rf, renal failure; SHR, spontaneously hypertensive rat; Str, stroke.

potentially involved in high-blood pressure. At least three gene loci are thought to be involved in the earlier-mentioned process, one of which might be in close association with the *angiotensinogen* (*AGT*) gene. A similar multiple gene interaction is thought to be involved in human essential hypertension.

Genome wide scans using these models of hypertension are powerful tools yielding quantitative trait loci (QTL) on almost every rat chromosome. Whereas blood pressure QTLs have been confirmed on rat chromosomes 1, 2, 10, and 13, they have been suggested on each of the other rat chromosomes except chromosomes 6, 11, and 15. The use of consomic, congenic, and subcongenic rat strains have confirmed the above loci. Consomic strains incorporate a full chromosome of one strain onto a genetic background of a contrasting strain. Congenic strains incorporate only a part of the chromosome including the full length QTL segment of interest. Subcongenics incorporate only part of the QTL, the so-called region of interest. Consomic and congenic strains are constructed to confirm the physiological and phenotypic significance of a QTL, whereas subcongenic strains facilitate the progressive decrease in the QTL span to enable eventual detection of the "gene of interest" within that chromosomal region. A technique called marker-assisted selection has accelerated greatly congenic strain construction, because the progeny in the first backcross generation are expected to have a 50% genome-wide heterozygosity. However, heterozygosity among individual progeny follows a normal distribution with a mean of 50%. The marker-assisted selection strategy uses this normal distribution of heterozygosity to accelerate the production of congenic strains.

THE MOUSE AS A MODEL OF HYPERTENSION

Polygenic diseases like hypertension can be studied by two basic approaches: a phenotype-driven approach and a genotype-driven approach. In the former, using the phenotype of hypertension, the genes responsible for the phenotype are determined. This approach has the added potential to facilitate the discovery of unknown genes. Studies have revealed 10 QTLs on nine different chromosomes associated with blood pressure. Six different QTLs have been associated with salt-induced hypertension. These studies utilized a backcross between salt-sensitive C57BL/6J and salt-resistant A/J inbred mice fed 1% saline for 2 wk. Two of the three loci were found to affect hypertension by interacting with each other. Another major QTL was found on chromosome 15 by crossing BALB/cJ and CBA/CaJ. These results suggest that mapping QTLs in rodent models might guide the search for human blood pressure genes.

In the genotype-driven approach, a known gene is studied in an attempt to discover its function in the regulation of blood pressure commonly using transgenic techniques to overexpress a gene or, with the use of homologous recombination, to create a knockout or nonfunctional gene. Some studies highlighting the usefulness of the knockout technique to study blood pressure regulation are discussed later.

Evidence suggests that renal and nervous system mechanisms are responsible for some forms of hypertension. Some of the complex systems involved in blood pressure regulation such as the sympathetic nervous-catecholamine system, the renin–angiotensin system, the kallikrein–kinin system, the nitric oxide system, the prostaglandin system and the vasopressin system have been well studied. Several neuropeptides that are colocalized and released with norepinephrine or other neuropeptides are known to modulate blood pressure; the vasoconstrictor neuropeptide Y and the vasodilators calcitonin gene-related peptide (CGRP) and substance P (SP) are some of the best-studied examples. Knock-out mice devoid of the calcitonin/α-CGRP peptide or the neurokinin-1 receptor, the SP receptor, have provided valuable insight into the role that these neuropeptides play in blood pressure regulation. α-CGRP is responsible for approx 30% of basal coronary blood flow. The deoxycorticosterone-salt model of hypertension shows that deletion of the α-CGRP gene leads to a greater elevation in blood pressure and renders the heart and kidney more vulnerable to hypertension-induced end-organ damage. In addition, the deletion of the α-CGRP gene in the renal reduced-mass model of hypertension leads to an augmented role for SP to attenuate the elevated blood pressure. The increasing use of mutagenesis to construct new mouse models has been the latest molecular tool employed in an effort to study the various interactions of the genes involved in hypertension. The mutagenic agent *N*-ethyl-N-nitrosourea has been used in the large-scale generation of mutant mice. As new mouse models for hypertension are either generated or characterized, and as newer tools for genetic research in mouse models are developed, the understanding of human hypertension and the ability to treat, prevent, or cure it will increase accordingly.

HUMAN HYPERTENSION

Hypertension accounts for 6% of adult deaths worldwide although wide variability exists in the global occurrence. In the United States, the prevalence of hypertension is highest in the southeast. Various determinants of geographic variation in hypertension have been quantified, including obesity, fat and sodium intake, genetics, environment, and ancestry especially among African Americans. Data from the Third National Health and Nutrition Examination Survey show that in the United States the overall prevalence of hypertension is about 24% in persons 18 yr or older. Hypertension is slightly more common in men (24.7%) than women (23.4%), whereas the age-adjusted prevalence of hypertension was higher in non-Hispanic African Americans than non-Hispanic Caucasians and Mexican Americans (32.4, 23.3, and 22.6%, respectively). Hypertension is 8.5 times more prevalent in African Americans and is associated with a higher risk of target-organ damage than in Caucasians. In the past two decades, the level of awareness among Americans of their hypertensive condition has risen, although only slightly. Data from the Third National Health and Nutrition Examination Survey suggest that hypertension awareness was greatest among non-Hispanic African Americans (74%) and non-Hispanic Caucasians (70%) compared with Mexican Americans (54%).

Clinical trials have documented the benefits of lifestyle changes and appropriate pharmacological antihypertensive intervention in hypertension treatment. Among Hispanics, a rapidly growing heterogeneous ethnic group in the United States, there is a lower incidence of hypertension than that of the general population. Hypertension in Hispanics varies by gender and the country of origin; most data is limited to Hispanics of Mexican and Puerto Rican origin with limited data available on Cuban Americans.

GENETICS OF HUMAN HYPERTENSION

As mentioned, there is evidence of a genetic component of blood pressure levels and of several intermediate phenotypes associated with hypertension in humans. A common measure of familial aggregation of hypertension is the use of family history, which can also reveal undefined familial risk factors. Identifying families with a positive history of hypertension for genetic studies is of importance because these families should be more likely to have genes and behavioral habits that lead to hypertension. Gene–gene interaction as well as gene–environment interactions on blood pressure and the intermediate phenotypes controlling blood pressure can be studied in such families. Using linkage analysis, research suggests the presence of hypertensive genes at several locations over all the human chromosomes. Some of the consistent areas are the chromosomal arm 1q, 2p, 2q, 8p, 17q, and 18q. Other less consistent regions might still harbor important hypertension genes.

MONOGENIC FORMS OF HUMAN HYPERTENSION

Monogenic diseases are typically severe but rare with an allelic frequency of <1% in the population. They define new physiological paradigms and signaling pathways and help identify candidate genes that could play a more frequent role in polygenic diseases like essential hypertension, diabetes, and obesity. Some of the monogenic forms of hypertension include familial hyperaldosteronism, Liddle's syndrome, and mutations in ENaC. Aldosterone, the major circulating mineralocorticoid in humans, participates in blood volume regulation and sodium, and potassium hemostasis. It might also play a role in tissue fibrosis contributing to the target organ damage secondary to hypertension yet independent of the degree of blood pressure elevation. Familial forms of hyperaldosteronism include type I (glucocorticoid-remediable) and type II, which are discussed in the next section. Hyperaldosteronism is also seen in multiple endocrine neoplasia

(MEN). In 1966, the first cases of autosomal, type-I familial hyperaldosteronism, a dexamethasone-suppressible form of hyperaldosteronism, were reported. The genetic locus and mutation causing this disease have been identified. Aldosterone is synthesized exclusively in the zona glomerulosa of the adrenal gland in a series of six biosynthetic steps. The *CYP11B2* gene plays an important role in the synthesis of aldosterone; its product is capable of catalyzing three of the six steps in aldosterone synthesis: the 18-hydroxydehydrogenase, 18-hydroxylase, and the 1β-hydroxylase enzyme reactions. The *CYP11B2* gene is located on human chromosome 8q24.3-tel, in close proximity to the highly homologous *CYP11B1* gene whose protein product (1β-hydroxylase) catalyses the final step in cortisol synthesis. The defect in familial hyperaldosteronism type I involves a crossover of genetic material between the closely linked *CYP11B1* and *CYP11B2* genes. Fusion of the adrenocorticotropic hormone-responsive promoter of the former with the coding region of the latter, allows aldosterone synthesis to be controlled by adrenocorticotropic hormone, resulting in pathologically high levels of aldosterone and suppressibility of aldosterone to exogenous glucocorticoid administration. The lack of hypokalemia in many subjects with glucocorticoid-remediable aldosteronism has been related to a blunted aldosterone response to potassium. Primary aldosteronism is a disorder characterized by hypertension and in more severe forms hypokalemia, primarily because of an aldosterone-producing adrenocortical adenoma, removal of which led to some of the earliest cures of hypertension or to zona glomerulosa hyperplasia. Improved screening techniques, including a genetic screening test and the use of plasma aldosterone and plasma renin activity determinations, have led to this disease being recognized and treated with increasing accuracy and efficacy. The advent of laparoscopic adrenalectomy has greatly reduced the morbidity of surgical treatment of the adrenocortical adenoma form of this disease.

Hypertension is rarely (approx 0.05% of all hypertension) caused by a catecholamine secreting tumor or pheochromocytoma that is benign in most (approx 90%) of cases. Surgical resection cures approx 90% of cases, but if left undiagnosed or untreated, the tumor is invariably lethal causing cerebrovascular or cardiovascular complications from excess circulating catecholamines. Pheochromocytomas usually arise within the adrenal medulla, but develop occasionally in extra-adrenal sympathetic ganglia, sometimes also referred to as paragangliomas. Pheochromocytomas are also component features of some inherited cancer syndromes including MEN-2, von Hippel-Lindau syndrome (VHL), pheochromocytoma-paraganglioma syndrome and type 1 neurofibromatosis. Germline mutations in the VHL tumor suppressor gene cause VHL and germline mutations in the RET protooncogene cause MEN-2. Also, a subset of pheochromocytoma-only families segregates the germline VHL mutation but not the RET mutation. Germline mutations in three of the succinate dehydrogenase (mitochondrial complex II) subunits (SDHD, SDHB, and SDHC) cause susceptibility to head and neck paragangliomas. In addition, SDHD and SDHB mutations might cause susceptibility to familial and isolated pheochromocytoma with or without head and neck paragangliomas. The mechanisms by which succinate dehydrogenase subunit mutations predispose to pheochromocytoma have not been defined in detail but dysregulation of hypoxia-responsive genes and impairment of mitochondria-mediated apoptosis have been suggested. Another putative mechanism involved in the initiation of pheochromocytoma is the binding of the VHL protein with fibronectin. It has been suggested that VHL protein binds directly to fibronectin thereby preventing the promotion of the fibronectin matrix assembly.

Another important monogenic form of hypertension is Liddle's syndrome, a rare autosomal-dominant disorder characterized by early onset of hypertension, excessive sodium retention, low plasma renin activity, and usually hypokalemia. Plasma levels of aldosterone are undetectable and mineralocorticoid receptor antagonism by spironolactone has no effect on blood pressure or serum potassium. Treatment includes ameloride therapy, which blocks sodium-reabsorption and potassium excretion by mineralocorticoid independent mechanisms. The defect in Liddle's syndrome results from a constitutive activation of ameloride sensitive ENaC on distal renal tubules, which causes excess sodium reabsorption. This channel is made up of at least three subunits normally regulated by aldosterone. Mutations of the cytoplasmic C-terminus of either β- or γ-subunits of ENaC cause Liddle's syndrome and have been localized on human chromosome 16. These mutations, mapped mainly to a proline-rich domain that promotes internalization and degradation of the ENaC molecules, lead to an increased cell surface expression of the ENaC molecule, which therefore explains a constitutive reabsorption of sodium accompanied by an increase in blood pressure. A mouse model for Liddle's syndrome has been generated by Cre-loxP mediated recombination, which mimics to an extent the human form of salt-sensitive hypertension. Under a high salt intake, the homozygous mice develop high-blood pressure and hypokalemic metabolic alkalosis accompanied by cardiac and renal hypertrophy. Interestingly, like their wild type counterparts, both the homozygotes and the heterozygotes develop normally for the first 3 mo and have normal blood pressure, but already demonstrate increased sodium reabsorption in the distal colon and low plasma aldosterone, suggesting chronic hypervolemia. This model also establishes a causal relationship between dietary sodium intake, the expression of a gene in the kidney, and hypertension.

Sympathetic activation plays an important role in cardiovascular homeostasis. Regulation of cardiac and vascular function is mediated primarily or in part by β-adrenergic receptors. Stimulation of β-adrenoreceptors by catecholamines in disease states such as hypertension, congestive heart failure, and ischemic heart disease has many deleterious effects. Although three β-subtypes are known, and a fourth one is hypothesized, in the myocardium the predominant receptor subtypes are the β_1 and β_2. The long arm of human chromosome 5 contains a cluster of genes encoding the α_1- and β_2-adrenergic receptors and the dopamine receptor type 1A, all of which are involved in blood pressure regulation. The activation of β_1 and β_2 subtypes is linked to an increased cAMP formation (through interaction with stimulating guanine nucleotide binding protein) resulting in the activation of the cAMP-dependent protein kinase phosphorylation group of intracellular proteins that increase myocardial inotropy and chronotropy. β_2-adrenoreceptors play an important role in vascular function. Stimulation of β_2 receptors results in smooth muscle relaxation (i.e., vasodilation), which results in a reduction in systemic vascular resistance. Nonselective β-blockers (e.g., Propranolol) exert their antihypertensive effects mainly through cardiac and renal receptors. Second generation β-receptor antagonists such as metoprolol and atenolol, are β_1-selective and were developed in part to overcome the increased bronchoconstriction and peripheral vasoconstriction seen with β_2-blockade. Third generation β-blockers like labetolol

and carvedilol are nonselective for β_1 and β_2 but also function as α-receptor antagonists, which overcome the increase in peripheral resistance caused by β_2-blockade. An increasing body of evidence suggests that three common β_2-polymorphisms and two common β_1-polymorphisms might play a role in the pathophysiology of cardiovascular disease including hypertension. Genetic variants of the β_2-receptor that decrease receptor number or enhance β_2-receptor downregulation (Gly16 and Gln27, respectively) appear to influence vascular tone and, thus, vascular reactivity and hypertension risk. However, conflicting reports on the studies of β_2-receptor codons 16 and 27 exist with differences in genetic background and linkage disequilibrium as possible reasons. In addition, a "gain of function" variant of the β_1-receptor, namely the Arg389 variant, also increases adrenergic tone and thereby the risk of hypertension. However, data demonstrating a role for the β_2-variant Ile164 in the pathophysiology of cardiac disease might be more convincing. Animal models and in vitro studies demonstrate that this mutation results in a loss of the receptor function. In clinical studies this mutation has an adverse impact on heart failure survival. In contrast, the β_1-Gly49 variant improves survival in heart failure, although no animal or in vitro data documents the functionality of this variant. Despite the presence of data implicating various β-receptor mutations in both hypertension and heart failure, little is known about the impact of these variants on the effectiveness of β-receptor blockade. Genetic background studies, specifically on the inherited patterns of β-receptor mutations, might help delineate patient subsets in whom β-blockade might be effective or ineffective. Thus, the potential to use genetic background screening to determine the effectiveness of potential β-blocker therapy remains an area for further investigation. Therefore, monogenic forms of hypertension although rare, play an important role in blood pressure regulation, and if left untreated, invariably lead to hypertension and debilitating secondary effects like renal failure, stroke, and even death.

POLYGENIC HYPERTENSION Essential hypertension results from the interaction of hereditary, environmental and demographic factors. These factors contribute to blood pressure variation even within an individual. It has been suggested that genetic factors account for about 40% of variation in blood pressure in human populations. The full expression of hypertension, therefore, is determined by the interaction of the various genes with each other and the environment resulting in a variety of phenotypes. Hence, essential hypertension does not follow the classic Mendelian rules of dominant or recessive inheritance. Several genes have been associated with blood pressure in general and more specifically with essential hypertension. One of the most systematically studied systems and their genetic components include the rennin-angiotensin-aldosterone system.

RENIN–ANGIOTENSIN SYSTEM AND ITS LINK TO HYPERTENSION The juxtaglomerular cells in the kidney synthesize renin, a single chain polypeptide, in response to macula densa signals of lowered cytosolic calcium, decreased renal arteriolar pressure, or increased renal α- or β-adrenergic nerve activity. Renin serves as a circulating enzyme for its substrate angiotensinogen (AGT) in the plasma to form a decapeptide called angiotensin (Ang)-I. Ang-I is further catabolized to an octapeptide Ang-II by the angiotensin-converting enzyme (ACE), which is endothelin bound and present in high concentration in the lung. Ang-II is a circulating vasopressor with various other functions such as sodium and volume retention secondary to stimulation of aldosterone release from the adrenal glands. The *AGT* gene has the strongest evidence supporting its role in the development of human hypertension. Several studies in animals and humans support a link between *AGT* and hypertension. For example, in transgenic mice, the increased number of *AGT* alleles correlates directly to increasing blood pressure levels. Variants in the *AGT* gene generally correlate with higher circulating AGT levels, but there is no conclusive proof of the involvement of mutations of the *AGT* gene in the development of hypertension. Two well-known polymorphisms of the *AGT* gene, –6 A/G and the Thr235 alleles, are associated with hypertension in a variety of populations. Carriers of the A variant in the –6 position within the promoter region of the gene show a greater blood pressure response to sodium reduction, as do carriers of the Thr235 allele, which is also thought to be associated with the development of preeclampsia. Two main receptors of Ang-II, AT1 and AT2, have been defined with most known adverse effects of Ang-II being mediated via the former. Both AT1 and AT2 belong to the seven transmembrane class of G protein coupled receptor family. The genes for all the above peptides and enzymes have been investigated for their association to hypertension and salt sensitivity. There is also convincing evidence in humans linking the ACE locus to its plasma levels. However, the association of ACE variants to hypertension remains to be proved conclusively.

TYPE-II FAMILIAL HYPERALDOSTERONISM AND ITS ROLE IN HYPERTENSION As mentioned, familial hyperaldosteronism type II is characterized by an inheritance consistent with an autosomal-dominant pattern of autonomous aldosterone hypersecretion and is not suppressible by dexamethasone. Linkage analysis and direct mutation screening shows that this disorder is unrelated to genes for aldosterone synthase or the angiotensin II receptor but is polygenic in origin with a potential polymorphic locus on chromosome 7p22 region.

SALT SENSITIVITY AND HYPERTENSION The interaction between genetic variations and environmental factors such as salt intake (diet), stress, and physical activity can contribute to the development of essential hypertension. A genotype that responds to changes in its environment is broadly classified as sensitive whereas a phenotype that is not influenced by its environment is called insensitive. Various hemodynamic mechanisms regulate the heterogeneous relationship between salt and water intake and the resultant blood pressure levels within individuals, which can be broadly classified as salt-sensitive or salt-resistant. The rennin–angiotensin system plays a major role in sodium–water balance, which influences blood pressure. Hypertensive individuals with low plasma renin activity often exhibit a greater blood pressure response to sodium loading, and salt-sensitive hypertensive persons show a blunted rennin–angiotensin response when there is a shift from low to high sodium intake in the diet. Several genes in this system such as *AGT*, *ACE*, *AT1*-, and *AT2*- receptors have been investigated for their association with hypertension. A widely studied polymorphism of the ACE gene is the insertion/deletion in intron 16, with linkage evidence implicating the gene in hypertension risk. The I variant confers greater blood pressure increase associated with changes from low-salt to high-salt diet whereas the D variant is closely associated with microvascular and macrovascular sequelae of hypertension.

GENE POLYMORPHISMS AND PHARMACOGENOMICS IN HYPERTENSION Hypertensive persons are known to respond heterogeneously to antihypertensive drug therapy, probably reflecting factors such as differences in pharmacokinetic and

pharmacodynamic properties of antihypertensive agents and differences in genetic response to various drug therapies. Pharmacogenetics, the study of genetic variations influencing the response to pharmacological agents, is an emerging field that mainly studies the gene–environment interaction. Genetic polymorphisms influence pharmacodynamic mechanisms of antihypertensive drug response. However, because most inter-individual variation in response to antihypertensive therapy remains unexplained, this is not a practical and clinically useful guide to select antihypertensive agents. Consequently, identifying and studying candidate genes that influence the pharmacodynamic determinants of blood pressure and the usage of genome wide scanning is the priority. The candidate gene approach has been studied, specifically the α-adducin gene and the genes within the rennin–angiotensin system. α-adducin is a heterodimeric, cytoskeletal protein involved in signal transduction. A Gly/Trp change at amino acid 460 (Trp460) at the human α-adducin locus was more frequent in 477 hypertensive patients than in 332 normotensive control subjects. Subsequently, heterozygotic patients with the Gly460Trp variant were shown to have a greater blood pressure reduction in response to diuretic therapy than did Gly460 homozygotes. These findings demonstrate that α-adducin polymorphisms might be useful in identifying a subset of salt-sensitive hypertensive patients who are more responsive to diuretic therapy. Further, studies such as those investigating the α-adducin gene demonstrate genes contributing to hypertension via a particular physiological mechanism (namely, increased renal sodium reabsorption and volume expansion) might serve as candidates to influence blood pressure response to antihypertensive therapy. Because the rennin–angiotensin-aldosterone system is directly related to sodium and volume homeostasis, genes encoding components of this system have been logical candidates for investigation to predict the blood pressure response to changes in dietary sodium and diuretic therapy. Because sex-specific effects of the ACE insertion/deletion polymorphism are present and appear to be mediated separately from effects on plasma renin activity or the generation of Ang-II, it has been hypothesized that local intrarenal and intraadrenal effects of this ACE polymorphism may differ between men and women.

With the sequencing of the human genome complete, pharmacogenomic studies that measure variations at a single gene locus as well as polygenic loci will improve the ability to predict individuals' responses to antihypertensive therapy. Current genome-wide search strategies to identify QTLs linking the blood pressure response to antihypertensive therapy are limited because they depend on the measurement of microsatellite markers in related family members. However, single-nucleotide polymorphism (SNP) measurements, which can be determined by microarray technology, have the potential to enable the discovery of novel genes influencing drug response by comparing haplotype frequencies between correlated individuals showing opposite extremes of distribution responses. SNPs are positions in the genome at which two alternative nucleotides occur at an appreciable frequency (>1%). As the most abundant form of polymorphism in the human genome, SNPs are estimated to occur about once in every 1000 bp. Thus there are more than three million SNPs per human genome (which consists of 3×10^9 bp). Importantly, DNA chips, which are synthesized oligonucleotides attached to a glass surface, facilitate the rapid genotyping of large numbers of SNPs in a reasonable time frame and cost. Such chips are commercially available to assess known mutations in the human cytochrome *P450* genes encoding the CYP2D6 and CYP2C19 enzymes, for example, which are responsible for metabolizing many commonly prescribed antihypertensive drugs. The P450 enzymes are well characterized with >150 different isoforms identified as products of >30 different *P450* genes. Two notable variants are the CYP2D2 and *N*-acetyltransferase 2 variants. CYP2D2 mutations lead to excessive β-blockade of alprenolol, bufarolol, carvedilol, metoprolol, propranolol, and timolol presumably resulting from reduced metabolism of these blockers. Carriers of the "rapid accelerator" *N*-acetyltransferase 2 polymorphism require a higher dose of the vasodilator hydralazine to control blood pressure. Thus, genotyping of participants might allow tailoring of antihypertensive drug therapy. Such measurements are a necessary step toward studying the interaction between environmental factors such as age, diet and other medications that influence antihypertensive drug response. This ability to accurately identify pathophysiological subgroups and reliably predict the blood pressure response in individually tailored therapies will lead to fewer adverse reactions and ultimately lowered therapeutic costs.

Human hypertension is a complex disease. With the exception of monogenic forms of hypertension, knowledge of essential hypertension and its therapy is severely restricted because of its polygenic nature and the compounding interaction between genes and the environment. With the use of the latest molecular technology of generating animal models, the sequencing of the human, mouse, and rat genomes, as well as the onset of the era of proteomics and genomics, this challenge might be overcome. Successful forays into the genetics of human hypertension should result in early intervention and more clinically and cost effective therapies that will limit complications of this common disease. The challenge for research is to develop "molecular profiles" of essential hypertension and drug response genes in order to develop individualized drug therapy. Drugs that are more specific for the molecular characteristics of individual patients should contribute to greater efficacy and reduced toxicity. With genetic screening of hypertensive patients as a possibility, and the availability of newer molecular techniques, there is the potential to revolutionize the way hypertension and its associated target organ diseases are diagnosed and treated.

17 Cardiac Hypertrophy

THOMAS FORCE AND JEFFERY D. MOLKENTIN

SUMMARY

Pathological cardiac hypertrophy develops in response to stresses, and can be concentric, eccentric, or both. An excess pressure load placed on the heart, for example, resulting from uncorrected hypertension or valvular disease, results in concentric hypertrophy. This hypertrophy is initially believed to be adaptive, normalizing systolic wall stress, though it is not clear that hypertrophy is necessary to maintain systolic function in the face of moderately elevated pressure loads. Eccentric hypertrophy results most often from volume loads such as those in valvular insufficiency. Finally, the hypertrophy that occurs in the remote noninfarcted myocardium, as part of the remodeling process following a myocardial infarction, may be both concentric and eccentric.

Key Words: Cardiac hypertrophy; concentric; eccentric; mechanical deformation; mTOR; NFAT; protein synthesis; reprogramming.

INTRODUCTION

Cells that are terminally differentiated, by definition, cannot undergo hyperplastic growth. Rather, normal growth of these cells, which include cardiomyocytes, is hypertrophic. This form of hypertrophy, termed physiological hypertrophy, is both concentric (characterized by addition of sarcomeres in parallel, leading to increased width of the myocyte) and eccentric (characterized by the addition of sarcomeres in series, leading to increased length of the myocyte). Pathological cardiac hypertrophy develops in response to stresses, and can be concentric, eccentric, or both. An excess pressure load placed on the heart, for example, resulting from uncorrected hypertension or valvular disease, results in concentric hypertrophy. This hypertrophy is initially believed to be adaptive, normalizing systolic wall stress, though it is not clear that hypertrophy is necessary to maintain systolic function in the face of moderately elevated pressure loads. Eccentric hypertrophy results most often from volume loads such as those in valvular insufficiency. Finally, the hypertrophy that occurs in the remote noninfarcted myocardium, as part of the remodeling process following a myocardial infarction (MI), may be both concentric and eccentric.

If the load placed on the heart is not normalized (such as via effective antihypertensive therapy), the heart may continue to hypertrophy, eventually leading to elevated filling pressures and the so-called diastolic heart failure. The hypertrophied heart may also begin to decompensate, leading to progressive dilatation, systolic dysfunction, and heart failure on that basis. Not surprisingly, left-ventricular hypertrophy is a significant risk factor for the development of heart failure, increasing the risk of this end point by 6- to 17-fold. Furthermore, within 5 yr of the first detection of left-ventricular hypertrophy, one-third of men and one-fourth of women are dead, usually from cardiac disease.

Given the importance of hypertrophy as a cardiac risk factor, investigators have begun to identify the molecular pathways that regulate the cardiac hypertrophic response in an attempt to identify novel pharmacological targets of potential clinical relevance. The focus of these investigations has been on the cell surface receptors for agonists that are believed to trigger the hypertrophic response, such as receptors for angiotensin (Ang)-II, endothelin (ET)-1, and α- and β-adrenergic agents, and therapies directed at the Ang-II receptor have been effective in regressing hypertrophy and in reducing cardiovascular end points even in patients with diabetes. However, given the vast number of agents that have been reported to induce hypertrophy (*see* below), and the increasing evidence that hypertrophy is multifactorial in origin, focus has shifted to intracellular signaling pathways that may function as final common pathways necessary for the hypertrophic response, irrespective of the inciting stimuli. With the rapid advances in the development of small molecule inhibitors of components of these pathways that can be used in vivo, it is essential to understand the signaling networks that regulate hypertrophic growth.

The hypertrophic response requires a dramatic reprograming of gene expression to upregulate gene products necessary for the growth of the cardiomyocyte. These include genes encoding contractile elements and proteins of the basic transcriptional and translational machinery that allow new protein production), and genes that encode proteins that remodel the extracellular matrix (e.g., matrix metalloproteases), allowing growth to proceed. Reprograming of gene expression occurs in response to specific growth signals that are generated from a multitude of sources and include soluble factors (growth factors and neurohormonal mediators), or biomechanical forces (stretch of the myocyte induced, for example, by an acute MI or an acute pressure load). To reprogram gene expression, these signals must be sensed at the cardiomyocyte membrane, and transmitted into the interior of the

Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

cell, and eventually into the nucleus. This process is called signal transduction. This chapter introduces the field of signal transduction, specifically as it applies to hypertrophy of the heart, and describes how gene expression becomes reprogramed. Many growth factors trigger growth of cardiomyocytes, and an even larger number of signaling molecules mediate the growth response. The complexity of the field makes it impossible to cover all pathways involved in the hypertrophic response; two pathways are reviewed for which strong evidence exists implicating components of the pathway in both physiological and pathological hypertrophic responses: the calcineurin pathway and the phosphoinositide 3-kinase (PI3-K)/Akt pathway and its interactions with the mammalian target of rapamycin (mTOR) pathway, which has been implicated in cellular growth of a wide variety of species. In each case, the role of these pathways is evaluated in the rapidly growing field of mouse models of human disease. Finally, dysregulation of these pathways in the hearts of patients with advanced heart failure is reviewed, and potential targets for the treatment of heart failure are discussed.

STIMULI TRIGGERING THE HYPERTROPHIC RESPONSE

Two types of stimuli are thought to trigger the hypertrophic response, mechanical deformation of the membrane (cell stretch) and growth-promoting ligands binding to their cognate receptors in the myocyte cell membrane, though mechanical deformation activates ligand/receptor interactions as well.

MECHANICAL DEFORMATION Stretch of cardiomyocytes in culture leads to protein synthesis and a pattern of gene transcription that resembles the load-induced hypertrophic response in vivo. Stretch triggers these responses both via the direct activation of signaling molecules and by inducing the release of prohypertrophic agonists that appear to be of paramount importance in the maintenance of the response. The identity of the stretch "sensor" is not known. However, stretch may directly activate integrin signaling and stretch-activated ion channels, and either or both of these could be the sensor of membrane deformation. Heterotrimeric G proteins (Gq and Gi), which transduce signals from prohypertrophic factors released following stretch (*see* Humoral Factors), and possibly small G proteins, are activated so early after stretch that it is possible that these are also directly activated. One critical consequence of activation of these proximal mediators of the stretch response is an increase in cytosolic calcium concentration, necessary for activating calcineurin (discussed later). Only when the sensors are identified will the mechanisms be understood by which stretch activates cytosolic signaling pathways. In most biological response pathways, however, a stretch signal gradually accommodates so that the response is lost unless a new or greater stimulus is applied. Thus, additional factors are needed to maintain the response and to induce long-term hypertrophic growth, and these factors may be humoral.

HUMORAL FACTORS One of the central tenets of hypertrophic signaling is that membrane deformation induces the release of growth factors that act in an autocrine or paracrine fashion to amplify hypertrophic responses. Ang-II was reported to be released by stretched cardiomyocytes in culture, and autocrine/paracrine effects of Ang-II were reported to be, at least in part, responsible for the hypertrophic response of cardiomyocytes to cell stretch. Ang-II activates prohypertrophic signaling pathways via two mechanisms, one triggered directly by the receptor and its associated heterotrimeric G protein, Gq (*see* below), and the other triggered by transactivation of growth factor receptors with intrinsic tyrosine kinase activity, most notably the epidermal growth factor receptor. Ang-II induces a cytosolic calcium transient (and production of reactive oxygen species) that activates a metalloprotease that releases heparin-binding epidermal growth factor-like growth factor. This then binds to its receptor, activating additional signaling pathways not directly activated by the Ang-II receptor. A second group of prohypertrophic factors released by mechanical stretch are the IL-6 family of cytokines, including cardiotrophin-1.

The insulin-like growth factor (IGF)-1 axis, including growth hormone, which acts in large part via inducing production of IGF-1, is the dominant regulator of normal postnatal growth of the mammalian heart, but IGF-1 may also play a role in pathological hypertrophy. In pathological states, IGF-1 is released in response to a variety of stimuli that induce remodeling including pressure overload and following MI. IGF-1 signaling is also activated in the remodeled hearts of patients with advanced heart failure.

Many of the prohypertrophic peptides, including Ang-II, ET-1, and α-adrenergic agents bind to receptors that are linked to heterotrimeric G proteins (i.e., consists of three subunits, α, β, and γ) of the Gq family. These G proteins convert receptor activation into mobilization of intracellular signaling pathways, and are the initial trigger for downstream events. Overexpression specifically in the heart of the α-subunit of Gq (the subunit that activates most of the signaling pathways downstream of receptors coupled to Gq) or of an activated mutant of αq led to cardiac hypertrophy. Expressing a peptide that inhibited Gq-dependent signaling significantly limits the hypertrophic response to pressure overload in vivo. Conditional inactivation of the gene encoding the α-subunit of Gq (and the related G_{11}) blunts the hypertrophic response. These studies confirm a critical role for Gq in hypertrophic signaling and in the hypertrophic response to pressure overload, and also support a central role for Gq-coupled receptors and their ligands in this process.

INTRACELLULAR SIGNALING PATHWAYS

There are two essential features of hypertrophic growth: reprograming of gene expression and protein synthesis. Each is regulated by a series of intracellular pathways activated by events at the membrane as described above. Each component is considered separately, though they are inextricably intertwined.

REPROGRAMMING OF GENE EXPRESSION To hypertrophy, the cardiomyocyte must upregulate the expression of a number of genes including those encoding components of the sarcomere and more specific growth-related and stress-induced genes. Other genes are downregulated as part of the response. Characteristic of the response is a re-establishment of a gene program that is often described as "embryonic" or "fetal" because several of the re-expressed genes are normally expressed *in utero*, but expression declines rapidly after birth. The genes induced by the hypertrophic response are often divided into three groups based on their time of expression: immediate early, intermediate, and late. Immediate early genes include the neurohormonal mediator, brain natriuretic peptide, and several stress-induced genes or genes involved in growth control. These include c-fos, c-jun, c-myc, egr-1, and heat shock protein 70. Intermediate response genes include atrial natriuretic peptide, angiotensinogen, and several sarcomeric components, β-myosin heavy chain (β-MHC) (and corresponding downregulation of α-MHC), myosin light chain-2, and skeletal α-actin (replacing cardiac α-actin). Late response genes include angiotensin converting enzyme and the Na/Ca exchanger.

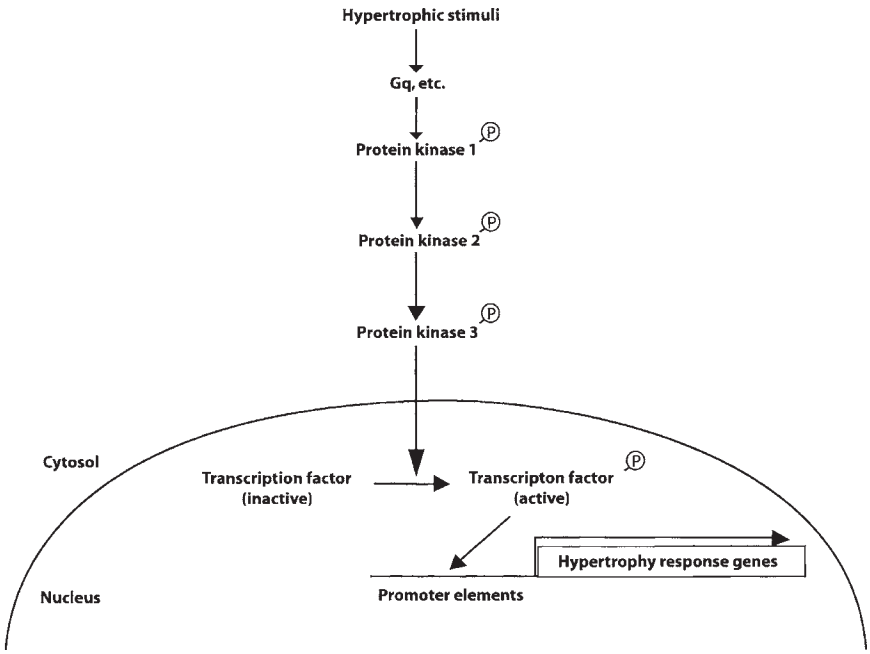

Figure 17-1 Schematic representation of a signal transduction pathway linking the cell surface receptor to nuclear events. Hypertrophic stimuli sensed at the membrane lead via a variety of signal transducers (e.g., Gq) to the activation of a protein kinase at the top of a multitiered cascade of protein kinases. This kinase phosphorylates kinase 2 in the cascade that in turn phosphorylates kinase 3. Kinase 3 then phosphorylates one or more transcription factors that bind to promoter elements in the regulatory regions of various "hypertrophic response genes" and activate gene expression. This multitiered cascade serves both to amplify the signal (one kinase molecule at each level activates many molecules at the next level) and to prevent the need for kinase 1 to translocate to the nucleus each time it is activated.

Reprograming of gene expression requires signal transmission from the cell membrane, in which the initiating stimulus is generated, to the nucleus. This is generally accomplished by linear cascades of proteins, most commonly protein kinases (but also the protein phosphatase calcineurin [*see* below]), phosphorylating and activating one another in sequence, culminating in the phosphorylation, and activation of one or more transcription factors (Fig. 17-1). The transcription factors then bind to promoter elements, specific DNA sequences, usually of approx 6–12 basepairs in length, within the promoters of genes. Thus each transcription factor usually targets several genes. The net result of the activation of the entire set of genes is the hypertrophic response. To illustrate how gene expression is reprogramed, the calcineurin-nuclear factor of activated T-cells (NFAT) signaling pathway, implicated as a key regulator of stress-induced hypertrophic growth, is used (Fig. 17-2). However, first the mouse models used to evaluate the role of signaling pathways in various disease states are reviewed and their advantages and disadvantages are examined.

Mouse Models of Cardiac Disease Two basic models are employed: transgenic models and so-called "knockouts." Transgenics generally express a gene of interest specifically in the heart by expressing it under the control of a promoter that is only active in cardiac myocytes. The most commonly employed promoter is the α-MHC promoter. Expression from this promoter is constitutive. The gene of interest can encode the normal gene, a constitutively active mutant of the gene (e.g., a protein kinase that does not require activation by an upstream regulator), or a dominant inhibitory mutant of the gene (such a protein kinase that cannot be activated, interferes with the normal functioning of the pathway by binding to and sequestering upstream activators and downstream targets of the normal kinase). A number of different pathways have been implicated in regulating the hypertrophic response. However, many of these studies relied exclusively on transgenic overexpression of a signaling molecule in the heart. Because the level of expression of the transgene is often many-fold higher than the level of the endogenous protein, producing nonphysiological levels of activation of normal downstream targets, caution in interpreting these studies is needed. In addition, gross overexpression of a transgene can lead to "cross talk" with other signaling pathways that are not normally regulated by that transgene. That said, many signaling pathways have fairly striking fidelity so that cross talk is often minimal and valuable information can be obtained using an overexpression approach. Transgenes have been expressed conditionally. That is, expression can be regulated by the investigator to occur at specific times. This approach may reduce the long-term adaptations that can occur with constitutive expression of a transgene.

The optimal proof of a role for a specific signaling factor in hypertrophic growth is that a specific molecule is sufficient to induce the hypertrophic response using a transgenic approach and that the molecule must also be demonstrated as necessary for the response. On rare occasions this can be accomplished with pharmacological inhibitors but usually it is done with strategies leading to deletion of a gene of interest (e.g., the complementary studies of the role of Gq in hypertrophic growth previously discussed). This is a much more difficult task because deleting a gene is technically much more demanding than creating a transgenic animal. In addition, the approach is often compounded by embryonic or neonatal lethality if the gene of interest serves essential functions in the organism. This problem has been addressed by an ingenious method (e.g., in the studies on Gq) employing transgenic (or adenovirus-mediated) expression of a viral protein, the Cre recombinase, expression of which can be induced at desired times in the life of the mouse. Cre then excises the target gene producing a so-called conditional knockout.

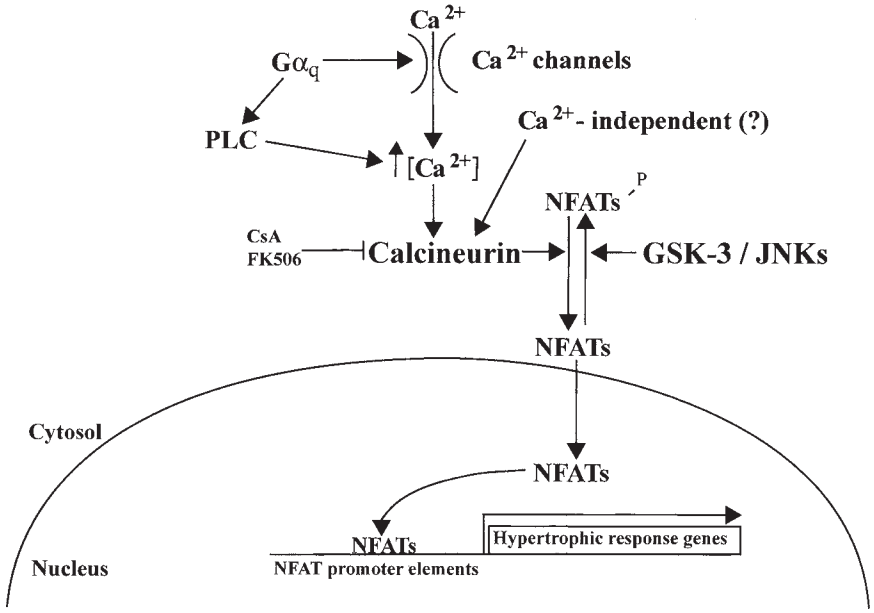

Figure 17-2 Schematic representation of the calcineurin/nuclear factor of activated T cells (NFAT) pathway. Diagram shows the possible sources of Ca^{2+} necessary for the activation of calcineurin and negative regulators of NFAT nuclear localization (GSK-3 and JNKs). The possible contribution of Ca^{2+}-independent inputs into calcineurin activation is also shown. *See* The Calcineurin-NFAT Signaling Pathway Reprograms Gene Expression for details.

Another problem with gene deletion strategies to study function of a gene is that many genes involved in hypertrophic signaling are members of multigene families and deletion of one is compensated for by the other family members. Crossing a mouse with one deleted gene with a second mouse with the other gene deleted can produce the desired knockout of all alleles within the family, but increases the likelihood of embryonic or neonatal lethality. Proving that a gene is necessary for a specific response, such as hypertrophy, remains an essential element in the evaluation of the role of a specific protein in that response.

The Calcineurin-NFAT Signaling Pathway Reprograms Gene Expression The calcineurin-NFAT pathway can serve to illustrate how gene expression is reprogramed. This pathway (Fig. 17-2) in a number of different models regulates hypertrophic growth. Calcineurin (also known as protein phosphatase 2B) is a calcium-calmodulin-activated protein phosphatase. It is uniquely activated by sustained elevations in intracellular calcium. Calcineurin specifically dephosphorylates proteins previously phosphorylated on serine or threonine residues. Calcineurin consists of a 59–63 kDa catalytic subunit referred to as calcineurin A, a 19 kDa calcium binding protein called calcineurin B, and the calcium binding protein calmodulin. Three mammalian calcineurin A catalytic genes have been identified (α, β, γ) that are highly homologous to one another. The calcineurin Aα and Aβ gene products are expressed in a ubiquitous pattern throughout the body, whereas calcineurin Aγ expression is more restricted.

Calcineurin catalytic activity is inhibited by the immunosuppressive drugs cyclosporine (Cs) A and FK506 through complexes with immunophilin protein. Thus, calcineurin plays a critical role in the regulation of T-cell reactivity and cytokine gene expression. Once activated, calcineurin directly dephosphorylates members of the NFAT family of transcription factors. When phosphorylated, NFATs are retained in the cytosol. Dephosphorylation by calcineurin exposes nuclear localization signals, promoting their translocation into the nucleus. Once in the nucleus, NFAT family members participate in the transcriptional induction of various immune response genes.

Calcineurin was identified as a hypertrophic signaling factor in the heart suggesting conservation in its function as a reactive signaling factor in multiple cell types. For example, overexpression of an activated form of calcineurin in the hearts of transgenic mice induced a profound hypertrophic response (two- to threefold increase in heart size) that rapidly progressed to dilated heart failure within 2–3 mo. These data demonstrated that calcineurin was sufficient to induce hypertrophy, and identified calcineurin as a potential causative factor associated with the transition to decompensation and heart failure. Investigation has focused on the evaluation of whether calcineurin is also necessary for the hypertrophic response to physiologically relevant stimuli. Hypertrophic agonists (e.g., phenylephrine, Ang-II, and ET-1) led to increased calcineurin enzymatic activity in cultured cardiomyocytes, and treatment of cultured neonatal cardiomyocytes with the calcineurin inhibitory agent CsA attenuated agonist-induced hypertrophy in vitro. Furthermore, calcineurin enzymatic activity and protein levels were upregulated in hearts from juvenile tropomodulin transgenic mice, a model of dilated heart failure. Similarly, increased cardiac calcineurin activity has been reported in hearts in which hypertrophy was induced by aortic banding, exercise, or salt feeding of salt-sensitive hypertensive rats. Other studies have examined the activity of calcineurin in samples from failing or hypertrophied human hearts. Analysis of hypertrophied human hearts or failing hearts because of ischemic or idiopathic dilated cardiomyopathy revealed a significant increase in calcineurin activity. Studies in patients with hypertrophic obstructive cardiomyopathy and aortic stenosis demonstrated a significant increase in cardiac calcineurin activity associated with a differentially processed form of the calcineurin catalytic subunit in the heart, presumably because of partial proteolysis. Collectively, these observations have demonstrated a link between cardiac hypertrophy and failure and the activation of a pivotal reactive signaling molecule in the heart, calcineurin.

Two approaches have been employed to determine whether calcineurin is necessary for the hypertrophic response in vivo, pharmacological inhibition with CsA or FK506 and gene targeting. Although CsA can attenuate agonist-induced cardiomyocyte hypertrophy in vitro, its effectiveness in vivo is somewhat more controversial, particularly when the hypertrophy is induced by pressure overload. Approximately 20 individual reports have shown that inhibition of calcineurin with either CsA or FK506 can antagonize cardiac hypertrophy and/or disease progression in a variety of rodent models. Thus, the majority of pharmacological animal studies support a role for calcineurin in the hypertrophic response, and the few negative accounts may reflect factors such as drug dosage, differences in the surgical preparations, sex, age, or type of animal model.

As with most pharmacological inhibitors, however, CsA and FK506 have targets other than calcineurin and inhibition of these targets, rather than calcineurin, could in theory account for the observed effects of the drugs on hypertrophy. To address the issue of specificity, targeted inhibition of calcineurin was achieved by creating a transgenic mouse overexpressing endogenous inhibitors of calcineurin. In one set of studies, the noncompetitive calcineurin inhibitory domains from the calcineurin interacting proteins, Cain/Cabin-1 and AKAP79, were expressed and in the other, muscle-enriched calcineurin inhibitory proteins MCIP1 and MCIP2 (DSCR1 and ZAKI-4) were expressed. Both models had reduced hypertrophy in response to pressure overload. In addition, transgenic mice expressing a dominant inhibitory mutant of calcineurin within the heart also demonstrated reduced cardiac hypertrophy to stress stimuli (aortic banding). Mice deleted for *calcineurinA*β were generated and had reduced cardiac calcineurin activity that was associated with an impaired hypertrophic response to Ang-II infusion, isoproterenol infusion, or abdominal aortic constriction. These data extend the transgenic approaches discussed, and more specifically implicate the *calcineurinA*β gene in regulating the hypertrophic response.

Calcineurin Targets Regulating the Hypertrophic Response The downstream transcriptional mechanisms whereby calcineurin might function in vivo remain largely uncharacterized. However, both NFAT and myocyte enhancer factor 2 transcriptional regulators are regulated by calcineurin (*see* Fig. 17-2), suggesting obvious candidates for genetic analysis in the heart. The NFAT family consists of five members, four of which (NFATc1-c4) are regulated by calcineurin. Calcineurin activation leads to dephosphorylation and nuclear translocation of NFATs where they activate gene expression. To identify the candidate downstream effectors of calcineurin that might mediate the hypertrophic response, *NFATc3* and *NFATc4* null mice were evaluated. Remarkably, *NFATc3* null mice, but not *NFATc4*, were determined to have impaired hypertrophy induced by activated calcineurin, abdominal aortic constriction, or Ang-II infusion. These data suggest that NFATc3 functions as a necessary transducer of calcineurin signaling in mediating the cardiac hypertrophic response. Collectively, analysis of multiple genetically-modified mouse models with altered calcineurin-NFAT signaling supports that calcineurin is an important regulator of the cardiac hypertrophic response. The calcineurin/NFAT pathway illustrates the paradigm of how a signal (increased cytosolic $[Ca^{2+}]$) generated in response to deformation of the membrane or to hypertrophic agonist binding to its receptor, activates one signaling factor (calcineurin), which then dephosphorylates and activates a transcription factor (NFATc3) that, in turn, translocates to the nucleus, reprograms gene expression and, in so doing, regulates hypertrophic responses.

REGULATION OF PROTEIN SYNTHESIS The second key component of hypertrophic growth is the ability to dramatically upregulate protein synthetic capabilities. This is regulated by two complex, interacting pathways: the mTOR pathway, and the PI3-K pathway that, in addition to its role in regulating protein synthesis, also functions in reprograming gene expression. These pathways are essential in determination of cell, organ, and body size (i.e., normal growth) in species as diverse as *Drosophila* and humans. The pathways are also recruited in, and regulate the response to, pathological stress-induced hypertrophic growth (Fig. 17-3). Both the mTOR and PI3-K pathways regulate protein synthesis by modulating the activity of various translation factors, either initiating factors (that initiate the translation of mRNAs into proteins) or elongation factors (responsible for elongation of the polypeptide chain).

The mTOR Pathway mTOR is a protein kinase whose importance is suggested by its conservation in structure and function, throughout evolution, from yeast to human. Rapamycin, a specific inhibitor of mTOR, attenuates the hypertrophic response to pressure overload in mice, demonstrating the importance of mTOR in regulating hypertrophic growth in vivo. Although mTOR is absolutely critical in the regulation of protein synthesis, and studies employing rapamycin have identified specific targets of mTOR that regulate protein synthesis, the mechanisms regulating mTOR activity remain ill-defined. In brief, mTOR is activated when amino acids and energy supplies are plentiful (*see* Fig. 17-3). Teleologically this makes sense because protein translation is an enormous consumer of cell energy, so translation proceeding at times of amino acid or energy deprivation is undesirable. In addition, growth factors, including those leading to cardiac growth such as insulin and IGF-1, also activate mTOR probably via activation of PI3-K signaling.

One of mTOR's major targets is a protein, 4E-binding protein 1, which binds to and inactivates the eukaryotic initiation factor (eIF) 4E, preventing the initiation of translation. When activated, mTOR leads to the phosphorylation of 4E-binding protein 1, causing it to dissociate from eIF4E, thus allowing translation to proceed (*see* Fig. 17-3). A second target activated by mTOR, acting in cooperation with the PI3-K pathway, is the p70S6 kinase that phosphorylates the S6 protein of the small ribosomal subunit. p70S6K may regulate the translation of a specific set of mRNAs, the so-called 5′-TOP (tract of pyrimidines) mRNAs that encode ribosomal proteins. In addition, it may regulate one of the elongation factors, eEF2. The importance of p70S6K in cell and organ growth is illustrated by the marked reduction in cell, organ, and body size in mice deleted for even one of the two p70S6K genes. Furthermore, p70S6K is activated by pressure overload, and it is likely that the ability of rapamycin to block pressure overload hypertrophy is, in part, because of the inhibition of p70S6K activation by rapamycin.

The PI3-K Pathway The PI3-K pathway is also highly conserved throughout evolution (*see* Fig. 17-3). This pathway is remarkable because virtually every component has been shown in animal models in vivo to regulate cell and organ growth, including growth of the heart. The pathway is activated by most (if not all) of the agonists implicated in inducing cardiac hypertrophy including pressure overload. When activated, the PI3-K phosphorylates

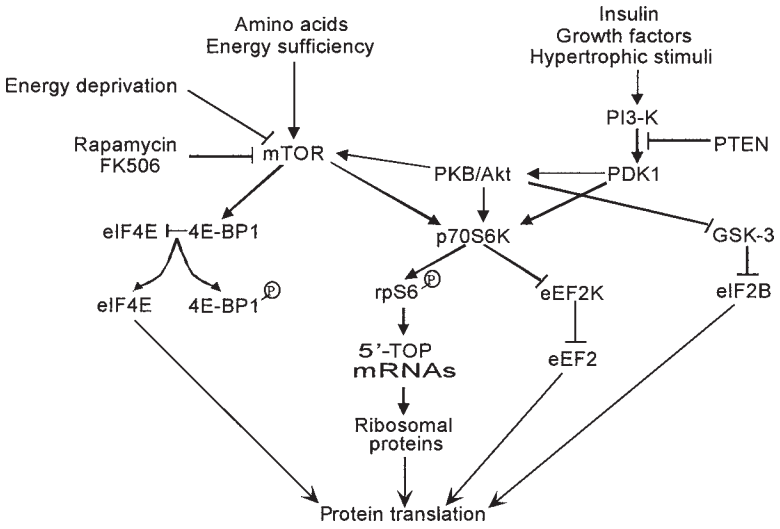

Figure 17-3 Schematic representation of the PI3-K and mTOR pathways. *See* the P13-K Pathway for details. rpS6, S6 ribosomal protein; eEF2K, the eukaryotic elongation factor 2 kinase that phosphorylates and inactivates eEF2 (eEF2K is inhibited by p70S6K).

the membrane phosholipid, phosphatidylinositol, at the 3′ position of the inositol ring, leading to the recruitment of the protein kinase, Akt (also known as protein kinase B [PKB]) to the cell membrane via interactions of a specific domain of PKB/Akt (the plekstrin homology domain) with the 3′-phosphorylated lipid. This brings PKB/Akt into proximity to its activator, the 3′-phosphoinositide-dependent protein kinase-1, which phosphorylates and activates PKB/Akt (in addition to the p70S6K discussed). PKB/Akt then plays a role in activating mTOR and, consequently, p70S6K and the protein translation machinery. Hence, it is probably not surprising that PI3-K, phosphoinositide-dependent protein kinase-1, and PKB/Akt all regulate cell and organ size, including size of the heart. One of the more striking cardiac-specific transgenic models is the mouse overexpressing PKB/Akt which has a markedly enlarged heart. Although activation of the translational machinery is probably an important mechanism driving the increased heart size in these mice, PKB/Akt also regulates transcription factors, either directly (e.g., members of the Forkhead family) or indirectly (via regulation of glycogen synthase kinase-3 [GSK-3]) that likely play a role in reprogramming gene expression in response to hypertrophic stress.

PKB/Akt regulates GSK-3, which also plays a role in regulating normal and pathological stress-induced growth of the heart. GSK-3β (and likely GSK-3α as well) is a negative regulator of cardiac growth. Transgenic animals expressing GSK-3β have dramatic reductions in normal cardiac growth and also have a markedly reduced hypertrophic response to pressure overload. Inhibition of GSK-3β, mediated by PKB/Akt, is necessary for the hypertrophic response to a number of agonists. GSK-3β-mediated inhibition of growth occurs via several mechanisms. For example, GSK-3β negatively regulates activity of the initiation factor, eIF2B. Thus inhibition of GSK-3β may be important for enhancing protein translation. However, GSK-3β also inhibits the activity of a number of transcription factors. Because several factors have been implicated in growth, including growth of the heart, GSK-3β may be particularly important in the reprograming of gene expression and relatively less important in regulating protein translation. This might make GSK-3β an attractive target for therapeutic intervention because therapies targeting the translation machinery can be expected to have significant toxicity with long-term use. The GSK-3β targets include the NFATs, and thus GSK-3β acts in opposition to the calcineurin pathway (Fig. 17-2). Phosphorylation of NFATs by GSK-3β leads to exclusion of NFATs from the nucleus, preventing access to target genes. When the GSK-3β transgenic was bred with the calcineurin transgenic, hypertrophy was markedly reduced. Other known growth regulators negatively regulated by GSK-3β include c-Myc, GATA-4, β-catenin, and c-Jun.

The PI3-K pathway is negatively regulated by a phosphatase that dephosphorylates 3-phosphorylated phosphoinositides at the 3′ position called phosphatase and tensin homolog (PTEN) (*see* Fig. 17-3). Overexpression of a catalytically inactive mutant of PTEN in cultured cardiomyocytes led to cardiomyocyte hypertrophy. Furthermore, conditional inactivation of the PTEN gene in the heart also led to hypertrophy, further supporting a critical role for the PI3-K pathway in regulating cardiomyocyte growth. In summary, the consistency of the message from studies of multiple components of the PI3-K pathway has confirmed a role for this pathway in normal growth and in pathological stress-induced hypertrophic growth. This pathway, acting in concert with the mTOR pathway, is a dominant determinant of cell and organ size in mammals.

OTHER PATHWAYS INVOLVED IN GROWTH REGULATION As suggested, a large number of signaling pathways have been implicated in the regulation of cardiomyocyte growth. However, either there are insufficient data to support a claim, or the data are too conflicting to make definitive statements concerning their role. This is probably most apparent from the literature on the role of stress-activated mitogen-activated protein (MAP) kinases in the hypertrophic response (Fig. 17-4). These kinases, the c-Jun N-terminal kinases (JNKs) and the p38-MAP kinases, have been exhaustively studied but there remains no consensus on their role, in large part owing to the lack of adequate pharmacological inhibitors that can be used in vivo. As a result, investigators have turned to gene-targeting approaches, but because both of these kinases are members of multigene families, studies have been complicated by functional redundancy, and crosses of knockouts have led to embryonic lethality. It is likely

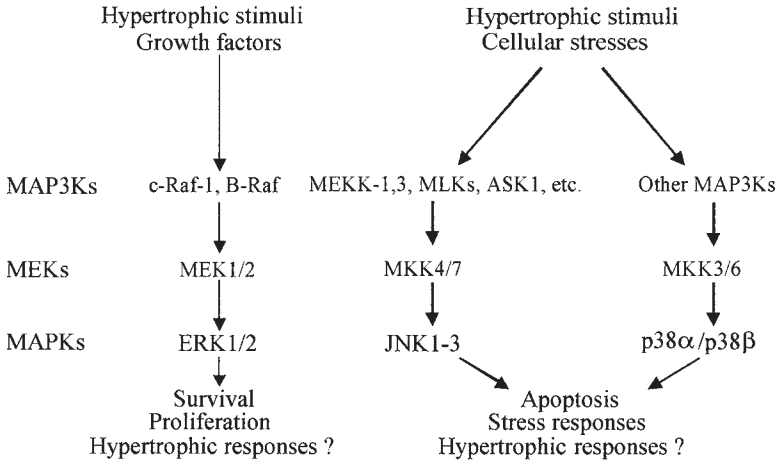

Figure 17-4 Schematic representation of the major MAPK pathways. The three-tiered kinase cascade consists of a MAP kinase kinase kinase (MAP3K) that phosphorylates and activates a MAP kinase kinase (also called MAPK and ERK kinase, MEK), that, in turn, phosphorylates the MAP kinases (MAPK), either the ERKs, JNKs, or p38-MAPKs.

that a definitive conclusion on the role of these kinases in hypertrophic growth awaits the availability of truly specific inhibitors of these kinases, or better yet, inhibitors of specific isoforms of these kinases, because there is evidence that different isoforms (and even different splice variants) may serve different functions within the cell. Assessment of the data suggests that the p38-MAP kinases may be more involved in the progression of heart failure, including remodeling of the matrix, and may play less of a role in hypertrophic growth. If confirmed, they may be attractive drug targets in the failing heart. Other work employing mice deleted for three of the four JNK1/JNK2 alleles suggests that the JNKs may reduce the hypertrophic response to pressure overload, in part by targeting NFATs much as GSK-3β does.

The extracellular signal-regulated kinases family (ERK) of MAP kinases (*see* Fig. 17-4) are also activated by hypertrophic stimuli. For studies of the role of the ERKs in hypertrophy, relatively specific inhibitors of the mitogen-activated protein kinase (MAPK) and ERK (MEKs) immediately upstream of the ERKs are available. Generally studies have found them to inhibit at least part of the hypertrophic response of cardiomyocytes in culture. Cardiac-specific overexpression of MEK1 (one of the immediate upstream activators of the ERKs) produced concentric cardiac hypertrophy, but unlike most other models, such as the calcineurin transgenic, the MEK1 transgenic animals did not progress to contractile failure. These data raised the concept of "beneficial" hypertrophy vs "detrimental" hypertrophy by clearly demonstrating that hypertrophy need not inexorably progress to heart failure, possibly because the ERKs (in contrast to many other prohypertrophic signaling molecules including calcineurin, the JNKs, and the p38-MAP kinases) are in many circumstances, cytoprotective. Of note, hypertrophy induced by overexpression of PI3-K also leads to hypertrophy without heart failure, and the PI3-K pathway, like the ERK pathway, is cytoprotective. These data suggest a potential approach to the treatment of patients with heart failure wherein pathways promoting progression of heart failure are inhibited whereas those prohypertrophic pathways that are also cytoprotective are stimulated.

The PI3-K and mTOR pathways are critical regulators of cell and organ growth via effects on the activity of several transcription factors regulating expression of hypertrophic response and on the general protein synthesis machinery. Calcineurin is another important regulator that appears to act largely via effects on the NFAT family of transcription factors. Although other pathways have been implicated, data supporting an important role for these other pathways in physiological or pathological hypertrophy are not nearly as convincing. Thus it seems likely as drugs become available for the treatment of hypertrophic disorders, the initial focus will be on the components of the calcineurin and PI3-K/mTOR pathways. Whether long-term inhibition of these pathways, which regulate basic cellular responses of all cells in the body, will be tolerated is unknown. Alternative approaches, such as gene therapy, which can be delivered in an organ-specific (and even cell type-specific) manner, or organ-specific drug delivery may be necessary to target these pathways safely.

ALTERATIONS IN SIGNALING IN THE DISEASED HUMAN HEART

Discussion of the signaling profile of the hearts of experimental animals exposed to pressure overload raises two questions: How do the signaling alterations seen in the hearts of these animals compare with signaling alterations in the hearts of patients with hypertrophy or heart failure? Is there any evidence that abnormalities in these clinical scenarios are a cause of heart failure (as opposed to a consequence of the heart failure) and, therefore, will manipulating their activity alter the progression of disease?

One study has examined the signaling profile of hypertrophied hearts. Patients were scheduled to be transplant donors but for various reasons were not considered appropriate. Several had significant cardiac hypertrophy, allowing a comparison of the signaling profiles in those hearts vs normal hearts that were also rejected as donors. Of the signaling factors examined (calcineurin, ERK1/2, JNK, p38-MAP kinase, Akt, and GSK-3), the only factor consistently found to be activated in the hypertrophied hearts was calcineurin. Of note, patients with hypertrophy clearly had hypertension, but they were not suspected of having any cardiac disorder and in all cases, systolic function was not depressed. Therefore, clinically, they would be described as "compensated" hypertrophy. These data raised calcineurin as one potential therapeutic target in this phase of the disease.

In contrast to the limited data available on hearts with compensated hypertrophy, several studies have examined the signaling

profile of hearts explanted from patients with advanced failure either going to transplant or undergoing left-ventricular assist device placement before transplant. These signaling factors were examined in at least one study: calcineurin, ERK1/2, JNKs, p38-MAP kinases, ERK5, the MAP kinase phosphatases (which inactivate the MAP kinases), Akt, GSK-3, and a signaling pathway activated by Ang-II and cytokines, the Janus kinase/signal transducer, and activator of transcription pathway. Where examined, calcineurin expression and activity were increased, though not to the same degree as in the hypertrophied hearts. Unfortunately, no clear consensus has emerged from the studies examining the MAP kinase pathways. The most consistent results appear to be for p38-MAP kinase activity, with three studies reporting activation of p38-MAP kinases in ischemic cardiomyopathy, and only one reporting inhibition. In contrast, in idiopathic cardiomyopathy, p38-MAPK activity has generally been reported to be decreased or unchanged; only one reported activation, although the magnitude of activation was very low. No consistent results have been reported for the JNKs and ERKs. Single reports examined the other factors. In these, ERK5 was inhibited and the MAP kinase phosphatases were activated. Akt was also found to be activated, irrespective of the etiology of the heart failure, and accordingly, its downstream target, GSK-3β, was inhibited. This profile suggested that the heart may be attempting to mount a hypertrophic response in the face of severe contractile dysfunction.

Thus, a signaling profile of the failing heart cannot be defined and it is unclear whether any signaling alterations cause or are consequential to the heart failure. It is unclear what if any effect manipulating these pathways would have on the progression of disease. Hearts that have been mechanically unloaded with left ventricular assist device show changes in activity of MAP kinases, with ERK1/2 and JNK activity decreasing and p38-MAP kinase activity increasing, concomitant with a decrease in cardiomyocyte size (i.e., regression of hypertrophy) and a decline in the rate of myocyte apoptosis. However, it is unclear if the regression of hypertrophy and reduction in apoptosis is because of the changes in activity of these MAP kinases.

Finally, the complexity of the heart failure signaling abnormalities and the changing activities of various pathways at various times in the progression of disease (as evidenced by the differences in signaling in the hypertrophied vs failing hearts) create uncertainty and lead to significant challenges for translational research. Patients with compensated hypertrophy vs advanced heart failure were at different ends of the pathophysiological spectrum of heart failure, and between these points, including the transition to and early progression of heart failure, very little data exists as to which pathways might be reasonable targets. It is likely, however, that interventions at different points in the progression of heart failure will have to focus on different targets, and it is not clear that these interventions will be equally or uniformly successful. Furthermore, the heterogeneity of signaling abnormalities, even among patients with the same clinical diagnosis, suggests that as has been proposed for cancer therapy directed at protein kinase pathways, therapy may need to be defined by the kinase "profile" of the individual patient rather than the clinical diagnosis. Otherwise, promising therapies may be discarded as ineffective because they were used in the wrong patients. Given the aggressive pursuit of inhibitors of these pathways by the pharmaceutical/biotechnology industry, the tools to be able to address these questions should be forthcoming.

18 Arrhythmias

BARRY LONDON

SUMMARY

Ion channel mutations cause long QT syndrome, Brugada syndrome, conduction disorders, catecholinergic ventricular tachycardia, and some forms of familial atrial fibrillation and pre-excitation. Transgenic and gene-targeted mouse models of these disorders have further increased the understanding of links between ion channel mutations and these rare arrhythmia syndromes. Molecular genetics, pathophysiology, and implications of these findings are discussed later. It is important to realize, however, that the genetic basis of other inherited arrhythmic syndromes remains unclear, as does the role of genes that are not ion channels. In addition, the relationship of common genetic variants (polymorphisms) to arrhythmic risk is only beginning to be studied. This chapter highlights the avenues of future research that seem most likely to yield results.

Key Words: Arrhythmias; atrial fibrillation; Brugada syndrome; conduction disease; ion channel; long QT syndrome: Wolff-Parkinson-White syndrome (WPW).

INTRODUCTION

Modern experimental electrophysiology began with the explanation of the basis of the action potential in the squid giant axon, and clinical cardiac electrophysiology began with the development of electrocardiography. The fields progressed in two rather independent directions. The development of intracellular electrodes, the voltage clamp, and the single channel patch clamp revealed the subcellular events that underlie cardiac excitability and automaticity. Meanwhile, arrhythmia mapping, devices, and clinical trials defined the mechanisms that underlie human arrhythmias and assessed the efficacy of therapeutic interventions. The cloning and molecular biological analysis of ion channels has linked structure to function, and human genetic analysis has identified the genes and mutations responsible for rare inherited arrhythmia syndromes. Although the relation of single channel properties to the more common arrhythmias associated with ischemic and cardiomyopathic processes has lagged behind, molecular electrophysiology holds great promise as a unifying discipline in the age following the completion of the human genome project.

Ion channel mutations cause long QT syndrome, Brugada syndrome, conduction disorders, catecholinergic ventricular tachycardia, and some forms of familial atrial fibrillation and pre-excitation. Transgenic and gene-targeted mouse models of these disorders have further increased the understanding of links between ion channel mutations and these rare arrhythmia syndromes. Molecular genetics, pathophysiology, and implications of these findings are discussed later. It is important to realize, however, that the genetic basis of other inherited arrhythmic syndromes remains unclear, as does the role of genes that are not ion channels. In addition, the relationship of common genetic variants (polymorphisms) to arrhythmic risk is only beginning to be studied. The avenues of future research that seem most likely to yield results are highlighted next.

INHERITED ARRHYTHMIA SYNDROMES

LONG QT SYNDROME

Clinical Presentation The autosomal-dominant form of the rare long QT syndrome was first described in the early 1960s. Although the exact gene frequency is not known, it is one of the more common causes of sudden cardiac death among otherwise healthy adolescents and young adults (along with hypertrophic cardiomyopathy and myocarditis). It is characterized by syncope, unexplained seizures, and sudden death. Symptoms often begin near adolescence and are preceded by emotional events such as surprise and fear. The electrocardiographic manifestation of the disease is a prolonged QT interval and an abnormal T-wave morphology on the surface ECG, although the QT interval has considerable variability and some symptomatic affected individuals have QT intervals within the normal range (Fig. 18-1A). The most common arrhythmia is *torsade de pointes*, or polymorphic ventricular tachycardia with a rotating axis (Fig. 18-1B). The symptoms often respond to treatment with β-blockers, although some patients are refractory. The role of sympathectomy and timing of implantable cardiac defibrillator (ICD) therapy remain uncertain.

The autosomal-recessive long QT syndrome is associated with congenital deafness, and is extremely rare. The acquired long QT syndromes are caused by medications (particularly type-IA and type-III antiarrhythmics, certain antibiotics, and nonsedating antihistamines), ischemia, metabolic disorders, and neurological disorders. Acquired long QT syndrome is considerably more common than the autosomal-dominant and -recessive forms, and plays a major role in the design of novel pharmaceutical agents.

Molecular Basis of the Disease QT prolongation results from action potential prolongation, and ion channel defects were therefore likely candidates. Positional cloning identified a number of K^+ channel and Na^+ channel mutations that cause the autosomal-dominant forms of this syndrome (Table 18-1). Of note, KvLQT1

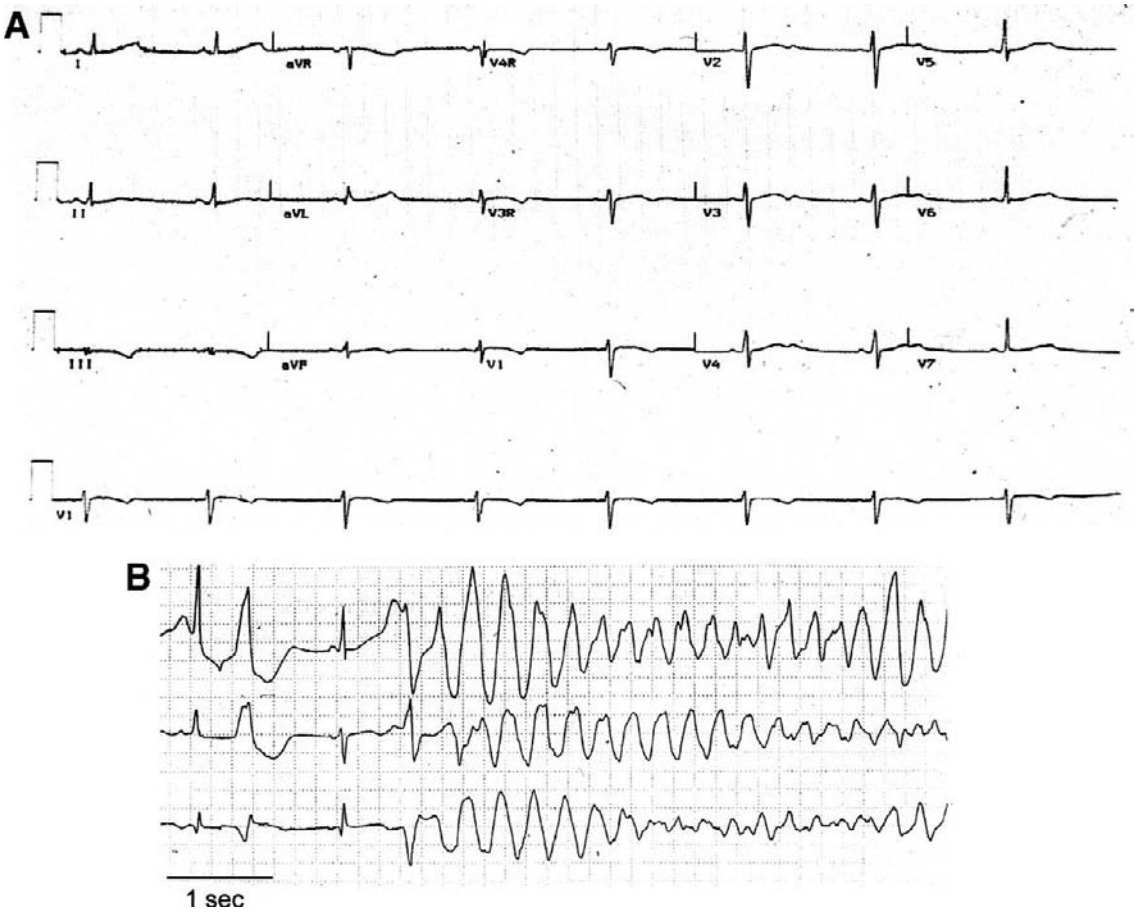

Figure 18-1 ECG manifestations of the long QT syndrome. **(A)** 12 Lead ECG of a child with the Romano-Ward autosomal-dominant long QT syndrome. **(B)** Lead II rhythm strip demonstrating *torsade de pointes*.

Table 18-1
Long QT Syndrome Loci

Locus	*Protein*	*Gene*	*Pathophysiology*	*Chromosome*
LQT1	KvLQT1	*KCNQ1*	$\downarrow I_{Ks}$	11p15.5
LQT2	HERG	*KCNH2*	$\downarrow I_{Kr}$	7q35-36
LQT3	$Na_v1.5$	*SCN5A*	$\uparrow I_{Na}$	3p21
LQT4	Ankyrin-B	*Ank-B*	?	4q25-27
LQT5	MinK/IsK	*KCNE1*	$\downarrow I_{Ks}$	21q21-22
LQT6	MiRP1	*KCNE2*	$\downarrow I_{Kr}$	21q21-22
LQT7	Kir2.1	*KCNJ2*	$\downarrow I_{K1}$	17q23

was first identified by the positional cloning at the LQT1 locus. Mutations of the K^+ channels KvLQT1 and HERG account for most cases, whereas Na^+ channel mutations are present in <5%. The ion channel mutations cause marked action potential prolongation, leading to reactivation of inward currents and triggered activity (Fig. 18-2). These early afterdepolarizations can then initiate re-entry and lead to syncope or sudden death.

Four K^+ channel α-subunits, with or without β-subunits, coassemble to form functional channels. Mutations of the K^+ channel α-subunit KvLQT1 (LQT1 locus) and the β-subunit IsK (minK; LQT5 locus) affect the slow component of the delayed rectifier K^+ current I_{Ks}, whereas mutations of the α-subunit HERG (LQT2 locus) and possibly the β-subunit MiRP1 (LQT6 locus) affect the rapid component of the delayed rectifier K^+ current I_{Kr}. Some KvLQT1 and HERG mutations act solely through loss of function or haploinsufficiency, whereas others also contribute to the long QT syndrome via a dominant negative mechanism. In the latter cases, mutant subunits coassemble with wild-type subunits to form an abnormal or nonfunctional channel protein. It is also clear that many HERG mutations affect channel function by interfering with the trafficking of the channel to the cell membrane. Lower temperature and drugs such as E4031 rescue some of these mutants.

Patients with the autosomal-recessive or Jervell and Lange-Nielsen syndrome are homozygous for mutations in either KvLQT1 or minK. KvLQT1 and minK are expressed in the hair

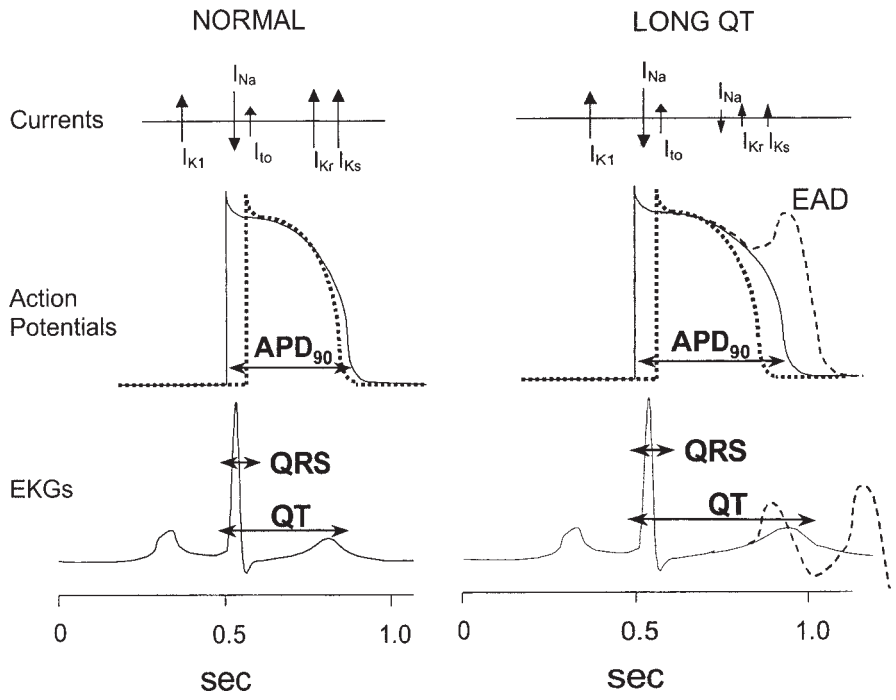

Figure 18-2 Ionic basis of the long QT syndrome. Schematic representation of transmembrane ionic currents (top), intracellular potentials (middle), and surface electrocardiograms (bottom) of a normal individual (left) contrasted with one having the long QT syndrome (right). For each individual, the shortest action potential (epicardial) is depicted by the dotted line and the longest (M-cell) by the solid line. Insufficient repolarizing K^+ currents (I_{Kr} or I_{Ks}) or a prolonged inward Na^+ current (I_{Na}) prolongs cellular action potential in different parts of the heart to different extents, leading to QT interval prolongation and T-wave broadening. The action potential prolongation can also lead to triggered activity (early afterdepolarizations) that can initiate runs of torsade (dashed line).

cells of the inner ear and play a key role in the production of endolymph, leading to congenital deafness in the recessive form. As expected, these patients have a more severe cardiac phenotype, and their parents are usually heterozygous for an ion channel mutation. In fact, the autosomal-dominant long QT syndrome can often be identified in each parent's family.

Mutations that interfere with inactivation of the cardiac Na^+ channel SCN5A cause long QT syndrome in families linked to the LQT3 locus on chromosome 3p21. Here, the Na^+ current fails to fully inactivate leading to a late inward current and action potential prolongation. Mutations in the ankyrin-B gene cause the rare LQT4 variant of long QT syndrome. Ankyrin-B interacts with a number of cardiac ion channels, receptors, and exchangers. The mechanisms that lead to QT prolongation and arrhythmias remain uncertain.

Sudden infant death syndrome (SIDS) is associated with QT prolongation. *De novo* and familial mutations in the long QT genes are responsible for some sudden infant death syndrome cases.

Some of the acquired forms of the long QT syndrome may also have a genetic basis. The pore region of HERG binds to a wide variety of drugs, and most pharmacological cases of the acquired long QT syndrome are caused by drugs that bind to HERG and decrease I_{Kr}. It is speculated that a decreased repolarization reserve in these individuals, possibly because of polymorphisms in other channel proteins, may lead to the increased susceptibility to certain K^+ channel blocking agents. In contrast, some mutations may cause drug-induced QT prolongation by directly affecting the blocking affinity of the drugs.

Andersen's syndrome is a congenital disorder associated with dysmorphic facial features, periodic paralysis, QT prolongation, and arrhythmias distinct from *torsade de pointes*. Mutations of the inward rectifier channel Kir2.1 (*KCNJ2*) lead to a decrease in the current I_{K1} that controls the resting membrane potential of heart cells. It is debated whether Kir2.1 should be included with the other long QT genes.

Gene-Based Diagnosis The mapping of the long QT syndrome and the identification of the responsible genes allow prenatal and presymptomatic testing for patients with this disorder and their family members. The severity of the phenotype varies as a function of the mutation and the family. Some families have multiple cases of sudden death, whereas others with the same mutation do not. It is also clear that long QT mutations have variable penetrance, and that individuals carrying mutations often have normal QT intervals.

In the long QT syndrome, the clinical phenotype is related to genotype. Patients with KvLQT1 mutations are most likely to have symptoms associated with exertion, possibly related to the role of channel phosphorylation by β-adrenergic agonists. Patients with HERG mutations appear susceptible to emotional triggers, whereas SCN5A mutations lead to bradycardia with increased cardiac events at night. In addition, the ECG phenotype is correlated to genotype. KvLQT1 mutations are associated with short ST segments and broad-based T waves, HERG mutations with bifid T waves, and SCN5A mutations with late onset peaked/biphasic T waves.

Screening individuals for long QT mutations is technically difficult, owing to the large number of genes identified and the large size of the channels. In addition, mutations cannot be found in up to 40% of cases. In some of these, the mutations are probably in the parts of known genes that are not normally screened (introns, promoter regions). In others, mutations in other unidentified genes are probably present. As a result of these factors,

molecular diagnostic evaluation of long QT syndrome patients is only now becoming available.

Screening of newborns for QT prolongation also remains controversial. Without a reliable means to diagnose mutations, the number of false-positive ECGs would be prohibitive.

Gene-Based Treatment Knowledge of the underlying genetic cause allows for testing of gene-specific therapies. For example, sodium channel blockers such as mexilitine eliminate the late inward current in vitro and normalize QT intervals in patients. It remains to be seen whether such therapies will prevent arrhythmias and sudden death. The finding that some HERG trafficking mutations can be rescued by temperature and channel blocking agents also raises the possibility of specific pharmacological therapy.

Animal Models A number of transgenic and gene-targeted mouse models of long QT syndrome gene mutations have been engineered (Table 18-2). Deafness in homozygous minK knockout mice suggested a role for the genes encoding I_{Ks} in the Jervell and Lange-Nielsen syndrome. Similarly, prolongation of the action potential and QT intervals in ankyrin-B knockout mice enhanced its status as a candidate gene at the LQT4 locus. Despite these insights, the rapid heart rate (approx 600 beats/min) and low abundance of the repolarizing currents I_{Kr} and I_{Ks} in the adult mouse ventricle greatly complicate the interpretation of long QT-related arrhythmias in this model system.

Summary Great progress has been made in the clinical and genetic analysis of the long QT syndrome. The identification of ion channel mutations as the cause of the long QT syndrome has spurred much work in the structure–function relationships in cardiac ion channels. It has also led to significant advances in the understanding of cardiac electrophysiology and arrhythmias.

BRUGADA SYNDROME

Clinical Presentation Syncope, ventricular fibrillation, and sudden cardiac death have been reported in patients without overt structural heart disease in association with a right bundle branch block pattern and ST elevation (STE) in the right precordial leads of the ECG (Fig. 18-3A). This condition is known as the Brugada syndrome. Brugada syndrome is inherited in an autosomal-dominant manner, is diagnosed predominantly in men, and is rare in the United States. Arrhythmic sudden death is common, may be the first manifestation of disease, and is not prevented by antiarrhythmic drug therapy (Fig. 18-3B). The surface ECG manifestations of the syndrome can transiently disappear in affected individuals, although the risk of arrhythmias may remain. This had led to the recommendation for ICD placement in symptomatic affected individuals and in asymptomatic individuals with a resting Brugada ECG pattern and inducible ventricular fibrillation during an invasive cardiac electrophysiology study.

The Brugada syndrome is rare in the United States, although the exact incidence is unknown. Sudden unexplained cardiac death is considerably more common in young southeastern Asian men, however, and has an incidence as high as 40/100,000 in northeast Thailand. At least some of the affected individuals have ECG findings similar to those seen in the Brugada syndrome, raising the possibility that it may be considerably more common in certain areas of the world. Another feature of the syndrome is male predominance. In a long-term follow-up in a series of 334 individuals with the Brugada ECG phenotype, most patients (67%) were male and an even greater percentage of the symptomatic patients were male (e.g., 86% of patients with aborted sudden death).

ECG abnormalities in Brugada syndrome are modulated by Na^+ channel blocking antiarrhythmic drugs. In particular, procainamide, flecainide, and ajmaline accentuate the STE on the ECG, and change the shape of the STE in the right precordial leads from saddleback to coved (the latter considered more diagnostic for the condition). This has led to the use of intravenous challenge with these medications to confirm Brugada syndrome in patients with suspicious ECGs and to diagnose the inherited form of the condition in asymptomatic relatives of affected individuals with near normal baseline ECGs. As the Brugada ECG pattern has become more recognized and screening with Na^+ channel blockers more prevalent, the apparent incidence of sudden death and malignant arrhythmias in affected individuals has fallen.

Invasive electrophysiology studies often demonstrate prolongation of the HV interval and easily inducible ventricular fibrillation during programmed stimulation in Brugada syndrome patients. Inducible ventricular arrhythmias during an electrophysiology study has a negative prognostic implication and should be used as an indication for ICD placement in asymptomatic individuals with a baseline abnormal ECG. Another study of 65 patients from 52 families with Brugada syndrome also demonstrated a less malignant phenotype in asymptomatic patients, but questioned the

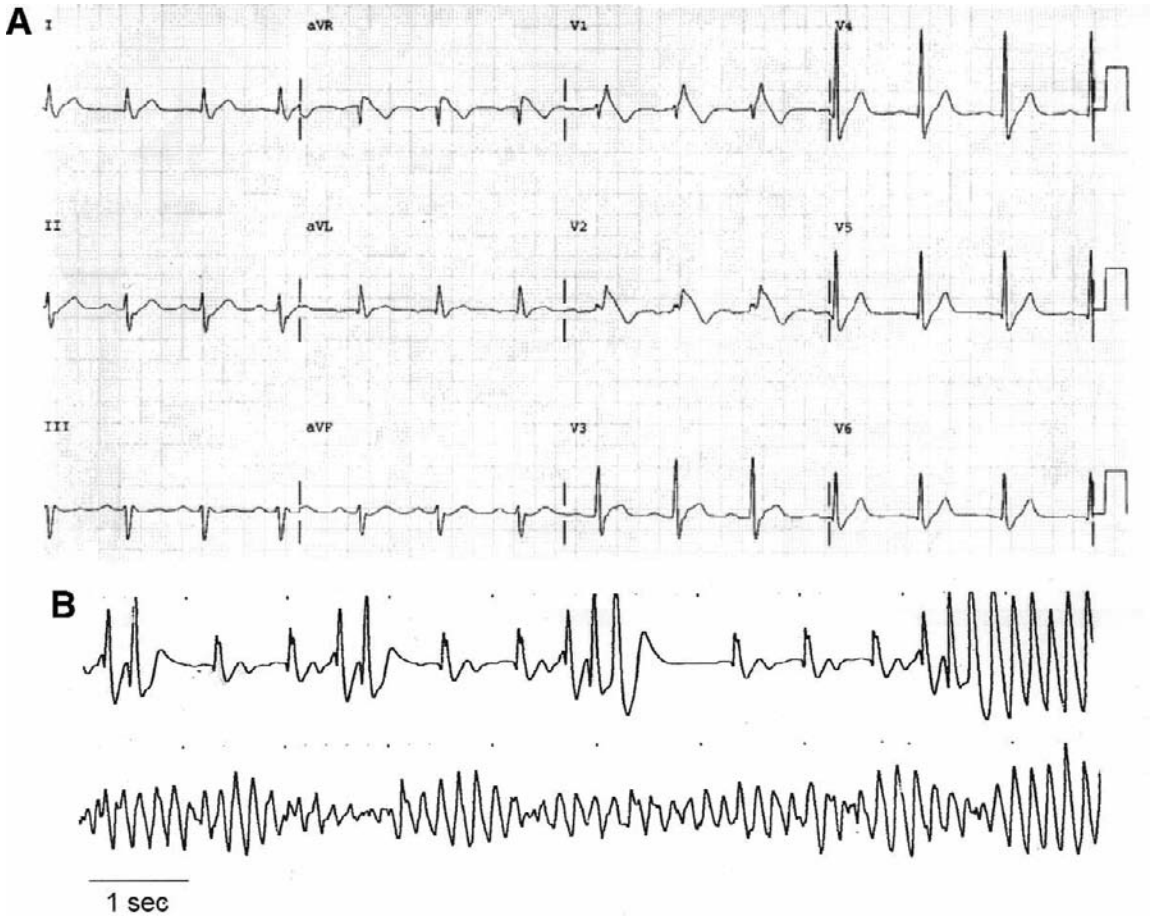

Figure 18-3 Electrocardiographic manifestations of Brugada syndrome. (**A)** 12 Lead ECG of an adult man with Brugada syndrome. (**B)** Telemetry strip demonstrating initiation of polymorphic ventricular tachycardia during syncopal spell prior to internal cardioverter-defibrillator shock.

utility of programmed electrical stimulation and drug testing with Na^+ channel blockers. The response to Na^+ channel blockers, originally reported as 100% sensitive, may also be unreliable in some families.

Molecular Basis of the Disease Mutations of the cardiac Na^+ channel SCN5A were initially identified in three small families with the Brugada syndrome. In one family, two missense mutations (R1232W in DIIIS1-S2 and T1620M in DIVS3-S4) resulted in a 10-mV rightward shift in the steady state inactivation curve of SCN5A and sped recovery from inactivation. In the other two families, single basepair deletions led to either a premature stop codon (ΔA1397 in DIIIS6) or a splice site mutation that likely truncated the channel (amino acid insertion in intron in DIS2-S3) and decreased the number of functional cardiac Na^+ channels. Several dozen SCN5A mutations responsible for Brugada syndrome have been reported; most decrease inward Na^+ current.

These Brugada syndrome SCN5A mutations differ from the SCN5A mutations that interfere with inactivation and cause the long QT syndrome in families linked to the LQT3 locus. Of interest, a family was identified that has characteristics of both long QT and Brugada syndromes resulting from a single SCN5A mutation. Similarly, flecainide (a Na^+ channel blocker and proposed therapy for patients with the LQT3 form of LQTS) produces a Brugada syndrome ECG pattern in some individuals from LQT3 families.

ST segment elevation on the ECG reflects current flow in the heart during electrical systole, and most commonly reflects the injury current seen in the setting of a myocardial infarction. Several lines of evidence relate the STE in the Brugada syndrome to the presence of a prominent early repolarizing current, I_{to}, that leads to a spike and dome action potential in the epicardium of the right ventricle and the corresponding J wave on the ECG. Mutations of the cardiac Na^+ channel SCN5A are thought to decrease the depolarizing inward Na^+ current and lead to early repolarization in the right ventricular epicardium in which the transient outward K^+ current (I_{to}) is large (Fig. 18-4). This causes a voltage gradient from endocardium to epicardium, STE on the ECG, and susceptibility to arrhythmias because of phase 2 reentry. The actions of the Na^+ channel blocking agents procainamide, flecainide, and ajmaline to exacerbate the STE and unmask the ECG phenotype support this theory. Experiments using wedge preparations from dog hearts also show that decreased depolarizing Na^+ current predisposes to loss of the action potential plateau (all-or-none repolarization) in the epicardium, prominent J waves, current flow from endocardium to epicardium with STE, and arrhythmias. In addition, I_{to} may be more prominent in males than in females, explaining the male predominance of the syndrome.

SCN5A mutations are found in <20% of patients with Brugada syndrome. A second Brugada syndrome locus was identified on chromosome 3p24 distinct from SCN5A by positional cloning in a large multigenerational family. In this family, conduction disease becomes more prominent with age, mitral regurgitation appears to be associated with the syndrome, and drug testing with intravenous

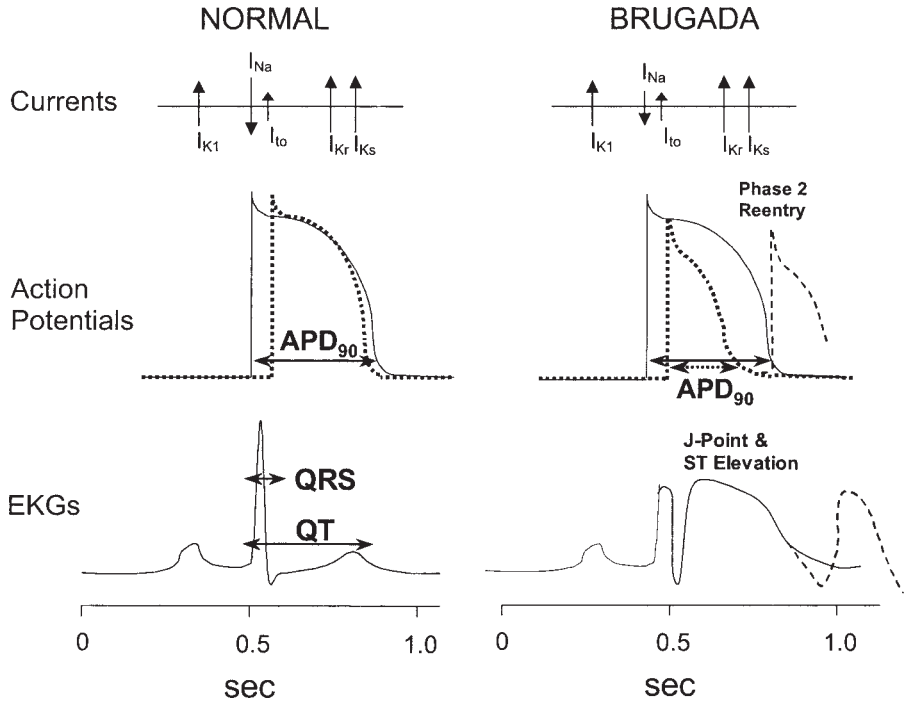

Figure 18-4 Ionic basis of the Brugada syndrome. Schematic representation of transmembrane ionic currents (top), intracellular potential (middle), and surface electrocardiogram (bottom) of a normal individual contrasted with one having Brugada syndrome. Insufficient depolarizing sodium (Na^+) current shortens the cellular action potential in the right ventricle leading to early repolarization of a part of the heart. This results in the potential for re-excitation of that cardiac muscle and the initiation of re-entry circuits.

procainamide is ineffective. In addition, other Brugada syndrome families have been identified that do not link to either of the chromosome 3 loci.

Gene-Based Diagnosis Patients with SCN5A mutations have longer PR intervals on surface ECG, longer HV intervals during electrophysiology study, and a greater increase in QRS duration during drug testing than those with no detectable SCN5A mutation. The efficacy of drug testing may also be gene or mutation dependent. It is unclear whether the male predominance in the syndrome is also gene dependent.

Summary Brugada syndrome is the second major arrhythmopathy that can result from ion channel mutations. Unlike long QT syndrome, the molecular basis for most cases remains uncertain. Elucidation of the remaining causes may uncover a new family of genes that interact with and modulate cardiac Na^+ channels.

PROGRESSIVE CARDIAC CONDUCTION DISEASE In addition to long QT and Brugada syndromes, SCN5A mutations cause progressive conduction system disease. Conduction disease has also been reported in LQT3 families and in Brugada families. Thus, Na^+ channel mutations can cause a spectrum of cardiac abnormalities that affect depolarization, repolarization, and conduction.

SHORT QT SYNDROME Families with an autosomal-dominant short QT syndrome and sudden cardiac death have been described. Of note, HERG mutations that abolish inward rectification and speed repolarization cause some of the cases. Thus, cardiac repolarization appears under tight control, with severe consequences resulting from either too little or too much HERG current.

FAMILIAL ATRIAL FIBRILLATION Atrial fibrillation usually occurs in elderly patients with hypertension, valvular disease, or ischemic heart disease, with atrial hypertension and stretch as the common underlying factor. A small fraction of cases are genetic, and loci on chromosomes 10q22-24 and 6q14-16 have been identified. In addition, atrial fibrillation runs in a family with a mutation in KvLQT1 that eliminates rectification. It is not clear why ventricular repolarization is unaffected in this family. In any case, these findings show that K^+ channel mutations can cause a spectrum of disease states that span multiple cardiac chambers.

CATECHOLINERGIC VENTRICULAR TACHYCARDIA AND ARRHYTHMOGENIC RIGHT VENTRICULAR DYSPLASIA Mutations of the Ca^{2+} release channel of the sarcoplasmic reticulum cause increased Ca^{2+} release in the presence of β-agonists, leading to some cases of the autosomal-dominant arrhythmogenic right ventricular dysplasia (ARVD) and to the rare inherited adrenergically mediated ventricular tachycardias. Of note, the genes and mutations at the other six loci associated with the autosomal-dominant forms of ARVD remain unidentified. In general, gene identification is easier once the class of candidates has been identified. Mutations in the structural protein plakoglobin at 17q21 cause Naxos disease, an autosomal-recessive syndrome associated with wooly hair, palmoplantar keratoderma, and ARVD. A knockout mouse model of plakoglobin has a similar phenotype. It has been recently been shown that mutations in related genes cause some autosomal-dominant forms of ARVD.

WOLFF-PARKINSON-WHITE SYNDROME Bypass tract-mediated reentrant tachycardias (Wolff-Parkinson-White syndrome, WPW) result from abnormal connections between the atria and ventricles. Mutations of the gene that encodes the γ-2 regulatory subunit of AMP-activated protein kinase (PRKAG2) cause a rare inherited form of WPW syndrome associated with hypertrophic cardiomyopathy. Transgenic mice overexpressing a mutant form of PRKAG2 are pre-excited, but suggest that the gene mutation results in accumulation of glycogen. Thus, this condition appears to be a form of a storage disease, and is probably unrelated to the common forms of WPW.

THE GENETIC BASIS OF COMMON ARRHYTHMIAS

SUDDEN DEATH IN HEART FAILURE

Clinical Presentation Cardiac arrhythmias are responsible for >250,000 cases of sudden cardiac death each year in the United States, and only a small fraction of these are caused by the autosomal-dominant and autosomal-recessive inherited conditions described previously. Ventricular tachyarrhythmias accompany acute myocardial ischemia and infarction, occur postinfarction in the scarred ventricle, and are also common in myocarditis and idiopathic dilated cardiomyopathies. Re-entry through intraventricular electrical circuits is often documented by electrophysiological studies. Pharmacological treatment for these conditions remains limited, as sudden death can be the presenting symptom. Implantable cardioverter defibrillators are effective, but their use is limited by high cost and limitations to quality of life.

Molecular Basis of the Disease Prolonged action potential duration and downregulation of the repolarizing K^+ currents I_{to} and I_{K1} are present in tissue and cardiac myocytes isolated from patients and animal models with heart failure. This delayed repolarization, along with enhanced dispersion of repolarization, may contribute to arrhythmias and sudden death. Mechanisms leading to arrhythmias may include triggered activity, such as early after depolarizations (resulting from recovery from inactivation of inward currents), and delayed afterdepolarizations (resulting from Ca^{2+} release from overloaded internal stores). In addition, re-entry leading to rotors and scroll waves may be enhanced by heterogeneities in ion channel distribution in the heart.

Polymorphisms that change protein function are widespread in genes that could affect cardiac rhythm, such as ion channels and β-adrenergic receptors. Although not proven, it is tempting to speculate that these subtle changes could predispose heart failure patients to arrhythmias. One such polymorphism in the cardiac Na^+ channel SCN5A, S1102Y, is relatively common in African Americans. This polymorphism is associated with an increased late sustained Na^+ current in vitro, mild QT prolongation in some families, and arrhythmias. Thus, it may be an important risk factor for arrhythmias in African Americans with heart disease. Caution is required in the interpretation of case–control association studies, however. As the authors note, "longitudinal studies will be required to confirm the predictive utility of Y1102."

Gene-Based Diagnosis and Treatment Aside from ejection fraction, the search for clinical markers that predict sudden death in patients with systolic dysfunction has been disappointing. Large clinical trials have shown that ICD implantation improves survival in these patients. Based on the Multicenter Automated Defibrillator Implantation Trial II study, there are approx 3,000,000 patients in the United States who meet the indications for ICD placement along with approx 400,000 new ischemic cardiomyopathy cases each year. At $20,000 per ICD, the cost to the health-care system would exceed $8 billion each year. If genetic markers could be used to identify a subgroup of heart failure patients at high risk for arrhythmias, the impact on clinical care would be extremely high.

FUTURE DIRECTIONS: FROM ION CHANNEL TO ARRHYTHMIA

Many ion channels, pumps, and exchangers have been cloned and studied in vitro using isolated membranes, vesicles, *Xenopus* oocytes and cultured cells. These proteins form the basis of the currents that depolarize and repolarize the heart. A complete catalog of their identity, a model of their structure, and an understanding of the biophysical mechanisms by which they open, close, inactivate, interact, and distinguish between different ions has become reality. The roles of post-translational modification, trafficking, and individual genes in generating cardiac currents, the action potential, the ECG, and rare inherited arrhythmias are becoming understood. The relationship of these basic and clinical findings to the diagnosis and treatment of common arrhythmias remains in the future. Establishing this link is essential, however, if the molecular analysis of cardiac electrophysiology is to have maximal impact in the understanding and treatment of arrhythmias.

19 Genomics

Calum A. MacRae and Christopher J. O'Donnell

SUMMARY

Genomics is the study of entire genomes and is now possible owing to the completion of the Human Genome Project. Genomic techniques are rapidly being exploited to discover susceptibility genes and to better understand the pathophysiology of cardiovascular diseases, both rare, Mendelian disorders, such as hypertrophic cardiomyopathy, and common complex disorders, such as myocardial infarction and atrial fibrillation. At present, the management of Mendelian disorders and of heritable complex disorders is grounded in a detailed family history and careful examination for signs and symptoms. Althought the application of genetic and genomic testing is limited in current clinical practice, a number of potential applications are anticipated in the nearterm future.

Key Words: Cardiomyopathy; family history; genetic association; genomics; genotype; heritability; mendelian disorders; mutation; myocardial infarction; pharmacogenomics; phenotype; single nucleotide polymorphism.

INTRODUCTION

Genomics has been proposed as the source of a revolution in medicine, although this revolution has yet to be realized in any practical sense. This is partly a reflection of the difficulties in applying the fundamental science to individuals or populations, but may also reflect intrinsic differences between the well-controlled context of the laboratory and the uncertainties of clinical medicine. This chapter discusses the general concepts of genomics, its immediate implications for human genetic studies, and the anticipated impact of genomics on the practice of cardiovascular medicine.

WHAT IS GENOMICS?

Genomics is in essence the study of entire genomes. It is made possible largely as a result of the success of the Human Genome Project, a multinational effort to sequence every base in a representative human genome. Although the Genome Project was successfully completed in 2003, final efforts to "finish" some sequences to the required level of accuracy continue. The technological advances spurred by this effort led not only to the comprehensive sequencing of the human genome, but also to the subsequent sequencing of a host of biologically and medically relevant organisms ranging from viruses to apes. Major efforts are now directed to identifying the variations between the genomes of individual humans, in the hope that these differences will characterize at a fundamental level the potential for developing disease, the prognosis of such disease, and the individual responses to drugs. The extent to which this promise will be realized remains the subject of intense debate, but it is clear that genomics will transform the study of biologic phenomena, irrespective of whether these phenomena are inherited.

The initial efforts to develop comprehensive catalogs of the most common genomic differences between individual humans, single nucleotide polymorphisms (SNPs), have revealed some of the fine structure of the human genome. It is now known that chromosomes are inherited as unique combinations of ancient building blocks of the order of only a few kilobases of DNA. These regions of low recombination, in which only a few different alleles might encompass all the variation that has ever existed, are interspersed with local regions of high recombination. This block structure allows much of a population's common variation to be captured by the typing of a relatively small proportion of the polymorphic sites, and will accelerate the advent of comprehensive genome mapping on a single "chip" or microarray. The intensive study of the basis for the noncontinuous nature of the genome will undoubtedly reveal other insights into human biology and disease.

Perhaps the most important and influential attributes of the discipline of genomics are its potential to study biological processes in a global and unbiased manner. For the first time, it is possible to study not just one gene, but rather all the genes and to relate variation in these genes directly to phenotype. The availability of complete sequence allows the expression levels of all the genes to be studied in parallel. Finally, it is feasible to understand in many ways how a genome functions, as a whole, using comparisons with the genomes of other organisms. This ability to define orthologous genes (both within coding sequences and beyond) also makes possible faithful modeling of human genetic diseases. Although far from complete, the success of this global strategy has heralded similar comprehensive approaches in whole tissues and organisms to the study of proteins (the proteome), metabolic pathways (metabolome), and noncoding RNA structure and function (the RNAome).

Genetic techniques have been applied to cardiovascular disease (CVD), and have been successful in dissecting the Mendelian disorders of lipids, cardiomyopathies, and arrhythmias. The comprehensive study of genes, and SNP expression, does not offer major theoretical advantages over conventional genetic markers, but will affect classic human genetics in several ways. First, the ready

Table 19-1
Basic Genomic Terminology

Allele	Any one of the sequence variants of a particular gene
Genome	The complete DNA sequence of an organism
Haplotype	A series of sequence variations that are linked together on a single chromosome
Introns and exons	Genes are initially transcribed as continuous sequences, but only some segments (the exons) of the resulting RNA molecules contain information that encodes the gene's protein product. The intervening regions between exons (the introns) are excised from the RNA and the exons are spliced together to form the final messenger RNA from which the protein is translated
Mutation	Any pathologic variation of the sequence from the reference state
Phenotype	The complete set of characteristics of an organism including morphology and function
Proteome	The complete repertoire of proteins encoded by a genome including post-translational modification
Single nucleotide polymorphism (SNP)	Most of the variation in DNA sequence between individual members of a population is the result of changes in single nucleotides
Transcription	The copying of a gene's RNA into DNA
Transcriptome	The complete repertoire of RNAs transcribed from a genome
Translation	The synthesis of a protein from the information encoded in a messenger RNA

availability of genomic data will ease the application of proven genetic strategies, allowing the relatively rapid identification and study of genes that were previously difficult or impossible to clone. The tools that the genomics revolution has spawned have already made mapping and mutation detection much faster and cheaper. Second, there is the potential that, if common alleles do cause common diseases, genomics will dramatically affect the mapping and cloning of common disease. Paradoxically the greatest legacy of genomics may be its role as a foundation for other "omics," ultimately influencing phenotyping more than genotyping.

GENOMICS FOR GENE DISCOVERY

In any disease, the presence of a major genetic effect has implications for molecular studies of the etiology of the disorder, and for the design and interpretation of studies of its diagnosis and management. These clinical inferences are often relevant long before the intricacies of the molecular pathways are understood. Studies of CVDs that are transmitted in a Mendelian fashion have identified rare variants in specific genes that can be proven, through empiric animal experimentation, to define the molecular basis of a number of relatively uncommon conditions—familial hypercholesterolemia, hypertrophic cardiomyopathy (HCM), and familial long QT syndrome. For the common, "complex" CVDs, such as myocardial infarction and congestive heart failure, that consist the leading cause of death and disability in developed nations, clear evidence exists for a modest underlying genetic basis. Completion of the sequence of the human genome has made possible extensive, and ultimately comprehensive, study of the associations with CVD of all common variants in all known genes. Dissection of the specific genetic variants underlying susceptibility to common CVDs is challenging and has met with modest success, due at least partly to the intrinsically smaller magnitude effects being studied, but it may also reflect the underlying limitations of the techniques. To place the clinical and molecular insights in context, Table 19-1 provides a background of vocabulary and techniques used in genetic analysis.

GENOMIC APPLICATIONS IN MENDELIAN DISEASES

Although cardiovascular disorders inherited in a Mendelian fashion account for a small proportion of the morbidity and mortality conferred by all CVDs, there have been significant successes in identifying genetic variants in many of the Mendelian disorders by use of classic genetic techniques. This section highlights the proven capabilities and limitations of Mendelian genetics and the potential pitfalls of simply extrapolating these techniques to the study of more complex disorders.

FAMILIAL AGGREGATION Although in some instances the genetic nature of a particular disorder is obvious, in many cases symptomatic individuals represent only a subset of those with the underlying trait. Large families with a clear family history of the disease may be the exception, even when a condition is highly heritable (Fig. 19-1). The expression of a phenotype may require additional genetic or environmental factors, or may vary stochastically. To gain an objective sense of how important genetic factors might be in a form of heart disease, systematic studies of familial aggregation and lineal transmission are necessary. Of the several ways of crudely estimating the degree of heritability, the most common is the simple sibling recurrence risk. Detailed assessment of the mode and magnitude of any heritable component requires more complex segregation analysis using multiple families. The genetic basis for HCM was obvious from simple inspection, but systemic analysis first suggested a large heritable contribution to dilated cardiomyopathy (DCM).

GENETIC LINKAGE Genetics has proven a powerful tool to define causal mechanisms in biology, not as a result of some unique property of DNA, but because of the magnitude of the underlying effect and the segregation of genes through families. In many situations in which disease genes have been cloned, the risk to first-degree relatives is several hundred times that in the general population. The theory behind proving causality using genetics parallels Koch's postulates in infection, another situation in which an abnormal genome is responsible for disease (Table 19-2). If

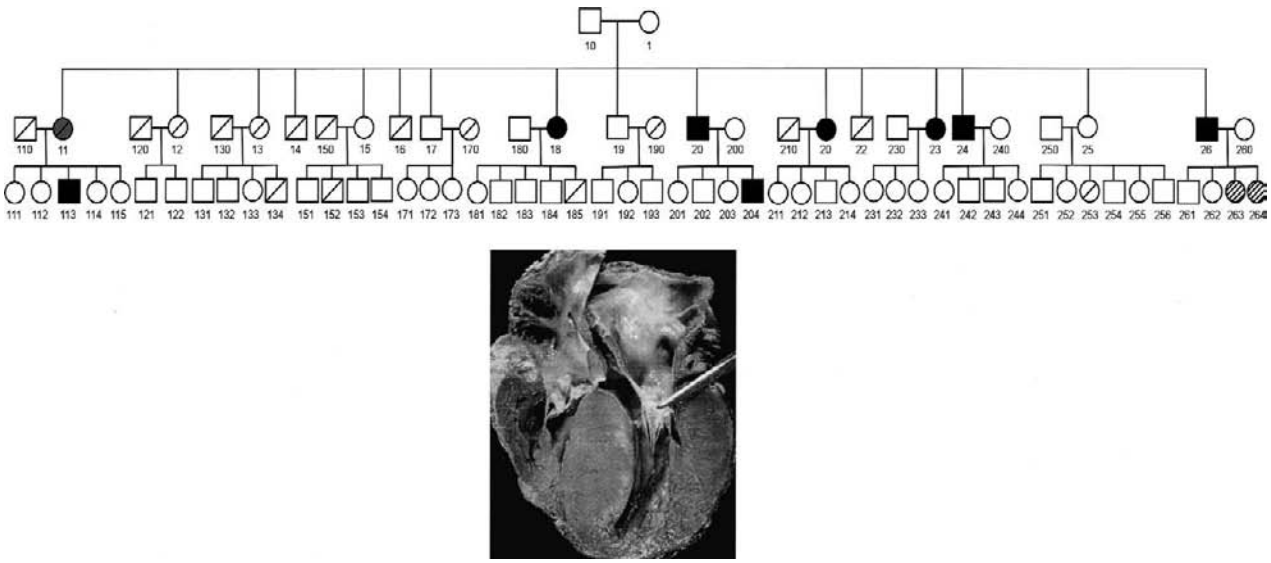

Figure 19-1 Hypertrophic cardiomyopathy: an archetypal monogenic cardiovascular disorder. Multiple alleles in multiple sarcomeric (and other) genes may cause this syndrome, characterized by unexplained left-ventricular hypertrophy and sudden death.

Table 19-2
Criteria for Defining a Causal Mutation: Discrimination From a Polymorphism

I	The "mutation" should segregate perfectly with disease. The sequence anomaly must be present in all the affected individuals and absent from all the unaffected individuals. Ideally two independent means should be used to confirm that this is the case. The best statistical support for this segregation is a LOD or logarithm of the odds score (also used in anonymous mapping studies), which estimates the likelihood of random cosegregation as a function of the number of informative events.
II	The "mutation" should not be present in a normal population. Rare polymorphisms may be overrepresented in any given large family. These polymorphisms may have functional significance, yet not be responsible for disease. For example, null alleles have been described for many genes including that encoding the cardiac beta myosin heavy chain, but when present in the heterozygous state may be of no import. It is necessary to screen a large normal population for any putative mutation to ensure that it is not simply an incidental polymorphism.
III	The "mutation" should effect substantial change on the gene sequence. There should be indirect evidence that the mutation will have a biological effect. This may be obvious for some mutations that disrupt the sense of the entire coding sequence of the gene. Other mutations will have more subtle effects, changing only a single amino-acid residue. The confirmation of these substitutions as disease-causing may require additional studies, such as comparative sequence analyses (with the same gene in other species, or similar genes in the same species, to see if a particular residue is highly conserved), in vitro structure function analysis or in vivo genetic analyses.
IV	The introduction of the "mutation" should be sufficient to cause disease. There should be direct evidence that the mutation has a biological effect. The ultimate proof of causality lies in the demonstration that the simple addition of the mutation is sufficient to recapitulate the disease. This is usually done in genetic model organisms, but the specific knock-in of a point mutation (the most common mutation calls in human disease) is rarely performed. Often a causal role is inferred from transgenic expression of a mutant gene or from knockout of the gene. The demonstration of disease in association with a *de novo* mutation in humans is the logical equivalent.

there is a large genetic effect, given the way in which DNA is transmitted to the next generation, it is possible to define a segment of mutated DNA that when transmitted is sufficient to cause the phenotype in question. This specific segment of DNA can potentially be isolated and shown to be distinct from the normal sequence at that location. Finally, the mutated gene or its ortholog, if introduced into a normal organism, should be capable of causing the disease phenotype. Clearly the literal fulfillment of these criteria is not feasible in humans, but the methods of human molecular genetics combined with empiric testing in genetically modified model organisms, allow similar logic to be applied. Ultimately, the availability of comprehensive genomic information may allow these insights to be widely applied to traits with smaller heritable components, but this will require additional theoretical and technical advances.

If the DNA of family members can be screened for segments of the genomes that are consistently transmitted with the phenotype, then the causative gene can be mapped. The development of panels of informative markers, polymorphic between individuals, made such genetic linkage analyses possible. These anonymous markers allow individual DNA segments to be followed as they pass through a family, defining their relationship (or lack of relationship) with disease. Using a panel of markers that "scans" the entire genome, in even a single large family with a given genetic disease, it is possible to define a minimal location for the disease, and ultimately to identify the causal mutation. The passage, or segregation, of a phenotype through a single lineage is the hallmark of a genetic trait. Segregation also allows other features that track with this phenotype to be identified, informing the investigator about relationships between apparently unrelated clinical findings.

The imminent availability of SNP arrays, which enable an entire genome to be mapped at high density in a single experiment, will significantly change the utility of classic genetic approaches. The time required to map a disease locus will be dramatically reduced, the potential resolution of mapping will be increased, particularly if there are founder effects, and even the minimum size of family required to map a trait will be affected.

CLINICAL DIAGNOSIS AND GENETIC MAPPING It is impossible to separate human molecular genetics from clinical cardiological assessment. A minimal disease interval is defined in terms of recombinants, i.e., individuals whose phenotypes and genotypes are discordant because of inferred recombination between the marker and the disease-causing mutation. The definition of recombinant events is thus completely dependent on the clinical phenotype. Given the central role of phenotype in mapping and cloning a disease gene, it is conventional to adopt conservative criteria for assigning positive and negative affection status in human molecular genetics. It is much better to define an individual as unknown, than to attempt molecular studies with the wrong diagnosis. The need to exclude many equivocal family members has restricted positional cloning efforts to very large kindreds with highly penetrant forms of disease. The closer to the disease-causing mutation marker lies the fewer recombinants are evident, until ultimately the mutation itself should segregate perfectly with the phenotype. No matter how high the resolution of the genetic map, the size of any disease locus is likely to depend on the number of family members who can be definitively phenotyped.

Definitive phenotyping is even more challenging when the assumptions of a single gene disorder are not applicable. As the Human Genome Project is completed, phenotyping in many conditions remains largely unchanged. Mendelian genetics revealed that even a simple mode of genetic inheritance can result in complex phenotypic variation. In many ways the unbiased approaches of genomics may be most helpful in redefining not the resolution of genotyping but the resolution of phenotyping (*see* The Central Importance of Phenotypic Resolution).

POSITIONAL CLONING Once a minimal disease interval has been defined by genetic mapping, the techniques of positional cloning are used to identify all the genes within this interval and to screen these genes for mutations. The ability to grow, in yeast or bacterial artificial chromosomes, long segments of up to several hundred thousand basepairs of human DNA, allows large stretches of a human chromosome to be cloned in an overlapping set of such segments. This "contig" of human DNA clones can be manipulated and eventually sequenced to define the disease gene. Importantly the cloning of the mutated gene does not require any *a priori* assumptions regarding the mechanism of disease. This lack of dependence on previous hypotheses has resulted in the discovery of truly novel pathways, and is particularly powerful in complicated disorders with multiple manifestations (Fig. 19-2). The comprehensive genomic data from the completion of the Human Genome Project ensures that no matter how large the final disease locus, it is possible to rapidly identify the genes within the final interval. This has expedited the cloning of disease genes, and broadened the scope of positional cloning projects to include progressively smaller families with less penetrant diseases.

LOCUS AND ALLELIC HETEROGENEITY The ability to distinguish discrete pathological processes and to undertake genetic analysis of these phenotypes is limited by the resolution of current diagnostic techniques. Mutations in many different genes may give rise to very similar phenotypes, a phenomenon known as genetic heterogeneity. This situation is compounded by the fact that inherited cardiac conditions often result in premature mortality, so founder mutations are rare. For example, most HCM families with mutations in a specific sarcomeric contractile protein have a different mutation (so-called allelic heterogeneity). This degree of heterogeneity exists for most other Mendelian cardiac conditions. Importantly, subtle differences between the clinical manifestations of different mutated genes may not be detectable until genetic studies have been completed, and "pure" populations studied.

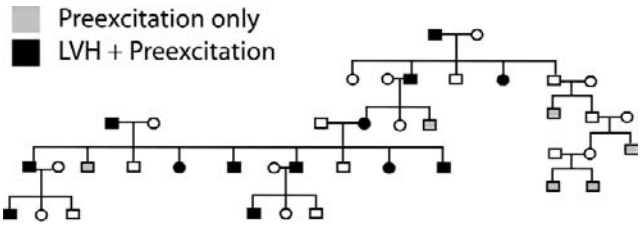

Figure 19-2 Mendelian conditions may have extremely pleiotropic manifestations. In families with AMP-activated protein kinase γ-2 mutations, affected family members may exhibit massive left ventricular thickening (not true hypertrophy), ventricular pre-excitation or atrioventricular block.

MODIFIERS OF SIMPLE TRAITS Any clinician who has cared for families with monogenic forms of CVD is likely to have been struck by the range of clinical manifestations seen in any single family, in which the primary genetic abnormality is identical in each affected individual (*see* Fig. 19-2). Although some of this variable expressivity represents the limited understanding of the phenotype itself, some variation is the result of modifier genes or of environmental factors. The discovery of such modifier loci or environmental agents is a major research focus.

The use of high-density SNP chips will allow investigators to identify the major locus in a single family and to genotype every family member across the entire genome, revealing other shared genomic regions that may be modifying the phenotype. If these modifiers can barely be discerned in the context of a simple disease caused by a single major gene, understanding the conditions in which multiple genes interact will be tremendously difficult.

GENOMIC APPLICATIONS IN COMMON, COMPLEX CVDS

HERITABILITY, DISEASE PHENOTYPES, AND QUANTITATIVE TRAITS Although there is generally no evidence for clearly dominant or recessive transmission of most common CVDs through families, there is compelling evidence for familial aggregation of risk factors for CVDs. For "qualitative" traits, such as myocardial infarction or stroke, evidence for familiality has been demonstrated by calculation of simple sibling recurrence risk ratios, or more sophisticated modeling of potential inheritance patterns. For "quantitative" traits such as low-density lipoprotein (LDL) cholesterol or systolic blood pressure, correlations among siblings or first-degree relatives can be calculated to estimate heritability, the proportion of variability in the quantitative trait that is attributable to shared genetic factors. Using these methods, a moderate (30–50%) degree of heritability has been demonstrated for several risk factors, including LDL cholesterol, systolic blood pressure, glucose levels, and body mass index, as well as quantitative subclinical vascular disease measures, such as carotid intima media thickness or coronary artery calcification.

GENETIC ASSOCIATION STUDIES Not all phenotypes segregate in large families and so other genetic techniques have been developed that do not use transmission probability, but rely on simple association of genotypes with phenotypes within a population. These studies are qualitatively different from linkage analyses, but have proliferated. The most commonly used association study design is the case–control study. Case–control genetic association studies have limitations. A primary and major potential problem is confounding bias from population stratification, which results in spurious association of a polymorphism with disease, simply because the disease and the unlinked sequence variant are found in the same population subgroup. This can be partly addressed by replicating the findings in large study cohorts drawn from genetically distinct populations. Another potentially important problem in multiple testing is the prior probability that any observed effect results from the specific polymorphism(s) studied is usually extremely low, resulting in an unacceptably high false-positive rate (through Bayesian inference). Confirmation associations in independent case–control studies provide increased support for the hypothesized genotype and phenotype association. However, because of these limitations, findings of associations in case–control studies are generally regarded as data that generate rather than confirm hypotheses.

Because segregation information is absent from these studies, it also is impossible to infer causality from the relationship between specific variants and a particular phenotype. If the genotype–phenotype association in question is not spurious, it may result from a functional variation within the candidate gene, but more commonly the association results from functional variation within a nearby or linked gene, in so-called linkage dysequilibrium with the tested polymorphism. These issues would partly be dealt with by using extended haplotypes of markers in large populations. Parallel evidence for a functional role of the putative variant is essential. These studies, which may use cell culture or model organisms, are possible much earlier because of the ready availability of detailed sequences for cognate genes in other genomes.

Family-based association studies are costly and difficult to conduct, but they offer distinct advantages over case–control designs. The conduct of family-based association tests such as transmission dysequilibrium testing in well phenotyped groups of nuclear families, such as trios of parents and an affected child, allows the study of transmission of alleles from parents to offspring, eliminating the possibility that population stratification may explain associations. Genetic association studies may be extremely difficult to interpret even when conducted in an exemplary fashion. Ideally, associations found from case–control studies can be confirmed in family-based association studies.

Association study designs may be used to analyze qualitative or quantitative traits. Large-scale screening studies of "complex" disease traits, such as myocardial infarction or congestive heart failure, have yielded interesting hypotheses regarding gene variants that may confer disease risk. However, very few genetic variants are strongly, consistently associated with a common CVD outcome in multiple studies, including family-based studies. Among the possible explanations, most common genetic variants may confer relatively small effects on a population-scale (thus, larger sample sizes may be needed) and important unmeasured environmental modifiers may play a substantial role but be substantially different in different populations. Further, clinically apparent disease traits, while heritable, may be heterogeneous. By contrast, quantitative preclinical disease phenotypes, such as decreased levels of high-density lipoprotein cholesterol, increased levels of hemostatic factors, or subclinical vascular disease, may represent more tractable measures for dissecting the role of specific genetic variants. Ideal quantitative phenotypes are heritable and strongly related to prospective risk for CVD. Some candidate gene variants have been consistently noted to explain a significant proportion of the interindividual variability of these "upstream" phenotypes, despite less consistent associations of the same variants with disease phenotypes. For example, although the angiotensin-converting enzyme deletion/insertion polymorphism is clearly associated with levels of serum angiotensin-converting enzyme, there are only modest associations of this polymorphism with blood pressure and inconsistent associations in dozens of studies with CVD outcomes such as coronary heart disease and congestive heart failure. Similarly, the *apolipoprotein E* polymorphism is clearly related to adverse lipid levels, but the totality of studies of associations with myocardial infarction has been less consistent in regards to the risk allele.

THE CENTRAL IMPORTANCE OF PHENOTYPIC RESOLUTION The precision and utility of a genotype–phenotype association is only as strong as the level of resolution of the underlying CVD phenotype, whether transmitted in a Mendelian fashion or via more complex inheritance patterns. Phenotypes defined by a heterogeneous collection of disease cases may obscure the real genotype–phenotype associations. For example, a collection of cases of congestive heart failure may include a diversity of etiologies, including HCM, DCM secondary to myocardial infarction, and DCM secondary to myocarditis. More refined phenotyping requires rigorous clinical evaluation and restriction of studies to fewer subjects with a homogeneous diagnosis. In some cases, current diagnostic criteria allow only limited phenotypic resolution, and further clinical refinement is necessary. Thus, a series of subjects with myocardial infarction may all be defined in a similarly restrictive manner using enzymatic, electrocardiographic, and angiographic criteria. However, further phenotype refinement may be necessary depending on underlying etiology of the atherothrombotic disease. Some subjects may suffer from familial hyperlipidemia, others from a strong genetic predisposition to arterial thrombosis, and still others from primary forms of arterial inflammation. It will be a challenge for future genomic studies to accurately resolve the substantial phenotypic heterogeneity underlying most disorders.

One potential response to this challenge arises from the ability to conduct massive analyses of gene expression and its responses. Microarrays are available that enable, in single experiments, characterization of the relative levels of expression of every gene in an organism (Fig. 19-3). These arrays will become available for humans, mouse, and other model organisms. Similarly unbiased efforts to characterize the quantitative dynamics of all expressed proteins (proteomics) and the totality of small molecules—lipid, carbohydrate, and metabolic substrate (metabolomics)—offers the potential to define phenotypes in multiple dimensions. The discovery of novel classes of regulatory (noncoding) RNAs have added (RNAomics) to this list. These approaches have been most successful in the study of clonal tissues such as neoplasms, but as investigators rigorously test the individual techniques in different situations their utility will be defined.

Although the statistical analysis and interpretation of the vast amounts of data from such experiments remains in its infancy, the implications of this technology are clear. No longer will it be

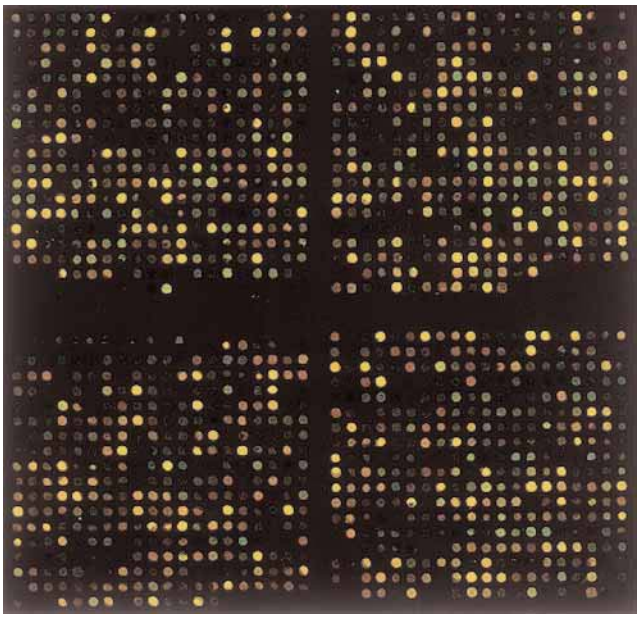

Figure 19-3 Microarray. The use of high resolution printing techniques has enabled the generation of dense microarrays with many thousands of features. These allow the detection of enormous numbers of sequences in parallel in a single hybridization experiment, dramatically reducing the time and effort for mapping and expression studies.

adequate to characterize phenotypes in only one or two dimensions. Comprehensive characterization in multiple dimensions will be necessary. The potential to uncover heterogeneity, as has been seen in clonal lesions, is particularly exciting for geneticists studying common disorders, in which occult phenocopies (similar phenotypes resulting from other causes) may represent the single most destructive confounder of genetic approaches.

CURRENT CLINICAL APPLICATIONS

Genomic information is not yet of any utility in patient management in CVD. However, genomic principles and clinical genetics have the ability to inform patient care long before the genes for all inherited CVD have been cloned (Fig. 19-3). The application of clinical genetic principles in the diagnosis and management of inherited heart disease is outlined, and potential applications of genomics are described.

FAMILY-BASED DIAGNOSIS A definitive diagnosis of Mendelian disease in a first-degree relative dramatically changes the implications of any cardiovascular evaluation. Thus, minor ECG abnormalities are viewed differently in the context of a family history of HCM than without such history. In some cases the definitive diagnosis in a particular patient is only clear from the integrated evaluation of multiple individuals within the same family. This is increasingly recognized in families in which several "discrete" phenotypes, such as DCM and arrhythmogenic right ventricular cardiomyopathy, cosegregate. Only the complete evaluation of an entire kindred would allow these important features to be detected. The ethical implications of family-based diagnosis remain to be fully explored, but informed consent is critical if the data from multiple individuals are to be collected.

DIAGNOSIS

History The history often offers evidence that the presenting condition results from an inherited diathesis. Patients may have had subtle evidence of disease, such as the cutaneous manifestations of a lipid disorder or a neural crest abnormality, from an early age. Functional limitations are often attributed to respiratory illnesses, but it is usually possible to discern other features of the underlying disease. Comparison of exercise capacity at various ages with that of peers is useful in the evaluation of symptoms such as dyspnea muscle pains or syncope. Other premature medical disorders may suggest specific conditions (*see* Online Mendelian Inheritance in Man weblink, Table 19-3).

A comprehensive family history is an integral part of every patient encounter, but is particularly important in the diagnosis and management of adult CVD in which the presenting symptoms may be sudden death. In addition to defining the basic structure of the family, it is vital to define in as much detail as possible any cardiac conditions (or even potential cardiac conditions) in first- or second-degree relatives. Once the basic family structure and an overview of any inherited traits is obtained, the symptoms, ages of onset, specific treatments (e.g., diuretics, pacemakers, ICDs, and surgery) and modes of death for every member of the nuclear family should be elicited. Specific enquiry regarding extracardiac phenotypes including skeletal or other myopathies, peripheral sensory or motor neuropathy, and premature diabetes or liver disease is recommended. Often a family history is not appreciated, simply because the potential connection between different phenotypes is not explicitly considered.

Other apparently unrelated disorders or events may represent *formes frustes* of the same primary abnormality. Probands will often be unaware of subtle distinctions between cardiac diseases, and many affected relatives of patients with one particular cardiovascular disorder may have been mislabeled with other cardiac conditions such as valvular heart disease or myocardial infarction. Thus, for example, atrial fibrillation in a young relative of a patient with cardiomyopathy is likely a manifestation of the same gene defect, and an unexplained motor vehicle accident may represent an undetected sudden death. The family history also allows some sense of the mode of inheritance to be obtained. A careful family history must also be a prominent feature in any follow-up visits. Patients often have gleaned additional family history from interactions with relatives because of the initial patient encounter. Indeed,

empowering the patient to obtain such information should be a goal of this encounter.

Clinical Evaluation The physical examination and subsequent clinical investigation of cardiac patients are also heavily influenced by the genetic basis of the major syndromes. The examination should look for general morphological abnormalities such as facial or other dysmorphism, midline defects, cutaneous anomalies, or the typical features of disorders such as myotonic dystrophy. Several forms of cardiomyopathy are associated with myopathy involving extraocular muscles, the limb girdles, or other muscle groups. Evidence of a skeletal myopathy may be subtle, such as a mild scoliosis or distorted pedal architecture. Finally, it is important to exclude tendon contractures, ataxia, peripheral neuropathy, or other neurological disorders. Many clinical diagnoses are, by definition, diagnoses of exclusion, and potentially reversible specific heart muscle diseases such as coronary artery disease, glycogen storage disorders, hemochromatosis, and dysthyroid heart disease should be formally eliminated.

Once appropriate permission has been obtained, objective data from other family members are extremely helpful. The direct examination of at-risk family members is often useful in making a diagnosis in equivocal cases. Pathognomonic components of the phenotype, including extracardiac features, may only be present in a subset of the family. Objective phenotypic assignment is especially helpful in inferring the mode of inheritance. Evidence of any mode of inheritance other than autosomal-dominant substantially changes the differential diagnosis in any CVD (*see* Online Mendelian Inheritance in Man weblink, Table 19-3). Mitochondrial patterns of inheritance usually occur in the context of left-ventricular hypertrophy or diabetes; X-linked and recessive syndromes are most often seen with DCM, but Freidereich's ataxia is also recessive. Progressive changes in the severity of a phenotype from one generation to the next, known as anticipation or reverse anticipation depending on the direction, are characteristic of triplet repeat expansion disorders such as myotonic dystrophy. The study of extended families offers a unique opportunity to investigate patient cohorts with remarkably homogeneous etiologies. In a family with a highly penetrant Mendelian disease an identical etiology may reasonably be inferred for each affected individual, and the key features of the specific disorder evaluated in exquisite detail. With the completion of the Human Genome Project, the potential is remarkable for molecular genetic analysis of even relatively small families, and referral to specialized centers for such studies should be considered.

Prognosis The remarkable range of clinical outcomes, even within a single kindred, plagues the clinical management of both Mendelian and complex forms of CVD. In some families with cardiomyopathy, multiple members have died suddenly or required transplant, and in others the disease is little more than an incidental echocardiographic finding. Initial studies of the presentation, natural history, and clinical physiology of the cardiomyopathies were based on highly selected series from large national referral centers. Subsequent series from regional centers have attempted to redress the balance. However, the major biases implicit in studies of inherited disease have not been addressed in most instances. Without knowing the extent to which individuals (particularly phenotypic outliers) are related, or the contributions of specific families to the overall cohort, it is impossible to begin to interpret even simple studies.

The identification of the underlying gene defects led to the hope that molecular diagnostics would revolutionize risk stratification. Preliminary work has suggested that specific mutations may be associated with high rates of adverse outcome, but these studies by necessity include multiple members from each family. Contradictory results have emerged from clinical and molecular studies. The extent of genetic heterogeneity, the large size of the genes involved, and the high rates of new mutation have slowed the arrival of genotype–phenotype studies based on serial probands. Understanding the distinctive contributions of the primary mutation, familial modifiers, and therapeutic interventions will require novel statistical methods for robustly extracting information from extended families.

In the absence of rigorous techniques to attribute risk to specific mutations, the effect of the mutation in different generations of the same family remains a reasonable (albeit imperfect) index of the likely natural history of the disease, and of the prognosis in an individual patient. Family members share not only the same causative mutation but also much of the genetic background, environment, and experiences. A complete family history and evaluation offers a sense of the range of expressivity of a particular genetic defect. It may be difficult to get any real overview of how a condition behaves in a small family, but in larger kindreds clear patterns of natural history sometimes emerge. It is usually possible to assess the penetrance, any major effects of gender and other features such as anticipation in larger families. These data are helpful in genetic counseling of potential parents.

The integration of imperfect data with similarly skewed results from heterogeneous clinical cohorts is unfortunately the current state of the art. Such data are susceptible to overinterpretation. Usually the disparate results between studies reflect the underlying etiologic heterogeneity of the study cohorts as much as any true biological differences. Large series of probands are being genotyped for several disorders, but the routine clinical use of genotyping will not be feasible until newer, less expensive sequencing methods are available. The rate of new mutations, and the fact that modifiers may significantly affect risk is also stimulating novel approaches to defining prognosis using proteomics or functional assays.

Another group of individuals who might benefit from screening are asymptomatic affected relatives. The risk of complications, including sudden death, is not clearly related to symptoms, and for both DCM and HCM there are available therapies, some of which are proven to reduce mortality. Systematic screening has been recommended for prognostic reasons in "at-risk" asymptomatic relatives of probands with DCM and HCM. It is possible to determine whether individuals have inherited the particular mutation segregating within the family if this is known, using lymphocyte-based DNA diagnostics. Although no objective data support any form of screening, if undertaken in specialist centers with appropriate counseling it is reasonable in the context of active research programs.

MANAGEMENT The management of the inherited cardiovascular disorders has also proven difficult to study. Because the literature contains many equivocal or contradictory studies, consensus is often lacking. This absence of evidence-based strategies reflects the rarity of many of the conditions, aggregation of heterogeneous populations, and ultimately the failure to deal with familial confounders. In the face of these uncertainties, clinical decisions must be based on the available information, and as outlined earlier much of that information is likely to come from the patient's extended family. Management strategies must often be tailored to the family and their experiences with the disease. For example, despite the lack of support from randomized controlled

trials, it is difficult not to implant an ICD in an affected young adult whose siblings have died suddenly from a familial disorder. A history of inherited disease is usually firmly embedded in the family psyche, and this may also require management approaches that extend beyond the individual patient. Family meetings and family counseling have a role, and involvement with a research group with long-term positive goals can be extremely helpful in engaging individuals who may have withdrawn from dealing with their disease.

POTENTIAL APPLICATIONS OF GENETIC TESTING IN COMPLEX DISORDERS

DIAGNOSTIC TESTING FOR PREVENTION As mentioned, genetic tests of individual polymorphisms may have low predictive value for determining susceptibility for CVD. However, screening of a diverse spectrum of multiple genetic polymorphisms and gene/protein expression profiles may improve risk stratification for CVD by use of technologies to simultaneously assay numerous SNPs and/or gene expression profiles that may be associated with increased CVD risk. Multilocus genotyping assays are commercially available to interrogate SNPs or expression profiles of thousands of cardiovascular-related genes that may influence myocardial development and cardiac function. Simultaneous examination of many polymorphisms/expression profiles will provide a comprehensive assessment of genomic influences on CVD, which may not be highly predictive of disease, but is anticipated to provide useful information for dissecting genetic risk.

Formal validation will be needed, however, to determine accuracy and reliability before multilocus predictions of disease risk can be incorporated into routine clinical practice. Ultimately, the value of multilocus DNA tests will rest on the strength of evidence that individual genetic polymorphisms confer increased or decreased susceptibility to disease and/or are importantly modified by other genes or environmental factors. The value of coordinated patterns of gene expression related to disease will need to be distinguished from short-term fluctuations in expression resulting from circadian variations or from daily environmental influences such as diet or medication use.

Genetic testing is not used in routine clinical practice for primary or secondary CVD prevention. As more information about genetic and environmental determinants of complex diseases accumulates, the ability to diagnose and treat genetic risk will increasingly become an essential skill for cardiovascular clinicians and primary-care providers. Initial uses of such tests may involve their incorporation into current clinical practice for screening and decision making regarding lifestyle modification or preventive drug treatments, complementing the routine measurement of modifiable risk factors and risk factor scores, as advocated by consensus guidelines.

PHARMACOGENOMICS The availability of comprehensive genomic data has led to exploration of the use of genetic information to predict the effects of specific medications. Much variation in drug responses is thought to be heritable, and in instances in which common pathways for drug metabolism are involved, several molecular mechanisms have been defined. For example, functional polymorphism in the cytochrome-*P450 2D6* gene is an important determinant of the active levels of drugs including codeine and azathioprine. The impact of such interindividual differences in drug absorption, metabolism, and excretion varies with the particular drug or combination of drugs. These polymorphisms may also have significant endogenous roles.

Genetic association studies, relating the incidence of individual candidate gene polymorphisms to particular outcomes, have proliferated in pharmacogenetics, as in the study of other complex traits. Although association studies may be the only method capable of unraveling population-wide genetic effects, these studies have proven difficult to reproduce and are of limited utility in defining causation. Locus resolution is often restricted, and ultimately even an important "disease gene" might be missed if it is represented by multiple uncommon alleles rather than a small number of common ancestral alleles. Because the principal target is known for many drugs, the application of association studies to pharmacogenetics has seemed more likely to succeed than in other settings. Suitable candidate genes are more readily defined, so the complexity of genome wide analyses is potentially reduced. However, even in this simplified context, significant limitations remain. Only a select proportion of the population is exposed to a given agent, and there may be a wide range of distinct responses, so that studies of sufficient power are impractical. The strategy is biased toward loci that have already been previously implicated in the drug's effect. Finally, many individuals take multiple drugs, which may confound the analyses. Theoretical and empiric evidence supports that to define the loci responsible for variation in the response to a drug and the interactions between these loci (the genetic architecture), classic segregation-based genetic techniques in model organisms will be necessary to complement human studies.

ETHICAL, LEGAL, AND SOCIAL ISSUES IN GENETIC TESTING

Potential issues that may arise when any form of genetic testing is being considered for general use, or in specific patients include ethical, legal, and social consequences of mapping and sequencing the human genome. As susceptibility testing for common CVDs becomes more widely available, and patients inquire about newly developed and emerging genetic tests, more responsibility for implementing, interpreting, and providing information about such testing will fall to cardiovascular specialists and physicians who may not be formally trained in genetics. To provide adequate genetic services, specialists and their care teams will need to develop strategies to communicate risk information and potential psychosocial consequences of genetic tests or testing to patients and family members, develop guidelines for obtaining informed consent and determining when genetic testing is appropriate, remain current with developments in genetics, provide patients with timely information, and become familiar with electronic and Internet resources. Optimal genetic services will include the active involvement of a board-certified genetic counselor.

CONCLUSION

Genomics, a direct result of the Human Genome Project, will allow complete characterization of variations between genomes of individual humans at the level of DNA, gene expression, and protein expression. The accelerating pace of genomic research is transforming the study of the biology of cardiovascular structure and function and the pathophysiology underlying CVD. The heralded promise of genomic medicine includes the potential for improved prediction of susceptibility to CVD and its prevention, risk stratification, and selection of optimal drug therapies. However, before genomic discoveries can be translated into clinical practice, there will need to be more detailed understanding of

the complexities of genotype–phenotype associations for Mendelian disorders and complex CVDs. Revolutionary changes in the practice of cardiovascular medicine are likely to result as evidence accrues that genomic approaches confer net benefits for individual patients.

20 Cardiovascular Gene Therapy

David A. Dichek

SUMMARY

A variety of mono- and polygenic cardiovascular diseases are potentially treatable with gene therapy. Extensive animal studies and initial human trials have confirmed that genes with therapeutic effects within the cardiovascular system may be introduced in vivo. Nevertheless, practical concerns relating to the achievement of safe, efficient, and long-lasting gene therapy continue to dominate the field.

Key Words: Cardiovascular; Duchenne muscular dystrophy (DMD); familial hypercholesterolemia (FH); hypertrophic cardiomyopathy (HCM); LDL cholesterol; polygenic; urokinase-type plasminogen activator (u-PA).

INTRODUCTION

Elucidation of the genetic mechanisms that contribute to cardiovascular pathology has stimulated the development of gene therapy for cardiovascular disease. Gene therapy involves the introduction and expression of recombinant DNA with a goal of ameliorating or curing a disease condition. Gene therapy approaches have been developed to treat a variety of cardiovascular diseases and many of these approaches have shown promise in animal models of human diseases. Nevertheless, clinical trials of cardiovascular gene therapy are at an early stage, and the place of gene therapy as a treatment for cardiovascular disease remains uncertain. This chapter is devoted principally to a review of the theoretical basis, tools, and approaches to cardiovascular gene therapy, as established by in vitro and preclinical animal experiments. In addition, the status of clinical cardiovascular gene therapy trials is reviewed, and the likely future directions of the field are summarized.

CARDIOVASCULAR DISEASES POTENTIALLY AMENABLE TO GENE THERAPY

MONOGENIC DISEASES Cardiovascular diseases potentially amenable to gene therapy are summarized in Table 20-1. The potential of gene therapy is most obvious in the rare cases in which cardiovascular disease is caused by a single-gene defect. Specific examples of these monogenic cardiovascular diseases include the cardiomyopathy associated with Duchenne muscular dystrophy (DMD; MIM 31020), an X-linked genetic disease caused by a defect in the gene that encodes dystrophin (Chapter 70) and atherosclerotic disease resulting from homozygous familial hypercholesterolemia (FH; MIN no. 14389), an autosomal-dominant disease with a gene dosage effect, caused by lowdensity lipoprotein (LDL) receptor deficiency (Chapter 15). Both DMD and homozygous FH are caused by absence of normal alleles (i.e., lack of one normal allele for DMD and lack of two normal alleles for homozygous FH). If heterozygotes are either asymptomatic (as in female carriers of DMD) or have a less severe form of the disease (as in FH), then homozygotes might be treated by the introduction of a normal allele. However, not all cardiovascular diseases arising from monogenic defects are clearly treatable by introduction of a normal allele. Hypertrophic cardiomyopathy (HCM), caused most often by dominant mutations in the genes encoding the β-myosin heavy chain, myosin-binding protein C, and troponin T (Chapter 11) cannot be treated with current gene therapy technology because the heterozygotes have a disease phenotype despite the presence of a normal allele. Gene therapy for this type of dominant mutation would require replacement or correction of the mutated allele, not simply addition of a normal allele. The technology for widespread gene replacement or correction in vivo does not yet exist.

POLYGENIC DISEASES Complex cardiovascular diseases such as atherosclerosis, thrombosis, heart failure, and hypertension have a polygenic basis and are also subject to significant modulation by environmental factors. Nevertheless, gene therapy approaches to polygenic cardiovascular diseases have been described, each of which is based on delivery of a normal allele of a single gene (Fig. 20-1). In each of these gene therapy approaches, delivery, and expression of the therapeutic gene are intended to stimulate metabolic pathways for which the therapeutic gene is rate-limiting. Stimulation of these pathways reverses the pathophysiology of the targeted disease. Thus, delivery of a single gene, such as antisense angiotensinogen, apolipoprotein (apo) A-I, or urokinase-type plasminogen activator (u-PA), may provide effective therapy for a complex disease process. This approach to gene therapy is similar to traditional pharmacotherapy, in which a therapeutic drug (e.g., a diuretic for essential hypertension, an angiotensin-converting enzyme inhibitor for heart failure, or coumadin for thromboembolic disease associated with atrial fibrillation) counteracts a disease process but does not correct the underlying cause.

Single-gene therapies for the polygenic diseases of atherosclerosis, thrombosis, heart failure, and hypertension have all shown promise in animal models. Gene therapy for atherosclerosis has focused primarily on manipulation of lipid metabolism. For example,

Table 20-1
Cardiovascular Diseases Potentially Amenable to Gene Therapy

Disease	*Therapeutic genes*[a]	*Anticipated mechanism*[b]	*Results*
Familial hypercholesterolemia (LDL receptor defective/absent)	LDL or VLDL receptor	LDL clearance	Ex vivo gene transfer in humans: 6–23% decrease in LDL cholesterol in three of five patients In vivo gene transfer in LDL receptor-deficient mice; correction of dyslipidemia
Dyslipidemia with no specific genetic defect	LDL receptor	LDL clearance	In vivo gene transfer into normal mice: decreased LDL cholesterol
	Apo A-I	Increase in HDL	In vivo gene transfer of apo A-I in atherosclerosis-prone mice: less atherosclerosis
Hypertension	Antisense to angiotensinogen or to β_2-adrenergic receptor	Vasodilation	Prolonged (>6 mo) blood pressure reduction in spontaneously hypertensive rats
Peripheral artery disease	VEGF	Angiogenesis	In vivo gene transfer in animal models of limb ischemia: increased vascularity and limb salvage In vivo gene transfer into patients with peripheral artery disease (in progress)
Occlusive arterial disease	Constitutively active retinoblastoma gene, hirudin, thymidine kinase, NO synthase	Cytostatic, cytotoxic, inhibition of smooth muscle cell proliferation	In vivo gene transfer into injured animal arteries: 35–70% reduction in neointimal formation
Thrombosis	Prostaglandin H synthase, t-PA, u-PA, thrombomodulin	Decreased thrombus formation, increased fibrinolysis	In vivo gene transfer in animal models of intravascular thrombosis: reduction in platelet deposition, fibrin accumulation, thrombus mass
Hypertrophic cardiomyopathy	Replacement of gene for mutated sarcomeric protein	Normalized sarcomere function	None; efficient in vivo gene correction currently technically unfeasible
Ischemic heart disease	VEGF, FGF	Angiogenesis	In vivo gene transfer in animal models of cardiac ischemia: increased vascularity, myocardial perfusion, and cardiac systolic function. Human trials in progress
Heart failure	Sarcoplasmic reticulum, calcium ATP-ase, β_2 adrenergic receptor	Improved calcium handling, increased contractility	In vivo gene transfer in animal models of heart failure: increased systolic function, decreased mortality

[a]Partial lists only.
[b]The anticipated mechanism has not always been experimentally verified in individual studies. ATPase, adenosine triphophatase; FGF, fibroblast growth factor; HDL, high-density lipoprotein; LDL, low-density lipoprotein; VEGF, vascular endothelial growth factor; VLDL, very low-density lipoprotein.

transfer of the gene that encodes the very low-density lipoprotein (VLDL) receptor that binds both LDL and VLDL significantly decreased plasma cholesterol and atherosclerosis in LDL receptor-deficient mice and gene transfer of apo A-I (the principal protein component of antiatherogenic high-density lipoprotein or HDL cholesterol), decreased atherosclerosis and promoted lesion regression in atherosclerosis-prone mice. Transfer of genes that encode either tissue-type plasminogen activator (t-PA) or u-PA into baboon endothelial cells decreased thrombus deposition in ex vivo arteriovenous shunts. Finally, myocardial transfer of the genes expressing either sarcoplasmic reticulum Ca^{2+}-adenosine triphosphatase (ATPase) or the β_2-adrenergic receptor improved cardiac function in animal models of heart failure. In each of these studies, overexpression of a single normal allele produced a therapeutic effect in an animal not known to have a specific genetic defect.

METHODS OF CARDIOVASCULAR GENE TRANSFER

To achieve delivery of a therapeutic gene product in vivo, three steps must occur: (1) recombinant DNA sequences must be introduced into the nucleus, (2) the DNA must be transcribed into RNA, and (3) the RNA must be translated into a functional protein. Steps 2 and 3 must occur in vivo; however, step 1, gene delivery, may be accomplished either "in vivo" or "ex vivo." In vivo gene transfer involves delivery of genetic material to cells within an intact animal (or human) tissue. Previously, ex vivo gene delivery involved removal of differentiated cells from the targeted tissue, gene transfer outside the organism, and reimplantation of the genetically modified cells into the tissue from which they were derived. However, the discovery that adult tissues may be colonized and possibly even regenerated by circulating or bone marrow-derived stem cells has opened the additional approach of stem cell removal, ex vivo gene transfer, and infusion of the genetically modified stem cells with targeting of the modified cells to a new location in a diseased tissue. Both in vivo and ex vivo gene therapy strategies have been used for cardiovascular gene therapy studies (Fig. 20-2).

EX VIVO GENE THERAPY In ex vivo gene therapy, cells are removed, maintained in culture, targeted with a therapeutic gene, and then reintroduced into the donor animal/patient. The role of the

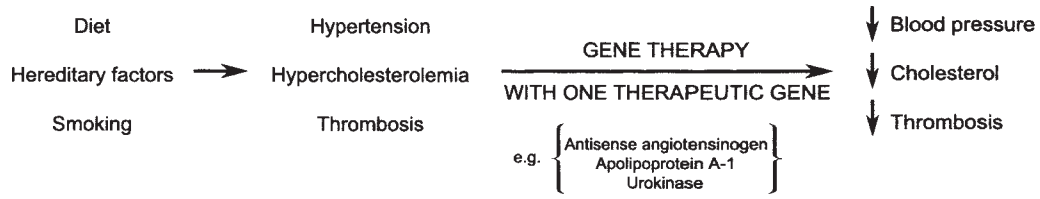

Figure 20-1 Gene therapy approaches to polygenic cardiovascular diseases. Environmental and hereditary factors are involved in the development of polygenic diseases such as hypertension, hypercholesterolemia, and thrombosis. Transfer of one therapeutic gene can potentially correct these polygenic diseases.

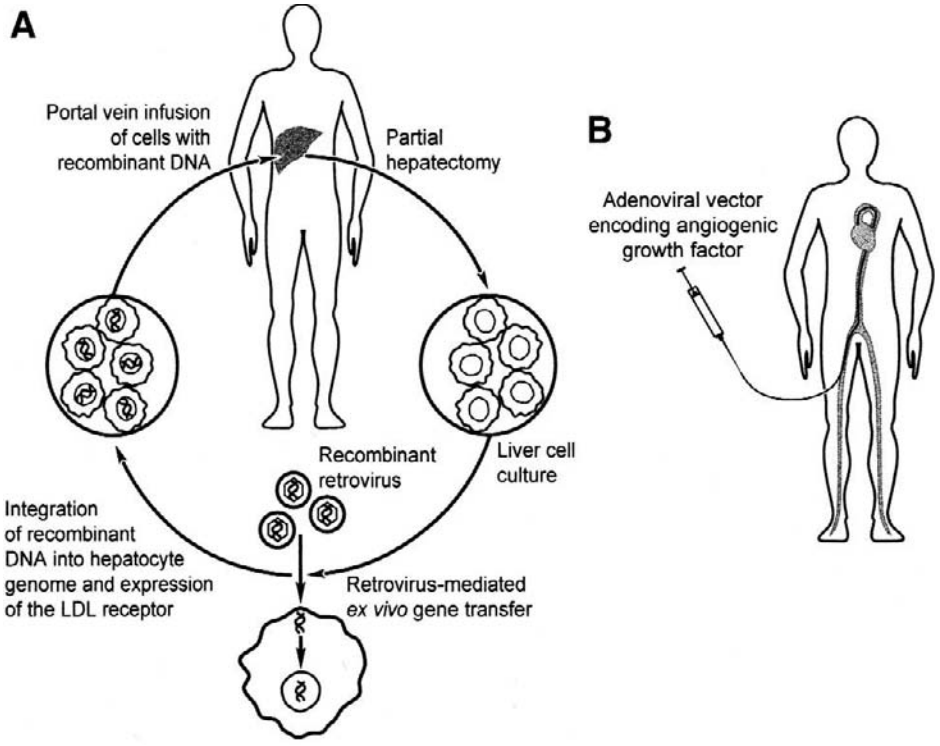

Figure 20-2 Methods for cardiovascular gene therapy. (**A)** Ex vivo gene transfer. This approach has been used to deliver the gene that encodes the low-density lipoprotein receptor to the liver in patients with FH. After partial hepatectomy, hepatocytes are transduced in vitro using a retrovirus vector, and recombinant DNA integrates into the hepatocyte genome. Finally, the transduced hepatocytes are reinfused via the portal vein. They exit the circulation and re-establish themselves within the liver. (**B)** In vivo gene transfer. A catheter is inserted into a peripheral artery and directed to the heart. This approach has been used to deliver genes that encode angiogenic growth factors, with the expectation that gene therapy will stimulate growth of collateral arteries and provide relief of myocardial ischemia.

reintroduced cells is primarily to deliver a recombinant gene product. The cells are usually not required to reconstitute a particular organ or tissue; therefore, the excised cells may be reimplanted in a location different from their site of excision. For example, hepatocytes harvested from one liver lobe and genetically modified ex vivo may be reinfused throughout the donor liver. Endothelial cells harvested from a donor vein or derived in vitro from progenitor cells harvested from the peripheral blood may be reimplanted as a luminal lining of an artery. Skeletal muscle cells or bone marrow stem cells might be harvested, genetically engineered to acquire biochemical features that are characteristic of cardiac myocytes, then reimplanted within the myocardium.

The primary advantages of ex vivo gene therapy are:

1. Gene delivery is performed under controlled, optimized conditions in which the efficiency of gene transfer into the targeted cells may be very high.
2. Gene delivery may be restricted to a specific cell type in which expression is optimized by careful design of a cell-type-specific transgene construct.
3. The potential for an immune response to the gene transfer vector is minimized by performing gene delivery in a setting remote from the host immune system (i.e., in a tissue culture dish).

The disadvantages of ex vivo gene transfer derive primarily from technical considerations:

1. Except in rare cases of monozygotic siblings, the requirements of histocompatibility mandate that the excised cells are reintroduced only into the donor individual. Thus, every animal (or human) receiving ex vivo gene therapy must undergo two invasive procedures: cell harvest and cell reintroduction.

2. Cell culture and ex vivo gene transfer must be performed under strict aseptic conditions to avoid the introduction of pathogenic microorganisms at the time of cell reimplantation.
3. The requirement that cells are removed and reinfused in ex vivo gene therapy imposes limitations on the type and number of cells that can be used. For cells to be removed for ex vivo genetic modification, they must be nonessential, and their removal and reimplantation must be practical. Thus, ex vivo cardiovascular gene therapy may be attempted with hepatocytes derived from partial hepatectomy and with endothelial and smooth muscle cells derived from excised, nonessential vessels. However, for cardiac gene therapy, the entire myocardium (or large sections of it) cannot be removed, engineered ex vivo, and reimplanted except as a brief, draconian procedure performed during cardiopulmonary bypass. Moreover, there is a limit to the number of cells that can be implanted en masse and survive after injection into the wall of a functioning heart.

IN VIVO GENE THERAPY The advantages and disadvantages of in vivo gene therapy are essentially the reverse of those of ex vivo gene therapy. Advantages of in vivo gene therapy include:

1. Only one invasive procedure is required (i.e., injection of the gene vector).
2. Laborious and technically demanding steps of cell harvesting and reimplantation are eliminated.
3. Any cell within an intact tissue or organ is theoretically a target for in vivo gene therapy.

The disadvantages of in vivo gene therapy are:

1. Gene delivery may be technically difficult. Gene transfer may need to be performed within the myocardium or in the presence of flowing blood in a narrow end-artery supplying an ischemic territory. In clinical settings such as these, the gene transfer vector may be washed away or undesirable clinical consequences (ischemia, infarction) may intervene before successful gene delivery.
2. The target cells for in vivo gene delivery are likely to be a heterogeneous population. Moreover, these cells are exposed to vector only transiently. Optimization of gene transfer and expression is more difficult under these conditions than with ex vivo, isolated cells.
3. There is an obligatory exposure of the gene transfer vector to the immune system. This exposure may produce an immune response that causes rejection of the transduced cells or blocks gene delivery entirely if the recipient organism is already immune to the gene transfer vector. In its most severe form, immune responses to the vector can precipitate a systemic inflammatory syndrome leading to multiorgan failure and death.

Despite these disadvantages, the practical advantages of in vivo vs ex vivo gene transfer are overwhelming. For this reason, virtually all ongoing cardiovascular gene therapy trials employ an in vivo gene transfer approach.

VECTORS

In general, the uptake of foreign genetic material (unmodified DNA or RNA) by mammalian cells is an inefficient process. This inefficiency makes sense teleologically, as there is little advantage for a cell to allow its highly regulated and evolved genetic program to be altered at random by fragments of DNA and RNA that land on its surface. Although there are notable exceptions, to introduce genetic material into mammalian cells with reasonable efficiency, it has been necessary for investigators to associate the genetic material with a "vector" that can mediate entry, nuclear transport, and, in some cases, chromosomal integration. Gene therapy vectors belong to two general categories: nonviral vectors, which mediate gene transfer largely by physical means; and viral vectors, which make use of viral proteins and nucleic acid sequences to mediate efficient gene transfer and occasional chromosomal integration (Table 20-2).

NAKED DNA AND NONVIRAL VECTORS Nonviral means of gene transfer include unmodified (naked) DNA, liposomes, and microparticle bombardment. The principal theoretical advantage of nonviral gene transfer is that the components can be prepared as standardized pharmaceutical reagents, which can maximize reproducibility and minimize toxicity. In some settings, nonviral gene transfer is quite effective. For example, muscle cells are particularly amenable to direct in vivo gene transfer with naked DNA. Promising preliminary clinical data has been reported from human trials using naked DNA injection into skeletal or cardiac muscle for cardiovascular gene therapy. However, the efficiency of gene transfer with nonviral vectors is low. In no case have naked DNA or other nonviral gene transfer approaches achieved long term, stable expression in the cardiovascular system nor have these approaches demonstrated unequivocal benefit in a clinical trial.

VIRAL VECTORS Retroviral, adenoviral, adeno-associated viral, and lentiviral vectors are in use for cardiovascular gene therapy in animal models. These vectors differ regarding their ability to integrate into chromosomal DNA, their efficiency of gene transfer, their capacity for incorporating foreign DNA, and their safety profiles. Retroviral and lentiviral vectors can mediate integration of therapeutic DNA into the target cell chromosome, permitting long-term expression of transgenes and ensuring transmission of inserted DNA to the progeny of transduced cells. Adeno-associated viral vectors integrate into chromosomal DNA in some cases, but are also able to persist as functional episomal (i.e., extrachromosomal) genetic elements. Adenoviral vectors integrate at a very low frequency but may also persist for years as functional episomal elements. In general, retroviral and lentiviral vectors are inefficient mediators of gene transfer to the cells of the cardiovascular system. Adeno-associated virus is able to transfer genes to hepatocytes and muscle cells with reasonable efficiency but is an inefficient vector for gene transfer to endothelium. In contrast, adenoviral vectors achieve efficient gene transfer to most cell types (including skeletal and cardiac muscle cells, hepatocytes, endothelial, and smooth muscle cells) and are, therefore, widely used in both preclinical studies and early cardiovascular gene therapy trials. Nevertheless, the clinical use of adenovirus has been limited by toxicity, immunogenicity, and brevity of expression. Engineering of the adenoviral genome and capsid proteins to decrease toxicity and immunogenicity has shown great promise in improving the safety profile of adenoviral vectors and in extending the duration of adenovirus-mediated transgene expression.

CURRENT STATUS AND FUTURE DIRECTIONS

ATHEROSCLEROSIS RESULTING FROM DYSLIPIDEMIA Because plasma LDL cholesterol is a genetically determined, major modifiable risk factor for the development and progression

Table 20-2
Major Advantages and Disadvantages of Available In Vivo Gene-Transfer Vectors

Method	*Advantages*	*Disadvantages*
Naked DNA	Favorable safety profile No integration into host genome[a] Permits large DNA inserts Easy to manipulate	Low efficiency
Liposomes	Favorable safety profile Wide range of target cells Permits large DNA inserts Commercially available	Low efficiency
Adenovirus	High efficiency Transduces nonreplicating cells No integration into host genome[a]	Derived from potential pathogen DNA insert size limited (<8 kb) except in helper-dependent vectors Direct toxicity Short duration of expression Inflammatory response Helper-dependent vectors difficult to produce
Retrovirus	Stable, long-term gene expression Probably safe in most clinical settings	Complex construction Low efficiency Potential reversion to replication competence Transduces replicating cells only Integration into host genome[a]; can cause insertional mutagenesis leading to malignancy
Adeno-associated virus	Long-term expression possible Parent virus is not a pathogen	DNA insert size limited (<5 kb) Less efficient than adenovirus, especially in vascular cells
Lentivirus	Stable, long-term expression Can transduce nondividing cells	Complex to produce Safety concerns regarding possible recombination with HIV Low efficiency

[a]Integration into the host genome might be favorable with respect to duration of expression; however, integration can also cause insertional mutagenesis.

of atherosclerotic cardiovascular disease, it is logical that gene therapy approaches for atherosclerosis have focused on lowering plasma LDL cholesterol. The first cardiovascular gene therapy trial, aimed at treatment of elevated plasma LDL cholesterol in patients with homozygous FH involved treatment of five FH patients with an ex vivo gene therapy strategy and revealed that the introduction of a normal LDL receptor allele was capable of increasing LDL catabolism and lowering LDL cholesterol in individual patients; however, in no case was LDL lowered to such an extent that any of the patients' cardiovascular disease risk was appreciably diminished. Moreover, the response of the patients was heterogeneous, with two of five showing no change in plasma LDL levels after gene therapy. The authors acknowledged that the inability to reconstitute more than a small fraction of the liver with genetically modified cells placed a severe limitation on this approach. The inefficiency of cell-based, ex vivo gene transfer forced them to forego further clinical trials and refocus their attention on achieving higher levels of hepatic gene transfer. This refocusing of attention eventually led to a clinical trial of in vivo adenovirus-mediated gene transfer for a metabolic disease. This trial, which appeared promising based on preclinical data, was terminated after a tragic death caused by a systemic inflammatory response to adenoviral vector infusion.

Other approaches to gene therapy for dyslipidemia that have shown promise in animal models include hepatic overexpression of the VLDL receptor to treat elevated LDL cholesterol and overexpression of apo A-I to raise plasma HDL levels. The rationale for the former approach is that the VLDL receptor can duplicate the function of the LDL receptor in removing atherogenic LDL particles from plasma. However, unlike the LDL receptor protein, which is a neoantigen and might therefore be immunogenic for patients with homozygous FH, the VLDL receptor protein is normally expressed by FH patients and should not be recognized as a neoantigen. The rationale for overexpression of apo A-I is that plasma HDL cholesterol is inversely correlated with atherosclerosis in humans; therefore, apo A-I expression leading to elevated plasma HDL might retard or reverse the progression of atherosclerosis. This rationale has received strong support in preclinical studies in which systemic infusion of adenoviral vectors expressing apo A-I have decreased atherosclerosis in animal models. Although expression of both the VLDL receptor and apo A-I appear powerful and feasible in animal models, these approaches generally require use of adenoviral vectors to achieve high levels of in vivo gene transfer to the liver. The unfavorable clinical experience with adenoviral gene transfer to the liver has therefore tempered enthusiasm for these approaches.

PERIPHERAL ARTERY DISEASE The identification and cloning of genes (such as vascular endothelial growth factor) that control the development and growth of blood vessels has inspired

several investigators to propose gene therapy for limb ischemia because of peripheral artery disease. According to this paradigm, delivery of a gene encoding an angiogenic protein in or near an ischemic territory will stimulate the growth of blood vessels and relieve the ischemia. Several groups have reported preclinical data generated in animal models of limb ischemia that support the validity of this approach. Based on these data, trials of human gene therapy for limb ischemia have been initiated, using either naked DNA or adenoviral vectors encoding vascular endothelial growth factor. Initial results show that this therapy appears safe and promising. However, definitive results showing persistent clinical benefits have not been reported.

Arterial aneurysm formation has also been a target of preclinical gene therapy studies. Transfer of genes encoding protease inhibitors to the artery wall has decreased the incidence of aneurysm rupture in animal models. These results are promising; however, technical challenges in achieving efficient in vivo gene transfer to human arteries and the likely requirement for long-term gene expression to prevent rupture of human aneurysms has thus far precluded clinical trials of this therapy.

ISCHEMIC HEART DISEASE Application of gene therapy to the treatment of ischemic heart disease has consisted primarily of efforts to stimulate growth of collateral vessels that bypass occluded or stenotic coronary arteries. These efforts are analogous to attempts (discussed earlier) to stimulate blood vessel growth in ischemic limbs. Again, studies in animal models of myocardial ischemia support the promise of a gene therapy approach. Clinical human gene therapy trials designed to promote myocardial angiogenesis, first reported in 1998, have been conducted using both plasmids and adenovirus, delivered either by direct myocardial injection during an open surgical procedure or by percutaneous catheter-based approaches. As with clinical studies of gene therapy for peripheral vascular disease, gene therapy trials for myocardial angiogenesis have shown that the therapy, as administered, appears safe. These trials have also suggested the presence of therapeutic effects, for example, improvements in myocardial perfusion scans, increased exercise tolerance, and decreased angina. Nevertheless, convincing evidence of patient benefit, obtained in an adequately powered, double blind, placebo-controlled trial, remains lacking. Larger trials, in progress, may provide this evidence.

Gene therapy approaches are also being developed with the goal of preventing myocardial damage during and after an ischemic episode. These approaches are based on the hypothesis that cardiomyocytes can be reprogrammed, by gene transfer, to resist both ischemia and postischemia reperfusion injury. Genes that have shown promise in animal models of ischemia/reperfusion include heme oxygenase, the antioxidants catalase and superoxide dismutase, and the protein kinase Akt. Challenges that must be met in extending these exciting findings to the clinic include achievement of efficient in vivo gene transfer to human myocardium and the need to accomplish gene delivery well in advance of a major ischemic episode. This latter consideration suggests that long-term, stable myocardial gene expression will be required in order for this approach to yield clinical benefit.

RESTENOSIS AFTER ANGIOPLASTY Demonstration of successful in vivo gene transfer into injured mammalian arteries with both viral and nonviral gene transfer systems, along with the availability of animal models of local arterial injury, have stimulated several groups to develop and test gene therapy approaches to prevent restenosis after angioplasty. Transfer into injured arteries of cytotoxic genes (such as herpesvirus thymidine kinase) or cytostatic genes (such as mutant, nonphosphorylatable retinoblastoma protein), decreased neointimal formation in animal models. Alternatively, transfer of "protective" genes, such as nitric oxide synthase, heme oxygenase, or hirudin, at the time of arterial injury also reduced neointimal formation. Other gene therapy approaches to the prevention of restenosis include expression of genes that block mitogenic signals, interfere with proteolysis (a process thought to play a major role in cell migration and remodeling), block matrix accumulation (e.g., by interfering with the action of transforming growth factor β_1), or maintain vascular smooth muscle cells in a contractile, nonproliferative state.

The overwhelming success of gene transfer in limiting neointimal formation in animal models has suggested that gene therapy to prevent restenosis would be the first human application of cardiovascular gene therapy. Indeed, restenosis is a reasonable target for gene therapy in that it is a focal disease, occurring at a location that is by definition accessible to percutaneous gene therapy approaches. However, gene therapy for restenosis was replaced by angiogenic gene therapy as the most clinically advanced cardiovascular gene therapy application. The reasons for the decline in interest in gene therapy for restenosis are instructive:

1. Alternative therapies, first metallic stents and then drug-eluting stents, have had a major impact on the incidence of restenosis. Gene therapy will always need to compete with other approaches and is most likely to be tried when effective therapies are lacking.
2. Local gene delivery in the human coronary circulation is far more challenging than in an isolated peripheral animal artery (Fig. 20-3). In contrast to animal experiments in which efficient gene therapy limits neointimal growth in a peripheral artery, it is unfeasible to isolate a human coronary artery lumen (maintaining both proximal and distal occlusion whereas preventing leakage via side branches) and maintain an elevated infusion pressure during 20 min of gene delivery. Although several local delivery catheters have been developed with the goal of optimizing gene delivery to the coronary artery wall, none appears able to achieve efficient, uniform vascular gene transfer while avoiding significant systemic vector release.
3. Direct vascular toxicity and proinflammatory effects of adenovirus (the most widely used vector for vascular gene transfer) may counteract the salutary effects of gene therapy.

Documentation of the proinflammatory effects of adenovirus when infused in the artery wall, a growing appreciation of the fundamental contribution of vascular wall inflammation to the pathogenesis of atherosclerosis, and the chilling effect of an adenovirus-related human death have moderated enthusiasm for restenosis gene therapy.

HEART FAILURE For many years, patients with heart failure because of impaired systolic function had a dire prognosis and few therapeutic options. For this reason, gene therapy to improve systolic function could fill a significant, unmet clinical need. This unmet need has inspired investigators to develop gene therapy approaches to improve cardiac systolic function. These approaches have been tested in animals in which heart failure is induced by interventions such as experimental infarction or aortic banding. They have also been tested in the cardiomyopathic hamster, an animal model of congenital, genetically based cardiomyopathy such as that found in humans with muscular dystrophy or storage diseases such as Pompe's disease.

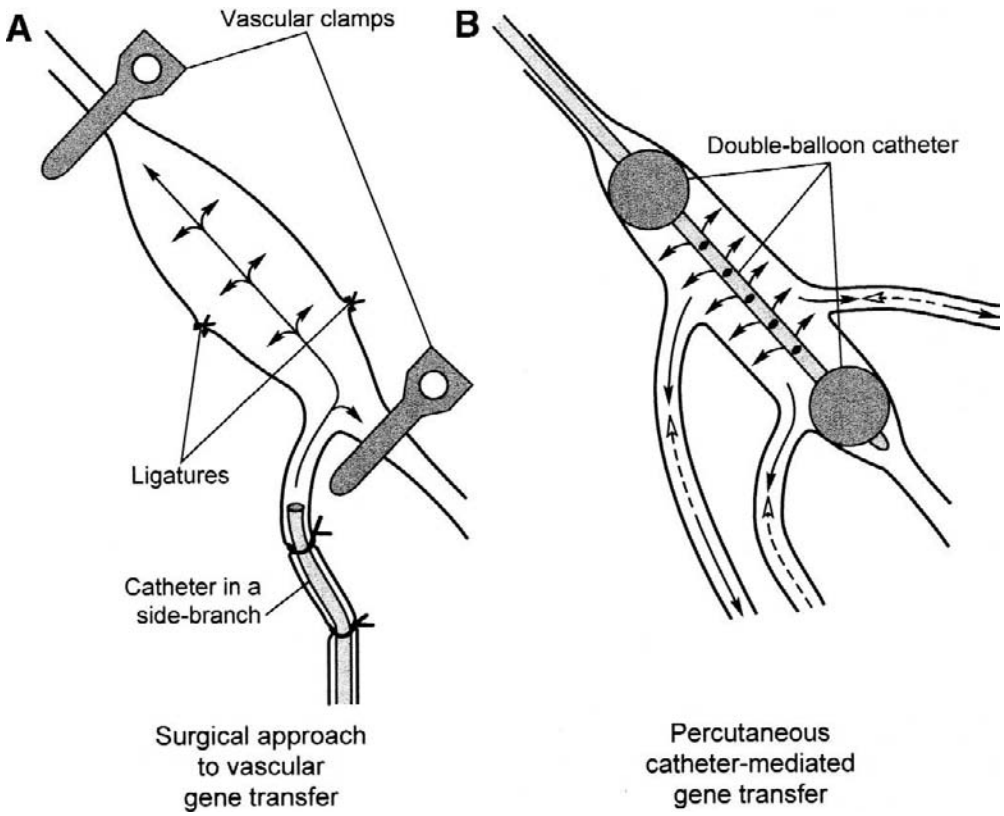

Figure 20-3 Methods for in vivo arterial gene transfer. (**A**) Surgical approach. Side branches are ligated and the target vessel segment is clamped proximally and distally. Infusion is performed under direct vision, and the vessel wall is maintained in a distended state by the infusion pressure. Systemic spread of the recombinant gene is limited. (**B**) Potential percutaneous approach. The recombinant gene is delivered through a double-balloon (or other local delivery) catheter. Systemic leakage via the side branches cannot be avoided, and distension cannot be maintained. In addition, collateral flow (dotted arrows) may enter the occluded artery and dilute or neutralize the vector solution. Gene delivery will likely be decreased and systemic exposure increased compared to the surgical approach. The use of double balloon catheters for arterial gene transfer has largely been via a surgical approach using direct vision and ligation of branch vessels as in (**A**).

Table 20-3
Hemodynamic Effects of SERCA2a Overexpression in Rat Hearts

Treatment	*HR, beats/min*	*LVSP, mmHg*	*+ dP/dt, mmHg/s*	*– dP/dt, mmHg/s*
Ad.βgal	442 ± 27	112 ± 24	5387 ± 818	–3748 ± 458
Ad.SERCA2a	440 ± 21	147 ± 22[a]	7924 ± 1857[a]	–6782 ± 971[a]

[a] $p < 0.05$ compared to Ad.βgal. (Reproduced with permission from Miyamoto MI, del Monte F, Schmidt U, et al. Adenoviral gene transfer of SERCA2a improves left-ventricular function in aortic-banded rats in transition to heart failure. Proc Natl Acad Sci USA 2000;97:793–798. Copyright 2000 National Academy of Sciences.)

Measurements were made 7 d after in vivo gene transfer with a control adenovirus expressing β-galactosidase (Ad.βgal) or an adenovirus expressing SERCA2a (sarcoplasmic reticulum calcium ATPase); HR, heart rate; LVSP, left-ventricular systolic pressure; + *dP/dt*, maximal rate of rise of left-ventricular pressure (a measure of cardiac contractile function); – *dP/dt*, maximal rate of decline of left-ventricular pressure (a measure of the ability of the heart to relax after contraction).

Cardiomyocyte-directed gene therapy for systolic dysfunction has produced impressive results in animal models. Gene delivery to cardiomyocytes is most often accomplished by intracoronary infusion of adenoviral vectors, either in vivo or ex vivo. To optimize myocardial gene transfer, in some cases the aorta is cross-clamped and the vector is injected either within the left ventricle or into the aortic root. Although the aorta remains clamped, the vector recirculates through the coronary arteries and veins as the heart contracts, providing repeated opportunities for gene transfer vectors to leave the vasculature and enter a cardiomyocyte. Using this approach, alteration of cardiomyocyte calcium handling by overexpression of sarcoplasmic reticulum Ca^{2+} ATPase (Table 20-3) or enhancement of β-adrenergic signaling either by overexpression of β_2-adrenergic receptors, expression of a dominant negative β-adrenergic receptor kinase (which interferes with downregulation of β-receptor signaling), or overexpression of adenylyl cyclase have all been effective in enhancing systolic function and decreasing progression to heart failure. Other animal studies reveal that myocardial gene transfer can inhibit the development of pressure-overload hypertrophy and prevent development of diastolic and systolic dysfunction.

Major challenges in applying gene therapy for heart failure to human disease include identification of a vector that will express a transgene in the heart for a prolonged period of time

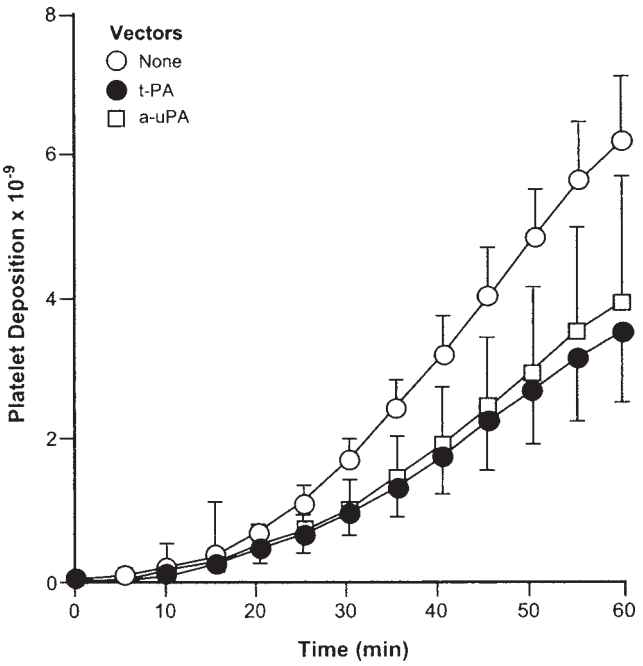

Figure 20-4 Gene therapy to prevent prosthetic graft thrombosis. Deposition of Indium-labeled platelets is measured on thrombi associated with synthetic vascular grafts. Grafts were seeded at equivalent densities with either untransduced endothelial cells or genetically engineered endothelial cells and exposed to flowing blood in a baboon ex vivo arteriovenous shunt. Data points are real-time measurements of platelet deposition, for untransduced endothelial cells (open circles; $n = 13$), endothelial cells transduced with a retroviral vector expressing human tissue plasminogen activator (t-PA; closed circles, $n = 8$), and a retroviral vector expressing a form of u-PA that is anchored to the cell membrane (a-uPA; $n = 5$). Bars represent standard error of the mean. (Reproduced with permission from Dichek et al., 1996.)

and verification that intracoronary vector infusion in humans is both safe and highly efficient in transducing cardiomyocytes. Reports of long-term transgene expression in animal hearts injected with adeno-associated viral and lentiviral vectors are encouraging. Nevertheless, a diseased heart in an octogenarian with a propensity to develop lethal arrhythmias is a far more challenging target for safe and effective gene transfer than the heart of an otherwise healthy laboratory animal. Finally, it is sobering to appreciate that certain medical interventions (such as phosphodiesterase inhibition) that have boosted systolic performance and improved patient well-being were ultimately linked with accelerated mortality. Gene therapy for systolic dysfunction will need to avoid this pitfall.

CARDIAC DYSRHYTHMIAS Increased understanding of the molecular basis of cardiac conduction and identification of the genes that control the electrical events leading to depolarization and repolarization of cardiomyocytes has suggested that disorders of cardiac conduction might be treated by gene therapy. A seminal study in this area showed that gene transfer leading to expression, within porcine atrioventricular nodal cells, of a gene that inhibits β-adrenergic signaling significantly decreased the ventricular response to atrial fibrillation. A subsequent study demonstrated that expression in porcine myocardium of a gene that inhibits a specific cardiac potassium channel created a cellular "pacemaker" capable of depolarizing the ventricular myocardium. This biologically driven pacemaker could potentially substitute for dysfunctional endogenous cardiac pacemaker tissue and prevent slow heart rates. These two studies reveal the potential for gene therapy to treat both tachyarrythmias (by increasing conduction block) or bradyarrythmias (by inducing spontaneous depolarizations). These are exciting findings; however, to be therapeutically useful, molecular electrophysiological approaches will need to rely on long-term, stable gene expression and will need to prove their value in comparison to well-established device and drug strategies for managing arrhythmias.

THROMBOSIS Gene therapy for thrombosis initially focused on the thrombotic problems of intravascular prosthetic devices such as grafts and stents and on preventing thrombosis associated with angioplasty-induced arterial injury. Because intravascular prosthetic devices are acellular and cannot be targeted by in vivo gene transfer, an ex vivo, cell-based gene therapy strategy is obligatory. According to this strategy, endothelial cells are harvested from a superficial, nonessential vein and transduced with genes that express either t-PA or u-PA. These fibrinolytically "enhanced" cells are then seeded onto the surface of prosthetic devices before the devices are implanted. When the devices are implanted in vivo, increased expression of t-PA or u-PA could prevent device thrombosis. With this approach, overexpression of t-PA or u-PA from seeded endothelial cells decreased thrombus deposition onto a synthetic arteriovenous shunt placed in a baboon (Fig. 20-4). This antithrombotic effect was unaccompanied by evidence of systemic fibrinolysis, proving the concept that genetic manipulation of endothelial cells can decrease local thrombosis without creating a systemic fibrino(geno)lytic state. Although theoretically promising, these data are derived from very short-term experiments (1 h), whereas the clinical problem that they address (device thrombosis) may extend over years. The clinical utility of seeding vascular devices with genetically "enhanced" cells will depend on the availability of data showing that these cells or their progeny survive for prolonged periods of time after introduction in vivo. Progress relevant to this area includes the development of vectors capable of long-term in vivo transgene expression, such as adeno-associated virus and lentivirus, and the discovery that endothelial progenitor cells may be harvested from human peripheral blood and expanded ex vivo. These circulating progenitor cells could serve as a convenient source of endothelial cells that would be genetically modified and then used to line surfaces of intravascular prosthetic devices.

Other work on antithrombotic gene therapy has focused on decreasing thrombus formation in native arterial tissue. The rationale for this approach is that enhancement of the antithrombotic properties of the arterial surface will prevent the intravascular thrombotic events that precipitate myocardial infarctions and strokes. This approach could also be applied to venous tissue, to prevent venous thromboembolism. Antithrombotic gene therapy with a goal of preventing strokes and infarctions is supported by a large amount of clinical data showing efficacy of systemic antithrombotic and anticoagulant drugs such as aspirin, other platelet inhibitors, and coumadin. Because the efficacy of these systemically administered drugs is limited by systemic side effects, it is rational to replace them with targeted, local antithrombotic therapy that is limited to the artery or venous wall. Using this strategy, antithrombotic therapy would be delivered to the site of disease, and systemic side effects would be minimized.

The feasibility of antithrombotic gene therapy has been demonstrated in animal models of nondenuding arterial injury and in models of balloon injury. In the latter case, the clinical application

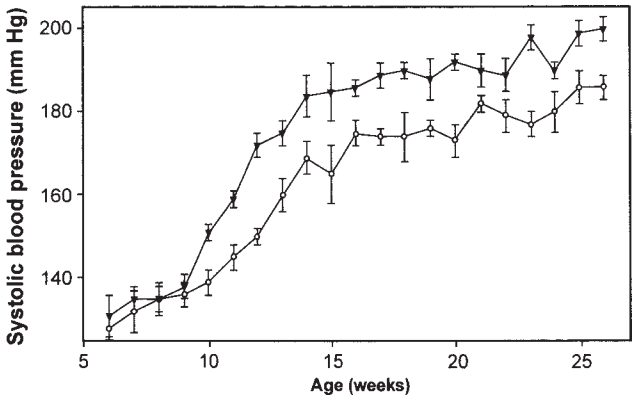

Figure 20-5 Gene therapy for hypertension. Spontaneously hypertensive rats (5-d-old) were given a single intracardiac injection of an adeno-associated viral vector expressing either sense angiotensinogen (triangles; $n = 6–10$) or antisense angiotensinogen (circles; $n = 8–15$). Systolic blood pressure was measured weekly. $p < 0.001$ between treatments and between times by two-way ANOVA. (Reproduced with permission from Kimura et al., 2001.)

of this technique would involve arterial gene transfer after angioplasty or surgical endarterectomy and would substitute antithrombotic gene therapy for the systemic antithrombotic drug therapy that is administered. Thus, both t-PA and thrombomodulin gene transfer decreased thrombus formation in nondenuded animal arteries. Gene therapy with tissue factor pathway inhibitor and C-type natriuretic peptide decreased thrombus formation in injured animal arteries. In all cases adenoviral vectors were used, and the studies were all short term. Improved vectors are needed to explore the potential of these approaches to provide durable protection against intravascular thrombosis and its complications.

HYPERTENSION Human hypertension is a lifelong disease treated with lifelong, often multiple-drug therapy. This therapy is usually effective; however it is expensive, tedious for patients, and often accompanied by side effects. Gene therapy for hypertension provides the exciting possibility that a common, lifelong disease could be more conveniently and effective treated by the transfer and expression of a single gene. The power of gene therapy and the potential that it might someday revolutionize medical care is perhaps most evident in the context of common diseases such as hypertension.

Preclinical studies in animal models of systemic hypertension have yielded promising results. Systemic gene therapy with genes expressing vasodilator proteins such as kallikrein, adrenomedullin, and nitric oxide synthase have been effective in lowering blood pressure in hypertensive animals for up to 12 wk. Other investigators have used viral vectors to express full-length antisense transcripts that decrease expression of molecules that contribute to elevated blood pressure. For example, an adeno-associated virus vector encoding antisense transcripts to angiotensinogen decreased blood pressure in spontaneously hypertensive rats for up to 6 mo (Fig. 20-5). Systemic, antisense-mediated inhibition of β_1 adrenergic receptor expression also produced an antihypertensive effect.

Phase one clinical trials of antihypertensive gene therapy may be near. As these trials are initiated, it will be important to address several issues:

1. The applicability of studies in specific animal models to the pathophysiology of hypertension in humans.
2. The requirement for long-term, stable expression and the potential need for repeated gene delivery.
3. The need to develop practical means for the adjustment or reversal of antihypertensive gene therapy, should the effect of the inserted gene prove detrimental over time.

CONCLUSION

A variety of mono- and polygenic cardiovascular diseases are potentially treatable with gene therapy. Extensive animal studies and initial human trials have confirmed that genes with therapeutic effects within the cardiovascular system may be introduced in vivo. Nevertheless, practical concerns relating to the achievement of safe, efficient, and long-lasting gene therapy continue to dominate the field. It might be said that the understanding of the genetic basis of cardiovascular disease has outpaced the development of genetic technologies to alter its natural history. To be therapeutically useful, gene transfer techniques must, in general, achieve high efficiency, prolonged gene expression, and tissue-specific targeting, whereas avoiding induction of destructive inflammatory and immune responses. Each of these goals represents a substantial technical challenge. In addition, as progress extends beyond the initial excitement of overcoming technical hurdles and beginning clinical trials, gene therapy must ultimately prove its safety, efficacy, and even its superiority in relation to more traditional therapeutic interventions. Only then will gene therapy gain acceptance as a treatment for cardiovascular disease.

21 Idiopathic Interstitial Pneumonias

TALMADGE E. KING, JR.

SUMMARY

In the past decade, concepts in classification, pathogenesis, and histopathology of the idiopathic interstitial pneumonias have undergone considerable change. This evolution has had a substantial impact on the approach to the diagnosis and clinical management of these patients. Some of the changes have led to considerable confusion, especially with entities such as nonspecific interstitial pneumonia. A firm grasp of the basis for separating these disorders is essential for any physician involved with the care of these patients. In this chapter, the importance of integrating clinical, radiological, and pathological information to achieve an accurate diagnosis will be emphasized.

Key Words: Acute interstitial pneumonia (AIP); cryptogenic organizing pneumonia (COP); desquamative interstitial pneumonia (DIP); familial pulmonary fibrosis; histopathology; idiopathic interstitial pneumonias; idiopathic pulmonary fibrosis (IPF); lung imaging; lymphoid interstitial pneumonia (LIP); nonspecific interstitial pneumonia (NSIP); pulmonary physiology; respiratory bronchiolitis-associated interstitial lung disease (RB-ILD).

INTRODUCTION

The consensus statement from the American Thoracic Society (ATS) and the European Respiratory Society (ERS) defined the idiopathic interstitial pneumonias (IIPs) as a heterogeneous group of non-neoplastic disorders resulting from damage to the lung parenchyma by the varying patterns of inflammation and fibrosis, which are sufficiently different from one another to be designated as separate disease entities (Fig. 21-1). The ATS/ERS IIPs classification includes seven clinico-radiological-pathological entities in order of relative frequency: idiopathic pulmonary fibrosis (IPF), nonspecific interstitial pneumonia (NSIP), cryptogenic organizing pneumonia, respiratory bronchiolitis-associated interstitial lung disease (RB-ILD), desquamative interstitial pneumonitis (DIP), acute interstitial pneumonia, and lymphoid interstitial pneumonia. As a group they can be distinguished from other forms of diffuse parenchymal lung disease by clinical methods including history, physical examination, chest radiology and laboratory studies, and pathology. Achieving a correct diagnosis is a dynamic process. The final diagnosis is rendered only after the pulmonologist, radiologist, and pathologist have reviewed the clinical, radiological, and pathological data.

Table 21-1 provides a brief summary of the clinical features of the IIPs. IPF is the most common and most lethal interstitial lung disease of unknown etiology. Of patients with IPF, approximately two-thirds are older than 60 yr at the time of presentation. IPF has no distinct geographic distribution and the majority of the patients reported are Caucasians. The incidence is estimated at 10.7 cases/100,000/yr for males and 7.4 cases/100,000/yr for females. The prevalence of IPF is estimated at 20/100,000 for males and 13/100,000 for females. The typical patient reports progressive dyspnea over months to years and a chronic nonproductive cough. Physical exam of the chest often reveals bibasilar fine inspiratory crackles (so-called "Velcro" crackles). Pulmonary function testing shows restrictive lung disease (decreased forced vital capacity and total lung capacity) and abnormal gas exchange (decreased carbon monoxide diffusion capacity and resting or exercise PaO_2). A surgical lung biopsy showing a histological pattern of usual interstitial pneumonia (UIP) is often required to make a definitive diagnosis. A remarkable feature is the relentless progression to death (often following an acute exacerbation) despite aggressive treatment with immunosuppressive drugs.

HISTOPATHOLOGICAL SUBGROUPS

The histological patterns seen by pathologists allow for better separation of the IIPs than the imaging patterns seen by radiologists. Therefore, the histological patterns provide the primary basis for the various categories of IIP and serve as the foundation for the classification.

The most important histopathological finding is the presence of UIP, the pattern seen in IPF. Importantly, the various histopathological patterns found among the IIPs can be seen in other conditions, for example, drug reactions, connective tissue diseases. This is especially true of NSIP pattern, which has been described in a variety of conditions including collagen vascular disease, hypersensitivity pneumonitis, recent acute lung injury, and drug reactions. Also, different histological subtypes can be found in the lungs of the same patient and even in the same lobe of the lung. Therefore, before the diagnosis of IIP is made, a careful clinical evaluation is important to rule out associated conditions.

USUAL INTERSTITIAL PNEUMONIA UIP is characterized by a heterogeneous, predominantly subpleural distribution of involvement, a pattern distinguishable even on low power magnification (Fig. 21-2). There is temporal heterogeneity, with areas of end-stage fibrosis and "honeycombing" (thickened collagenous septae surrounding airspaces lined by bronchial epithelium) abutting

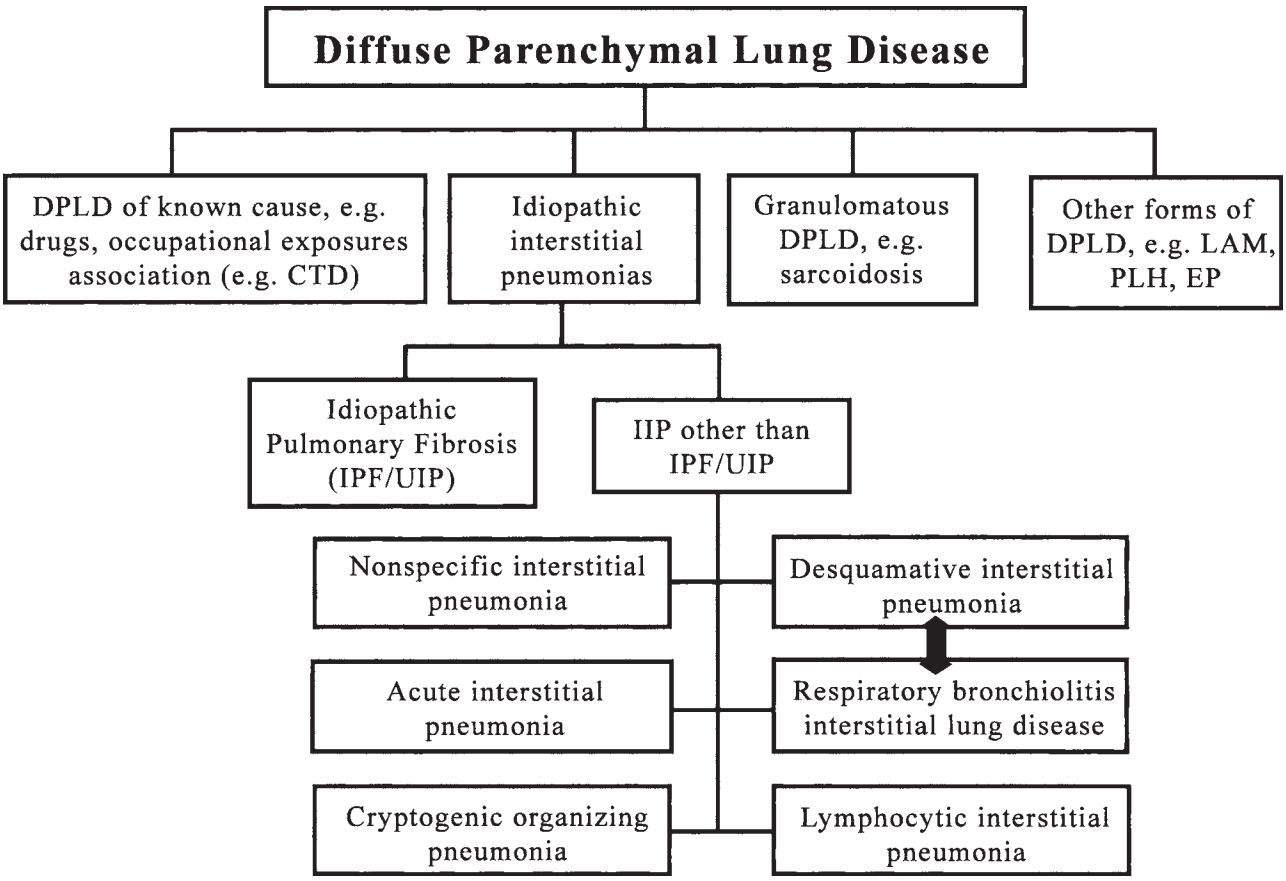

Figure 21-1 Diffuse parenchymal lung diseases consist of disorders of known causes (connective tissue diseases, environmental and occupational exposures, or drug related) as well as disorders of unknown cause. The latter include IIPs, granulomatous lung disorders (e.g., sarcoidosis), and other forms of interstitial lung disease including lymphangioleiomyomatosis, pulmonary Langerhans' cell histiocytosis/histiocytosis X, and eosinophilic pneumonia. The most important distinction among the IIPs is that between IPF/UIP and the other interstitial pneumonias, which include NSIP, DIP, respiratory bronchiolitis-associated interstitial lung disease (DIP and respiratory bronchiolitis-associated interstitial lung disease are considered part of the same spectrum of smoking-related diseases), AIP, cryptogenic organizing pneumonia, and lymphocytic interstitial pneumonia. (Adapted with permission from Travis WD, King TE Jr, Bateman ED, et al. CTD, connective tissue disease; EP, eosinophilic pneumonia; IPF, Idiopathic pulmonary fibrosis; LAM, lymphangioleiomyomatosis; UIP, usual interstitial pneumonia.

areas of active proliferation of fibroblasts and myofibroblasts. These discrete areas of acute fibroblastic proliferation have been termed "fibroblastic foci," and are essential to the histopathological diagnosis of UIP. There is generally minimal interstitial inflammation, and if present in significant amounts, the histopathological diagnosis should be reconsidered.

NONSPECIFIC INTERSTITIAL PNEUMONIA NSIP is characterized by varying degrees of inflammation and fibrosis (Fig. 21-3). Although NSIP may have significant fibrosis, it is usually of uniform temporality, and fibroblastic foci and honeycombing, if present, are rare. The temporal uniformity is distinctly different from the lack of temporal uniformity seen in UIP. Nonetheless, fibrotic NSIP can be difficult to reliably distinguish from UIP and there is significant interobserver variability even among expert histopathologists.

ORGANIZING PNEUMONIA Organizing pneumonia shows patchy lung involvement by loose plugs of connective tissue within alveolar ducts and alveolar spaces with or without bronchiolar intraluminal polyps (Fig. 21-4). The majority of changes center on small airways. There is a mild associated interstitial inflammatory infiltrate, type-II cell metaplasia, and an increase in alveolar macrophages, some of which may be foamy. A small amount of airspace fibrin may be focally present. The architecture of the lung is preserved and the connective tissue is all the same age.

DESQUAMATIVE INTERSTITIAL PNEUMONIA AND RESPIRATORY BRONCHIOLITIS INTERSTITIAL LUNG DISEASE DIP (Fig. 21-5) and RB-ILDs (Fig. 21-6), once considered distinct entities are arguably different manifestations of the same condition. DIP/ RB-ILD is distinct in histopathological appearance from UIP, with a much more homogeneous geographic distribution. There is significantly less septal thickening, and fibroblastic foci and honeycombing are absent. The most striking feature of these two conditions is the filling of alveoli by pigment-laden macrophages. If the macrophage infiltrate is predominantly peribronchiolar, the term RB-ILD is used. If there is widespread alveolar involvement, the process is called DIP.

ACUTE INTERSTITIAL PNEUMONIA (DIFFUSE ALVEOLAR DAMAGE) Acute interstitial pneumonia is a diffuse, fibroproliferative process indistinguishable from the organizing stage of diffuse alveolar damage, the histopathological corollary of acute respiratory distress syndrome (Fig. 21-7). The exudative phase shows edema, hyaline membranes, and interstitial acute inflammation. Thrombi

Table 21-1
Clinical Features of the IIPs

	IPF/UIP	*NSIP*	*COP*	*DIP/RB-ILD*	*AIP*	*LIP*
Prodrome	Chronic (>12 mo); Men > women	Subacute to chronic (months to years); women > men	Subacute (<3 mo)	Subacute (weeks to months); current or former smoker	Abrupt (1–2 wk)	Chronic (>12 mo); women
Chest X-ray	Bilateral, lower zones, reticular opacities; volume loss; ± honeycombing	Bilateral hazy and reticular opacity	Patchy bilateral consolidation	Ground glass opacities in the lower zones	Diffuse, bilateral, ground glass opacities/progression to consolidation	Reticular opacities, nodules
HRCT	Peripheral, subpleural, basal predominance; reticular opacities, architectural distortion; traction bronchiectasis/ bronchiolectasis; honeycombing	Peripheral, subpleural, basal, symmetric; ground glass attenuation; consolidation; lower lobe volume loss	Subpleural/peribronchial; patchy consolidation and/or nodules	DIP: Diffuse ground glass opacity in the middle and lower lung zones; RB-ILD: bronchial wall thickening; centrilobular nodules; patchy ground glass opacity	Diffuse, bilateral ground glass opacities often with lobular sparing	Diffuse; centrilobular nodules, ground glass attenuation, septal and broncho-vascular thickening, thin-walled cysts
Treatment	Poor response to corticosteroid or cytotoxic agents	Corticosteroid responsiveness	Corticosteroid responsiveness	Smoking cessation; corticosteroid responsiveness	Mechanical ventilation; corticosteroid responsiveness unknown	Corticosteroid responsiveness
Prognosis	50–70% mortality in 5 yr	Unclear; <10% mortality in 5 yr	Rare deaths	5% mortality in 5 yr	60% mortality in <6 mo	Not well defined.

AIP, acute interstitial pneumonia; COP, cryptogenic organizing pneumonia; DIP, desquamative interstitial pneumonitis; IPF, idiopathic pulmonary fibrosis; LIP, lymphoid interstitial pneumonia; NSIP, nonspecific interstitial pneumonia; RB-ILD, respiratory bronchiolitis-associated interstitial lung disease; UIP, usual interstitial pneumonia.

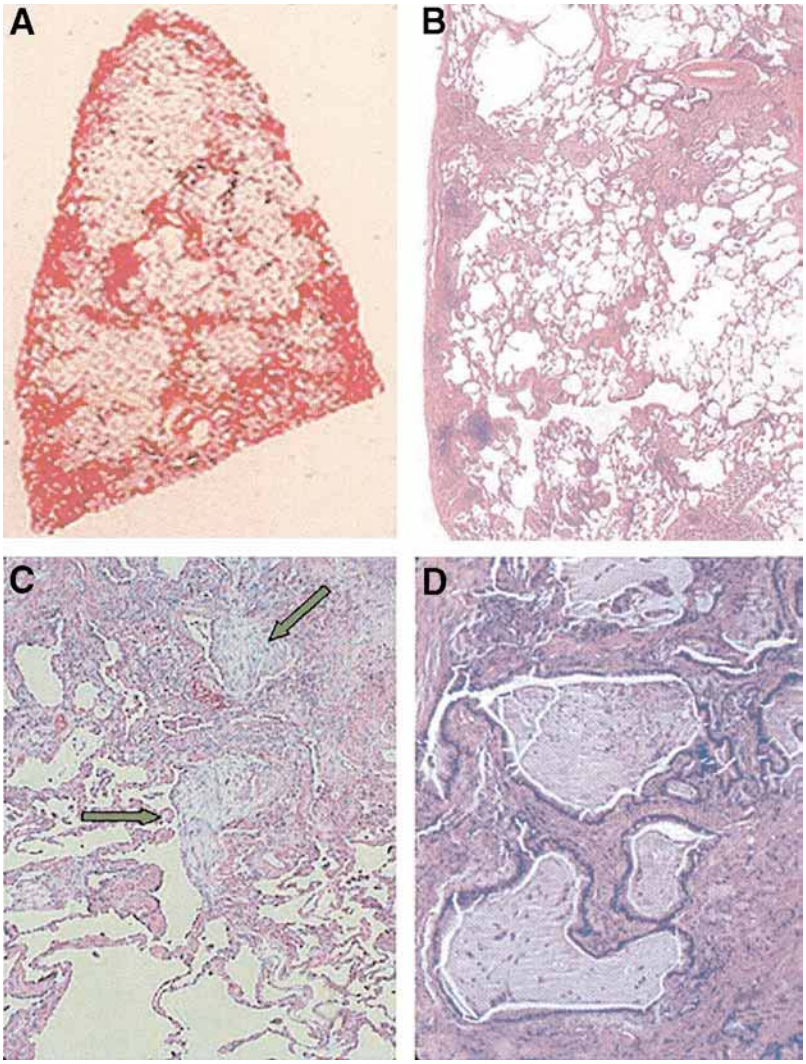

Figure 21-2 UIP pattern. These photomicrographs (H&E) of the pathological lesions appear to characterize the steps in progression of UIP. **(A)** Macroscopic view of lung biopsy showing that the lung injury is patchy and confined to the subpleural region. **(B)** Low magnification view shows marked fibrosis and cystic changes, with a striking subpleural distribution. Interstitial chronic inflammation is mild with a few lymphoid aggregates. **(C)** Multiple fibroblastic foci (arrows) of loose organizing connective tissue are the "leading edges" of the progressive fibrotic process. **(D)** Microscopic view of honeycombing. This process is irreversible.

are common in small to medium-sized pulmonary arterioles. The organizing phase shows loose organizing fibrosis, mostly within alveolar septa and type-II pneumocyte hyperplasia. There is widespread proliferation of fibroblasts and myofibroblasts, with minimal inflammatory infiltrate. The fibrotic changes are temporally homogeneous, and may be accompanied by the presence of hyaline membranes. With time, end-stage fibrosis develops and large cystic airspaces form. These cystic spaces are lined with alveolar epithelium, not bronchial epithelium as seen in the honeycombed spaces in UIP. The lungs may also progress to end-stage honeycomb fibrosis. However, if the patient survives, the lungs may resolve to normal.

LYMPHOID INTERSTITIAL PNEUMONIA Lymphoid interstitial pneumonia is characterized by a dense interstitial lymphoid infiltrate, including lymphocytes, plasma cells, and histiocytes with associated type-II cell hyperplasia and a mild increase in alveolar macrophages (Fig. 21-8). The alveolar septa are usually extensively infiltrated. Lymphoid follicles (follicles with germinal centers) are often present, usually in the distribution of pulmonary lymphatics. Some architectural derangement (including honeycombing) and non-necrotizing granulomas may be seen. Intra-alveolar organization and macrophage accumulation may also be present, but only as minor components.

PATHOGENESIS OF LUNG FIBROSIS

Lung fibrosis is the final common pathway of a variety of insults to the lung including infectious, toxic, drug-induced, autoimmune, or traumatic injuries. The pathogenesis of lung fibrosis remains incompletely understood. However, there has been a major paradigm shift away from the prevailing theory that generalized inflammation progressed to widespread parenchymal fibrosis. The model emphasizing the role of inflammation may remain applicable to interstitial lung diseases that respond to anti-inflammatory agents (e.g., NSIP, hypersensitivity pneumonitis, and organizing pneumonia). However, the lack of a similar response to anti-inflammatory agents in patients with the UIP pattern provides strong evidence that inflammation does not play a critical role in the progressive and irreversible phase of this disease. In this context, there are two

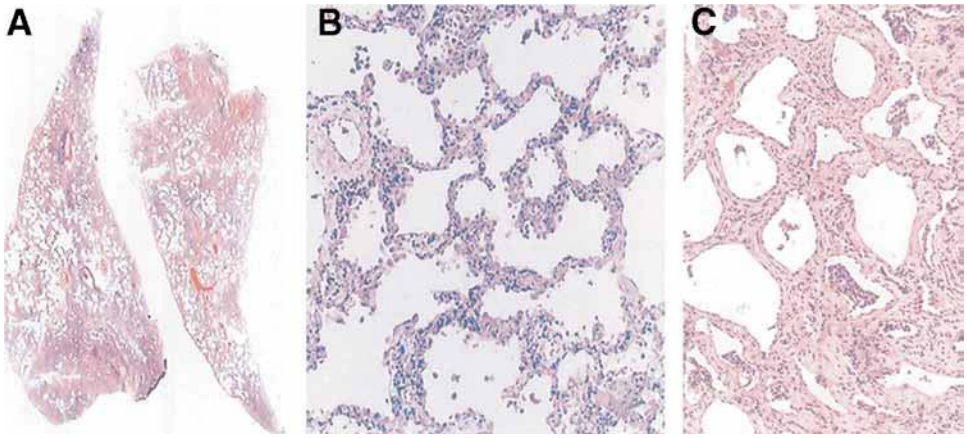

Figure 21-3 NSIP pattern. These photomicrographs (H&E) of the pathological lesions appear to characterize the steps in progression of NSIP. **(A)** Macroscopic view of lung biopsy showing that the lung is diffusely injured. **(B)** Early stage showing a cellular chronic interstitial inflammation (small lymphocytes and plasma cells)—this process appears to be reversible. **(C)** A later stage that shows diffuse thickening of the alveolar by fibrosis and mild interstitial inflammation. Alveolar pneumocyte hyperplasia is present. No fibroblastic foci are present.

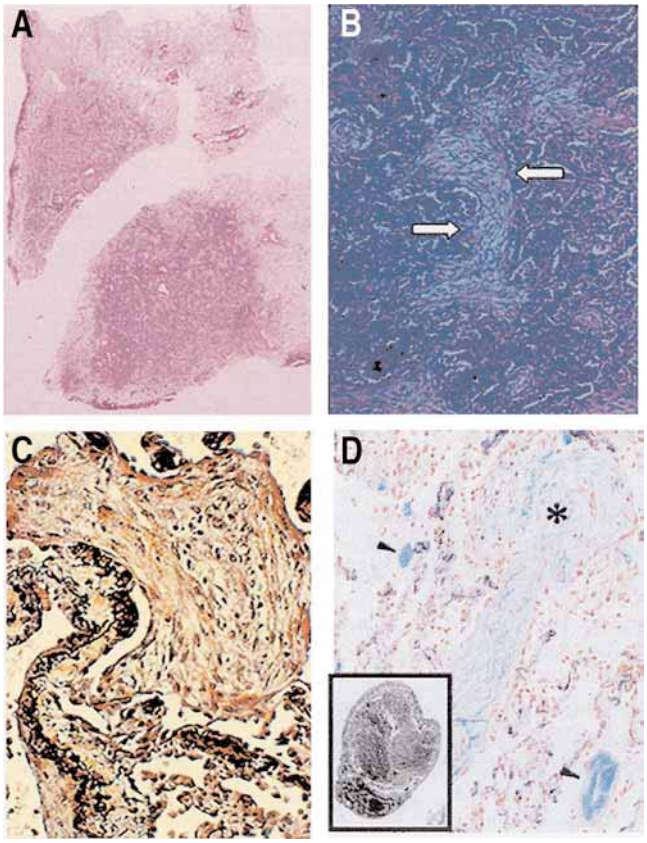

Figure 21-4 Organizing pneumonia pattern. These photomicrographs of the pathological lesions appear to characterize the steps in progression of organizing pneumonia. **(A)** Macroscopic view of lung biopsy showing that the process is patchy with normal lung adjacent to nodular areas of consolidation (H&E). **(B)** Low magnification view shows polypoid plugs of loose connective tissue within alveolar ducts and alveolar spaces (H&E). The connective tissue is all about the same age. **(C)** Higher magnification view shows a polypoid plug (pentachrome). The architecture of the lung is preserved. The connective tissue has a myxoid appearance owing to the abundant mucopolysaccharides and paucity of collagen. **(D)** Polypoid plugs of loose connective tissue within alveolar spaces (*) and dense collagen globules *(arrowheads)*. The insert shows an electron microscopic picture of a collagen globule. The structure of collagen globule is covered by type-I alveolar epithelial cell. Collagen fibrils are densely arranged, and thin cytoplasm of fibroblasts is found between these fibrils. (Original magnification, ×5000.) (Reproduced with permission from Fukuda Y, Ishizaki M, Kudoh S, Kitaichi M, Yamanaka N. Localization of matrix metalloproteinases-1, -2, and -9 and tissue inhibitor of metalloproteinase-2 in interstitial lung diseases. Lab Invest 1998;78:687–698. Copyright Nature Publishing Group.)

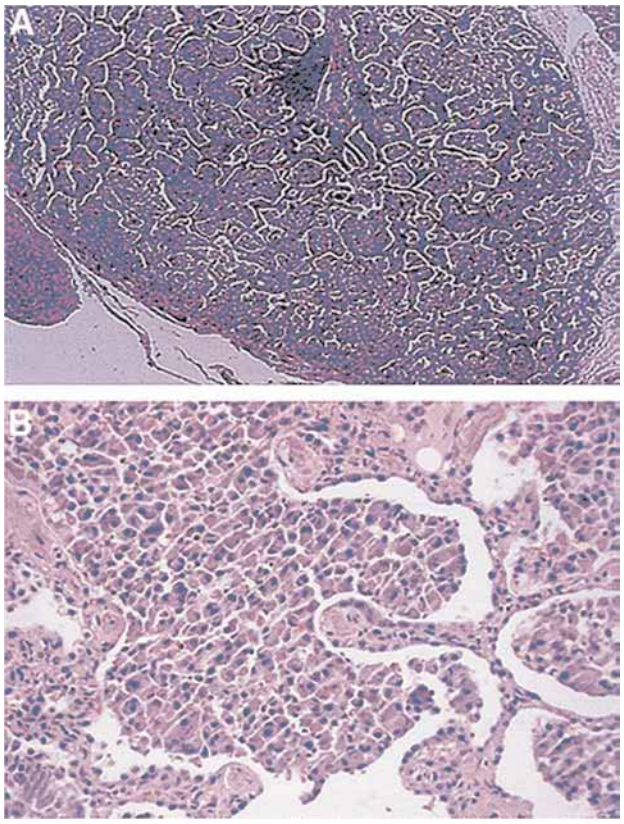

Figure 21-5 DIP pattern. These photomicrographs of the pathological lesions appear to characterize the steps in progression of DIP (H&E). **(A)** Low magnification view shows the alveolar spaces are diffusely involved by marked alveolar macrophage accumulation and there is mild interstitial thickening. **(B)** Higher magnification view shows the alveolar walls are mildly thickened by fibrous connective tissue and a few chronic inflammatory cells. The alveolar spaces are filled with macrophages.

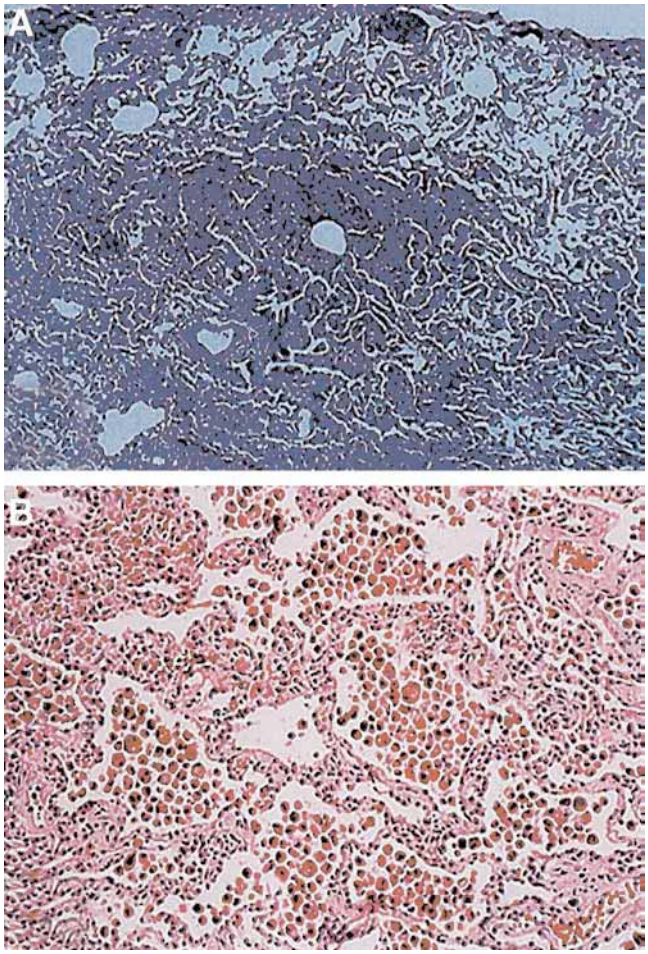

Figure 21-6 Respiratory bronchiolitis-associated interstitial lung disease pattern. These photomicrographs of the pathological lesions appear to characterize the steps in progression of respiratory bronchiolitis-associated interstitial lung disease (H&E). **(A)** Low magnification view shows bronchiolocentric consolidated process. Interstitial thickening confined to the peribronchiolar parenchyma. **(B)** A higher magnification view shows mild thickening of the wall of the respiratory bronchiole and adjacent alveolar walls. Faintly pigmented alveolar macrophages fill the lumen of respiratory bronchioles and the surrounding airspaces.

prominent schemes proposed for the development diffuse lung fibrosis: (1) an "inflammatory-fibrotic pathway" represented by most forms of ILD, in which there is an early, clearly distinguishable phase of inflammation, followed by a subsequent fibrotic phase, and (2) "epithelial damage and fibroblast activation pathway," represented by IPF.

THE INFLAMMATORY-FIBROTIC PATHWAY The normal host response to injury, regardless of the type of injury, is to evoke an inflammatory response that involves a complex set of interactions that appear to be tightly controlled in a time and context-dependent manner (Fig. 21-9). It appears that this initial inflammatory response to tissue injury (i.e., cell damage and disruption of normal structure) also sets into motion the repair responses. In most instances, the inflammation resolves naturally and the tissue returns to normal; the injured cells are replaced and the overall tissue structure is restored with minimal production of granulation tissue. In fact, in many of the apparently reversible interstitial lung disorders (e.g., NSIP and organizing pneumonia) the response to damage and inflammation involves rapid re-epithelialization, fibrin formation, and the development of granulation tissue (i.e., a vascularized fibrotic response). As the epithelium repairs itself the granulation tissue resolves and the lung returns to a more normal structure and function. The bleomycin mouse model of lung injury is an example of this resolvable inflammatory and fibrotic reaction.

EPITHELIAL DAMAGE AND FIBROBLAST ACTIVATION PATHWAY The rationale for the theory that inflammation precedes fibrosis in UIP was the supposition that intra-alveolar macrophage-neutrophil accumulation (i.e., "alveolitis") was the earliest lesion in UIP. However, in UIP such intra-alveolar inflammation is rarely observed. Even in the thickened alveolar septa in UIP there is only a sparse inflammatory infiltrate. Moreover, in interstitial lung diseases (e.g., hypersensitivity pneumonitis, NSIP) in which inflammation is a prominent feature of early disease, fibroblastic foci are not seen and the extensive fibrotic pattern common in UIP does not develop. The agent(s) that incites this fibroproliferation remains unknown. Investigations have provided evidence that UIP may be the result of ongoing diffuse microscopic alveolar epithelial injury (in the absence of a prominent inflammatory response) and abnormal wound healing (Fig. 21-10).

Epithelial Injury and Failure of Re-Epithelialization An intact epithelial barrier is crucial to maintaining normal alveolar function (Fig. 21-10B). The epithelium plays a key role in the regulation of the inflammatory process in the lung. It is hypothesized that epithelial cells are not only the sites of initial injury in UIP, but also are major determinants of the repair process.

Following an injury in the normal repair process, the alveolar epithelium initiates wound healing to restore the integrity of this barrier. This rapid re-epithelialization of the denuded area, through epithelial cell migration, proliferation, and differentiation is critical to normal repair. Evidence shows that re-epithelialization may be mediated, in part, by adult stem cells.

Alveolar epithelial cell death is an early and consistent finding in UIP. In UIP, the alveolar epithelium shows a marked loss of or damage to type-I cells, hyperplasia of type-II cells, as well as altered expression of adhesion molecules and major histocompatibility complex antigens. The cause of the delayed or ineffective re-epithelialization in UIP is unknown and could result from loss of proliferative capacity, increased apoptosis, or ineffective migration of alveolar epithelial cells. Thus, delayed or ineffective re-epithelialization is a key trigger for recruiting, activating, and sustaining mesenchymal cells.

During wound healing, tissue injury causes disruption of blood vessels and extravasation of blood constituents into the wound. These constituents re-establish hemostasis and provide a provisional extracellular matrix for the repair process to begin. The epithelial cells must dissolve the fibrin barrier before migrating throughout the denuded wound surface. However, in patients with IPF, there is increased local procoagulant activity that may result from the dysfunctional alveolar epithelial cells. For example, tissue factor, a potent procoagulant factor, and plasminogen activator inhibitor-1 and -2 are both strongly expressed by alveolar epithelial cells in IPF. This procoagulant activity may impede epithelial cell movement through the extracellular matrix, prohibiting the repair process.

In areas where the basement membrane remains intact, type-II cells attempt to recover the epithelial surface as evidenced by their expression of a number of enzymes, cytokines, and growth factors. However, in UIP, the capacity of type-II alveolar cells to restore damaged type-I cells is seriously altered. Consequently, epithelial

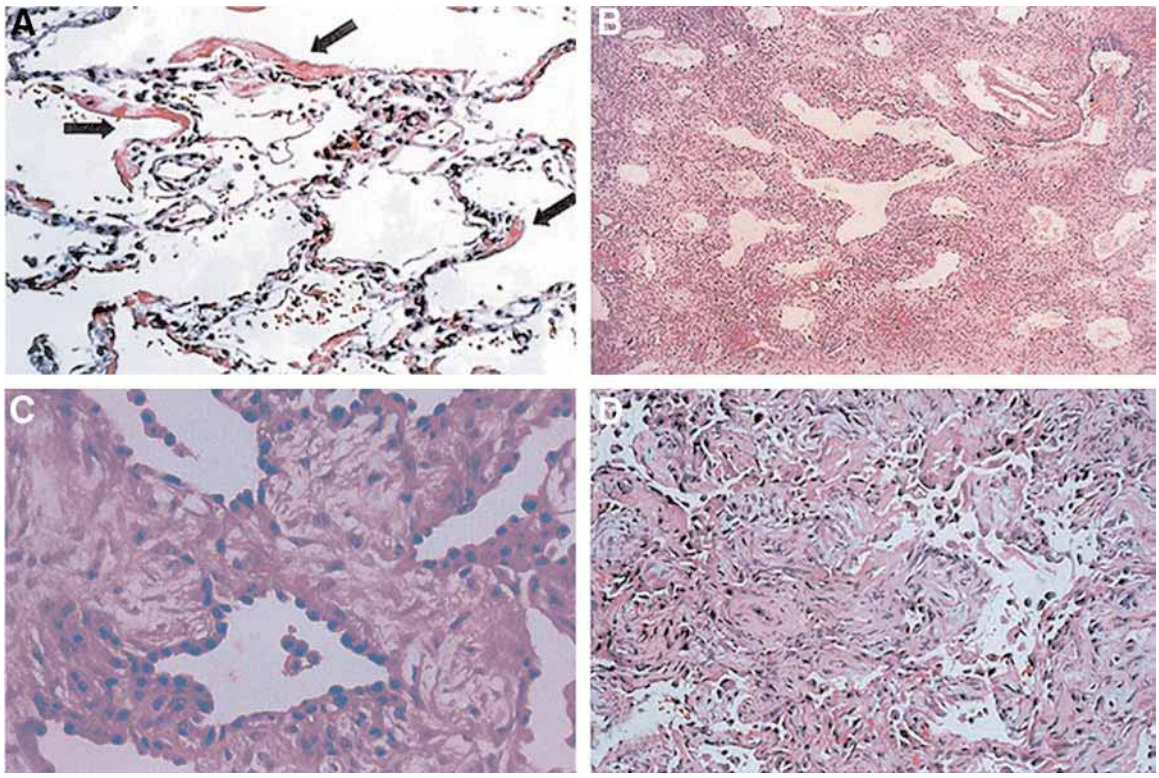

Figure 21-7 Diffuse alveolar damage (DAD) pattern. These photomicrographs of the pathological lesions appear to characterize the steps in progression of DAD in a patient with AIP (H&E). **(A)** The lung shows the early (exudative) stage with edema, diffuse alveolar wall injury, and hyaline membranes (arrows). **(B)** The lung shows diffuse alveolar wall thickening by proliferating connective tissue, type-II pneumocytes, and hyaline membranes. **(C)** A higher magnification view shows alveolar wall thickening by proliferating connective tissue and inflammation and prominent type-II pneumocyte proliferation. **(D)** The lung shows the organizing pattern of DAD with fibrosis in the alveolar septal walls consisting of a loose organizing type of connective tissue.

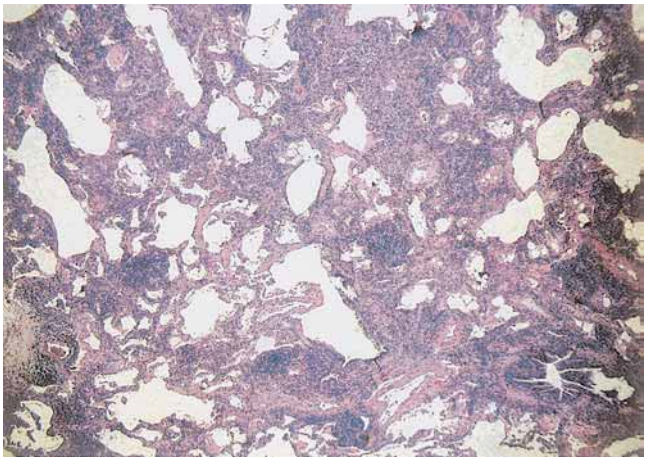

Figure 21-8 Lymphocytic interstitial pneumonia pattern. There is diffuse thickening of alveolar walls by a moderately severe infiltrate of lymphocytes and plasma cells.

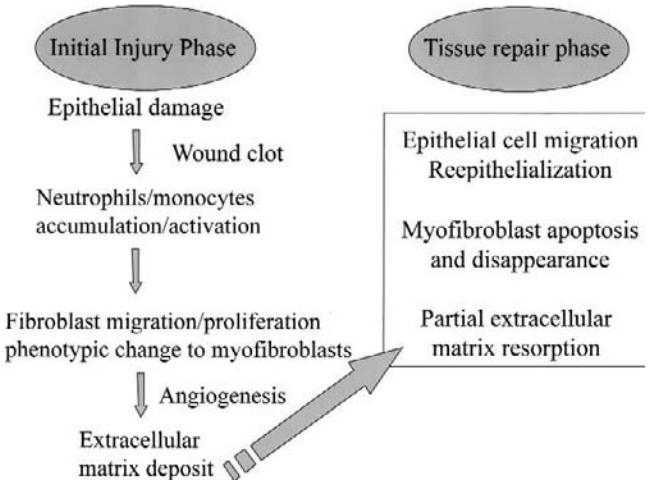

Figure 21-9 The normal wound healing model. (Adapted with permission from Selman M, King TE Jr, Pardo A. Idiopathic pulmonary fibrosis: Prevailing and evolving hypotheses about its pathogenesis and implications for therapy. Ann Intern Med 2001;134:136–151.)

cuboidalization, transitional reactive phenotypes, and alveolar collapse are observed. This failure to restore the alveolar epithelium and the disruption of the epithelial basement membrane allow fibroblast/myofibroblasts to migrate and proliferate in the alveolar space. This process leads to the deposition of intra-alveolar extracellular matrix.

Basement Membrane Disruption The basement membrane is a complex structure of a variety of proteins that plays a dynamic role in maintaining the integrity and differentiation of the overlying alveolar epithelium (*see* Fig. 21-10B). In addition to the alveolar epithelial cell injury, basement membrane disruption is also likely important in the pathogenesis of lung fibrosis. This physical disruption does not facilitate orderly repair of the damaged alveolar type-I epithelial cells. Instead, the damaged basement membrane allows migration of fibroblasts/myofibroblasts into the

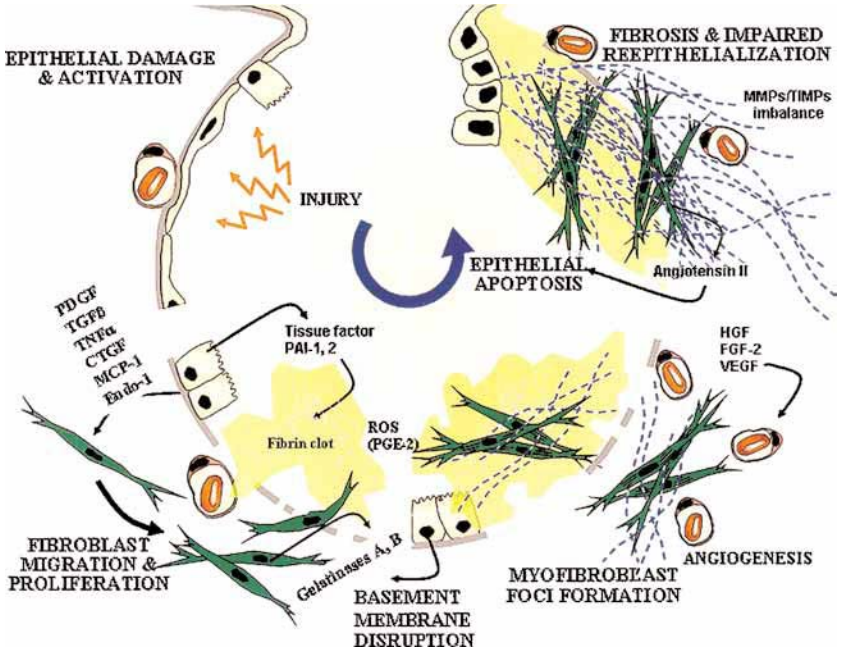

Figure 21-10 Hypothetical scheme of the key events leading to lung fibrosis in UIP. An unknown injury provokes multiple microinjuries that damage and activate alveolar epithelial cells (*top left*). A fibrin clot forms and serves as a provisional matrix for the migration and proliferation of reparative type-I alveolar epithelial cells. Neutrophils secrete proinflammatory mediators, reactive oxygen species, and metalloproteinases. Lymphocyte recruitment leads to the production of Th2-type cytokines, IL-4, and IL-13. Reepithelialization is delayed leading to a denuded, disrupted basement membrane. Alveolar epithelial cells secrete growth factors and induce migration and proliferation of fibroblasts and differentiation into myofibroblasts (*bottom left*). Subepithelial myofibroblasts and alveolar epithelial cells produce gelatinases that may increase basement membrane disruption and allow fibroblast-myofibroblast migration (*bottom right*). Fibroblasts migrate into the wound and produce extracellular matrix proteins and mediators such as angiotensin II, which may further promote alveolar epithelial cell apoptosis. Angiogenic factors may be elaborated, leading to the formation of nascent vasculature early in the disease process. Reciprocal communication between alveolar epithelial cells and mesenchymal cells results in a positive feedback loop that promotes ongoing fibrosis and destruction of alveolar architecture. Alveolar macrophages and epithelial cells secrete TGF-1, which promotes myofibroblast differentiation, increases ECM production, and inhibits apoptosis of fibroblasts/myofibroblasts. An imbalance between interstitial collagenases and tissue inhibitors of metalloproteinases provokes the progressive deposit of extracellular matrix (*top right*). Myofibroblasts produce angiotensinogen that as angiotensin II provokes alveolar epithelial cell death, further impairing reepithelialization. Signals responsible for myofibroblast apoptosis seem to be absent or delayed in UIP, increasing cell survival. As ECM deposition progresses, regression of blood vessels may occur. (*See* text for details about this process.) Endo-1, endothelin-1; CTGF, connective tissue growth factor; ECM, extracellular matrix; FGF-2, fibroblast growth factor-2; HGF, hepatocyte growth factor; MCP-1, monocyte chemoattractant protein-1; MMP, metalloproteinase; PAI, plasminogen activator inhibitor; PGE, prostaglandin E; PDGF, platelet-derived growth factor; ROS, reactive oxygen species; TGF-β, transforming growth factor-β; TIMP, tissue inhibitors of metalloproteinases; TNF-α, tumor necrosis factor-α; VEGF, vascular endothelial growth factor. Ann Intern Med 2001;134:136–151.)

alveolar spaces. Increasing evidence suggests that myofibroblasts themselves actually play a role in the degradation of basement membrane, thus facilitating their migration into the alveolar spaces. Gelatinases A and B, two members of the matrix metalloproteinases family that are produced by several lung cell types, degrade different components of the basement membrane, primarily type-IV collagen. In UIP, subepithelial myofibroblasts produce these gelatinases in some areas with denuded alveolar basement membranes.

Angiogenesis Evidence for the role of angiogenesis in the etiology of IPF remains limited and controversial (Fig. 21-10C). In contrast, although neovascularization is a prominent feature in organizing pneumonia, a usually reversible fibrogenic process, it is not a prominent feature of UIP. In fact, proangiogenic proteins have low levels of expression in fibroblastic foci in UIP compared with granulation tissue in organizing pneumonia. One study suggested that there is a net vascular ablation and redistribution of blood vessels in areas of interstitial thickening in UIP.

Myofibroblast Foci Evidence suggests that the earliest, and possibly the only, morphological changes associated with subsequent progression to dense fibrosis in patients with UIP are the presence and extent of fibroblastic foci in the injured lung (Fig. 21-10D). Fibroblasts within these foci continually modify their interactions with the microenvironment. The extent of fibroblastic foci in UIP correlates with poor prognosis and survival.

Presumably, fibroblasts assume a migratory phenotype, followed by a proliferative phenotype, and finally a profibrotic phenotype during which they produce abundant extracellular matrix components. Most cells in the fibroblast foci are myofibroblasts: spindle-shaped cells aligned parallel to one another. The myofibroblasts in the UIP lesions are a synthetically active phenotype responsible for the connective tissue synthesis. They also appear to contribute to active contraction, which results in the distorted lung architecture characteristic of the UIP lesion. This is accompanied by imbalances in the production of matrix metalloproteinases and tissue inhibitors of metalloproteinases. In particular, TIMP-2 expression by the myofibroblasts in UIP appears to contribute to the irreversible structural remodeling in this disease. The UIP myofibroblasts have several additional features: they secrete angiotensin peptides that may induce apoptosis of adjacent alveolar epithelial cells;

there is diminished cyclooxygenase-2 expression/prostaglandin E2 synthesis; they express surface receptors such as CD40 typically associated with immune cells and are capable of producing a number of chemokines and cytokines.

GENETIC FACTORS IN LUNG FIBROSIS

Several findings support a potential genetic basis for the IIPs:

1. Familial pulmonary fibrosis, including its description in identical twins (some of whom have been separated geographically for many years), has been reported.
2. Alveolar inflammation has been identified in clinically unaffected family members of patients with familial pulmonary fibrosis. The significance of these findings remains unknown, but it is speculated that these unaffected family members might be at risk for the development of familial pulmonary fibrosis.
3. Pulmonary fibrosis appears in association with inherited disorders such as neurofibromatosis, Hermansky-Pudlak syndrome, tuberous sclerosis, Gaucher's disease, lymphangiomyomatosis, and the hypocalciuric hypercalcemia syndrome.
4. There is marked variation in response to profibrotic agents observed in humans despite similar levels of exposure (e.g., roentgenographically evident asbestosis occurs in only 25–50% of workers exposed to the highest cumulative dose of asbestos; hence, at least half of those heavily exposed to asbestos appear to be "resistant" to the fibrogenic effects of this dust).
5. Certain animal strains have a susceptibility to fibrotic agents, which suggests an inheritable predisposition.

FAMILIAL PULMONARY FIBROSIS In Finland, it was estimated that the prevalence for familial pulmonary fibrosis was 5.9/million. The familial form explained 3.3–3.7% of all Finnish cases of IPF diagnosed according to the revised ATS/ERS international guidelines. Geographic clustering has been noted suggesting a recent founder effect in patients with familial pulmonary fibrosis. Familial cases of lung fibrosis account for 0.5–2.2% of all patients with IIPs, with a prevalence of 1.34 cases/10^6 population in the United Kingdom.

The clinical, roentgenographic, physiological, and morphological manifestations of familial pulmonary fibrosis are similar to the nonfamilial forms of lung fibrosis. Patients with familial pulmonary fibrosis presenting at a younger age usually appear to have more aggressive disease. However, the longest survivals have been seen in those presenting between the ages of 10 and 20 yr (this may have resulted from "lead time bias"—i.e., overestimation of survival duration owing to earlier detection). There may be a slight male predominance, and women tend to have a more favorable prognosis.

Familial pulmonary fibrosis has been associated with multiple pathological subsets of the IIPs: DIP, lymphocytic interstitial pneumonitis, and UIP. Mutations in the surfactant protein (SP)-C gene (*SFTPC*) are associated with familial desquamative and nonspecific interstitial pneumonitis and may cause type-II cellular injury (Fig. 21-11). The mutation was not seen in control chromosomes and thus is not likely to be a polymorphism. Electron microscopy of affected lung revealed alveolar type-II cell atypia, with numerous abnormal lamellar bodies. The authors hypothesized that the presence of two different pathological diagnoses in affected relatives sharing this mutation indicated that in this kindred, these diseases might represent pleiotropic manifestations of the same central

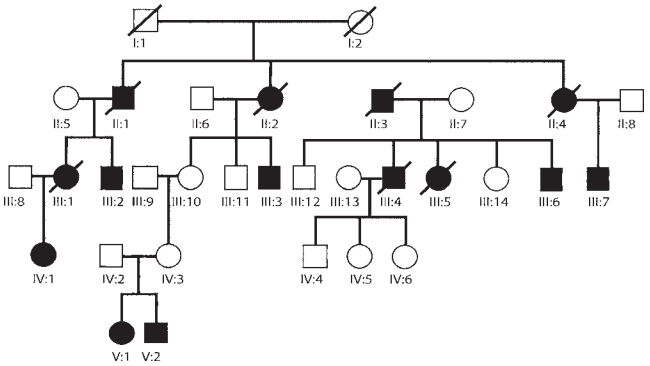

Figure 21-11 A mutation in surfactant protein C gene (*SFTPC*) caused familial pulmonary fibrosis (FPF). This kindred spans five generations, contains 97 total members, including 11 adults with FPF, including 6 with biopsy-proven usual interstitial pneumonitis, and 3 affected children (III : 5, V : 1,V : 2) with cellular nonspecific interstitial pneumonitis. (Reproduced with permission from Loyd JE. Pulmonary fibrosis in families. Am J Respir Cell Mol Biol 2003;29[3 Suppl]:S47–S50. Copyright American Thoracic Society.)

pathogenesis. Multiple heterozygous mutations in SP-C gene have been reported in association with children suffering from interstitial lung disease (DIP or NSIP), including familial and sporadic occurrences. In addition, a deficiency of SP-C has been described in a small kindred suffering from a poorly defined form of interstitial pneumonitis, despite no sequence variation in SP-C gene. It appears that the nature and biology of the SP-C mutation, amounts of production of the active SP-C peptide, the inheritance of other genetic modifiers or exposure to environmental factors may influence the variability in histopathological pattern among affected individuals. Taken together, these findings support a model in which misfolded proSP-C or SP-C protein can cause type-II alveolar cell injury that results in interstitial lung disease.

IMPLICATIONS OF THE PATHOGENETIC PATHWAYS OF LUNG FIBROSIS FOR THE TREATMENT OF LUNG FIBROSIS

Although the clinical course of IPF patients varies, their long-term survival is dismal, only 20–30% of IPF patients survive for 5 yr after their diagnosis. Individual patients may remain relatively stable (or experience very slow declines in lung function or progression of radiographic abnormalities) for an extended period of time (months to years) whereas others experience an accelerated phase with a rapid clinical decline and subsequent death (*see* Acute Exacerbation of IPF). Conventional management of IPF has been primarily based on the concept that suppressing inflammation would prevent progression to fibrosis. Clearly, this approach has failed; there is no effective treatment in use. Most therapeutic regimens have not targeted specific components of the epithelial damage/fibroblast activation pathway described earlier. It is hoped that as a result of better understanding of the natural history of IPF and the sequence of the pathogenic mechanisms (as well as of the plethora of biological events that control the fibrotic response), improved therapeutic strategies will be developed to improve patient outcome.

Because of the often poor responsiveness of IIP to corticosteroids, immunomodulatory agents have been tried with mixed results. Antifibrotic agents have been tried alone or in combination with corticosteroids in patients with UIP. A randomized control

trial of interferon γ-1b and prednisolone compared with prednisolone alone failed to show an improvement in progression-free survival, pulmonary function, or the quality of life. There is increasing interest in these and other antifibrotic agents as the fibroproliferative nature of the pathophysiology is further defined.

ACUTE EXACERBATIONS OF IPF It is increasingly apparent that "acute exacerbations" or an "accelerated phase of rapid clinical decline" characterizes the clinical course of IPF. These episodes are defined as acute worsening (occurring over <4 wk):

1. More dyspnea with same level of exertion.
2. Progressive hypoxemia.
3. New opacities on chest imaging studies.
4. Exclusion of infection or heart failure.

Occasionally, systemic symptoms such as fever, fatigue, and weight loss are present. In fact, rapid progression and hospitalization because of respiratory decompensation were both independent predictors of mortality in the subsequent 3 mo. Better understanding and management of these episodes appear critical to reducing the death rate in IPF.

ACKNOWLEDGMENT

The author thanks Thomas V. Colby and Jeffrey L. Myers for photomicrographs of the pathological lesions.

22 Asthma

Stephen T. Holgate, Gordon Dent, and Mark G. Buckley

SUMMARY

Understanding of the molecular basis of asthma has progressed significantly in the last decade. The roles of immune recognition and effector cells in orchestrating airway inflammation have been developed, and a picture of how these cells—as well as structural cells within the airways—control long-term tissue remodeling is emerging, which provides a comprehensive view of the pathophysiological processes involved in the disease. Phenotypic changes in the asthmatic bronchial epithelium, and its interaction with other cells, have been identified which explain many features of asthma. Moreover, major steps have been taken in characterizing the genetic basis of the disease.

Key Words: ADAM33; cell–cell interactions; epithelium; fibroblasts; genetics; growth factor receptors; immunoglobulin E; inflammation; leukocytes; oxidants; remodeling.

INTRODUCTION

Asthma is often defined as a lung disease with three characteristics: reversible airway obstruction, bronchial hyperresponsiveness (BHR) to inhaled stimuli, and inflammation. The disease is generally a chronic condition that affects 5–7% of adults and up to 20% of children. However, the diagnosis of asthma is often difficult in children because of the high prevalence of virus-induced wheezing that may occur in the absence of asthma. The impact of asthma on any individual is highly dependent on the extent of control of the underlying disease process that can best be achieved by elimination of precipitating factors and effective use of drug therapy. Despite improved understanding of environmental factors underlying the origins and progression of chronic asthma and the availability of more effective drugs for its treatment, the prevalence of this disease and the numbers of hospitalizations and deaths attributed to the disease have been increasing, both in the developed and the developing world. At least some of these rising trends are based on lack of appropriate diagnosis and poor use of medication, in particular inadequate long-term treatment with antiinflammatory drugs. Nonetheless, the marked increases in frequency and severity of asthma serve to underscore the need for a better understanding of the molecular basis for the disease.

Perhaps the single most important conceptual "advance" in defining molecular mechanisms of asthma has been the recognition that it is an inflammatory disease. Evidence that inflammation is an important component of asthma was clear even in early descriptions of the cytopathology and histopathology of the disease. For example, analysis of sputum samples and airway tissue indicated that epithelial desquamation and airway eosinophilia were invariably present during acute attacks. However, the critical role of inflammation as a cause of the abnormal physiology was only firmly established in experimental models of the disease induced by nonallergic and allergic stimuli in which pathophysiology was closely linked to the development of an inflammatory response, and in bronchial biopsy and bronchoalveolar lavage (BAL) studies of asthmatic subjects under baseline conditions and during spontaneous or experimentally provoked exacerbations, in which evidence of abnormal airway function was again closely correlated with the presence of inflammatory cells and mediators.

In the context of airway obstruction, BHR and inflammation, morphological studies of asthma indicate that an overexuberant inflammatory response underpins much of the disordered airway function linked to disease expression, but certainly not all, especially in patients refractory to corticosteroids. Alteration in airway wall structure (sometimes referred to as remodeling) is also important through increased smooth muscle, matrix deposition, and increased vascular and neural networks. In addition, mucus hypersecretion is an important feature in chronic severe disease and in exacerbations.

The challenges that now confront researchers and clinicians are (1) defining the biochemical mechanisms responsible for asthmatic airway inflammation, and (2) determining the environmental and pharmacological means to more effectively inhibit inflammatory pathways or potentiate antiinflammatory ones. This chapter reviews prominent cellular and biochemical pathways responsible for airway immunity and inflammation. Defining these pathways has provided initial clues to the identity of genes activated during asthmatic disease.

MECHANISMS OF AIRWAY INFLAMMATION

The concept that inflammation leads to BHR and narrowing has led to a widening search for the types of inflammatory cells and mediators responsible for the cascade of events linking the initial stimulus to the final abnormality in airway function. Cell types implicated in the development of airway inflammation include immune cells (including mast cells, basophils, eosinophils, lymphocytes, neutrophils, and macrophages) as well as sentinel structural cells (including airway epithelial cells, vascular endothelial cells, and airway smooth muscle cells). Cell–cell interactions are

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

attributed to classes of mediators that include lipids, proteases, peptides, cytokines, and chemokines. It is not yet possible to integrate all of this information into a single model for the development of asthmatic airway inflammation. However, engagement of the allergic antibody IgE and the classification of T-cell responses to allergic and nonallergic stimuli that are inhaled into the airway have provided a useful framework. Using a scheme that was first developed in murine models of the immune response, T-cell dependent inflammation may be classified broadly into the T-helper 1 (Th1) and Th2 types. Th1 cytokines characteristically mediate delayed-type hypersensitivity involving interleukin (IL)-2, IL-12, interferon (IFN)-γ and tumor necrosis factor (TNF)-α, whereas Th2 responses promote B-cell-driven humoral immunity with coordinated upregulation of the cytokine gene cluster encoded on chromosome $5q_{32\text{-}34}$ with secretion of IL-3, -4, -5, -6, -9, -13, and granulocyte/macrophage colony-stimulating factor (GM-CSF). Engagement of both B and T cells is critical to the evolution of asthma.

IMMUNE CELLS

B Lymphocytes B lymphocytes, as the source of immunoglobulins, are crucial to any immune reaction. In the case of allergic reactions, such as those underlying the disease process of asthma, the function of allergen-specific B cells that differentiate into IgE-secreting plasma cells is of central importance.

Immunoglobulin E Immunoglobulin E antibodies are secreted in response to parasitic infestations and in the course of allergic diseases. Although IgE antibodies account for just 0.002% of the immunoglobulin pool, they have considerable biological activity, because of their ability to sensitize mast cells and basophils to allergens by binding to cell surface receptors. Atopy, the predisposition of an individual to produce large amounts of IgE, is associated with an increased risk of developing allergic diseases such as allergic rhinitis, atopic dermatitis, and asthma. However, it must be acknowledged that in a minority of asthma patients, often with marked disease, it has proven difficult to demonstrate allergen sensitivity. Plasma cells secrete IgE and the synthesis of these antibodies is regulated by a variety of cytokines. IL-6 causes B cells to switch to the production of IgE class antibodies, and IgE synthesis is promoted by IL-4 and IL-13, products of Th2 cells, which are associated with allergic disease. In addition, IgE binding to its receptors on B cells provides a mechanism for feedback (*see* below).

Receptors for IgE fall into two main categories: those with high affinity and those with low affinity (Table 22-1). High affinity receptors (FcεRI) on mast cells and basophils mediate many of the classical functions of IgE in type-I hypersensitivity reactions. These cells express an FcεRI receptor made up of one α-, one β- and two γ-subunits ($\alpha\beta\gamma_2$), whereas antigen-presenting cells, such as dendritic cells and monocytes, express a truncated form lacking the β-subunit ($\alpha\gamma_2$). Immunoglobulin E binds to the extracellular portion of the α-subunit of FcεRI. On receptor dimerization by multivalent antigen, the intracellular portion of the α-subunit becomes phosphorylated and associates with other components of the signaling cascade. The β-subunit, expressed selectively by mast cells and basophils (*see* Table 22-1), amplifies the signal intensity by enhancing γ-chain phosphorylation, and it is noteworthy that genetic studies have linked polymorphisms in the β-subunit to asthma (*see* Asthma as a Genetic Disease: DNA Markers and Molecular Genetics). Expression of high affinity IgE receptors on mast cells and basophils is upregulated by IgE binding without the need for receptor crosslinking by antigen. Thus, in the context of an allergic environment characterized by increased IgE production, the capacity of mast cells and basophils to bind IgE, and therefore respond to allergens, is likely to be increased.

Table 22-1
The Receptors for IgE

Receptor	*FcεRI*	*FcεRII*
Synonyms	High affinity IgE receptor	Low affinity IgE receptor CD23
Affinity constant	10^{10}–$10^{9}/M$	10^{7}–$10^{6}/M$
Gene family	Immunoglobulin supergene family	Lectin family
Regulation of expression	Increased by IgE binding	Increased by IL-4 and IL-13 IFN-α/γ can upregulate or downregulate
Cell expression	Mast cells ($\alpha\beta\gamma_2$) Basophils ($\alpha\beta\gamma_2$) Dendritic cells ($\alpha\gamma_2$) Monocytes ($\alpha\gamma_2$) Eosinophils ($\alpha\gamma_2$)	B lymphocytes T lymphocytes Dendritic cells Monocytes Eosinophils
Function	Release of inflammatory mediators, histamine and eicosanoids Antigen presentation	Regulation of IgE synthesis Proliferation and differentiation of B lymphocytes Antigen presentation

IFN, interferon; IL, interleukin.

Dimerization of the FcεRI on mast cells or basophils by multivalent allergen results in phosphorylation of tyrosine residues within the immunoreceptor tyrosine-based activation motifs of the β- and γ-subunits. These act as a scaffold for the assembly of a complex with cytoplasmic signaling molecules such as protein tyrosine kinase Syk. Many signaling events follow, including increases in inositol-1,4,5-trisphosphate and intracellular calcium ion concentration, culminating in the release of granule contents and generation of arachidonic acid metabolites. Many of these mediators, including histamine, leukotrienes, IL-4, and IL-13, are thought to be important contributors to the pathology of asthma.

Low affinity IgE receptors (FcεRII, CD23) are expressed by a variety of cell types including B lymphocytes (*see* Table 22-1), and production of IgE itself is regulated by binding to its low affinity receptor. CD23 exists either as an intact, membrane-bound molecule (iCD23) or as soluble fragments (sCD23), the latter being the products of cleavage of iCD23 through a poorly understood sequence of proteolytic events. Membrane-bound iCD23 has a number of functions, including downregulation of B cell IgE synthesis in response to high local concentrations of IgE. In contrast, some sCD23 fragments, when bound to IgE, exert cytokine-like effects leading to increased IgE secretion from B cells and TNFα secretion from monocytes. Excessive formation of 29-, 33-, and 37-kDa sCD23 fragments has been implicated in the overproduction of IgE associated with allergic disease, and specific protease inhibitors targeting the proteolysis of iCD23 have exhibited inhibitory actions on IgE secretion that may prove beneficial in asthma.

An evaluation of the contribution of IgE to asthma pathophysiology has been made possible by clinical trials of a humanized recombinant antibody to IgE. The antibody employed bound solely to

circulating IgE, sequestering it and reducing the amount available for binding to mast cells or basophils. Treatment of atopic asthmatic patients with this anti-IgE antibody was found to decrease exacerbations and symptom scores and enabled a reduction in corticosteroid usage. These trials support a central role for IgE in the pathogenesis of allergic asthma.

T Lymphocytes In common with other allergic responses, asthmatic reactions depend on the outputs of allergen-specific T lymphocytes of the Th2 type. Activation of these cells leads to the production of Th2 cytokines, including IL-4, -5, and -13, which amplify the inflammatory response by contributing to further recruitment of Th2 cells and eosinophils.

T lymphocytes respond to numerous chemoattractants generated within the airways, including IL-16, lipid mediators, such as platelet-activating factor (PAF), and numerous chemokines. Of these, a small number attract Th2 cells selectively. The most important of these include agonists at the Th2/platelet CC chemokine receptor 4 (CCR4), such as macrophage-derived chemokine (MDC, CCL22) and thymus and activation-regulated chemokine (TARC, CCL17), as well as the mast cell-derived lipid mediator prostaglandin D_2 (PGD_2), which acts through the Th2/eosinophil/basophil-restricted receptor, chemo-kine receptor-homologous molecule expressed on Th2 cells (CRTHR). A further selective Th2 receptor, CCR8, which is activated by the mast cell-derived chemokine I-309 (CCL1) and also mediates chemotactic responses of monocytes and vascular endothelial cells, is under investigation.

Resident or transient T cells within the airways may act as a source of their own chemoattractants, as indicated by the dependence of IL-16 release from allergen-challenged mild asthmatic bronchial explants on the CD28/B7 T-cell costimulatory signals. The source of these factors in more severe disease remains open to question, however, because IL-16 makes little contribution to the T-cell chemotactic activity in moderate/severe asthmatic individuals' airway secretions. Moreover, the release of both IL-16 and IL-5 from allergen-stimulated moderate/severe asthmatic bronchial biopsies is independent of CD28/B7 costimulation. Although this might simply indicate the predominance of other costimulatory mechanisms in T cells within more severe asthmatic airways, it may also suggest that other cellular sources, such as the bronchial epithelium and eosinophils, may represent major sources of these cytokines in severe disease.

The role of IL-16 itself is the subject of extensive research. Although this cytokine had been considered primarily as a T-cell chemoattractant, studies have shown that it also acts to suppress the production of Th2 cytokines and may render T cells unresponsive to allergenic stimulation. The relative contributions of IL-16 and the selective Th2 chemoattractants, MDC, TARC, I-309, and PGD_2, might, therefore, prove important in determining the local outcome of recruitment of T cells to sites of inflammation in the airways.

Although Th1 and Th2 populations have been postulated to balance each other's responses, with Th1 cytokines suppressing Th2 cell differentiation and proliferation and vice versa, this model is not reflected in disease. Thus, IFN-γ-secreting Th1 cells do not suppress Th2-mediated inflammatory reactions in animal models of asthma but, rather, cause severe neutrophilic inflammation in addition to the Th2-driven eosinophilic inflammation. Similarly, in Th1-driven processes such as experimental autoimmune encephalomyelitis (a model of multiple sclerosis) and type-1 diabetes, the presence of Th2 cells exacerbates local inflammation rather than ameliorating it, as would be expected from the Th1/Th2 balance model. Both Th1 and Th2 inflammatory reactions are, however, suppressed by the cytokine synthesis inhibitor, IL-10, and the possible significance of this is indicated by the findings that spontaneous IL-10 generation is lowered in the airways of asthmatic individuals and that a polymorphism in the promoter region of the IL-10 gene is associated with elevated serum IgE levels and clinical history of asthma. The identification of IL-10-secreting regulatory T cell (Tr) and transforming growth factor (TGF)-β-secreting Th3 populations suggests mechanisms through which inflammatory reactions are suppressed at the specific sites in which these suppressive cells localize. The hypothesis that a deficiency of Tr cells may underlie heightened and persistent inflammation in diseases such as asthma is under investigation and may provide important information about the regulation of inflammatory reactions.

Mast Cells Mast cells are pivotal not only to initiating acute bronchoconstriction in asthma through the release of autacoid mediators, but also contribute to ongoing cell recruitment in the chronic phases of the disease. Mast cells are distributed widely in the airways, being found in the smooth muscle layer, the *lamina propria*, between epithelial cells and in the epithelial lining fluid sampled by BAL. In asthma, there is a substantial increase in the mast cell population of the lungs, and measurements of mast cell mediators such as histamine and β-tryptase in BAL fluid indicate that these cells are active. Although various cell populations are increased in asthma, it is noteworthy that mast cells, but not T lymphocytes or eosinophils, are more numerous in the bronchial smooth muscle layer when compared to that of healthy controls.

Mast cells develop from bone marrow progenitors that enter the blood as immature cells and migrate into the tissues, maturing under the influence of locally generated cytokines (Fig. 22-1). The most important of these cytokines is stem cell factor (SCF), which is produced mainly by structural cells with which mast cells interact closely, such as epithelial cells, fibroblasts, endothelial cells and smooth muscle cells. SCF can be secreted and is a chemoattractant for mast cells. However, findings that, mice that secrete soluble SCF, but are homozygous for a mutation in the gene encoding the membrane-bound form of this cytokine (the Steel-Dickie allele [Sl^d]), are deficient in mast cells suggest that the SCF expressed on the cell membrane is more important for mast cell development. Other cytokines within the microenvironment, including T-lymphocyte-derived cytokines, influence mast cell development and thus mast cells obtained from different tissues produce a pattern of mediators and respond to activating stimuli in a manner that depends on their source.

The interaction of antigen with specific IgE is likely to be the most important trigger for mast cell activation in allergic disease. These cells express large numbers of high affinity receptors for IgE on their surfaces, and bind IgE circulating in the plasma. However, the binding of monomeric IgE molecules does not cause mediator release. Rather, mast cell activation occurs when multivalent antigen crosslinks receptor-bound IgE molecules, resulting in the secretion of the contents of their many cytoplasmic granules and the generation of newly synthesized PGD_2 and leukotriene C_4 (LTC_4). PGD_2 and LTC_4, together with mast cell-derived histamine, induce bronchial smooth muscle constriction and increase vascular permeability and thus make a major contribution to the edema and bronchoconstriction of the acute response to allergen inhalation.

In addition to these classical mediators of allergic reactions, mast cells produce an extensive repertoire of proinflammatory cytokines,

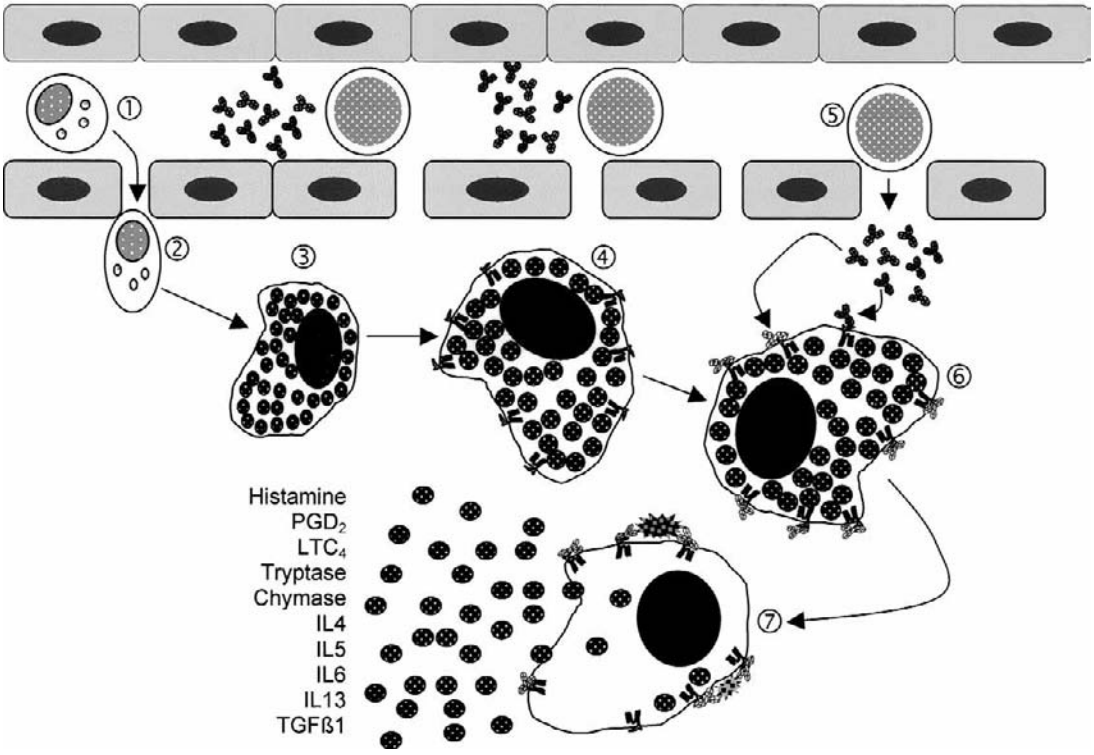

Figure 22-1 Mast cell progenitors leave the bone marrow and enter the circulation①. These progenitor cells migrate into the tissues in response to cytokines such as SCF, TGF-β, eotaxin, and RANTES②. Mast cells mature in the tissues and produce secretory granules③ and express high affinity IgE receptors④. IgE antibodies produced by B lymphocytes⑤ sensitize mast cells by binding to FcεRI receptors⑥. Crosslinking of FcεRI by multivalent allergen interacting with IgE results in mast cell degranulation and the secretion of mediators of inflammation and tissue remodeling⑦. IL, interleukin; LTC_4, leukotriene C_4; PGD_2, prostaglandin D_2; RANTES, regulated on activation normal T-cell expressed and secreted; SCF, stem cell factor; TGF-β_1, transforming growth factor-β_1.

including TNFα, IL-4, IL-5, IL-6, IL-8 (CXC chemokine ligand 8 [CXCL8]), IL-13, and GM-CSF. Mast cells generate these in substantial quantities and are unusual in that they store cytokines in their granules preformed and ready for rapid release. Of particular relevance to asthma, immunohistochemical studies have revealed that airway mast cells store IL-4, -5, and -13, cytokines associated with allergic-type immune responses, which promote processes such as IgE synthesis and eosinophil development.

Mast cells may also contribute to inflammation by means of their neutral proteases, tryptase and chymase, which are restricted to these cells. β-tryptase is found in the secretory granules of all mast cells and, as their most abundant product, has proved a valuable marker of mast cell activity. This enzyme has the capacity to regulate the behavior of a variety of cell types, inducing the release of IL-8 from endothelial cells and epithelial cells and secretion of both IL-6 and IL-8 by eosinophils. Injection of β-tryptase into the skin of guinea pigs or the peritoneum of mice results in the recruitment of inflammatory cells, whereas injection into the skin of guinea pigs provokes increased vascular leakage. These actions of β-tryptase require proteolytic activity, and one of the principal means by which cell behavior may be regulated by β-tryptase is thought to be through cleavage of the protease-activated receptor PAR2. This receptor is activated by certain proteases that cleave the N-terminal peptide at a specific site to generate a new amino-terminal, which functions as a tethered ligand that binds intramolecularly to the second extracellular loop of the receptor, resulting in the activation of intracellular signal transduction mechanisms. Of particular relevance to asthma, challenge of sheep with inhaled tryptase causes bronchoconstriction and airway hyperresponsiveness. Furthermore, in animal models of asthma, low molecular weight inhibitors of β-tryptase protect against reductions in lung function provoked by inhalation of allergen. In addition to β-tryptase, mast cells produce two other forms of tryptase; α-tryptase, which is similar in sequence to α-tryptase, but secreted constitutively, and γ-tryptase, which is a transmembrane protein. γ-tryptase increases the expression of IL-13 by T lymphocytes, and in a mouse model this was found to promote airway hyperresponsiveness.

Chymase is produced in appreciable quantities only by a subset of mast cells most commonly found in submucosal and connective tissues. This enzyme activates IL-1β precursor and thus may play a proinflammatory role. As mentioned for tryptase, such a role is supported by animal studies in which injection of chymase into the skin of guinea pigs increases vascular leakage and injection into the peritoneum of mice causes inflammatory cell infiltration.

In addition to the inflammation that occurs in the asthmatic lung, structural changes take place, referred to collectively as airway remodeling (*see* Mechanisms of Airway Inflammation: Epithelial-Mesenchymal Communication in Asthma). Typical features of airway remodeling in asthma include thickening of the bronchial smooth muscle, subepithelial fibrosis, and epithelial cell metaplasia with increased formation of mucus-secreting goblet cells. Because mast cell numbers and mediator release are increased in fibrotic lung disorders, it seems likely that mast cells may be active contributors to airway remodeling in asthma. Mast cells produce considerable quantities of fibrogenic cytokines such as basic fibroblast

growth factor (FGF) and TGF-β. Furthermore, mast cell proteases may have direct actions on structural cells to induce tissue remodeling. Thus, β-tryptase acts on multiple facets of fibroblast behavior, promoting fibroblast chemotaxis and proliferation, collagen deposition, and synthesis of basic FGF. Expression by dermal fibroblasts of α-smooth muscle actin (SMA) (an indicator of fibroblast to myofibroblast transformation) is increased by β-tryptase and this could be one mechanism promoting myofibroblast differentiation in the asthmatic airways. In addition, β-tryptase is a mitogen for both epithelial cells and airway smooth muscle cells and may thus promote remodeling. A cardinal feature of asthma is BHR, and application of this enzyme to isolated airway preparations causes hyperresponsiveness to histamine. Potential roles for chymase in remodeling processes are still under investigation, but it is known that chymase cleaves stromelysin (matrix metalloproteinase 3) to an active form and degrades human airway smooth muscle cell pericellular matrix. Most mast cells inhabiting the bronchial smooth muscle layer of asthmatic airways express chymase.

Thus, cell culture experiments (as summarized in Table 22-2) and animal models support a prominent role for mast cell mediators in reproducing key features of the pathophysiology of asthma. Although antihistamines are not effective in the treatment of asthma, a potential role for β-tryptase in the pathophysiology of asthma is supported by a trial in which a selective tryptase inhibitor protected against late phase bronchoconstriction after inhaled allergen challenge.

Granulocytes Asthma is associated with an inflammation of the airways that is characterized by large numbers of granulocytes within both the tissues and the luminal space. Although an association of asthma with airway eosinophilia has been recognized for many years, the recognition that neutrophils may also be involved in some forms of severe asthma is more recent.

Eosinophils Eosinophils are the characteristic infiltrating cells at sites of IgE-mediated immune reactions, including parasite infestation and allergy. Increased numbers of eosinophils are observed in the blood, sputum, BAL fluid, and submucosal tissues of allergic asthmatic subjects, with a broad relationship apparent between eosinophil numbers in the sputum and severity of disease. Increased numbers of eosinophil progenitor cells are also observed in the bone marrow of allergic asthmatics. Histological examination of asthmatic airways reveals both intact eosinophils and clusters of free eosinophil granules, indicating necrotic cytolysis, but little evidence of apoptotic eosinophils. It has been suggested that eosinophils are cleared from the mucosal tissues by migration into the lumen, in which the cells may undergo apoptosis or be eliminated through the mucociliary escalator.

The range of products released from activated or necrotic eosinophils indicates the potential for these cells to contribute to both the acute and chronic features of asthma. For example, LTC_4 is a potent bronchoconstrictor and mucous secretagogue, while reactive oxygen species (ROS, including superoxide anion radical and hydrogen peroxide) and basic granule proteins such as eosinophil cationic protein and eosinophil peroxidase act individually or in combination to injure respiratory epithelium. These so act along with eosinophil-derived cytokines such as IL-13 and TGF-β to stimulate fibroblast proliferation (*see* Mechanisms of Airway Inflammation: Epithelial-Mesenchymal Communication in Asthma), with consequences for tissue remodeling.

The abundant eosinophils in the airways may represent both mature cells recruited from the circulation and cells derived from IL-5-driven differentiation of progenitors within the lung. The importance of the latter source of eosinophils in asthmatic airways remains to be established. In contrast, evidence supports a relationship between asthma and the expression in the airways of factors that attract and promote the survival of eosinophils. The importance of eosinophil recruitment in asthma has been called into question by the finding that the elimination of IL-5 by treatment of asthmatic subjects with an anti-IL-5 antibody leads to the reduction of blood and sputum eosinophils to negligible numbers without affecting the magnitude of early or late asthmatic reactions or airway responsiveness over a 30-d period. Because IL-5 is also required for the differentiation of lung precursors into eosinophils, it is unlikely that locally derived eosinophils account for the persistent asthmatic reactions, although mature tissue eosinophils do persist within asthmatic airways after anti-IL-5 treatment. The traditional view of eosinophil recruitment, secondary to the activation of resident inflammatory cells, being responsible for the late asthmatic reaction would appear to have been disproved. However, a contribution of resident eosinophils to the late reaction cannot be discounted. Furthermore, the role of eosinophils in the chronic tissue injury and remodeling underlying the pathology of asthma remains entirely open to investigation. It may be significant that eosinophils appear to play a distinct role in central pathological features such as subepithelial basement membrane thickening, even in severe, corticosteroid-resistant forms of asthma in which neutrophils form the predominant leukocyte type in airway exudates. Circumstantial evidence from the interactions of eosinophils with airway structural cells supports a role for eosinophils in these processes but experimental testing of the hypothesis is required to allow any conclusion to be made.

Eosinophils respond to a range of chemoattractants, including eotaxin (CC chemokine ligand 8 [CCL11]), regulated on activation,

Table 22-2
Selected Cellular Targets for Mast Cell Mediators Likely to be of Importance in Asthma

Mediator(s)	*Cellular target*	*Action*
Immediate response		
Histamine, PGD_2, LTC_4	Smooth muscle	Constriction
	Endothelium	Increased permeability
Inflammatory responses		
IL-4, IL-13, TNFα	Endothelium	Upregulation of adhesion molecule expression
IL-4, IL-13	B lymphocytes	IgE production
IL-5	Eosinophils	Development and survival
β-tryptase	Endothelial cells	Vascular leakage, IL-8 production
	Eosinophils	IL-6 and IL-8 production
γ-tryptase	T lymphocytes	IL-13 production
Tissue remodeling		
Basic FGF	Fibroblasts Smooth muscle	Proliferation
TGF-β	Fibroblasts	Production of extracellular matrix components
β-tryptase	Epithelium Smooth muscle	Proliferation
	Fibroblasts	Proliferation, chemotaxis, synthesis of α-smooth actin, basic FGF and collagen

FGF, fibroblast growth factor; IL, interleukin; LTC_4, leukotriene C_4; PGD_2, prostaglandin D_2; TGF-β, transforming growth factor-β.

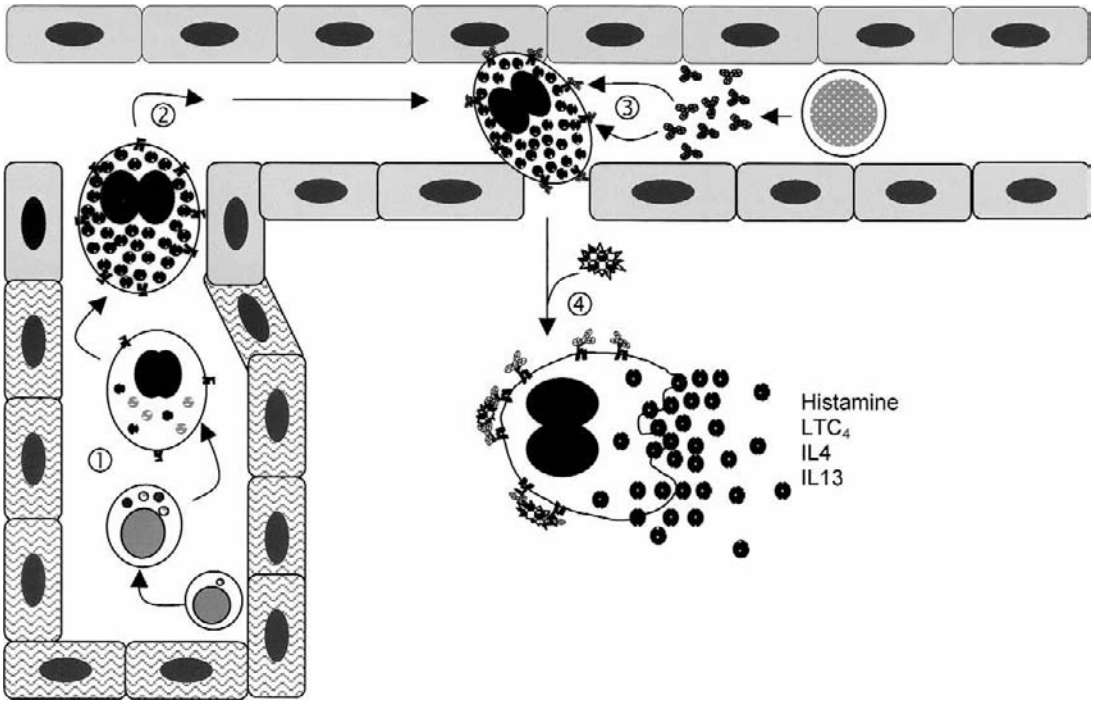

Figure 22-2 Basophils develop and mature within the bone marrow① before entering the circulation②. IgE antibodies produced by B lymphocytes bind to FcεRI on basophils, sensitizing them to allergens③. Crosslinking of the high affinity receptors by binding of multivalent allergens to IgE on the basophil surface causes secretion of granule contents and generation of mediators of allergic reactions ④. IL, interleukin; LTC_4, leukotriene C_4.

normal T cell expressed and secreted (RANTES; CCL5), IL-16, PAF, and PGD_2; they are also influenced by a range of survival factors, principally IL-3, IL-5, and GM-CSF. Sources of these factors include structural and resident inflammatory cells in the airways, such as the epithelium, fibroblasts, alveolar macrophages, mast cells and Th2 lymphocytes. In addition to attracting the cells into the airways and prolonging their survival, soluble factors in airway secretions can prime eosinophils for activation by secondary stimuli. For example, mediators, including PAF and CC chemokine receptor (CCR) 3 agonists such as eotaxin and RANTES, mobilize cytoplasmic lipid bodies, which are the subcellular structures in which the leukotriene-forming enzymes assemble to generate LTC_4 in eosinophils and basophils. This leads to greatly enhanced generation of LTC_4 in response to subsequent stimulation.

Basophils Investigations of the role of basophils in asthma pathogenesis were hampered for years by the lack of reagents for their reliable identification in tissue sections. Although basophils express highly sulfated proteoglycans in their secretory granules and may be stained with basic dyes such as toluidine blue and Alcian blue, and express high affinity IgE receptors on their cell surfaces that may be detected by immunohistochemistry, these are properties shared with the often more numerous mast cells. However, the advent of monoclonal antibodies specific for antigens unique to the secretory granules of basophils is now facilitating an assessment of their contribution to asthma. Basophils can be identified in the lungs of asthmatic patients, and are increased in number following inhaled allergen challenge, but they are much less numerous than other infiltrating cells such as eosinophils. However, an immunohistochemical study of the airways of patients who had died of asthma indicated the presence of much more substantial numbers of basophils, suggesting that basophils have a greater role in fatal asthma. Findings of infiltration of large numbers of basophils into the nasal mucosa within an hour of allergen instillation indicate that, under some circumstances, basophils can be mobilized rapidly to the airways on allergen exposure.

Basophils develop from $CD34^+$ bone marrow progenitors and mature before entering the peripheral blood (Fig. 22-2). They are comparatively rare leukocytes, typically comprising <1% of those circulating. Various cytokines contribute to basophil production and maturation, but chief among these is IL-3. Basophils express chemokine receptors CCR2 and CCR3 and may be recruited into the tissues by chemokines such as RANTES, monocyte chemotactic protein 1 and MCP3. They release mediators after stimulation with complement component C5a and bacterial formylated peptides but, in the context of asthma, activation is most likely to occur by IgE-dependent means. Basophils express FcεRI on their cell surface, and when this is crosslinked by IgE and multivalent allergen, secretion of mediators occurs. The responsiveness of basophils to activating stimuli can be increased by preincubation with "priming" cytokines such as IL-3, IL-5, GM-CSF or eotaxin, and thus basophils in an inflammatory environment may be more sensitive to activators. Basophil activation results in the secretion of histamine and LTC_4, both mediators of bronchoconstriction, and the release of considerable amounts of cytokines IL-4 and IL-13. These cytokines promote the generation of IgE antibodies and are associated with allergic reactions. It is noteworthy that while basophils produce IL-4 and IL-13, which are often thought of as Th2 cytokines, they do not generate Th1 cytokines such as IFN-γ or IL-2, or the more generally proinflammatory cytokines such as TNF-α, IL-1, or IL-6. Thus, basophil activation seems to favor the development of Th2 type responses associated with allergic reactions. Basophil-derived mediators are produced by other cell types

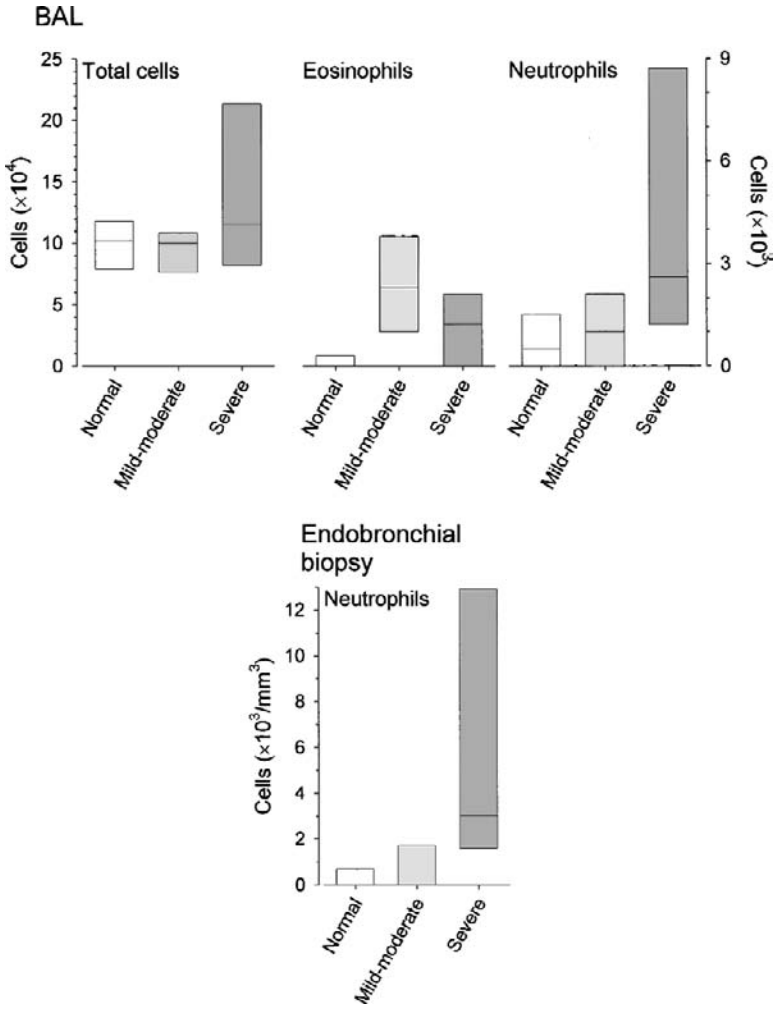

Figure 22-3 Inflammatory cells in BAL (upper panel) and endobronchial biopsies (lower panel) from normal individuals, mild/moderate asthmatic individuals requiring bronchodilator and inhaled glucocorticoids only, and severe asthmatic individuals treated with oral glucocorticoids for more than 5 yr. (Data are shown as median and interquartile range and are extracted from Wenzel SE, Szefler SJ, Leung DY, Sloan SI, Rex MD, Martin RJ. Bronchoscopic evaluation of severe asthma: persistent inflammation associated with high-dose glucocorticoids. Am J Respir Crit Care Med 1997;156:737–743.)

also, but it is possible that the antibodies specific for basophils could recognize novel mediators produced solely by basophils, and that the identification of their antigens may provide further insights into the nature of the contribution of basophils to asthma.

A number of therapies for asthma such as corticosteroids, leukotriene receptor antagonists and IgE sequestration using recombinant antibodies are likely to affect basophil function, but the extent to which actions on basophils underlies their clinical usefulness is unclear.

Neutrophils An association between neutrophils and acute severe asthma has become apparent from the demonstration of neutrophilic inflammation in postmortem lung specimens from sudden-onset fatal asthma and status asthmaticus, as well as in sputum samples collected during acute asthma exacerbations. Exacerbations of asthma are due predominantly to infection of the lower airways by rhinoviruses and respiratory syncytial viruses, which promote the production of neutrophil chemoattractants by the respiratory epithelium and induce upregulation of epithelial intercellular adhesion molecule (ICAM) 1, a molecule that enables adhesion of neutrophils through binding of β_2 integrins.

A contribution of neutrophils to severe persistent asthma has been suggested, particularly in cases resistant to high-dose glucocorticoid treatment. This is based on bronchoscopic studies in which elevated neutrophil numbers were observed in BAL and endobronchial biopsies taken from severe persistent asthma patients treated with oral corticosteroids in comparison with healthy and bronchodilator-treated mildly/moderately asthmatic individuals (Fig. 22-3). Eosinophil numbers, in contrast, were elevated in steroid-free mildly/moderately asthmatic subjects but not in the corticosteroid-treated severe asthma patients. Similar findings have been reported in studies of induced sputum, in which neutrophil numbers were significantly raised in oral glucocorticoid- treated severe asthma subjects compared to bronchodilator-treated mildly asthmatic individuals. Although direct actions of glucocorticoids on cell survival have been demonstrated—with steroids enhancing neutrophil survival although hastening eosinophil apoptosis—other pathophysiological explanations for the differential cellular composition of the inflammatory exudates are possible. The neutrophil numbers in asthmatic airways are directly related to the concentrations of two major neutrophil

chemoattractants—IL-8 and LTB_4—in the airway lining fluid and may, therefore, reflect a persistent secretion of these factors from the bronchial epithelium and alveolar macrophages, respectively.

Recruitment of Immune and Inflammatory Cells IL-4 has a number of actions that influence the development of airway inflammation. As noted, it is critical for the gene activation underlying differentiation of B cells into antibody-forming cells and consequent production of IgE and IgG isotypes. In the context of the scheme for Th2-type immune cell recruitment to the airway, IL-4 may also exert a separate but critical influence. In particular, IL-4-driven expression of vascular cell adhesion molecule 1 (VCAM1) on the endothelial cell surface might serve in the recruitment of inflammatory cells from the circulation (especially T cells and eosinophils bearing the $\alpha_4\beta_1$- and $\alpha_4\beta_7$-integrins). This possibility is supported by evidence of increased levels of immune cell IL-4 and endothelial cell VCAM1 in tissue from asthmatic subjects as well as inhibition of allergen-induced airway inflammation in animals lacking the IL-4 gene or treated with anti-VCAMl antibodies. The precise mechanism underlying the regulation of VCAM1 expression by IL-4 is uncertain, but it appears that it is not dependent on signal transducer and activator of transcription (STAT) 6-driven gene activation. Instead, IL-4 acts in concert with other cytokines (TNFα and IL-1). These cytokines are responsible for transcriptional activation of the VCAM1 gene through two adjacent nuclear factor-κB sites in the promoter region, whereas IL-4 stabilizes the resulting mRNA. This cytokine synergy results in exaggeration and prolongation of VCAM1 levels on the endothelial cell surface. Cytokine synergy may also reflect an important cell–cell interaction in which TNF-α (and in some cases IL-1) derived from mast cells and eosinophils acts in concert with IL-4 (and in some cases IL-13) derived from mast cells, eosinophils, Th2 cells and basophils to promote immune cell recruitment to the airway.

Other Mechanisms for Recruitment of Immune Cells In addition to IL-4 and TNFα effects on VCAM1, other events in endothelial cells and immune cells are also critical for full development of the Th2-type inflammatory response. For example, at least two other cell adhesion systems appear to be activated during allergen-triggered airway inflammation: (1) selectin binding to mucin-like molecules and (2) other cell adhesion molecules of the Ig supergene family that bind to integrin receptors. In the case of endothelial cells, allergen may trigger endothelial-leukocyte adhesion molecule 1 (ELAM1, CD62E, E-selectin) expression, which enables binding to a corresponding leukocyte sialyl-Lewis X carbohydrate ligand; and ICAM1 expression, which allows for binding to the leukocyte β_2-integrins leukocyte function associated antigen 1 (LFA1, $\alpha_L\beta_2$, CD11a/CD18) and Mac1 ($\alpha_M\beta_2$, CD11b/CD18). In addition to these cell adhesion systems for direct cell–cell contact, endothelial cells and immune cells also appear capable of generating a series of chemokines that may act over a greater distance to direct immune cell movement and activation in airway tissue. These three systems—selectin binding to mucin-like molecules, cell adhesion molecules binding to integrins and chemokine binding to G-protein-coupled receptors—may act in a specific combination to dictate the type of immune cells that enter or are retained in the airway tissue. These same systems also serve to control the activation status of immune cells acting, at least in some cases, through distinct signal transduction pathways.

Once inflammatory cells are recruited from the circulation, they are often directed toward the epithelial surface. It appears that epithelial cells (along with other parenchymal cells and resident immune cells) also possess at least two important mechanisms for influencing the movement of inflammatory cells after they arrive in the airway tissue: (1) concomitant activation of cell adhesion molecules on the epithelial cell surface that may interact with corresponding integrin receptors on the immune cell surface and (2) release of chemotactic factors that bind to specific receptors on the immune cell. In the case of airway epithelial cells, these systems appear to be more responsive to Th1-type cytokines, but there is evidence that they are also influenced by the level of TNF-α. Thus, even in the absence of a Th1-type response, expression by epithelial cells of cell adhesion molecules (especially ICAM1) and certain chemokines (from the CC- and CXC-chemokine families) is capable of supporting transepithelial migration and activation of immune cells.

Interestingly, there is no evidence of selectin or VCAM1 expression on airway epithelial cells (or fibroblasts and smooth muscle cells); thus, it is likely that these cell types present fewer ligands than do endothelial cells for directing leukocyte movement. The biological basis for this difference is not certain, but it makes sense; endothelial cells must be armed with ligands that slow down passing leukocytes (to allow tethering and triggering) and then select a specific leukocyte subset (to allow adhesion and transmigration) from the diverse circulating pool. This requires multiple specific molecular interactions. By contrast, parenchymal cells (epithelial cells, fibroblasts, and smooth muscle cells) come into contact with immune cells after selection and some degree of activation, so that they are required only to facilitate further leukocyte migration and retention. ICAM1 is well suited to mediate this process because nearly all immune cells constitutively express the β_2-integrins LFA1 or Mac1. In the case of T-cell traffic, the endothelial cells (and likely epithelial cells) also express a series of receptors (designated homing receptors or addressins) that serve to direct distinct subsets of lymphocytes to appropriate locations of lymphoid tissue. This type of cell adhesion (exemplified by some of the β_7-integrin interactions) is probably most important in maintaining a resident population of immune cells, but whether this system is also regulated during airway inflammation remains uncertain. The discovery that asthmatic airway smooth muscle secretes the mast cell chemoattractant IP10 might explain the increased numbers of mast cells in the smooth muscle layer that have been linked to heightened airway responsiveness.

EPITHELIAL-MESENCHYMAL COMMUNICATION IN ASTHMA Asthma is an inflammatory disorder of the airways involving T cells, mast cells and eosinophils characteristic of the Th-2 response. However, inflammation alone does not explain many of the features of this chronic and relapsing disease. Although atopy is an important risk factor for asthma, in the general population it only accounts for 40% of the attributable risk of having the disease. Eosinophils have been assumed to play a central role in disease pathogenesis; however, studies with an IL-5 blocking monoclonal antibody and recombinant human IL-12 have failed to reveal efficacy, despite markedly reducing circulating and airway eosinophil numbers (*see* Mechansisms of Airway Inflammation: Granulocyte Interactions With Airway Structural Cells). Thus, although being associated with asthma, atopy and airway eosinophilia would not seem to be critical requirements for disease expression. Genetic studies have also demonstrated that atopy and BHR have different patterns of inheritance. These findings imply that locally operating factors play an important role in

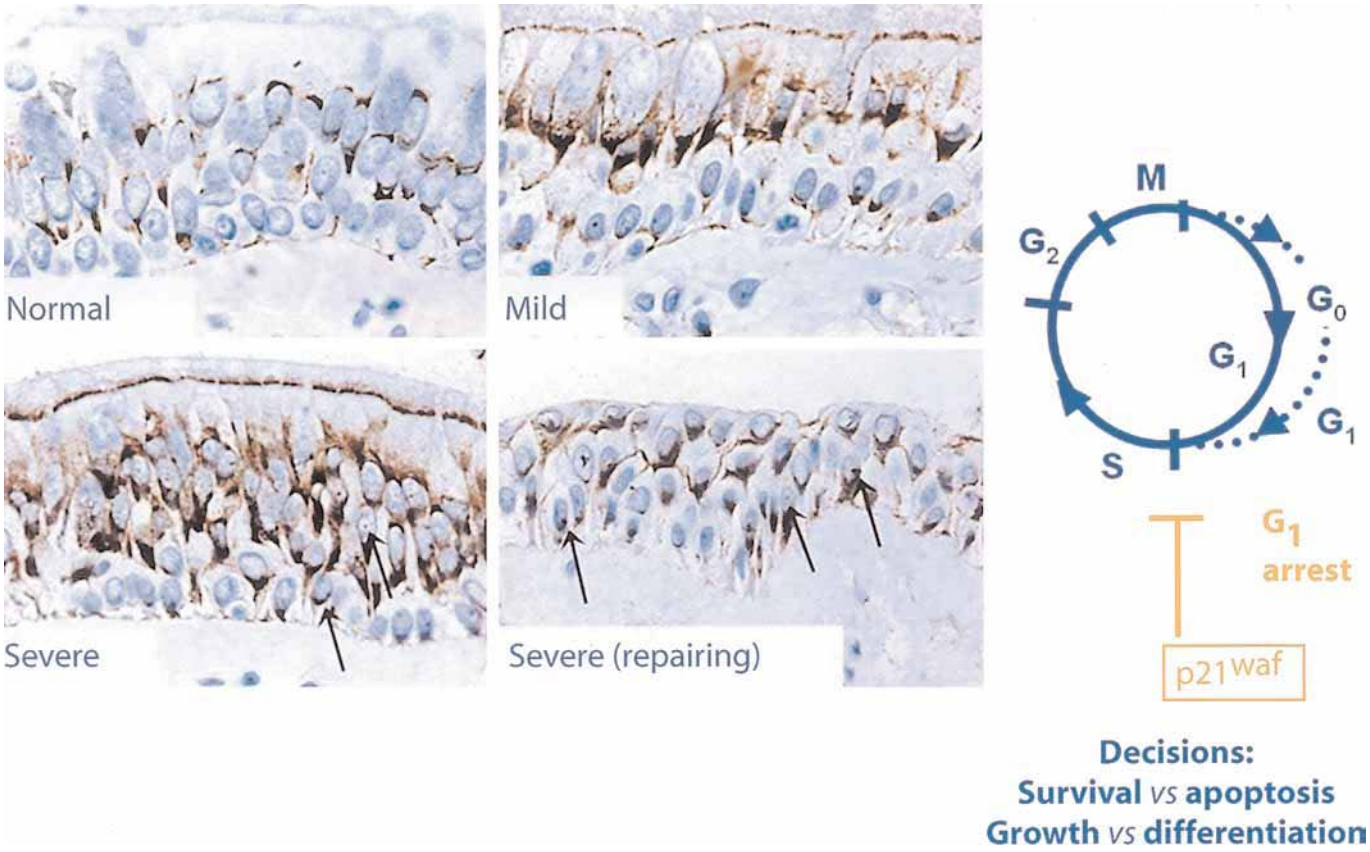

Figure 22-4 Increased expression of p21^{waf} in asthmatic epithelium in proportion to disease severity (left) and mechanisms of action of p21^{waf} in promoting cell cycle arrest. Note the nuclear localization of p21^{waf} in severe asthma.

predisposing individuals to asthma and provide an explanation for epidemiological evidence that identifies pollutant exposure, diet, and respiratory virus infection, which all increase oxidant stress in the airways, as important risk factors.

Morphometry has revealed that thickening of asthmatic airways accounts for a large component of BHR and is associated with resistance to corticosteroids. This failure of corticosteroids is reflected in the findings of the recent European Network for the Understanding Mechanisms of Severe Asthma (ENFUMOSA) study, which has revealed that these patients exhibit a greatly impaired quality of life, a component of fixed airway obstruction and have clear evidence of airway wall remodeling. In such patients, there is evidence of persistent matrix turnover with higher levels of cleaved tenascin C, matrix metalloproteinase 2 and collagen VI, indicating active tissue remodeling. Airway remodeling in adult asthma also provides an explanation of the accelerated decline in lung function observed over time. The Childhood Asthma Management Program (CAMP) study in children 5- to 11-yr-old showed that the beneficial effect of an inhaled corticosteroid on the postbronchodilator improvement in airway function observed during the first year of treatment was lost over the following 3 yr. This is best explained by airway remodeling that is insensitive to corticosteroids. A biopsy study has identified tissue remodeling as an early and consistent component of childhood asthma with fibroblast proliferation and collagen deposition in the subepithelial *lamina reticularis* being of greater diagnostic significance that tissue eosinophilia. Although remodeling had been considered secondary to long-standing inflammation, biopsy studies in young children have shown tissue restructuring up to 4 yr before the onset of symptoms, indicating processes that begin early in the development of asthma and occur in parallel with, or may be obligatory for, the establishment of persistent inflammation.

Epithelial Susceptibility to Injury and the Repair Phenotype in Asthma The normal bronchial epithelium is a stratified structure consisting of a columnar layer supported by basal cells to serve as a physical and chemical barrier to the external environment. In asthma, the epithelium shows evidence of activation linked to structural damage and goblet cell metaplasia. Epithelial stress is seen in the form of widespread activation of the transcription factors NFκB, activator proteins (e.g., AP-1) and (STAT1), and by the increased expression of heat-shock proteins and the cyclin-dependent kinase inhibitor p21^{waf} (Fig. 22-4 *see* below). The altered epithelium also becomes an important source of autacoid mediators, chemokines and growth factors that sustain ongoing inflammation. To explain the disordered morphology and extent of activation, whether the asthmatic epithelium is more susceptible to injury and/or has an altered response to damage has been investigated.

Epithelial Susceptibility Epithelial disruption is characteristically increased in the asthmatic bronchial epithelium. It has been proposed that this damage is artefactual; however, the finding of enhanced expression of the epidermal growth factor receptor (EGFR, HER-1, c-erbB1) and the epithelial isoform of CD44 indicate that injury has occurred in vivo. EGFR and CD44 expression in asthma increases with disease severity and is evident throughout the epithelium, suggesting that damage is widespread. Significantly, EGFR overexpression is insensitive to the action of corticosteroids

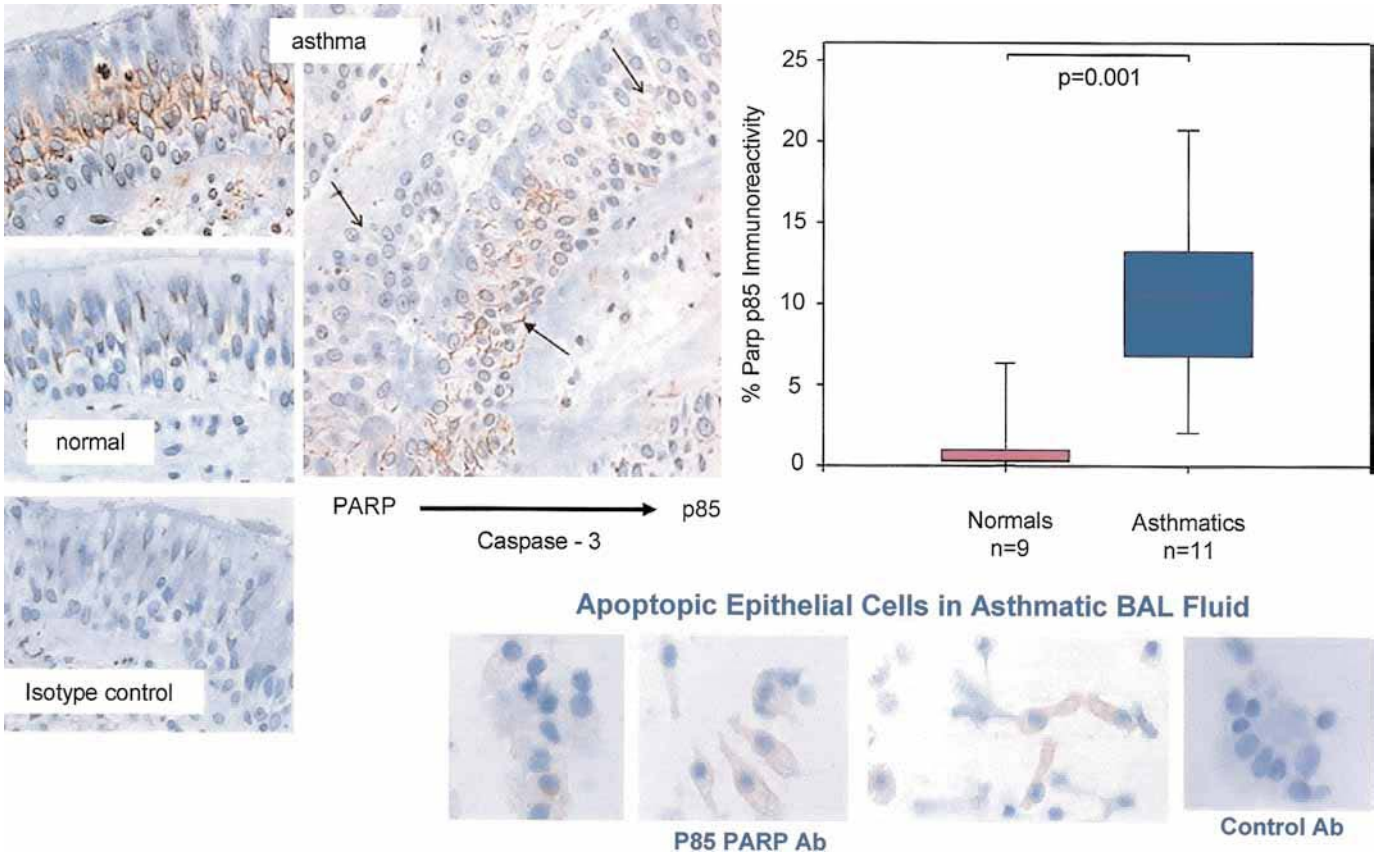

Figure 22-5 Increased immunostaining for the caspase-3 p85 cleavage product of poly ADP-ribose polymerase in asthmatic mucosal biopsies and BAL epithelial cells. (Please *see* color insert.)

and is positively correlated with the thickness of the *lamina reticularis*, linking epithelial injury to underlying remodeling. The extent of epithelial shedding in asthma is not observed in other inflammatory diseases, such as chronic obstructive pulmonary disease (COPD), in which the epithelium becomes multilayered owing to squamous metaplasia whereas the underlying *lamina reticularis* remains normal. Although these differences may reflect the quality of inflammation, airway eosinophilia is observed in the absence of asthma and neutrophils may dominate inflammation in severe asthma, as in COPD.

There also occurs increased epithelial expression of Fas and Fas ligand in patients who have died with asthma. In bronchial biopsies, there is markedly increased immunostaining of asthmatic columnar (but notably not basal) epithelial cells for p85, the caspase-3 cleavage product of polyADP polymerase, indicating that epithelial apoptosis is increased with disease (Fig. 22-5). Although such observational studies are able to identify differences between normal and asthmatic subjects, they are unable to determine whether the changes are a cause or consequence of inflammation. To address this, primary cultures of bronchial epithelial cells brushed from the airways of normal and asthmatic subjects have been established to compare responses under identical conditions in vitro. Although no difference in the rate of proliferation of these cultures under optimal growth conditions has been found, when rendered quiescent by growth factor depletion, those from asthmatic airways exhibit a significantly greater sensitivity to oxidant-induced apoptosis in the face of normal apoptotic response to the DNA and RNA synthesis inhibitor actinomycin D. This susceptibility to oxidants is unlikely to be a secondary effect of airway inflammation, because it is preserved through several generations in vitro. Because epidemiological studies and limited investigations in primates have identified multiple interacting risk factors for asthma, including inhalant pollutants and diets low in antioxidants, the effect of environmental oxidants on a susceptible epithelium may provide a plausible triggering mechanism for the induction of epithelial activation and damage in asthma. Once initiated, the resulting inflammatory cell influx causes secondary damage through the production of endogenous ROS, resulting in chronic tissue injury and persistent inflammation. Consistent with this proposal, the epithelial expression of the neutrophil chemoattractants IL-8 and macrophage inflammatory protein 1 α (MIP1α) is increased in severe asthma, and their appearance correlates with increased EGFR expression as a marker of epithelial damage. Further in vitro studies have revealed that oxidant or epidermal growth factor (EGF) treatment of primary bronchial epithelial cells enhances MIP1α or IL-8 release, respectively. Thus, the susceptibility of the epithelial barrier to the action of different components of the inhaled environment may play a key role in determining the asthmatic phenotype.

Growth Arrest and Epithelial Repair In vitro studies point to a central role for activation of the EGFR in the restoration of the bronchial epithelium following injury because (1) EGF is a mitogen for bronchial epithelial cells; (2) mechanical damage induces rapid phosphorylation of the EGFR irrespective of the presence of exogenous ligand; and (3) wound closure is enhanced by EGF but not by the unrelated ligand keratinocyte growth factor (FGF7). Recognizing that EGF is a potent mitogen, the increase in epithelial EGFR in

asthma is paradoxical because it is not matched by increased proliferation to replace columnar cells that have been shed and, in this way, contrasts with the hyperproliferative state of the epithelium seen in COPD. Although studies with primary cultures of normal and asthmatic bronchial epithelial cells have shown similar proliferation rates when maintained in medium supplemented with exogenous EGF, a potential mechanism for reduced EGFR-mediated proliferation in vivo emerges because the cyclin-dependent kinase inhibitor $p21^{waf}$ is overexpressed in basal, as well as columnar, epithelial cells in bronchial biopsies from patients with severe asthma (Fig. 22-4). In response to injury, $p21^{waf}$ acts as a checkpoint at the G1 to S-phase transition of the cell cycle, causing growth arrest to enable DNA repair to be completed before progression into S-phase or, in which damage is irreparable, to direct exit from the cell cycle and activate apoptosis. In this way, the decisions to survive or to enter into apoptosis are irrefutably linked. The EGFR ligands (EGF, TGF-β, amphiregulin, heparin-binding epidermal growth factor-like growth factor [HB-EGF], epiregulin and betacellulin) are pivotal determinants of the epithelial cell fate through their ability to act as survival factors that protect against proapoptotic stimuli and as mitogens that signal cell cycle progression. Although the ability of EGF to protect against oxidant-induced apoptosis in vitro has not been characterized, studies in animal models have shown that EGF can protect against smoke-induced tracheal injury in sheep.

As expression of $p21^{waf}$ is strongly induced by oxidant stress, the finding that asthmatic bronchial epithelial cells are more susceptible to oxidant injury provides one explanation for the high expression of $p21^{waf}$ in the asthmatic epithelium. However, $p21^{waf}$ is also induced by the antiproliferative growth factors TGF-β_1 and TGF-β_2, the levels of which are elevated in asthma, in COPD and in response to epithelial injury in vitro. The overall fate of the epithelium reflects the integration of survival and proliferation signals provided by EGF-like growth factors that activate mitogen-activated protein kinases (MAPK) and the counterbalancing proapoptotic and antiproliferative signals caused by injury and members of the TGF-β family. Although expression of EGF, TGF-β, and HB-EGF is unchanged in asthmatic bronchial epithelium relative to normal controls, markedly increased TGF-α production occurs in COPD. Thus in COPD, increased activation of the EGFR by EGF and analogous ligands protects against cigarette smoke-induced injury and overrides the antiproliferative effect of TGF-β, whereas in asthma an insufficiency of these ligands provides a unifying mechanism for increased epithelial susceptibility and impaired repair. This is supported by the finding of a marked decrease in epithelial immunostaining for phosphotyrosine (a global marker of tyrosine kinase activation) in the bronchial epithelium of mild asthma and the reported lack of MAPK activation. In contrast, in corticosteroid-refractory asthma, tyrosine kinase activity is markedly increased in relation to disease severity or treatment. Although the phosphorylated proteins within the asthmatic epithelium have not been identified, they are more likely to be linked to stress-induced changes than to proliferation because, in the bronchial epithelium of severe asthmatic subjects, $p21^{waf}$ is elevated whereas proliferating cell nuclear antigen remains low.

In asthma there is no increase in epithelial expression of the structurally related heregulin receptors HER2 (c-erbB2) or HER3 (c-erbB3), whereas in COPD both these receptors are overexpressed in parallel with the EGFR. As EGFR/EGFR homodimers are only weak activators of the MAPK pathway, this will further contribute to the inability of the asthmatic epithelium to counter antiproliferative signals provided by the TGF-β. In contrast, EGFR:HER2 heterodimers are able to promote cell survival because of the presence of multiple binding sites for phosphatidylinositol 3-kinase on this receptor. Based on these findings, the duration of the epithelial repair may be prolonged in asthma resulting from an imbalance between proliferation and survival signals involving the EGFR/HER family and antiproliferative signals involving the TGF-β.

The Epithelial-Mesenchymal Trophic Unit

Epithelial-Mesenchymal Signaling High resolution computed tomography, postmortem and biopsy studies in chronic asthma have all revealed airway wall thickening. This involves deposition of interstitial collagens in the *lamina recticularis*, matrix deposition in the submucosa, smooth muscle hyperplasia and microvascular and neuronal proliferation (Fig. 22-6). Thickening of the *lamina reticularis* is diagnostic of this disease and, on the basis of measurements made in human airways and in a guinea pig model of chronic antigen exposure, it appears to reflect events linked to thickening of the entire airway wall. A layer of subepithelial mesenchymal cells has been described with features of myofibroblasts, the number of which was increased in asthma in proportion to the thickness of the reticular collagen layer. These cells correspond to an attenuated fibroblast sheath lying adjacent to the *lamina reticularis* and forming a network similar to hepatic stellate cells which, when activated by liver damage, are the key receptor cells responsible for fibrosis. Because the bronchial epithelium is in intimate contact with the attenuated fibroblast sheath, these two cellular layers are in a key position to coordinate responses to challenges from the inhaled environment into the deeper layers of the submucosa. Injury to epithelial monolayers in vitro results in increased release of fibroproliferative and fibrogenic growth factors including FGF2, insulin-like growth factor (IGF) 1, platelet-derived growth factor (PDGF), endothelin (ET)-1 and latent and active TGF-β_2. TGF-β, FGF2, and ET-1 are also increased in asthma, with TGF-β and FGF2 being encrypted in the extracellular matrix, as shown by their colocalization with the proteoglycans decorin and heparan sulfate, respectively. To further establish the relationship between EGFR signaling in the repair and remodeling processes, an EGFR-selective tyrosine kinase inhibitor has been used that suppresses epithelial repair in vitro with a resultant increase of release of TGF-β_2 by the damaged epithelial cells. This suggests parallel pathways operating in repairing epithelial cells, some of which direct efficient restitution and are regulated by EGFR, whereas others control profibrogenic growth factor production independently of the EGFR. In asthma, it seems likely that impaired epithelial proliferation causes the bronchial epithelium to spend longer in a repair phenotype, resulting in increased secretion of profibrogenic growth factors (Fig. 22-7).

Using a coculture model, there is direct evidence that epithelial injury causes myofibroblast activation. Thus, polyarginine (a surrogate for eosinophil basic proteins) or mechanical damage to confluent monolayers of bronchial epithelial cells grown on a collagen gel seeded with human myofibroblasts leads to enhanced proliferation and increased collagen gene expression owing to the combined effects of FGF2, IGF1, PDGF-BB, TGF-β, and ET-1. Furthermore, in mild–moderate asthma, inhaled corticosteroids reduce airway inflammation and levels of IGF1 and FGF2 but with minimal improvement in BHR and no effect on collagen deposition in the *lamina reticularis* or on TGF-β levels. Because corticosteroids reduce submucosal eosinophils by approx 80%, the persistently high TGF-β in BAL fluid most likely derives from the injured and repairing epithelium and associated matrix turnover rather than

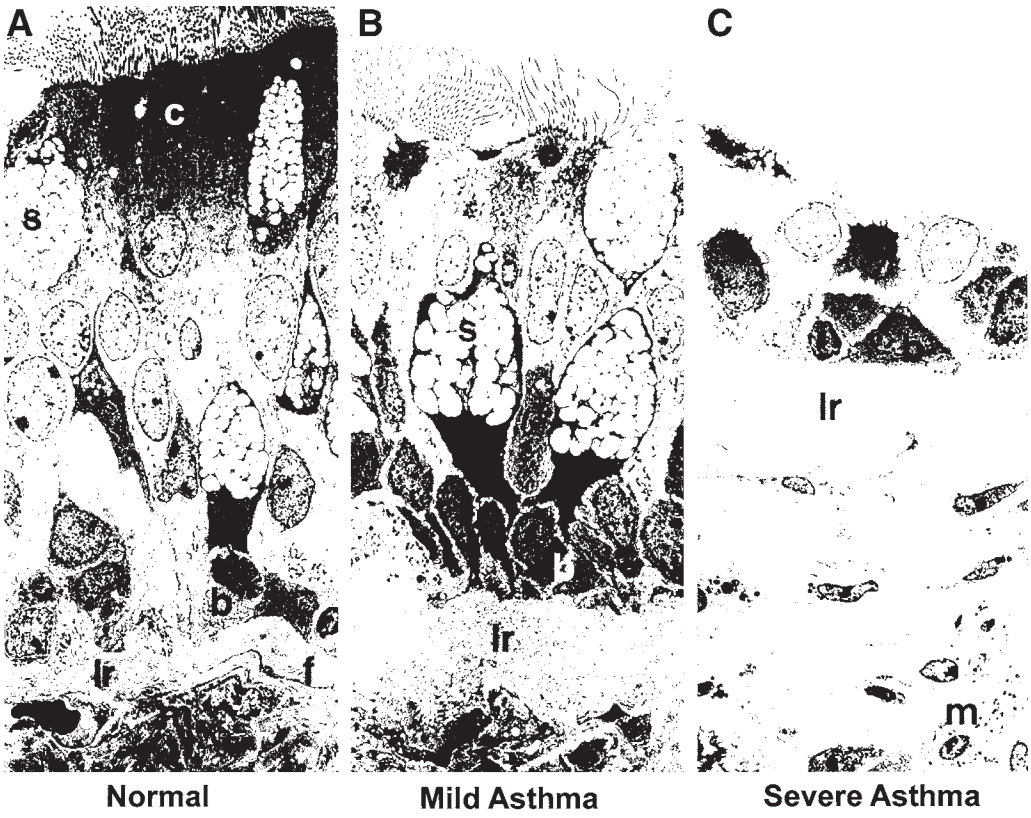

Figure 22-6 Transmission electron micrographs of airway epithelium in normal, mild asthma and severe asthma demonstrating disease-related thickening of the *lamina recticularis* and epithelial changes.

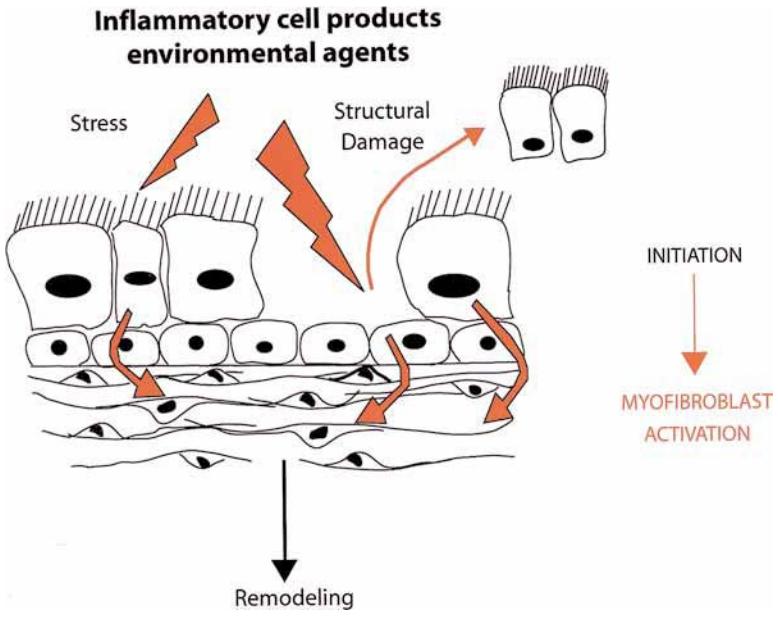

Figure 22-7 Schematic representation of epithelial-mesenchymal communication in chronic asthma.

from eosinophils. Both epithelial EGFR expression and TGF-β production are refractory to corticosteroids, and the combined effects of these signaling pathways on the epithelial-mesenchymal trophic unit (EMTU) could provide mechanisms for tissue remodeling and explain the incomplete resolution of lung function with inhaled corticosteroids observed in chronic asthma.

Communication between the epithelium and the subepithelial fibroblast sheath is reminiscent of the processes that drive physiological development of the airways during embryogenesis, in which the epithelium and mesenchyme act as a "trophic unit" to regulate airway growth and branching. Consequentially, it is proposed that the EMTU is reactivated in asthma to drive pathological

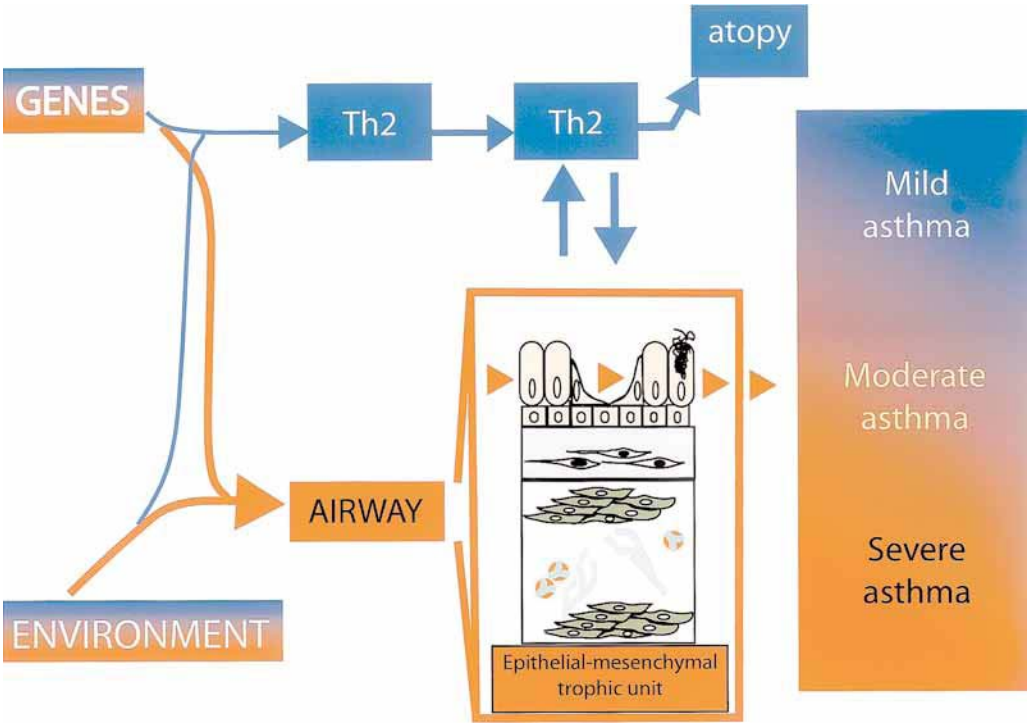

Figure 22-8 Schematic representation of the epithelial mesenchymal trophic unit and its relationship to Th2-related inflammation in asthma. Th, T-helper.

remodeling of the airways (Fig. 22-8). In subjects with asymptomatic BHR, longitudinal studies show that those who progress to asthma show parallel changes in inflammation and remodeling. Thickening of the *lamina reticularis* in bronchial biopsies from young children is also present several years before asthma becomes clinically manifest. During lung development, epithelial and mesenchymal growth is regulated, in part, by the balance of EGF and TGF-β signaling, as suggested also occurs in chronic asthma. In susceptible individuals, environmental factors may interact with EMTU in early life to initiate structural changes in the airways that may account for the decrease in lung function observed in young children who are susceptible to early wheezing and for the loss of corticosteroid responsiveness on baseline lung function observed in the CAMP study and related long-term studies investigating the disease-modifying effects of inhaled corticosteroids. This is supported by studies in nonhuman primates, in which intermittent exposure to ozone in the presence of allergen creates a phenotype resembling chronic asthma. Therefore, bronchial epithelial susceptibility seems either to precede or occur in parallel with factors predisposing to the Th2-mediated inflammation and is an absolute requirement to establish the microenvironment for inflammation to become persistent in the airways and for remodeling to occur.

Propagation of the Remodeling Responses by the EMTU To study the mesenchymal cells that are involved in the remodeling responses in asthma, protocols have been established for their outgrowth from bronchial biopsies. These vimentin-positive fibroblasts can be grown readily from asthmatic mucosal biopsies and differ from those from normal airways in adopting stem cell characteristics, by proliferating rapidly in the absence of exogenous growth factors and in their ability to overcome contact inhibition in the presence of TGF-β_1 or TGF-β_2, enabling higher cell densities to be achieved. In this regard, TGF-β treatment in vitro also causes submucosal fibroblasts to adopt a myofibroblast phenotype, as evinced by the induction of α-SMA, acquisition of contractile phenotype and synthesis of interstitial (repair) collagens. The relationship between myofibroblast activation and the underlying smooth muscle mass in asthma has yet to be studied. However, following allergen exposure, activation of the smooth muscle increases. In addition, mitogen treatment of asthmatic mucosal fibroblasts in vitro causes them to release both ET-1 and another vascular mitogen, vascular endothelial growth factor (VEGF). Thus, in addition to increased matrix deposition, activation of myofibroblasts contributes to smooth muscle and microvascular proliferation, which are both characteristic features of the remodeled asthmatic airway.

In a rabbit model of partial outflow obstruction in the bladder, TGF-β causes serosal thickening resulting from accumulation of myofibroblasts, which, over time, change phenotype into smooth muscle cells. In developing capillaries, endothelial cells and smooth muscle cells also share a common stem cell progenitor with vascular endothelial growth factor and PDGF acting as the key determinants of cell fate. Studies of normal and asthmatic airway (myo)fibroblasts reveal that these cells exhibit phenotypic plasticity, have some early features of smooth muscle (e.g., expression of the SM-22 protein) and can be further differentiated by TGF-β_1 and TGF-β_2 to express heavy chain myosin and α-SMA. This suggests that the cells have properties of both myofibroblasts and smooth muscle cells and are probably derived from a common (stem cell) progenitor. Thus, mediators released by the repairing bronchial epithelium provide a mechanism for myofibroblast activation to propagate and amplify airway remodeling. Such a mechanism would fit well with the findings on airway smooth muscle cultured from asthmatic airways.

GRANULOCYTE INTERACTIONS WITH AIRWAY STRUCTURAL CELLS The mechanisms through which eosinophils become activated are largely dependent on adhesion events, in

Eosinophil adhesion molecule	Counterligand
CD44	Hyaluronan

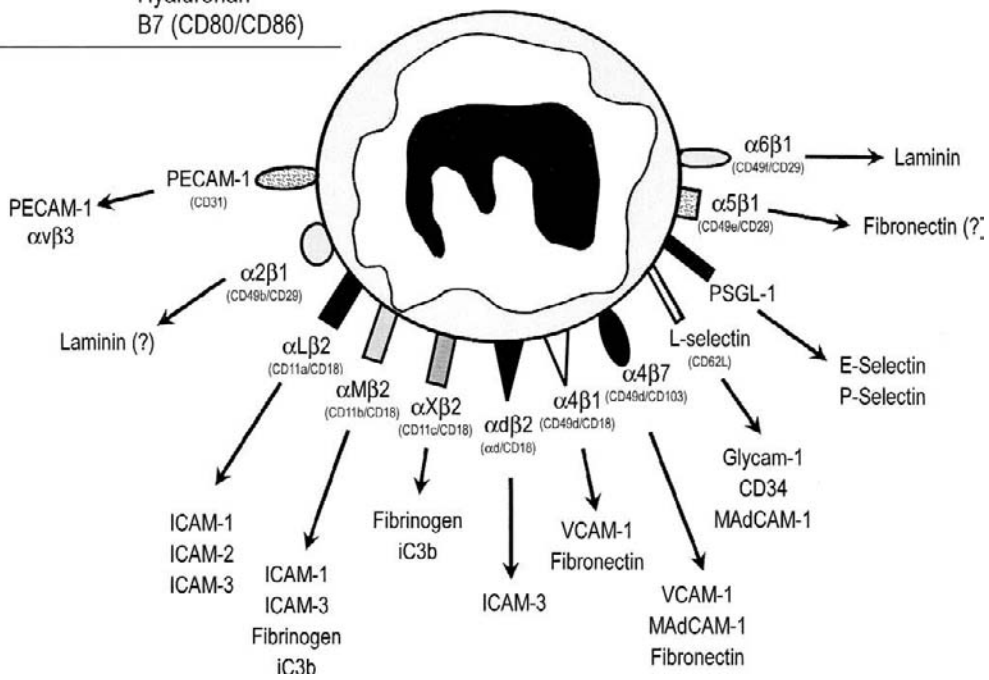

Figure 22-9 Eosinophil adhesion molecules and their counterligands. Inset: Recently identified eosinophil adhesion molecules. (Reproduced with permission from Giembycz MA, Lindsay MA. Pharmacology of the eosinophil. Pharmacol Rev 1999;51:213–340.)

which adhesion molecules on the cell's surface bind to counterligands on vascular endothelial cells, extracellular matrix, fibroblasts and epithelial cells (Fig. 22-9). For example, the release of IL-13 from eosinophils is dependent on ligation of CD28 by CD86 on adjacent eosinophils or by CD80 or CD86 on dendritic cells, macrophages or B lymphocytes. Similarly, TGF-β secretion from eosinophils is stimulated strongly by binding of cell-surface CD44 to the matrix glycosaminoglycan hyaluronan. Ligation of Mac1, which is responsible for eosinophil adhesion to bronchial epithelial cells through interaction with ICAM1, is a prerequisite for significant stimulation of ROS generation or degranulation; ligation of very late antigen 4 ($\alpha_4\beta_1$ integrin)—either by VCAM1 or by extracellular fibronectin—greatly enhances the production of ROS and LTC_4, the latter evinced by the ability of supernatants of VCAM1/PAF-stimulated eosinophils to provoke contraction of bronchial smooth muscle.

Lung fibroblasts represent a major source of the eosinophil chemoattractant, eotaxin, and also promote eosinophil survival through the release of GM-CSF. Because tissue-infiltrating eosinophils themselves represent a source of IL-13 and TGF-β, which potently and synergistically induce eotaxin release from fibroblasts, they have the potential to stimulate their own recruitment. This may provide a mechanism for amplified eosinophilic inflammation in airways in which fibroblast numbers and/or responsiveness are increased. Fibroblasts, whose synthesis of hyaluronan is upregulated by inflammatory cytokines such as IL-1β, provide a substrate for eosinophil adhesion through the ligation of eosinophil CD44, which promotes the secretion of TGF-β and may further amplify the production of eotaxin and, consequently, the recruitment of eosinophils. Adherence of eosinophils to the fibroblast surface also occurs through β_1-integrin-dependent mechanisms that promote production of ROS and LTC_4, as well as release of granule proteins. Supernatants of activated eosinophils stimulate the proliferation of human lung fibroblasts, thereby providing a larger source of both hyaluronan and eotaxin.

The ability of eosinophils and neutrophils to activate the bronchial epithelium remains largely unexplored. Although neutrophil proteases are known to be highly potent mucous secretagogues, little is known about the actions of other leukocyte-derived products on the epithelium. In animal models, activated eosinophils and neutrophils promote the production of the bronchoconstrictor thromboxane A_2 by tracheal epithelium but this has not been confirmed in human cells. Eosinophil cationic protein stimulates epithelial secretion of IGF1, itself a stimulus for lung epithelial cell proliferation, whereas adherent eosinophils stimulate the release of secretory leukoprotease inhibitor from bronchial epithelial cell lines. The latter response may indicate a contribution of eosinophils to the suppression of acute inflammatory responses, with a shift toward chronic TGF-β-driven remodeling.

The airway epithelium is a major source of neutrophil chemoattractants, including IL-8 and growth-related oncogene α (CXCL1). Inflammatory activation of the epithelium would, therefore, be expected to promote neutrophil recruitment, although direct evidence of this is lacking. Neutrophils themselves are capable of causing epithelial detachment, via the action of serine proteases such as elastase and cathepsin G, and can stimulate epithelial IL-8 secretion via an action of defensins. Curiously, however, these neutrophil products are mutually antagonistic: defensins inhibit the cytotoxic actions of serine proteases whereas proteases inhibit the secretory response to defensins. It is difficult to deduce how these

actions are balanced in vivo and to predict whether neutrophils primarily destroy or activate the airway epithelium.

ASTHMA AS A GENETIC DISEASE

POPULATION AND FAMILY STUDIES Evidence that genetic factors are important in common diseases often comes initially from studies comparing the frequency of disease among genetically related individuals with that in the general population. Accordingly, the evidence for a genetic component to the development of asthma includes (1) family studies indicating more frequent occurrence of asthma in first-degree relatives of asthmatic subjects; (2) familial aggregation patterns in which the rates of asthma were found to be significantly higher in those families with one or more asthmatic parent; and (3) studies showing that monozygotic twins are significantly more concordant for asthma than dizygotic twins. Reports during the past 50 yr have proposed both simple Mendelian and multifactorial models to explain the familial clustering of asthma (or allergy). These studies provided the general conclusion that the expression of asthma is likely to be heterogeneic and polygenic and to be the result of an interaction between genetic and environmental factors. Statistical analysis of data was often hampered by the absence of physiological criteria for a specific asthmatic phenotype, the difficulty in separating inheritance of the atopic predisposition from the inheritance of asthma, or the lack of controls for environmental factors. The development of phenotypic markers for asthma (or subtypes of asthma) has served to facilitate studies of its inheritance.

PHENOTYPIC INHERITANCE BHR is a common phenotypic marker of asthma, and family studies suggest that BHR is under genetic influence. In fact, concordance among identical twins is significantly greater for BHR than for asthma symptoms. In addition, BHR may be found in asymptomatic parents of asthmatic children without evidence of positive allergen skin tests or increased serum IgE, and the hyperresponsiveness is inherited in an autosomal-dominant pattern. Other studies have provided similar results, but some indicate that the trait may not be caused by segregation at a single autosomal locus.

The discovery of IgE and the observation that its levels may increase in association with atopic disease quickly placed IgE (and in particular its level of biosynthesis) as a candidate marker for atopy. Several observations indicate that the level of total serum IgE may correlate even better with the development of asthma than for atopy. These results suggested that asthma resulted from IgE-dependent mechanisms even in the absence of identifiable allergen sensitivity. A separate follow-up study confirmed the relationship between asthma and IgE levels and established a similar link between BHR and total serum IgE levels. Other investigators have confirmed these results and have added that an increase in circulating eosinophils may also be linked to the asthma phenotype. Genetic models for the inheritance of IgE levels were proposed in a series of population and family studies to support the existence of a relatively common recessive regulatory locus, with recessive homozygotes maintaining persistently high levels of IgE. In addition, a significant multifactorial background was detected.

DNA MARKERS AND MOLECULAR GENETICS By using markers for DNA polymorphisms, at least two genetic loci have been linked to atopy and possibly to asthma. Initial work defined a single dominantly inherited locus located on chromosome 11q13 controlling IgE hyperresponsiveness. The apparent discrepancy in mode of inheritance between results derived from segregation vs linkage analysis may be related to the definition of phenotypes employed by the two types of studies. In the linkage studies, the definition of atopy was expanded to include asymptomatic subjects (identified by abnormal IgE responsiveness). Subsequent work on the 11q13-linked atopy "gene" suggested that it may be genetically linked to the site of the β-subunit of FcεRI and that a variation within this gene ($Ile^{I8}Leu$) may be associated with atopy. These findings suggest that the FcεRI β-subunit is a candidate gene predisposing to atopy. The discovery that a single-nucleotide polymorphism (SNP) in the FcεR1-β gene produces a dysfunctional, alternatively spliced variant that is not transported to the cell surface provides a plausible explanation of how genetic variation in the IgE receptor can influence the expression of atopy. Additional work has linked markers for chromosome 5q31-33 with atopy (defined by total serum IgE) and BHR. The 5q31-33 site is near the genes for IL-4, IL-6, IL-9, and IL-13 (which are implicated in the control of IgE biosynthesis) as well as additional candidate genes encoding other cytokines, growth factors, and receptors (including the β_2 adrenoceptor). Fine mapping of this region is aimed at better definition of candidate genes linked to asthma.

Because antigen-dependent immune and inflammatory mechanisms participate prominently in the expression of the asthmatic phenotype, investigators have also attempted to establish linkage of asthma to loci within the major histocompatibility complex (MHC). The MHC/human leukocyte-associated antigen (HLA) class I (HLA-A, -B, and -C) and class II (HLA-DP, -DQ, and -DR) genes are among the most polymorphic human genes described, with more than 10 alleles defined for each locus. The nature of this polymorphism has been investigated extensively using serological reagents and nucleic acid typing probes. In some studies, significant HLA associations with asthma have been found, but in others there is no association between asthma and specific HLA alleles. It is likely that weak or conflicting associations are related to the heterogeneity of the phenotype and the possibility that a discrete abnormality may be restricted to a subset of asthmatic subjects. It appears likely that a particular sequence is necessary, but not sufficient, for responsiveness to a particular antigenic epitope, and that further genetic and environmental factors are required for the expression of specific immune responsiveness. Because considerable linkage disequilibrium exists between the MHC alleles and other putative candidate genes on chromosome 6p, such as TNF-α and TNF-β, it is highly likely that gene–gene as well as gene–environmental interaction in this chromosomal region explain the genetic associations with asthma.

NEWLY IDENTIFIED ASTHMA GENES There have been major breakthroughs in the discovery of novel asthma and atopy genes through positional cloning. A combination of microsatellite linkage and SNP association studies applied to populations enriched for asthma and allergy, followed by fine mapping and gene sequencing of segments of the human genome cloned into artificial bacterial chromosomes (contigs), has identified ADAM33, PHF11 (linked to IgE), and DPP10 (linked to T cell/chemokine responses) as entirely novel disease associated genes.

ADAM33 on chromosome 20p13 encodes a disintegrin and metalloprotease that is preferentially expressed by mesenchymal cells (Fig. 22-10). This Zn^{2+}-dependent metalloprotease has enzymatic properties to cleave a number of cell surface procytokines and their receptors, but whether the disease associated SNPs are related to this or another activity of the ADAM protein is not

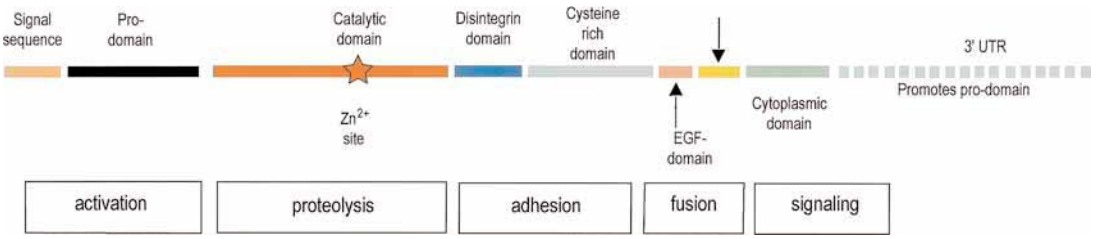

Figure 22-10 Schematic representation of the ADAM 33 gene and domain structure related to functions. EGF, epidermal growth factor; UTR, untranslated region.

known. PHF11 on chromosome 13q14 encodes a product containing two Pro-His-Asp zinc fingers that regulate transcription involved in IgE synthesis. DPP10 on chromosome 2q14 encodes a homologue of dipeptidyl peptidases with the property of cleaving terminal peptides from cytokines, chemokines and growth factors. Thus, it seems likely that ADAM33 is more closely involved in the BHR and remodeling aspects of asthma whereas PHF11 and DPP10 are more mechanistically linked to the allergic and inflammatory aspects of the disease.

CONCLUSION

Understanding and treating asthma depends on an appreciation of how inflammatory cells infiltrate the pulmonary airway and how the resulting infiltrate leads to characteristic pathological changes in airway tissue. In this context, investigators have pursued the regulatory controls over genes encoding critical components of the immune response to inhaled allergic and nonallergic stimuli. Initial evidence indicates that allergic and nonallergic asthma exhibit separate but overlapping cell–cell interactions orchestrated by immune cells and airway parenchymal cells.

23 Pulmonary Emphysema

STEVEN D. SHAPIRO

SUMMARY

Chronic obstructive pulmonary disease (COPD) is a disease state characterized by airflow limitation that is not fully reversible caused by a noxious agent. COPD is the fourth leading cause of mortality and affects more than 16 million people in the United States, a number that has increased about 40% since 1982. As COPD and other cigarette-related diseases become epidemic worldwide, the biology of emphysema is clearly complex and poorly understood with limited translation into effective pharmacotherapy.

Key Words: Chronic obstructive pulmonary disease; cigarette; pulmonary emphysema.

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) has been defined by the Global Initiative for Chronic Obstructive Lung Disease as a disease state characterized by airflow limitation that is not fully reversible caused by a noxious agent. The agent is almost uniformly long-term cigarette smoke exposure. COPD includes emphysema, an anatomically defined condition with destruction and enlargement of the lung distal to the terminal bronchioles; chronic bronchitis, a clinically defined condition with chronic cough and phlegm; and small airways disease, a condition related to narrowing of small bronchioles. COPD is only present if chronic airflow obstruction occurs; chronic bronchitis without chronic airflow obstruction is not included within COPD.

EPIDEMIOLOGY

CIGARETTE SMOKE EXPOSURE The death rate for COPD in the United States has also been increasing in contrast to falling death rates from heart and cerebrovascular diseases over the same interval. In 2001, for the first time ever, death rates for women exceeded those for men in the United States. Global burden of disease estimates suggest that COPD will rise from the sixth to the third most common cause of death worldwide by 2020.

Cigarette smoking is by far the most important risk factor for the development of COPD. Accelerated deterioration of ventilatory function is common among smokers; however, its magnitude is relatively small in most smokers. The relationship between amount of smoking and risk of COPD is unpredictable on an individual basis. Many persons with a high number of pack-years of smoking still have a normal or near-normal forced expiratory volume in the first second (FEV_1) whereas some individuals have a reduced FEV_1 with relatively modest smoking histories. Among smokers who have already sustained reductions in FEV_1, the consequences of continued smoking on ventilatory function are much more impressive than when all smokers are lumped together. The Lung Health Study found that among middle-aged smokers with an FEV_1 of 55–90% of predicted, differences of several hundred milliliter of FEV_1 developed within 5 yr between those who quit smoking and those who did not quit.

Although passive smoke exposure has been associated with reductions in pulmonary function, the importance of this risk factor in the development of the severe pulmonary function reductions in COPD remains uncertain. Although cigar and pipe smoking may also be associated with the development of COPD, the evidence supporting such associations is less compelling, likely related to the lower dose of inhaled tobacco byproducts during cigar and pipe smoking.

OTHER FACTORS The considerable overlap between subjects with asthma and COPD in airway responsiveness, airflow obstruction, and pulmonary symptoms led to the formulation of the Dutch hypothesis. It suggests that asthma, chronic bronchitis, and emphysema are variations of the same basic disease, which is modulated by environmental and genetic factors to produce these pathologically distinct entities. The alternative British hypothesis contends that asthma and COPD are fundamentally different diseases: asthma is viewed as largely an allergic phenomenon, whereas COPD results from smoking-related inflammation and damage. Determination of the validity of the Dutch hypothesis vs the British hypothesis awaits identification of the genetic predisposing factors for asthma and/or COPD, as well as the interactions between these postulated genetic factors and environmental risk factors.

Respiratory infections are important causes of COPD exacerbations; however, the association of both adult and childhood respiratory infections to the development and progression of COPD remains to be proven. Although several specific occupational dusts and fumes are likely risk factors for COPD, the magnitude of these effects appears to be substantially less important than the effect of cigarette smoking.

PATHOLOGICAL MECHANISMS IN COPD

Cigarette smoking leads to changes in the large airways, small airways, and lung parenchyma (Fig. 23-1). The effects of cigarette smoke exposure on different lung compartments is variable

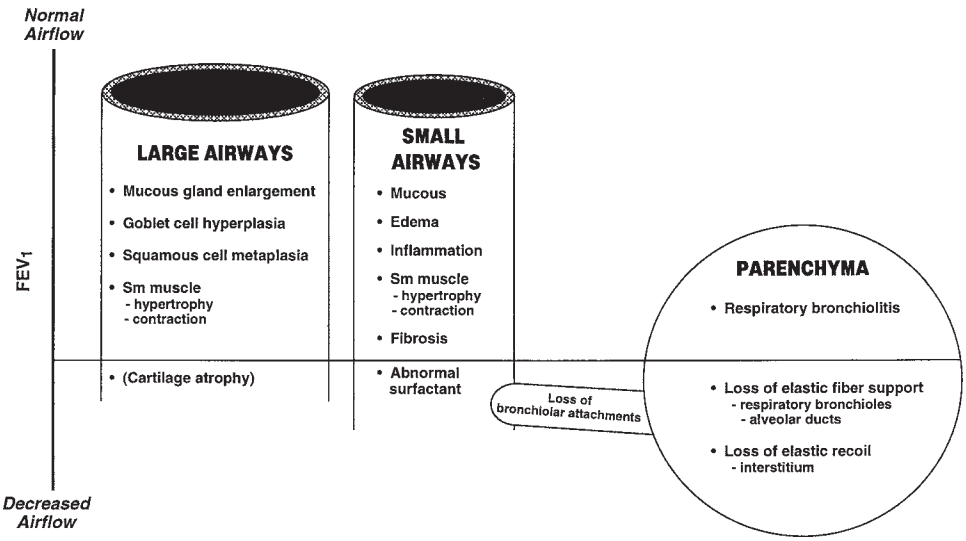

Figure 23-1 Pathological changes in relation to airflow in COPD. Changes observed in large airways (>2 mm), small airways (<2 mm), and lung parenchyma are depicted. Abnormalities above the line are associated with normal airflow (normal FEV_1), whereas those below the line are likely to cause decreased airflow (low FEV_1). Note, although controversial, most airway changes associated with excess material in the airway may not cause airflow obstruction. A unifying hypothesis for airflow obstruction involves loss of lung elastin resulting both in decreased small airway attachments and decreased parenchymal elastic recoil.

both within and between individuals, hence leading to disease heterogeneity within a given lung, and the contribution of the airways and lung parenchyma to airflow obstruction differs among individuals. Overall, small airway changes likely contribute to airflow obstruction initially, whereas emphysema predominates in advanced disease.

AIRWAY DISEASE

Large Airways The changes in the large airways, which include mucous gland enlargement and goblet cell hyperplasia, are responsible for chronic bronchitis. Epithelial cells undergo squamous metaplasia with loss of cilia. This not only predisposes to carcinogenesis, but impaired mucociliary clearance increases the risk of airway infections. Both bacterial and inflammatory host proteinases may promote airway remodeling further decreasing bacterial clearance. The serine proteinase neutrophil elastase (NE) also causes goblet cell degranulation and mucin production.

Small Airways (<2 MM) Changes that predispose to airway narrowing include goblet cell metaplasia, smooth muscle hypertrophy, excess mucus, edema, and inflammatory cellular infiltration. Reduced surfactant may increase surface tension at the air-tissue interface predisposing to airway narrowing or collapse. Emphysema, discussed next, appears to lead to airflow obstruction because the alveolar wall attachments that help maintain the patency of small airways by producing outward traction on their walls are decreased in number and the capacity of the attachments that do remain to develop traction is decreased. Airway remodeling with subepithelial fibrosis might be a critical factor in small airway narrowing. Little is known regarding mechanisms of airway fibrosis in COPD, but there are several potential mechanisms whereby a proteinase can predispose to fibrosis. This might seem counterintuitive because proteinases degrade matrix; however, the net effect on collagen depends on whether a particular proteinase can degrade collagen as well as other nonmatrix substrates. For example, matrix metalloproteinases (MMPs) degrade insulin-like growth factor (IGF) binding proteins releasing profibrotic insulin-like growth factor. Plasmin and other proteinases could release and activate transforming growth factor-β. MMP-2 causes fibroblast proliferation. Thus, proteinases have multiple effects on cells and matrix that could result in net accumulation of collagen.

EMPHYSEMA Emphysema, characterized by destruction and enlargement of the gas-exchanging airspaces, that is, the respiratory bronchioles, alveolar ducts, and alveoli, characterized by obliteration and perforation of airspace walls with coalescence of airspaces into much larger ones than normal. The pathogenesis of emphysema can be dissected into at least four interrelated events: (1) chronic exposure to cigarette smoke leads to inflammatory cell recruitment within the lung's terminal airspaces; (2) these inflammatory cells release proteinases that damage the extracellular lung matrix; (3) cell death: loss of alveolar units must also encompass death to structural cells of the airspace (whether cell death is a cause or consequence matrix destruction is unknown); and (4) ineffective repair of the extracellular matrix and cellular constituents results in pulmonary emphysema.

Inflammation Synthesis of existing data regarding inflammatory cell response in human lungs following cigarette smoke exposure suggests the following sequence of events. Macrophages patrol the lower airspace under normal conditions. Cigarette smoke comes in contact with and activates lung epithelial cells and alveolar macrophages leading to cytokine/chemokine release followed by acute neutrophil recruitment, and subacute macrophage accumulation in the respiratory bronchioles and alveolar space. T cells ($CD8^+ > CD4^+$), and perhaps other inflammatory and immune cells, are also recruited. Concomitant cigarette smoke-induced loss of cilia in the airway epithelium predisposes to bacterial infection with neutrophilia. Cigarette smoke exposure might also directly impair immune cell function. Surprisingly, in end-stage lung disease, long after smoking cessation, there remains an exuberant inflammatory response suggesting that mechanisms of cigarette smoke-induced inflammation that initiate the disease differ from mechanisms that sustain inflammation after smoking cessation. Thus multiple interacting inflammatory cell types are present and likely contribute to the pathogenesis.

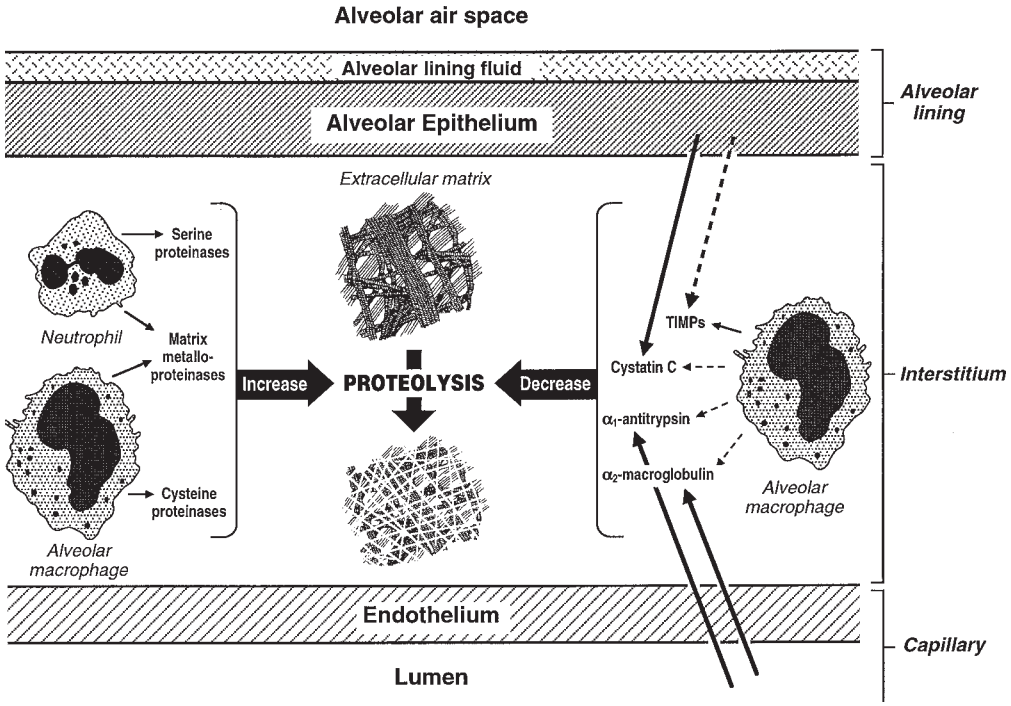

Figure 23-2 Proteinase–antiproteinase balance in the lung parenchyma determines the risk of proteolytic degradation of lung extracellular matrix. Proteinases released by neutrophils, macrophages, and perhaps resident cells have the capacity to degrade lung extracellular matrix components including elastin, thus predisposing to emphysema. Matrix proteolysis is limited by the presence of inhibitors to each class of proteinases. Some inhibitors are locally derived (TIMP, cystatin C) whereas others arrive via the bloodstream (α_1-AT, α_2-macroglobulin). The predominant sources are depicted by solid arrows; lesser sources are indicated by dashed arrows. (Adapted from Evans MD, Pryor WA. Cigarette smoking, emphysema, and damage to α_1-proteinase inhibitor. Am J Physiol 266 [Lung Cell Mol Physiol 10] 1994; L593–L611).

Proteinase–Antiproteinase Hypothesis In 1963, an association was reported of chronic airflow obstruction and emphysema with deficiency of serum α_1-antitrypsin (α_1-AT), the endogenous inhibitor of NE. In 1964 the first reproducible model of emphysema was described in experimental animals by injecting papain, a plant-derived proteinase, into the lungs via the trachea. Together these observations indicated that emphysema could be induced by proteolytic injury to the lung extracellular matrix, and eventually led to the proteinase–antiproteinase hypothesis of emphysema that has since been the prevailing concept of emphysema pathogenesis. Because only instillation of elastolytic enzymes caused the lesions, it is often called the elastase/antielastase hypothesis. However, there is evidence that collagen overexpression in transgenic mice is associated with airspace enlargement. Moreover, despite increased collagen accumulation in COPD, loss of alveolar units must also encompass collagen turnover.

According to the proteinase–antiproteinase hypothesis of emphysema, there is a steady or episodic release of proteolytic enzymes with elastolytic activity into the lung parenchyma (Fig. 23-2). Normally, plasma proteinase inhibitors, especially α_1-AT, permeate lung tissue and prevent proteolytic enzymes from digesting structural proteins of the lungs. Proteinase inhibitors synthesized locally in the lungs also contribute to the antiproteinase shield. Emphysema results from an augmentation of proteinase release in the lungs, a reduction in the antiproteinase defense within the lungs, or a combination of both increased proteinase burden and decreased proteinase inhibitory capacity. Accordingly, emphysema occurs when there is an imbalance between proteinases and antiproteinases in favor of proteinases.

From the study of proteinases in emphysema it has become appreciated that events controlling proteolytic injury to the extracellular matrix of the lung do not necessarily operate over the lungs as whole. Important events are tightly controlled and occur at or near the cell membrane of inflammatory cells. Thus, the proteinase–antiproteinase hypothesis has been modified to consider "imbalance" between proteinases and their inhibitors in compartments as small as the microenvironments immediately surrounding inflammatory cells.

Cigarette smoke exposure leads to a variety of changes in both airways and lung parenchyma that result in the syndrome termed COPD. A variety of proteinases participate in COPD with their major role being destruction of extracellular matrix, particularly elastin. However, proteinases also play a role in regulating inflammation through generation of chemokines and cytokines and by creating paths for cells through tissue barriers. NE is also a potent secretagogue. Thus, proteinases participate in multiple activities in several anatomic sites in the lung in the development of COPD.

Inflammatory Cells and Their Proteinases in the Lungs Defining the cells and proteinases responsible for destruction of lung extracellular matrix associated with cigarette smoking will be critical for development of appropriate proteinase inhibitors for application in COPD. For example, neutrophils are armed with a distinct set of serine proteinases and MMPs, whereas macrophages possess cysteine proteinases and the capacity to produce several MMPs. The profiles of proteinases differ between these inflammatory cell types, and regulation of proteinase expression is distinct. Neutrophils are short-lived and package active proteinases into

Table 23-1
Elastases Present in the Lung Parenchyma

Enzyme class	*Enzyme*	*Molecular mass[a] (kDa)*	*Cell of origin*	*Matrix substrates other than elastin*	*Relative elastolytic activity, pH 7.5*
Serine	Neutrophil elastase	27–31	Neutrophil (monocyte)	bm components[b]	100%
	Proteinase 3	28–34	Neutrophil (monocyte)	bm components [b]	40%
	Cathepsin G	27–32	Neutrophil (monocyte) (mast cell)	bm components [b]	20%
Matrix metalloproteinase	92 kDa gelatinase	92–95	Macrophage, neutrophil, eosinophil	Denatured collagens, types IV, V, and VII collagen	30%
	Metalloelastase	54	Macrophage	bm components[b]	35%
Cysteine	Cathepsin L	29	Macrophage	(Inactive at pH 7.5)	0%[c]
	Cathepsin S	28	Macrophage	(Unknown)	80%

Parentheses denote minor cellular sources.
[a]Denotes (pre)proenzyme forms.
[b]Basement membrane (bm) components include fibronectin, laminin, entactin, vitronectin, and type-IV collagen (nonhelical domains).
[c]These enzymes are significantly more potent than neutrophil elastase at pH 5.5.

granules ready for quick release, optimal for rapid egress from the vasculature and eradicating microorganisms. Macrophage metalloproteinase expression, however, is highly regulated by inflammatory cytokines, matrix fragments, and other agents resulting in much slower release but sustained synthesis. Thus, macrophages appear to monitor and respond to their environment; properties that could allow for tissue remodeling and possibly control of other inflammatory events.

Neutrophils As noted, smoking causes lung retention of neutrophils, apparently by increasing adhesiveness of neutrophils and pulmonary microvascular endothelium, and possibly by increasing neutrophil stiffness so that the cells cannot deform enough to get through pulmonary capillaries normally. Neutrophils are thought to also become deformable and burrow through preformed holes in the basement membrane. Evidence for this is direct transmission electron microscopy visualization and the inability to prevent neutrophil migration through extracellular matrices with proteinase inhibitors. Bronchoalveolar lavage fluids from smokers contain more neutrophils than lavage fluids from nonsmokers, indicating that smoking leads to recruitment of neutrophils into lung tissue.

Neutrophil Serine Proteinases Serine proteinases are characterized by conserved His, Asp, and Ser residues that form a charge relay system that functions by transfer of electrons from the carboxyl group of Asp to the oxygen of Ser, which then becomes a powerful nucleophile able to attack the carbonyl carbon atom of the peptide bond of the substrate. Serine proteinases are synthesized as preproenzymes in the endoplasmic reticulum and processed by cleavage of the signal peptide (pre-) and removal of a dipeptide (pro-) by cathepsin C, and stored in granules as active packaged proteins. Distinct subsets of serine proteinases are expressed in a lineage-restricted manner in immune and inflammatory cells. Serine proteinases are also expressed in a developmentally specific manner. For example, NE, proteinase (PR) 3, and cathepsin G (CG) are major components of primary or azurophil granules that are formed during a specific stage during the development of myeloid cells. The fact that neutrophil serine proteinases have a pH optimum of about 7.4 suggests that these enzymes could damage lung tissue if liberated from the neutrophil. Also, active NE's and CG's concentration on the outer face of their plasma membrane of activated neutrophils may help explain how these enzymes can function in the extracellular environment despite large excesses of α_1-AT and other inhibitors.

NE has activity against a broad range of extracellular matrix proteins including elastin (Table 23-1). Following the discovery of α_1-AT deficiency and the capacity of NE to cause emphysema in experimental animals, NE has been considered of primary importance in the pathogenesis of pulmonary emphysema. Further evidence supporting involvement of NE in this disease process includes: (1) the presence of human neutrophil elastase (HNE) and neutrophils in the lung tissue and bronchoalveolar lavage of patients with emphysema in some studies, (2) that smoking leads to an acute increase in a specific peptide released by HNE action on fibrinogen, and (3) that cigarette smoke can oxidize a methionine residue in the reactive center of α_1-AT, inactivating α_1-AT, and, thus, altering the NE: α_1-AT balance. Whether oxidative inactivation occurs in vivo is uncertain.

Gene targeting of NE has also demonstrated a role for NE in the development of emphysema. NE-deficient mice have been used to demonstrate a role for NE in killing Gram-negative bacteria. NE-mediated bacterial killing is related to proteolytic degradation of outer membrane proteins on the outer wall of Gram-negative bacteria. NE also degrades Gram-negative toxins. Application of NE null mutant mice to cigarette smoke exposure demonstrated 60% less airspace enlargement than wild-type mice. Many interactions between neutrophils/macrophages and NE or MMP-12 appear to explain that the deficiency of either protein significantly protects against emphysema in mouse models.

PR3 is approx 40% as potent as HNE against elastin. PR3 causes emphysema in experimental animals. This molecule has been identified as the autoantigen target of cytoplasmic-staining antipolymorphonuclear autoantibody in Wegener's granulomatosis. CG is stored in neutrophil primary granules and to a lesser degree in mast cells and a subset of peripheral blood monocytes. CG is chymotryptic, but also has matrix degrading activity with nearly 20% the elastolytic capacity of HNE. Moreover, CG increases elastolytic activity of HNE and may facilitate neutrophil penetration of epithelial and endothelial barriers by increasing their permeability.

Table 23-2
Proteinase Inhibitors Present in the Lung Parenchyma

Inhibitor	*Molecular mass (kDa)*	*Cell of origin*	*Class of proteinases inhibited*
α_2-macroglobulin	725	Hepatocyte, lung fibroblast, macrophage	Serine, metallo, cysteine
α_1-AT	52	Hepatocyte, macrophage	Serine[a]
SLPI	12	Large airway epithelial cell, type-II pneumocyte	Serine[b]
Elafin	12	Large airway epithelial cell	Serine
TIMP-1	27.5	Macrophages, resident lung parenchymal cell	Metallo
Cystatin C	13	Bronchial epithelial cell, macrophage	Cysteine

Parentheses denote minor cellular sources.
[a]α_1-AT has greater affinity for neutrophil elastase than for proteinase 3 and cathepsin G.
[b]SLPI does not inhibit neutrophil elastase.

Neutrophil metalloproteinases; neutrophils contain three MMPs (*see* below for general discussion of MMPs): the gelatinase B (MMP-9), neutrophil collagenase (MMP-8), and membrane-type metalloproteinases (MT6-MMP). In the neutrophil MMP-8 and MMP-9 are stored within specific granules. Neutrophil collagenase can degrade interstitial collagens, but is less active against other extracellular matrix components. MMP-9 is active against a number of substrates including denatured collagens (gelatins), basement membrane components, and elastin. MMP-9 is an important enzyme mediating vascular injury and aneurysm formation. MT6-MMP is a cell surface-bound MMP that has not been studied in detail.

Monocytes Monocytes resemble neutrophils in that they contain NE and CG in peroxidase-positive granules that are similar to the azurophil granules of neutrophils. These proteinases are synthesized by monocyte precursors in the bone marrow, and can be rapidly released by the circulating cell, perhaps for transvascular migration. Interestingly, expression of both of these serine proteinases is limited to a subset of "proinflammatory" monocytes (approx 15% of total) that appear to be those capable of tissue penetration. As monocytes differentiate into macrophages in tissues, they lose their NE and CG, but acquire the capacity to synthesize and secrete metalloproteinases.

Macrophages Alveolar macrophages are the most abundant defense cells in the lung under normal conditions and during states of chronic inflammation. Alveolar macrophages are prominent in the respiratory bronchioles of cigarette smokers where emphysematous changes first manifest. Because they are capable of producing factors that both promote destruction of extracellular matrix and protect against matrix destruction, macrophages may have a complex role in the pathogenesis of emphysema. Clearly, alveolar macrophages do have the capacity to degrade elastin by means of several different proteolytic enzymes (*see* Table 23-1).

Cysteine (Thiol) Proteinases Cysteine proteinases represent a large, diverse group of plant and animal enzymes with amino acid homology at the active site only. They are inhibited by cystatins, which are produced ubiquitously in local tissue environments (Table 23-2). Human alveolar macrophages produce the lysosomal thiol proteinases, cathepsins B, H, L, and S. These enzymes share similar sizes of 24–32 kDa and high mannose side chains (typical of proteins targeted for lysosomal accumulation). Cathepsins B and H have little endopeptidase activity and may function to activate other proteins similar to interleukin converting enzyme. Cathepsins L and S have large active pockets with relatively indiscriminate substrate specificities that include elastin and other matrix components. These enzymes have an acidic pH optima but cathepsin S retains approx 25% of its elastolytic capacity at neutral pH (making it approximately equal to NE). Thus, these enzymes have the capacity to cause lung destruction if they are targeted to the cell surface or extracellular space (especially if macrophages can acidify their microenvironment). These properties are plausible but remain to be proven. Cathepsin L production is increased in smokers' alveolar macrophages.

Matrix Metalloproteinases MMPs comprise a family of matrix degrading enzymes thought to be essential for normal development and physiological tissue remodeling and repair. Abnormal expression of metalloproteinases has been implicated in many destructive processes, including tumor cell invasion and angiogenesis, arthritis, atherosclerosis, arterial aneurysms, and pulmonary emphysema. MMP family members generally share 40–50% identity at the amino acid level, and they possess common structural domains. MMPs are secreted as inactive proenzymes that are activated at the cell surface or within the extracellular space by proteolytic cleavage of the N-terminal domain. Catalytic activity depends on coordination of a zinc ion at the active site and is specifically inhibited by members of another gene family, called TIMPs for tissue inhibitors of MMPs (*see* Table 23-2). Optimal activity of MMPs is around pH 7.4. All MMPs except matrilysin have a carboxyl terminal hemopexin-like domain that is important for conferring substrate specificity and for TIMP binding. The gelatinases have an additional fibronectin-like domain that mediates their high-binding affinity to gelatins and elastin.

Individual members of the MMP family can be loosely divided into groups based on their matrix degrading capacity. As a whole, they are able to cleave all extracellular matrix components. The collagenases have the unique capacity to cleave native triple helical interstitial collagens but have a restricted substrate specificity. There are two gelatinases of MMP-2 (gelatinase A) and MMP-9 (gelatinase B), which differ in their cellular origin and regulation, but share the capacity to degrade gelatins (denatured collagens), type-IV collagen, elastin, and other matrix proteins. Stromelysins (MMP-3, -10, -11) have a broad spectrum of susceptible substrates, including most basement membrane components. Matrilysin

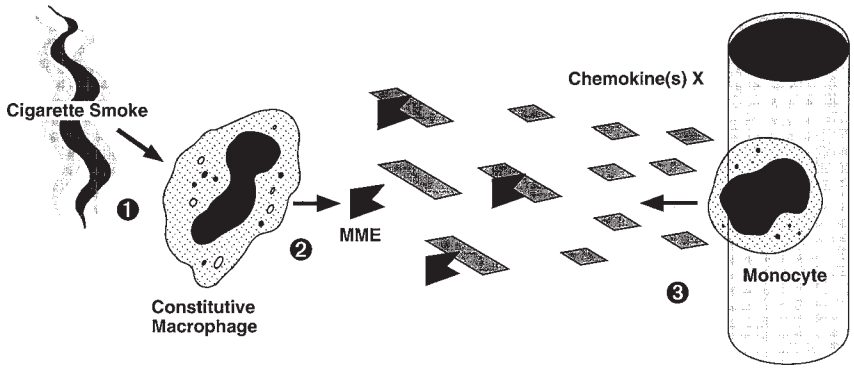

Figure 23-3 Mechanism of metalloelastase-mediated monocyte recruitment in response to cigarette smoke. Inhaled cigarette smoke induces constitutive lung macrophages to produce macrophage metalloelastase (MME). MME proteolytically generates a chemotactic gradient, presumably by cleaving a protein into a chemotactic fragment (chemokine[s] X) which attracts blood monocytes into the lung parenchyma.

(MMP-7), the smallest MMP (28 kDa as a proenzyme) has broad substrate specificity of stromelysin plus it has some elastase activity. Macrophage elastase (MMP-12) also has a potent broad substrate specificity that includes elastin. The newest members of the MMP family are MT-MMPs. MT1-MMP (MMP-14) activates MMP-2. MMPs are active against a variety of proteins besides extracellular matrix. They cleave and activate latent tumor necrosis factor-α, thereby regulating inflammation. MMPs degrade and inactivate α_1-AT, thus indirectly enhancing the activity of HNE. However, closely related cell surface ADAMs (a disintigrin and metalloproteinase domain), most notably ADAM-17, are thought to most efficiently "shed" active tumor necrosis factor-α.

Alveolar macrophages produce several MMPs including significant amounts of MMP-1, MMP-9, MMP-12, and smaller amounts of MMP-3 and MMP-7. Expression of these MMPs is highly regulated, and under quiescent conditions, such as in normal mature lung tissue, expression is limited. MMPs are induced and their production and activity are carefully controlled during normal repair and remodeling processes. With chronic inflammation, regulation of MMPs can go awry, and MMPs can be overexpressed and produced at inappropriate sites.

Because several MMPs are associated with COPD, manipulation of expression in mice has led to insights regarding potential roles of these enzymes in emphysema. Overexpression of a human collagenase (MMP-1) transgene driven by the haptoglobin reporter resulted in lung-specific expression in several independent founder lines of mice. These mice developed enlarged airspaces characteristic of emphysema. This was the first demonstration that an MMP could directly cause emphysema. Also, because MMP-1 is inactive against mature elastin, this result suggested that collagen degradation was sufficient to cause emphysema. However, it is not certain whether the alveolar pathology in these animals was owing to destruction of collagen in mature lung tissue or whether expression of the transgene during growth and development interfered with normal elastic fiber assembly, perhaps through destruction of the elastic fiber microfibrillar scaffold. However, sensitive techniques have shown that some of the founder lines do not express MMP-1 during early lung development.

Targeted mutations in genes of embryonic stem cells allow generation of strains of mice deficient in specific proteins. Strains of mice deficient in individual candidate elastases can be compared with each other and normal littermates with respect to their capacity to develop emphysema in response to cigarette smoke. Wild-type mice, like humans, chronically exposed to cigarette smoke develop a macrophage predominant inflammatory infiltrate in the lungs, followed by airspace enlargement. In contrast to wild-type littermates, mice deficient in macrophage elastase (MMP-12) failed to recruit macrophages and did not develop pulmonary emphysema in response to cigarette smoke exposure. Whether human emphysema is also dependent on this single MMP is of course uncertain. Certainly this study demonstrates a critical role of macrophages in the development of emphysema and unmasks a proteinase-dependent mechanism of inflammatory cell recruitment that may have broader biological implications (Fig. 23-3).

Many cells in the lung have the capacity to produce MMPs. Eosinophils produce significant amounts of the MMP-9. T lymphocytes interacting with endothelial cell vascular cell adhesion molecule-1 are induced to express the MMP-2. Various resident lung cells can produce MMPs. Fibroblasts, for example, are a potential prominent source of MMP-1, MMP-2, MMP-3, and MT1-MMP. Type-II alveolar epithelial cells produce MMP-7 and perhaps other MMPs. Considering the variety of lung cells capable of producing MMPs, it seems plausible that MMPs participate in the lung destruction resulting in emphysema.

α_1-Antitrypsin Deficiency α_1-AT is a glycoprotein of 52 kDa synthesized primarily by the liver, consisting of a single polypeptide chain of 394 amino acids. Fully processed α_1-AT has three carbohydrate side chains that account for 12% of its molecular mass. The gene for α_1-AT is 12.2 kb located on chromosome 14 near the gene for α_1-antichymotrypsin, the inhibitor for CG, which like NE is contained in neutrophil azurophil granules. The α_1-AT gene has seven exons and six introns. Exons 4–7 code for the mature protein. The first two exons and a 5′ segment of exon three are encoded in the transcript expressed in macrophages, but not in hepatocytes. α_1-AT is an acute phase reactant. Plasma levels of α_1-AT rise with trauma, estrogen therapy, birth control pills, and pregnancy.

Proteolytic inhibition of NE and other serine proteinases by α_1-AT involves cleavage of the "strained" reactive open center of α_1-AT between methionine^{358} and serine^{359}, resulting in an altered, "relaxed" α_1-AT conformation in complex with the proteinase. Formation of the complex renders the proteinase inactive and, because the complex is stable, inactivation is essentially permanent. α_1-AT inhibits many serine proteinases on a 1/1 molar basis; however, α_1-AT associates with NE much faster than with trypsin or other serine proteinases suggesting that inhibition of

NE is the primary function of α_1-AT. Because α_1-AT inhibits NE and other serine proteinases besides trypsin some authors prefer the designations α_1-proteinase inhibitor or α_1-antiproteinase, but the name α_1-AT is still commonly used for historic reasons. When α_1-AT is complexed with a proteinase, the complex binds to receptors (called serpin/enzyme complex receptors) on hepatocytes and monocytes.

α_1-AT is transmitted codominantly. Thus, the gene product from each parent is expressed in the offspring. A large number of α_1-AT alleles are known, but most involve a single amino acid change that does not alter expression of the protein or its function. The states produced by these different alleles are referred to as follows: normal, in which there is a normal serum concentration of functional α_1-AT; deficient, in which the serum α_1-AT is lower than normal; null, in which there is no measurable serum α_1-AT; and dysfunctional in which there is a normal serum concentration of α_1-AT, but it does not have the normal antiproteinase activity.

The nomenclature for the α_1-AT polymorphism uses letters to specify the allelic variants. The original letters were chosen to reflect electrophoretic mobility: F = fast; M = medium; S = slow; and Z = ultraslow. The normal phenotype, Pi M, exists in >90% of the population, with the MS and MZ phenotypes the next most common. The MS, MZ, and SS phenotypes, which are associated with modest deficiencies of α_1-AT (about half of the normal serum concentration), do not present an increased risk of emphysema, although there is an increased frequency of Pi MZ individuals in some COPD populations. Pi MS individuals may have an increased frequency of airway hyperreactivity. Because individuals with Pi SZ, who have an average of 37% of normal (1-AT serum concentration, rarely develop emphysema, serum levels >35% of normal are thought to be enough to provide protection.

As mentioned, cigarette smoke can oxidize a methionine residue in the reactive center of α_1-AT, inactivating its capacity as a proteinase inhibitor. The potential consequences of this reaction were demonstrated in a model in which dogs treated with chloramine-T, an agent that profoundly depresses α_1-AT functional activity, developed pulmonary emphysema. However, the initial studies in smokers that demonstrated oxidatively inactivated α_1-AT in the bronchoalveolar lavage fluid have not been corroborated.

Several α_1-AT phenotypes are associated with very low serum concentrations of α_1-AT. Of these, the Pi Z phenotype is by far the most common, accounting for >95% of such individuals. Pi Z individuals have approx 15% of the normal serum concentration of α_1-AT. The prevalence of the Pi Z phenotype in the United States is approx 1/3000 people. The Z allele is rare in Asians and African-Americans. The small number of other individuals with marked deficiency of α_1-AT have Pi SZ, Pi null–null, or Pi null–Z phenotypes.

Most Pi Z individuals eventually become symptomatic with COPD, resulting from emphysema, but there is considerable variation and some individuals reach advanced age with minimal symptoms. The wide variability in pulmonary function has been confirmed among Pi Z subjects with evidence for familial factors that segregated with deterioration in pulmonary function. Smoking has a marked effect on the age at which shortness of breath appears. On the average Pi Z smokers have symptoms by age 40, about 15 yr earlier than Pi Z nonsmokers.

The Pi Z phenotype is because of a point mutation involving a single nucleotide at codon 342 that results in coding for lysine instead of glutamic acid. This amino acid substitution alters the charge attraction between the amino acids at positions 342 and 290 present in the normal form of α_1-AT and prevents the formation of a fold in the molecule. This change in tertiary structure promotes dimerization of α_1-AT molecules. The dimerization leads to the aggregation of α_1-AT in the endoplasmic reticulum that impedes secretion of the protein from the cell and results in the low levels of α_1-AT in plasma and other body fluids The Z form of α_1-AT also has a rate of association with NE that is significantly slower than the association rate of normal α_1-AT with NE. Thus, the Pi Z phenotype leads to both a deficiency of α_1-AT protein and a form of α_1-AT that is less effective than normal α_1-AT as an inhibitor of NE.

The S variant of α_1-AT, which involves a single nucleotide alteration leading to substitution of glutamic acid[264] with a valine, does not accumulate in the liver. This protein is less stable, presumably resulting from loss of a salt bridge between the glutamic acid in position 264 and the lysine in position 387. The Pi null phenotype arises either because the α_1-AT gene is missing or there is a mutation in the α_1-AT gene that results in premature termination of the gene's transcription.

Cell Death Airspace enlargement with loss of alveolar units requires disappearance of both extracellular matrix and cells. Traditional theories suggest that inflammatory cell proteinases degrade lung extracellular matrix as the primary event with subsequent loss of cell anchoring leading to apoptosis. Studies suggest that endothelial and epithelial cell death could be the primary event (presumably with secretion of proteinases to dissolve the matrix). Whether these mechanisms play a role in human COPD is unknown; however, there is increased septal cell death associated with reduced lung expression of vascular endothelial growth factor and vascular endothelial growth factor receptor-2 (KDR/Flk-1) in human emphysematous lungs.

Repair Following injury, the ability of the adult lung to repair damaged alveoli appears limited. Whether the process of septation that is responsible for alveogenesis during lung development can be reinitiated is not clear. In animal models, treatment with all-trans retinoic acid resulted in limited but significant repair. Also, lung resection results in compensatory lung growth in the remaining lung in animal models. In addition to restoring cellularity following injury, it appears difficult for an adult to completely restore an appropriate extracellular matrix, particularly functional elastic fibers.

Lung Elastin The seminal observations about α_1-AT deficiency and production of emphysema in animals with elastolytic enzymes (and only with elastolytic enzymes) led to the concept that destruction of elastin in the lung parenchyma is key to the development of emphysema.

Elastin is the principal component of elastic fibers. Elastic fibers, which possess rubber-like reversible extensibility, come under tension, and provide elastic recoil throughout the respiratory cycle. In the lung parenchyma, elastic fibers loop around alveolar ducts, form rings at the mouths of the alveoli, and penetrate as wisps into the alveolar septae in which they are concentrated at bends and junctions.

Elastin is secreted as a soluble protein of 60–70 kDa called tropoelastin (Fig. 23-4). Tropoelastin molecules, encoded by a gene on chromosome 7 in the human, are deposited into the extracellular space and aligned on a "scaffold" of microfibrils that consists of a number of proteins, including fibrillins, microfibril associated proteins, and latent transforming growth factor-β

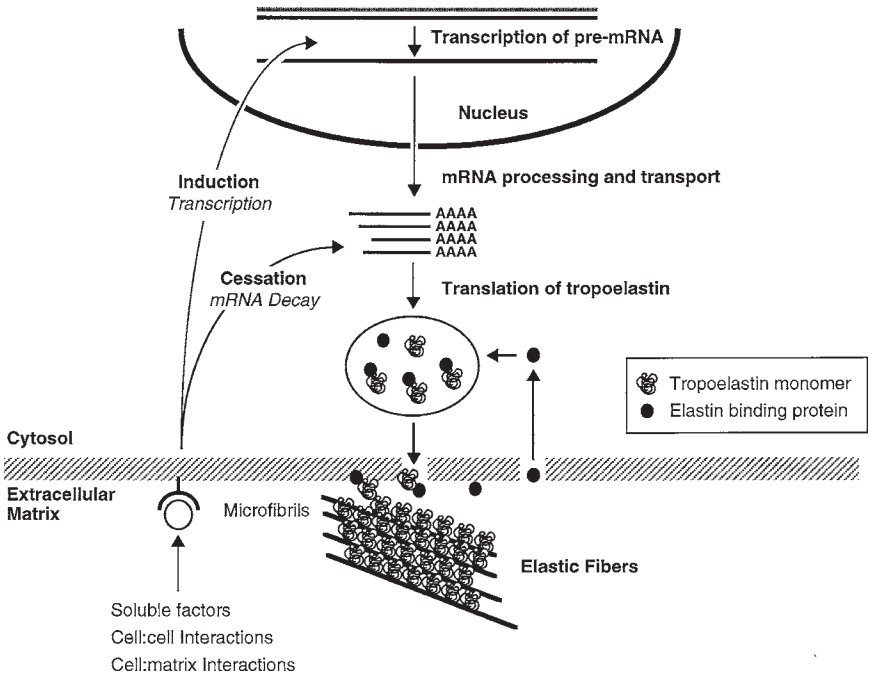

Figure 23-4 The synthesis of tropoelastin and assembly of the elastic fiber. Under the influence of extracellular and intracellular factors, tropoelastin pre-mRNA is transcribed within nucleus of the elastogenic cell. Differential splicing of tropoelastin pre-mRNA leads to different tropoelastin mRNAs and tropoelastin isoforms. After tropoelastin is secreted from the cell it associates with microfibrils adjacent to the cell surface. Uncertainty exists whether there is a carrier protein that facilitates the secretion of tropoelasin. Microfibrils are thought to be a scaffold on which tropoelastin monomers align. On the microfibril, most of the lysines in tropoelastin monomers are modified by lysyl oxidase to form covalent crosslinks (desmosines) between the monomers. The resultant polymer is elastin. (Courtesy of William C. Parks, PhD.)

binding proteins. In the extracellular space, lysyl oxidase modifies most of the lysine residues in tropoelastin monomers causing them to crosslink and form elastin, a highly insoluble, rubber-like polymer. The lysine-derived crosslinks in elastin are known as desmosines. Desmosines are unique to elastin, and therefore can be used to quantify elastin in tissues and as markers of elastin degradation in body fluids.

Elastin is resistant to many proteinases, most notably the collagenases that cleave interstitial collagens, but there are a number of enzymes that may come in contact with the lung that can degrade elastin (*see* Table 23-1). Under normal conditions, elastin synthesis in the lung begins in the late neonatal period, peaks during early postnatal development, continues to a much lesser degree through adolescence paralleling lung growth, and stops in adult life. There is some evidence that the tropoelastin gene always remains transcriptionally active but rapid mRNA degradation prevents expression of the protein. Multiple cell types are responsible for elastin synthesis in the lungs and associated structures. Lung elastin normally lasts a human life span, and there is virtually no elastin synthesis in the normal adult lung.

Although destruction of lung elastin appears to be necessary for the development of emphysema because of smoking, it remains unknown precisely how the breakdown of elastin translates into the deformity recognized as emphysema. Elastin depletion appears to be restricted to the sites of emphysema, rather than being a global deficiency of the lung that contains regions of emphysema. It has also been difficult to determine the capacity of the lung parenchyma to undergo repair after proteolytic injury. It is not known if normal elastic fibers can be properly formed in the lung after the period of growth and development. After an intratracheal injection of HNE into an experimental animal, there is acute depletion of elastin followed by a burst of extracellular matrix synthesis so that over a few weeks the elastin content of the lungs returns to normal, although the lungs develop emphysema. However, the newly synthesized elastic fibers appear disorganized, similar to the elastic fibers in human emphysema. Studies of lung growth after pneumonectomy in adult rats indicate that elastin synthesis can be reinitiated in the adult lung and deposited at the sites at which elastin is normally produced during lung development. Nothing is known about the turnover of other extracellular matrix components in human lungs affected by COPD.

Collagen Collagen turnover in COPD is complex. Studies indicate increased collagen per unit volume of airspace wall in emphysematous lungs from smokers and in experimental animals subjected to chronic cigarette smoke inhalation. These findings suggest that the concept of emphysema formation as a purely destructive process may be in error. Although total collagen content is increased in emphysema, it appears logical that with loss of alveolar units, all local collagen must also be lost. Excessive collagen deposition, particularly in the small airways that might contribute to airflow obstruction, more than compensates for this loss.

CONCLUSION

As COPD and other cigarette-related diseases become epidemic worldwide, the biology of emphysema is clearly complex and poorly understood with limited translation into effective pharmacotherapy. This may change as critical questions are addressed regarding the pathogenetic mechanisms of COPD, including: what are the signals that initiate and perpetuate inflammation in the lungs during the development of emphysema associated with

smoking? Inflammatory cells are the presumed source of injurious proteinases, but specifically which inflammatory cells are the culprits? Which proteolytic enzymes are involved in lung destruction, and how do they make contact with the lung extracllular matrix and maintain their catalytic activity in the presence of an abundance of proteinase inhibitors? Is it possible that resident cells of the lungs, such as fibroblasts, also contribute to alveolar septal destruction? Although elastin degradation may be central to emphysema, what is the role of other extracellular matrix components, particularly collagens, and what limits matrix repair? Use of genetic engineering, modern genetics, imaging, and bioinformatics among other techniques are being applied to understand the molecular basis of COPD.

24 Pulmonary Hypertension

Brian Fouty and David M. Rodman

SUMMARY

Pulmonary arterial hypertension results from the pathological elevation in pulmonary vascular resistance owing to a combination of increased vascular tone and vessel wall remodeling. It is a heterogeneous disorder with the vascular phenotype dependent on the mechanism and severity of injury. What is clear is that with increasing duration and severity, pulmonary hypertension is associated with progressive vessel wall remodeling ultimately resulting in fixed, irreversible lesions. All three cell types within the vessel wall contribute to these vascular lesion through the combined effect of cell proliferation, cell migration, and matrix deposition. Current therapies are aimed at restoring vasodilator function although limiting mitogen-induced proliferation. New therapies need to reverse these vascular lesions by breaking down extracellular matrix and inducing controlled regression (apoptosis) within the vessel wall. This provides the best chance to restore the pulmonary circulation to its natural low resistive state and reduce the morbidity and mortality associated with this disease.

Key Words: BMPR; endothelial cells; nitric oxide; vascular pulmonary hypertension; remodeling.

INTRODUCTION

The lung has two blood supplies, the bronchial and the pulmonary circulation (Fig. 24-1). The bronchial vessels arise from the aorta and, therefore, have systemic pressures. They are important in fetal development and likely protect the lung against the infarcting effects of pulmonary embolism. Most causes of bleeding in the lung arise from the bronchial circulation. In contrast, the pulmonary circulation is a low resistance, high capacitance bed designed to deliver blood under low pressure to the microcirculation to allow for adequate exchange of carbon dioxide and oxygen. Normal pulmonary artery (PA) pressures are approx 25/10 mmHg with a mean of approx 15 mmHg, approx 1/6 that of the systemic circulation. The pulmonary vessels are approximately seven times more compliant than systemic ones primarily because of less smooth muscle and elastic fiber content. Because the right ventricle propels blood through such a low resistance system, it has a much thinner wall than the left ventricle. Consequently, when the pulmonary resistance increases pathologically (pulmonary hypertension) the right heart is put under significant stress that can lead to right heart failure and premature death.

Pulmonary hypertension is defined as a mean pressure >25 mmHg at rest and 30 mmHg with exercise. Pulmonary hypertension is a pathophysiological state, however, not a specific disease, and understanding its underlying cause is required to make progress at clinical and scientific levels. Because the pulmonary circulation is made up of an arterial bed and a venous bed, separated by the pulmonary capillaries, the most important causes of pulmonary hypertension clinically are increases in left atrial pressure (pulmonary *venous* hypertension) or increases in pulmonary vascular resistance (pulmonary *arterial* hypertension).

Pulmonary venous hypertension is usually resulting from congenital or acquired heart disease (Table 24-1). Anything that increases left atrial pressure such as mitral stenosis or induces left ventricular failure (valvular incompetence, ischemia, hypertension, or nonischemic cardiomyopathy) leads to an increase in the mean pulmonary pressure and the development of pulmonary hypertension. Noncardiac causes of postcapillary pulmonary hypertension include veno-occlusive disease, fibrosing mediastinitis, or pulmonary vein stenosis, all conditions that directly affect the venules or veins. The topic of this chapter, pulmonary arterial hypertension, refers to an increase in resistance in the pulmonary arterial circulation owing to pathological increases in vascular tone and vessel remodeling. Pulmonary arteries and arterioles, the major site of resistance to blood flow in the pulmonary vascular bed, consist of endothelial cells, smooth muscle cells (SMCs), and fibroblasts. Understanding how these three cell types, responding to genetic and environmental influences, contribute to the increased vascular tone and vessel remodeling characteristic of pulmonary arterial hypertension is critical in designing targeted therapy to prevent and reverse this disease.

VASOCONSTRICTION

In vascular smooth muscle an increase in cytosolic calcium is an initiating event for contraction. As intracellular calcium increases, it binds to calmodulin and this complex activates myosin light-chain kinase, which then phosphorylates the light chain of myosin. In an adenosine triphosphate-dependent reaction myosin then binds to actin filaments causing contraction. The increase in intracellular calcium occurs owing to the release of intracellular stores from the sarcoplasmic reticulum (SR) and to an influx of calcium from the extracellular space through a variety of selective and nonselective ion channels.

Although sustained contraction within SMCs is initiated by calcium–calmodulin mediated phosphorylation of myosin light

chain kinase (and ultimately by the phosphorylation of myosin light chain) the duration of contraction is modulated by the activity of myosin phosphatase (Fig. 24-2). Myosin phosphatase dephosphorylates the light chain of myosin leading to relaxation. As intracellular calcium is lowered resulting from sequestration in the SR or extrusion from the cell, myosin phosphatase activity increases, which leads to cell relaxation. Inhibiting the activity of myosin phosphatase prevents the dephosphorylation of myosin light chain and allows for a sustained, calcium-independent contraction. Myosin phosphatase activity is regulated by upstream messengers, particularly the RhoA/Rho kinase pathway. Activation of RhoA/Rho kinase pathway leads to the phosphorylation of myosin phosphatase rendering it inactive even when intracellular calcium drops. Sustained activation of the RhoA/Rho kinase pathway therefore is central to the calcium sensitization that maintains vascular tone. Pathological activation of the RhoA/Rho kinase pathway has been hypothesized to contribute to the development of pulmonary hypertension. Inhibition of RhoA/Rho kinase by fasudil causes relaxation of the pulmonary circulation even in the presence of vasoconstrictors such as hypoxia or endothelin (ET)-1.

Hypoxia is an important and reliable vasoconstrictor of the pulmonary circulation, contrasting with its dilatory effect in the systemic circulation. This likely represents a residual function of the fetal circulation in which high resistance in the pulmonary vascular bed leads to proper blood distribution within the fetus. Even well acclimated individuals living at high altitude have this vasoconstrictor response and it is a common experimental model of inducing chronic pulmonary hypertension in animals. Hypoxia increases intracellular calcium primarily by depolarizing the cell sufficiently to activate voltage-dependent dihydropyridine-sensitive L-type calcium channels. These channels, which allow selective calcium entry, open when the cell depolarizes from its normal resting membrane potential of –50 to –60 mV to about –40 mV. In the mature circulation, acute hypoxia induces PA SMC depolarization through the inactivation of voltage-gated potassium channels on the cell membrane. Hypoxia does not cause pulmonary vasoconstriction in the absence of extracellular calcium, demonstrating that influx of calcium is critical. However, L-type channel blockers do not completely inhibit hypoxia-induced vasoconstriction suggesting that calcium enters through other pathways as well. Another voltage-gated calcium channel, the T-type calcium channel that has lower conductance than the L-type channel and is activated at more negative membrane potentials (around –70 mV), may also allow calcium into the cell in response to hypoxia. However, evidence suggests that this channel has a greater effect on cell proliferation than on cell contraction. Finally, nonselective cation channels and ligand-gated channels that are not specific for calcium, but also permit sodium entry, may contribute to the increase in intracellular calcium.

Vasoconstriction of the pulmonary circulation can also be initiated by circulating mediators such as ET-1, serotonin (5-hydroxytryptamine [HT]), and angiotensin II (AGII). Similar to the effects of hypoxia, none of these agents can induce vasoconstriction in the absence of calcium, but unlike hypoxia, they have a similar vasoconstricting effect on the pulmonary and systemic circulations. They increase intracellular calcium through multiple mechanisms directed by binding to G protein coupled receptors. These receptors stimulate phospholipase C activity, leading to the formation of two important intracellular signaling messengers, inositol triphosphate and diacylglycerol. Binding of inositol triphosphate to the SR triggers calcium release into the cytoplasm; diacylglycerol

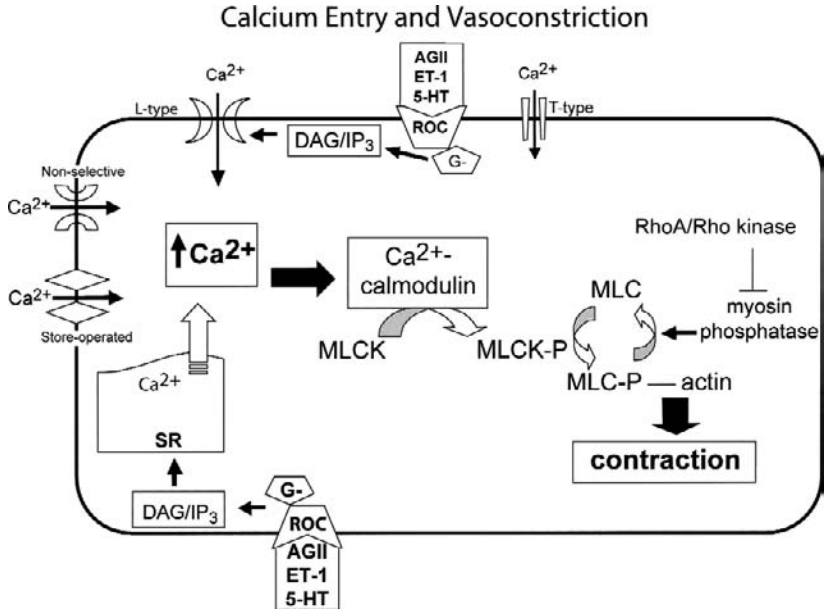

Figure 24-2 Calcium entry and signaling. Increases in intracellular calcium are the initiating event in vascular smooth muscle contraction. Calcium can enter the cell from the extracellular space through voltage-activated L-type and T-type channels or through voltage-independent nonselective or store-operated cation channels. Intracellular calcium can also be increased by the release of stores within the SR. SR release occurs in response to activation of receptor operated channels and subsequent generation of the intracellular messengers inositol triphosphate and diacylglycerol. The increase in cytosolic calcium activates calcium-calmodulin-dependent pathways including the phosphorylation of myosin light chain kinase. Activated myosin light chain kinase phosphorylates the light chain of myosin and allows it to interact with actin to cause contraction. Myosin phosphatase dephosphorylates myosin light chain and allows relaxation. AGII, angiotensin II; ET-1, endothelin-1; 5-HT, 5-hydroxy-tryptamine.

along with calcium activates protein kinase C, which phosphorylates specific target proteins important in contraction and proliferation. In addition to the release of calcium stores, receptor activation allows calcium to enter the cell through ion channels. These include the L- and T-type voltage-activated channels and voltage-independent channels such as nonselective cation channels and store-operated channels. Store-operated channels allow calcium to enter the cell in response to depletion of calcium in the SR.

Although vasoconstriction requires active contraction of PA SMCs, endothelial cells play an important role in regulating the degree and duration of this contraction. This is achieved through the release of two important vasodilators, prostacyclin, and nitric oxide (NO). Prostacyclin is produced by the enzyme prostacyclin synthase and causes vasodilation when given intravenously. Increases in intracellular cAMP, with consequent activation of protein kinase A, is thought to mediate a number of the vasodilatory functions of prostacyclin. cAMP lowers intracellular calcium concentrations and decreases calcium sensitization so that for equal concentrations of cytosolic calcium there is less myosin light chain phosphorylation. Consistent with prostacyclin's vasodilatory effect on the pulmonary circulation, mice genetically engineered to overexpress prostacyclin synthase (and thus produce more prostacyclin) have a blunted vasoconstrictor response to acute hypoxia; they also develop less pulmonary hypertension when exposed to chronic hypoxia.

NO is also produced by endothelial cells through the actions of the enzyme endothelial nitric oxide synthase (eNOS) on L-arginine. NO produced by eNOS is used locally to promote SMC relaxation. NO produced in the endothelium diffuses into PA SMCs and binds to soluble guanylyl cyclase. Guanylyl cyclase generates cGMP, an intracellular messenger that promotes vasodilation principally through the actions of its main substrate, protein kinase G. Similar to the mode of action for cAMP, it is thought that cGMP induces vasodilation either by reducing cytosolic calcium or by decreasing the calcium sensitivity of the contractile proteins. cGMP is degraded by phosphodiesterases (PDE) to inactive 3′5′cGMP terminating the vasodilating effects of NO. Mice lacking the eNOS gene develop increased pulmonary pressures even at mild altitude; the elevated pressures can be reversed by the administration of exogenous NO. Supporting the putative role of prostacyclin and NO in maintaining the low resistance of the normal pulmonary vascular bed, patients with severe pulmonary hypertension demonstrate decreased expression of both prostacyclin synthase and eNOS in PA endothelial cells. Whether the loss of these vasodilators is a cause of, or a result of, pulmonary hypertension is unclear.

PULMONARY VASCULAR REMODELING

The mechanistic relationship between vasoconstriction and vascular remodeling has begun to be elucidated. Most agents that induce pulmonary vasoconstriction, such as hypoxia, ET-1, 5-HT, and AGII, also stimulate vessel wall remodeling. For remodeling to occur, quiescent cells must be stimulated to proliferate (leading to hyperplasia and hypertrophy), activated cells must be able to migrate (leading to neointimal formation and neomuscularization of small arteries and arterioles), and cells (primarily fibroblasts) must be stimulated to increase the extracellular matrix through deposition of collagen and elastin. This combination of cell proliferation with an increase in extracellular matrix makes the pulmonary vessels less compliant increasing pulmonary vascular resistance. Chronic increases in blood flow (congenital heart disease), chronic hypoxia (long-term exposure to high altitude or in patients with primary alveolar hypoventilation), direct toxins (diet supplements), autoimmune disease (scleroderma), thromboembolic

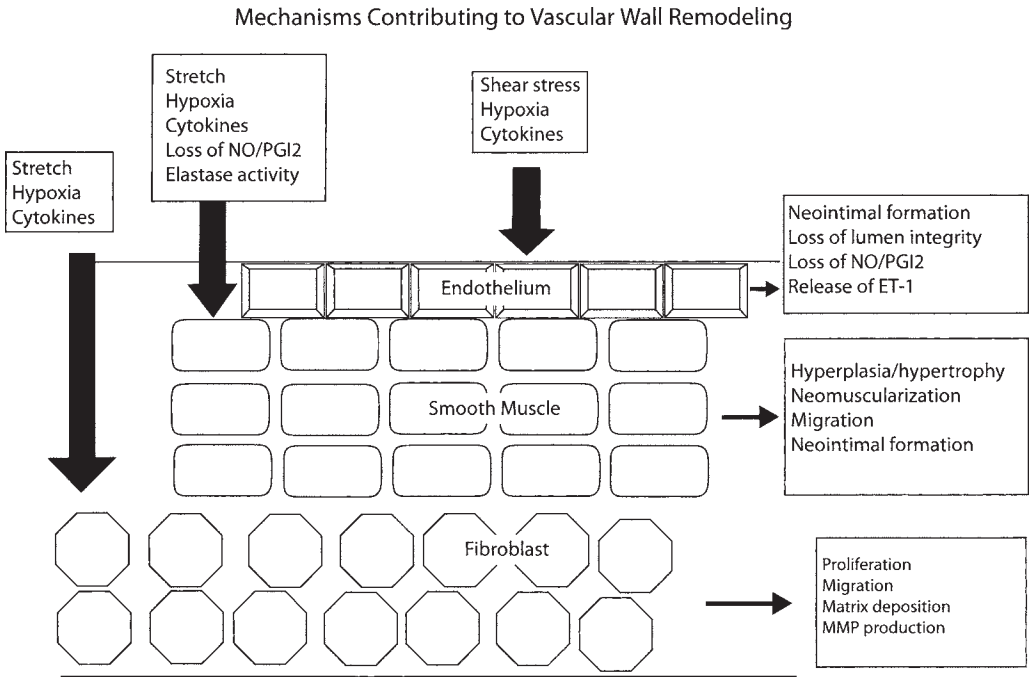

Figure 24-3 Cellular contributions to PA remodeling. All cell types within the pulmonary vessel are involved in pulmonary vascular remodeling. The response of each cell type depends on the type, severity, and duration of injury. Therapies to control and reverse pulmonary vascular remodeling need to address these pathological cell responses. ET-1, endothelin-1; NO, nitric oxide; PGI2, prostacyclin.

disease, or genetic causes (primary pulmonary hypertension [PPH]) can all initiate remodeling of the pulmonary vasculature.

All three cell types within the arterial wall, endothelial cells, SMCs, and fibroblasts, are involved in the vascular remodeling associated with pulmonary hypertension (Fig. 24-3). Endothelial cells line the vessel lumen and are directly exposed to circulating mitogens, shear stress, and changes in flow. Injury to the endothelium can lead to the loss of lumen integrity, thus exposing SMCs directly to the effects of circulating mediators and shear stress that can promote medial proliferation. Smooth muscle hyperplasia and hypertrophy occur in most forms of pulmonary hypertension. Extension of smooth muscle into previously nonmuscularized arteries and arterioles, termed neomuscularization, also occurs in most forms of pulmonary hypertension. This occurs resulting from the differentiation of precursor cells (pericytes) within the vessel wall into contractile smooth muscle, although some studies suggest that migration of SMCs into these arterioles also plays a role. Neomuscularization not only increases pulmonary vascular resistance by reducing lumen size, it plays an important role in increasing pulmonary vascular tone.

Fibroblasts compose the outer vessel layer and some evidence suggests they play a key role in pulmonary vascular remodeling. Fibroblasts possess a number of attributes that likely contribute to vascular remodeling. In response to stimuli such as flow or hypoxia they can proliferate, migrate, and release components of the extracellular matrix via the secretion of matrix metalloproteinases (MMPs). In addition they can secrete cytokines and growth factors such as transforming growth factor (TGF)-β, epithelial growth factor, and insulin growth factor that operate in a paracrine fashion to stimulate SMC proliferation and extracellular matrix deposition. Subsets of fibroblasts have been identified in bovine pulmonary arteries that are highly proliferative in response to hypoxia and growth factors. These subsets express different isoforms of protein kinase C that may explain their distinct proliferative phenotypes.

INITIATORS OF PULMONARY REMODELING

INCREASED PULMONARY BLOOD FLOW Congenital heart defects with significant left-to-right shunts can cause pulmonary hypertension that progresses over time. The initial response of the pulmonary circulation to chronically increased flow is the extension of muscle into previously nonmuscularized small arteries and arterioles. With time, the previously muscularized arteries respond to the increased flow and stretch by undergoing medial hypertrophy and hyperplasia. Combined with the deposition of extracellular matrix the medial thickness of the arteries and arterioles is increased and the compliance drops. If the shunt persists arterial concentration is reduced and neointimal formation develops. In advanced disease there is occlusive neointimal formation (plexiform lesions) and pulmonary pressures can exceed systemic ones initiating reversal of flow through the shunt. This is termed Eisenmenger's syndrome and is thought to represent an irreversible form of pulmonary hypertension. Figure 24-4 shows an example of a plexiform lesion with the small, residual lumen indicated by the arrows. The normal appearance of alveolar septae can be readily appreciated. Infants with large ventricular septal defects or a patent ductus arteriosus are at especially high risk for developing this complication. Infants whose shunts are repaired within the first 8 mo of life usually normalize their pulmonary pressures over time; those repaired after 2 yr of age invariably have elevated pressures throughout their life.

Loss of endothelial vasodilator function has been identified as an early finding in animal models of left-to-right shunts. Endothelial injury also exposes the SMC directly to the circulating mitogens and shear stress, an unnatural environment that promotes proliferation. Changes within the adventitial layer are also seen in

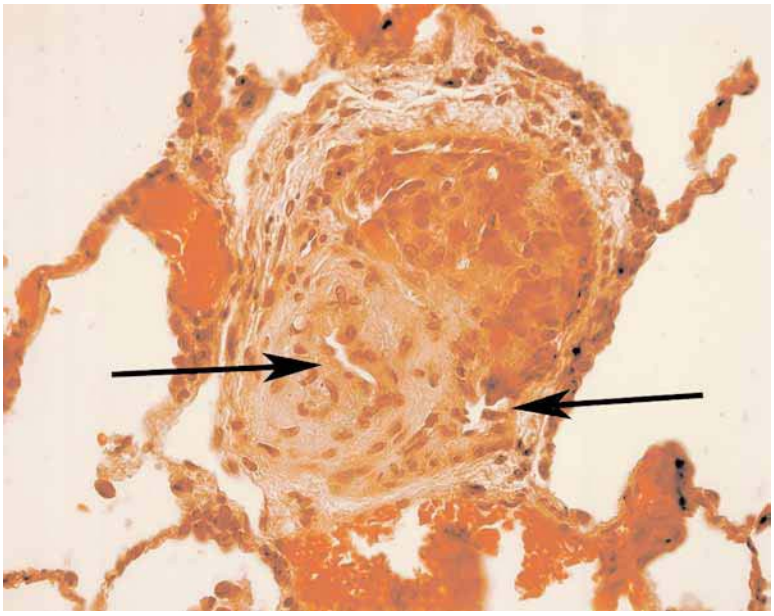

Figure 24-4 Plexiform lesion. The end-stage of pulmonary hypertension is associated with the formation of occlusive intimal lesions. Despite the often bizarre appearance of the lesions, adjacent lung tissue is generally normal, and distal blood vessels may also appear surprisingly unaffected. Clonal expansion of genetically abnormal endothelial cells may contribute to abnormal proliferation within the lesions, and chronic viral infection by human herpesvirus type VII may also be a predisposing factor to development of plexiform lesions. PAH, pulmonary arterial hypertension. (Please *see* color insert.)

individuals with chronically increased pulmonary blood flow. Immunostaining from lung biopsies demonstrates increased deposition of the glycoproteins tenascin C and fibronectin in the matrix. Association of tenascin C with proliferating SMCs has been demonstrated in animal models of pulmonary hypertension and in patients with congenital heart disease suggesting a facilitating role in promoting hyperplasia and hypertrophy. Also identified in humans and animal models of left-to-right shunt was an increase in elastase activity. Increased elastase activity can break down the extracellular matrix and release mitogens such as fibroblast growth factor 2 and basic growth factor. This is likely important in promoting the proliferation and migration of medial and adventitial cells.

HYPOXIA Acute hypoxia causes pulmonary vasoconstriction whereas chronic hypoxia additionally leads to vascular remodeling. The remodeling associated with chronic hypoxia is most pronounced in the medial layer of larger arteries in which hyperplasia and hypertrophy of SMCs occur and in small arteries and arterioles in which new smooth muscle is formed. Hypoxia increases shear stress, tension, and pressure all of which can initiate vascular remodeling. Whether hypoxia is a direct inducer of vessel remodeling or whether the stimulus to proliferate is related to the changes in shear stress resulting from vasoconstriction is unclear. In an animal model using unilateral banding of the main PA, hypoxia without flow did not lead to vascular remodeling or medial hypertrophy. This suggests that the effect of hypoxia on flow and shear stress is central to its induction of remodeling. Hypoxia has also been demonstrated to reduce the production and release of prostacyclin and NO while stimulating ET-1 release effectively tipping the balance in favor of vascular proliferation.

The extracellular matrix is a biologically active composition of collagen, elastin, and proteoglycans. Cells within the vessel and matrix can detect small changes, and disruption of the matrix in response to atherosclerosis and hypertension can stimulate vessel remodeling. Specific proteolytic enzymes, MMPs, regulate the composition and integrity of the extracellular matrix. Their expression is regulated by growth factors and cytokines; they are commonly upregulated in malignancies, closely correlating with a tumor's ability to metastasize. They are released by cells in the connective tissue particularly fibroblasts and myofibroblasts. MMP-2 and MMP-9 are two subtypes important in vascular smooth muscle cell (VSMC) activation and neointimal formation after balloon injury. Inhibitors of MMP-2 and MMP-9 decrease VSMC migration in primate arterial explants and overexpression of MMP-9 enhances VSMC migration in vitro. Secretion of MMPs by endothelial cells is an important step in angiogenesis. As endothelial cells migrate they secrete bursts of MMP-9 to degrade the basement membrane and allow cell transit. This ability to break down extracellular matrix to allow cells to migrate is critical for neovascularization.

Activated MMPs are not usually present in the quiescent adult pulmonary vessel. Hypoxia increases the activity of collagenolytic metalloproteinases, which results in the appearances of collagen breaks and fragments. The breaks in collagen allow migration of SMCs or fibroblasts from the media or adventitia and can lead to neointimal proliferation. Cleaved collagen fragments can also induce SMC and fibroblast proliferation. Extracts from the small peripheral pulmonary arteries of chronically hypoxic rats have an increase in collagenolytic activity relative to normoxic controls. This activity was most pronounced at 4 d and then again during recovery from hypoxia when resolution of vessel remodeling occurs. Inhibitors of MMPs can prevent hypoxia-induced pulmonary hypertension in rats, providing support for an important role of MMPs in pulmonary vascular remodeling.

ENDOTHELIN-1 ET-1 is a vasoactive peptide synthesized by the endothelium. It can bind receptors on both endothelial and SMCs although with different actions on each. ET-1 is a ligand for both the ET_A and ET_B receptors on the SMC and promotes

vasoconstriction and proliferation. ET-1 also binds ET_B receptors on endothelial cells that promote the release of prostacyclin and NO. Elevated circulating levels of ET-1 are present in most forms of pulmonary hypertension suggesting a pathogenic role in its development or perpetuation. Elevated circulating levels of ET-1 are found in almost every type of vascular disease including atherosclerosis and vasculitis, however, suggesting that it is a nonspecific marker of vascular injury.

SEROTONIN 5-HT is a known mitogen for SMCs isolated from bovine and rat pulmonary arteries. The ability of 5-HT to remodel the pulmonary circulation has received great interest because of the development of pulmonary hypertension in individuals taking appetite suppressants that are known to interfere with the metabolism of 5-HT. Similar to ET-1, circulating 5-HT levels are elevated in most individuals with pulmonary hypertension. Treatments that increase 5-HT levels in rats exposed to long-term hypoxia worsen pulmonary hypertension, an effect that can be blocked by inhibitors of 5-HT uptake. In addition, mice that lack the 5-HT transporter required for the internalization of 5-HT develop less severe pulmonary remodeling when exposed to chronic hypoxia.

ANGIOTENSIN II Evidence that AGII plays a role in the development of pulmonary hypertension comes from experiments demonstrating induction of hypertrophy and hyperplasia in rat PA SMC in vitro. Expression of the angiotensin-converting enzyme (ACE) in the endothelial layer of small arteries and evidence of increased AGII binding to its receptor in the arterial walls of rats with hypoxia-induced pulmonary hypertension all support a role for AGII as a causative agent for the development of pulmonary hypertension. Additional evidence is provided by the ability of ACE inhibitors to attenuate pulmonary vascular remodeling.

CHRONIC LUNG DISEASE Pulmonary hypertension also develops in many forms of chronic lung disease including emphysema, interstitial lung disease, cystic fibrosis, and sickle cell disease. Pulmonary hypertension resulting from chronic lung disease is likely a different process than pulmonary hypertension arising from isolated involvement of the pulmonary vessels (like PPH, collagen vascular-associated pulmonary hypertension, and chronic increases in blood flow from congenital heart disease). Hypoxia, inflammation, and increases in flow/shear stress appear to be the initiating events. Inflammation in particular may play a role in the pulmonary hypertension associated with emphysema. Cigarette smoke impairs endothelial vasodilator function in vitro. Vascular remodeling similar to that seen in patients with hypoxia has been demonstrated in smokers with relatively preserved oxygenation. Whether the similarity is because of the like effects of cigaret smoking on shear stress or flow is not clear. It does suggest that direct injury to the pulmonary vessels from inflammation can occur independent of its impact on airways and lung parenchyma.

PULMONARY ARTERIAL HYPERTENSION AS A GENETIC DISEASE

The effect of mutations within the TGF-β superfamily of genes on the development and progression of pulmonary hypertension has received a great deal of attention. Of patients with PPH, approx 6% demonstrate an autosomal-dominant pattern of inheritance. In 2000, two separate groups identified germline mutations in the bone morphogenic protein receptor type 2 (BMPR2) that strongly correlated with the development of familial PPH. Additionally, mutations in the *Alk1* gene, a TGF-β type-I receptor, were also identified in families with hereditary hemorrhagic telangectasia and PA hypertension. BMPR2 is a member of the TGF-β superfamily that transduces signals by binding to heterotrimeric complexes of type-I and -II receptors to activate serine/threonine kinases. This leads to the activation of intracellular messengers known as SMADs that act as transcriptional regulators. In PA SMC culled from the conduit PA of patients with PPH, it was demonstrated that TGF-β stimulated DNA incorporation and proliferation whereas it had a growth inhibitory effect on cells from normal controls. In addition, the normal antiproliferative effect of the secreted cytokine bone morphogenic protein 7, which is a ligand for BMPR2, was lost in cells from patients with PPH. However this loss of effectiveness was not seen in cells obtained from individuals with secondary pulmonary hypertension. In a mouse model, expression of a dominant negative BMPRII mutation in smooth muscle led to the development of pulmonary hypertension, providing strong support for the theory that mutations in this receptor can lead to PPH. Which intracellular signaling mechanisms are disrupted because of these mutations, the role of mutations in endothelium and other cell types, and how these mutations lead to pulmonary hypertension is not understood.

Epidemiological data also indicate that mutations in BMPR2 are present in the majority of individuals with sporadic (nonfamilial) forms of PPH. Mutations of the BMPR2 have also been identified in patients with veno-occlusive disease, a form of postcapillary pulmonary hypertension resulting from the obliteration of small pulmonary venules and veins. No clear defects in systemic vascular remodeling have been identified in these individuals suggesting some specificity of this pathway in regulating pulmonary vascular remodeling.

THERAPIES FOR PULMONARY HYPERTENSION

Attempts to treat pulmonary hypertension have adopted two general strategies: the use of specific blockers against mitogens (including calcium), which are known mediators of pulmonary hypertension, and attempts to increase the concentration and duration of action of the endothelial derived vasodilators, prostacyclin, and NO.

Calcium channel blockers such as nifedipine prevent the influx of calcium through the voltage-gated calcium (L-type channels) and are the first-line therapy in patients with pulmonary hypertension (Fig. 24-5). They can reverse vasoconstriction in some patients and blocking calcium entry may also have an antimitogenic function on SMCs. Unfortunately, in humans they are effective in only a minority of individuals with pulmonary hypertension. Elevated circulating levels of ET-1 are present in all forms of pulmonary hypertension. Bosantan, a nonspecific ET_A/ET_B blocker, has been approved for the treatment of PA hypertension. Although experimentally ACE inhibitors can attenuate the vascular remodeling associated with hypoxia-induced pulmonary hypertension, they are not used clinically because of their effects on systemic blood pressure.

NO is a potent vasodilator whose effect is mediated through the cyclic nucleotide cGMP. Intense scientific and pharmaceutical effort has investigated ways to augment NO's and cGMP's effects on the pulmonary circulation. Experimentally, gene therapy using adenovirus to overexpress eNOS has had some success in limiting pulmonary vascular remodeling. Technical barriers make it unsuitable for clinical use at this time, however. Nitroprusside and nitroglycerin are NO donors that can induce vasodilation even in the presence of an injured endothelium. Unfortunately, both can cause

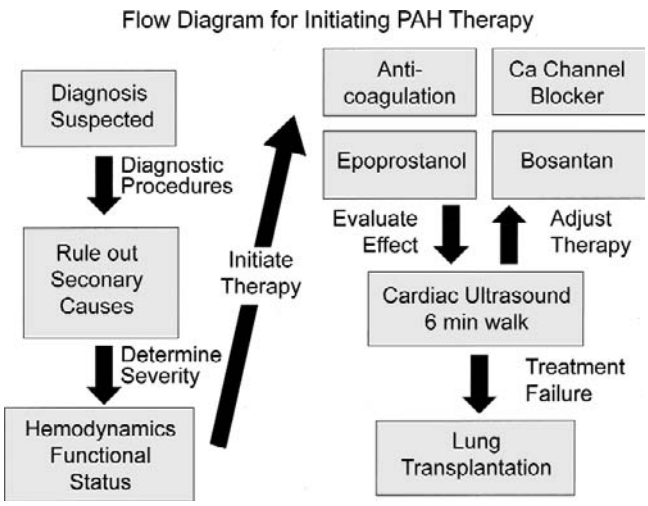

Figure 24-5 Flow diagram for initial therapeutic decision making in pulmonary arterial hypertension. Because of the complexity of caring for patients with pulmonary hypertension, initiation and maintenance of therapy should only be undertaken by a care team with extensive experience and adequate access to tertiary care services, including lung transplantation.

systemic hypotension making them less than ideal drugs to treat pulmonary hypertension. Inhaled NO has the advantage of acting locally in the pulmonary circulation because it is inactivated by hemoglobin long before reaching the systemic circulation. Toxicity of the gas as well as difficulties with delivery make this useful only in hospitalized patients particularly those awaiting lung transplant.

Another strategy to prolong the vasodilator and antiproliferative effects of NO is to prevent the degradation of cGMP. cGMP is generated when NO binds soluble guanylyl cyclase, which is central to the vasodilating and antimitogenic effects of NO. cGMP is hydrolyzed by PDE, a family of enzymes (numbering 20 and counting) that bind and inactivate cAMP and cGMP thus terminating their intracellular effects. Each PDE varies in location and specificity of substrate. PDE5 is primarily located in vascular smooth muscle and is specific for cGMP making it an attractive pharmacological target. Inhibitors of PDE5 such as zapronist and sildenafil prolong the half-life of cGMP and promote vascular relaxation. In cooperation with agents that increase NO availability such as inhaled NO or nitroglycerin, PDE5 inhibitors have a potent (and potentially dangerous) vasodilator effect. Clinical trials looking at the effect of PDE5 inhibitors on persistent pulmonary hypertension of the newborn and PPH are ongoing.

Intravenous prostacyclin is the drug of choice for individuals with PPH or scleroderma-associated pulmonary hypertension. Although prostacyclin is an effective vasodilator acutely, its ability to act as an anti-proliferative agent is central to its beneficial effect in pulmonary hypertension. Even patients who have no acute vasodilatory response to prostacyclin demonstrate improvement in pulmonary hemodynamics over 18 mo. Unfortunately, intravenous prostacyclin is expensive and the delivery system, which requires a central venous catheter, has many technical limitations. Inhaled and oral forms of prostacyclin are being studied as an alternative.

POTENTIAL NEW THERAPIES

The only approved therapies for PA hypertension are calcium channel blockers, intravenous prostacyclin, and the nonselective ET-1 blocker bosantan. All act at least in part to reduce pulmonary vascular tone. New therapies specifically targeted at reversing the vascular remodeling associated with pulmonary hypertension are being investigated. Serine elastase inhibitors are an example of this strategy. Serine elastase activity is increased in animal models of pulmonary hypertension and is also elevated in humans with congenital heart disease. The increased activity leads to proteinase-dependent deposition of extracellular matrix proteins such as elastin, fibronectin, and tenascin C, which contributes to SMC proliferation. When given orally serine elastase inhibitors completely reversed the vascular lesions and normalized pulmonary pressures in an animal model of monocrotaline-induced pulmonary hypertension. This was associated with PA SMC apoptosis and loss of extracellular matrix, specifically elastin and tenascin C.

Inhibitors of the RhoA/Rho kinase pathway are also being considered as a treatment for pulmonary hypertension. RhoA GTPase mediates a number of cellular responses central to the development of pulmonary hypertension including activation of the contractile proteins, cell proliferation, and induction of gene expression. Animal models indicate a role for activation of the RhoA/Rho kinase pathway in both acute and chronic hypoxia. Acute administration of Rho kinase inhibitors attenuate acute hypoxic vasoconstriction in isolated mouse lungs whereas chronic administration decreases the degree of right ventricular hypertrophy and neomuscularization following 3 wk of hypoxia.

The HMG Co-A reductase inhibitors, (the statins) have replaced aspirin as the new wonder drug and look promising as a potential therapy for pulmonary hypertension. Statins have a potent antiproliferative effect on VSMCs, independent of cholesterol metabolism. They inhibit isoprenylation, which is required for the membrane localization and subsequent activation of small G proteins such as Ras and Rho, which are important intracellular messengers. In vitro, HMG Co-A reductase inhibitors not only block VSMC proliferation in response to serum but can also induce apoptosis. Already approved for the treatment of coronary artery disease they are being considered for clinical trials to treat PA hypertension.

CONCLUSION

PA hypertension results from the pathological elevation in pulmonary vascular resistance because of a combination of increased vascular tone and vessel wall remodeling. It is a heterogeneous disorder with the vascular phenotype dependent on the mechanism and severity of injury. With increasing duration and severity, pulmonary hypertension is associated with progressive vessel wall remodeling ultimately resulting in fixed, irreversible lesions. All three cell types within the vessel wall contribute to these vascular lesions through the combined effect of cell proliferation, cell migration, and matrix deposition. Therapies aim to restore vasodilator function while limiting mitogen-induced proliferation. New therapies need to reverse these vascular lesions by breaking down extracellular matrix and inducing controlled regression (apoptosis) within the vessel wall to provide the best chance to restore the pulmonary circulation to its natural low resistive state and reduce the morbidity and mortality associated with this disease.

25 Acute Lung Injury

David C. Christiani and Michelle Ng Gong

SUMMARY

The acute respiratory distress syndrome (ARDS)/acute lung injury is a major cause of morbidity and mortality throughout the world. ARDS is an acute syndrome of lung inflammation and increased permeability associated with severe hypoxia and bilateral infiltrates on chest radiographs with no evidence of left heart failure. This chapter reviews the evidence for genetic determinants in acute lung injury and ARDS with a focus on potential candidate gene polymorphism that may be important in the development and outcome of ARDS.

Key Words: Acute lung injury (ALI); acute respiratory distress syndrome (ARDS); angiotensin-converting enzyme (ACE); glutathnione-*S*-transferase (GST).

INTRODUCTION

The acute respiratory distress syndrome (ARDS)/acute lung injury (ALI) is a major cause of morbidity and mortality throughout the world. Annually approx 150,000 cases are reported in the United States with a reported mortality of 40–60%. The American-European Consensus Committee on ARDS defines ARDS as an acute syndrome of lung inflammation and increased permeability associated with severe hypoxia and bilateral infiltrates on chest radiographs with no evidence of left heart failure. Major risk factors for the development of ARDS have been described and include sepsis, trauma, pneumonia, burns, multiple transfusions, cardiopulmonary bypass, and pancreatitis. Other factors such as older age, chronic alcoholism, tobacco abuse, absence of diabetes, and greater severity of illness have also been found to contribute to the risk of developing ARDS. Despite the common occurrence of these risk factors, only a minority of patients with the acute injuries listed above develops ARDS. It is likely that given the same type and degree of insult, there are individual differences in susceptibility to developing ARDS.

Since the initial description of ARDS in 1967, research has focused on defining the pathogenesis, clinical presentation, course, and outcome of the syndrome. Initially, studies investigated the role of complement and endotoxin in lung injury. Then research concentrated more on the role of inflammation in the pathogenesis and course of ALI/ARDS. Additionally, clinical studies have evaluated variables that may influence the development and outcome of ALI. Although many animal studies have been consistent, many human studies have reported conflicting results. Consequently, efforts to find clinical characteristics or biomarkers to predict, diagnose, or prognosticate outcomes in ARDS have been often disappointing. The understanding of why some patients develop and die from ARDS whereas others do not is incomplete. For example, although major risk factors for ARDS have been identified, most patients with these risk factors do not develop ARDS. Only approx 4% of patients with documented bacteremia and 41% of patients with sepsis syndrome develop ARDS.

Likewise, the search for molecular biomarkers in ARDS has been disappointing. Some studies have found increased plasma levels of tumor necrosis factor (TNF)-α to correlate with the development of ARDS and the severity and mortality in ALI. Other studies from different institutions did not detect the same association. Variable timing, sample type, and method of measurement may explain some of the conflicting results on cytokines in ARDS.

The role of genetic variability in the development and course of ALI had previously not been considered. However, discoveries about the genetic control and regulation of the innate immune defense and inflammatory response have raised the question of whether the multiple polymorphic alleles of genes that encode for cytokines and other mediators of inflammation may result in phenotypic differences in host inflammatory response. These differences may account for some of the heterogeneity in individual susceptibility to, and prognosis in, ARDS.

This chapter reviews the evidence for genetic determinants in ALI and ARDS with a focus on potential candidate gene polymorphism that may be important in the development and outcome of ARDS.

EVIDENCE FOR GENETIC DETERMINANTS OF ALI/ARDS

Almost all cases of ARDS/ALI occur as a complication of an initial injury such as sepsis, pneumonia, trauma, or aspiration. Whether a patient develops ARDS as a result of this initial injury depends partly on environmental factors such as comorbid diseases and treatment adequacy. Genetic variability is likely to affect development of ARDS in multiple aspects of this pathway (Fig. 25-1). There may be heritable determinants to the likelihood of developing ARDS after the initial injury. Alternatively, there may be variable genetic susceptibility to developing and manifesting the initial injury of sepsis or pneumonia. The likelihood by which a person with infection presents with shock may be genetically influenced.

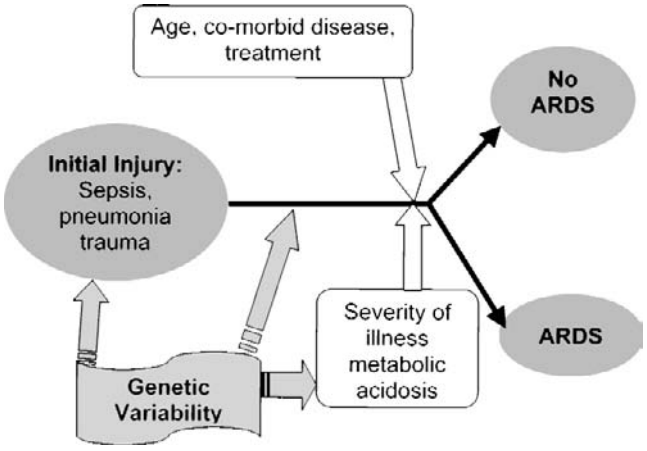

Figure 25-1 Genetic determinants in the development of ARDS. Genetic variability is likely to play a role in multiple aspects in the pathogenesis of ARDS from the susceptibility to developing the initial injury, to variable presentation of the injury (i.e., with or without shock) and ultimately to the likelihood of the progression from initial injury to ARDS.

Finally, genetic variability may influence outcome once ALI/ARDS develops.

Classic approaches to determining the genetic vs environmental contribution to diseases using twin, adoptees, or families to determine heritability are not feasible in ARDS. Workable criteria for a consistent diagnosis of ARDS were not available until 1988. The current definition of ARDS and ALI was proposed in 1994. Thus, it is likely that ARDS was underdiagnosed in the past. Additionally, the high mortality and older age of onset of ALI/ARDS limits the availability of affected family members for analysis. Thus, it is not surprising that there are no known family aggregates of ARDS. Nevertheless, intriguing studies indicate likely genetic determinants in ARDS.

There have been multiple reports of recurrent ARDS in some individuals. One report describes six patients with multiple episodes of biopsy-proven diffuse alveolar damage. The discovery of a group of patients prone to repeated lung injury raises the possibility of an inherent, possibly heritable, predisposition to ARDS. Because mortality in ARDS is high, it is not surprising that these cases of recurrent ARDS are rare. However, with mortality in ARDS improving, genetically susceptible patients may be more likely to survive their first bout of lung injury to develop another episode.

Although there are no family studies on ARDS, there are intriguing twin and adoption studies on serious infections and premature deaths. Genetic susceptibility to severe infection has important implications for ALI. Sepsis is the leading cause of ALI/ARDS and is associated with worse mortality than ALI secondary to other etiologies. Bacterial infection is found frequently in ARDS patients, with one autopsy study indicating a prevalence of 98%. Most ARDS fatalities result from refractory infection and sepsis, not from respiratory failure. Thus, it is likely that genetic polymorphisms that are important in developing severe infections may also be important in ALI.

In an epidemiological study of 218 pairs of Danish twins, a monozygotic twin whose cotwin died prematurely before the age of 60 had a significantly increased risk of dying prematurely. In another study involving 960 families with adopted children, the relative risk (RR) of dying prematurely from infections in an adopted individual is 5.81 (95% confidence interval [CI] 2.47–13.7) if one biological parent died before the age of 50 from infection. In contrast, if the adopted parent were to die prematurely of infection, the RR of dying from infection was 0.73 (95% CI 0.1–5.36) in the adoptee. These data suggest that premature death from infection has a stronger genetic than environmental component.

POTENTIAL CANDIDATE GENES IN ALI/ARDS

As a result of these studies, there have been some preliminary investigations into genetic susceptibility in sepsis and ALI. Although promising, these preliminary studies also demonstrate the difficulties involved in designing genetic studies on complex diseases like ALI/ARDS. A number of common genetic variants may have a role in ALI/ARDS because of their role in altering function (e.g., protein production or post-translational expression) in various pathophysiological steps that are important in the development of ALI/ARDS (Table 25-1). Some of these polymorphisms have been associated with variable protein levels or expression, but caution is advised in interpreting such associations. Plasma levels of protein are a crude assessment of the functional consequence of the polymorphism and a positive or negative association does not necessarily mean the polymorphism is the functional causative loci. Below is a brief evidence-based review of a few genes that can serve as potential candidates for investigation into the genetic susceptibility of ALI.

INFLAMMATORY/ANTI-INFLAMMATORY PATHWAY It is generally accepted that the development and evolution of ALI involves the activation of the inflammatory cascade. Instillation of inflammatory cytokines such as TNF-α and interleukin (IL)-6 in animals can result in histological changes identical to ARDS. In human studies, the results of these inflammatory cytokines in ALI have been inconsistent. Proinflammatory cytokines, such as TNF-α, IL-1, IL-6, IL-8, and anti-inflammatory modulators such as IL-10 and IL-1-receptor antagonists (IL-1ra) have featured prominently in studies of ALI, but there have been conflicting results on their role in predicting the development of or mortality in ALI. Potential reasons abound for the heterogeneous results from these studies of individual biomarkers in ALI. Given the complexity of the condition, it is unlikely that any particular mediator will dominate in the pathogenesis of ALI. Also, the cytokine profile may differ by the type of injury that predisposes an individual to ALI. Soluble intercellular adhesion molecule-1 and E-selectin concentrations are significantly higher in ARDS patients with sepsis than in trauma-related ARDS patients. Interest in the role of genetic variability in the development and course of ALI has grown. It is possible that multiple alleles of genes that encode for cytokines and other mediators of inflammation can result in phenotypic differences in host inflammatory response.

A number of candidate genes in the inflammatory/anti-inflammatory pathway may be important in the pathogenesis of ALI. Pre-B-cell colony enhancing factor (PBCEF) is a cytokine that have been previously found in sepsis to inhibit neutrophil apoptosis (Jia et al., 2004). Recently, the *PBCEF* gene was recently implicated in ALI (Ye, SQ et al., 2005). Increased expression of PBCEF was found in both animal models of ALI and in humans with ALI and increased PBCEF protein was found in the blood and serum of ALI patients. Two single-nucleotide polymorphisms (SNPs) were identified on the *PBCEF* gene, T-1001G and C-1543T. The *G* allele of

Table 25-1
Potential Candidate Genes for Risk or Clinical Course of ALI/ARDS

Potential role in ALI/ARDS	*Candidate gene*	*Association with variable protein levels or function*	*Association with sepsis or ARDS*
Inflammatory cytokines	*PBCEF*	Yes	Yes
	TNF-β	Variable	Variable
	TNF-B	Variable	Variable
	IL-6	Yes	Yes
Anti-inflammtory modulators	*IL-1ra*	Yes	Yes
	IL-10	Yes	Yes
Coagulation/Fibrinolysis pathway	*PAI-1*	Yes	No
Antioxidant	*GST*	Yes	No
Cell repair	*HSP*	Yes	No
Innate immunity	*TLR-2*	Yes	No
	TLR-4	Yes	Yes
	MBL	Yes	No
Lung function	*SP-B*	No	Yes
Fibrosis and inflammatory	*TGF-β_1*	Yes	No
Unclear	*ACE*	Yes	Yes

the T-1001G polymorphism and the GC haplotype was found to be associated with increased odds of developing ALI although no association with mortality in ALI was found.

TNF-α has often been studied in ALI. The –308 G to A transition polymorphism in the promoter region of *TNF-α* gene and the *Nco*I restriction fragment length polymorphism in intron 1 of the *TNF-α* gene are in linkage disequilibrium and have found to be associated with variable plasma levels of TNF-α and variable risk for sepsis and cerebral malaria in some but not all studies. We have found that the *–308A* allele of the *TNF-α* gene but not the *TNFB2* allele of the *TNF-α* gene was associated with the development of ARDS but only in the presence of a gene–environment interaction with whether the etiology for ARDS was directly pulmonary vs extrapulmonary. The *–308A* allele was significantly associated with increased mortality in ARDS (Gong et al., 2005).

Another potentially important candidate gene in ALI is *IL-6.* A SNP in position –174 in the promoter region of the *IL-6* gene on chromosome 7 has been identified. The *GG* genotype was found to be associated with increased plasma IL-6 levels although others have found higher IL-6 levels with the C allele. The *GG* genotype is associated with a twofold increased risk of culture positive sepsis in neonates, whereas in adults, there was no association to sepsis but the *GG* genotype was associated with survival in sepsis. The *variant C allele* was not associated with ARDS but it was found in lower frequency in nonsurviving critically ill individuals with and without ARDS.

Anti-inflammatory genes that are potentially important in ALI include *IL-10* and *IL-1ra.* Increased plasma levels of IL-10 correlate with severity of illness in pneumonia and mortality in sepsis and menningococcemia. A SNP in position –1082 is associated with increased IL-10 and increased severity of illness and risk of septic shock in patients with pneumonia. A functional pentaallelic polymorphism of *IL-1ra* consists of 86 basepair variable number of tandem repeats in intron 2. In vitro and in vivo studies have shown allele 2 of this polymorphism to be associated with increased IL-1ra. Allele 2 is associated with sepsis development and, along with polymorphisms of IL-1, with mortality in sepsis.

Other gene polymorphisms may be relevant in ALI but have not been associated with sepsis or lung injury. One example is NF-κβ, a regulatory protein for many of the proinflammatory cytokines such as TNF-α, IL-1, and IL-6. Because it serves as a gatekeeper to many inflammatory mediators and function, variability in the *NF-κβ* gene could be important in variable susceptibility to ALI. Although polymorphisms of the *NF-κβ* gene have been identified, none has been associated with functional variability, sepsis, or lung injury.

COAGULATION/FIBRINOLYSIS PATHWAY Interaction exists between the activation of the coagulation and fibrinolysis system and the inflammatory/anti-inflammatory pathway in sepsis and ARDS. Disseminated intravascular coagulation is a strong predictor of ARDS and mortality in sepsis. Commonly, microvascular thrombi are found in the lungs of patients with ARDS on autopsy and ARDS associated with disseminated intravascular coagulation has a high mortality rate.

Several polymorphisms of coagulation/fibrinolysis factors such as protein C and fibrinogen have been described in thrombotic diseases. Only one, the *plasminogen activator inhibitor* (*PAI)-1* gene, has been implicated in severe infectious disease. PAI-1 is an inhibitor of the fibrinolysis system in that it can complex with plasminogen activator compromising their ability to convert plasminogen to the active form, plasmin. Increased PAI-1 level is a good predictor for ARDS and mortality in ALI. A 4G/5G deletion/insertion polymorphism at position –675 in the promoter region of the *PAI-1* gene has been described, and is associated with increased serum PAI-1 levels and worse outcome in menningococcal disease. It is possible that *PAI-1* polymorphism may be associated with risk of development and/or outcome in ARDS.

ANTIOXIDANT/CELL REPAIR A number of studies have found a possible imbalance between reactive oxygen species and antioxidants in the pathogenesis of ALI. The glutathione *S*-transferase (GST) are a family of enzymes that help regulate glutathione, a major cellular antioxidant. Several subtypes of GSTs include GST-α, GST-μ, GST-π, and GST-θ. Multiple polymorphisms of the GST enzymes have been found, some with demonstrated functional consequences. The genes for these subtypes have been implicated in the genetic susceptibility to lung cancer, chest abnormalities in rheumatoid arthritis, severe bronchial hyper-responsiveness in asthma, and chronic obstructive pulmonary disease (COPD). As yet, no clinical studies link the *GST* genes to sepsis or ALI.

Heat shock protein (HSP)-70 is the best-studied member of a group of intracellular stress proteins that protect against cell death from physiological stress like hyperthermia, environmental toxicants, or Gram-negative bacteria. HSP-70 limits lung injury in animal models of ALI. Peripheral blood monocytes from patients with ARDS had significantly lower expression of HSP-70 after hyperthermic stress compared with healthy controls with a positive correlation between HSP-70 inducibility and duration of mechanical ventilation.

Three genes encode for HSP-70 on chromosome 6. One, *HSP-70-2*, exhibits a biallelic *HSP-70-2 G/A Pst I* polymorphism that is associated with a lower expression of mRNA for *HSP-70* after stimulation. However, human studies have not demonstrated an association with sepsis or worse outcome in trauma. Another *Nco*I polymorphism on the *HSP70-Hom* gene was associated (but not significantly) with increased risk of ARDS (odds ratio 2.1, 95% CI 0.8–5.9) in one small ($N = 80$) study. Case–control studies of sepsis and ARDS/ALI are needed to evaluate the potential role of *HSP-70* gene polymorphisms, disease risk, and outcome.

INNATE IMMUNITY As noted, sepsis and ALI are closely linked. Sepsis is a leading cause of ARDS and the leading cause of mortality in ARDS. Thus, it is possible that interindividual variation in host defense may also influence susceptibility to, and mortality in, ALI. To defend against infection, the innate immune system needs to be able to detect foreign pathogens, eliminate them rapidly before they can propagate or if needed, trigger a cascade of specific inflammatory response to contain and eradicate the organism. Thus, genes involved in innate immunity may be important in the pathogenesis of ALI.

A family of toll-like receptors (TLR) binds to bacterial constituents such as lipopolysaccharide and institutes the appropriate innate response. A SNP at *A-896G* in exon 4 of the *TLR-4* gene is associated with a replacement of an aspartic acid residue with glycine at amino acid 299 (*Asp299Gly*) and results in an alteration of the extracellular domain of the TLR-4. The variant allele of this polymorphism is associated with hyporesponsiveness to inhaled lipopolysaccharide. Although one study did not find any association with meningococcal disease, others found that the variant allele was associated with septic shock and Gram-negative infections. A SNP in TLR-2, *G2258A*, was associated with decreased response to bacterial peptides derived from *Borrelia burgdorferi* and *Treponema pallidum*. In one study, the variant allele was found in 2/22 (9%) of patients with Gram-positive septic shock compared with 0/69 (0%) of patients with other types of septic shock, although the sample size was too small for analysis. It is possible that polymorphism in *TLR-2* or *TLR-4* genes may play a role in susceptibility to ARDS/ALI.

Another potential candidate gene in ALI is the *mannose-binding lectin* (*MBL*) gene. MBL is a serum protein in the innate immune system that binds to polysaccharides on the surface of various bacteria and viruses, and facilitates opsonization and phagocytosis. SNPs have been identified on exons 1, 3 (known collectively as allele O) and in the promoter region of the *MBL* gene. The variant alleles of these polymorphisms are associated with lower serum levels of MBL. These variant alleles are associated with an increased risk of meningococcal disease, increased infections in children and patients with COPD and lupus, and greater severity of illness and worse outcomes in patients with cystic fibrosis. No studies of *MBL* variants in ARDS have been published.

OTHER POTENTIAL CANDIDATE GENES A deletion polymorphism in the *angiotensin-converting enzyme* (*ACE*) gene, which is associated with higher ACE levels and activity, has been implicated in a number of diseases including myocardial infarction and hypertension. The biological role of *ACE* in sepsis and ALI is unclear. Most studies report *ACE* levels or activity to be low in ARDS. However, the high *ACE* producing *DD* genotype was found to be associated with severe meningococcal disease, ARDS, and increased mortality in ARDS. Further study is needed to confirm this finding.

After an acute injury, the lung often responds with evidence of fibrogenesis. Evidence of early pulmonary fibrosis in biopsy of ARDS patients has also been associated with a poorer outcome. Transforming growth factor (TGF)-β is likely to play a key role in the fibrinogenesis of the lung in ARDS. TGF-β is a cytokine produced in response to tissue injury. Its actions include the regulation and inhibition of inflammatory cytokines like TNF-β, IL-1, platelet-derived growth factors, and fibroblast growth factor; the induction of extracellular matrix deposition; the inhibition of protease degradation of the matrix; and the modulation of the expression of integrins to increase cellular adhesion to the matrix. Increased TGF-β mRNA has been found in the rat model of shock-induced ARDS. A SNP at position –509 in the promoter region of *TGF*-β_1 gene has been described that is associated with variable TGF-β levels. Polymorphisms in *TGF*-β_1 may be useful in predicting susceptibility to developing fibrosis, making them potential candidate genes for ALI.

Pulmonary surfactant is synthesized primarily by type-II alveolar cells and it has multiple important functions in the lung including lowering the surface tension on the alveolar surface and enhancing bacterial phagocytosis and chemotaxis of alveolar macrophages. One surfactant protein (SP), SP-B is predictive of ARDS development. Polymorphisms in the *SP-B* gene have been associated with ARDS in a few studies. In one small study, the frequency of an insertion/deletion variant polymorphism in intron 4 was 46.6% among 15 ARDS patients in contrast to 4.3% in the control group of normal blood donors ($p < 0.05$). An increased association has been found between the variant *SP-B* polymorphism and ARDS in women at risk for ARDS secondary to sepsis, aspiration, pneumonia, trauma, or massive transfusion after adjusting for age, race, and severity of illness. No association was found for the men, indicating possible gender modification of the risk conferred by the variant polymorphism of the *SP-B* gene. Another study found an association between the (1580C/T missense mutation in exon 4 of the *SP-B* gene and the development of ARDS especially in those patients with lung injury from predominantly direct pulmonary insults such as pneumonia. Another study on a different population of patients with community acquired pneumonia confirmed the association between the –1580 *C* allele and ARDS (Quasney et al., 2004).

ALI AS A COMPLEX DISORDER

Although there are likely to be genetic determinants in the development and evolution of ALI, elucidating these determinants will not be straightforward, because ALI is a complex disorder with complex genetic and exogenous determinants. The innate immune and inflammatory response, like many other mechanisms in physiology, involves a number of integrated biochemical and physiological systems that respond to and are modulated by environmental stimuli. To ensure stability and adaptability, the inflammatory

response has both pro- and anti-inflammatory pathways with built-in redundancies, biofeedback loops for modulation, and counter-regulatory mechanisms. Although this system is under genetic regulation, it is likely to be controlled by multiple genes (genetic heterogeneity) with interaction between genes (gene–gene interaction) and between gene and exogenous stimuli such as infection, trauma, or other lung injuries (gene–environment interaction). The redundancies built into the system could result in a threshold effect in which the function of several genes needs to be affected before ALI will be manifested. Because of these multiple interactions, any single susceptibility gene in ALI will exhibit incomplete penetrance (i.e., not all individuals with the gene polymorphism will develop ALI). Epidemiologically, penetrance translates to RR, in which a highly penetrant gene corresponds to high RR of disease for the individual, whereas a low-penetrant gene confers a low to moderate RR of the disease.

The role of the environment is particularly critical in influencing the genetic determinants in a complex disorder like ALI. A predisposing injury is essential to its development. In two prospective studies on the development of ARDS, 78% of the ARDS cases developed after known conditions such as trauma, aspiration, sepsis, massive transfusion, drug overdose, near drowning, or pneumonia. In one of these studies, only 9% of the patients did not have a clearly recognized acute condition leading to ARDS. In addition, the type of injury affects the incidence of ARDS, the cytokine profile, and mortality. Thus, it is likely that any genetic determinants of ALI/ARDS will be modified by the type of injury that led to lung injury. Just as it is important to account for tobacco use in genetic studies of lung cancer and COPD, it is important to account for the type of injury that predisposes to lung injury in studies of populations at risk for ARDS/ALI.

Because of incomplete penetrance and interactions with other factors such as age, other genes and the environment, susceptibility genes for complex diseases like ALI may not determine the development and outcome of the disease. Rather, these gene polymorphisms, singly or in combination, will affect the probability of developing the syndrome after an injury. Traditionally, epidemiology has been concerned with discovering causal associations for diseases and disorders. Molecular epidemiology combines the use of molecular biological techniques such as modern genetics with epidemiology to identify and characterize disease in populations in the context of environmental exposures. In sorting out the genetic basis for lung injury, the discipline and tools of classic epidemiology will be important in study design and in accounting for multiple interactions and environmental influences.

CONCLUSION

The use of molecular epidemiology to better understand the genetic basis for ALI on a population level has important implications for research. This approach is an example of translational research in which significant findings in the laboratory are examined on a population level to determine their relative contribution to actual disease occurrences. There is also the potential for "backward" translation. Given the large number of molecules implicated in the pathogenesis of lung injury and the complex interactions between different molecular pathways, it is not always easy to discern in the laboratory which mechanism may be most important. The identification of a particular gene or genetic polymorphism that is important in a large population and the identification of environmental conditions in which genetic contribution is strongest can help guide the molecular biologist to focus on the protein or molecular pathway with the greatest potential impact for the largest number of patients.

In addition, the identification of a group of patients who may be genetically at a higher risk for the development of ARDS under certain conditions has important implications for prevention and treatment. A goal of epidemiology is the identification of risk factors by which a population can be identified for future intervention. Although an individual's genetic susceptibility cannot be changed, the physician and the patient can alter other risk factors to decrease the overall risk of disease. In addition, the identification of individuals who are genetically susceptible to ARDS can pinpoint subgroups of patients who may most benefit from certain therapeutic modalities. Surfactant replacement therapy was not found to be beneficial in ARDS. However, it is possible that certain individuals with genetic susceptibility to ALI/ARDS because of a polymorphism in the *SP* genes may be more responsive to surfactant replacement because the lack of surfactant is more pivotal in the pathogenesis of their lung injury than other individuals with high or normal surfactant production. A better knowledge of the genetic predisposition to ALI could lead to individually tailored therapy.

Molecular epidemiological studies represent an exciting and novel approach to the study of ALI. It is not likely that a single susceptibility gene produces disease. Rather, susceptibility genes will be additional but important risk factors for determining the ultimate probability of disease. Although it will be undoubtedly challenging, the quest for genetic determinants in ALI holds great promise in helping clarify the risks and outcomes in this condition. Unlike other risk factors for ARDS, the nature of genetics allows for the prospective determination of individuals at high risk for the development of or mortality from ALI. This knowledge will be important in the design of future preventive and therapeutic trials.

26 Primary Ciliary Dyskinesia

PEADAR G. NOONE, MAIMOONA ZARIWALA, AND MICHAEL R. KNOWLES

SUMMARY

Mucociliary clearance is an important part of airway host defense. Abnormalities in this system may result in disease, for example, cystic fibrosis and primary ciliary dyskinesia (PCD). PCD reflects genetic-based abnormalities of airway ciliary structure, resulting in disease predominantly in the sinuses, middle ear, and lung. Although the biology of PCD has been known for decades, it is only recently that the genetics of the disease have begun to be elucidated. This chapter primarily focuses on the molecular basis of PCD, with a brief review of biology of ciliary structure/function, and the clinical aspects of the disease.

Key Words: Axonemes; bronchiectasis; cilia; dynein; mucus; mucociliary clearance; neonatal respiratory distress; nitric oxide; nontuberculous mycobacteria; obstructive pulmonary disease; otitis media; primary ciliary dyskinesia; *Pseudomonas aeruginosa*; sinusitis; situs inversus.

INTRODUCTION

Efficient airway defense is critical for protection of all lung surfaces, including the airways and distal alveolar surfaces, given the exposure of the lung to the potentially harmful contents of the outside atmosphere. Mucociliary clearance (MCC), which includes effective ciliary function, the integrated actions of airway epithelia to regulate surface liquid properties, and mucus secretion, is a key component of this defense system in the lung. Abnormalities in this defense system are reflected in the clinical expression of lung diseases. Cystic fibrosis (CF) is a prototype genetic disease of airway host defense that has been intensively studied, and the molecular basis of classic and nonclassic disease has largely been elucidated, though not completely. Abnormalities in the CF transmembrane regulator result in airway epithelial ion transport defects, and abnormal mucociliary/cough clearance, leading to chronic sinopulmonary disease and bronchiectasis as primary phenotypic manifestations. There is some phenotypic overlap of CF with another genetic disease of airway host defense, primary ciliary dyskinesia (PCD), although the latter has a completely different molecular and cell biological basis. PCD is a disease that reflects genetic abnormalities of airway ciliary structure and function, with a phenotype that reflects the anatomic distribution of ciliary organelles—i.e., otosinopulmonary disease and female and male fertility problems. Although the ciliary ultrastructural and functional defects in PCD were described several decades ago, this disease's genetics have only begun to emerge. This chapter primarily focuses on the molecular basis of PCD, but first reviews ciliary structure and function and the clinical aspects of PCD.

PATHOGENESIS AND CLINICAL ASPECTS

The clinical presentation of PCD, a disease associated with defective ciliary structure and function with associated abnormalities in MCC, is predictable given the anatomic location and function of cilia in the human body. Ciliated epithelia are located in many tissues, including that of the embryo (nodal "monocilia," important for left–right [L–R] asymmetry), the ependyma of the brain, the middle ear and Eustachian tube, the conducting airways (including the sinuses), and the Fallopian tubes in females. The sperm tail in the male also has a structure and function analogous to that of the cilium. Thus, defective ciliary function results in clinical disease expressed predominantly in those tissues; *situs inversus* (resulting from abnormal monociliary function in early embryogenesis), otosinopulmonary disease, reduced female fertility, and male infertility.

CILIARY ULTRASTRUCTURE AND FUNCTION Because the clinical phenotype is related directly to the location and function of cilia, it is worth considering normal ciliary ultrastructure and function before addressing the spectrum of disease associated with PCD. The molecular aspects of dyneins and related dynein genes are discussed later. Electron microscopic studies have led to significant insights into the structure of human cilia and similar structures. In addition, parallel studies in the flagellate protozoa, *Chlamydomonas*, have led to an increased understanding of the molecular and biochemical aspects of both normal and abnormal cilia structure and function, given the homology between the organelles of these primitive organisms and those of the human.

Cilia are projections of the cell membrane, with a "root system" made up of the ciliary necklace at the base of the cilium, and a ciliary rootlet and basal body embedded in the cell itself (Fig. 26-1). Adjacent cilia are functionally oriented in the same direction, as measured by the direction that the rootlets are facing, which has implications for overall mucociliary function in a synchronous, organized fashion—i.e., with all cilia beating in the same direction. The long axis of the ciliary shaft contains several microtubule-associated proteins (MAP, also termed axonemal proteins), the most obvious of which are dynein arms (DAs), arranged

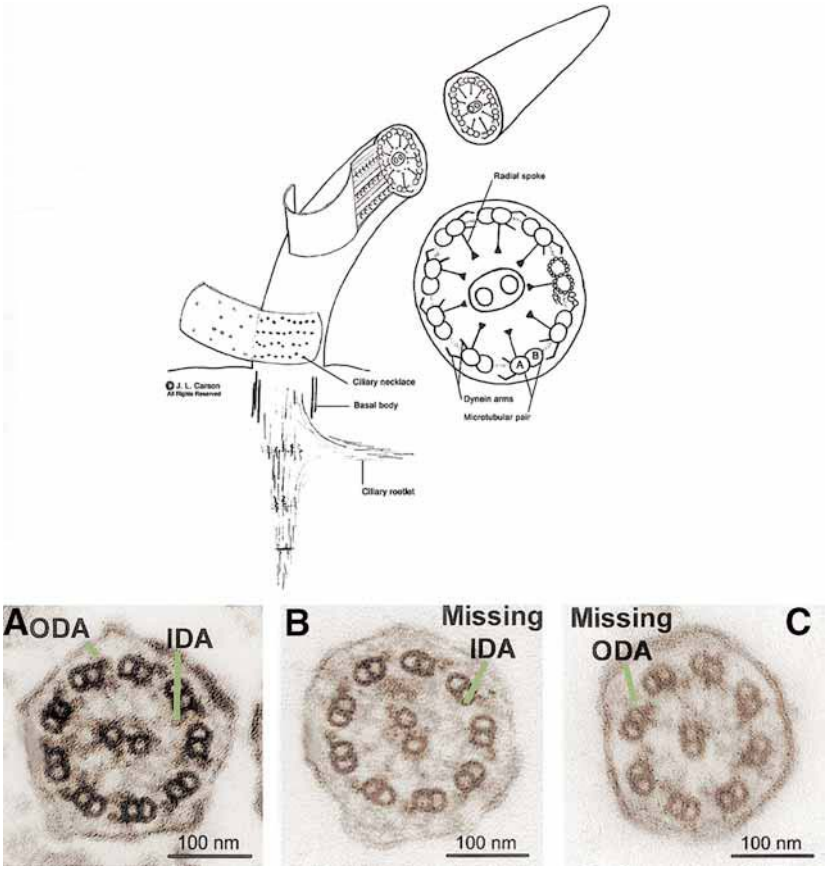

Figure 26-1 **Top panels:** Diagram of a longitudinal and cross-section of a cilium showing complex arrangement of axonemes and dyneins. The central complex and radial spokes are not labeled, but are clearly visible in both this diagram and the images in the bottom panel. (Image courtesy of Johnny Carson PhD, UNC Chapel Hill.) **Bottom panel: (A)** Cross-sectional electron micrograph images of human cilia from healthy control subject. **(B** and **C)** Two subjects with PCD. **(A)**, Normal ODA and normal IDA visible. **(B)**, Normal ODA, missing IDA. **(C)**, Missing/stubby ODA, normal IDA. in pairs and in a configuration of nine outer microtubule pairs and a central pair (9 + 2 configuration) (*see* Fig. 26-1). Spokes radiate from the two central microtubules (the central apparatus [CA]) toward the peripheral microtubule doublets. The DAs (inner dynein arm [IDA] and outer dynein arm [ODA]) are spaced at 24-nm intervals along the length of one of the microtubule doublets (microtubule A), and are the "motor" proteins of cilium. Each cilium (5 μm long) contains approx 4000 DAs in pairs. Dynein utilizes ATP to effect conformational changes in the ciliary microtubules relative to each other, such that ciliary bending results.

The molecular aspects of DAs are discussed in detail later; however, a brief outline to illustrate the relationship between DA structure/function, and overall ciliary function is valuable at this stage. ODA structure appears less complicated than IDA structure. Electron microscopic techniques to visualize DAs in ciliary cross-sections from human epithelial specimens show that the ODA is easier to visualize in the normal and abnormal (missing, shortened) state than the IDA, which can be difficult to distinguish (*see* Fig. 26-1, bottom panel). The composition and arrangement of the IDA is complex, and varies along the flagellar axoneme (*see also* below, dynein structure/function). The IDA includes several subunits, termed light, intermediate, and heavy chains. From a functional standpoint, this structural difference between IDA and ODA appears to relate to the different role these structures play in ciliary function. From a genetic standpoint, different genetic mutations lead to different "ciliary" phenotypes (abnormal ODA vs IDA vs "other"), although the clinical phenotype may be similar. Overall, ciliary beat consists of a power stroke, followed by a relaxation stroke, which makes biological sense when thinking about the swimming actions of protozoa, or the actions of cilia to propel mucus and inhaled "debris" proximally out of the respiratory tract in humans. Evidence from both mutant *Chlamydomonas* and humans with clinical disease, suggests that the ODA relates primarily to ciliary beat frequency and force, whereas IDA appears to relate more to ciliary bending patterns ("stiff"/"less supple"). For example, several mutant loci in the ODA in *Chlamydomonas* result in slow swimmers, and humans with abnormal ODA have reduced ciliary activity as compared with humans with abnormal IDA. However, *Chlamydomonas* with mutant inner DA systems exhibit reduced shear amplitude. High-speed video microscopy analyses of ciliary activity may further elucidate abnormal ODA and IDA, in terms of specific defects and their relationship with abnormal ciliary frequency/bending/"stiffness." Regulation of shear force is also required for effective ciliary beat, which involves rotational mechanisms between the CA, the radial spokes, and the outer axonemes. Mutant *Chlamydomonas* with defective CA show paralysis of flagellar beat, suggesting that this structure acts as a distributor for the regulation of dynein activity. Patients with PCD generally have visible

ultrastructural and functional abnormalities in cilia that lead in vivo to abnormal MCC, loss of the protection afforded by this mechanical clearance system, and, thus, organ level expression of clinical disease manifested mainly in the ear, sinuses, and lung. However, occasionally patients may have structurally normal cilia; yet have a strong clinical "PCD phenotype." This suggests that there may be a spectrum of PCD; from that of "classic" disease with overt, defined ciliary abnormalities, to variant or nonclassic disease, with less easily defined ciliary ultrastructural defects.

Finally, one clinical observation in PCD relates to an unexpected role for another ciliary structure. "Monocilia" are ciliary structures similar to respiratory cilia but lacking a central doublet, which have an important role in early organ development in the embryo. When abnormal in PCD, defective monocilia are associated with another significant phenotypic marker of PCD, *situs inversus*.

ASSOCIATED CLINICAL DISEASE The clinical spectrum of PCD has been well described for decades, although reviews continue to refine the phenotype. A neonatal respiratory syndrome, similar to transient tachypnea of the newborn, is a usual presenting feature of PCD, suggesting a link between effective ciliary function and the clearance of lung liquid in the neonatal period. Another striking phenotypic feature that may be detected at birth is *situs inversus* totalis (SI, known as Kartagener's syndrome when accompanied by PCD). Interestingly, SI is not genetically predetermined in patients with PCD, but occurs as a random phenomenon. Studies in a mouse model with abnormal situs suggest a role for nodal primary cilia (monocilia) in cell signaling in the formation of normal L–R asymmetry, such that defective monocilia structure and function lead to randomization of L–R asymmetry in affected animals. Monocilia are structurally different to epithelial cilia, for example, lacking a central doublet, and functionally beat in a rotatory manner, rather than the usual ciliary beat patterns. Thus, the normal rotatory action of monocilia initiates an asymmetric calcium signal at the left side of the node, and thus normal L–R asymmetry. In contrast, abnormalities of monociliary structure and rotatory beat (as occurs in PCD) lead to randomization of L–R cell signaling, and SI. Note that abnormalities in axonemal dynein also result in malfunction of monocilia. The combination of SI with any neonatal respiratory symptoms, or subsequent airway, sinus, or ear infections should prompt a diagnostic workup for PCD. In the vast majority of patients with *situs inversus* and PCD, the organs are a mirror image of normal, with no other structural or functional defects.

As patients with PCD grow older, several phenotypic markers feature prominently in the disease. A series from a large North American cohort of patients showed a phenotypic pattern consistent with earlier reports from Europe and Australia. Symptoms and signs of chronic airways infection, sinusitis, and otitis media are the cardinal features of the disease, and are responsible for the morbidity and mortality associated with PCD. Ear infections and "glue-ear" may be a prominent symptom in childhood, such that patients may be referred first to an otolaryngologist, who thus must retain a high degree of suspicion for the disease in the appropriate setting. Most patients and family members report a chronic cough as a prominent symptom. It appears that cough compensates for the lack of effective MCC in the disease and allows a degree of lung protection. Physiological data have shown that "effective" coughs may result in lung clearance almost equal to normal MCC over short time periods, even in PCD subjects with

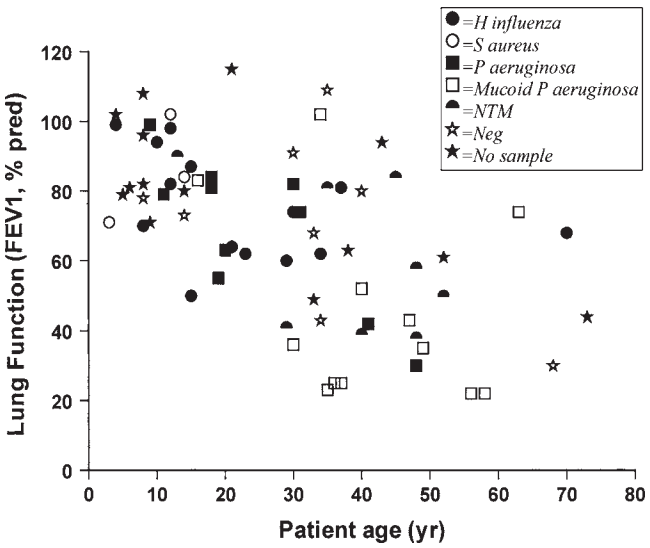

Figure 26-2 Lung function (forced expiratory volume in the first second [FEV_1]; % predicted) vs age in subjects with PCD (n = 70), plotted by the main organisms isolated in airway secretions (some subjects cultured more than one organism). Closed circles represent *H. influenza* (n = 14), open circles *S. aureus* (n = 3). Closed squares represent smooth *P. aeruginosa* (n = 10), open squares represent mucoid *P. aeruginosa* (n = 12, approx 35% of subjects, most over the age of 30 yr). Closed half circles represent nontuberculous mycobacteria (n = 8 [five of whom also cultured smooth *P. aeruginosa*]). Open stars represent subjects in whom sputum culture was negative for bacterial pathogens (n = 8), closed stars represent subjects in whom no sample was obtained (n = 15). Thirteen subjects had respiratory failure and an $FEV_1 \leq 40\%$ predicted. (Adapted with permission from Noone PG, Leigh MW, Sannuti A, et al., 2004.)

no clearance at baseline. Clinical and radiographic evidence of bronchiectasis usually develops as the disease progresses. Comparisons with CF as a similar disease phenotype are useful, as PCD appears to run a milder course, presumably because of the different pathogenesis of the two diseases, CF being more complex. For example, there are overlaps in the microbiology of PCD airway secretions with CF. One study showed a variety of organisms in the sputum of patients with PCD (Fig. 26-2): *Haemophilus influenza, Staphylococcus aureus, Pseudomonas aeruginosa* (including mucoid *P. aeruginosa* in individuals over 30 yr of age) and nontuberculous mycobacteria, for example *Mycobacterium avium* complex and *M. abscessus*. The isolation of mucoid *P. aeruginosa* is interesting, as this organism has traditionally been associated with CF, even at a young age. Its isolation in a significant number of patients with PCD suggests that chronic failure of the mucociliary apparatus allows colonization/infection in the airways with this alginate (hence mucoid) secreting organism. Most patients with these organisms (especially mucoid *P. aeruginosa* and nontuberculous mycobacteria) in their airway secretions will be screened for CF, but with an appropriate phenotype, consideration should be given to screening for PCD also (*see* below, diagnostic workup).

Generally, PCD is a milder disease than CF, and cross-sectional studies of lung function across a wide age spectrum suggest that the loss of lung function over time is not as rapid as that of CF: approx 0.8%/yr loss of forced expiratory volume in the first second (FEV_1) in PCD vs approx 3.6%/yr loss of FEV_1 in CF. This likely relates to the complex pathogenesis of CF lung disease (loss

of both mucociliary and cough clearance), as compared with the more discrete ciliary defect in MCC in PCD, in addition to the gastrointestinal, endocrine, and bone complications that occur in CF. However, data do suggest a negative impact of the disease on quality of life as PCD patients grow older. There are no generally devised and accepted "state-of-the-art" treatment protocols for PCD as a disease, other than to follow the general rules for that of non-PCD bronchiectasis. Thus, a therapeutic plan for PCD that is probably appropriate involves judicious use of pharmacological methods (e.g., bronchodilators, hypertonic saline, and "directed" antibiotics), and nonpharmacological methods (airway clearance, exercise). Not all drugs for use in CF have usage in other diseases such as PCD; for example, use of DNA-ase, a developed drug for use in CF may be less useful in non-CF bronchiectasis because of a different anatomic distribution of disease in non-CF bronchiectasis. As patients with PCD grow older, many develop more severe symptoms, and most develop digital clubbing. A significant percentage (up to 25% in one series) may develop respiratory failure as defined by hypoxemia, or an FEV_1 less than 40% predicted (*see* Fig. 26-2); a small proportion may eventually require lung transplantation.

Male infertility results from abnormal sperm tail function, whereas female fertility is more variable (some women being infertile, with others reporting a delay in conception following unprotected intercourse), presumably resulting from abnormal ciliary function in the Fallopian tube.

DIAGNOSIS The diagnosis of PCD requires a compatible clinical phenotype, in combination with laboratory studies demonstrating abnormal ciliary structure and/or function. The traditional approach is to search for ciliary ultrastructural defects (*see* Fig. 26-1). Samples of nasal ciliated epithelium can easily be obtained from the inferior turbinate using a plastic rhinoprobe and a nasoscope, without the need for local anesthesia, or invasive techniques. Analyses of ciliary cross-sections obtained from these nasal samples show structural abnormalities consisting of absent (or shortened) DAs in most patients with PCD. Defective ODA or IDA, or both, occur in more than 90% of patients with PCD, whereas a few patients may have other miscellaneous abnormalities, such as radial spoke defects, or "ciliary disorientation." Significant expertise is required in the technical aspects of producing high quality transmission electron micrographs, and in the interpretation of ciliary ultrastructure. For example, IDA defects may be more difficult to interpret than defects of the ODA, for reasons previously outlined. In addition, the IDA may look abnormal in non-PCD patients, presumably resulting from the nonspecific effects of inflammation and infection. Occasionally, patients with a strong phenotype (e.g., otosinopulmonary disease with *situs inversus*) have apparently normal looking cilia, which, given the complex structure of cilia, probably reflects abnormalities in structures not easily visible on electron microscopy, and may also relate to different genetic mutations encoding for structures other than dyneins, or for functional rather than structural abnormalities. A firm diagnosis is difficult to establish in such patients, and they may be labeled as having "nonclassic" disease, pending further advances in the molecular etiology of PCD in general.

From a functional standpoint, in vivo assessments may be determined using measures of nasal MCC (the saccharin test), or measures of lung MCC employing radio isotopic techniques. The significant limitation with the saccharin test is "noise" in the data generated. Valid results of the test, for example, depend on voluntary suppression of swallow, head tilting, and other positional changes, which may be difficult for children and those with intractable cough. Measures of isotopic clearance from airway surfaces are more quantitative, although less available than other tests. Patients with PCD have no (or little) clearance of isotope from the lung when cough is suppressed. More rigorous techniques using high-speed video microscopy may provide better quantitation of ciliary beat frequency and patterns. Qualitative assessments of ciliary beat can define a dyskinetic beat pattern or immotility, and may provide an approximate, semi-quantitative assessment of "ciliary activity." Such methodology may yield false negatives, however, as some patients with PCD may have normal looking ciliary activity by this method.

Thus, structural assessments of cilia obtained from patients suspected of having PCD are the diagnostic "gold standards" for PCD. These studies of structure and adjunctive functional tests require the availability of significant expertise in terms of equipment and personnel, which may be prohibitive outside academic and research institutions. In addition, there is room for subjective error in diagnosing abnormalities in cilia structure, particularly that of the inner DA. As seen in the next section, nasal nitric oxide (NO) measures provide an additional noninvasive test that reliably helps diagnose PCD.

REGULATION OF CILIARY BEAT FREQUENCY AND THE ROLE OF NITRIC OXIDE: NASAL NO AS AN ADJUNCTIVE DIAGNOSTIC TEST Regulation of ciliary beat is complex, and several factors are involved, including intracellular calcium concentrations, cAMP, extracellular nucleotides such as ATP and UTP, and NO. Despite ciliary immotility in most patients with PCD, certain pharmacological agents that modulate ion transport as well as ciliary beat frequency (such as UTP), increase cough clearance in PCD, presumably acting via changes in airway surface liquid rheology rather than any direct actions on MCC. Ion transport appears normal in PCD, in contrast to the deranged sodium and chloride ion transport observed in CF airway epithelia.

Biological observations may lead to increased insights into the regulation of ciliary activity in vivo. Early observations of very low levels of nasal NO as measured in air from the upper respiratory tract in patients with PCD have been verified in larger datasets across a wide age and lung function spectrum, including pediatric and adult patients. There is a striking difference in the levels of NO produced in the upper airway of patients with PCD (very low levels) as compared with normal and disease controls (Fig. 26-3). There was no relationship between the levels of NO in PCD and the magnitude of lung disease as measured by FEV_1, or ciliary activity, or ciliary structural defect. Further, there was little overlap in nasal NO levels between PCD and disease controls such as CF, so that the test may prove to be a useful diagnostic tool.

The mechanism of the low NO in PCD remains elusive. Because NO has been linked to the upregulation of ciliary beat frequency, it is intriguing to speculate that low NO in PCD is related to the primary ciliary defect. NO is formed by the nitric oxide synthase (NOS) enzyme system, consisting of three NOS isoforms (NOS1, NOS2, and NOS3), in the presence of appropriate substrate (L-arginine and oxygen) and cofactors tetrahydrobiopterin. Of these, NOS3 appears to be the best candidate for involvement in ciliary beat regulation, because it is localized close to the base of cilia. NOS3 is activated in endothelium by stress; by analogy,

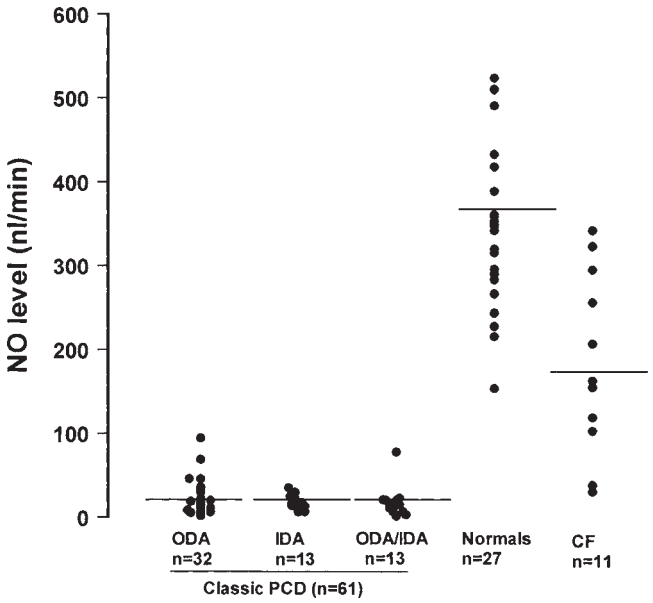

Figure 26-3 Nasal nitric oxide levels in subjects with PCD ($n = 61$ in total); $n = 16$ with both DA defective, $n = 32$ with ODA defective, and $n = 13$ with IDA defective. The data are compared with healthy controls ($n = 27$), and disease subjects with CF ($n = 11$). No differences were seen between any of the PCD subgroups, but significant differences were seen between PCD and healthy controls ($p = 0.0001$). Levels of nasal nitric oxide in CF were also different (higher) than PCD ($p = 0.0001$). (Adapted with permission from Noone PG, Leigh MW, Sannuti A, et al., 2004.)

the "stress" of ciliary bending may activate NOS3 via signaling mechanisms, and stimulate the production of NO, which in turn plays a role in regulation of ciliary beat in an autocrine or paracrine fashion. NOS3 is bound to caveolin-1 at the apical membrane of ciliated airway cells, in which it can be dissociated from this inhibitory binding and also activated by calmodulin and Ca^{2+}. In PCD, one hypothesis to explain low NO levels relates to reduced or absent ciliary "force" leading to reduced NOS3 activity, with a decrease in airway epithelial NO production. To more fully elucidate the role of NO in ciliary regulation, studies addressing NOS expression in PCD vs controls and physiological studies of ciliary beat and NO production in various normal and disease states are needed.

Thus, although a mechanistic explanation is lacking, reduced production of NO in the upper airway is a useful phenotypic marker of PCD that may serve as an adjunct "clinical" test in the diagnostic workup in PCD. From a research standpoint, low nasal NO levels in PCD may serve as a useful physiological marker of the deranged ciliary beat/NO axis.

MOLECULAR ASPECTS

As discussed, ciliary structure is complex, with many different structural components required for normal function. Thus, when addressing the genetics of PCD, research challenges include the appropriate selection of candidate genes for further study and prioritization of work. Because DA defects comprise the majority of ultrastructural defects in patients with PCD (or stated another way, PCD associated with DA defects is within the limits of diagnostic capability), it seems logical to start with a study of DA structure and function: that is, the ODA, the IDA, and then other "non-dynein" ciliary structures (e.g., radial spokes, central doublets). Increased understanding of the structure and function of the various dyneins will augment knowledge of the relations between the various ciliary components and how mutations in different genes result in different "ciliary" phenotypes.

DYNEIN ARM STRUCTURE AND RELATED CANDIDATE GENES The axoneme is conserved phylogenetically, and the unicellular organism *Chlamydomonas* provides the opportunity to study the components of ciliary ultrastructure, and more specifically, DAs, radial spokes, and the CA (Fig. 26-4). Thus, there is a high degree of homology between structural components of *Chlamydomonas* and human cilia, and genes that encode for structural proteins. The 9 + 2 axoneme contains about 250 well-conserved polypeptides.

Dyneins are molecular "motors," with a mass of approx 1–2 MDa. Up to 15 different heavy chains have been identified. The ODA in *Chlamydomonas* possesses three dynein heavy chains, two intermediate chains, and at least eight light chains (*see* Fig. 26-4, top panel). Evidence suggests that mammalian ODA contain only two heavy chains. Several human homologs of *Chlamydomonas* ODA components are candidates for study in patients with PCD. Dynein heavy chain candidate genes are *DNAH5* (γ-heavy chain) and *DNAH9* (β-heavy chain), intermediate chain candidate genes are *DNAI1* (IC78) and *DNAI2* (IC69) and light chain candidate genes include LC1 (which is directly attached to heavy chain motor domain), *TCTEX2* (LC2) and LC4. Heavy and intermediate chains are good candidates with which to start, as these are likely to be defective in humans with missing or shortened ("stubby") ODA, evaluable using electron microscopic techniques, as shown by studies of patients with genetic mutations encoding for heavy or intermediate-chain dyneins (ICs) that show missing or stubby ODA.

The IDA appears to be different from the ODA, and is both structurally and functionally diverse (*see* Fig. 26-4, bottom panel). There are ICs, light-chain dyneins (LC), and heavy-chain dyneins, with different isoforms, with a very complex arrangement. Of several (approx 7–11) dynein heavy chain genes in the IDA, three have been identified (*DNAH1*, *DNAH3*, and *DNAH7*). To generate synchronous ciliary beat, the various IDA motors must coordinate with each other, with the ODA, the central pair and the radial spokes. Thus, elucidation of the many potential IDA defects that might relate to the expression of disease in humans presents significant challenges, particularly with reference to selection of candidate genes for testing in human disease models. Candidate genes for patients with PCD and IDA defects include *DNAH1*, *DNAH3*, and *DNAH7* (heavy chains), *hp28* and *TCTEL1* (light chain), and *DPCD*.

Candidate genes for patients with both ODA and IDA defects include *DNAI1* and *DNAI2* (intermediate chains), and also *DNAH3* and LC8, which are expressed by both IDA and ODA.

As discussed, other structural components of cilia also require attention because they may be structurally and functionally defective, leading to PCD. A pair of axonemes lies in the center of each cilium—the central pair—and appears to serve an anchoring function for the radial spokes, which themselves connect outward from the central pair to the peripheral doublets (*see* Fig. 26-4). Twenty-two polypeptides comprise the radial spoke and at least seven *Chlamydomonas* genes specifically affect the function of the flagellar radial spoke, with similar radial spoke defects observed in humans. The CA is made up of two single microtubules designated as C1 and C2. CA-associated structures

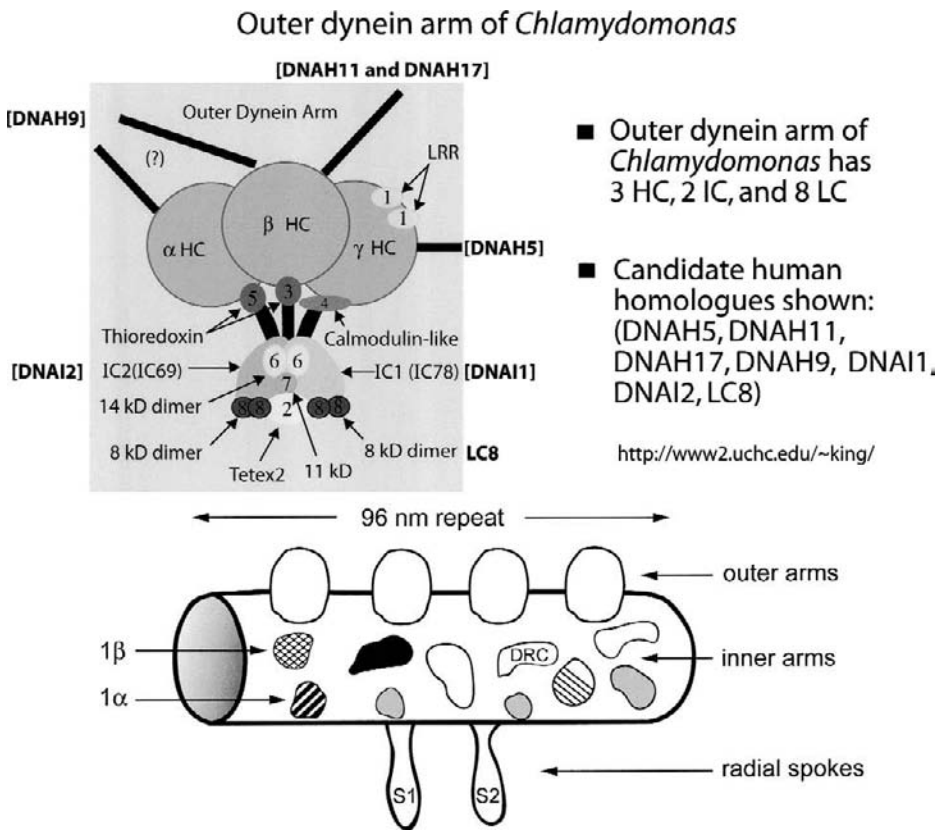

Figure 26-4 **Top panel:** ODA of *Chlamydomonas*. Human homologs are shown (DNAH5, DNAI1, DNAI2, DNAH9). (Adapted with permission from S.M. King http://www2.uchc.edu/˜king/ .) **Bottom panel:** diagrammatic representation of the complexity of the arrangement of structures along one axoneme of the outer pair. Visible are the repeating nature of the structures (96 nm), the ODA on top, the radial spokes on the bottom, and the IDA represented by a complex "islands" of structures—the dynein heavy chains (DHC) 1α and 1β in a trilobed structure known as I1 IDA isoform, made up of dynein-heavy chains, three intermediate chains, and three light chains. DRC, dynein regulatory complex; located above the second radial spoke, S2. This illustration shows the complexity of the IDA particularly, and how different mutations in different structures result in IDA function, and thus ciliary abnormalities. (Adapted and reproduced with permission from Porter ME, Sale WS, 2000.)

include the central pair projections, the central pair bridges linking the two tubules and the central pair cap, which are attached to the distal or plus end of the microtubule. In *Chlamydomonas*, the CA includes 23 polypeptides ranging in molecular weight from 14 to 360 kDa. Ten of these polypeptides are unique to C1 and seven are unique to C2. CA ultimately regulates dynein-driven microtubule sliding in a pathway involving the radial spoke. CA agenesis was reported as causing clinical disease in three related patients with a strong phenotype for PCD. Thus, for patients who have no detectable DA defect, candidate genes include not only genes that encode ODA and IDA function, but also include genes that encode radial spoke proteins (*RSHL1*, *RSP3*, and *RSHL2*), and the CA (*PF15*, *SPAG6*, and *hPF20*).

Thus, the opportunity arises for the selection and testing of candidate genes derived from studies of *Chlamydomonas*, and studies in human disease, in which a well-defined PCD phenotype has been correlated to specific visible electron microscopic defects in ciliary structure.

GENETICS PCD is inherited as an autosomal-recessive trait in most cases. Occasional reports suggest an autosomal-dominant inheritance. Digenic mode of inheritance (i.e., a genetic disease caused by interplay of a recessive mutation in two different genes that are functionally related) for PCD has not been seen, but it is possible, as it occurs in other diseases. As might be predicted from the complexity of ciliary structure and function discussed, the disease is genetically heterogeneous at a ciliary structural level. Hence patients with PCD may resemble each other at a clinical phenotype level, whereas having a diverse array of ciliary abnormalities, and, thus, a completely different genetic basis for the same disease. This presents difficulties for categorization of patients, and identification of mutated genes. However, the emerging definition of ciliary ultrastructure in lower organisms and humans offers an excellent opportunity for the selection of candidate genes.

Although the disease appears to be relatively uncommon (at least in terms of a clear diagnosis), the prevalence is estimated to be approx 12,000–17,000 individuals in the United States, as extrapolated from radiographic surveys in Norway and Japan, based on the presence of dextrocardia, in association with clinical evidence of bronchiectasis. It might be hypothesized that PCD, or alternately, lung disease associated with genetic-based abnormalities in ciliary structure and function, is more common than generally appreciated. As the diagnosis may not be obvious or straightforward, especially in the absence of *situs inversus*, accurate numbers are not available. An added complication is the lack of a central registry for patients with PCD, though efforts are underway with a patient support group to establish such a registry.

Another dimension is the possibility of variant ("nonclassic") forms of PCD, manifested by a milder or intermediate phenotype, intermediate (or no) changes in ciliary ultrastructure, and with less severe functional derangements in ciliary beat. These patients may have "milder" mutations in genes associated with subtle defects in ciliary structure/function, but still be able to mount a partially effective MCC defense mechanism, in a manner analogous to the scenario that has emerged over the past decade with CF. Identification of the genetic mutations associated with "classic" PCD will enable further study of individuals suspected of having disease related to abnormal ciliary structure and function. For example, splice mutations on one allele might lead to partial protein function conferring a milder (than "classic") phenotype on that individual. Studies of the level of expression of mRNA from known mutated genes (e.g., splice mutations), performed using methodologies already tested in atypical CF (using e.g., nasal epithelial scrape samples), will likely offer the opportunity to expand such hypotheses and studies to other genes.

STRATEGIES FOR IDENTIFYING ASSOCIATED MUTATIONS Genome-wide linkage analysis is one approach to identify candidate loci putatively involved in PCD. This approach requires access to large numbers of families to yield meaningful data, and involves collection of sufficient numbers of DNA samples from affected patients and family members for significant results. More importantly, genetic heterogeneity presents a major challenge, because multiple genes are likely to be involved. For example, in a large study published in 2000, 61 families from Europe and North America were reviewed, and despite sophisticated analyses and biostatistics using 31 multiplex families (169 individuals, including 70 affected with PCD), no major locus for disease was found, although several potential loci on different chromosomes were described. However, the two genes identified as disease causing in PCD (*DNAI1* and *DNAH5*; *see* below) were not identified using this approach.

An alternate way to address the problem of genetic heterogeneity is to subgroup the patients into categories based on the ciliary ultrastructural defect. The categories would include clear-cut DA defects: specifically, in individual patients with an ODA defect alone, an IDA defect alone, either DA defective, or finally those with less common central pair/radial spoke defects. As indicated, this approach relies on high-quality electron microscopic images and rigorous analysis of adequate ciliary samples (ideally with more than one observer, at least one of whom is blinded to the identity of the subject), followed by careful segregation of multiple patients into categories depending on the ciliary ultrastructural defect. Once patients have been categorized as such, genetic testing can be targeted using a stepwise approach: those with ODA defects being tested (using genomic DNA) for known mutations in ODA genes (e.g., *DNAI1* and *DNAH5*), those with IDA defects for IDA mutations (e.g., *DNAH7, DPCD*), and other genes as the field advances and other candidate genes become known. If a genetic mutation is detected on one allele, full gene sequencing can be conducted to search for the novel mutation on the opposite allele. This strategy was successfully used to isolate mutations in *DNAI1* and *DNAH5*, which have now been established as disease-causing in PCD (*see* below). To "include" or "exclude" families of interest, testing for patterns of inheritability using intragenic polymorphisms may also be useful if parental/sibling DNA is available. If the mutation is not discovered in these initial tests, other techniques could be used, such as reverse transcription (RT)-PCR to check for the possible splice defects, or Southern blot analysis to check for the possible large rearrangements.

GENES TESTED TO BE DISEASE-CAUSING Two genes have been identified as causing PCD—*DNAI1* (an IC) and *DNAH5* (a heavy-chain dynein), both associated with defective ODA (http://www.gentest.org). Other genes have been tested in variable numbers of patients, and disease-causing mutations have not been found in patients with PCD, for example, *DNAH7, DNAH9, DNA12, LC8, hp28, LC4, SPAG6, hPF20, TCTEX2, HFH4/FoxJ1, DPCD,* and *POLL* (Table 26-1).

A defined mutation as the molecular basis for PCD was first reported in 1999. *DNAI1* (homologous to the *Chlamydomonas* IC IC78) gene was cloned as a candidate gene because it was found to be disrupted in an ODA-deficient mutant of *Chlamydomonas*. *DNAI1* (a 20 exon gene located on 9p13-p2) was tested in patients with defective ODA, and loss-of-function mutations were reported in one individual with PCD. One mutation was a 4-bp insertion in exon 5 (285′286insAATA), the other was a splice mutation in intron 1 (219 + 3insT now known as IVS1 + 2_3insT); both mutations result in a premature termination signal. Further reports of mutations in *DNAI1* in patients with PCD and ODA defects followed. Twelve mutant alleles of *DNAI1* have been found from six families tested, of which six mutant alleles harbored the "original" 219 + insT mutations. Two novel mutations were found in the same codon (568) in two other families. One was a missense mutation (W568S) and the other was a nonsense mutation (W568X). In the remaining families, all three carried the 219 + insT mutation on one allele, with novel mutations (G515S and a 12-bp deletion from codons 553 to 556) found on the opposite allele. Further genetic studies of *DNAI1* and PCD are ongoing at many centers. Other candidate genes have also been cloned by the group who cloned *DNAI1, DNAI2* (orthologous to *IC69* in *Chlamydomonas*), and *Hpf20* (orthologous to *pf20* in *Chlamydomonas*).

DNAH5 is another candidate gene located on chromosome 5p14-p15, which was cloned by a homozygygosity mapping strategy. This gene encodes a protein highly similar to *Chlamydomonas* γ-dynein heavy chain. Mutations in this gene have been identified in 8 patients from 25 tested families with PCD and ODA defects. One consanguineous family from the United States was homozygous for a splice site mutation in *DNAH5* (IVS74→–1G > C), which presumably leads to an inframe deletion of exon 75. This family with the splice mutation is of particular interest because it raises the possibility of measuring levels of gene expression in affected and unaffected (carrier) individuals, as compared with noncarriers. Homozygous disruption of the mouse *DNAH5* gene led to a PCD-like phenotype, and this mouse model may be useful to decipher the biochemical interaction of the *DNAH5* gene with other ciliary components.

OTHER CANDIDATE GENES Although the following genes have not been specifically associated with clinical expression of PCD, these candidates remain of interest for further investigation. For example, a deletion of DNA polymerase (Poll) was reported to cause a ciliary IDA defect in mice associated with hydrocephalus, *situs inversus*, chronic sinusitis, and male infertility. The mechanism(s) proposed might reflect the absence of the polymerase BRCT motif, which might be necessary for protein–protein interactions and ciliary formation, or transcription of genes necessary for cilia formation. Unexpectedly, work suggests that an alternative candidate gene (D*pcd*) in the genomic region around the *Poll* might be the real gene of interest in the

Table 26-1
Candidate Genes for PCD

Ciliary ultrastructure	*Chain type/ structure*	*Gene (human)*	*Homolog*	*Chromosome (human)*	*Comments*	*Reference*
ODA defect	Heavy	*DNAH5*	Chlamy.HC	5p14-p15	Mutations detected in PCD (eight families tested) Mouse KO yield hydrocephalus, *situs inversus*, sinusitis, immotile cilia with ODA defect	Olbrich H, Haffner K, Kispert A, et al., 2002; Ibanez-Tallon I, Gorokhave S, Heintz N, 2002.
		DNAH9 (*DNEL1*)	*S. urchin* β-HC	17p12	No mutations detected in PCD (two families tested)	Bartoloni L, Blouin JL, Chung E, et al., 2001.
	Intermediate	*DNAI1*	*Chlamy. IC78*	9p21-p13	Mutations detected in PCD (six families tested)	Pennarun G, Escudier E, Chapelin C, et al., 1999; Zariwala M, Noone PG, Sannuti A, et al., 2001; Guichard C, Harricane MC, Lafitte JJ, et al., 2001.
		DNAI2	*Chlamy. IC69*	17q25	No mutations detected in PCD (16 families tested)	Pennarun G, Chapelin C, Escudier E, et al., 2000; Bartoloni L, Mitchison H, Pazour G, et al., 2000.
	Light	Seq. not available	*Chlamy.* LC1	Not available	The only light chain associated with motor domain of γ-HC. Not tested in PCD patients	Benashski SE, Patel-King RS, King SM., 1999.
		DNLC2A	*Chlamy.* LC2?	20q11.22	Not tested in PCD patients.	Benashski SE, Patel-King RS, King SM., 1999.
		DNAL4	*Chlamy.* LC4?	22q13.1	No mutation detected in 54 unrelated PCD patients	Benashski SE, Patel-King RS, King SM., 1999. Gehrig C, Albrecht C, Duriaus-Sail G, et al., 2002.
		TCTE3 (*TCTEX2*)	*Murine Tcte3* (*Tctex2*)	6q25-q27	No mutation detected in 36 PCD families	Neesen J, Dreckhahn JD, Tiede S, et al., 2002.
IDA defect	Heavy	*DNAH3*	*Chlamy.* HC	16p12	Sequence variant of unknown significance detected in PCD (six patients tested)	Blouin JL, Gehrig C, Jeganathan D, et al., 2001.
		DNAH7	*Chlamy.* HC	2q31-q33.2	No mutation detected in PCD (one patient tested)	Zhang YJ, O'Neal WK, Randell SH, et al., 2002.
	Intermediate	Seq. not available	Chlamy. *IC140*	Not available	IC140 is required for the assembly and docking of I1 complex to the doublet microtubule cargo	Perrone CA, Tritschler D, Taulman P, Bower R, Yoder BK, Porter ME., 2003.
		Seq. not available	*Chlamy. IC138*	Not available	Critical phosphoprotein required for the regulation of flagellar motility	Habermacher G, Sale WS., 1996.
	Light	*hp28*	Chlamy.LC p28	1p35.1	No mutation detected in 65 PCD families (four from UNC)	Gehrig C, Albrecht C, Duriaus-Sail G, et al., 2002. Pennarun G, Bridoux AM, Escudier E, Anselem S, Duriez B., 2001.
		TCTEL1	*Chlamy. Tctex1*	6p25.2-p25.3	Flagellar inner arm I1 dynein; attaches cargoes to dynein motor	DiBella LM, Benashski SE, Tedford HW, Harrison A, Patel-King RS, King SM., 2001.
	Others	*DPCD*	Murine D*pcd*	10q23	This gene resides in a close proximity of DNA POLL. No mutation detected in 51 PCD families	Zariwala M, O'Neal WK, Noone PG, Leigh MW, Knowles MR, Ostrowski LE., 2004.

Both DAs defects	Heavy	*DNAH3*	*Chlamy.*HC	16p12	IDA protein, locus linked in PCD patients with ODA defect	Jeganathan D, Meeks M, Gehrig C, et al., 2001.
	Light	LC8	*Chlamy*.LC8	17q	Associates with ICs C*hlamydomonas* ODA, and also associates with IDA. No mutation detected in 58 PCD families	Bartoloni L, Mitchison H, Pazour G, et al., 2000. Benashski SE, Patel-King RS, King SM., 1999.
Other defects (normal DAs)	Heavy	*DNAH1*	*Murine MDHC7*	3p21.3	KO of this IDA dynein in mice yield reduced CBF, but no abnormal ultrastructure	Neesen J, Kirschner R, Ochs M, et al., 2001.
		DNAH11	*Murine lrd* *S. urchin* β-HC	7p	One homozygous mutation in motor domain in PCD patient with 7 UPD	Bartoloni L, Blouin JL, Pan Y, et al., 2002.
	Radial spoke	*RSHL1*	*Chlamy.* RSP4 and RSP6, *S. urchin* p63	19q13.3	RSP 4 and RSP 6 make up a radial spoke head and important for regulation of DA activity and flagellar beating	Eriksson M, Ansved T, Anvret M, Carey N., 2001.
		RSP3 (*AKAP*)	*Chlamy.RSP30*	6q25.3	Located near the inner arm dynein, regulates flagellar motility	Gaillard AR, Diener DR, Rosenbaum JL, Sale WS., 2001
	Central apparatus genes	*hPF20*	*Chlamy.PF20*	2q34	No mutation detected in five PCD families	Pennarun G, Bridoux AM, Escudier E, et al., 2002.
		SPAG6	*PF16*	10p12.2	No mutation detected in 54 PCD patients	Blouin JL, Albrecht C, Gehrig C, et al., 2003.
		Seq. Not available	Chlamy.*PF15, KLP1*	Not available	*Chlamydomonas* mutants lacking central apparatus have paralyzed flagella; central apparatus important for motility	Smith EF, Lefebvre PA., 1997.
	Cilia absent	*HFH4/FoxJ1*	*Mouse*	17q22-q25	KO mice yield *situs inversus* and absence of cilia	Brody SL, Yan XH, Wuerffel MK, Song S, Shapiro S., 2000. Maiti AK, Bartoloni L, Mitchison HM, et al., 2000.
			Hfh4/FoxJ1		No mutation detected in eight PCD families	

clinical expression of a PCD phenotype. Moreover, subsequent studies have shown that another *Poll* knockout mouse (which did not knockout D*pcd*) did not exhibit a PCD phenotype. Supporting its relationship with ciliary function is the observation of increasing expression of DPCD during ciliogenesis. Although no mutations have been discovered in 51 unrelated PCD patients, *DPCD* remains a good candidate gene for patients with an IDA defect, especially in relation to splicing mutants, which have not been tested.

A human inner arm dynein-heavy chain (*DNAH7*; 12 kb in coding sequence) has also been cloned, using a proteomics approach. The entire coding region of *DNAH7* has been sequenced from overlapping segments of RT-PCR products from airway epithelial RNA from a PCD patient with missing IDA, and no disease-causing mutations have been identified. However, intragenic polymorphisms have been detected and are being used for further analysis.

Finally, a splice mutation in the gene encoding *p28*, a light chain of the IDA of *Chlamydomonas* axonemes, results in absent IDAs. No mutations in the human homologue (*hp28*) have been found to be associated with clinical PCD. Table 26-1 lists other candidate genes of interest with the associated references.

CONCLUSION

PCD is associated with significant morbidity from birth to adulthood. An increased understanding of the molecular pathophysiology of the structural and functional abnormalities in PCD will undoubtedly lead to an increased understanding of normal and abnormal physiology in the sinopulmonary and reproductive tracts. It will also lead to easier diagnosis through genetic testing, as well as open possibilities for targeted, novel treatments for PCD and other similar diseases. Identification of the genetic basis of "classic" PCD will also make it possible to identify less severe molecular abnormalities leading to milder disease phenotypes ("nonclassic" disease), and exploration of the hypothesis that less severe defects in cilia structure and function contribute to other airway and lung diseases. Recent exciting developments, to increase awareness of PCD from both a clinical and a research standpoint, include the formation of a patient advocacy and support group (www.pcdfoundation.org), and an NIH-funded consortium (http://rarediseasenetwork. epi.usf.edu/gdmcc/index.htm) of clinical research centers. This will allow large-scale efforts to increase the numbers of patients to receive an expert diagnostic workup (including research and genetic studies), as well as receive continuing care for their disease. Finally, therapeutic approaches will likely evolve to increase MCC in these patients with potentially conserved or "partially conserved" ciliary function.

27 Cystic Fibrosis

SCOTT H. DONALDSON AND RICHARD C. BOUCHER

SUMMARY

Cystic fibrosis is a genetic disease that affects multiple organ systems, yet leads to respiratory failure and premature death in most afflicted patients. Rapid advancements in our understanding of disease pathogenesis have occurred because of the cloning of the cystic fibrosis transmembrane conductance regulator gene. Recent work has shown that volume depletion of the periciliary fluid layer and mucus dehydration reduces mucus clearance and promotes the initiation and progression of CF lung disease. Therapies that correct dysregulated salt and water transport in the lung, either by correcting or bypassing the basic cystic fibrosis transmembrane conductance regulator defect, are now being developed and hold great promise.

Key Words: Airway surface liquid; bronchiectasis; Cftr; cystic; ENaC; fibrosis; ion transport; mucus clearance; mucociliary; *Pseudomonas*.

INTRODUCTION

In 1938, Anderson et al. first described "cystic fibrosis of the pancreas" as a distinct clinical entity. At that time, malnutrition resulting from insufficiency of the exocrine pancreas and overwhelming respiratory infection typically led to death within the first year of life. Subsequent observations began to lay the framework on which the understanding of the cystic fibrosis (CF) disease process has been built. Initially, it was recognized that multiple epithelial lined organs contained abnormally viscous mucus, whereas sweat from CF patients contained excessive amounts of salt. In the 1980s, multiple investigators described the altered epithelial ion transport processes that are characteristic of CF airways epithelia, raising the possibility that these abnormalities were fundamental to CF disease pathogenesis. Finally, the *cystic fibrosis transmembrane conductance regulator* (*CFTR*) gene was cloned in 1989 and was found to encode a cAMP-regulated plasma membrane polypeptide. From these seminal observations, our understanding of the CF disease process has evolved, although considerable controversy and competing hypotheses about aspects of the disease persist. As a result of this ongoing progress, clinical outcomes have continued to improve and novel therapies are being developed at an unprecedented rate. The predicted survival of patients with CF has increased to 34 yr of age, although further improvement in survival may require the development of new therapeutics. This chapter outlines the clinical CF phenotype, describes the pathogenesis of CF lung disease, and suggests how new therapies may utilize the growing knowledge of CF pathogenesis to delay or prevent the development of this devastating disease.

CLINICAL DESCRIPTION OF A MULTISYSTEM DISEASE

Pulmonary disease accounts for considerable morbidity and greater than 90% of the mortality from CF. However, a broad spectrum of clinical manifestations is encountered in CF, stemming from epithelial dysfunction in multiple organ systems. The spectrum of disease manifestations greatly increases the complexity of care required by this population, mandating the establishment of specialized CF care centers in which accumulated expertise and experience has improved patient outcomes.

RESPIRATORY MANIFESTATIONS Newborns with CF have normal lung function and sterile, uninflamed airways. Early in life, however, persistent airway infection and inflammation develop as the result of impaired airway host defenses. The nature of this host defense deficit has been intensively studied and debated and is discussed later. CF lung disease progresses from subclinical infection and inflammation to overt symptoms (episodic or persistent cough, sputum) and airway obstruction (demonstrated by spirometry) in a highly variable fashion, but the disease process is usually evident during childhood. Overtime, periods of clinical worsening termed "exacerbations" can be identified, which require intensification of secretion clearance and antibiotic therapy aimed at the patient's airway microbial flora. Progressive lung destruction results from the relentless infectious/inflammatory process that is characteristic of CF airways, culminating in the pathological finding of bronchiectasis, obstructive lung disease, and ultimately respiratory failure and death in the majority of patients.

CF lung infections are caused by a typical group of pathogens. Early in life, viral infections are normal in frequency but may cause significantly more morbidity and may trigger the onset of persistent airway inflammation. *Haemophilus influenzae* is frequently encountered during childhood but rarely persists. *Staphylococcus aureus* and *Pseudomonas aeruginosa*, however, often occur early in life and generally persist, especially *P. aeruginosa*. Although these pathogens are also found in other clinical settings, and certainly in other causes of bronchiectasis, the frequency of *Pseudomonas* infection (80% of adults) and tendency to convert to the mucoid phenotype is particularly striking and suggests that the CF airway provides a unique environmental niche that favors this organism.

Similarly, the inability to clear *Pseudomonas* from the CF airway, despite the aggressive use of antibiotics and an intense host inflammatory response, defines the problem confronted by clinicians who treat CF lung disease. The persistence of *P. aeruginosa* likely reflects adaptation of this organism to the CF airway milieu and the development of bacterial mechanisms that allow evasion of secondary host defenses and therapeutic interventions. A number of other organisms are less commonly encountered in the CF lung, including *Stenotrophomonas maltophilia* and *Alcaligenes xylosoxidans*. Perhaps most notable, however, is the emergence of the *Burkholderia cepacia* complex as a group of pathogens with the capacity to lead to rapid clinical deterioration and frank sepsis ("cepacia syndrome"). Unfortunately, organisms in the *B. cepacia* complex are often resistant to most, if not all, known antibiotics and certain strains have proven to be highly transmissible between patients.

Other respiratory manifestations of CF are also encountered frequently. With increasing age, the incidence of pneumothorax and massive hemoptysis rises. Pneumothoraces (16–20% incidence in adult CF patients) result from the rupture of subpleural cysts. Hemoptysis is common and may occasionally be life-threatening (approx 5% incidence) in CF because the arterial circulation of bronchiectatic airways is often massively hypertrophied and vulnerable to erosion from mucosal ulcerations consequent to persistent intralumenal infection/inflammation. Less life-threatening but common respiratory tract manifestations include allergic bronchopulmonary aspergillosis (1–4% incidence), chronic sinusitis, and nasal polyposis.

EXTRAPULMONARY MANIFESTATIONS The function of the exocrine pancreas is insufficient at birth or becomes so early in life in the majority of patients. Pancreatic insufficiency in CF results from the obstruction of pancreatic ducts with inspissated secretions and the subsequent autodigestion of pancreatic acinar regions. The inability to secrete pancreatic enzymes results in protein and fat malabsorption, causing steatorrhea. If unaddressed, persistent malabsorption leads to malnutrition, impaired growth, and fat-soluble vitamin deficiencies (vitamins A, D, E, and K). A small number of CFTR mutations are associated with retention of pancreatic sufficiency, however, and these patients typically are better nourished and typically have less severe respiratory phenotypes. Pancreatic sufficient patients are at risk for pancreatitis, however, which likely reflects the presence of residual exocrine tissue and opportunity for acute duct obstruction.

Endocrine pancreatic function is preserved in CF patients at birth, but may also be progressively lost overtime. The development of "cystic fibrosis-related diabetes" is age dependent, with the incidence peaking at 25% in 35–44 yr olds. Many more patients will have episodic hyperglycemia, especially during times of respiratory exacerbation. Of note, unrecognized or poorly controlled diabetes is thought to negatively impact nutrition and lung health and, therefore, must be screened for and managed carefully in these patients. Calorie restriction must be avoided to prevent worsening the patient's nutritional status, and insulin therapy is usually required to treat cystic fibrosis-related diabetes.

The CF intestinal tract epithelium has a limited ability to secrete chloride and water resulting from the absence of CFTR chloride channel function in the apical membrane of enterocytes lining the gut. As a result, patients may manifest both diarrhea from malabsorption and/or severe constipation and intestinal obstruction as the result of insufficient hydration of bulky, poorly digested intestinal contents. When terminal ileum obstruction occurs at birth (17% incidence), the resulting "meconium ileus" is nearly diagnostic of CF. A similar phenomenon occurring later in life is termed the "distal intestinal obstruction syndrome" (20% incidence). Rectal prolapse and gastroesophageal reflux are common in children with CF, and fibrosing colonopathy may occur in any patient treated with very high doses of pancreatic enzymes.

Focal biliary cirrhosis is an extremely common pathological finding in CF at autopsy, but produces clinically apparent disease in less than 5% of CF patients and is the cause of death in approx 2% of CF patients. Unlike many complications of CF, hepatic disease has a peak incidence during adolescence and a decreased prevalence in patients over age 20. Hepatic abnormalities can present as hepatosplenomegaly or as a persistent elevation of hepatic enzymes. Rarely, patients may present with esophageal varices and hemorrhage resulting from portal hypertension. Fatty liver is also common, and may improve with adequate nutrition. Finally, 10–30% of patients have dysfunctional gallbladders or gallstones.

More than 98% of men with CF are infertile because of azoospermia from vas deferens obstruction. The vas deferens may be absent at the time of birth, and its absence serves as a diagnostic clue pointing toward CF in situations of previously undiagnosed bronchiectasis. It appears that the male reproductive tract is the most sensitive organ to CFTR mutations, as a sizeable percentage of infertile men with congenital, bilateral absence of the vas deferens, who have no other demonstrable CF manifestations, have mild *CFTR* mutations. Interestingly, these mutations may be in gene regions that cause abnormal RNA splicing but produce normally functioning, though reduced amounts of CFTR protein. This syndrome explains that although 5% of normal CFTR message levels may be insufficient for male reproductive tract function, it is often sufficient to maintain normal pancreatic and respiratory tract function. This observation has important implications when considering therapies aimed at either delivering a normal *CFTR* gene ("gene therapy") or improving the processing/function of the existing, mutant CFTR protein. Importantly, female patients with CF maintain near normal fertility when factored for nutritional and respiratory status.

PATHOGENESIS OF CF LUNG DISEASE

The requirement to explain how CF lung disease results from *CFTR* gene mutations has spurred a great deal of research and a number of competing hypotheses. Fortunately, a more clear vision of CF disease pathogenesis is emerging as discussed in the following sections.

THE *CFTR* GENE AND PROTEIN The *CFTR* gene was localized to a region on the long arm of chromosome 7 via positional cloning and consists of 250 kB of genomic DNA containing 27 exons. The *CFTR* gene encodes a 1480 amino acid protein, belonging to the adenosine triphosphate-binding casset family of transport proteins, which is typically targeted to the apical membrane of epithelial cells. The protein can be viewed as having two halves, each made up of six transmembrane domains and a nucleotide-binding domain, which are separated by a highly charged "R domain" containing multiple protein kinase A and protein kinase C phosphorylation sites. Nearly 1300 mutations have been reported, although the ΔF508 mutation accounts for 66% of mutant *CFTR* alleles. Because CF is an autosomal-recessive disorder, patients carry two mutant *CFTR* gene alleles, whereas parents are "carriers" with a normal *CFTR* gene and a single mutant *CFTR* allele and exhibit no clinical stigmata of the CF disease.

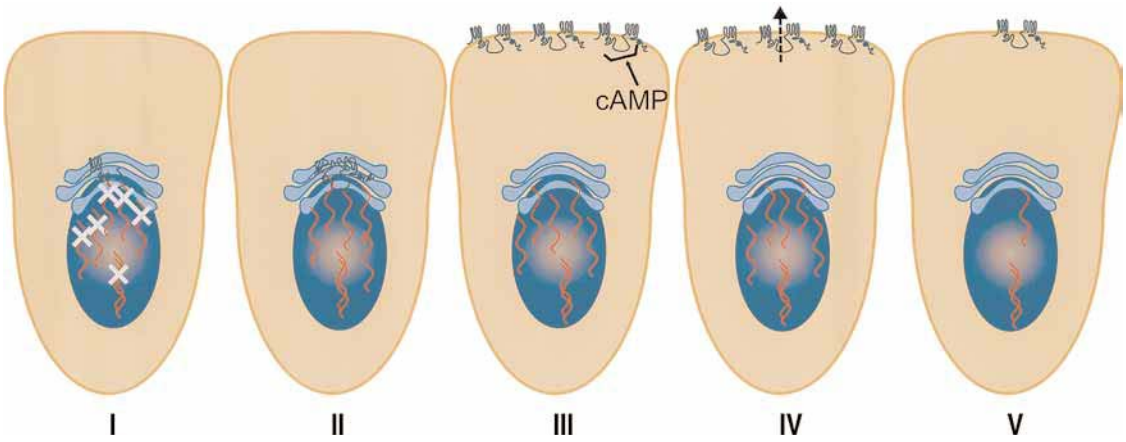

Figure 27-1 CFTR mutation classifications. Class I mutations result in the complete absence of CFTR protein production. Class II mutations cause protein misfolding, impaired cellular processing and retention in the endoplasmic reticulum. Class III mutations yield CFTR molecules that reach the plasma membrane but are resistant to activation by usual (e.g., cAMP) signaling pathways. Class IV mutations result in CFTR channels with reduced ionic conductivity. Class V mutations result in dramatically reduced quantity of normal CFTR protein.

CFTR mutations may be grouped into classes that reflect the mechanism by which loss of CFTR function occurs (Fig. 27-1). Class I mutations, including nonsense (i.e., stop mutation), frameshift and splice junction mutations generally result in the loss of protein production and complete absence of full length CFTR. Class II mutations reflect abnormal protein folding, and hence processing and targeting to the plasma membrane. This class of mutations includes the common ΔF508 mutation, in which misfolding prevents normal maturation and transport to the apical cell membrane. Class III mutations in the *CFTR* gene affect the regulation/activation of a mutant CFTR chloride channel that folds correctly and reaches the plasma membrane. Class IV mutations also reach the plasma membrane, but the mutant CFTR exhibits poor chloride conductance through the channel pore. Finally, class V *CFTR* mutations decrease the abundance of full-length CFTR mRNA and, hence, protein levels, and include mutations in the *CFTR* promoters and regions that influence mRNA splicing. These mutations may, however, permit the production of enough CFTR protein and function to yield a less severe disease phenotype. The concept of mutation classes carries therapeutic implications in that novel therapies are being developed to: (1) produce "read-through" of premature termination mutations (class I mutation; e.g., topical gentamicin); (2) promote movement of ΔF508 CFTR to the plasma membrane in which it may function adequately (class II mutation; e.g., 4-phenylbutyrate); and (3) activate mutant channels that reach the plasma membrane (class III/IV mutations; e.g., genistein).

CFTR AND EPITHELIAL TRANSPORT Even prior to the cloning of the *CFTR* gene, it was recognized that a cAMP-stimulated chloride conductance was deficient in CF epithelia. Expression of the cloned *CFTR* gene in various heterologous systems demonstrated that *CFTR* itself encoded this missing chloride channel. Further, as the name implies, CFTR regulates other epithelial functions/ion channels, most notably the epithelial sodium channel (ENaC). Through a poorly defined mechanism, normal CFTR in airway epithelia provides a tonic inhibition of ENaC activity. In CF, therefore, ENaC activity is dysregulated and sodium hyperabsorption represents the dominant basal ion transport activity measured in many experimental systems, including the human nasal epithelium in vivo. CFTR may also regulate the activity of calcium-activated chloride channels (CACC), as the activities of CACC and CFTR are reciprocally related in many epithelia.

A number of hypotheses have attempted to explain the development of CF lung disease via mechanisms that do not require CFTR channel function, including: (1) increased binding of *Pseudomonas* to CF airway surfaces resulting from observed alterations in glycosylation of membrane and/or secreted proteins; (2) persistent airway infection resulting from loss of CFTR-mediated epithelial phagocytosis of pseudomonas; and (3) intrinsic hyperinflammation of CF airways via an unexplained mechanism. Each of these hypotheses is not widely accepted resulting from conflicting experimental observations and the possibility that they may represent a secondary phenomena resulting from chronic airway infection/inflammation. More generally accepted are hypotheses that directly link CFTR malfunction to altered ion transport processes.

AIRWAY SURFACE LIQUID REGULATION IN NORMAL AND CF AIRWAYS The liquid bathing airway surface is composed of two components, a periciliary gel (PGL) layer and a more viscous mucus layer that is positioned between the PGL and the airway lumen. This configuration allows the mucus layer to efficiently trap inhaled pathogens and particulates. The underlying PGL layer provides a physical environment in which cilia can beat freely and, thus, propel the mucus layer toward the mouth. The PGL also acts as a lubricant layer that prevents adhesion of the mucus layer to cell surfaces. Proper regulation of airway surface liquid (ASL) volume and the hydration of its component layers, therefore, are critical to the maintenance of mucus clearance. Whereas maintenance of PGL height is necessary to facilitate cilia motion, adequate hydration of the mucus layer is a key determinant of viscoelastic properties and transportability.

As ASL moves from distal airways toward the trachea, an enormous reduction in airway surface area occurs, necessitating active absorption of liquid across the airway to prevent obstruction of airway lumens. Conversely, there may be situations (e.g., exercise) or lung regions in which addition of liquid to ASL is necessary. The superficial epithelium lining airway surfaces regulates PGL height and mucus hydration through the coordinate regulation of Na^+-mediated liquid absorption and Cl^--mediated liquid secretion.

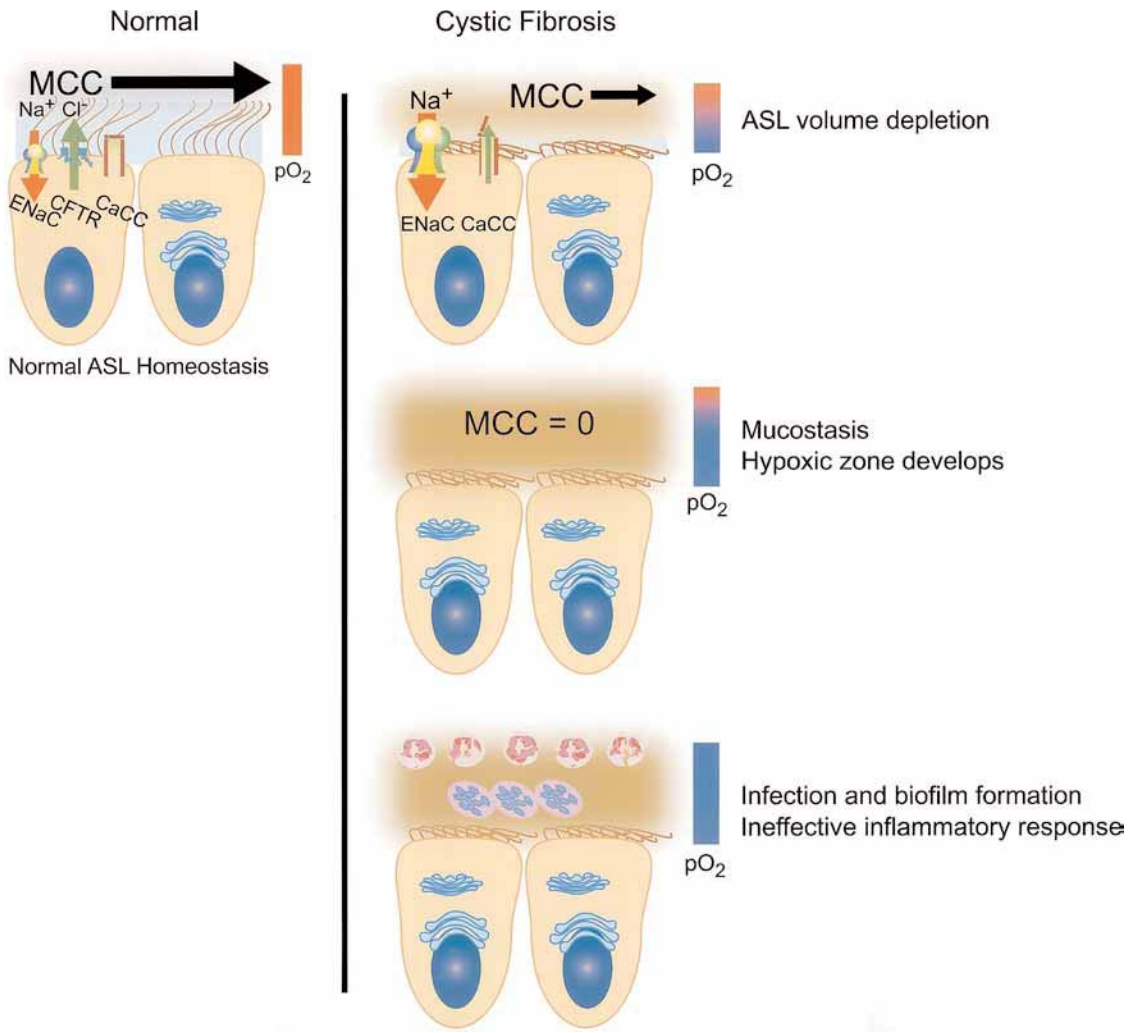

Figure 27-2 Pathogenesis of CF lung disease. (Upper left**)** Normal regulation of ASL volume requires the reciprocal regulation of CFTR and ENaC activities, which in turn supports normal MCC. (Upper right**)** In CF, absent CFTR and excessive ENaC activities result in depletion of ASL volume and concentration of airway mucus. (Middle right**)** Mucostasis ensues and is accompanied by the development of a hypoxic zone within mucus plaques. (Lower right**)** Finally, infection with typical CF pathogens, conversion to a biofilm mode of growth, and exuberant but ineffective inflammation results in clinically apparent CF lung disease. CaCC, calcium-activated chloride channels.

The absorption of airway liquid is accomplished via active sodium transport, with ENaC mediating the rate-limiting step in this process. Liquid secretion across the superficial epithelium is mediated, at least in part, by CFTR. Liquid may also be added to the PGL layer via bulk flow from converging distal lung units and by chloride/water secretion from submucosal glands (in part via CFTR). The relative contribution of each process is unclear but must vary between proximal airways, in which glands are present, and distal airway regions in which glands are not. As noted, CF epithelia hyperabsorb liquid resulting from dysregulation of ENaC and have lost the capacity to secrete liquid to restore ASL volume homeostasis on CF airway surfaces. As the result, the PGL layer is depleted and the mucus layer becomes concentrated and poorly transportable, thus impairing mucus clearance and predisposing the patient to airway infection.

The consequence of PGL depletion in CF is profound. First, absence of the PGL layer eliminates the low viscosity solution for cilia beat, and hence slows cilial-dependent mucus clearance, and also eliminates the lubricant activity that prevents the mucus layer from interacting with the cell surface. Second, mucins in the mucus layer become concentrated, greatly reducing the mesh diameter of the mucin network and increasing its adhesivity. The reduction in mesh size reduces bacterial motility, perhaps stimulating biofilm formation, and retards the ability of neutrophils to penetrate thickened mucus plaques to kill bacteria. Ultimately, the mucus layer becomes adherent to cell surfaces, making clearance via cough impossible as well. Adherent mucus plaques narrow and obstruct small airways and provide a nidus for infection. The cycle is then set for chronic infection, airway inflammation, mucin hypersecretion, and progressive airway obstruction and destruction. Importantly, restoration of PGL volume in CF cultures allows resumption of ciliary beating and mucus transport, giving hope that similar maneuvers will improve the CF condition in vivo.

In addition to the described changes in ASL volume homeostasis, an ASL compositional change in CF has been proposed by investigators. Initial reports of differences in ASL sodium and chloride concentrations between normal and CF subjects have largely been refuted by direct and indirect measures of ASL ionic composition (demonstrating isotonicity of ASL) using a variety of techniques and experimental systems. However, ASL may be

relatively acidic in CF, owing to the absence of CFTR-dependent bicarbonate secretion. Lower ASL pH in CF could contribute to disease pathogenesis through adverse effects on mucus viscosity, as well as increased adhesion between secreted and tethered cell-surface mucins via electrostatic mechanisms. Further, acidification of the CF airway lumen might interfere with bactericidal activity, thus promoting further inflammation and airway damage.

SECONDARY PATHOGENIC STEPS: MUCUS, *PSEUDOMONAS,* AND INFLAMMATION As described, the reduced ASL volume that produces progressive mucostasis and airway obstruction likely initiates the cascade of events that lead to clinically apparent CF lung disease. Studies are beginning to clarify the subsequent steps in this process (Fig. 27-2). First, thick mucus plaques adherent to airway surfaces paradoxically provide an anaerobic niche within the lung. Direct measurements in CF patients demonstrated that occluding mucopurulent plugs creates a dramatically hypoxic zone, with a pO_2 of less than 2 torr. In vitro studies demonstrated that the combination of a thick mucus plaque and increased oxygen consumption by CF epithelia (owing to heightened Na^+ transport) leads to the development of relatively hypoxic ASL in CF (vs normal and disease control) cultures. Importantly, *P. aeruginosa* contained in droplets added to the surface of these cultures can migrate into anaerobic zones within mucus plaques and grow by shifting to anaerobic metabolism. An increase in alginate production, characteristic of clinical CF *pseudomonas* isolates, is observed as well. Together, it has been speculated that the unique CF environment, initiated by mucostasis and hypoxia, triggers *P. aeruginosa* to convert to an anaerobic biofilm mode of growth. This shift in bacterial growth pattern can lead to increased resistance to secondary host defense mechanisms (e.g., neutrophils and soluble antimicrobials) and persistence of this infection. Indeed, persistent failure of certain defenses, for example, neutrophils, may lead to inadvertent damage to airway walls.

IMPLICATIONS FOR CURRENT AND FUTURE THERAPIES

The ability to increase the quality and duration of life in CF may rest on the ability to target multiple steps in the disease pathogenesis cascade (Table 27-1). Cornerstones of CF therapy have included the physical removal of airway secretions via chest percussion and postural drainage and treatment of airway infections. Aerosolized antipseudomonal antibiotics have added significantly to the ability to treat patients with established lung disease, and new additions to the inhaled antibiotic armamentarium are expected. Utilization of aerosolized recombinant human DNase (rhDNase) (Pulmozyme®) to reduce the viscosity of CF airway secretions by cleaving intraluminal DNA (rhDNase), thus facilitating mucus clearance, also improves lung function. Early institution of this agent in children with minimal lung disease may also slow the progression of lung disease. Other agents that target mucus properties or mucin production are under investigation to determine whether further improvements may be gained.

The concept of modulating the CF inflammatory response is not new and was tested through the use of high dose corticosteroids over long periods of time. This approach did slow the progression of lung disease, but was associated with unacceptably high toxicities (cataracts, osteoporosis, diabetes mellitus). Ibuprofen was subsequently used for its effects on neutrophil function/migration, and indeed greatly slowed the progression of lung disease in a subset of patients (age <14; mild lung disease). These successes have spurred further efforts to develop safe, new anti-inflammatory therapies for CF lung disease.

Table 27-1
Therapeutic Targeting of Pathogenic Events

Pathogenic step	*Therapeutic options*
ASL volume depletion	Functional CFTR restoration • Gene therapy • Pharmacotherapy of mutant CFTR (e.g., genistein, phenylbutyrate) Activation of nonCFTR chloride channels (e.g., P2Y2 agonists) Inhibition of ENaC (e.g., PS-552) Hyperosmolar solutions (e.g., hypertonic saline, mannitol)
Mucostasis and mucus adhesion	Mucus modifying agents • rhDNase (Pulmozyme) • Nacystelyn • Gelsolin Reduce mucin secretion (e.g., MARCKS-related peptide, Talniflumate (LoMucin®)
Infection and biofilm formation	Inhaled and systemic antibiotics Azithromycin
Excessive/ineffective inflammation	Ibuprofen Antielastase agents Novel anti-inflammatory agents

ASL, airway surface liquid; CFTR, cystic fibrosis transmembrane regulator.

Because ASL volume depletion may be a key pathogenic step toward the development of CF lung disease, agents that reduce sodium/water hyperabsorption (via ENaC) and/or promote chloride/water secretion may be useful early in the disease process. In addition, these therapies might improve the hydration and transportability of viscous secretions in the setting of established CF lung disease. Hyperosmotic solutions, including hypertonic NaCl (7%), promote movement of liquid into the ASL compartment, stimulate mucociliary clearance (MCC) and have beneficial effects on lung function. Poorly absorbed osmotic particles (e.g., mannitol) may also stimulate MCC and improve lung function in CF, though their effects on clinical outcomes in long-term trials have not been tested. Aerosolized amiloride, an ENaC blocker, may improve ASL volume and acutely improves MCC in CF, although its effect on lung function in the context of usual CF therapies is negligible. Because the failure of amiloride to achieve therapeutic benefit may reflect its short duration of action, longer acting ENaC inhibitors are being developed. Pharmacological agents that promote chloride/water secretion across the CF epithelium hold promise and are being studied. Most notable are long-acting nucleotide receptor (P2Y2) agonists, which stimulate liquid secretion via CACC and increase MCC. Finally, the concept of "combination therapy" with agents that simultaneously promote liquid movement into the ASL compartment, while preventing its rapid removal, may yield synergistic effects.

Reconstitution of a normally functioning CFTR channel is perhaps the most rational therapeutic goal of CF research, but has proven to be a difficult challenge. As previously discussed, various mutant CFTR gene products may be amenable to pharmacological

"rescue," either in the form of cellular chaperones (to encourage movement of the ΔF508 channel to the plasma membrane), channel activators (e.g., for class III and IV mutations), or agents that promote read-through of stop mutations (e.g., topical gentamicin). Significant investment in high-throughput screening of novel compounds has stimulated hope that safe and effective therapies will emerge. Finally, the transfer of a normal *CFTR* gene into airway epithelial cells should restore all of the cellular functions carried out by the wild-type protein. This goal also has been problematic, in that multiple hurdles must be crossed before "clinical efficacy" is achieved. These include significant barriers to vector (viral and nonviral) entry into epithelial cells, avoidance of a potentially harmful immune response, and establishment of adequate and persistent gene expression. Ongoing work on vector development and strategies to improve cell entry, however, continue to push this goal forward.

CONCLUSION

CF is a systemic disease that results from CFTR dysfunction in multiple epithelial lined organs. Optimal care of these complex patients, therefore, requires a comprehensive understanding of the myriad disease manifestations and the integrated delivery of care by multiple disciplines. Advances in the understanding of the pathogenesis of CF lung disease have highlighted the importance of reduced ASL volume. This initiating event allows the creation of a unique airway niche that favors the establishment of chronic infection by specific CF pathogens. Improved understanding of lung disease pathogenesis is also elucidating therapeutic targets that should yield significant improvements in longevity and quality of life.

28 Gene Therapy for Lung Diseases

Jane C. Davies, Duncan M. Geddes, and Eric W.F.W. Alton

SUMMARY

Gene therapy is under development for a variety of lung disease, both those caused by single gene defects, such as cystic fibrosis and α_1-antitrypsin deficiency, and multifactorial diseases such as cancer, asthma, lung fibrosis, and ARDS. Both viral and nonviral approaches have been explored, the major limitation to the former being the inability to repeatedly administer, which renders this approach perhaps more applicable to conditions requiring single administration, such as cancer. Progress in development and clinical trials in each of these diseases is reviewed, together with some potential newer approaches for the future.

Key Words: α_1-antitrypsin deficiency; ARDS; asthma; cystic fibrosis; fibrosis; lung cancer; lung inflammation; lung transplantation; pulmonary edema.

INTRODUCTION

At first sight, given both the accessibility of the airways and the genetic basis of certain pulmonary diseases, the lung seems an ideal candidate for gene therapy. Several routes of access are available, including topical administration to the airway, intravascular administration, and direct injection. Two respiratory diseases, cystic fibrosis (CF) and α_1-antitrypsin (α_1-AT) deficiency, are common single gene disorders for which the genetic basis is known, and for which treatment strategies are not curative. These inherited diseases are the obvious initial target for gene therapy, but it has become clear that nongenetic and acquired diseases including cancer may also be amenable to this approach. Following early optimism, a wide range of barriers has emerged to gene expression in both the airway and alveolar region, some of which are of limiting success. The background to these barriers, methods being employed to overcome them, and the clinical progress in CF, α_1-AT deficiency, lung cancers, and a variety of other pulmonary diseases are discussed.

VECTORS FOR GENE TRANSFER IN LUNG DISEASE

Although naked DNA is capable of transfecting cells, low levels of efficiency have led investigators to explore the use of vectors, systems designed to transport the DNA into the cell. The majority of those in clinical trials have been based on either a recombinant virus or a nonviral system such as liposomes or polymers. Each approach has advantages and disadvantages (Thomas, 2003; Niidome, 2002); although a detailed discussion of each is outside the scope of this chapter.

VIRAL VECTORS Modified, replication-deficient adenoviruses (Ad) have been by far the most widely used of the viral vectors, despite the fact that their receptor (coxsackie adenovirus receptor) is not available from the apical side of the cell, but is situated basolaterally (Walters, 1999). Attempts to overcome this problem are discussed later. Adeno-associated virus (AAV) is a small replication-defective virus. In naturally acquired infection, which occurs in the presence of adenoviral coinfection, the AAV inserts into a specific site in the host genome, providing the potential advantage, therefore, of increased duration of transgene expression. However, this integration probably does not occur with the current generation of recombinant viruses (Snyder, 1999). In any case, opinion is divided as to whether this would be desirable, unless it could be targeted to a quiescent area of the genome rather than being random. An additional drawback is the small size of the virus, which makes insertion of the large pieces of cDNA, such as cystic fibrosis transmembrane conductance regulator (CFTR), problematic. Retroviruses also integrate, although this is not normally site-specific, but certain of these, such as lentiviruses have the added advantage of transfecting nondividing cells (Quinonez, 2002). The paramyxovirus, Sendai virus possesses several advantages, such as rapid penetration of mucus, binding to the cell surface via its apically situated receptor, sialic acid, and the capacity for cytoplasmic expression, which overcomes the potential of the nuclear membrane as a barrier. Based on these advantages, one group is exploring this virus as a vector for gene transfer in CF (Yonemitsu, 2000). A common drawback of all viral vectors is the host immune response. Recognition of viral proteins leads to both inflammation at the time of administration and to significantly reduced efficacy of any subsequent application, largely related to the development of neutralizing antibodies (Yei, 1994). Attempts to combat these mechanisms have included removal of various parts of the viral genome (Boucher, 1994) and the coadministration of anti-inflammatory or immunosuppressive agents (Chirmule, 1999; Kolb, 2001) although the safety of the latter approach remains to be confirmed. The requirement for repeated application will depend on which disease is being targeted. Clearly, for certain cancers, a single injection may suffice, and in fact, a strategy of transfecting cells in order to render them immunogenic and trigger cell killing is being utilized in some cancer trials (Tursz, 1996). In contrast, however, in a life-long disease such as CF, repeated application will almost certainly be required. In such a context, a viral vector may be inappropriate.

NONVIRAL VECTORS Many synthetic vectors are being explored for gene therapy; those used clinically have mainly been cationic liposomes or synthetic polymers. The full details of the

mechanism by which the cationic liposome delivers DNA into the cell are incompletely understood, but the concepts have been well reviewed (Lee, 1996; Nishikawa, 2001). As much of the DNA delivered in this fashion fails to reach the nucleus, the system, at least theoretically, may be less efficient than some viral vectors. However, this does not appear to have been the case in clinical trials. More importantly, the relative lack of toxicity or immunogenicity is a major benefit. As discussed later, however, these approaches are not completely free from adverse effects. Nanoparticles, short pieces of DNA, are compact, small diameter particles, which may facilitate their transport through the nuclear pore. Addition of a receptor to mediate cellular uptake, serpin enzyme complex receptor, has shown promise with this approach in animal models (Ziady, 2002). Efficiency of nonviral gene transfer methods may be enhanced by a variety of adjunctive physical interventions including electroporation (Taylor, 2003; Sumner, 2003) or complexing the vector with magnetic particles and applying a magnetic field (Plank, 2003). There are clearly advantages and disadvantages to both the liposomal and the recombinant viral approaches. Future systems may be designed to incorporate the best of each.

ROUTES OF ADMINISTRATION

The route of administration depends on the desired cellular distribution and function of the therapeutic protein. Topical administration, directly onto the airway surface, would seem most appropriate for epithelial membrane-bound proteins such as CFTR, or proteins to be secreted into the airway, such as α_1-AT or cytokines. Such airway epithelial expression is likely to be most easily achieved by inhalation or nebulization, both of which have been extensively studied for delivery of nongene-based drugs. Some gene transfer studies have used bronchoscopic instillation. Although this could be impractical for diseases requiring repeated application such as CF, it may be useful for endobronchial tumors, in which direct visualization and targeted application would be of benefit. Localized injection, for example, into a tumor or pleural space may be highly appropriate for certain cancers, although limitations arise when only a small proportion of the tumor is accessible endobronchially, or when metastatic spread has already occurred. Intravascular injection may be appropriate to target the alveolar epithelium. For diseases such as α_1-AT deficiency or certain inflammatory diseases, in which the desired protein is secreted and circulates systemically, gene transfer to a distant organ, such as muscle or liver, which could serve as a "factory," is an attractive option.

BARRIERS TO GENE EXPRESSION IN THE AIRWAY

Limited success in early studies of gene transfer to the lung and airway led to the recognition of a wide range of barriers, both to cell entry and gene expression. An understanding of these mechanisms is beginning to lead to the rational design of either novel vectors, of adjunct therapies directed at the barrier itself, or of nondirected physical delivery methods. A series of barriers can be considered during the passage of a vector from outside the host through to the nucleus of the desired cell. With topical application to the lung, the vector must evade the mucociliary clearance system, penetrate the mucus barrier (which may be made more difficult by certain disease states, e.g., CF) (Stern, 1998) enter the cell through the glycocalyx and avoid lysosomal degradation to reach the nucleus, whereupon it must cross the nuclear membrane. Although the systemic approaches or local injection may help to overcome certain of these early barriers, the latter ones clearly still pose a challenge. Additionally, for application by any route, the fact that both the vector and the DNA are composed of foreign material renders the complex potentially immunogenic. The vector, the DNA, or the expressed transgene product could trigger a host response, which could result in elimination of the applied complex, death of the expressing cell, or both. Details of the identified barriers in this journey and the methods being attempted to overcome these are described in detail.

CELL ENTRY: TOPICAL ADMINISTRATION

Reaching the Cell Surface The conducting airways are lined with both ciliated and mucus-secreting epithelial cells, the major integrated function of these being the rapid removal of inhaled material (Houtmeyers, 1999). The mucus barrier also serves to prevent direct contact between inhaled particles and the cell surface, which in the case of airborne infection, for example, serves to limit the epithelial inflammatory response to pathogens. These successful host defense strategies are clearly potentially detrimental for topical gene transfer. In certain disease states this problem may be even more pronounced; for example, CF sputum, which is abnormal both in volume and composition, inhibits gene transfer by both viral and liposomal vectors (Stern, 1998; Perricone, 2000) as may pre-existing nonspecific inflammation at the airway surface (van Heekeren, 1998). Recognition of these barriers may lead to the pursuit of adjunctive therapies to increase efficacy, some such approaches such as the use of recombinant human DNase (Stern, 1998) or Nacystelyn (Ferrari, 2001) to reduce mucus viscosity, have shown promise in preclinical studies. Finally, several investigators have explored the use of either surfactant (Raczka, 1998) other low surface tension liquids (Weiss, 1999) or thixotropic agents (Seiler, 2002) to facilitate spreading of gene transfer vectors throughout the respiratory tract and increase contact time with the airway surface. These compounds may increase the distal airway and alveolar expression of therapeutic genes at the expense of more proximal airway expression, so the target area needs to be clearly identified before this approach could be considered applicable. The cell surface glycocalyx also inhibits entry; with one study demonstrating significantly enhanced Ad-mediated reporter gene expression after the removal of sialic acid with neuraminidase (Pickles, 2000).

Entering the Cell Some vectors require a specific cell surface receptor in order to enter the cell. For example, although Ad naturally infects respiratory epithelia, the coxsackie adenovirus receptor to which it binds is not expressed on the apical cell surface. In vitro studies have demonstrated increased gene transfer after breakdown of intercellular tight junctions (Parsons, 1998), permitting access to basolaterally situated receptors, although the clinical applicability of such approaches remains to be determined as this could lead to potentially deleterious loss of epithelial integrity. Other groups are developing an interest in pseudotyping of viruses, adding a ligand specific for a cell surface receptor, in an attempt to increase efficiency (Romanczuk, 1991). With an alternative approach, the efficiency of both Ad and AAV has been increased by coprecipitation of these vectors with calcium phosphate, which appears to increase nonreceptor-mediated uptake via the apical cell surface, but may also aid endosomal release (Fasbender, 1998; Walters, 2000). One advantage of vectors such as Sendai virus is the direct cell entry via membrane fusion, which bypasses the endosome, allowing the virus to avoid degradation (Yonemitsu, 2000).

CELL ENTRY: SYSTEMIC ADMINISTRATION Attempts have been made to circumvent barriers at the mucosal surface by delivering transgenes systemically. The intravenous route might make it possible to access the basolateral membrane of airway epithelial

cells, characterized by a higher rate of endocytosis and an increased density of viral receptors. However, most studies have demonstrated that the cells transfected via the systemic circulation are pulmonary endothelial cells or alveolar epithelial cells (Griesenbach, 1998), with only a minority reporting airway epithelial cell transfection (Zhu, 1993; Koehler, 2001). This is likely to be related to a number of barriers including reticuloendothelial system clearance, escape from the vasculature, the interstitium, and the epithelial basement membrane. Various attempts to overcome these barriers have been reviewed (Fenske, 2001; Niidome, 2002).

CROSSING THE CYTOPLASM Once inside the cell, lysosomal breakdown (Zabner, 1995) and destruction by cytoplasmic DNases (Lechardeur, 1999) may further limit gene expression (Duan, 2000). Preliminary data with AAV suggest that the use of proteasome inhibitors may improve gene expression, and another group has demonstrated that specific sugar moieties conjugated to nonviral vectors may influence endosomal escape (Grosse, 2002). Alternative approaches include the addition of peptides to facilitate cytoskeletal transport, or the breakdown of cytoskeletal elements such as microtubules or microfilaments (Kitson, 1999).

ENTERING THE NUCLEUS In contrast to the situation with rapidly dividing cells, such as those grown in vitro, in nondividing or slowly dividing cells in vivo, the nuclear envelope successfully prevents the entry of foreign material into the nucleus. Molecules that need to enter, for example, transcription factors, do so through the nuclear pore complex, mediated by nuclear localizing sequences. This barrier is likely to be a major limiting step in successful gene transfer. In attempts to increase nuclear entry, investigators have explored the addition of a variety of moieties, for example, peptide sequences from the HIV TAT protein (Snyder, 2001) and novel nuclear localizing sequences (Munkonge, 1998). Alternatively, this barrier can be overcome completely by the use of vectors, which do not require nuclear entry for gene expression, such as Sendai virus or the development of cytoplasmic expression systems such as those incorporating T7 promoter and RNA polymerase (Brisson, 1999).

THE HOST IMMUNE RESPONSE The duration of gene transfer can be limited by a variety of mechanisms including transcriptional silencing of the promoter, or loss of the transfected cell, either naturally or via host defense recognition. Regarding the former, some progress has been reported with human polyubiquitin, UbC (Gill, 2001) or UbB promoters (Yew, 2001). Both innate and adaptive immune responses can limit the efficiency and duration of gene transfer, and may pose problems with all routes of administration, including production of a secreted protein at a distant site. Within the respiratory tract, alveolar macrophages can act either directly as phagocytes or indirectly as antigen presenting cells, resulting in fairly rapid clearance of a topically applied gene transfer vector (Worgall, 1997). Similarly, macrophages in the reticuloendothelial system can mediate clearance of a systemically applied vector (Plank, 1996). If vectors are not cleared by such innate immune mechanisms, the adaptive immune system has the potential to significantly impair gene transfer and expression. Both cell-mediated and humoral responses have been demonstrated with viral or synthetic vectors although the major problems in clinical trials have been encountered with viral vectors. Initiation of a cytotoxic T-lymphocyte response may result in killing of the transduced cells, thus effectively limiting the duration of transgene expression. Recognition of viral coat proteins and the production of neutralizing antibodies have created problems in some trials of repeated application of viral-mediated gene transfer (Yei, 1994), and naturally acquired anti-Ad antibodies in the sputum of CF patients have been shown to inhibit transduction (Perricone, 2000). Selective deletions in the viral genome, and coadministration of agents to reduce the cytotoxic T-lymphocyte response (Chirmule, 1999), are showing some promise in increasing the duration of gene expression. However, this problem is not limited to viral vectors. The presence of unmethylated CpG motifs on plasmid DNA has been suggested as a cause for an observed inflammatory response with nonviral vectors (Schwarzt, 1997; Yew, 1999). Efforts are being aimed at either selectively methylating such motifs (although this can reduce expression levels) (McLachlan, 2000) or inhibiting the pathways through which they signal with agents such as chloroquine (Yew, 2000). Unlike the situation with viral vectors, cationic liposomes are equally effective on subsequent application (Hyde, 2000), which may render them more useful for diseases requiring repeated administration. Although apparently not a significant problem in clinical trials, the possibility of antibody production to previously unencountered transgene-derived protein also exists.

SPECIFIC LUNG DISEASES

CYSTIC FIBROSIS CF results from a variety of mutations in the gene encoding the CFTR protein, a cAMP-regulated chloride channel, leading to abnormal ion transport at the apical surface of epithelial cells (Welsh, 1993). Pulmonary disease dominates the clinical picture, leading to death in more than 90% of patients (Foundation, 1995). The hallmarks of CF lung disease are early, severe, and sustained neutrophil-mediated inflammation, and persistent infection (Armstrong, 1995). Conventional treatment for CF patients has advanced greatly, but at best, it slows the inevitable progression of lung damage. New approaches are therefore required.

Gene Therapy Although other organs are affected in CF, the lung is the major site of pathology, and thus has been the target in the majority of gene therapy trials. Topical gene delivery to the airway epithelium aims to normalize the functions of CFTR including ion transport. There are several unresolved questions with this approach, including (1) which types of cell should be transfected, (2) what degree of correction is required, and (3) how success should be measured. With respect to the cell type targeted, maximal CFTR expression in non-CF airways appears to be in the submucosal glands (Engelhardt, 1992), although clinically detectable disease begins in the distal small airways, in which expression in the surface epithelium is lower (Engelhardt, 1994). Topical application, for example via inhalation, is likely to target the surface epithelium, but is less likely to reach the deeper submucosal gland cells. Whether gene transfer to these cells will be necessary to elicit a clinical effect remains to be determined. Furthermore, surface epithelial cells are terminally differentiated (Warburton, 1998); loss of the transgene therefore occurs with the eventual death of the cell. Interest is focusing on identification of respiratory stem cells, gene transfer to which may have the potential to effect long-term CFTR expression in progeny cells. Regarding what degree of transfection is required; this is made more complex by the realization that different levels of expression may be required to restore the various functions of CFTR. For example, lower numbers of cells need to be corrected to restore chloride transport compared with those required for normalization of sodium absorption (Johnson, 1995), and differences have also been observed regarding the correction of glycoconjugate sulfation and ion transport (Zhang, 1998). Which function(s) of CFTR are most important and whether all identified functions (and perhaps as yet unrecognized ones) need to be corrected is an important question that remains to be resolved. However, based on

genetic studies, it would seem that as little as 5–10% of wild-type levels of CFTR in each cell might be sufficient for a normal disease-free phenotype (Gan, 1995). The final issue is one of the assessment of success. Detection of either mRNA or CFTR protein provides evidence of gene expression but no confirmation of functional correction. Ion transport was the first function of CFTR identified, and is thought to be key in the disease pathophysiology. As such, it is the function most commonly assessed in both gene-based and pharmacological clinical studies. Ion transport is assessed most readily in vivo by measurement of transepithelial potential difference (PD), both at baseline and in response to a variety of drugs, including those that block the sodium channel, such as amiloride, and that stimulate chloride secretion (Knowles, 1981; Middleton, 1994). These measurements can be obtained in the airway via the bronchoscope (Alton, 1999), as well as from the nasal epithelium. Additional ex vivo techniques such as epifluorescence microscopy have also proved useful in some studies (Stern, 1995), and alternative functions of the protein, such as those involved in bacterial adherence (Alton, 1999), have also been utilized as end points.

Clinical Studies

Viral Vectors Many studies conducted in the nose and the lower airway, particularly those in the lower airway, have relied on molecular rather than functional evidence of gene expression. Expression has been transient, with variable dose responses. In one of the earliest studies, Ad/CFTR was administered to both the nose and lower airway bronchoscopically (Crystal, 1994). One of the highest dose patients became unwell with fever, hypoxia, and pulmonary infiltrates. The problem was attributed to vector-induced inflammation as no infective virus was detected. Significant local inflammatory reactions and the stimulation of neutralizing antibodies was a feature of the high-dose arm of another nasal study (Boucher, 1994), and flu-like symptoms and a cell-mediated immune response were seen at a high vector dose in a bronchoscopic study (Zuckerman, 1999). Interestingly, a study from France found no acute toxic effects at doses up to 5.4×10^8 plaque-forming units, and no increased inflammatory parameters or antiviral antibodies in bronchoalveolar lavage or serum (Bellon, 1997). Molecular analysis confirmed successful gene transfer, although no functional end points were employed. Attention has focused on the potential problems with repeated administration, with clinical trials addressing this issue in the nose and in the lower airway. In the nasal study, despite there being no detectable adverse effects, the ability of the Ad/CFTR to correct the abnormal chloride transport was reduced on subsequent application (Yei, 1994). In the lower airway study, Ad/CFTR was administered via an endobronchial spray in three doses over a 9-mo period to patients with CF, with bronchoscopic assessment 3 and 30 d after administration (Harvey, 1999). Almost 3 d after the first administration, vector-derived mRNA was detected in a dose-related manner, with those in the high-dose group expressing levels in the 5% of wild-type range, which has been demonstrated in vitro to be sufficient for phenotypic correction. Examination of distribution was unfortunately not possible, as the vector could not be identified with fluorescent *in situ* hybridization. mRNA levels were undetectable in all patients by d 30. The second administration resulted in some nondose-dependent expression, but the third administration produced no expression in any sample. Similarly to the study previously reported, these investigators detected no increase in serum neutralizing antibodies, although gene expression was not seen in patients with high preexisting levels of antibody. This study, therefore, confirms, that although repeated administration of adenoviral vectors appears safe, efficacy is severely compromised, although the exact mechanism for this is uncertain. AAV-mediated *CFTR* transfer has been assessed in CF patients using preexisting antrostomies into the maxillary sinus for ease of administration and assessment (Wagner, 1998). Ten patients received escalating doses in an unblinded fashion with no significant inflammatory response. Molecular end points demonstrated gene transfer, with DNA detected up to 41 d after administration, but assessment of expression was difficult. Functional assessment with PD responses to isoprenaline and amiloride demonstrated some changes, although numbers were small. This group then performed a phase II study using a similar technique, which did not show significant changes in PD or time to sinusitis exacerbation, but in which there was some evidence of changes in inflammatory parameters (Wagner, 2002). Safety was confirmed in a phase I study in which AAV-*CFTR* was administered by nebulization to the lungs of mildly affected patients and the results of a multicenter placebo-controlled trial by the same group have been reported in abstract form (Moss, 2002). Forty-four patients from eight centers were recruited and small but significant changes in both lung function and inflammatory markers were described.

Nonviral Vectors Several early placebo-controlled clinical trials of liposome-mediated *CFTR* gene transfer to the nasal epithelium confirmed safety and demonstrated a degree of functional correction (Sorscher, 1994; Caplen, 1995; Gill, 1997; Porteous, 1997; Knowles, 1998). These studies led us to the first trial of liposome-mediated *CFTR* to the lower airway of patients with CF (Yonemitsu, 2000). Administration was well tolerated, but respiratory symptoms including mild chest tightness and cough were seen in both groups. This had not been observed with liposome alone in non-CF subjects (Chadwick, 1997), and may relate to the pulmonary inflammation present in the lungs of the CF patients. In addition, all patients in the treatment group reported mild influenza-like symptoms within the first 24 h. The reason for this was unclear, but it may relate to the presence of unmethylated CpG groups on the bacterially derived DNA. Importantly, these symptoms were not reported after nasal administration, which was included for comparison purposes, suggesting that for safety at least, the nasal epithelium may not be a good surrogate site for such trials. The major efficacy end point was lower airway PD. In neither group was there any change in the parameters of sodium absorption (baseline or amiloride response). The treatment group however demonstrated a significant response to perfusion with low chloride and isoprenaline, of approx 25% of non-CF values. Unlike the reported problems with readministration of adenoviral-mediated gene transfer, a study using DC-Chol/DOPE reported that repeated nasal administration was well tolerated and could be effective (Hyde, 2000).

α-1-ANTITRYPSIN DEFICIENCY Deficiency of α_1-AT, the principal endogenous antiprotease, leads to pulmonary emphysema and in some cases, liver disease. The disease is inherited in an autosomal-recessive fashion, with several mutations having been identified resulting in absent or severely low levels of circulating protein (Coakley, 2001). The principal action of α_1-AT in the lung is to counter the adverse effects of proteases such as neutrophil elastase in the distal conducting airways and alveoli. Therapy involves avoidance of damaging environmental triggers such as cigarette smoke, and symptomatic treatments. Plasma-derived α_1-AT can be administered intravenously, but is costly and has a short half-life necessitating frequent administration (Pierce, 1997). Its purification from human serum also raises the possibility of viral transmission. Gene therapy has, therefore, been considered as an alternative approach.

In contrast to the situation with CF, the secreted nature of the deficient protein makes expression at a distant site a possibility for exogenous gene transfer, and simplifies end point assays. The liver, as the natural site of synthesis, would seem the logical choice, and in vivo studies in animals have assessed several delivery systems and routes of administration including tail and portal vein injections, biliary infusion, and direct intrahepatic injection (Stecenko, 2003). Although successful, these initial studies reported inadequate levels of protein. AAV has also been used to transduce muscle, and one group has reported higher protein levels by implantation of genetically modified myoblasts in mice (Bou-Gharios, 1999). Another approach has been to transduce hematopoetic cells with a retrovirus encoding human α_1-AT, and reinfuse the bone marrow into mice (Saylors, 1998). A postulated advantage of this approach might be high expression of the transgene at sites of inflammation. The treated animals demonstrated extremely low levels of human protein at a 3-wk time-point, after which levels declined.

Several studies have assessed the feasibility of targeting the respiratory epithelium directly, in a fashion similar to that described for CF. In early studies on the cotton rat, adenoviral-mediated α_1-*AT* gene transfer via the trachea led to the detection of functional protein within epithelial cells for up to a week (Rosenfeld, 1991). Although the cells were capable of secreting the protein, the extracellular levels were once again too low to be therapeutically effective. Since then, studies demonstrating that airway epithelia can secrete the protein both apically and basolaterally provide encouraging evidence that the interstitium can be reached. In a study of aerosolized cationic liposome-mediated α_1-AT gene transfer to the rabbit lung, protein was demonstrated both in the airway and alveolar cells (Canonico, 1994).

The first clinical study of α_1-AT gene transfer has been reported (Brigham, 2000). Patients with α_1-*AT* deficiency received a single dose of cationic liposome-α_1-*AT* complex into one nostril, with the other nostril acting as a control. Protein was detected in nasal lavage fluid, with levels peaking at d 5 at approx one-third of normal values. This rise was not seen in fluid from the control nostril. In addition, levels of the proinflammatory cytokine, interleukin (IL)-8, were decreased in the treated nostril. Most interestingly this anti-inflammatory effect was not observed when intravenous-administered purified α_1-AT protein achieved levels within the normal range in nasal lavage, leading the authors to speculate that different routes of administration may lead to a variable response in different sites of expression. Future studies will address this issue and assess administration to the lower airway. One potential difficulty in later-phase studies will be the design of end points to assess clinical benefit in this disease, which progresses extremely slowly in nonsmoking patients.

CANCER In comparison to the two previous single gene disorders, cancer may seem a less obvious choice for gene therapy. Although cancer is fundamentally a disorder of genes, many mutations of different genes are usually necessary to produce disease. However, this is a rapidly growing field, with several approaches demonstrating some success.

Tumor Suppressor Gene Therapy Mutation of the tumor supressor gene, *p53*, is one of the commonest findings in certain types of lung cancer (nonsmall cell) (Rom, 2000). Importantly, patients bearing mutations in *p53* on tumor cells are less likely to respond to treatment, either chemotherapy or radiotherapy. Early evidence that *p53* could be a useful therapeutic target came from in vitro studies (Fujiwara, 1994). Transduction with normal *p53* rendered lung cancer cell lines more susceptible to apoptosis, an effect that was enhanced in the presence of the chemotherapeutic agent, cisplatin. Significantly, in animal models, a bystander effect has been observed, in which a subset of cells expressing the gene inhibits the growth of neighboring nontransfected cells.

Several viral-mediated clinical trials have been reported on patients with demonstrated *p53* mutations who were failing to respond to conventional treatment, although none of these has been controlled (Roth, 1996; Schuler, 1998; Swisher, 1999; Nemunaitis, 2000; Yen, 2000). The gene transfer agent has been administered locally into the tumor either via the bronchus or percutaneously under CT guidance. Side effects have been generally well tolerated, with some evidence of gene expression at high doses. Some studies have reported either stabilization or regression of growth in the injected tumors, with an absence of effect seen at uninjected sites. However, one multicenter study involving 25 patients with nonresectable tumors showed no evidence of benefit over conventional chemotherapy alone (Schuler, 2001).

Suicide Gene Therapy The basis of this approach is the transfer of a gene encoding an enzyme capable of converting a nontoxic to a toxic chemotherapeutic agent (Smythe, 2000). This limits the activity of the active drug to the site of gene expression and thus minimizes side effects. The most commonly used system has been the herpes simplex thymidine kinase (HSV*tk*) gene, which converts ganciclovir into a triphosphorylated derivative. This is incorporated into DNA in place of guanosine triphosphate and leads to inhibition of cell replication. Two major advantages of this approach are a significant bystander effect owing to local spread of toxic metabolites, and the stimulation of a local immune response. The approach is being utilized in trials of malignancies in many sites, including in patients with pleural mesothelioma (Sterman, 1998). With an adenoviral vector, intrapleural administration of HSV*tk* to 21 patients led to expression of transgene protein in just over 50%. Strong immune responses against Ad were initiated, although this was well tolerated. Partial regression of tumors has been reported in some patients.

Immunotherapy Immunogenetic therapy is based on the transfer of genes encoding molecules involved in the host immune response in an attempt to enhance immune recognition and destruction of tumor cells. Such genes include various cytokines, interferon (IFN)-γ, granulocyte-macrophage colony-stimulating factor, and heat shock proteins (Leroy, 1998). An alternative strategy has been to introduce a foreign gene, such as the bacterially derived β-*galactosidase*, in the hope that cells expressing this gene will be targeted for destruction. Two clinical trials examining feasibility demonstrated local tumor regression and the induction of strong antibody responses both to the adenoviral vector and the transgene (Tursz, 1996; Gahery-Segard, 1997). Other studies have administered vaccinia virus-mediated *IL-2* intrapleurally to patients with mesothelioma (Mukherjee, 2000). No clinical benefit has been shown despite increases in T-cell infiltrates. Preclinical studies are exploring the possibilities of using cytokine cocktails.

Oncolytic Adenovirus There are several replication-specific Ad, such as ONYX-015, which has a deletion in the E1B-55 kDa gene region that is required for inhibition of wild-type p53 function. Therefore, viral replication is prevented in cells with normal p53 function, but permitted in tumor cells with mutant p53, in which it leads to cell death, and a significant bystander effect (McCormick, 2000). This effect has been confirmed in preclinical studies (Bischoff, 1996; Heise, 1997), with the latter study showing synergy with conventional chemotherapeutic agents. One clinical study

confirmed both safety and feasibility of intravenous-administered ONYX-015 in patients with end-stage metastatic lung cancers (Nemunaitis, 2001). Infusions were administered weekly with or without conventional chemotherapeutic agents. No dose-limiting toxicity was detected at doses up to 2×10^{13} particles, mild adverse events being fevers, rigors, and transient elevation of liver enzymes. All patients showed an increase in neutralizing antibody levels, and raised levels of circulating cytokines. Viral infection of tumor deposits was seen in one patient and at doses above 2×10^{12} circulating viral genome indicated replication. Replication-specific oncolytic viruses may therefore become a useful approach. Future studies may address the effects of transient immunosuppression, reduction in hepatic clearance of virus, and combination of this approach with cytotoxic drugs or therapeutic transgenes.

INFLAMMATORY AND MISCELLANEOUS DISEASES

Acute Lung Injury Acute lung injury (ALI) (adult/acute respiratory distress syndrome) is the end result of a variety of insults, including severe sepsis, aspiration, trauma, near-drowning, and pancreatitis (Dennehy, 1999). The clinical hallmarks of ALI include impaired oxygenation, which is often poorly responsive to invasive ventilation and patchy infiltrates on chest X-ray in the absence of a raised pulmonary arterial wedge pressure or left atrial hypertension. Despite the improvements in intensive care management, which have led to a reduction in mortality, ALI carries a poor prognosis, particularly in children. No specific therapy exists, and management is largely supportive (Weinacker, 2001). The pathophysiology of ALI is a sequential process of immediate injury, exudative alveolar inflammation with edema and, finally, fibroproliferative repair (Dennehy, 1999). The recognition that the early stages of this process are characterized by generalized intravascular activation, endothelial damage and high levels of proinflammatory cytokines, has led to the development of novel gene and small molecule-based approaches to treatment. These have some theoretical advantages over the use of proteins, including the potential for cell specificity, the possibility of delivering intracellular proteins, duration of action, and possibly cost. Most approaches target either inflammation or oxidative stress, although other investigators have explored the potential for increasing fluid reabsorption and reducing pulmonary edema in this disease process.

Anti-Inflammatory Approaches As with other inflammatory diseases, inflammation can be targeted either by antagonizing proinflammatory cytokines, or by increasing the levels or effects of anti-inflammatory cytokines. In the context of ALI, studies have been undertaken both with conventional gene transfer techniques, and with antisense oligonucleotides, which reduce translation to protein by specific binding to mRNA. Ad-mediated *tumor necrosis factor* (*TNF*)-α *receptor* gene transfer reduces septic shock in mice injected with lipopolysaccharide (LPS), and reduces pulmonary inflammation (Rogy, 1995). IM delivery of Ad/*IL-10*, a major anti-inflammatory cytokine, showed similar benefits, with a marked suppression of LPS-induced TNF-α and IL-6 production (Xing, 1997). Both *prostaglandin synthase* and *nitric oxide synthase* genes have demonstrated potential therapeutic benefit in animal models of ALI (Conary, 1994; von der Leyen, 1995). Antisense technology has also been used in this context: oligonucleotides against ICAM-1, a major intercellular adhesion molecule, reduced endotoxin-induced neutrophil influx to the lung (Kumasaka, 1996). Hyperoxia has been implicated in lung damage seen in both ALI and infant respiratory distress syndrome. The demonstration that this effect occurs via a mitogen-activated protein kinase, p38MAPK (which also mediates LPS and TNF-α induced damage) (Lee, 1994), has led to another novel approach. This pathway is attenuated by CO, a byproduct of heme degradation catalyzed by hemoxygenase. Ad-expressing inducible *hemoxygenase*, *HO-1*, instilled intratracheally, increased the survival of rats with hyperoxic lung damage (Inoue, 2001).

Targeting Pulmonary Edema In the healthy state, alveolar liquid is cleared by the basolaterally situated Na^+,K^+-ATPase, which is upregulated during the resolution phase of pulmonary edema (Factor, 2001), a recognized feature of ALI. A variety of vectors have been used to overexpress this ATPase in animal models of lung injury with pulmonary edema, with studies reporting both improved fluid clearance and enhanced survival (Factor, 2000; Stern, 2000). An alternative approach has been to increase activity of the epithelial sodium ion channel, ENaC, the levels and function of which are both upregulated by β(2)-adrenoreceptor (β[2]-AR) expression. β(2)-AR increased alveolar fluid clearance by more than 100% in a rat model (Dumasius, 2001), suggesting that this approach may be applicable in pulmonary edema clearance.

Asthma Asthma is a disease of high prevalence characterized by type-2 T-helper lymphocyte-mediated inflammation (Lee, 2001) and airway hyperreactivity. Treatment with bronchodilators and anti-inflammatory agents is successful in treating wheeze, cough, and breathlessness in the vast majority of patients (Suissa, 2001). However, for the subgroup who does not respond, novel therapeutic approaches may be relevant. Following success in animal models with Th1-type cytokine protein therapy (IFN-γ [Lack, 1994] or IL-12 [Schwarze, 1998]), beneficial effects have been demonstrated with *IFN-γ* (Dow, 1999), *IL-4 receptor antagonist* (Zavorotinskaya, 2003), and *IL-12* (Hogan, 1998) gene transfer. Thus, in line with the multifactorial nature of the disease, many options are being explored for new gene therapies for asthma. Given the success of conventional treatment however, it is likely that such therapies may only be useful for a minority of patients who do not respond to standard regimes.

Fibrotic Lung Disease Lung fibrosis can be idiopathic, part of a multisystem (e.g., autoimmune) disorder, or iatrogenic (following radiotherapy or drugs such as bleomycin [Fonseca, 1999]). The prognosis is often poor and available therapies are limited. A variety of growth factors, in particular transforming growth factor (TGF)-β are considered key in the progressive nature of the disease (Sime, 2001), leading to these molecules as targets for novel therapies. Both Smad7, a TGF-β antagonist (Nakao, 1999), and decorin, an endogenous proteoglycan with anti-TGF-β activities (Kolb, 2001) administered intratracheally to bleomycin-treated mice led to a significant reduction in fibrosis. Another group has demonstrated prevention of radiation-induced lung fibrosis and improved survival with liposome-mediated *manganese superoxide dismutase* (Epperly, 1998). The design of radiation-induced promoters (Scott, 2000) may help to limit sites of expression of therapeutic transgenes both in radiation-related fibrosis and lung cancers. Finally, a clinical study has shown dramatic success with IFN-γ 1β protein therapy, which in combination with prednisolone, led to improvements in pulmonary function and oxygen saturation (Ziesche, 1999); in contrast, the group treated with the corticosteroid alone deteriorated. This, and other reports suggesting a role for Fas-mediated alveolar cell apoptosis (Kuwano, 1999), may lead to new gene-based strategies for this disease.

Lung Transplantation The major obstacle to organ transplantation programs worldwide remains the lack of sufficient donor organs. Medium to long-term success is, however, further limited both by acute ischemia-reperfusion injury, which is particularly problematic for lung transplantation (Mal, 1998), and by the host

response leading to organ rejection (Ward, 2000). Given the shortage of available organs, strategies to attenuate these processes would be of major benefit. Organ transplantation theoretically creates a unique window of opportunity for gene therapy; in addition to administration to the host before removal of the organ, or the recipient after surgery, therapeutic genes could be administered to the organ ex vivo during the procedure. The feasibility of *Ad-β-gal* transfection either before procurement (via tracheostomy) or ex vivo after surgical removal has been demonstrated (Cassivi, 1999). At the critical time of reperfusion, significantly greater transgene levels were shown in lungs transfected via the tracheostomy than in those transfected ex vivo. Levels in other organs were virtually absent, confirming limitation to the lungs. However, another study using liposomes demonstrated that ex vivo transfection was superior to intravenous injection of donors prior to organ harvesting (Boasquevisque, 1999). Another concern may be the cold preservation of organs prior to transplantation, which adversely affects efficacy of gene transfer (Boasquevisque, 1998). The optimal route and timing of gene administration may therefore depend on the vector and the desired function and site of transgene expression.

Various mediators have been implicated in ischemia-reperfusion injury, including stimulated leukocytes and platelets, complement, proinflammatory cytokines, and oxidants (Mal, 1998). Attempts to combat this process with exogenous recombinant proteins have been limited, thought largely to be related to the inability to achieve and maintain high local levels. Gene transfer may therefore be a more useful approach. Ad/*hIL-10* was administered intravenously to rats 24 h before organ harvest (Itano, 2000). When assessed 24 h after isotransplantation, dose-dependent IL-10 expression was observed along with significant improvements in gas exchange and neutrophil sequestration when compared with controls (Ad-*LacZ*). In the higher dose group, myeloperoxidase and NO synthase were also decreased, suggesting that IL-10 may be of benefit in reducing injury at the time of reperfusion. Several groups have reported a reduction in rejection of donor lungs with a variety of methods. Lipid-mediated *Fas ligand* was administered retrogradely through the pulmonary venous system, prior to lung removal along (Schmid, 2000) with a single dose of cyclosporine. Compared with controls, the rats receiving *Fas*-transfected lungs had better d 5 gas exchange, and demonstrated significantly less histological evidence of acute rejection. Other groups have reported success with *TGF*-β both lipid-mediated ex vivo (Mora, 2000) and Ad IM into donor post-transplant (Suda, 2001). However, similarly to the situation with CF and α_1-AT deficiency, robust end point assays in lung transplantation trials will be complicated by the clinical heterogeneity of the patient groups studied.

FUTURE DIRECTIONS AND SUMMARY

The principle of gene therapy for lung disease has been proved, with clinical trials showing successful gene transfer in a variety of genetic and acquired disorders. The major problem is with low levels of efficiency, both in terms of cell entry and, for chronic diseases, duration, and the limitation by the host immune response of repeated application with viral vectors. Regarding efficiency, research is ongoing into both overcoming barriers to gene transfer and vector design, including viral pseudotyping and the development of newer generation cationic liposomes and synthetic vectors. Regarding long-term expression, approaches being investigated include manipulation of either the vector or the host to permit repeated administration, the use of integrating vectors, and attempts to identify and target respiratory epithelial progenitor cells. Focused efforts on these areas are likely to lead to the development of successful gene therapy approaches in the near future for a number of respiratory diseases.

29 Sarcoidosis

KELLY D. CHASON AND STEPHEN L. TILLEY

SUMMARY

Sarcoidosis is a disease characterized by granulomatous inflammation in organs and tissues, which is believed to develop in genetically predisposed individuals following exposure to a triggering antigen. Although the etiology of sarcoidosis remains unproven, recent molecular investigations suggest that an immune response against mycobacterial and propionibacterial antigens may play a role in pathogensis. The immune response of sarcoidosis is characterized by a highly polarized Th1 cytokine profile elaborated by lymphocytes and macrophages within granulomas. Elucidation of the specific cytokine mediators of inflammation has led to better markers of disease activity as well as novel targets for new therapies.

Key Words: Antigen; etiology; genetics; granuloma; MHC; *Mycobacteria*; pathogenesis; *Propionibacteria*; sarcoidosis; treatment.

INTRODUCTION

Sarcoidosis is a systemic inflammatory disease characterized by granulomatous inflammation most commonly involving the intrathoracic lymph nodes and lung parenchyma, but with the capacity to involve almost any organ in a random, unpredictable fashion. Although it was previously proposed that sarcoidosis develops in genetically predisposed individuals following exposure to an immunogenic stimulus, significant insight has been gained into the genetic basis for this predisposition and the triggering agent(s). Cellular and molecular biology has improved the understanding of the immunopathogenesis of sarcoidosis, suggested better markers of disease activity, and fueled the development of more selective and potentially more potent therapies for this enigmatic disease.

IMMUNOPATHOGENESIS

ANTIGEN PRESENTATION Granuloma formation is thought to begin when poorly soluble antigenic material is either phagocytosed or internalized by receptor-mediated endocytosis by activated macrophages and dendritic cells. Endosomes containing antigen fuse with lysosomes and the antigenic proteins are broken down into peptide fragments, which are then loaded within the α-helices of human leukocyte-associated antigen (HLA) class II molecules. The resultant major histocompatibility complex (MHC)/peptide complexes are transported to the cell surface of these antigen presenting cells (APCs) where they are exposed for interaction with T-cell receptors (TCRs) present on antigen-specific T cells. Formation of this trimolecular complex (MHC/peptide/TCR) provides the first activation signal, whereas costimulatory molecules provide the additional signal necessary for T-cell activation. On activation, T cells produce cytokines and growth factors that drive the development of granulomas (Fig. 29-1).

PATHOLOGY The granulomatous inflammation of sarcoidosis is characterized by the accumulation of activated lymphocytes, macrophages, and dendritic cells in affected organs. Macrophages aggregate and differentiate into epithelioid histiocytes and multinucleated giant cells, whereas CD4+ T lymphocytes become interspersed within the developing granuloma. In additon, T lymphocytes, and to a lesser extent B lymphocytes, accumulate around the periphery of the granuloma, along with a rim of concentrically arranged fibroblasts.

The physical association of APCs and lymphocytes within the granuloma suggests that the inflammation of sarcoidosis is antigen driven. The oligoclonal expansion of T cells at sites of active disease provides direct evidence for this hypothesis. Perhaps the best example is the expansion of AV2S3 (Vα2.3)+ T cells in the bronchoalveolar lavage (BAL) fluid from HLA-DR17+ (DR*0301) Scandinavian patients with sarcoidosis. The oligoclonal expansion of other specific αβ+ T cells have also been found in the lung, skin, and blood, of other sarcoidosis patients.

CELLS AND CYTOKINES

Lymphocytes T-cell subsets in the BAL fluid of patients with sarcoidosis have been extensively characterized. Early in the disease CD4+ T cells predominate and release a highly polarized Th1 cytokine profile consisting of IL-2, interferon (IFN)-γ, and lymphotoxin. Interestingly, only alveolar T cells and not those of the peripheral blood secrete IL-2, further suggesting that interaction with APCs of the affected organ is required for their activation. Similar cytokine profiles are seen in other granulomatous disorders in which activation of cell-mediated immunity is triggered by microorganisms such as *Mycobacteria* and fungi.

B-cell activation also occurs in sarcoidosis. Many cases are associated with hypergammaglobulinemia, and immune complexes have been detected in a majority of patients. Although the contribution of the B-cell to disease pathogenesis is not as clear as that for the T-cell, it is speculated that a robust humoral immune response, like that typically seen in Lofgren's syndrome (acute sarcoidosis characterized by fever, hilar adenopathy, arthralgias,

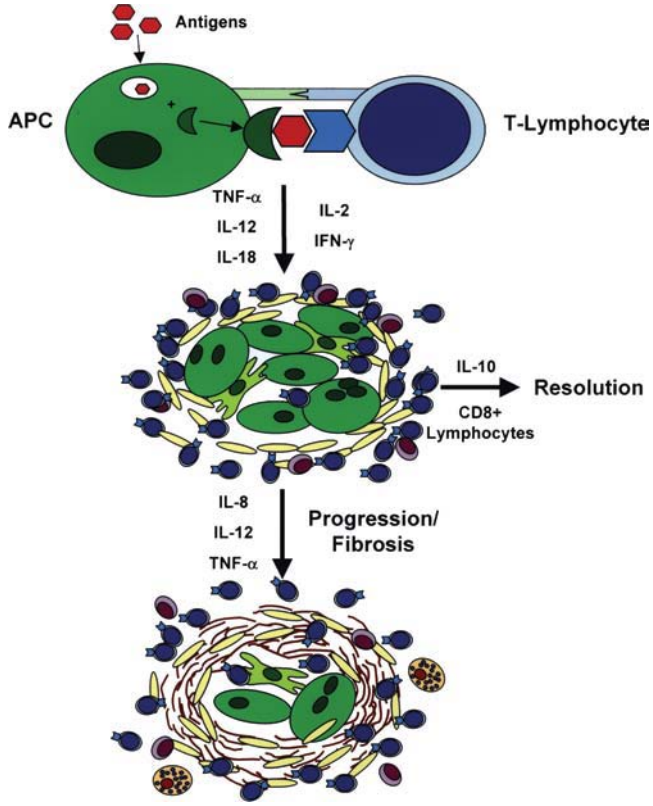

Figure 29-1 Development of granulomatous inflammation. APCs interact with CD4+ T lymphocytes by presenting antigenic peptides, bound to MHC molecules, to TCRs. When a costimulatory signal is also provided by CD40/CD28 binding, the T-cell becomes activated. Th-1 cytokines (IFN-γ, IL-12, IL-18) and TNF-α, released by activated lymphocytes and macrophages, promote the development of granulomas, which consist of clusters of epithelioid histiocytes (differentiated macrophages), dendritic cells, and T lymphocytes, and to a lesser extent B lymphocytes and fibroblasts. Granulomas may involute under the direction of anti-inflammatory cytokines (e.g., IL-10) or persist in the presence of a continued TNF-α stimulation and a Th-1 cytokine milieu. Fibrosis ensues as activated fibroblasts deposit collagen from the periphery of the granuloma to the center, under the direction of activation signals from macrophages and mast cells. (Please *see* color insert.)

and erythema nodosum), may contribute to antigen clearance and subsequent remission of disease.

Macrophages Acting in concert with the T lymphocyte, the macrophage is another key player in disease pathogenesis. The alveolar macrophage pool expands in sarcoidosis, and these cells spontaneously release a number of proinflammatory cytokines that act with the T-cell-derived cytokines described above to drive the granulomatous inflammation. Alveolar macrophages obtained from patients with sarcoidosis spontaneously release IL-1, tumor necrosis factor (TNF)-α, macrophage inflammatory protein-1α, RANTES, IL-8, IL-12, and IL-18. IL-12 and IL-18 are thought to play a central role in disease pathogenesis by stimulating macrophage activation, IFN-γ production, and granuloma formation. In addition, IL-18 can enhance the cytotoxicity of natural killer cells and T cells.

Tumor Necrosis Factor Perhaps the most studied cytokine produced during granulomatous inflammation is TNF-α. An increased release of TNF-α occurs from alveolar macrophages from patients with sarcoidosis, and release is significantly higher in patients with active vs inactive disease. Levels also correlate with response to corticosteroid or immunosuppressive therapy. Perhaps the best evidence for the critical role of TNF-α in granuloma formation comes from in vivo experiments in which levels of this cytokine are reduced either genetically or pharmacologically. In mice deficient in TNF-α or mice treated with anti-TNF antibodies, granuloma formation in response to bacille Calmette-Guerin and *Mycobacterium tuberculosis* is significantly impaired. In humans treated with infliximab, a monoclonal antibody against TNF-α, tuberculous granulomas fail to develop and *M. tuberculosis* becomes disseminated throughout the body. Taken together, this evidence suggests that TNF-α may play a critical role in granuloma development in sarcoidosis, and provides rationale for trials of anti-TNF therapies for patients.

FIBROSIS The course of sarcoidosis ranges from spontaneous remission to progressive, end-organ fibrosis. The course varies because granulomas may either involute or become encased by a dense band of activated fibroblasts capable of laying down collagen. Fibrosis proceeds from the periphery of the granuloma to the center, and unchecked, this fibrotic response can affect the normal physiology of the involved organ as well as result in irreversible organ destruction. Genetic factors clearly play a role in the propensity of an individual to develop disease remission or progression, and are described in detail next. At the cellular level, data suggests that maintenance of the granuloma may be controlled by IL-12, whereas resolution is associated with an influx of CD8+ lymphocytes and release of IL-10, a mediator known to suppress the inflammatory response. Interestingly, some of the same cytokines that promote the cellular immune response described above (e.g., IFN-γ) may also inhibit fibrosis.

Chronic disease is characterized by the continued production of IL-8, IL-12, and TNF-α. Although IL-8 is not seen in the BAL fluid of early disease, concentrations in patients with chronic disease approach levels seen in patients with idiopathic pulmonary fibrosis. IL-8 recruits neutrophils to the lung, and BAL neutrophilia distinguishes patients undergoing spontaneous remission from those with progressive disease. Thus, neutrophilic alveolitis in sarcoidosis may promote progression to fibrotic disease. Although the mechanisms by which IL-8 and neutrophils promote fibrosis in sarcoidois are incompletely understood, an association between increases in IL-8 and the fibrosis-promoting cytokine transforming growth factor (TGF)-β has been shown. TGF-β has been localized to macrophages within granulomas, a cell type critical for the induction of fibroblast proliferation and secretion of collagen within the lung. Similarly, mast cells contribute to fibrosis in granulomas through the release of fibroblast growth factors.

Although early sarcoidosis is clearly a Th1 polarized disease, it has been speculated that a shift to a Th2 cytokine production may contribute to the development of fibrosis. Th2 cytokines IL-4 and IL-13 can promote fibrosis by enhancing the production of collagen by fibroblasts. Such speculation is in part based on animal models showing that Th2-mediated granulomatous inflammation is more fibrotic than Th1-mediated models. However, human data confirming this paradigm in fibrotic sarcoidosis are lacking, and it is likely that profibrotic mediators such as TGF-β expressed in the lungs of patients with fibrotic disease influence fibrosis in a cytokine milieu unique to progressive sarcoidosis that is not necessarily confined to a prototypic Th1 or Th2 profile.

GENETICS

DISEASE SUSCEPTIBILITY GENES A genetic basis for developing sarcoidosis has been suspected based on observations of familial clustering of disease and racial differences in disease

prevalence. A case–controlled etiological study of sarcoidosis, involving more than 700 patients with sarcoidosis throughout the United States, revealed an approximately fivefold increase in relative risk of developing the disease in first-degree relatives. With advances in genomics technology, genome-wide microsatellite linkage analysis has been used to identify chromosomal regions that may contribute to the risk of sarcoidosis. Findings from these studies have revealed several areas of linkage suggesting that sarcoidosis is a "complex" genetic disease, with the resultant phenotype dependent on the interaction of multiple genes rather than a single mutation. The strongest linkage has been found on the short arm of chromosome 6 in the MHC region. These findings are consistent with other studies that have shown associations between specific MHC class II alleles and sarcoidosis, and provide further support that antigen presentation is involved in disease pathogenesis (Table 29-1). Some alleles associated with disease susceptibility include HLA DR 11,12,14,15, and 17. Several protective alleles have also been identified, with HLA DR1, DR4 being consistently protective across all ethnic populations evaluated. Interestingly, some of the proteins encoded by protective alleles share characteristic bulky, highly hydrophobic residues within a pocket of the HLADR complex antigen binding groove, while nonprotective alleles encode sequences with hydrophilic residues within this pocket. These observations of differences in avidity of antigen binding suggest one mechanistic explanation of how genotype may affect phenotype in sarcoidosis.

GENETIC DETERMINANTS OF DISEASE REMISSION VS PROGRESSION In addition to alleles conferring protection from or susceptibility to sarcoidosis, a genetic basis for remitting vs progressive disease has also been identified (*see* Table 29-1). In addition, some MHC haplotypes associated with resolving disease have been correlated with specific TCR repertoires also shown to predict remitting disease. T cells from patients carrying some of these protective alleles, such as the DRB1*0301 allele, have a tendency for diminished Th1 responses. Thus, a diminished capacity to produce a robust Th1 immune response may be an important requisite for remitting disease.

Many non-HLA candidate gene association studies have also been performed in sarcoidosis with variable degrees of reproducibility across populations. Table 29-1 summarizes some of the major associations. An excellent example of genotype–phenotype correlation emerging from one of these studies involves a mutation in the CC10 protein produced by clara cells. This protein is a counter-regulator of the inflammatory response, acting by several different mechanisms including the inhibition of IFN-γ, TNF-α, and IL-1β; and through inhibition of monocyte and fibroblast chemotaxis and phagocytosis. In sarcoidosis, increased levels of CC10 have been found in serum and BAL fluid from patients whose disease resolved compared with those whose disease progressed. An A to G substitution at position 38 (A38G) downstream from the transcription initiation site within the noncoding region of exon 1 correlates with reduced BAL fluid levels of CC10 and disease progression. Further studies such as these will begin to define the repertoire of mutations that collectively determine the phenotype of subgroups of patients with sarcoidosis.

Table 29-1
Candidate Genes in Sarcoidosis

Susceptibility genes	
MHC class I	HLA-B7, B8
MHC class II	HLA-DR 11,12,14,15,17
MHC class III	D6S1666 microsatellite marker locus
Chemokines	CCR5delta32 (32-bp deletion)
Cytokines	TNF–857 promoter polymorphism
Vitamin D receptor	*Bsm*I restriction site in intron 8
Protective genes	
Major histocompatibility complex	HLA-DR1, DR4
Chemokines	CCR2-64I (valine to isoleucine substitution)
NRAMP	CA repeat polymorphism in immediate 5′ region
Genes associated with disease remission	
MHC II	HLA-DR3, DR5, DQB1*0201, DRB1*0301
Cytokines	TNF–308 promoter polymorphism
Genes associated with disease progression	
MHC II	HLA-DR14, DR15, DQB1*0602
Clara cell	G38A exon 1 polymorphism
Other associated genes in some studies	
MHC II	HLA-DQ*0202
Angiotensin converting enzyme	267 bp insertion/deletion in intron 16
Antigen processing and presentation genes	TAP, HLA-DM, DO, LMP2, LMP7
Cytokines	IL-1α*137 + F13A*188

HLA, human leukocyte-associated antigen; IL, interleukin; MHC, major histocompatibility complex; NRAMP, natural resistance associated macrophage protein; TCR, T-cell receptor; TNF, tumor necrosis factor.

ETIOLOGICAL TRIGGERS

Several lines of evidence, made possible by modern molecular genetic technology, support a pathophysiological construct in which granulomatous inflammation in sarcoidosis is antigen driven. Analysis of TCRs shows that the disease is neither a monoclonal proliferation of T cells, nor is it polyclonal as would be seen from nonspecific, diffuse immune activation. Rather, all characterizations of the T-cell response in sarcoidosis show an oligoclonal expansion of restricted T-cell clones, consistent with an antigen-driven process. Previously the putative antigen or antigens of sarcoidosis have remained elusive. Speculated environmental antigens such as pine pollen were not identified in large epidemiological investigations (a case–controlled etiological study of sarcoidosis).

The available data best supports microbial antigens as etiological triggers of sarcoidosis. A transmissible agent has long been suspected based on observations of localized disease outbreaks among individuals with close contact, increased rates of disease among health care workers, suspected transmission via organ transplantation, and sensitivity and specificity of the Kveim–Siltzbach reagent, in which an extract of tissue from sarcoid involved spleen elicits a cutaneous granulomatous reaction when administered subcutaneously to patients with sarcoidosis. This latter observation suggests that specific memory T cells are required for a positive test. Thus, sarcoid patients with a positive Kveim–Siltzbach reaction may already possess this T-cell repertoire resulting from previous exposure to or current colonization with the offending organism.

Although cultures from sarcoidosis tissue have only been reported to grow *Propionibacteria*, DNA from a number of different organisms has been amplified by polymerase chain reaction (PCR)

from sarcoidosis tissue. Most of these studies have either been insufficiently robust or nonreproducible to seriously implicate these agents as putative pathogens. However, *Mycobacteria* and *Propionibacteria* have emerged as the most plausible candidates.

MYCOBACTERIA Because of the clinical and pathophysiological similarities between sarcoidosis and tuberculosis (TB), extensive investigation for evidence of *Mycobacteria* in sarcoid tissue has been carried out. Although never consistently cultured from sarcoid granulomata, some studies have identified *Mycobacterial* DNA in these lesions. At least twenty PCR-based studies have examined the role of *Mycobacteria* in sarcoidosis (Table 29-2). These studies, with variable degrees of methodological strength, have yielded extremely variable results with mycobacterial DNA detected in 0–80% of cases. Mycobacterial catalase-peroxidase (mKatG) DNA and protein was found in 5/9 sarcoidosis patients in one study using a combination of molecular techniques including mass spectrometry, immunoblotting, and *in situ* hybridization. IgG antibodies to mKatG were detected in the sera of 12/25 patients. Detection of mKatG protein detergent/protease-treated sarcoidosis tissue suggests that poorly soluble protein aggregates containing mKatG may be the antigenic stimulus driving the granulomatous inflammation in a subset of patients with this disease.

PROPIONIBACTERIA *Propionibacteria* are anaerobic, Gram-positive bacteria that reside in the skin of humans around hair follicles. Because of a thick cell wall as well as other factors, a commensal relationship with the human host is the norm. An enhanced immune response against these organisms is thought to contribute to the pathogenesis of acne. In somewhat similar fashion, some investigators have proposed that sarcoidosis is the result of an activated immune response against *Propionibacteria*. Colonization of the respiratory tract and intrathoracic lymph nodes by these bacteria, and the development of an immune response against them, may explain the predilection of this disease for the chest. Table 29-3 summarizes the molecular studies of *Propionibacteria* on human sarcoid tissue. In contrast to the molecular studies of *Mycobacteria*, *Propionibacteria* have been consistently detected in high percentages of sarcoid lymph nodes. Because studies with *Propionibacteria* represent one example of how molecular medicine is forwarding our understanding of disease pathogenesis, these studies are described below.

Cultures of Sarcoid Lymph Nodes In 1978, Homma and colleagues investigated the bacterial growth (aerobic and anaerobic) from lymph nodes removed under aseptic conditions from patients with sarcoidosis. Although no aerobic bacteria were isolated, *Propionibacterium acnes* grew from approx 75% of the lymph nodes obtained from sarcoid patients (solid media: 28/40, liquid media: 31/40). No other bacteria or fungi grew in culture. In 1984, a second study with similar findings was published. Although *P. acnes* was cultured from 31/40 (77.5%) of sarcoid lymph nodes, only 38/180 (21%) of lymph nodes from control patients (cancer) grew the organism ($p < 0.001$). The percent positivity correlated strongly with the extent of granulomas within the cultured node. If greater than 75% of the node was involved with granulomatous inflammation, then 100% of cultures were positive. If 50–75% of the node was involved with granulomas, then 78% were positive. Nodes made up of less than 50% granulomas had a 67% positive culture rate. Despite these findings, *Propionibacteria* never emerged as a strong etiological candidate until the following molecular studies were reported.

Quantitative PCR In 1999, Ishige and colleagues published their initial findings using quantitative PCR to look for mycobacterial and propionibacterial DNA in lymph nodes from patients with sarcoidosis. Tissue samples were obtained from 15 patients with sarcoidosis, 15 patients with TB, and 15 control lymph nodes (without metastases) from patients with gastric cancer undergoing surgery. DNA was extracted from all 45 tissue blocks and subjected to quantitative PCR using probes specific for *P. acnes*, *Propionibacterium granulosum*, and *M. tuberculosis*. As expected, TB DNA was amplified in 15/15 nodes from TB patients. Genomes of *P. acnes* were found in 12/15 nodes from sarcoid patients. The remaining three nodes in which *P. acnes* was undetectable were remarkable for the amplification of DNA from *P. granulosum*. Although 2/15 TB nodes and 3/15 control nodes showed some amplification of *P. acnes*, levels of amplification were just above the threshold of detection and the number of genomes was significantly lower than that seen in sarcoid nodes.

These findings were extended in a multicenter study involving two Japanese and three European centers involving 108 patients with sarcoidosis, 65 patients with TB, and 86 controls. Control nodes were obtained from patients with either nonspecific lymphadenitis or cancer patients with no evidence of nodal metastases.

With robust methodology using real-time (TaqMan) PCR with primers specific for *P. acnes*, *P. granulosum*, *M. tuberculosis*, *Mycobacterium avium*, *Escherichia coli* (negative control), and β-globin (positive control), these investigators found either *P. acnes* or *P. granulosum* in lymph nodes from 106/108 patients with sarcoidosis. *P. acnes* was detected more frequently than *P. granulosum*, similar to the previous pilot study. Amplification of *P. acnes* from TB and control nodes ranged from 0 to 60%, depending on the center and source of the nodal tissue. Importantly, total numbers of genomes of *P. acnes* was lower in TB and control nodes than in nodes from patients with sarcoidosis. The only other country in which *Propionibacteria* have been investigated by this methodology is Greece. In contrast to the universal presence of *Propionibacteria* (98%) in sarcoid lymph nodes from the multicenter study described above, a study with Greek patients found propionibacterial genomes in 44% of sarcoid nodes examined from 46 patients, with no amplification in control nodes.

***In Situ* Hybridization** Evidence for *Propionibacteria* as a granulomatogenic stimulus of sarcoidosis was bolstered when the *in situ* localization of *P. acnes* in and around sarcoid granulomas was shown. With digoxigenin-labeled oligonucleotide probes specific for *P. acnes*, *in situ* hybridization was performed using catalyzed reporter deposition for signal amplification. Nine sarcoid lymph nodes and nine control nodes were examined. In all sarcoid nodes a signal was detected in epithelioid cells within granulomas and in mononuclear cells around granulomas. A similar signal was absent in control nodes, which included tuberculous granulomas. Although further characterization is necessary to confirm that these mononuclear cells with positive signal for *P. acnes* were indeed antigen-presenting cells, their location is highly suggestive. Moreover, this study, by showing *P. acnes* deep within the granuloma, refutes the hypothesis that findings by PCR represent contamination and suggests that *Propionibacteria* may indeed play an etiological role in sarcoidosis.

Animal Studies Animal studies with *Propionibacteria* show that granulomas develop in the lungs, lymph nodes, liver, and spleen following intravenous or intraperitoneal injection. Other features similar to sarcoidosis seen in mice following inoculation with these organisms include hilar adenopathy with nodal replacement by granulomatous inflammation, lymphopenia in the peripheral blood, and resistance to bacterial infection.

Taken together, these findings with *Propionibacteria* support what could be argued is one of the most attractive pathophysiological constructs for the immunopathogenesis of sarcoidosis. Propionibacterial DNA has been repeatedly and convincingly identified within granulomatous nodal tissue of large numbers of patients in Japan and Europe, DNA from this organism has been identified *in situ* within the granulomas on histological sections, and *Propionibacteria* are potent stimulators of granulomatous inflammation in animal models. Another interpretation of these findings, however, is that *Propionibacteria* propagate in nodal tissue of sarcoid patients resulting from an intrinsic immune defect in cell-mediated immunity, and that they may be associated with but not etiologically responsible for the development of disease.

MARKERS OF DISEASE ACTIVITY

PERIPHERAL LYMPHOPENIA One of the difficulties in managing patients with sarcoidosis is ascertaining the activity of disease at a given point in time. Peripheral lymphopenia is a simple marker of disease activity. The biological explanation for this phenomenon is that circulating lymphocytes are recruited to sites of active granulomatous inflammation, thus depleting the peripheral lymphocyte pool. As inflammation resolves with concomitant reductions in secreted cytokines and chemokines, as well as reduced adhesion molecule expression, a normal lymphocyte population is restored in the circulating blood.

ANGIOTENSIN-CONVERTING ENZYME Historically, the serum angiotensin-converting enzyme (ACE) was proposed and used as a serological marker of disease activity. Granulomas from some, but not all, patients secrete ACE, and levels can correlate with the activity of granulomatous inflammation. However, many patients with active sarcoidosis have normal ACE levels; therefore, this marker cannot be universally applied.

LYSOZYME Lysozyme is an antibacterial protein released from activated mononuclear phagocytes. Although it is nonspecific, levels of this enzyme are elevated in the serum of patients with sarcoidosis. Lysozyme levels have been shown to correlate with number of organs involved, radiographic stage, and are frequently elevated even in patients with normal ACE levels.

CYTOKINE MARKERS Following the identification of biological mediators present in sarcoidosis, several studies have been conducted regarding their potential use as markers of disease activity. Although levels of IFN-γ , IL-12, and IL-18 are indeed elevated in patients with sarcoidosis, there is considerable variability between individual patients as well as overlap with values observed in controls. Soluble forms of the TNF receptors are released into the BAL fluid and the bloodstream during active granulomatous inflammation. Elevated levels of soluble TNF-receptor II have been demonstrated in the serum of patients with active sarcoidosis, and these levels decrease in response to steroid therapy. Thus, serum levels of this soluble receptor may directly reflect the activation of macrophages within granulomas and may provide a novel serological marker of sarcoid inflammatory activity.

MECHANISMS OF THERAPY

With the remarkable progress in the understanding of the pathophysiology of sarcoidosis over the past decades, the mechanisms of action of the available therapies have become increasingly clear. Moreover, new, more selective, biologicals targeting some of the key mediators of disease have the potential to more potently suppress the inflammatory response of sarcoidosis with less toxicity than older agents.

CORTICOSTEROIDS Corticosteroids have been the mainstay of therapy for sarcoidosis since 1951, and their diverse actions on multiple cell types are responsible for their efficacy. Steroids enhance the expression of inhibitor κB, therefore reducing the amount of nuclear factor-κB available for translocation to the nucleus in which it can induce proinflammatory gene transcription. In part through this mechanism, steroids inhibit the expression of a number of proinflammatory cytokines important to granulomatous inflammation, including IL-2, IL-8, IL-12, IFN-γ, and TNF-α. In addition, they promote apoptois of activated T cells and reduce cellular activation. Despite these potent immunosuppressive effects, some studies suggest that long-term outcomes in sarcoidosis are only minimally affected by corticosteroid treatment. Moreover, although most patients appear to be at least somewhat steroid responsive, some have steroid refractory disease. Because of these issues and the well-known complications of long-term corticosteroid therapy, alternative agents are often necessary.

ANTIMALARIALS Chloroquine and hydroxychloroquine have been used to treat sarcoidosis and are particularly efficacious for cutaneous and mucosal disease. These drugs interfere with MHC–peptide interactions by altering the intravesicular pH, and thus are thought to reduce the amount of presented antigen. They inhibit the degradation of proteins by acid hydrolases within lysosomes, and inhibit the assembly and transport of MHC–peptide complexes to the cell surface.

METHOTREXATE Methotrexate interferes with purine metabolism and polyamine synthesis by inhibiting dihydrofolate reductase and transmethylation reactions. Low doses of methotrexate have anti-inflammatory properties by enhancing adenosine release from cells. Adenosine acts through G-protein coupled-cell surface receptors to produce a variety of effects including suppression of TNF, IL-6, IL-8, and reactive oxygen species release from macrophages, suppression of lymphocyte proliferation, and reduction in the expression of adhesion molecules important for lymphocyte trafficking.

TNF INHIBITORS In light of the critical role of TNF in granuloma formation, drugs that inhibit TNF production or action have become attractive therapeutic options for sarcoidosis. Pentoxyfylline is a methylxanthine derivative that acts by inhibiting phosphodiesterase and thus raising intracellular cAMP. This drug inhibits TNF production by alveolar macrophages and inhibits IL-12 production by blood mononuclear cells. Unfortunately, because of gastrointestinal side effects, it remains difficult to achieve therapeutic doses of sufficient magnitude to suppress cytokine production in vivo.

Thalidomide also inhibits TNF production by mononuclear cells and has shown efficacy in cutaneous sarcoidosis. In addition to TNF inhibition, thalidomide also has suppressive effects on several other cytokines. However, thalidomide both suppresses and enhances IL-12 production depending on the experimental conditions, and its efficacy for granulomatous involvement of organs other than the skin is questionable. Finally, its use has been limited by important toxicities including teratogenicity and peripheral neuropathy.

Infliximab is a chimeric mouse/human monoclonal antibody that binds TNF-α, preventing its interaction with the TNF-receptor. Its efficacy in rheumatoid arthritis and Crohn's disease suggests that it may also be beneficial in sarcoidosis. Indeed, several case reports and small case series have reported impressive results in patients with sarcoidosis. Given the important role of TNF in immunity, it is not surprising that infliximab increases susceptibility to infection, and can lead to disseminated disease in patients with indolent TB masquerading as sarcoidosis. The efficacy and safety of infliximab for sarcoidosis is being evaluated in large, multicenter trials.

ANTIBIOTICS Because accumulating data suggest that sarcoidosis may be caused by an exaggerated immune response against microbial peptides, antibiotics may have the potential to eradicate the triggering antigen. One small, uncontrolled study with minocycline for chronic, cutaneous sarcoidosis yielded impressive results with 83% of patients responding (67% complete remission of lesions, 16% partial remission). All patients with elevated ACE levels and lymphopenia at the onset of the trial showed normalization of ACE and resolution of lymphopenia with antibiotic therapy. Although bacterial killing may, in part, explain the efficacy of this intervention, tetracyclines have many anti-inflammatory properties that may contribute to the suppression of granulomatous inflammation in sarcoidosis. For example, tetracyclines inhibit chemotactic and phagocytic functions of leukocytes, block lymphocyte proliferation, and inhibit granuloma formation in vitro. Minocycline inhibits the proliferation of CD4+ T cells in response to TCR activation as well as the secretion of IL-2, IFN-γ, and TNF-α by them. Finally, minocycline inhibits TNF-α production by human keratinocytes. Although these results with mincocyline in cutaneous sarcoidosis are intriguing, larger, randomized clinical trials will be required to confirm the observations of this pilot study and to determine, if reproducible, the efficacy in other affected organs as well as in other diverse populations.

CONCLUSION

More effective treatment of sarcoidosis depends critically on a fundamental understanding of disease pathogenesis, at both the cellular and molecular levels. Significant strides have been made in the knowledge of the immunopathogenesis of sarcoidosis. Immunological studies have provided compelling evidence that an antigen is indeed driving the granulomatous inflammation of sarcoidosis, and molecular studies have revealed that components of an endogenous microbial organism may be one of the elusive antigens. The same technology that has made these studies possible can potentially be translated into a diagnostic test in hospital molecular genetics labs for the detection of putative antigens in individual patients.

In addition to an inciting antigen, the genetic make-up of the host appears to be a critical determinant not only for the initial development of an immunological response against the sarcoid antigen(s), but also for determining the course of disease. In this regard, the MHC region on the short arm of chromosome 6 has been most intensely investigated, and a number of genes in this area have been associated with risk and clinical course of disease. In a genome wide microsatellite linkage analysis to identify chromosomal regions contributing to the risk of sarcoidosis, the most prominent peak was found at the MHC. Candidate genes in this region include HLA genes, as well as immune response genes such as TNF-α.

The observation that TNF-α is critical for granulomatous inflammation has had important clinical translation. A serum assay that measures levels of the soluble receptor for TNF has been developed and may emerge as a sensitive marker of disease activity that can be used to follow the course of disease in the clinic. Anti-TNF therapies have been developed and early studies suggest that they may be the most potent suppressors of granulomatous inflammation available. If additional evidence continues to support a role for microbes as etiological triggers, then combination therapy with antibiotics aimed at eradicating the inciting organism, in combination with targeted immunosuppressive therapy to dampen an exuberant immune response, may offer patients a novel treatment approach with less toxicity and better efficacy than other options.

30 Disorders of Pulmonary Surfactant Homeostasis

Jeffrey A. Whitsett, Susan E. Wert, and Bruce C. Trapnell

SUMMARY

Pulmonary surfactant is required for adaptation to air breathing after birth, reducing surface tension at the air–liquid interface in the alveolus to maintain lung volumes during the respiratory cycle. Disorders of pulmonary surfactant homeostasis are associated with acute and chronic respiratory disease in infants and adults. Mutations in the surfactant protein genes encoding SP-B and SP-C cause severe respiratory failure in infancy and chronic interstitial lung disease in older individuals.

Key Words: ABCA3 transporter; pulmonary alveolar proteinosis (PAP); pulmonary surfactant; *SFTPB*; surfactant proteins B (SP-B).

INTRODUCTION

Pulmonary surfactant is required for adaptation to air breathing after birth, reducing surface tension at the air–liquid interface in the alveolus to maintain lung volumes during the respiratory cycle. Pulmonary surfactant is a complex mixture of proteins and lipids whose synthesis, packaging, secretion, and catabolism are tightly controlled at transcriptional and post-transcriptional levels. It is well established that the lack of pulmonary surfactant causes respiratory distress syndrome (RDS) in preterm infants. Abnormalities in surfactant content, composition, and function are also associated with acute RDSs in older patients in a variety of clinical conditions associated with lung injury. As the genetic and cellular systems regulating surfactant homeostasis are increasingly understood, gene mutations, and abnormalities in the pathways mediating surfactant homeostasis are being implicated in the pathogenesis of both acute and chronic pulmonary disorders (Table 30-1). This chapter summarizes disorders of surfactant metabolism, including lung diseases caused by mutations in genes encoding surfactant proteins (SP)-B, -C the ABCA3 transport protein, and those related to abnormalities in granulocyte macrophage-colony stimulating factor (GM-CSF) signaling.

THE PULMONARY SURFACTANT SYSTEM Pulmonary surfactant is a lipid/protein complex that is synthesized by type-II epithelial cells lining the alveoli of the lungs (Fig. 30-1). Surfactant lipids, predominantly phosphatidylcholine, and SP-B and SP-C, are cotransported to lamellar bodies, the major intracellular storage organelle of pulmonary surfactant. Lamellar bodies are exocytosed into the airspace in response to stretch, β-adrenergic, and purinergic agonists. After exocytosis, lamellar bodies unravel and undergo a dramatic change in ultrastructural morphology, producing tubular myelin that represents the major extracellular pool of surfactant lipids from which mono- and multilayered films are formed. The lipid-rich films spread at the air–liquid interface in the alveoli and reduce surface tension, preventing alveolar collapse. Heavy (lamellar bodies and tubular myelin-rich forms) and light (lipid vesicles) can be isolated by differential centrifugation of lavage fluid obtained from the lung. The small aggregate fraction likely represents lipid remnants that are destined for uptake and reutilization or catabolism by type-II cells and alveolar macrophages (AMs). The large aggregate surfactant fraction is highly surface active. Surfactant pool sizes are relatively large at birth (50–100 mg/kg) and fall postnatally to adult levels of approx 5–10 mg/kg. Deficiency of pulmonary surfactant is associated with RDS in preterm infants, a common cause of infant morbidity and mortality. Intracellular and extracellular surfactant pool sizes are precisely maintained by the regulation of synthesis, secretion, reuptake, reutilization, and catabolism.

DISORDERS OF SP-B GENE *(SFTPB)*

SP-B is a 79 amino acid, amphipathic polypeptide that is produced by proteolytic processing of a 381 amino acid precursor as it is trafficked through the endoplasmic reticulum, Golgi apparatus, and multivesicular bodies, to the lamellar bodies in which the active peptide is stored. SP-B and SP-C are packaged together with surfactant lipids in the lamellar bodies and are secreted into the alveolus. The active 79 amino acid peptide is an amphipathic structure that interacts strongly with the choline and glycerol head groups of the surfactant phospholipids. SP-B is fusiogenic, creating extended lipid layers (monolayers and multilayers) that form highly stable films in the alveoli. SP-B enhances the spreading and stability of surfactant lipids and is critical for surfactant tension reduction during respiration. The importance of SP-B in pulmonary homeostasis was shown in SP-B gene knockout mice (*Sftpb*$^{-/-}$) and in infants bearing mutations in the *SFTPB* gene. SP-B null mice and infants with mutations in *SFTPB* die of respiratory distress after birth. Marked ultrastructural abnormalities are observed in type-II epithelial cells in the lungs of SP-B-deficient mice, including the lack of lamellar bodies, accumulation of

Table 30-1
Disorders of Surfactant Homeostasis

Gene	*Inheritance*	*Phenotype*	*Defect*
ABCA3	Autosomal-recessive	RDS, ILD	Surfactant packaging
SFTPB	Autosomal-recessive	RDS	Surfactant packaging function
SFTPC	Autosomal-dominant	RDS, ILD	Surfactant function misfolded protein
GM-CSF	Not familial	PAP	Defect in alveolar macrophage

GM-CSF, granulocyte macrophage-colony stimulating factor; ILD, interstitial lung disease; PAP, pulmonary alveolar proteinosis; RDS, respiratory distress syndrome.

abnormal, large multivesicular bodies (lamellar body precursors), absence of tubular myelin, and lack of surfactant activity.

HEREDITARY SP-B DEFICIENCY Hereditary SP-B deficiency was first recognized in full-term infants dying from respiratory distress following birth. Since then, more than 75 infants in unrelated families have been identified with this disorder. Hereditary SP-B deficiency is an autosomal-recessive disease caused by mutations in the *SFTPB* gene that is located on human chromosome 2. More than 25 distinct mutations, including nonsense, missense, and stop codons have been identified. Mutations in the *SFTPB* gene results in either lack of SP-B mRNA with lack of protein production or the production of abnormal SP-B proproteins that result in misprocessed protein and lack of synthesis of the active SP-B protein. SP-B is required for the normal routing and packaging of surfactant lipids and SP-C in type-II epithelial cells of the lung. Thus, deletion of SP-B also results in the absence of SP-C in the airspaces. Mutations in SP-B generally cause lethal respiratory distress following birth. Several patients with partial defects in SP-B synthesis have been identified, their mutations causing severe chronic lung disease in infancy.

GENETICS Hereditary SP-B deficiency is a relatively rare, autosomal-recessive disorder; the carrier rate for mutations in *SFTPB* is estimated to be 1 in 600. A number of distinct mutations in the SP-B gene have been associated with hereditary SP-B deficiency. Mutation in exon 4 (termed the 121 insert) is the most common allele associated with this disorder, being detected in 50–60% of the affected individuals. Homozygous *SFTPB* 121 insert, and compound *SFTPB* 121 insert inherited in association with other *SFTPB* mutations have been detected. Although most mutations result in complete lack of SP-B protein in lung lavage, mutations in which alternative splicing results in production of some SP-B have been associated with chronic lung disease. Although mutations in *SFTPB* generally cause fatal respiratory distress after birth, haploinsufficiency has not been associated with a recognizable clinical disease in the few carriers studied. Heterozygous SP-B knockout mice are susceptible to lung injury and have subtle abnormalities in lung physiology at baseline, suggesting that partial reduction of SP-B may enhance susceptibility to pulmonary disease.

CLINICAL FINDINGS AND DIAGNOSIS IN HEREDITARY SP-B DEFICIENCY Human SP-B deficiency generally presents in full-term infants who develop respiratory distress after birth. In the most affected infants, grunting, retractions, and cyanosis are observed immediately after birth. Symptoms are generally observed before 12 h of age. History of affected family members and/or consanguinity has been associated with the disorder. Consistent with those of RDS in preterm infants, radiographic findings in full-term infants without other underlying causes of respiratory failure include diffuse alveolar infiltrates, alveolar collapse, reticular-granular infiltrates, and air bronchograms. Respiratory distress is progressive. In spite of oxygen and assisted ventilation, surfactant replacement, and/or extracorporeal membrane oxygenation, most infants die in the first weeks or months of life. Surfactant replacement is not effective, the infants generally having no or transient responses to therapy. Definitive diagnosis is made by identification of mutations in both alleles of the *SFTPB* gene. Lung histology is influenced by age and therapies that have been used to support the infant. Marked histological abnormalities are observed at autopsy or biopsy, with evidence of diffuse alveolar and bronchiolar damage, atelectasis, hyaline membrane interstitial thickening, type-II cell hyperplasia, accumulation of AMs, and proteins in the alveoli, often diagnosed as infantile desquamating interstitial pneumonitis (DIP) or congenital pulmonary alveolar proteinosis (PAP) (Fig. 30-2). Immunohistochemical staining for SP-B or pro-SP-B antibody results in lack of staining when SP-B mRNA is not produced (121 insert). Abnormal accumulation of mutant pro-SP-B or its processing intermediates has been observed in lungs of patients with mutations in which the abnormal proteins are produced and accumulate in either lung cells or within the airspace. Enzyme-linked immunosorbent assay and immunoblot analysis of lung secretions or lung tissue homogenates have been useful in screening for hereditary SP-B deficiency but may not be specific. The absence of SP-B in tracheal aspirates indicates an increased likelihood of the disorder but is not diagnostic. Because SP-B is required for the processing and secretion of SP-C, most mutations in SP-B also cause misprocessing of pro-SP-C and accumulation of an abnormal pro-SP-C peptide in the alveoli that can be detected immunohistochemically or by Western blot analysis. Detection of this pro-SP-C fragment is relatively specific for human SP-B deficiency. Hereditary SP-B deficiency is generally fatal in the neonatal period and no effective therapies have been identified. A number of infants have undergone lung transplantation with prolongation and improvement of life.

DISORDERS OF THE SP-C GENE *(SFTPC)*

A single gene encoding SP-C *(SFTPC)* is located on human chromosome 8. SP-C RNA produces a 191 amino acid proprotein from which the active peptide is produced by proteolytic processing in type-II epithelial cells of the lung. The active SP-C peptide associated with surfactant in the airspaces is a 35 amino acid polypeptide expressed only in type-II epithelial cells in the alveoli of the lung. SP-C was initially isolated from surfactant lipid extracts that were used to treat RDS in replacement surfactant preparations, prepared from mammalian lung. Pro-SP-C is palmitoylated and cotrafficked with pro-SP-B through the endoplasmic reticulum and multivesicular bodies to the lamellar bodies of type-II epithelial cells. Proteolytic processing occurs during transit to lamellar bodies. The active SP-C peptide is associated with surfactant lipids, packaged in lamellar bodies and secreted into the alveolar space with the active SP-B peptide and lipids. SP-C inserts into phospholipid films and vesicles via an extremely hydrophobic, α-helical domain that interacts with the acyl groups of the surfactant lipids. The active SP-C peptide is palmitoylated via covalent linkage to cysteine residues near its amino terminus. SP-C disrupts acyl group packaging in lipids, enhances their

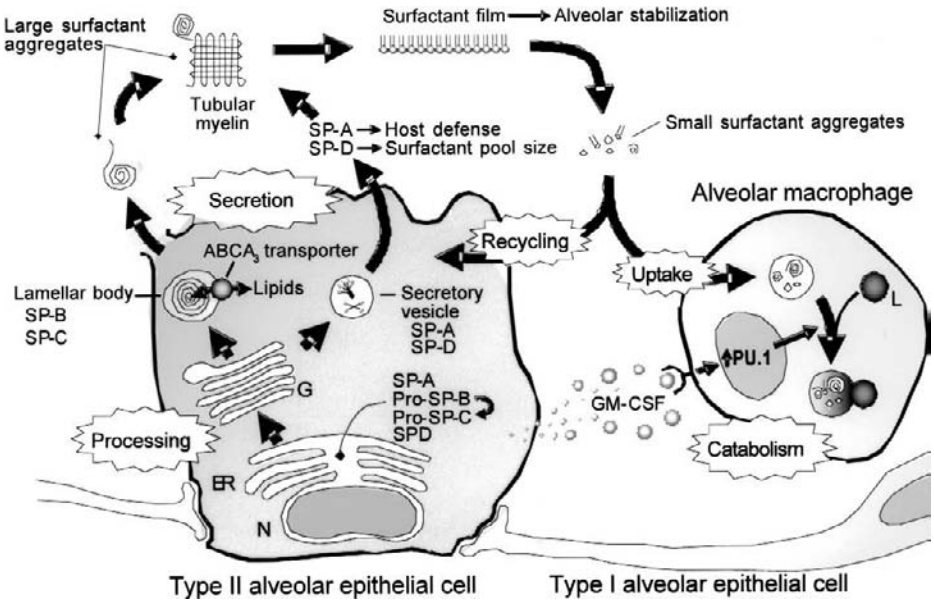

Figure 30-1 Pulmonary surfactant metabolism and homeostasis. The genes encoding surfactant protein (SP)-A, pro-SP-B, pro-SP-C, and SP-D are transcribed in the nucleus of alveolar type-II epithelial cells, translated into nascent polypeptides in the endoplasmic reticulum and processed in the Golgi network (processing). SP-B and SP-C are assembled into lamellar bodies along with surfactant phospholipids, the transport of which may be regulated by the ABCA3 transporter molecule, which is found in the limiting membrane of these organelles. SP-A and SP-D are secreted via nonlamellar body secretory vesicles. Following exocytosis of lamellar bodies and secretory vesicles into the alveolar surface liquid (secretion), lamellar bodies assemble into structures known as tubular myelin as well as large and small aggregate forms. Phospholipids from these extracellular structures move to form a continuous surfactant film that lines the alveolar spaces and airways with polar heads oriented toward the liquid and acyl chains toward the air. Surfactant large aggregate forms, extracellular lamellar bodies and tubular myelin, all have surface-active properties. Surfactant is inactivated by mechanical and biological processes and converted into the surface-inactive, small aggregate forms. Of surfactant small approx 70–80% aggregate forms are taken up by alveolar type-II cells, sorted to lysosomes and reutilized (recycling) or catabolized (not indicated). Alveolar macrophages internalize (uptake) and degrade the remaining small surfactant aggregates (catabolism). The latter process is critical for surfactant homeostasis and is dependent on granulocyte macrophage-colony stimulating factor, which acts via the transcription factor, PU.1, to stimulate catabolism of surfactant lipids and proteins as well as a number of other immune functions of alveolar macrophages.

spreading, and recruits lipids to the surface films to confer surfactant-like activity to purified surfactant lipids. Although SP-B and SP-C interact with lipids via distinct structures, both enhance surfactant activity and are active components of surfactant replacement preparations used clinically. Targeted disruption of the *SFTPC* gene in mice produces an unstable surfactant. In some strains of mice, deletion of SP-C causes severe interstitial lung disease, providing strong evidence for its importance in surfactant function and pulmonary homeostasis.

HEREDITARY SP-C DEFICIENCY Both lack of SP-C and mutations in the gene encoding SP-C *(SFTPC)* have been associated with acute and chronic lung disease in infants and adults. One family has been identified in which the mother and two daughters developed severe interstitial lung disease associated with the lack of production of SP-C, as assessed in lung lavage fluid, and by decreased immunostaining for pro-SP-C in lung biopsies. These findings are consistent with the observation that mice bearing a null allele for the *Sftpc* gene develop severe interstitial lung disease in the postnatal period. Mutations in the *SFTPC* gene cause both acute and chronic pulmonary disease in humans. *SFTPC* mutations also have presented with respiratory failure in the first days of life in full-term infants who develop unexplained respiratory distress, with clinical findings similar to those in SP-B deficiency. More commonly, mutations in *Sftpc* have been associated with chronic interstitial lung disease in infants, with histology being variably classified as chronic pneumonitis of infancy, nonspecific chronic interstitial pneumonitis, and DIP. In adults, the disorder is classified as idiopathic pulmonary fibrosis, usual interstitial pneumonitis, nonspecific interstitial pneumonitis, or DIP. Although the age of onset and severity of the disease and pathological findings are highly variable, mutations in *SFTPC* are generally inherited in an autosomal-dominant manner, resulting in severe interstitial lung disease and susceptibility to acute respiratory failure following injury or infection. Variability in histopathological findings is likely related in part to distinct mutations, age, and environmental factors, and other genetic modifiers that influence the course of the disease and the pathology observed. A number of *SFTPC* alleles have been associated with severe pulmonary disease. An extended family bearing a dominantly inherited *SFTPC* gene was described in kindred of 16 individuals, most of whom developed severe interstitial lung disease. Chronic lung disease caused by *SFTPC* mutations manifests at various ages from childhood to adulthood. Dyspnea, clubbing, cyanosis, oxygen requirement, and pulmonary exacerbations following viral and other infections are common features of the disorder. Pathological findings include alveolar proteinosis, DIP, alveolar thickening, fibrosis, and mononuclear infiltration (*see* Fig. 30-2). Definitive diagnosis is made by identification of mutations in the *SFTPC* gene. A history of dominantly inherited idiopathic pulmonary fibrosis and RDS supports the likelihood of the diagnosis. However, *de novo* mutations in *SFTPC* appear to occur relatively frequently in this disorder. Immunostaining for pro-SP-C reveals intense staining of pro-SP-C or pro-SP-C peptides in type-II epithelial cells, likely representing accumulation of misfolded or

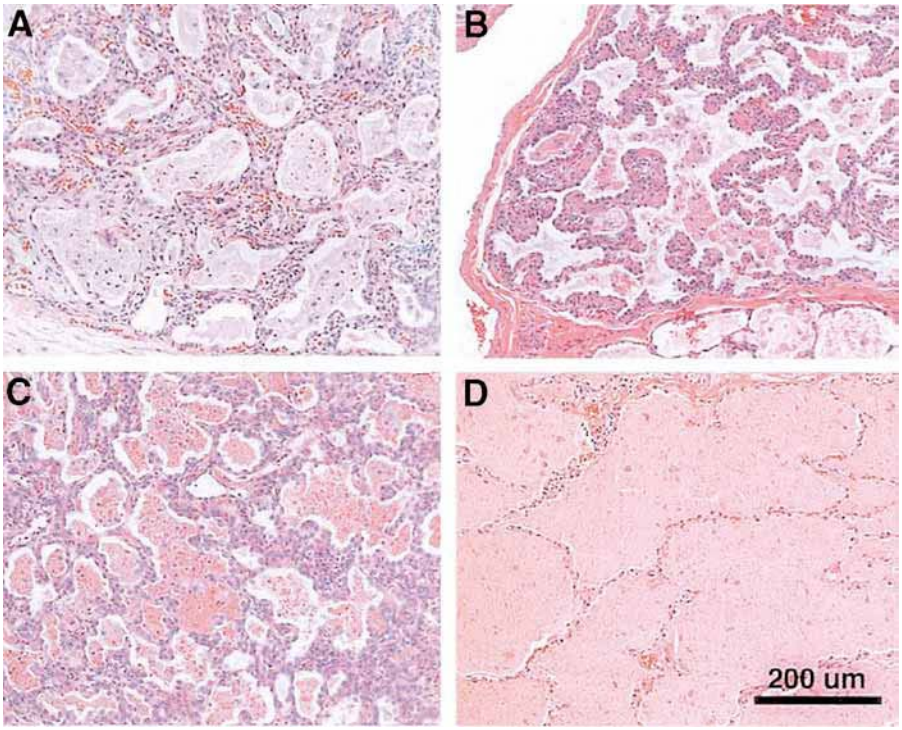

Figure 30-2 Histopathology of surfactant abnormalities found in the lungs of human patients with **(A)** mutations in the *SFTPB* gene, **(B)** mutations in the *SFTPC* gene, **(C)** mutations in the *ABCA3* gene, **(D)** and antibodies to granulocyte macrophage-colony stimulating factor. The histopathological findings in infants with mutations in the *SFTPB*, *SFTPC*, and *ABCA3* genes (panels A, B, and C, respectively) are remarkably similar, demonstrating varying degrees of interstitial thickening and muscularization of the alveolar septae, remodeling of the alveolar epithelium with type-II cell hyperplasia, as well as accumulation of eosinophilic, proteinaceous, granular material, and alveolar macrophages in the airspaces. However, histopathological findings in adults with antibodies to GM-CSF demonstrate thin-walled, expanded alveoli filled with very uniform, granular, eosinophilic material that is relatively devoid of macrophages. All tissue sections were stained with H&E. All panels are shown at the same magnification. Bar = 200 μm.

misprocessed pro-SP-C. The abnormal pro-SP-C protein interferes with the routing and processing of the pro-SP-C produced from the normal *SFTPC* allele. The pathogenesis of lung disease associated with mutations in *SFTPC* is not known with clarity. It is unclear whether the lack of the active SP-C peptide, pro-SP-C or cytotoxic effects of the accumulation of mutant pro-SP-C proteins contribute to the disease pathogenesis. Definitive therapies for *SFTPC* mutations have not been developed, and many of these patients develop severe respiratory disease. Lung transplantation has resulted in improved longevity and quality of life for some individuals with *SFTPC* mutations.

DISORDERS OF THE ABCA3 TRANSPORTER

Mutations in the ABCA3 transporter have been identified as a cause of acute RDS in term and newborn infants, and the cause of chronic interstitial lung disease in older individuals. ABCA3 is a 1704 amino acid, multiple transmembrane protein of the family of ABC transport proteins, of which the cystic fibrosis transmembrane regulator (CFTR) and the multiple drug resistance protein are members. Although the precise function of the ABCA3 transporter is unknown, its homologues are involved in lipid transport. ABCA3 is expressed in type-II epithelial cells of the lung, being detected at the limiting membranes of lamellar bodies in type-II epithelial cells (*see* Fig. 30-1). The structure of the ABCA3 transporter and its localization suggest its potential role in lipid transport to or from the lamellar bodies, implying its role in intracellular lipid homeostasis.

MUTATIONS IN *ABCA3*: CLINICAL FINDINGS Mutations in the human *ABCA3* gene have been associated with fatal RDS in term newborn infants. The disorder is inherited in an autosomal-recessive manner. History of consanguinity and a family history of fatal neonatal respiratory distress support the likelihood of the disorder. Mutations have been found throughout the *ABCA3* gene. Like CFTR, ABCA3 is a relatively large multiple transmembrane protein. Like *CFTR*, mutations in *ABCA3* are likely to influence the levels of protein folding, routing, and trafficking to lamellar bodies, and its degradation or function. Although clinical findings in older individuals with the mutations in *ABCA3* are not fully clarified, chronic interstitial lung disease has been associated with the disorder and is under intense clinical study. Radiological findings are consistent with RDS in the newborn infants. Diffuse pulmonary opacification, reticular-granular infiltrates, and air bronchograms are observed. Infants present with grunting, retractions, and cyanosis in the first days of life, and rapidly develop respiratory failure that is refractory to ventilation, surfactant replacement, and extracorporeal membrane oxygenation. Alveolar proteinosis, and mixed AMs, alveolar wall thickening, and type-II cell hyperplasia, consistent with diagnosis of chronic pneumonitis of infancy and PAP, have been observed by microscopy at light and electron microscopic levels (*see* Fig. 30-2). Lamellar bodies are lacking or small, supporting the concept that the ABCA3 transporter affects surfactant lipid transport pathways. There are no known definitive therapies for lung disease caused by mutations in *ABCA3*. In spite of intensive care, affected individuals generally

die from respiratory failure in the neonatal period. Clinical findings and disease progression in older individuals with *ABCA3* mutations are not known with certainty.

PULMONARY ALVEOLAR PROTEINOSIS

PAP is a rare disorder characterized by accumulation of lipoproteinaceous material within alveoli, a variable clinical course ranging from respiratory failure to spontaneous resolution and a predilection for secondary opportunistic infections. PAP occurs in three clinically and pathogenetically distinct forms: congenital, secondary, and acquired. Congenital PAP is a heterogeneous group of disorders arising from mutations in the genes encoding SP-B, SP-C, and the ABCA3 transporter as described earlier. Secondary PAP can occur in clinical contexts associated with either functional impairment or reduced numbers of AMs including some hematological malignancies, pharmacological immunosuppression, inhalation of inorganic dusts (e.g., silica) or toxic fumes, and in certain infections. Acquired PAP (also known as idiopathic, primary, or autoimmune PAP), initially described in 1958, has a prevalence of 0.37/100,000 individuals. It occurs primarily as a primary disorder of unknown etiology; however, findings strongly suggest that acquired PAP is an autoimmune disorder directed toward the cytokine, GM-CSF. The acquired form accounts for 90% of PAP in adults and is the focus of the remainder of this chapter.

CLINICAL FINDINGS AND DIAGNOSIS OF PAP Acquired PAP usually presents in male smokers in the third decade, although it occurs without a gender bias in nonsmokers and also, albeit less commonly, in young children. Progressive exertional dyspnea of insidious onset and cough are typical (75%), whereas fever, chest pain, or hemoptysis also occur less commonly, especially if infection is also present. Significant pulmonary exposure is not a feature in most cases. The physical exam can be unremarkable or may show tachypnea, mild inspiratory crackles (50%), dyspnea (25%) and, infrequently, digital clubbing.

The plain chest radiograph reveals a patchy bilateral airspace disease often similar in appearance to pulmonary edema but without other radiographic signs of left heart failure. High-resolution CT shows patchy ground-glass opacifications with superimposed interlobular septal and intralobular thickening, which are typical but not diagnostic of PAP. Interestingly, the extent of the radiographic abnormalities can be disproportionately greater than expected based on the associated symptoms and physical findings. Routine laboratory tests are frequently within the normal range, however, serum lactate dehydrogenase can be elevated and may be a useful marker of disease severity or exacerbation. When abnormalities are present, pulmonary function tests reveal a restrictive ventilatory defect and a disproportionate, severe reduction of the diffusing capacity. Hypoxia can be significant and is caused by ventilation–perfusion mismatch and intrapulmonary shunt.

A diagnosis of PAP can be established by bronchoalveolar lavage in approx 75% of cases suspected resulting from clinical and radiographic findings. The bronchoalveolar lavage fluid is milky in appearance and forms waxy sediment on standing. Microscopically, it is acellular with relatively few inflammatory cells. AMs are abnormal in appearance ranging from small and monocyte-like to large foamy cells that are fragile and are destroyed during cytocentrifugation leaving large acellular eosinophilic bodies in a diffuse background of granular basophilic material. Both the proteinaceous material and AMs stain positively with periodic acid-Schiff reagent and SP immunohistochemical stains. Ultrastructural analysis reveals that the amorphous granular intra-alveolar material consists of surfactant. Open lung biopsy, the gold standard for diagnosis of PAP, reveals parenchymal architecture that is relatively preserved unless secondary infection is present. Alveoli are filled with granular material that is eosinophilic (*see* Fig. 30-2D) and stains strongly with periodic acid-Schiff reagent or by SP immunohistochemistry. A serological test has been developed for diagnosis of acquired PAP that is reported to have high sensitivity (100%) and specificity (98%).

The natural history of PAP typically is marked by persistent symptoms, which vary somewhat in intensity over time. Some individuals show spontaneous improvement (approx 8%) whereas others show progressive deterioration resulting in a 5-yr survival of 74.7 ± 8.1%. Most PAP deaths result directly from respiratory failure (approx 72%), whereas a smaller proportion are the result of uncontrolled infection (approx 20%). Secondary infections are common in PAP, unexpectedly owing to opportunistic pathogens such as *Nocardia* spp. The relatively frequent occurrence of extrapulmonary infections in PAP suggests a defect in systemic host defense.

PATHOGENESIS OF PAP The initial description of PAP established that the material accumulating in alveoli in PAP was made up phospholipids, lesser amounts of proteins, and minimal carbohydrates. Subsequent studies suggested that this material was pulmonary surfactant but failed to determine if the alveolar filling abnormality was because of increased production, decreased clearance, or the expression of abnormal surfactant lipids or proteins. Ultrastructural, biochemical, and functional studies together with studies in genetically modified mice strongly support the concept that the alveolar material in PAP is, in fact, surfactant, which accumulates resulting from reduced clearance rather than overproduction. The association of acquired PAP with smoking suggests a possible etiological link, however the mechanism of this is unknown. A prolonged search over three decades to identify a presumed "irritant" (e.g., silica or an infectious agent) thought to stimulate increased surfactant production was fruitless. Notwithstanding, a number of AM abnormalities were identified, perhaps the most striking of which were large membrane-bound, surfactant-filled intracellular inclusion bodies that imparted a foamy appearance to the cells. Functional abnormalities were also noted including defects in chemotaxis, adhesion, phagocytosis, microbicidal activity, and phagolysosome fusion. The "overstuffed AM" theory was advanced to explain these findings, however, support for the theory was weakened by the finding that lung lavage fluid from PAP patients could recapitulate some of these abnormalities in normal AMs. Further, identification of an "immunoinhibitory" activity in the lungs and sera of these patients, which blocked mitogen-stimulated proliferation of normal monocytes, suggested a circulating factor might be involved in the pathogenesis of PAP.

ROLE OF GM-CSF IN MURINE PAP An unexpected but important clue about the pathogenesis of PAP came in 1994 with the discovery that mice deficient in GM-CSF owing to gene ablation developed a pulmonary phenotype histologically similar to acquired PAP in humans. Before then, GM-CSF, a 23-kDa cytokine expressed similarly in humans and mice, was thought to primarily regulate growth of hematological cells in the bone marrow. However, the absence of gross baseline hematological disturbances in GM-CSF-deficient mice cast doubt on this belief. In contrast, development of PAP in these mice established a critical role for GM-CSF in the lung. Biochemically, histologically, and ultrastructurally, the alveolar material in murine PAP was similar to that derived from the lungs of human individuals with acquired PAP. Biochemical and molecular biological studies of these mice established that the disruption in surfactant homeostasis was not

because of a decrease in production of surfactant. Rather, it was owing to a decrease in surfactant clearance secondary to decreased catabolism of both surfactant lipids and SP by AMs. Despite this catabolic defect, uptake of both surfactant lipids and proteins by AMs is not impaired, which accounts for the large foamy appearance of these cells that is characteristic of PAP.

A series of studies established that GM-CSF maintains surfactant homeostasis by regulation of surfactant catabolism by AMs. Double transgenic mice carrying an ablated GM-CSF gene and a transgene that expressed GM-CSF specifically in the lungs failed to develop PAP, thus demonstrating the lung as the site of action of GM-CSF. However, this study did not identify the precise cellular target of GM-CSF: did the critical regulation of surfactant homeostasis by GM-CSF involve AMs or alveolar type-II epithelial cells? This question was answered using another murine model of PAP caused by GM-CSF receptor gene ablation. Transplantation of bone marrow from mice with normal GM-CSF common β-chain receptor ($R_\beta c$) expression into GM $R_\beta c^{-/-}$ mice resulted in resolution of defective surfactant metabolism in PAP. Because in the recipient mice, only the AMs derived from the donor mice, but not alveolar type-II epithelial cells were responsive to GM-CSF; these results demonstrated that AMs were the principal therapeutic target of GM-CSF replacement.

The discovery that GM-CSF- and GM-CSF $R_\beta c$-deficient mice develop PAP prompted a re-evaluation of the pathogenesis of human-acquired PAP as a disorder of GM-CSF deficiency. No genetic mutations in either GM-CSF or its receptor have been identified in adult individuals with acquired PAP. Furthermore, the levels of immunoreactive GM-CSF are increased in PAP, not decreased as would be predicted based on the mouse findings.

AUTOIMMUNE ANTI-GM-CSF AUTOANTIBODIES A critical observation was made by researchers linking the pathogenesis of human-acquired PAP to GM-CSF through a series of experiments that re-examined the "immunoinhibitory" activity present in these patients. PAP lung lavage fluid, but not that of normals, inhibited GM-CSF-dependent proliferation of TF-1 cells and competitively inhibited binding of GM-CSF to cellular GM-CSF receptors or an anti-GM-CSF monoclonal antibody. This group subsequently identified the inhibitory activity in acquired PAP to be a neutralizing anti-GM-CSF antibody of the immunoglobulin G isotype class. The antibody is present in all cases of acquired PAP but not in cases of congenital or secondary PAP, other lung disorders or normal controls. Anti-GM-CSF autoantibodies are polyclonal, present at very high levels in blood and lungs, and bind GM-CSF with very high affinity. Importantly, they eliminate GM-CSF bioactivity from the lungs; the neutralizing capacity exceeds the GM-CSF concentrations by up to 20,000-fold. Thus, although GM-CSF itself is not absent in the lungs in acquired PAP, it is biologically inactivated by the neutralizing anti-GM-CSF autoantibody.

GM-CSF AND TERMINAL DIFFERENTIATION OF AM The clinical laboratory abnormalities of AMs in acquired PAP prompted detailed studies in GM-CSF deficient mice ($GM^{-/-}$). AMs from $GM^{-/-}$ mice had numerous abnormalities including defects in cell adhesion, cell-surface pathogen recognition receptor expression, nonspecific and receptor-mediated phagocytosis, superoxide production, microbial killing, and proinflammatory cytokine secretion. These diverse abnormalities suggested that pulmonary GM-CSF deficiency may cause a maturational defect in AMs. Strong support for this hypothesis came from the observation that the presence and level of pulmonary GM-CSF regulates the presence and level of PU.1 in AMs. PU.1 is a transcription factor known to stimulate proliferation and differentiation of myeloid progenitors and is required for production of macrophages. The maturational defect hypothesis was further strongly supported by the observation that retroviral-mediated replacement of PU.1 in cultured AMs from GM-CSF-deficient mice restored all of the abnormalities described above and corrected abnormalities in catabolism of surfactant lipids and protein. Together, these data demonstrated that GM-CSF, via PU.1, stimulated the terminal differentiation of murine AMs in the lungs. These studies have established that GM-CSF, via PU.1, regulates surfactant homeostasis as well as several mechanisms of AM-mediated innate immunity in the murine lung (Fig. 30-3). The striking similarities in PAP histopathology, AM morphology, and parallels in macrophage dysfunction in murine and human PAP suggest a common pathogenic mechanism: elimination of pulmonary GM-CSF signaling causes incomplete maturation and dysfunction of AMs.

IMPLICATIONS OF PULMONARY GM-CSF FOR MECHANISMS OF LUNG HOST DEFENSE As the pulmonary resident of the mononuclear phagocyte system, the AM plays a central role in lung host defense. Thus, dysfunction of these cells because of the absence of pulmonary GM-CSF signaling might be expected to impair lung host defense. Consistent with this concept, GM-CSF deficient mice have increased susceptibility to pulmonary infection by group B *Streptococcus*, and *Pneumocystis carinii* (after $CD4^+$-depletion) and had severely impaired pulmonary clearance of bacterial, fungal, and viral pathogens. Patients with acquired PAP have increased susceptibility to microbial lung infections, suggesting a defect in lung host defense. Based on the strong similarities in murine and human PAP, it is tempting to speculate that the presence of autoimmune anti-GM-CSF antibody may impair AM-mediated lung host defense mechanisms in humans, too. However, further studies are required to determine if this is true.

THERAPY OF PAP Treatment of PAP depends on the clinical context. Congenital PAP is treated by supportive care, although lung transplantation has been reported. Secondary PAP generally resolves with treatment of the underlying condition, for example, chemotherapy for hematological malignancy. The standard of care for acquired PAP is whole lung lavage. Although not documented in prospective, randomized trials, whole lung lavage improves clinical, physiological, and radiographic findings and improves survival in acquired PAP (5-yr survival: 94 ±2% with lavage vs 85 ±5% without lavage; $n = 146$, $p = 0.04$). In patients requiring repeated lavage, the median duration of clinical benefit from lavage has been reported to be 15 mo.

Several experimental therapeutic trials of GM-CSF administration in patients with acquired PAP have been or are being conducted. One trial evaluated subcutaneous GM-CSF in 14 PAP patients, and found an overall response rate of 43% with an improvement. An ongoing study in the United States is also evaluating subcutaneous GM-CSF therapy in acquired PAP. In Japan, a network of investigators is evaluating aerosolized GM-CSF in acquired PAP. Although early results from these trials are encouraging, no firm conclusions can be drawn regarding the effectiveness of GM-CSF therapy for acquired PAP. Interestingly, however, a decrease in pulmonary anti-GM-CSF antibody levels in association with clinical improvement has suggested that "desensitization" to GM-CSF may be involved. Other experimental therapeutic approaches under current consideration include plasmapheresis, immune globulin, and agents to decrease B-lymphocyte antibody production.

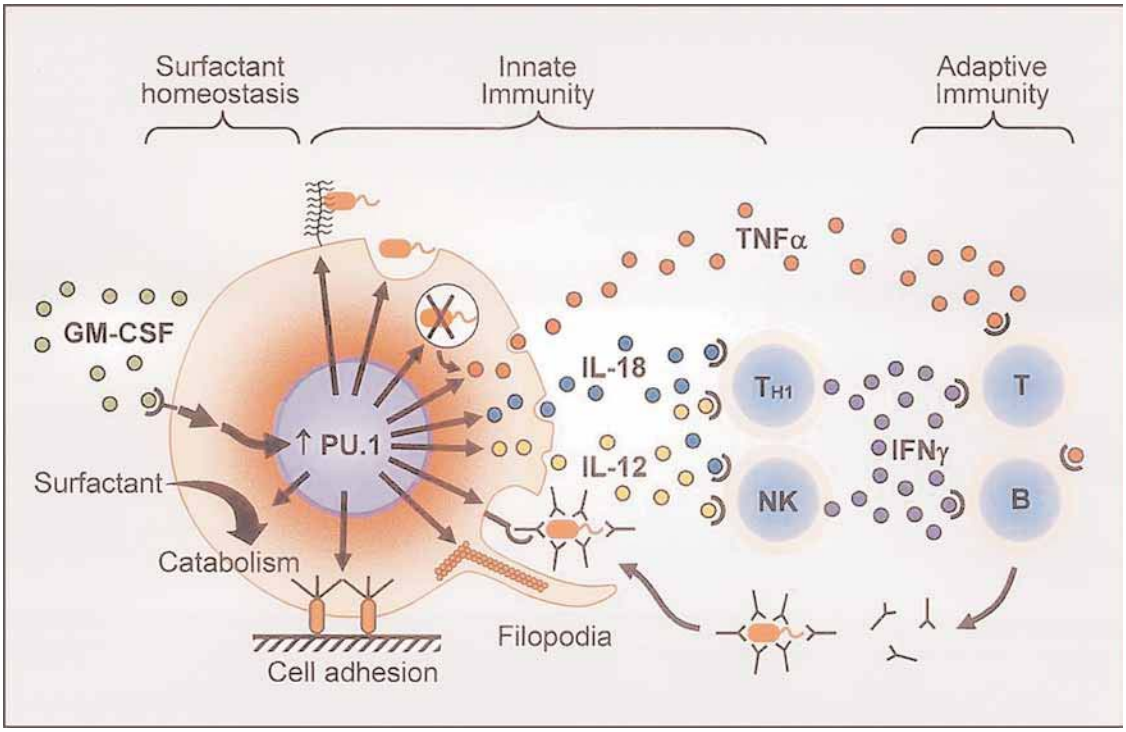

Figure 30-3 Model illustrating role of granulocyte macrophage-colony stimulating factor in modulation of murine alveolar macrophage function. Pulmonary GM-CSF stimulates PU.1 levels in alveolar macrophages in the lung. Alveolar macrophages from GM-CSF knockout mice have a number of functional abnormalities including defects in cell adhesion, surfactant catabolism, expression of microbial pathogen-associated molecular pattern receptors (e.g., Toll-like receptors, mannose receptor), phagocytosis of bacteria, fungi and virus, intracellular killing of bacteria (independent of uptake), pathogen-stimulated secretion of cytokines (tumor necrosis factor-α, IL-12, IL-18), Fc receptor-mediated phagocytosis, and SP and lipid uptake/degradation. Cytoskeletal organization is abnormal and may in part account for defects in phagocytosis. The inability of alveolar macrophages to release IL-12/IL-18 severely impairs the interferon (IFN)-γ response to pulmonary infection, thus impairing an important molecular connection between innate and adaptive immunity in the lung. Retroviral vector-mediated constitutive expression of PU.1 in AMs from $GM^{-/-}$ mice corrects all of these defects, suggesting that GM-CSF stimulates terminal differentiation of alveolar macrophages through the global transcription factor PU.1.

CONCLUSION

Disorders of pulmonary surfactant homeostasis are associated with acute and chronic respiratory disease in infants and adults. Mutations in the SP genes encoding SP-B and SP-C cause severe respiratory failure in infancy and chronic interstitial lung disease in older individuals. Mutations in the ABCA3 transport protein disrupt lamellar body function and surfactant function to cause acute and chronic lung disease with histological features similar to those associated with mutation in the SP genes. Mutations in SFTPB, SFTPC, and ABCA3 disrupt surfactant function and cellular homeostasis in the respiratory epithelium. In contrast, alveolar proteinosis, associated with accumulation of normal SP and lipids, is a disorder of surfactant catabolism by AMs.

ENDOCRINOLOGY IV

SECTION EDITOR:
MICHAEL J. MCPHAUL

Abbreviations

IV. ENDOCRINOLOGY

17β-HSD	17β-hydroxysteroid dehydrogenase
17-OHP	17α-hydroxyprogesterone
17α-OH	17α-hydroxylase
21-OH	21-hydroxylase
21-OHD	21-hydroxylase deficiency
3β-HSD	3β-hydroxysteroid dehydrogenase
7-DHCR	7-dehydrocholesterol reductase
7-DHCR-D	7-dehydrocholesterol reductase deficiency
7TM	seven-transmembrane domain
AA	amino acid
ABC	ATP-binding cassette
ACTH	adrenocorticotropic hormone
ACTH-R	adrenocorticotropic hormone receptor
AD	adrenodoxin
αGSU	α glycoprotein subunit
AHC	adrenal hypoplasia congenita
AIS	androgen insensitivity syndromes
AITD	autoimmune thyroid disorders
ALD	adrenoleukodystrophy
ALK	activin receptor-like kinase
AME	apparent mineralocorticoid excess
AMH	anti-Müllerian hormone
AMH-R	anti-Müllerian hormone receptor
AMHR2	anti-Müllerian type II receptor
AMN	adrenomyeloneuropathy
ANP	atrial natriuretic peptide
APS-1	autoimmune polyglandular syndrome type 1
APS-2	autoimmune polyglandular syndrome type 2
AR	androgen receptor
ARE	androgen response element
ARTN	artemin
ATC	anaplastic thyroid carcinoma
ATF	activating transcription factor
ATRX	α-thalassemian/mental retardation, X-linked
AZF	azoospermia factor
bFGF	basic fibroblast growth factor
BMD	bone mineral density
BMP	bone morphogenetic protein
BMP-2	bone morphogenetic protein-2
BMPRIB	type I receptor for bone morphogenetic protein
BNP	brain natriuretic peptide
CAH	congenital adrenal hyperplasia
CAIS	complete androgen insensitivity syndrome
calpain	calcium-activated neutral proteases
CaM	calmodulin
cAMP	cyclic adenosine monophosphate
CaR	calcium-sensing receptor
CAT	chloramphenicol acetyltransferase
CATCH-22	cardiac anomalies, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia with deletion at 22q
CBAVD	congenital bilateral absence of vas deferens
CBP	CREB-binding protein
CDK	cyclin-dependent kinase
CDKI	cyclin-dependent kinase inhibitors
CFTR	cystic fibrosis transmembrane conductance regulator
CG	chorionic gonadotropin
CG-R	chorionic gonadotropin receptor
CLAH	congenital lipoid adrenal hyperplasia
CMO	corticosterone methyloxidase
CPHD	combined pituitary hormone deficiency
CREB	cAMP response-element binding protein
CRH	corticotropin-releasing hormone
CVS	chorionic villus sampling
CYP17	17α-hydroxylase 17,20-lyase
DAX1	dosage-sensitive sex reversal-adrenal hypoplasia congenita locus on the X chromosome, gene 1
DAX-1	DSS-AHC critical region of the X chromosome, gene 1
DAZ	deleted in azoospermia
DBD	DNA-binding domain
DGS	DiGeorge syndrome
DHEA	dehydroepiandrosterone
DHEA-S	dehydroepiandrosterone-sulfate
DHH	desert hedgehog
DHT	5α-dihydrotestosterone
DIDMOAD	diabetes insipidus, diabetes mellitus, optic atrophy and deafness
DIO	iodothyronine deiodinase
DIT	diiodotyrosine
DM	diabetes mellitus
DM1	dystrophia myotonica 1
DM2	dystrophia myotonica 2
DMD	Duchenne muscular dystrophy
DMPK	dystrophia myotonica protein kinase gene
DMRT1	doublesex/MAB-related transcription factor 1
DMRT2	doublesex/MAB-related transcription factor 2

DOC	11-deoxycorticosterone
DOC	deoxycorticosterone
DRIP	vitamin D receptor–interacting protein
DSS	dosage-sensitive sex reversal
E	embryonic day
EGF	epidermal growth factor
EGR	early growth response
Egr1	early growth response 1
ELISA	enzyme-linked immunosorbent assay
Emx2	empty spiracles 2
ENaC	epithelial sodium channel
Epac	exchange protein directly activated by cAMP
ER	endoplasmic reticulum
ER	estrogen receptor
ERβ	estrogen receptor β
ERK	extracellular signal-regulated kinase
FAD	flavin adenine dinucleotide
FDH	familial dysalbuminemic hyperthyroxinemia
FGF	fibroblast growth factor
FGFR-1	fibroblast growth factor receptor-1
FHH	familial hypocalciuric hypercalcemia
FISH	fluorescence *in situ* hybridization
FMN	flavin mononucleotide
FMPP	familial male limited precocious puberty
FMRP	fragile X mental retardation protein
FMTC	familial medullary thyroid carcinoma
FOG	Friends of GATA
Foxl2	forkhead transcription factor 2
FSH	follicle-stimulating hormone
FSHR	follicle-stimulating hormone receptor
FTC	follicular thyroid carcinoma
FtzF1	fushi tarazu factor 1
GABA	γ-amino-butyric acid
GAD	glutamic acid decarboxylase
GAP	GTPase-activating protein
GBY	Y-linked gene predisposing to gonadoblastoma
GC	guanylyl cyclase
GDF	growth and differentiation factor
GDNF	glial cell-derived neurotrophic factor
GFL	GDNF family ligands
GFRα	GDNF family receptor-α
GGR	generalized glucocorticoid resistance
GH	growth hormone
GHBP	growth hormone-binding protein
GHR	growth hormone receptor
GHRH	growth hormone-releasing hormone
GHRHR	growth hormone-releasing hormone receptor
GK	glycerol kinase
GnRH	gonadotropin-releasing hormone
GnRHa	synthetic agonist analogues of GnRH
GnRHR	GnRH receptor
GNRHR	GnRH receptor gene
GPCR	G protein-coupled receptor
G proteins	guanine nucleotide-binding proteins
GR	glucocorticoid receptor
GRA	glucocorticoid-remediable aldosteronism
Grb-2	growth factor receptor-binding protein 2
GRH	glucocorticoid remediable hyperaldosteronism
GRK	G-protein receptor kinase
Gsα	α-subunit of the stimulatory G protein
GTPase	guanosine 5′-triphosphatase
hCG	human chorionic gonadotropin
Hd	hypodactyly
HDR syndrome	hypoparathyroidism with deafness and nephrosis
HH	hypogonadotropic hypogonadism
HHG	hypogonadotropic hypogonadism
HLA	human leukocyte antigen
HMG	high mobility group
HNF	hepatocyte nuclear factor
HP	hypothalamic-pituitary
HPA	hypothalamus, anterior pituitary, and adrenal cortex
HPG	hypothalamus–pituitary–gonadal
HPT-JT	hyperparathyroidism-jaw tumor
HRE	hormone-response element
HSD	hydroxysteroid dehydrogenase
ICSI	intracytoplasmic sperm injection
IGD	isolated glucocorticoid deficiency
IGF	insulin-like growth factor
IGF-I	insulin-like growth factor-1
IGF-II	insulin-like growth factor-2
IGHD	isolated growth hormone deficiency
IL	interleukin
IL-1	interleukin-1
ILD	isolated 17,20-lyase deficiency
IP_3	inositol 1,4,5-trisphosphate
IPF-1	insulin promoter factor-1
IR	insulin receptor
IRS	insulin-related substrate
IRS-1	insulin receptor substrate-1
ISS	idiopathic short stature
JAK	Janus-activated kinase
KHD	kinase homology domain
KS	Kallmann syndrome
KTS	lysine/threonine/serine triad
LAMB	lentigines, atrial myxoma, mucocutaneous myxoma, blue nevi
LBD	ligand-binding domain
LCAH	lipoid congenital adrenal hyperplasia
LCH	Leydig cell hypoplasia
LDL	low-density lipoprotein
LEP	leptin gene
LEPR	leptin receptor gene
LH	luteinizing hormone
LHCGR	luteinizing hormone/chorionic gonadotropin receptor
LHR	luteinizing hormone receptor
LHX9	LIM homeobox gene 9
LIF	leukemia-inhibitory factor
LIM	Lin-11, Islet-1 and Mec-3
LIM1	LIM homeobox gene 1
LOH	loss of heterozygosity
MAPK	mitogen-activated protein kinase
MAS	McCune-Albright syndrome
Mb	million base pairs

MC2R	melanocortin 2 receptor
MEK	mitogen-activated extracellular reponse kinase
MEKK	MEK kinase
MELAS syndrome	mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes
MEN	multiple endocrine neoplasia
MEN1	multiple endocrine neoplasia type 1
MEN2A/CLA	MEN2A with cutaneous lichen amyloidosis
MHC	major histocompatibility locus
MIS	Müllerian inhibitory substance
MIT	mono-iodotyrosyl
MODY	maturity onset diabetes of the young
MR	mineralocorticoid receptor
MRKH	Mayer-Rokitansky-Kuster-Hauser
MTC	medullary thyroid carcinoma
MTC	sporadic medullary thyroid cancer
NAD	nicotinamide adenine dinucleotide
NAME	nevi, atrial myxoma, myxoid neurofibromata, and ephelides
NC21-OHD	non-classic 21-hydroxylase deficiency
NFκB	nuclear factor κB
NIH	National Institutes of Health
NIS	sodium-iodide symporter
NP	natriuretic peptide
NPC	nuclear pore complex
NR	nuclear receptor
NRTN	neurturin
NSHPT	neonatal severe hyperparathyroidism
OMI	oocyte maturation inhibitor
p	short arm
P450arom	aromatase
$P450_{c17}$	17α-hydroxylase/17,20-lyase
P450c21	mitochondrial cytochrome P450 enzyme steroid 21-hydroxylase
$P450_{scc}$	P450 cholesterol side-chain cleavage
PA	plasminogen activators
PAI	plasminogen activator inhibitor
PAIS	partial forms of androgen insensitivity syndrome
PC1	prohormone convertase-1
PCO	polycystic ovary
PCOS	polycystic ovary syndrome
PDGF	platelet-derived growth factor
PDK1	3-phosphoinositol-dependent kinase
PH	Pleckstrin-homology domain
PHA	pseudohypoaldosteronism
PHD	plant homeodomain
PHP	pseudohypoparathyroidism
PHP1A	pseudohypoparathyroidism, type 1A
PHP1B	pseudohypoparathyroidism, type 1B
PI3K	phosphatidylinositol-3-kinase
PKA	protein kinase A
PKB	protein kinase B
PKC	phosphokinase C
PLCγ	phospholipase C-γ
PMDS	persistent müllerian duct syndrome
POF	premature ovarian failure
POMC	pro-opiomelanocortin
POR	P450 oxidoreductase
PP	pancreatic polypeptide
PP2A	protein phosphatase 2A
PPAR	peroxisome proliferator-activating receptor
PPAR-γ	peroxisome proliferator-activated receptor-γ
PPKAR1A	type 1 regulatory subunit of cAMP-dependent protein kinase A
PPNAD	primary pigmented nodular adrenocortical disease
PR	progesterone receptor
PRL	prolactin
PSPN	persephin
PTB	phosphotyrosine binding domain
PTC	papillary thyroid carcinoma
PTH	parathyroid hormone
PTHrP	PTH-related protein
PTP	phosphotyrosine phosphatase
PWS	Prader–Willi syndrome
q	long arm
RAR	retinoic acid receptor
RARE	retinoic acid-response elements
Rb	retinoblastoma susceptibility gene
RBM	RNA binding motif
RGS	regulator of G protein signaling
RIA	radioimmunoassay
RRA	radioreceptor assay
R-Smads	receptor activated Smads
rT3	reverse triiododothyronine
RTH	resistance to thyroid hormone
RTKs	tyrosine kinase family of membrane receptors
RXR	retinoid X receptor
SAPK	stress-activated protein kinase
SBMA	spinal and bulbar muscular atrophy
SCF	stem cell factor
SCOS	sertoli-cell-only syndrome
SD	standard deviations
SDF	stromal cell-derived factor
Sec	selenocysteine
SF-1	steroidogenic factor-1
SH2	src-homology domain 2
SH3	src-homology domain 3
SHBG	sex hormone-binding globulin
Shh	sonic hedgehog
SHP	SRC-homology 2-domain phosphatase
SLOS	Smith-Lemli-Opitz syndrome
SNP	single-nucleotide polymorphism
SOD	septo-optic dysplasia
SOS	son of sevenless
SOX	SRY homeobox-like gene
SRIF	somatostatin
SRY	sex-determining region on the Y chromosome
StAR	steroidogenic acute regulatory protein
START	StAR-related lipid transfer
STAT	signal transducers and activators of transcription
STS	sequence-tagged sites
SUR1	sulfonylurea receptor

T	testosterone
T3	triiodothyronine
T4	tetraiodothyronine (thyroxine)
T4	thyroxine
TBG	thyroxine-binding globulin
TF	transcription factor
TG	thyroglobulin
TGF-β	transforming growth factor-β
TGF	transforming growth factor
TIOD	total iodide organification defect
TNF	tumor necrosis factor
TNF-α	tumor necrosis factor-α
tPA	tissue plasminogen activator
TPO	thyroperoxidase
TR	thyroid hormone receptors
TRAP	thyroid receptor-associated protein
TREs	thyroid hormone response elements
TRH	thyrotropin-releasing hormone
tRNA	transfer RNA
TSAb	autoantibodies against the TSH receptor
TSH	thyroid-stimulating hormone
TSH	thyrotropin
TTF	thyroid transcription factor
TTR	transthyretin
UPD14	uniparental disomy for chromosome 14
UV	ultraviolet
VDR	vitamin D receptor
VEGF	vascular endothelial growth factor
VIP	vasoactive intestinal polypeptide
VLCFA	very long-chain fatty acids
VNTR	variable number of tandem repeats
Wnt	wingless-type MMTV integration site family
WT1	transcription factor product of Wilms' tumor gene
WT1	Wilms Tumor 1
XIC	X inactivation center
XIST	X-inactive specific transcript
Xp	short arm of an X chromosome
Yp	distal end of the Y chromosome
ZF	zinc finger
ZG	zona glomerulosa

31 Mechanisms of Hormone Action

Stephen R. Hammes, Carol A. Lange, and Michael J. McPhaul

SUMMARY

The completion of the human genome sequence has permitted the identification of additional signaling molecules of many different classes. The impact of this new information on the understanding of the pathophysiology of disease is already evidenced in terms of the ability to predict specific receptors or pathways that might harbor mutations in different disorders. Selected examples of such mutations are cited this chapter, and the reader is referred to other chapters in this section for detailed discussions of these disorders. Although written from a perspective that is grounded in endocrinology, the concepts regarding the receptor classes and signaling pathways are generally applicable to all areas of biology and medicine.

Key Words: Amino acids; cytokines; hormone; nuclear receptor; phosphotyrosine phosphatases; peptides; proteins; steroids; transmembrane domain receptors.

INTRODUCTION

Hormones provide a form of communication between different cells and from one organ to another. The dramatic effects of hormones on physiological functions such as growth and metabolism have promoted studies to elucidate their sources of production, sites of action, and how they are controlled. Because hormones exert their effects by binding to specific receptors, studies defining their mechanisms of action have also provided important paradigms for how receptors activate intracellular signaling cascades that lead to altered cellular responses.

Endocrine disorders ultimately involve abnormalities of hormone production or action. Etiologies of a relatively large number of these diseases with well-defined genetic bases have been identified. Numerous examples exist of mutations in genes that encode hormones, their receptors, second messenger signaling pathways, and of the factors that transduce hormone signals. This chapter reviews basic principles of hormone signaling through their receptors. A remarkable expansion of knowledge in this area has included information about the structures and many of the signal transduction networks for membrane receptors. In addition, numerous members of the nuclear receptor (NR) family have been cloned, revealing an unexpectedly complex family of proteins that serve as direct regulators of gene expression. Because of the breadth of knowledge available, this chapter is not comprehensive, but introduces the major classes of receptors and the mechanisms by which their signals are transduced. The completion of the human genome sequence has permitted the identification of additional signaling molecules of many different classes. The impact of this new information on the understanding of the pathophysiology of disease is already evidenced in terms of the ability to predict specific receptors or pathways that might harbor mutations in different disorders.

CLASSIFICATION OF HORMONES AND RECEPTORS

Hormones can be divided generally into three major classes:

1. Derivatives of amino acids (e.g., dopamine and catecholamines).
2. Peptides and proteins (e.g., thyrotropin-releasing hormone [TRH] or insulin).
3. Derivatives of steroids (e.g., estrogen or cortisol).

Amino acid derivatives and peptide hormones predominantly interact with membrane receptors on the cell surface, whereas the steroid hormones act by crossing the plasma membrane to interact with intracellular receptors.

As described later, membrane receptors can be divided into several distinct classes. After binding hormones, these receptors activate a complex array of second messenger signaling pathways that often involve cascades of kinases. NRs, such as the glucocorticoid or progesterone receptors (PRs), bind hormones in the cytoplasm before translocation into the nucleus (Fig. 31-1). Other receptors in this family, such as the thyroid hormone receptor, bind hormone in the nucleus without a separate hormone-induced translocation step. In the nucleus, these receptors interact with DNA target sites to either stimulate or repress the expression of specific genes.

Regardless of the class of receptors, certain principles apply to hormone–receptor interactions. Hormones bind to receptors with high affinity and specificity to allow appropriate physiological responses. Most receptors bind hormones with affinity constants that approach the circulating levels of hormones (usually $<10^{-9}$ *M*) to allow responses over a dynamic range of physiologically relevant changes in hormone levels. Receptor numbers vary greatly in different target tissues, providing one of the major determinants of specific cellular responses to widely circulating hormones. For

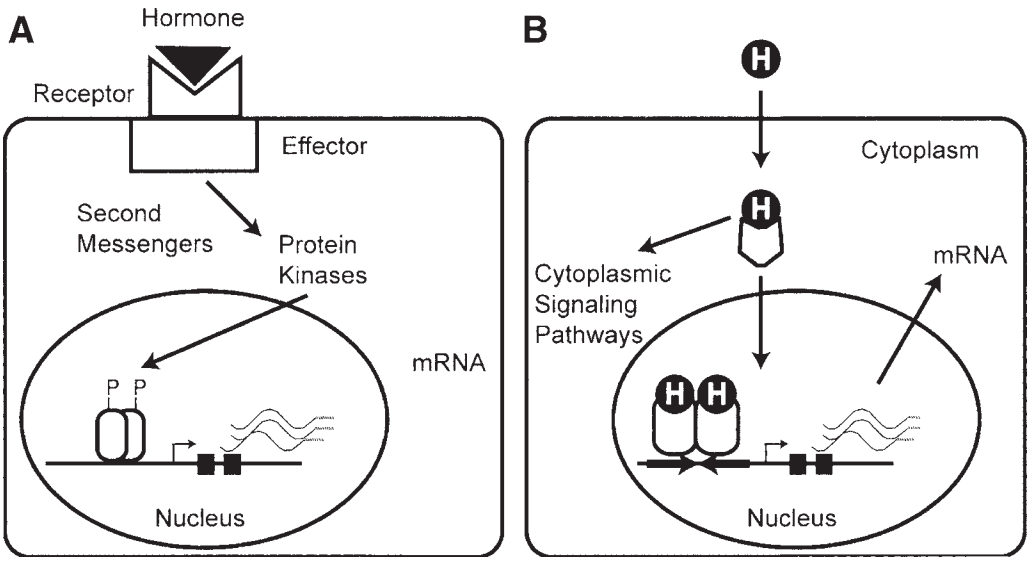

Figure 31-1 Membrane and NRs mediate hormone action. A membrane receptor is shown at the left and a nuclear receptor is shown to the right. **(A)** Hormones and growth factors bind with high affinity to the extracellular domain of the receptors. Membrane receptors modulate intracellular signaling pathways, which typically include cascades of protein kinases. These kinases act on many different cellular targets, including other receptors, ion channels, the cytoskeleton, metabolic pathways, and transcription factors. **(B)** NRs reside within the cytoplasm or the nucleus before hormone binding. Hormones traverse the plasma membrane and induce nuclear translocation and receptor activation. The activated receptors act as TFs to alter levels of gene expression. (Redrawn after Jameson JL. Principles or hormone action. Oxford Textbook of Medicine, 1996. Reprinted with permission from Oxford University Press.)

example, luteinizing hormone (LH) receptors are located almost exclusively in the gonads. In contrast, insulin receptors are widely distributed, reflecting the need for insulin-induced metabolic responses in most tissues.

Receptor specificity is a reflection of differential affinities of the receptor for structurally related molecules. Although structurally similar, LH, follicle-stimulating hormone (FSH), and thyroid-stimulating hormone (TSH) are highly selective for their individual receptors. Similarly, steroids such as progesterone, estrogen, and glucocorticoid exhibit no physiologically significant cross-reactivity among their receptors. There are important exceptions to these examples of specificity. Parathyroid hormone (PTH) and parathyroid hormone-related peptide appear to share a common receptor. Insulin, insulin-like growth factor (IGF)-I, and IGF-II cross-react to some degree with their respective receptors. This latter circumstance might explain why some malignancies that overproduce IGF-II can cause hypoglycemia because of inappropriate stimulation of insulin receptors by IGF-II.

FEEDBACK REGULATION IN ENDOCRINE AXES

Feedback regulatory systems are pervasive in the field of endocrinology. Each of the major hypothalamic–pituitary hormone axes is governed by negative feedback, which serves to maintain hormone levels within a narrow range. The principle of feedback control is represented by the example of the hypothalamic-pituitary-thyroid axis (Fig. 31-2). TRH stimulates TSH secretion from the pituitary. TSH stimulates the synthesis and secretion of thyroid hormones thyroxine (T4) and triiodothyronine (T3), which in turn suppresses the production of hypothalamic TRH and pituitary TSH. A typical regulatory loop therefore has both positive (TRH, TSH) and negative (T4, T3) components, providing exquisite control over hormone levels and action.

In addition to classic endocrine feedback loops in which hormones are produced by one gland and act on different tissues, a variety of local regulatory systems have also been characterized (Fig. 31-3). These autocrine and paracrine systems are used commonly during development and by most growth factors. Local control of growth factor production and action helps to restrict their sites of action. For example, circulating levels of activin are relatively low, but local production in the gonads and pituitary might permit localized biological effects without a requirement for systemic exposure to high levels of hormone. In many cases, the distinction between endocrine and paracrine actions might become blurred. For example, IGF-I appears to act both as a true hormone and a paracrine factor. In the liver, growth hormone (GH) increases production of circulating IGF-I. However, in most other tissues, the production of IGF-I is also regulated locally.

The clinical practice of endocrinology is intimately linked to these principles of feedback control systems and hormone action. With these concepts, it is often possible to localize whether a disorder is caused by hormone excess or deficiency, or by an abnormality in tissue sensitivity to hormone action. Advances in molecular genetics are allowing these diagnostic algorithms to expand by another dimension. In addition to measuring hormone levels, it is possible to test for enzyme deficiencies by identifying mutations in affected genes (e.g., 21-hydroxylase), or to predict genetic risk in inherited syndromes such as the multiple endocrine neoplasia (MEN) syndromes.

MEMBRANE RECEPTORS

Receptors on cell surfaces provide an essential component of communication with extracellular ligands. These membrane receptors fall into three general classes based on their structure and mechanisms of signal transduction: (1) the single transmembrane domain receptors; (2) the seven transmembrane domain

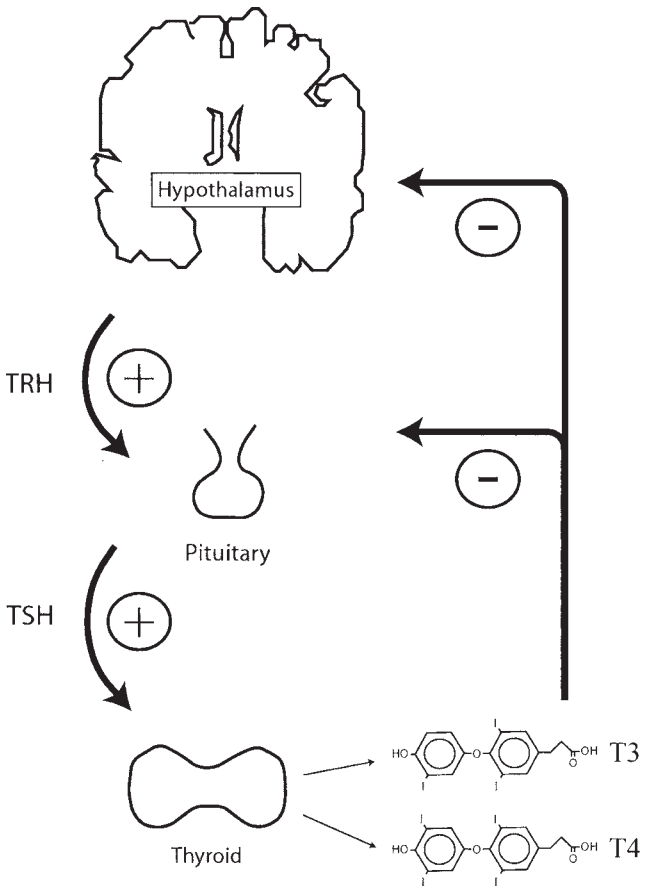

Figure 31-2 Positive and negative feedback regulation by hormones. The hypothalamic-pituitary-thyroid axis provides a prototypical example of feedback regulatory pathways in the endocrine system. Hypothalamic TRH stimulates TSH secretion by the pituitary gland. TSH stimulates the biosynthesis and secretion of thyroid hormones (T4 and T3) from the thyroid gland. Thyroid hormones feed back to inhibit the production of TRH and TSH. Because the pituitary integrates both positive and negative regulation, it establishes a set-point for TSH and consequently, thyroid hormone levels. (Redrawn after Jameson JL. Principles or hormone action. Oxford Textbook of Medicine, 1996. Reprinted with permission from Oxford University Press.)

receptors; and (3) the four transmembrane domain receptors. The latter class functions as neurotransmitter-gated ion channels and will not be described in this chapter.

SINGLE TRANSMEMBRANE DOMAIN RECEPTORS

TYROSINE KINASE RECEPTORS The tyrosine kinase family of membrane receptors (RTKs) consists of cell surface single transmembrane domain molecules that contain intrinsic tyrosine kinase activities. These receptors can be classified into several different subfamilies, including the (1) insulin/IGF; (2) epidermal growth factor (EGF)/neu/HER2; (3) platelet-derived growth factor (PDGF)/CSF1/vascular endothelial growth factor; and (4) GDNF/Ret classes. With the exception of the insulin/IGF receptor subfamily, whose members are constitutively expressed on the cell surface as dimers, the RTKs require ligand-activated dimerization to initiate signaling. The ligand binding domains are located in the amino-terminal extracellular region, where as the tyrosine kinase domains are located in the carboxyl-terminal cytoplasmic region (Fig. 31-4). Ligand binding induces stable dimerization of receptor monomers. Each monomer transphosphorylates its partner within the activation loop of the kinase domain, resulting in receptor activation. Once activated, tyrosine residues in the cytoplasmic domains are autophosphorylated by the intrinsic tyrosine kinase. These phosphorylated tyrosine residues then serve as targets for multiple intracellular scaffolding and signaling molecules, recruiting them to the plasma membrane to form a membrane signaling complex that mediates a variety of signaling responses. The specificity of the signaling response of an individual RTK therefore depends on its location within the target cells as well as the milieu of phosphotyrosine binding molecules and other signaling proteins within the target cell.

Many different phosphotyrosine-binding molecules bind to RTKs. These proteins usually contain either a src-homology domain 2 (SH2) or a phosphotyrosine binding (PTB) domain (Table 31-1). In addition to PTBs, the formation of membrane signaling complexes is achieved through the use of multiple specific interaction domains. For example, Pleckstrin homology (PH) and FYVE domains bind to phospholipids within the internal plasma membrane, thus retaining proteins at the cell surface. Protein–protein interactions are mediated by src-homology 3 (SH3) and WW domains that recognize and bind to proline-rich regions, where as PDZ domains recognize and bind to hydrophobic C-terminal domain residues.

An example of a RTK recruiting a signaling complex to the inner cell surface is the activation of protein kinase B (PKB, or Akt) (Fig. 31-4A). Ligand binding to a RTK such as PDGF receptor leads to dimerization and autophosphorylation of tyrosine residues in the receptor carboxyl-terminal tails. Phosphatidylinositol-3-kinase (PI3K) then binds to these phosphotyrosines through SH2 domains, leading to activation of PI3K and subsequent PI3K-mediated phosphorylation of membrane-bound PIP2 to form PIP3. PIP3 in the membrane promotes localization of 3-phosphoinositol-dependent kinase (PDK1) and PKB to the inner plasma membrane through interactions with PH domains. Once together at the membrane, PDK1 phosphorylates and activates PKB, which then promotes multiple signals within the target cell. Similarly, phospholipase C (PLC)-γ binds to phosphorylated RTKs, such as the EGF and PDGF receptors through SH2 domains, where as binding to membrane phospholipids through PH domains. This leads to its phosphorylation and activation by the receptor kinase. PLCγ then converts PIP2 to inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol, which promotes calcium mobilization and phosphokinase C (PKC) activation, respectively (Fig. 31-4B).

In addition to directly recruiting signaling molecules to the membrane receptor complex, phosphorylated RTKs can bind to scaffolding proteins that in turn bring signaling molecules to the membrane. For example, Shc binds to phosphorylated receptors through PTB domains, leading to RTK-mediated phosphorylation of Shc. The adaptor, growth factor receptor-binding protein 2 (Grb-2), then binds to phosphorylated Shc through an SH2 domain, followed by association of the guanine nucleotide exchange protein Sos, which then activates membrane bound Ras. Ras is a member of a large family of small guanine nucleotide binding proteins (G proteins) that act as "molecular switches." When bound to GDP, Ras proteins remain inactive and are thus unable to bind to downstream signaling "effector" molecules. Guanine nucleotide exchange factors, such as Sos, induce the exchange of GDP for GTP, thereby stimulating a conformational change that allows Ras to bind to one or more kinases from the Raf or, mitogen-activated extracellular reponse kinase kinase

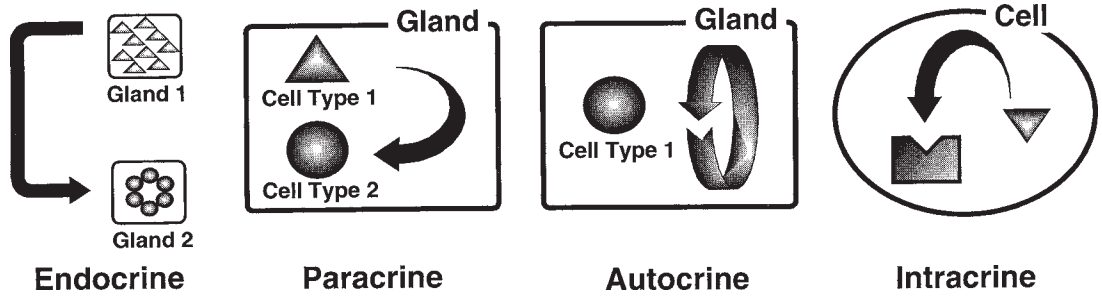

Figure 31-3 Hormones and growth factors can act at a distance or locally. Endocrine action often refers to hormones that are selected from one gland and enter the circulation to act on a different target gland. Paracrine action involves hormones or growth factors that are produced by one cell but act locally on an adjacent cell. In autocrine action, a growth factor acts on the same cell from which it is produced. Intracrine action suggests that some hormones act on intracellular receptors in the same cells in which they are produced. (Redrawn after Jameson JL. Principles of hormone action. Oxford Textbook of Medicine, 1996. Reprinted with permission from Oxford University Press.)

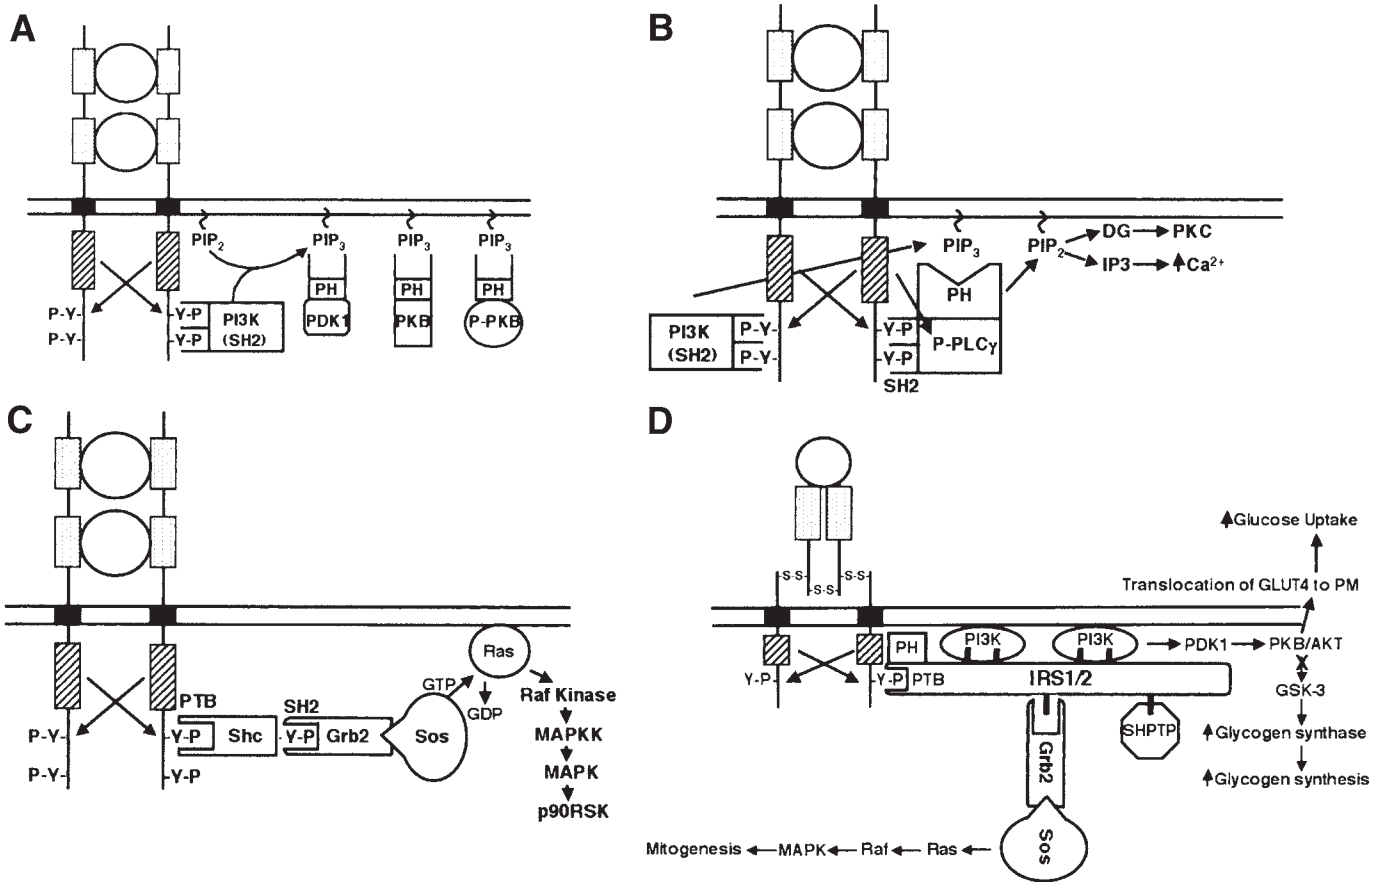

Figure 31-4 Activated RTKs recruit signaling complexes to the inner plasma membrane in many different ways. **(A)** Two ligands (circle) bind two receptors, leading to dimerization and phosphorylation of cytoplasmic tyrosine residues by the receptor's intrinsic tyrosine kinase. Phosphatidylinositol-3-kinase (PI3K) then binds to the phosphorylated tyrosines through its SH2 domains to bring it in close proximity to the membrane, where it mediates the conversion of PIP2 to PIP3. Phosphoinositide-dependent kinase (PDK) and phosphokinase B (PKB, also known as Akt) are then recruited to the membrane through binding to PIP3 through their Pleckstrin-homology (PH) domains, where PDK phosphorylates and activates PKB. **(B)** Phospholipase C (PLCγ) binds phosphorylated receptor and the inner cell membrane through src-homology 2 (SH2) and PH domains, respectively, where it is itself phosphorylated and activated by the receptor tyrosine kinase. PLCγ then mediates the conversion of PIP2 to diacylglycerol (DG) and inositol 1,4,5-trisphosphate (IP_3), which activate phosphokinase C (PKC) and calcium mobilization, respectively. **(C)** The scaffolding protein Shc binds to phosphorylated receptor through its PTB domain, in which it is phosphorylated by the receptor kinase. The Grb-2/Sos complex then binds to phosphorylated Shc through an SH2 domain in Grb-2, bringing Sos in close proximately to membrane-bound Ras. Sos mediates the exchange of GTP for GDPon Ras, which in turn activates the mitogen-activated protein kinase (MAPK) cascade. **(D)** Constitutively dimerized insulin/IGF receptors are activated by single ligands, leading to phosphorylation of cytoplasmic tyrosines. Insulin-related substrate (IRS) proteins then bind to the receptor and the inner plasma membrane through PTB and PH domains, respectively, where they are phosphorylated at many sites by the receptor tyrosine kinase. Multiple scaffolding and signaling molecules then bind to phosphorylated IRS proteins, leading to activation of a myriad of signaling pathways.

Table 31-1
Protein Interaction Domains

Domain	*Target*
PTB	Phosphotyrosine with amino-terminal specific sequences (NPXY)
SH2	Phosphotyrosine with carboxyl-terminal specific sequences (YXX(L/I)X)
SH3	Proline-rich (PXXP)
WW	Proline-rich (PXPX)
PH	Phosphoinositols (PIP2, IP_3)
FYVE	Phosphoinositols (PtdIns-3-P)
PDZ	C-terminal hydrophobic residues

Intracellular signaling complexes rely on multiple signaling modules. Phosphotyrosine binding (PTB) and src-homology 2 (SH2) domains interact with sequences containing phosphotyrosine residues in either the carboxyl-terminal or amino-terminal positions, respectively (L/I, hydrophobic amino acid; X, any amino acid). Src-homology 3 (SH3) and tryptophan-conserved (WW) domains bind to proline-rich sequences as indicated. Pleckstrin-homology (PH) and FYVE domains recognize phospholipids. Finally, PDZ domains interact with hydrophobic carboxyl-terminal residues.

(MEKK) families. For example, the interaction of GTP-bound Ras with the Ser/Thr protein kinase, Raf-1, acts to bring Raf-1 to the membrane, in which it is phosphorylated and activated. Raf-1 then mediates the direct phosphorylation and activation of MEK/ERK kinases, MEK1, and MEK2. MEKs 1 and 2 in turn activate MAPKs p42 and p44 by dual phosphorylation on threonine and tyrosine residues. The activation of three kinases within a cascade (Raf-1/MEK/MAPK) is collectively termed a "MAPK module." Because several isoforms exist for each kinase family member within the three-kinase cascade, many MAPK modules are possible. The specificity of MAPK modules is determined by interaction with scaffold proteins, which bind two or more components within the module and provide subcellular localization, organization, and insulation from other modules. Finally, to turn off the signal, a family of GTP-ase activating proteins (Ras-GAPs) then induce the intrinsic guanosine 5′-triphosphatase (GTPase) activity of Ras, returning it to its GDP- associated "off" conformation (Fig. 31-4C).

As a final example of RTK-mediated signaling, activation of other tyrosine kinase receptors (RTKs), including the insulin or IGF receptors, leads to insulin-related substrate (IRS) binding through PTB domains. IRS is then phosphorylated by the receptor, allowing multiple phosphotyrosine binding proteins to interact with the signaling complex, including PI3K and Grb-2 and activation of Ras and MAPK modules (Fig. 31-4D).

RTK activity is tightly regulated by a number of distinct mechanisms that have been identified as effecting control of the activity of specific receptors. These include inhibition of RTK activity (by phosphorylation or by association with specific inhibitory proteins), dephosphorylation by protein tyrosine phosphatases, and the internalization and degradation of activated receptors.

Mutations in RTKs are infrequently associated with diseases. For example, homozygous mutations in several regions of the insulin receptor have been associated with leprechaunism, characterized by severe growth retardation and death in infancy (Chapter 32). Heterozygous mutations in the insulin receptor have been associated with the less severe Type A insulin resistance or Rabson-Mendenhall syndrome, both of which are characterized by marked insulin resistance, acanthosis nigricans, hyperandrogenism, and polycystic ovarian syndrome. However, RTK overexpression occurs in a wide variety of epithelial cancers and is indicative of a poor prognosis.

Another fascinating series of RTK mutations leading to disease occurs with the RET proto-oncogene, a tyrosine kinase receptor. Activating mutations of the RET protein have been associated with MEN type 2A, an autosomal-dominant disorder characterized by a high incidence of medullary thyroid cancer and pheochromocytoma. Other activating mutations of RET have been associated with familiar medullary thyroid carcinoma. In contrast, inactivating mutations in the RET protein have been related to Hirchsprung's disease, a congenital malformation characterized by aganglionosis of the gastrointestinal tract.

CYTOKINE RECEPTOR FAMILY

Cytokines include traditional hormones, such as growth hormone and erythropoietin, as well as colony-stimulating factors and interleukins. In several cases, such as the interleukins, a variety of different endocrine, neural, hepatic, and hematopoietic systems are targets of the cytokines. The cytokine receptor family includes receptors for a broad range of molecules. Members of this family are single transmembrane receptors with extracellular ligand binding and intracellular domains (Fig. 31-5). In contrast to the RTKs, the cytoplasmic domains of this class of receptors do not possess intrinsic kinase activity. Moreover, although functional receptors many contain only a single type of subunit (e.g., GH, prolactin, erythropoietin, leptin), others consist of several subunits, some of which are shared among different cytokine receptors. The formation of oligomeric complexes (homodimeric, in the case of the growth hormone receptor [GHR] for example; heteromeric, in the case of most others) is required for the high affinity binding of ligand and the propagation of intracellular signals. Mutations within the receptor or ligand that interfere with the formation of these active multimers will attenuate or abrogate the generation of the intracellular signal. For example, Pegvisomant®, a mutant GH molecule that interferes with the ability of the GHR to dimerize, has been used to treat individuals with excess GH secretion and acromegaly. In addition, some members of this receptor family secrete soluble forms of the receptor that can bind circulating ligands. In the case of the GH receptor, the extracellular domain is shed into the circulation and functions as a GH binding protein.

The mechanism of cytokine-induced signal transduction was poorly understood for many years in view of the lack of intrinsic enzyme activity in the cytoplasmic domain of these receptors. Subsequent studies established that members of the cytokine receptor family signal by the activation of Janus kinases (JAKs) (*see* Fig. 31-5). The JAK family members, which include JAK1, JAK2, JAK3, and Tyk2, are cytoplasmic protein tyrosine kinases that associate with the cytoplasmic domain of cytokine receptors through conserved receptor motifs. The activated JAKs phosphorylate tyrosines in the cytoplasmic domain of the cytokine receptors, which creates binding sites for signal transduction molecules that contain SH2 domains. In addition, the JAKs transmit intracellular signals by phosphorylating a family of latent transcription factors (TFs) called the signal transducers and activators of transcription (STAT) proteins. It is likely that each specific receptor elicits responses from a constellation of kinases and STAT proteins. There also appear to be alternate pathways by which STAT proteins can be activated and considerable "cross talk" between these and other signaling pathways. Finally, the duration of the

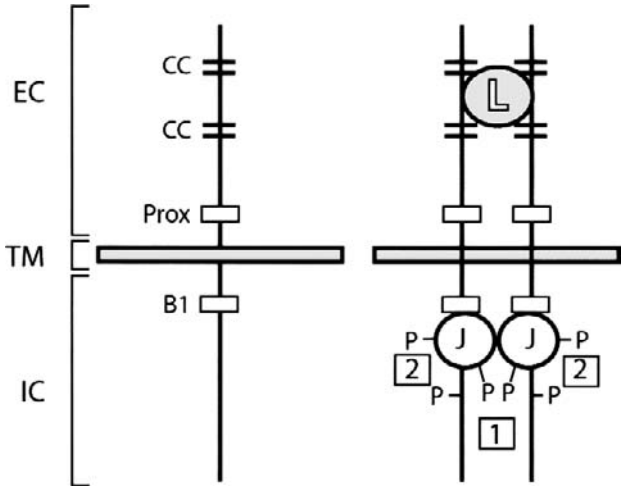

Figure 31-5 Signaling by the cytokine receptor family. Members of the cytokine receptor family are single transmembrane (TM) receptors that share conserved motifs within their extracellular (EC) and intracellular (IC) domains. In general, type-I cytokine receptors, such as the GH receptor, have conserved pairs of cysteine residues within their extracellular domains and a conserved WSXWS motif in the region adjacent to the transmembrane segment (Prox). A conserved element (PXP; box 1,"B1") forms a motif important to the recruitment of intracellular signaling molecules (left panel). The binding of ligand (L) results in the dimerization of the receptor, the recruitment of Janus-activated kinases (JAKs), and the phosphorylation of specific residues on the adjacent JAK molecules and on the receptor (labeled 1 and 2). These events are critical to the docking and phosphorylation of the STAT proteins. J is JAK and L is ligand.

signal transduced by the activated JAKs can be modulated by STAT-mediated induction of a class of proteins that serve to inhibit the activity of the JAKs. These suppressors of cytokine signaling (SOCS) proteins inhibit cytokine signaling by a number of mechanisms, including binding to the JAKs or the receptors to inhibit the activation of the JAKs or to the STATs to inhibit the binding STATS to the cytokine receptors.

Endocrine diseases associated with mutations of cytokine receptors include alterations in GH signaling (Chapter 34). Patients with familial GH resistance or Laron-type dwarfism have proportionate short stature associated with elevated plasma GH levels and do not respond to exogenous treatment with GH. In most cases, the syndrome is inherited in an autosomal-recessive fashion, and patients lack functional GH receptors secondary to gene deletions or point mutations in the receptor. The GH receptor from some patients with this syndrome has a point mutation in the extracellular domain that results in a small reduction in receptor affinity, but which abrogates the ability of the receptor to dimerize, thus demonstrating the importance of receptor dimerization in signal transduction. In a selected group of children with idiopathic short stature, approximately one-third had mutations in the GH receptor that affected the level of receptor expression or its affinity for GH.

SERINE–THREONINE KINASE RECEPTOR FAMILY Although some receptors function as tyrosine kinases, others contain intrinsic serine/threonine kinase activity. These serine/threonine kinase receptors mediate signaling by members of the transforming growth factor (TGF)-β superfamily, which consists of a large number of multifunctional signaling proteins that play important roles in a myriad of processes, including inflammation, cellular proliferation, and tissue development. Members of this superfamily include TGF-β proteins (regulators of cellular proliferation), activins (activators of FSH), bone morphogenetic proteins, or BMPs (inducers of bone and cartilage formation), and anti-Müllerian hormone (dedifferentiates the Müllerian duct system in males).

Although the TGF-β ligand superfamily is extraordinarily large and diverse, the serine/threonine kinases make up a relatively small family of transmembrane receptors made up of two subunits defined as type I and II receptors. The type I receptors are similar in structure to the type II receptors, and both contain serine-threonine kinase domains. Unlike the type II receptors; however, the type I receptors do not have the ability to bind ligand. In mammals, only five type II receptors and seven type I receptors have been identified for ligands belonging to the TGF-β superfamily. Ligands bind to cell surface type II receptors as homo- or heterodimers. This high-affinity interaction allows the recruitment of type I receptors to the ligand-receptor complex, resulting in a heteromeric complex consisting of two type I and two type II receptors. The type II receptor contains constitutive serine-threonine kinase activity that phosphorylates the type I receptor on serine and threonine residues on its recruitment to the cell surface. The type I receptor subsequently phosphorylates downstream signaling molecules, including members of the Smad family of TFs. Eight different Smad proteins have been identified and fall into three distinct classes: the receptor activated Smads (R-Smads) (Smads 1, 2, 3, 5, and 8), which are phosphorylated by the type I receptors, the common mediator Smad (Smad 4), which associates with the activated R-Smads as an obligate heterodimeric partner, and the inhibitory Smads (I-Smads) (Smads 6 and 7), which compete with the R-Smads for interaction with the type I receptors and act to antagonize TGF and BMP signaling. Activation of R-Smads results in the localization of the complexes to the nucleus and the binding of the Smad complexes to target genes within the genome. Smads act to both directly regulate transcription and modulate transcription mediated by a number of different transcription factors (TFs), including c-Jun, c-Fos, and the coactivator p300.

Mutations in Smad proteins have been associated with human carcinomas. For example, pancreatic and colon carcinoma cells often contain deletions in the Smad 4 gene. Alterations in other components of the TGF-β signaling cascade have also been linked to human disease. This is exemplified by male patients with mutations in the gene encoding the Müllerian-inhibiting substance or in the receptor that binds this ligand. Such men exhibit normal virilization of their internal and external genitalia, but retain Müllerian structures (Chapter 41).

PHOSPHOTYROSINE PHOSPHATASE FAMILY Years of research have led to the definition of the importance of protein phosphorylation in mediating multiple signaling pathways. Additional studies have demonstrated that dephosphorylation of proteins is an equally important regulatory process. More than 100 phosphotyrosine phosphatases (PTPs) have been identified. This family can be divided into three groups: tyrosine specific phosphatases, which are intracellular integral membrane proteins; dual specific phosphatases, which dephosphorylate serine and threonine residues in addition to tyrosines; and low molecular weight tyrosine phosphatases.

Prototypical membrane-bound tyrosine specific PTPs are PTPα and CD45. These proteins contain an extracellular ligand binding domain, a single transmembrane domain, and 1-2 cytoplasmic phophotyrosine phosphatase domains. CD45 is a positive

regulator of T-cell activation, where, as PTPα appears to be a negative regulator of insulin signaling. Typical intracellular PTPs include PTP1B and SRC-homology 2-domain phosphatase-2 (SHP-2). These proteins contain a single catalytic domain with variable amino- or carboxyl-terminal extensions that often contain SH2 domains. Examples of dual-specific PTPs include MAPK phosphatases, as well as the cdc25 and PTEN phosphatases.

PTPs have been associated with many important physiological processes. For example, the intracellular phosphatase SHP-1 is a negative regulator of cytokine signaling, and mice with disruptions in the SHP-1 gene have sustained tyrosine phosphorylation of multiple signaling molecules with enhanced cellular proliferation. In addition, the dual-specific PTEN phosphatase appears to be a tumor suppressor that is mutated in multiple cancers, including brain, prostate, and breast tumors. The intracellular phosphatase PTP1B is a negative regulator of insulin signaling, and some evidence suggests that increased PTP1B activity might contribute to the insulin resistance seen in type-II diabetes mellitus. In support of this hypothesis, mice with disruptions in the PTP1B gene display increased insulin sensitivity and are resistant to obesity. Furthermore, PTP1B inhibitors lower blood glucose levels in ob/ob mice.

GUANYLYL CYCLASE RECEPTOR FAMILY The guanylyl cyclases (GCs) are enzymes that play important roles in many physiological processes of the cardiovascular, renal, and reproductive systems. The GCs are expressed in both soluble and particulate forms, with the latter serving in part as receptors for natriuretic peptides (NPs). Soluble GCs are discussed later. The particulate GCs generally consist of four domains: a variable extracellular peptide binding domain, a transmembrane domain, a relatively well-conserved intracellular kinase homology domain (KHD), and an intracellular GC catalytic domain. The KHD region appears to serve as an inhibitor of constitutive GC activity. Peptide binding to the extracellular domain results in a conformational change in the KHD region that allows it to bind to ATP. ATP binding in turn leads to activation of the intrinsic GC activity. Treatment with the drug amiloride prevents ATP binding to the KHD region and renders receptors unresponsive to ligand, emphasizing the importance of ATP binding for normal receptor function.

The particulate GC family consists of seven members, GC-A through GC-G, that are expressed on cell surfaces as homodimers or homo-oligomers. GC-A and GC-B bind to and are activated by NPs such as ANP (atrial), BNP (brain), and C-type. GC-C is expressed primarily in the small intestine, binds heat-stable enterotoxin and endogenous ligands, such as guanylin. GC-D is expressed in a subset of olfactory sensory neurons and might serve a role in olfaction. Two GC receptors, GC-E and GC-F, are expressed in the cones and rods of the retina, and mediate the restoration of levels of cGMP and calcium within the retina following excitation by light. Further, GC-E and GC-F are modulated by the GC activating proteins, which respond to intracellular calcium concentrations. GC-G is present in a number of tissues, particularly intestine, muscle, and lung. Activation of these receptors by the binding of peptide ligand or by other modulators, such enterotoxin or guanylin, leads to an increase in the intracellular concentrations of cGMP. These changes of intracellular cGMP lead to modulation of the activities of cGMP modulated protein kinases, cGMP-responsive phosphodiesterases, and cGMP-regulated ion channels.

The NPs are vasoactive hormones that play important roles in regulating blood pressure and cardiovascular homeostasis. ANP and BNP are expressed in the heart, and their secretion is stimulated by atrial stretching or increased pressure. They function to increase fluid and electrolyte excretion, inhibit vasoconstriction, increase glomerular filtration rate, and antagonize the renin-angiontensin system by inhibiting synthesis and release of renin and aldosterone.

Interestingly, alterations in GC receptor expression or activity have been associated with the control of important physiological processes. Animals with salt-sensitive hypertension appear to be less responsive to ANP, whereas disruption of the GC-A receptor gene in mice results in salt-resistant hypertension. In addition, ANP and BNP expression are markedly elevated in patients with congestive heart failure, and serve as sensitive markers for this condition. Mutations of the GC-E receptor protein and other components of cGMP-signaling pathways have been identified in patients with specific forms of inherited retinal dystrophies.

THE SEVEN-TRANSMEMBRANE DOMAIN RECEPTORS The seven-transmembrane domain (7TM) family of receptors is the largest family of membrane receptors, containing >800 members that respond to a myriad of different ligands, including light, catecholamines (e.g., dopamine, epinephrine, and norepinephrine), amino acids (e.g., glutamate), peptide hormones (e.g., LH, FSH, TSH, TRH, and PTH), elements (e.g., calcium), odors, and proteases (e.g., thrombin). These receptors are characterized by a conserved 7TM configuration, with an extracellular amino-terminal domain and a carboxyl terminal cytoplasmic domain. The amino-terminal domain appears to mediate membrane targeting of the receptor, and, along with the hydrophobic domains, ligand binding and receptor dimerization. The cytoplasmic domain appears to interact with signaling and shutoff molecules located at or near the internal plasma membrane.

The 7TM receptors are also called G protein-coupled receptors (GPCRs), because G proteins mediate most of the signals induced by these receptors (Fig. 31-6). Three G proteins, Gα, Gβ, and Gγ form an inactive heterotrimeric complex at the inner plasma membrane. Agonist binding to a GPCR alters the receptor's conformation, allowing association of the receptor's cytoplasmic surfaces with the G proteins. This interaction leads to dissociation of the heterotrimeric G protein complex into separate Gα and Gβγ signaling molecules. The Gα family consists of at least 16 members that signal in a complex array of pathways (Table 31-2). Two of the best-characterized subfamilies are the $G\alpha_s$ and $G\alpha_i$ proteins, which stimulate or inhibit adenylyl cyclase, respectively. The resultant changes in intracellular cAMP concentrations mediated by these two proteins in turn promotes several secondary responses, including activation of protein kinase A (PKA). Gα subunits are activated by association with a ligand-bound GPCR, which leads to the exchange of GTP in place of GDP on the Gα subunit. The Gα subunit is structurally related to the Ras family of small G proteins; in yeast, Ras functions to stimulate yeast adenylyl cyclase and is functionally equivalent to $G\alpha_s$ in mammalian cells. Similar to Ras, hydrolysis of GTP to GDP by intrinsic GTPase activity then inactivates the Gα subunit. This cycle continues until the Gα subunit re-complexes with Gβγ. Gβγ subunits signal as heterodimers to mediate a number of signals, including modulation of adenylyl cyclase activity and activation of MAPK and phospholipase C-β.

The desensitization, or shutoff, of GPCRs also plays an important role in regulating GPCR-mediated signaling. Shutoff is achieved through several complex steps (Table 31-3). First, heterologous

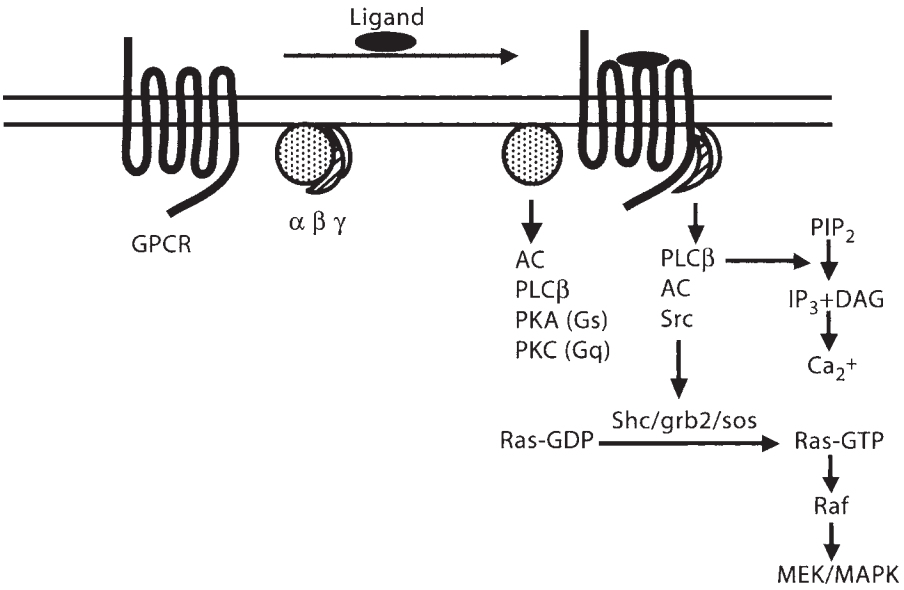

Figure 31-6 Agonist binding to a GPCR alters the receptor's conformation to promote association of the receptor with the G proteins. This interaction leads to dissociation of the heterotrimeric G protein complex into separate Gα and Gβγ signaling molecules. The resultant dissociated Gα and Gβγ subunits then mediate a number of signaling pathways, including modulation of adenylyl cyclase activity and activation of phospholipase C-γ (PLCγ), PKC, and Src. Signaling is shut off by the mechanisms listed in Table 31-3.

Table 31-2
G Proteins and Their Effectors

G protein	*Expression*	*Effectors*
$G\alpha_s$	Ubiquitous	Increase AC, Ca^{2+} channel activity; activate c-Src tyrosine kinases
$G\alpha_{olf}$	Olfactory	
$G\alpha_{t1}$	Rods	Increase cGMP phoshodiesterase activity
$G\alpha_{t2}$	Cones	
$G\alpha_{gust}$	Taste cells	Increase phosphodiesterase activity
$G\alpha_{i1}$	Neural > other tissues	Decrease AC; increase potassium channel activity; activate c-Src tyrosine kinases
$G\alpha_{i2}$	Ubiquitous	
$G\alpha_{i3}$	Other tissues > neural	
$G\alpha_o$	Neuroendocrine	Decrease potassium channel activity; activate Rap1GAP1
$G\alpha_z$	Neural, platelets	
$G\alpha_q$	Ubiquitous	Increase PLC-β1, PKC; activate LARGRhoGEF
$G\alpha_{11}$	Ubiquitous	
$G\alpha_{14}$	Liver, lung, kidney	
$G\alpha_{15/16}$	Blood cells	
$G\alpha_{12/13}$	Ubiquitous	Activate Rho proteins
Gβγ	Ubiquitous	Increase AC, PLC, GIRK channels, MAPK, PI3K; inhibit $G\alpha_I$

The expression patterns and effectors of 15 subtypes of Gα subunits and Gβγ are shown. AC, adenylyl cyclase; cGMP, cyclic GMP; GAP, GTPase activating protein; GEF, guanine nucleotide exchange factor; PLC, phospholipase C; PKC, phosphokinase C; GIRK, G protein-regulated inwardly rectifying potassium channel; MAPK, mitogen-activated protein kinase; PI3K, phosphatidylinositol 3-kinase.

shutoff is mediated by PKA or PKC-induced phosphorylation of serine and threonine residues on the GPCR cytoplasmic tail, which leads to G protein uncoupling and formation of the inactive G protein heterotrimer. In addition, the cytoplasmic regions of GPCRs can be phosphorylated by G protein receptor kinases (GRKs). GRK-mediated phosphorylation can by itself lead to G protein uncoupling; however, GRK-phosphorylated GPCRs are also targets for arrestin binding, a process that further uncouples the receptor from G proteins. Arrestins in turn can mediate GPCR internalization, often through clathrin-coated pits, to further shut off GPCR-mediated signaling. Depending on the GPCR, receptors are then either targeted to lysosomes for degradation, ubiquinated by intracellular factors, or dephosphorylated and returned to the cell surface in a process known as resensitization. Finally, GPCR shutoff is regulated by regulator of G protein signaling (RGS) proteins that function as GAPs to promote the conversion of GTP to GDP and Gα subunit shutoff. The extent of each of these mechanisms in regulating shutoff depends on the individual receptor as

Table 31-3
Mechanisms of GPCR Shutoff

Type of shutoff	*Mediators*	*Mechanism*
Second messenger	PKA, PKC	Phosphorylation of GPCR, uncoupling of G proteins
GRK/Arrestin-mediated	GRK 1-6 Visual and cone arrestins, β-arrestins 1 and 2, arrestins D and E	Phosphorylation of GPCR by GRK, arrestin binding to GPCR, GPCR Internalization, G protein uncoupling
Trafficking	Arrestins, clathrin, adaptin, caveolae	Internalization, lysosomal targeting, ubiquitinylation
RGS Proteins	>25 isoforms	GTPase activating proteins (GAPs)

Shutoff of GPCR-induced signaling is mediated by several different mechanisms. Receptors can be phosphorylated by second messengers (PKA and PKC). Alternatively, GPCRs can be phosphorylated by G protein-receptor kinases (GRKs), followed by arrestin binding and receptor internalization and trafficking. Finally, intrinsic GTPase activity in the Gα subunit can be accelerated through interactions with regulator of G protein signaling (RGS) molecules.

well as the levels of the many GRK, arrestin, and RGS isoforms expressed in the target cell.

Many disease states have been associated with mutations in either G proteins or GPCRs. For example, patients with McCune-Albright syndrome have somatic mutations in the $G\alpha_s$ subunit that render it constitutively activated. Many of these mutations disrupt the intrinsic GTPase activity of the $G\alpha_s$ subunit, thus resulting in a $G\alpha_s$ protein that is resistant to inhibition by RGS proteins. Individuals with McCune-Albright syndrome have abnormalities that would be expected from overstimulation of $G\alpha_s$-coupled receptors, including precocious puberty (LH receptor), thyroid tumors (TSH receptor), adrenal hyperplasia (adrenocorticotropic hormone receptor), growth-hormone secreting pituitary adenomas (growth hormone-releasing hormone receptor), café au lait spots (melanocyte-stimulating hormone receptor), and polyostotic fibrous dysplasia (PTH receptor). In contrast, patients with inactivating mutations in $G\alpha_s$ suffer from a complex array of syndromes known as pseudohypoparathyroidism. The clinical and biochemical phenotype of pseudohypoparathyroidism, which is inherited in an autosomal-dominant fashion, varies depending on the parent from which the mutated gene was inherited, ranging from hypocalcemia to the syndrome of Albright's hereditary osteodystrophy. Many of the abnormalities associated with pseudohypoparathyroidism appear to be related to PTH resistance; however, resistance to other hormones that signal through $G\alpha_s$ have been reported as well.

Diseases stemming from mutations in the GPCRs themselves are numerous; for example:

1. Inactivating mutations in the calcium sensor receptor that reduce the ability of the parathyroid glands to appropriately respond to serum calcium levels, resulting in increased PTH production, hypercalcemia, and hypophosphatemia. Heterozygotic mutations lead to the benign syndrome of familial hypocalciuric hypercalcemia, whereas homozygous mutations lead to neonatal severe hyperparathyroidism.
2. Activating mutations in the LH receptor in males that lead to precocious puberty and Leydig cell hyperplasia, whereas inactivating mutations lead to XY pseudohermaphroditism and Leydig cell hypoplasia.
3. Somatic activating mutations in the TSH receptor that result in hyperfunctioning thyroid nodules, and even thyroid cancer. Inactivating mutations have been associated with nonimmune hypothyroidism.
4. Inactivating mutations in the vasopressin receptor that result in accelerated receptor desensitization and internalization. These mutations are associated with nephrogenic diabetes insipidus, or vasopressin resistance.

INTRACELLULAR SIGNALING PATHWAYS

As described, membrane receptors represent a critical cellular link to the extracellular environment. Within the cell, an intricate set of signaling pathways communicate receptor responses to other receptors, as well as to the cytoplasmic and nuclear compartments. For the most part, these signaling pathways consist of enzyme cascades, although there are exceptions, including gases such as nitric oxide (NO), lipids, and TFs (such as the STAT proteins). In many cases, receptors activate multiple signaling cascades. It appears that the use of combinations of pathways provides an important mechanism for generating specific cellular responses. Another characteristic of signal transduction pathways is the potential for "crosstalk" in which one pathway might activate or inhibit another pathway. Again, this generates the potential for diverse responses. In the next section, specific examples are provided for some of the better-studied signaling pathways central to endocrine responses.

p21RAS AND MITOGEN-ACTIVATED PROTEIN KINASES

Because growth factors induce a variety of cellular responses, including proliferation, there has been great interest in delineating the pathways that mediate growth factor responses. Tremendous progress has occurred in the elucidation of numerous cytoplasmic and nuclear kinases involved in growth responses. The number of different kinases is enormous, and they have been estimated to account for as many as 5–10% of transcribed genes. The family of MAPKs includes the extracellular signal-regulated kinases (ERKs), stress-activated protein kinases (SAPKs) or c-Jun N-terminal protein kinases, p38-kinases, and ERK5 (Fig. 31-7). As noted, tyrosine phosphorylation of growth factor receptors, such as EGF, creates a binding site for a variety of adaptor proteins. One adaptor,

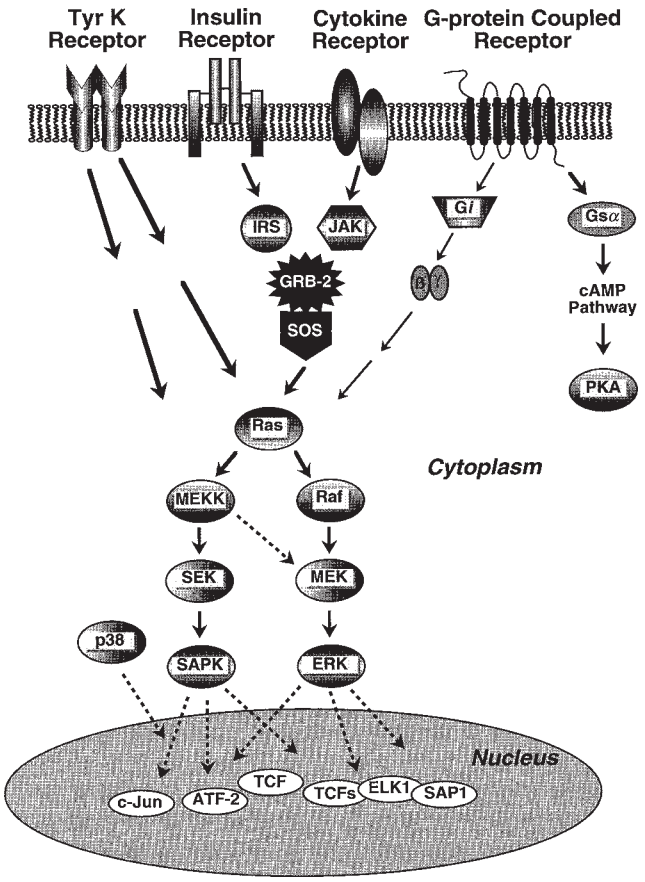

Figure 31-7 Signal transduction cascades. Most cells express a wide variety of different growth factor receptors. Each of these receptors can activate an array of signaling pathways, not all of which are shown. Tyrosine kinases induce the binding of src-homology 2 (SH2) domain proteins, such as Grb-2. Grb-2 binds to guanine nucleotide exchange factors, such as son of sevenless (SOS). This pathway can also be activated by the insulin receptor through insulin-related substrate (IRS) or by cytokine receptors through JAKs. Although Gsα-coupled receptors act primarily through the camp pathway, they can also activate mitogen-activated kinases (MAPK) through their β- and γ-subunits. This figure emphasizes that different receptors can activate the ras pathway along with one or more downstream kinase cascades. Ras activates several downstream kinases in a cell type-specific manner. The preferential activation of a particular MAPK module, such as activation of the ERK rather than the SAPK pathway, provides a mechanism for specific responses. Many cellular targets, including these kinases and a variety of transcription factors, are involved in cellular growth responses.

Grb-2, binds to tyrosine-phosphorylated proteins through its central SH2 domain. Grb-2 contains flanking SH3 domains that recruit proline- rich guanine nucleotide exchange factors, such as SOS (Drosophila son of sevenless). After growth factor treatment (e.g., EGF), the Grb-2–SOS complex associates with the tyrosine-phosphorylated receptor, which leads to the activation of p21ras and induction of downstream kinases.

The signal transduction pathways downstream of growth factor receptors involve a complex interplay of parallel, diverging, and converging pathways. The Ras proteins link growth factor receptor activation to protein phosphorylation and gene regulation through cascades of protein kinases. Induction of MAPKs requires dual phosphorylation on threonine and tyrosine residues by dual specificity MEKs. Several different protein kinases are capable of functioning as MEKKs, including Raf-1 (*see* Fig. 31-7). In some cell types, the SAPKs and p38 kinases are activated by cellular stresses, including specific stimuli such as tumor necrosis factor (TNF)-α, ultraviolet (UV) irradiation, or genotoxic alkylating chemicals. The mechanisms by which one particular MAPK module is activated in response to a particular stimulus might depend on which combinations of kinases are present as well as interactions among various signaling cascades and specific scaffold molecules that bind to and organize the kinases participating in a particular MAPK module.

TFs (e.g., c-Jun, c-Fos, activating transcription factor [ATF]-2, Elk-1) are one of the targets of MAPK cascades and provide an important mechanism for altering patterns of gene expression in response to extracellular signals. Phosphorylation of such TFs can alter interactions with transcriptional partners, change DNA binding affinity for a particular DNA sequence, or affect the activation surfaces that interact with the basal transcription apparatus. As an example, c-Jun is phosphorylated by several different kinases, including ERKs and SAPKs. Amino-terminal phosphorylation of c-Jun by the SAPKs enhances transactivation function, whereas phosphorylation of c-Jun near its DNA binding domain enhances DNA binding.

As with many hormone regulatory systems, negative feedback is critical for dampening signal transduction systems once they have been activated. Because most of these pathways involve reversible protein phosphorylation, protein phosphatases provide a mechanism for temporally modulating specific signals. There might be as many as 1000 distinct protein phosphatase genes. The physiological importance of these phosphatases is exemplified by the ability of SV40 small t antigen to exert its cellular transforming effects by inhibiting protein phosphatase 2A, with consequent induction of MEK and ERK activity in the cell. Various growth factors induce phosphatases differentially. This might explain, in part, why treatment with one growth factor can result in sustained activation of ERK, whereas another factor causes transient stimulation of the kinase. Differences in the duration of signaling result in part through differential activation of G proteins in the Ras family. For example, rapid transient ERK activation is mediated by Ras coupling to Raf-1, whereas prolonged ERK activation involves an alternate small G protein family member known as Rap1, which couples to B-Raf in order to activate ERK. Additionally, signal strength and duration is translated into differential biological responses by altering the phosphorylation state, and thus the protein stability of short-lived TFs that are ERK substrates. Multisite, sequential phosphorylation of immediate early gene products, such as c-jun, c-fos, and c-myc, in response to sustained ERK activation stabilizes these molecules, resulting in their prolonged transcriptional activation, leading to increased cell proliferation.

CALCIUM SIGNALING Many cellular responses involve alterations in intracellular calcium concentration as a mechanism for transmitting signals. There are two main pathways that initiate Ca^{2+} signaling. In excitable cells, the activities of voltage-dependent Ca^{2+} channels result in alterations of intracellular Ca^{2+} concentration. In nonexcitable cells, the slow inositol pathway (IP_3) predominates, initiated either by receptor tyrosine kinases or by GPCRs of the seven transmembrane domain class. These receptors stimulate the hydrolysis of the membrane lipid phosphatidylinositol 4,5-bisphosphate by phospholipase C, leading to the production of diacylglycerol and IP_3. IP_3 binds to one of the

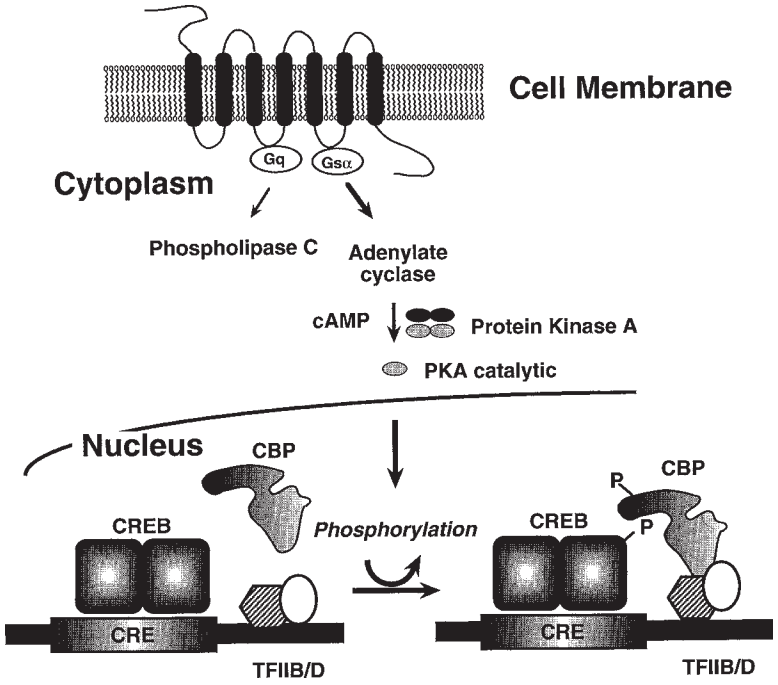

Figure 31-8 cAMP stimulation of transcriptional responses. GPCRs provide a major pathway for the generation of cAMP by adenylate cyclase. Increased cAMP levels within the cell cause dissociation of the tetrameric protein kinase A (PKA) holoenzyme leading to the release of the active catalytic subunit of PKA. The active catalytic subunit is translocated to the nucleus, in which it phosphorylates transcription factor (TF) CREB, which binds as a homodimer to specific cAMP response elements (CREs) on target genes. The phosphorylation of CREB induces the binding of the coactivator, CREB-binding protein (CBP), which is also a substrate for phosphorylation. These transcription factors act by interacting with basal TFs such as TFIIB and TFIID. Several other kinases might phosphorylate CREB, including the calcium-regulated kinases.

members of the InsP3R family of integral endoplasmic reticulum (ER) membrane proteins, activating it as a Ca^{2+} channel to liberate stored Ca^{2+} from the ER lumen into the cytoplasm. The effects modulated by such changes in free intracellular Ca^{2+} are transient, owing to the actions of intracellular calcium binding proteins and pumps that serve to rapidly lower the concentration of free calcium. Such rises in intracellular calcium concentration regulate numerous processes by binding to intermediary proteins, such as calmodulin (CaM), which serves as an intracellular sensor of calcium concentration. CaM binds to a number of enzymes (CaM-dependent protein kinases), protein phosphatases, ion channels, phosphodiesterases, and adenylate cyclases to modify their activities.

cAMP-DEPENDENT SIGNALING Alterations in intracellular cAMP concentration represent an important mechanism by which extracellular signals are transduced to regulate cellular function. cAMP is synthesized by nine members of the adenylate cyclase family from ATP. These membrane-associated enzymes are composed of conserved membrane-spanning and cytoplasmic catalytic domains and are regulated by the binding of hormones and drugs to GPCRs to modulate the levels of intracellular cAMP. cAMP levels can be further modulated by the effects of other influences, including processes intrinsic to the cell, such as the cell cycle, and the actions of members of the phosphodiesterase family. This large family of enzymes includes members grouped into 11 different protein families that serve to hydrolyze either cAMP and/or cGMP.

Many of the pleiotropic array of cellular effects of cAMP are mediated by PKA, which acts on a number of cellular substrates, including enzymes, the cytoskeleton, and TFs. The effects of cAMP are mediated by its intracellular receptor PKA, which is made up of two distinct subunits (regulatory [R] and catalytic [C]) in a tetrameric holoenzyme complex (R_2C_2). The regulatory subunits (RI and RII) contain two cAMP-binding domains at their carboxyl termini that regulate the assembly and activity of the complex. After the binding of cAMP, the holoenzyme dissociates into an R_2 dimer and two free active catalytic kinase subunits (C), which phosphorylate cytoplasmic and nuclear target proteins (Fig. 31-8). An additional complicating factor is that the effects of cAMP in the cell might not be uniformly distributed. Instead, proteins such as the A-kinase anchoring proteins might lead to a gradient of cAMP activation, even within different regions of individual cells.

Specific TFs are important targets of the PKA pathway. These include the CREBs and ATFs that are members of the bZIP class of TFs. Posttranslational modification of CREB by phosphorylation at specific serine residues induces conformational changes that alter the affinity of CREB for coactivator proteins, such as CREB-binding protein (CBP) or the TATA box-binding protein coactivator TAFII 110. CBP is thought to form a bridge between CREB and the basal transcription apparatus (Fig. 31-8). CBP also interacts with other bZIP proteins, such as c-Jun and c-Fos, other TFs, including c-Myb, as well as specific kinases. In addition to a clear role in cAMP signaling, CBP has also been implicated in mitogenic signaling and functions as a transcriptional coactivator with intrinsic histone-acetylase and ubiquitin ligase activities; both enzyme activities play key roles in transcription. Consistent with its role in multiple cell signaling pathways and transcriptional regulation, mutations of CBP cause Rubinstein-Taybi syndrome, which is associated with mental retardation, multiple congenital anomalies, and predisposition to malignancy. The bZIP dimerization structure of the CREB and ATF proteins provides the basis for

numerous combinations of different members of this family. The closely related cAMP response element modulator gene product can act as a dominant negative regulator of CREB transcriptional activity, either by forming inactive heterodimers with CREB or by binding to the CRE as a component of an inactive complex.

Several other DNA regulatory elements and TFs are capable of stimulating gene transcription in response to increased cAMP and PKA activation. The TF, activator protein 2, also functions in basal, phorbol ester, and cAMP-mediated transcriptional induction. The CAAT enhancer binding protein (C/EBP) induces transcription of the adipocyte protein 2 gene promoter and stearoyl acyl CoA desaturase through a region that is also regulated by cAMP through PKA. cAMP-responsive regions of several genes appear to overlap with binding sites for NRs, some of which might also transduce cAMP effects.

Despite the range of effects mediated by these pathways, some effects of cyclic AMP could not be reproduced by the effects of activated PKA, suggesting that cAMP might regulate cellular processes by distinct mechanisms. Cyclic nucleotide gated ion channels have been identified that are directly modulated by the binding of cAMP to a ligand binding pocket on the cytoplasmic surface of the channel. In addition, two novel cAMP receptors, Epac1 and Epac2 (exchange protein directly activated by cAMP; also called cAMP-GEFI and cAMP-GEFII), have been identified. EpacI and II are guanine nucleotide exchange factors that activate the small G proteins Rap1 and Rap2 following the binding of cAMP.

cGMP-DEPENDENT SIGNALING In addition to the GCs that are structural components of membrane receptors (above), a smaller number of soluble GCs (also referred to as NO-sensitive GCs) have been identified. Two different α and two different β-subunits have been identified: α1, α2, β1, and β2. The active complexes are heteromeric, consisting of one α and one β-subunit. Each subunit consists of carboxyl terminal GC catalytic domains, which are conserved compared to the peptide receptor GCs. The amino termini of these proteins are less conserved and encode the segment responsible for coordinating a heme prosthetic group. This heme prosthetic group serves as the NO sensor and is responsible for the modulation of GC activity in response to changes in the intracellular concentration of NO. The NO is produced locally by members of the NO synthase family of enzymes, or pharmacologically, by agents such as nitroglycerine. As with members of the GC receptor family, the cellular effects of cGMP are mediated by effects on the activities of cGMP-dependent protein kinases, cyclic nucleotide-regulated ion channels, and cGMP-regulated cyclic nucleotide phosphodiesterases. Members of the phosphodiesterase family can further serve to modulate levels of cGMP; Sildenafil enhances the effect of NO in the regulation of vascular smooth muscle tone by inhibiting phosphodiesterase type 5.

NF-κB/REL FAMILY OF TRANSCRIPTION FACTORS

NF-κB was originally identified as a protein in nuclear extracts of B cells that bound to the enhancer element of the κ light chain gene. This binding activity was demonstrated to be present in the cell in a "latent" fashion, which could be rapidly activated in the presence of protein synthesis inhibitors by a variety of stimuli, including TNF, lipopolysaccharide, interleukin-1, phorbol esters, growth factors, and UV irradiation. The basis for the rapid and protein synthesis-independent nature of NF-κB activation was found to reflect the association of the active binding moiety with an inhibitory subunit, IκB. The dissociation of IκB from NF-κB results in the rapid appearance and translocation of NF-κB DNA binding activity to the nucleus. The active form of NF-κB was found to be dimeric, exerting its effects by binding to specific target sequences with the genome to regulate gene expression.

Subsequent studies have considerably complicated this scenario. Five members of the NF-κB/Rel protein family have been identified, each with substantial sequence homology in what is termed the Rel homology domain. This segment is located at the amino terminus of each protein and contains elements critical for interaction with the inhibitory IκB proteins, dimerization, and DNA binding. Members of this protein family function as dimers, which may consist of identical or nonidentical subunits. In their inactive state, dimers of the NF-κB/Rel proteins are associated with monomers of the IκBα or IκBβ proteins. NF-κB activation is mediated by the IκB (IKK) complex, made up of catalytic components (IKKα and IKKβ) and a regulatory subunit (IKKγ or NEMO). Following stimulation by a number of important effectors, the IKK complex phosphorylates IκB on specific residues, promoting its ubiquitination and degradation.

NF-κB activation is central to the regulation of immune response, owing to its role in the regulation of a host of cytokines and chemokines. It has become clear that NF-κB activation plays an important role in the regulation of apoptosis. Indeed, in some systems, activation of NF-κB has been demonstrated to antagonize the effects of chemotherapy and radiation in inducing apoptosis. Such findings have led to attempts to sensitize tumors to the actions of chemotherapy and radiation by blocking the activation of NF-κB. In addition to diseases in which abnormalities of NF-κB expression occur, defects of the NF-κB signaling pathways have been identified. Incontinentia pigmenti is a rare X-linked-dominant disorder that affects ectodermal tissues resulting in abnormal skin pigmentation, retinal detachment, anodontia, alopecia, nail dystrophy and central nervous system defects. Over 90% of IP carrier females have a recurrent multiexon deletion of the IKKγ gene, which is required to activate the NF-κB pathway. In IP, mutations in IKKγ lead to the complete loss of NF-κB activation creating a susceptibility to cellular apoptosis in response to TNF-α. Although females, hemizygous as a result of X-chromosome inactivation, survive, this condition is lethal for males.

CELL-CYCLE REGULATORY SIGNAL TRANSDUCTION PATHWAYS Phosphorylation plays an essential regulatory role in the cell cycle, and a large array of cyclin-dependent kinases (CDKs) has been identified (Chapter 4). The regulatory subunits of the CDKs, known as cyclins, form complexes with their catalytic partners to function as heterodimeric holoenzymes that phosphorylate specific proteins, including the tumor suppressor protein pRb (Chapter 4). Phosphorylation of pRb blocks its critical inhibitory function, allowing cell-cycle progression and differentiation to occur. Several proteins capable of binding cyclins and inhibiting CDK activity have been identified and are referred to as CDKIs. The CDKIs inhibit cell-cycle progression and inhibit tumor formation. Translocation of the cyclin D1 gene has been associated with certain cases of hyperparathyroidism (Chapter 36), and actually led to the identification of cyclin D1 in humans. In these cases, a somatic inversion of chromosome 11 brings cyclin D1 under the control of the PTH promoter. Consequently, cyclin D1 is overexpressed in the parathyroid cell and results in cellular proliferation. The proliferative and transforming effects of cyclin D1 are independent of its ability to activate cyclin-dependent protein kinases,

but instead require its interaction with the CEBP/β TF, in which cyclin D1 relieves the transcriptional repressive activity of CEBP/β at multiple gene promoters.

NUCLEAR RECEPTORS

Nuclear Receptor Action The NR superfamily consists of structurally related proteins that are important modulators of gene expression in eukaryotes. The structures of the different family members are widely distributed in many species and are highly conserved, particularly in the segments encoding the DNA-binding domain (DBD) and ligand-binding domain (LBD) of the receptor proteins.

In humans, 48 different members of this family have been identified, based on sequence analysis of the human genome. In some circumstances, the NRs mediate the physiological actions of small cell-permeable hormones, such as the sex steroids (estrogen, testosterone, and progesterone), cortisol, aldosterone, thyroid hormone, and vitamin D, as well as retinoids that are derived from dietary vitamin A. In other instances, no ligand has been identified. These receptors might not require the binding of a ligand for functional activation and as a group are referred to as "orphan" NRs.

Structure and Classification of Nuclear Receptors From the first analyses of NR structure and function, it was apparent that these proteins were organized in a modular fashion. The DBD, made up of two centrally located "zinc fingers," is the most highly conserved segment (Fig. 31-9). The structure of this segment has been well characterized using site-directed mutagenesis, X-ray crystallography, and nuclear magnetic resonance studies. Residues at the carboxyl terminal base of the first zinc finger are principal determinants of DNA binding specificity, where, as adjacent sequences at the base of the second zinc finger are critical to the formation of the dimerization interface. The DBDs of NRs that bind as monomers differ slightly in carboxyl terminal extensions of the DBD that contribute to the DNA binding by this element. Regions carboxy-terminal to the DBD specify sequences that localize the protein to the nucleus.

Other functionally important segments of the NRs have been delineated. For members that bind ligand, the LBD is located in the carboxyl terminus of the receptor. In addition to its role in ligand binding, this region contains several overlapping domains, including regions required for dimerization of the receptor and for transcriptional activation and repression. The structures of the LBDs of a number of NR family members have been solved by X-ray crystallography. These studies demonstrate that ligand binding induces important conformational changes that underlie the changes of activity of the NR in the regulation of gene activity. The amino-terminal segments of the NRs are the most variable and the least well characterized. In some cases, it contains additional transcription-activating domains and serves as a "docking site" for interactions with other proteins.

NRs can be classified by several different schemes. One useful method employs the mechanisms by which these molecules recognize DNA (*see* Fig. 31-10). The classic steroid receptors share a similar DBD and bind to DNA sequences similar to the inverted palindromic sequence depicted. This group includes receptors for glucocorticoids, mineralocorticoids, progesterone, and androgens. The steroid receptors have been particularly well characterized and exist in the cell complexed with proteins of the heat shock family in the absence of ligand. Following the binding of ligand, the receptors dissociate from the heat shock proteins, translocate to the nucleus, and bind monomers to target DNA sequences within or adjacent to responsive genes.

Other NRs differ in the manner that they bind to target DNA sequences. The diverse patterns of recognition include the binding as monomer, heterodimers, and homodimers (*see* Fig. 31-10). The retinoid X receptors (RXRs) serve as heterodimeric partners for several different NRs, including retinoic acid receptors (RARs), thyroid hormone receptors, vitamin D receptor (VDR), and peroxisome proliferator-activating receptors (PPARs). The heterodimers typically bind to hormone response elements (HREs) that are arranged as direct repeats rather than in a palindromic manner. The spacing between these half-sites, and variations in some of the contextual bases, provide specificity to different receptors, providing a partial explanation for how so many different receptors can share a common binding motif but elicit distinct cellular responses.

A number of members of the NR family were identified on the basis of sequence homology to the DBDs of characterized members of the NR family (e.g., the steroid receptors). This cloning exercise yielded cDNAs encoding proteins with structural similarities to the NRs (e.g., with the LBDs and DBDs), but for which no ligand had been defined. With time, ligands for several of these 'orphan' receptors have been identified. For example, the RXRs were initially classified as orphan receptors, but are known to bind 9-cis retinoic acid. The PPARs bind a variety of eicosanoids, as well as thiazolidinediones that are used to treat noninsulin-dependent diabetes. It remains to be determined whether ligands exist for all orphan members of the NR family. It appears likely that some members might not bind ligand, and instead might be constitutively active or regulated by other mechanisms, such as phosphorylation.

In addition to the diversity in types of receptor the NR family, in several cases receptor isoforms encoded by different genes provide an additional level of control. For example, there are two separate genes for TRs, two ERs, three for all-trans RARs, and three RXRs. In addition, many of these genes generate multiple receptor subtypes by virtue of alternate mRNA splicing or alternate promoter or initiator methionine usage. The function of individual isoforms has been defined in only a small number of instances, but in the case of the PR, the A- and B-isoforms have physiologically distinct roles. Receptor subtype expression is highly regulated during development, and there is striking tissue-specific expression of various NR isoforms in adult organs. Therefore, like the peptide hormone receptors, tissue responsiveness to the hormone signal is regulated at its most fundamental level by selective expression of the NR in responsive tissues.

Nuclear Receptor Function and the Modulation of Gene Expression NRs interact with specific DNA sequences that are frequently located within or adjacent to promoter regions of regulated genes. After the receptor binds to DNA, it is positioned to interact with other TFs to alter rates of gene transcription. Considerable progress has been made toward defining the mechanism(s) by which NRs modulate these effects. Several of the NRs physically interact with the basal TF, TFIIB. Using in vitro transcription analysis, the NRs have been shown to facilitate the rate of assembly and stabilize basal TFs in the preinitiation complex that forms at the sites of transcriptional initiation.

An additional level of transcriptional control occurs through NR interactions with "coactivator" or "corepressor" proteins, which in turn interact with proteins of the basal TF complex. Several of these proteins have been identified on the basis of their ability to interact with NRs, using biochemical techniques or genetic screens in yeast. In general, coactivators recruit proteins that result

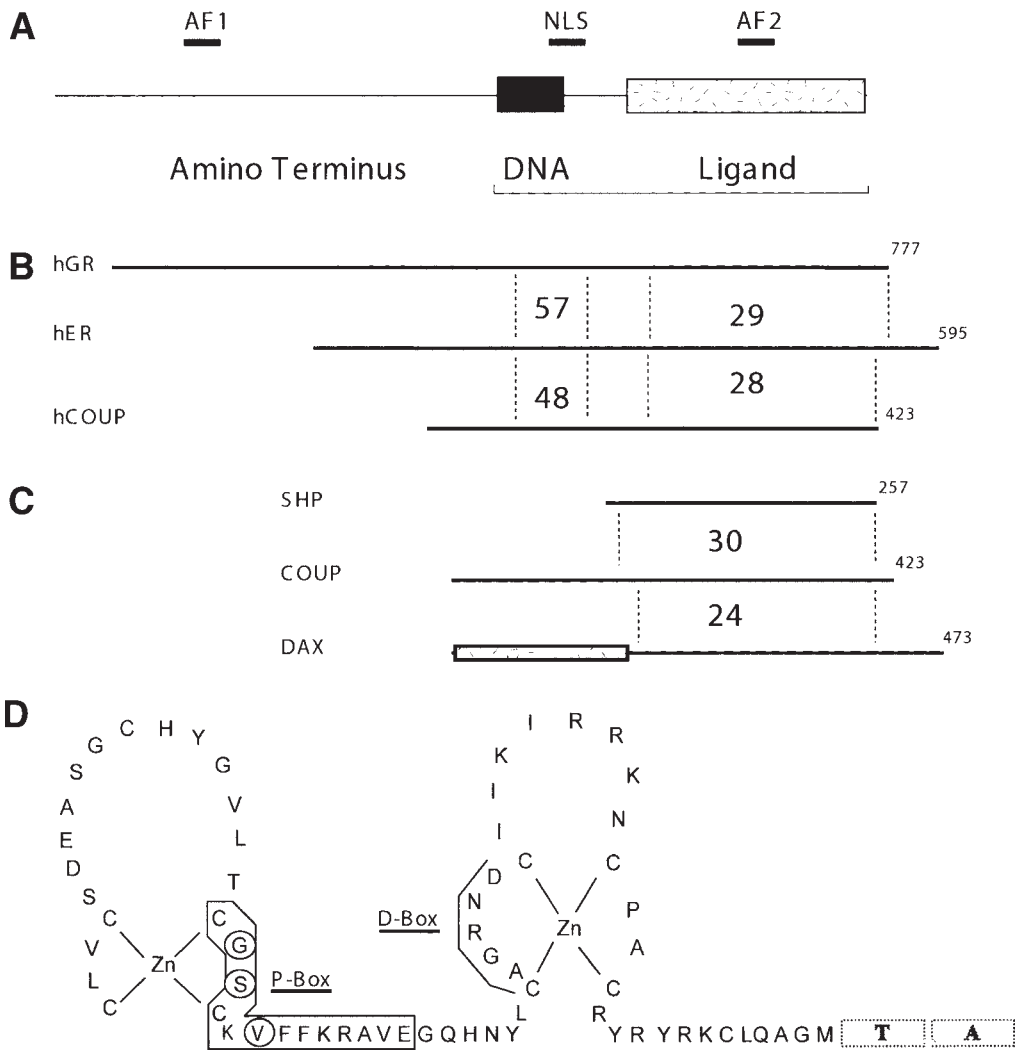

Figure 31-9 Modular structure of the NR family. Members of the NR family contain segments that are conserved to varying degrees among the family members. **(A)** A schematic structure of a prototypic NR is shown. The conserved ligand binding and DNA binding domains are indicated (hatched and filled rectangles, respectively). The relative positions of the activating functions (AF)-1 and -2 within the amino terminus and carboxyl terminus of the receptor proteins are shown. Sequences responsible for the nuclear localization of these proteins have been localized to the carboxyl terminal end of the DNA-binding domain. **(B)** Although the relative positions of the individual domains are in most instances maintained, the degree of sequence conservation varies widely. Members of the nuclear receptor family exhibit the highest degree of conservation when the amino acid sequences of the DNA binding domains of the receptor proteins are compared. Lesser degrees of homology are evident between the sequences that are made up of the LBDs of the receptors. In the example shown, the predicted amino acid sequences of three different members of the nuclear receptor family are compared. The degree of relatedness is shown for each of the two receptors when aligned with the predicted amino acid sequence of the human glucocorticoid receptor. The amino-terminal segments of the receptors differ considerably in size and sequence. The extent of homology is <15% when the amino termini of the receptor proteins are compared. **(C)** In some members of the nuclear receptor family, differences are evident even in the fundamental organization of the receptor proteins. The COUP-TF protein exhibits a structure similar to that of the other nuclear receptor protein, with a small amino terminus, a DNA binding domain comprised of two zinc fingers, and a segment corresponding to the ligand binding domains of the steroid receptors (COUP-TF is an orphan receptor). By contrast, although the amino acid sequence of the orphan nuclear receptor, DAX-1, predicts a segment homologous to the LBD of other nuclear receptors, the amino terminal segment is composed of distinctive segments that mediate the binding of this nuclear receptor to DNA (stippled box). SHP, short heterodimer partner, while in which as encoding segments similar to the ligand-binding domains of other nuclear receptors, lacks segments that mediate its binding to DNA. **(D)** Schematic organization of the human glucocorticoid receptor DNA binding domain. The zinc ions serve as nucleation centers for the two "zinc finger" modules of the DNA binding domain. The regions identified by mutagenesis studies as being important for receptor dimerization (D-box) and for target gene specificity (P-box) are indicated. In some members of the nuclear receptor family, carboxyl terminal extensions (CTE) of the DNA binding domain are important determinants of the high affinity binding of the receptor proteins to its DNA targets (the T- and A-boxes). (Reprinted with permission from Zoppi S, Young M, McPhaul MJ. Regulation of gene expression by the nuclear receptor family. Genetics of Steroid Biosynthesis and Function, Mason, JI, ed., Harwood Academic Publisher, 2002, pp. 376–403.)

in a more active chromatin configuration, and are associated with increases in transcription. By contrast, corepressors enable the recruitment of proteins that result in the compacting of chromatin and lowering of the transcriptional activity of genes.

In parallel with such studies, other investigators used biochemical fractionation methods to isolate the protein complexes that associate with ligand-bound forms of the NRs, such as the thyroid receptor and VDR. These studies led to the characterization of

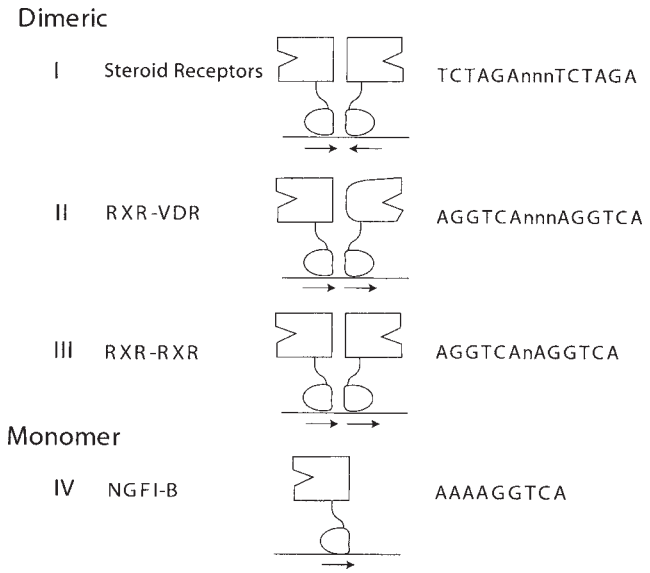

Figure 31-10 Schematic representations of the different mechanisms by which members of the nuclear receptor family recognize DNA. In many instances, members of the steroid receptor family (Class I) bind to sequences similar to the inverted palindromic sequence shown at right. In this type of recognition sequence, a three-nucleotide "spacer" (nnn) separates the individual half sites. Nuclear receptors (NRs) with nonsteroidal ligands (Class II) bind to DNA in association with the obligate heteromerization partner, retinoid X receptor (RXR). Depending on the receptor (e.g., vitamin D receptor, thyroid hormone receptor, peroxisome proliferator-activated receptor, or retinoic acid receptor) the spacing between the two individual half sites is distinct. Class III NRs bind as homodimers to their target sequences. Some members of the nuclear receptor family (Class IV) bind to their target DNA sequences as monomers. In these instances, nucleotide residues adjacent to the core response element form a critical component of the recognized sequence. (Reprinted with permission from Zoppi S, Young M, McPhaul MJ. Regulation of gene expression by the nuclear receptor family. Genetics of Steroid Biosynthesis and Function, Masson, JI, ed., Harwood Academic Publisher, 2002, pp. 376–403.)

large multiprotein complexes such as the thyroid receptor-associated proteins (TRAPs) and vitamin D receptor-interacting proteins (DRIPs). Subsequent analyses demonstrated that these protein complexes share considerable relationship to one another and to other multiprotein assemblies that interact with other transcriptional activators (e.g., ARC). Furthermore, each of these complexes shares considerable similarity to the transcriptional regulator complex, Mediator, which was originally defined genetically and biochemically in yeast.

These considerations led to the emergence of the puzzling dichotomy of transcriptional regulation by NRs. On one hand was the participation of nuclear coregulators, such as the coactivators and corepressors. However, biochemical and genetic studies suggested the importance of complexes such as the DRIP and TRAP complexes. This apparent duality has been partially reconciled by the demonstration that components of both types of complexes can be demonstrated at the sites of transcriptional regulation at different times following stimulation with hormone. These observations suggest that the complement of proteins that can be detected at important regulatory sites within a regulated gene are dynamic and might differ substantially at different times following the addition of hormone. The complement of such proteins that is present in different cell types might help explain the differential effects of ligands in different tissues.

Nongenomic Functions of Nuclear Receptors Exploration of the mechanisms by which members of the NR family modulate the transcription of responsive genes is ongoing. In general, these effects require sufficient time (e.g., hours) for the effects on the transcription of responsive genes to be exerted. In other circumstances, the timing of the observed effect is so rapid regarded to be inconsistent with regulation at the transcriptional level. These transcription-independent steroid responses are often termed "nongenomic," and in many cases appear to be mediated by interactions between classic NRs and membrane signaling molecules. Examples include estrogen-induced activation of the MAPK cascade and endothelial NO synthase activity in breast and endothelial cells, respectively; estrogen and androgen-mediated protection from apoptosis in bone cells; and progesterone- and testosterone-induced maturation of oocytes.

Although distinct in terms of mechanism, these two types of effect are not mutually exclusive. For example, growth factor signaling pathways alter the function of some NRs, such as the ER and PR. Such influences might exert important effects on the growth or gene expression patterns of cells in response to specific classes of ligand. For example, direct phosphorylation of ER or PR by MAPK can lead to responses to very low concentrations of steroid hormone ligands at hormone-responsive elements containing gene promoters, whereas activation of MAPKs by ER or PR might regulate genes targeted by Ets factors that are primarily phosphorylated and activated by MAPK family members.

Antagonism of Nuclear Receptor Function The reproductive NRs are notable owing to the existence of clinically important receptor antagonists. RU-486 binds with high affinity to the PR LBD (it also binds the glucocorticoid receptor) in such a manner that the ligand-receptor complex recruits corepressors, blocking its transcriptional activating properties. In like fashion, although ICI 164, 382, Tamoxifen and Raloxifene are bound in the ligand-binding cavity of the ERα, they cause the ER to adopt conformations that cause the recruitment of molecules that do not permit full transcriptional activation of estrogen-regulated genes. The conformation of the ER differs when bound to these different ligands, accounting for the recruitment of differential complements of corepressors and coactivators, and their activities as "pure" or selective ER modulators. The development of specific receptor antagonists for these and other members of the NR family is an active area of investigation (Table 31-4). The definition of functionally critical surfaces and the demonstration that the binding of small molecules to these surfaces (such as peptides) results in selective decreases in receptor function suggests that reagents to modulate the activity of many members of the NR might be possible.

Physiological Effects of Nuclear Receptors Members of the NR family serve important roles in development, cell differentiation, metabolism, and reproduction. Examples of these functions are described briefly to illustrate how NRs affect physiology.

The glucocorticoid receptor mediates the widespread effects of cortisol on blood pressure, blood glucose levels and insulin action, neuropsychiatric status, diurnal variation in body temperature, and immune responses. The closely related mineralocorticoid receptor binds aldosterone and regulates the renal handling of potassium and sodium.

The sex steroid receptors determine the phenotypic appearance of secondary sexual characteristics and control the production of oocytes and sperm. The androgens testosterone and 5α-dihydrotestosterone both bind to a single high-affinity receptor protein, the androgen receptor. In many systems, testosterone exhibits lower activity as

Table 31-4
Ligands and Antagonists for NRs

Receptor	*Ligand*	*Antagonists*
Glucocorticoid subfamily		
GR	Cortisol	RU-486
PR	Progesterone	RU-486
MR	Aldosterone, cortisol	Spironolactone
AR	Dihydrotestosterone	Flutamide, cyproterone
ER/TR subfamily		
ER	Estrogen	Tamoxifen, clomiphene, ICI 164,384
TR	Triiodothyronine (T3)	None
VDR	1,25-Dihydroxyvitamin D	None
RAR	All-*trans* retinoic acid	Ro 41-5253
RXR	9-*cis* Retinoic acid	None
PPARγ	Prostaglandin J_2, Thiazolidinedione	None

PR, progesterone receptor; GR, glucocorticoid receptor; MR, mineralocorticoid receptor; AR, androgen receptor; ER, estrogen receptor; TR, thyroid hormone receptor; VDR, vitamin D receptor; RAR, retinoic acid receptor; RXR, 9-*cis* retinoic receptor; PPAR, peroxisome proliferator activated receptor.

Table 31-5
Disorders Caused by Mutations in NRs

Receptor	*Disorder*	*Mechanism*	*Inheritance*
Androgen receptor	Androgen insensitivity	Loss-of-function: premature termination, DBD and LBD missense mutations	X-linked
	Prostate cancer	Gain-of-function: point mutations	Somatic
Estrogen receptor	Estrogen resistance	Loss-of-function: missense mutations, deletions	Autosomal-recessive
	Breast cancer	Gain-of-function: Missense mutations	Somatic
Glucocorticoid receptor	Glucocorticoid resistance	Loss-of-function: premature termination, DBD and LBD missense mutations	Autosomal-dominant
Thyroid hormone receptor β	Resistance to thyroid hormone	Loss-of-function: LBD missense mutations	Autosomal-dominant
Vitamin D receptor	Vitamin D-resistant rickets	Loss-of-function: DBD and LBD missense mutations	Autosomal-recessive
Retinoic acid receptor	Promyelocytic leukemia	Gain-of-function: fusion protein lacking RAR DBD	Somatic translocation
HFN4	MODY	Loss-of-function:	Autosomal-dominant
PPARγ	Obesity	missense	
Mineralocorticoid receptor	Hypertension	Gain-of-function: missense mutation	Autosomal-dominant
	Type I pseudo hypo aldosteronism	Loss-of-function: missense mutations	Autosomal-dominant

RAR, retinoic acid receptor.

an androgen, compared to DHT, presumably on the basis of a slightly lower affinity and stability of binding to the AR. Thus, the conversion of T to the more active metabolite DHT, by one of the two 5α-reductase isoenzymes, represents a mechanism by which tissue- or cell type- specific variations in androgenic effects can be modulated.

In the examples earlier, the physiological pathways regulated by the receptors were defined before the receptors were isolated and characterized. This is not true for many members of the NR family; the recognition of the biological importance of many members of this family has awaited the definition of phenotypes in humans and in animal models of disease. For example, steroidogenic factor (SF)-1 is an orphan receptor that was originally identified on the basis of its role in modulating the expression of genes encoding the steroidogenic cytochromes P450. Although these studies demonstrated that SF-1 is selectively expressed in the adrenal gland and in reproductive tissues, it was not until the targeted disruption of SF-1 was accomplished in the mouse that the critical role of this protein in the development of the adrenals and gonads was recognized. The subsequent identification of human patients with SF1 mutations has demonstrated the relevance of these findings in the mouse to humans.

NRs play a prominent role in human disease, many of which are described in detail in subsequent chapters (Table 31-5). Although the most well defined disorders are those of resistance to nuclear hormone action (loss-of-function mutations), an increasing number of diseases have been traced to alteration of structure that leads to an activation of the receptor protein.

32 Diabetes Mellitus

William L. Lowe, Jr.

SUMMARY

Diabetes mellitus is characterized by fasting and postprandial hyperglycemia. Type 1 diabetes occurs secondary to autoimmune destruction of the insulin-secreting pancreatic β-cells, whereas type 2 diabetes results from a deficiency of insulin action secondary to a combination of insulin resistance and relative β-cell dysfunction. Familial clustering of type 1 and 2 diabetes has suggested a genetic contribution to the etiology of the diseases, but monozygotic twin and other studies have indicated that environmental factors also contribute to their etiology. Although relatively rare monogenic forms of diabetes have been described, type 1 and 2 diabetes are, in general, complex, polygenic diseases.

Key Words: Autoimmunity; genetics; insulin; major histocompatibility complex; maturity onset diabetes of the young; mitochondria; peroxisome proliferator-activated receptor-γ; sulfonylurea receptor; type 1 diabetes; type 2 diabetes; Wolfram syndrome.

INTRODUCTION

Diabetes mellitus affects approx 5% of the general population with its prevalence varying among ethnic groups and geographic regions. Two types of diabetes, type 1 and 2, account for approx 10 and 90% of diabetes cases, respectively. Although these two disorders share a common phenotype, fasting and postprandial hyperglycemia, their etiology is distinct. Type 1 diabetes is characterized by pancreatic β-cell deficiency with a resulting absolute deficiency of insulin. The β-cell deficiency is most commonly secondary to autoimmune-mediated destruction. Type 2 diabetes, in contrast, is characterized by a deficiency of insulin action resulting from a combination of insulin resistance and relative β-cell dysfunction that is manifest as inadequate insulin secretion in the face of insulin resistance and hyperglycemia.

The familial clustering of both type 1 and 2 diabetes has long suggested a genetic contribution to the etiology of the diseases. In the case of type 1 diabetes, the concordance rate among monozygotic twins is 30–40% compared with a concordance rate of 5–10% among dizygotic twins. The risk of type 1 diabetes for siblings of an affected individual is approx 6%, whereas the risk in the general population is approx 0.4%. Although these data are consistent with a genetic contribution to the etiology of the disease, the lack of 100% concordance in monozygotic twins suggests that environmental factors make a significant contribution to the disease pathogenesis. These environmental factors are not clearly defined, but some studies suggest that certain viral infections or early childhood diet may affect the risk of type 1 diabetes. Prenatal exposure to rubella is a clear risk factor, as 20% of children with the congenital rubella syndrome develop type 1 diabetes. Other potential risk factors for which there are conflicting or unconfirmed data include enterovirus infections and early introduction of either cow's milk protein, cereal, or gluten into the diet. Familial clustering of disease is much more apparent in type 2 diabetes. The concordance rate among monozygotic twins is 50–90%, whereas approx 40% of siblings and 30% of offspring of affected individuals develop either type 2 diabetes or impaired glucose tolerance. Again, these data are consistent with a significant genetic contribution to the development of type 2 diabetes but suggest that environmental influences are also important.

With the advent of molecular genetics, significant progress has been made in defining the genetics of rare, monogenic forms of diabetes as well as more typical type 1 and 2 diabetes. Progress is reflected in the classification of diabetes, which includes diagnostic categories of genetic defects in β-cell function and insulin action. This chapter describes the advances in the genetics of both type 1 and 2 diabetes, as well as monogenic forms of diabetes.

GENETICS OF TYPE 1 DIABETES MELLITUS

Type 1 diabetes often presents abruptly with marked hyperglycemia, polyuria, and ketoacidosis, which occur as a result of insulin deficiency. This dramatic presentation suggested initially that type 1 diabetes was the result of an acute event, but with an improved understanding of the pathogenesis of the disease, it is clear that disease onset is a chronic process that can be divided into a series of stages. As discussed next, individuals have a genetic predisposition for diabetes. In certain of these individuals, an autoimmune process is initiated, presumably in response to some environmental exposure. There is then a period of active autoimmunity characterized by the presence of autoantibodies and progressive β-cell destruction but with maintenance of normal blood sugars and glucose tolerance. With sufficient β-cell destruction, impaired glucose tolerance, which is typically not clinically evident, ultimately diabetes develops. Depending on the rate of decline of β-cell function, older patients may be presumed to have type 2 diabetes mellitus because of residual insulin secretion, albeit not sufficient insulin secretion to maintain euglycemia. As destruction of the residual β-cells continues, a new stress, for example, infection, often results in the acute presentation of diabetes.

Ultimately, absolute insulin dependence develops because of total or near-total β-cell destruction.

The autoimmune-mediated destruction of pancreatic β-cells is characterized by two features, autoantibodies and insulitis. Autoantibodies present in type 1 diabetes mellitus are directed against a variety of β-cell antigens, including insulin, glutamic acid decarboxylase (GAD65 and 67), and a catalytically inactive member of the transmembrane protein tyrosine phosphatase family (IA-2). Although the presence of two or more of these antibodies is predictive of progression to diabetes in relatives of affected individuals, they likely play little role in the immune-mediated destruction of the islets cells. Insulitis is characterized by inflammatory infiltrates in the islets consisting primarily of $CD8^+$ cells but also of $CD4^+$ cells, B-cells, macrophages, and natural killer cells. The cause of type 1 diabetes mellitus, and thus, the trigger for the autoimmune process, is complex and involves both a genetic predisposition and environmental factors.

Type 1 diabetes does not follow a simple Mendelian pattern of inheritance. As demonstrated by studies in identical twins, there is not 100% concordance between a susceptible genotype and disease presence. Presumably the penetrance of the disease genes is influenced by environmental factors. Moreover, studies in mice and humans clearly demonstrate that the disease is polygenic, suggesting that a sufficient complement of genes must be inherited to confer susceptibility to diabetes. Two approaches have been used to define genes that predispose to type 1 diabetes-identifying candidate genes by comparing the frequency of alleles of specific genes in diabetic and control populations (case–control or association studies) and genome scanning to identify chromosomal loci linked with disease susceptibility. Given the autoimmune etiology of type 1 diabetes, the major histocompatibility (MHC) locus or human leukocyte antigen (HLA) region was examined initially as a candidate susceptibility locus. Association studies identified this region as a potential susceptibility locus, and this was confirmed in subsequent linkage studies. This locus is referred to as *IDDM1*. One measure of the degree of familial clustering of a disease is to determine λ_s, which is the ratio of the disease risk in siblings of affected individuals compared with the risk of the disease in the general population. For type 1 diabetes, the λ_s is 15, whereas the λ_s for *IDDM1* is estimated to be 3.4, suggesting that *IDDM1* accounts for 45–50% of the familial aggregation of the disease.

The MHC is located on the short arm of chromosome 6 (6p21) and encodes proteins involved in the regulation of the immune process. The MHC consists of three major regions, A, B, and C, that encode class-I genes, and the D region that encodes class-II genes. The class-I molecules, which are expressed on most cell types, are highly polymorphic and present peptide fragments of endogenous antigens to cytotoxic $CD8^+$ cytotoxic T-lymphocytes. The class-II molecules are expressed on a more limited subset of cells, which are primarily antigen-presenting cells (macrophages, dendritic cells, B-cells, and activated T-cells). Class-II molecules present foreign processed antigen to $CD4^+$ helper T-cells and are, thus, involved in initiating the immune response. Class-II molecules consist of an α- and β-chain that are encoded by different genes. There are three major classes of class-II genes, the DP, DQ, and DR genes. The β- but not the α-chain in the DR molecules is polymorphic, whereas both the α- and β-chains are polymorphic in DQ and DP molecules. Indeed, 17, 30, and 177 different alleles encoding the DQ-α- and -β-chain and DR-β-chain, respectively, have been described.

Initially an association between class-I alleles and type 1 diabetes was demonstrated, but it is clear that class-II molecules are most important in conferring risk. The original association with class-I molecules was likely because of the nonrandom association of class-I alleles with the class-II alleles (linkage disequilibrium). Moreover, linkage disequilibrium of the DQ and DR alleles has created extended haplotypes (the presence of several genetic variants on the same chromosome) that modulate risk. Some of these class-II alleles predict susceptibility to type 1 diabetes, whereas others either confer protection or are neutral. As noted, the risk of type 1 diabetes in the sibling of an affected individual is 6%, but, if the sibling has inherited the same HLA haplotypes as their affected sibling, their risk of type 1 diabetes is 20%. The HLA alleles DR4 and DR3 are strongly associated with diabetes. Linkage disequilibrium between DR* and DQ* contributes to this association. The major determinants of risk in this region are the DRB1 and DQB1 loci, although other loci in the HLA region may modulate risk. Among type 1 diabetic subjects, 95% have either the DRB1*0301-DQB1*0201 or the DRB1*04-DQB1*0302 haplotype. The contribution of both the DRB1 and DQB1 loci to disease risk is illustrated by the ability of different DRB1*04 alleles on the same haplotype to modify the risk conferred by DQ8 (DQA1*0301-DQB1*0302). The DRB1*0401, *0402, and *0405 alleles are associated with high susceptibility, DRB1*0404 with moderate susceptibility, and DRB1*0403 with protection. In addition to alleles conferring risk, several HLA alleles conferring protection from diabetes have been identified. The best known of these is DQB1*0602. The haplotype DQA1*0102-DQB1*0602 is present in 20% of Europeans and North Americans but in less than 1% of children with diabetes. Although the mechanism by which different HLA molecules affect diabetes susceptibility is still being elucidated, it is likely that changes in peptide binding sites of different class-II molecules alter the specificity of the immune response to foreign or self-antigens by affecting the binding affinity of different peptide antigens for the class-II molecules. Because of the strong and extended linkage disequilibrium present in the HLA region, it has not been possible to determine whether other genes in this region, many of which affect antigen presentation and immunoregulation, also have an effect on disease susceptibility.

A second susceptibility locus, the insulin gene locus on chromosome 11p15.5, was identified using both a candidate gene approach and linkage analyses. Among the polymorphisms in this region is the variable number of tandem repeats (VNTR) locus in the 5′-flanking region of the insulin gene. The VNTR consists of tandem repeats of a 14–15 bp core sequence. Three different alleles have been identified. The class-I allele contains 30–60 repeats, and homozygosity for this allele is associated with a two to fivefold increased risk of type 1 diabetes. The class-III allele contains 141–209 repeats and has a dominant protective effect. The class-II allele has approx 80 repeats but is rare, and its association with disease susceptibility has not been defined. The impact of *IDDM2* on susceptibility to type 1 diabetes is modest. The λ_s for *IDDM2* is 1.2, and it accounts for 10% of the familial clustering of type 1 diabetes.

As defined by linkage analyses, *IDDM2* is located within a 50-kbp region of chromosome 11 that contains the genes encoding tyrosine hydroxylase, insulin, and insulin-like growth factor II. Multiple polymorphisms are present within this region, but an extensive series of genetic analyses mapped the *IDDM2* susceptibility locus to the VNTR in the 5′-flanking region of the insulin gene, suggesting that the variable number of repeats in some manner confers

susceptibility to disease, perhaps because of effects on insulin gene expression. In vitro studies using the VNTR in reporter gene constructs have demonstrated that the VNTR modulates insulin gene expression, although conflicting data were obtained. In vivo studies have demonstrated that the class-III allele is associated with decreased pancreatic insulin gene expression compared with transcription from the class-I allele. A mechanism by which the VNTR could affect disease susceptibility via its effects on pancreatic expression of the insulin gene was not obvious. Subsequent studies, however, examined effects of the VNTR on pre- and postnatal expression of the insulin gene in the human thymus. Interestingly, the class-III allele is associated with an approx 2.5-fold increase in insulin gene expression in the thymus compared with the class-I allele. Similarly, increased levels of proinsulin are present in thymi from class-III/I heterozygotes compared with class-I/I homozygotes. Increased expression of insulin in the thymus might facilitate tolerance to insulin by promoting deletion of insulin-specific T-lymphocytes, and, thus, provide protection from type 1 diabetes.

Because *IDDM1* and *IDDM2* account for only approx 50% of the familial clustering of type 1 diabetes, additional genes must be involved. Two other susceptibility loci that have been identified based on association studies are *CTLA4*, which encodes cytotoxic T-lymphocyte-associated 4, and *PTPN22*, which encodes lymphoid-specific phosphatase (LYP). Susceptibility to type 1 diabetes was mapped to a 6.1 kb 3′ region of *CTLA4* that appears to modulate alternative splicing of *CTLA-4* mRNA. CTLA-4 downregulates T-cell activation. The susceptibility allele results in decreased formation of a soluble isoform of CTLA-4. Although not confirmed in humans, the soluble isoform appears to be a more potent regulator of T-cell inhibition. Interestingly, this same susceptibility allele also confers an increased risk of Grave's disease and autoimmune hypothyroidism. LYP also inhibits T-cell activation. A single nucleotide polymorphism (SNP) in *PTPN22* that results in substitution of tryptophan for arginine at codon 620 is present with increased frequency in subjects with type 1 diabetes compared with the general population. The Trp^{620} variant alters the association of LYP with intracellular signaling molecules and, presumably, its ability to regulate T-cell activation. Like *CTLA-4*, the *PTPN22* variant is associated with other autoimmune diseases, including Grave's disease, rheumatoid arthritis, and systemic lupus erythematosis.

Another approach to identify type 1 diabetes susceptibility genes is genome scans using DNA from sibling pairs affected by type 1 diabetes. The aim of genome scans using affected sib pairs is to scan the entire genome with a collection of genetic markers, calculate the degree of allele sharing at each marker or locus, and identify those chromosomal loci in which allele sharing by the affected siblings occurs with greater frequency than expected, based on the frequency of the allele in the population. Increased sharing of alleles at a specific locus suggests that a gene(s) within that chromosomal locus contributes to the pathogenesis of the disease. Multiple genome scans have been performed resulting in the identification of many potential type 1 diabetes susceptibility loci (Table 32-1). Unfortunately, many of the findings have not been replicated in the different genome scans. Possible reasons for this are many. None of these potential loci has an effect approaching the magnitude of *IDDM1*. Rather, they likely confer a modest increase in susceptibility similar to that conferred by *IDDM2*. To demonstrate linkage of loci with a modest effect on disease susceptibility requires a large number of subjects. Most studies have lacked sufficient subjects to reliably demonstrate linkage of the different loci to type 1 diabetes. Indeed, despite clear association of the *IDDM2* locus with type 1 diabetes and a clear biological explanation for this association, linkage of *IDDM2* to type 1 diabetes has not been reliably demonstrated by genome scans. Similarly, the *PTPN22* locus on chromosome 1p13 has not been identified by genome scans. Analysis of a merged data set that contained 1435 families with 1636 affected sib pairs was recently reported. These data provided continued support for the contribution of *IDDM1* and *IDDM2* to disease susceptibility and identified eight additional non-HLA-linked loci that confer susceptibility. Three of these loci, 2q31-q33 (*IDDM7* and *IDDM12*), 10p14-q11 *(IDDM10)*, and 16q22-q24 provided significant evidence of linkage. There were six additional regions that exhibited somewhat weaker evidence for linkage, including 6q21 (*IDDM15*), 3p13-p14, 9q33-q34, 12q14-q12, 16p12-q11.1, and 19p13.3-p13.2. Unfortunately, except for *IDDM2* (insulin gene) and *IDDM12* (*CTLA4*), the specific genetic variants within these loci conferring disease susceptibility have not been identified. Other potential susceptibility loci with little support for linkage were *IDDM4*, *IDDM6*, *IDDM9*, *IDDM11*, *IDDM16*, *IDDM17*, and *IDDM18*. Thus, these loci either do not harbor susceptibility genes or have a very small effect that is difficult to detect.

Definition of the genetic etiology of type 1 diabetes will have several clinical implications. Most affected individuals are identified subsequent to the onset of diabetes when nearly complete β-cell destruction has occurred. A relatively limited subset of individuals at risk for developing type 1 diabetes can be identified before disease onset based on a family history of type 1 diabetes and the presence of antibodies directed against islet cells. Not all such individuals develop type 1 diabetes, however, and the risk of developing diabetes in these individuals is defined by the degree of loss of first phase insulin secretion during an intravenous glucose tolerance test. This loss of first phase insulin secretion occurs secondary to β-cell destruction and indicates activity of the autoimmune process. Because a significant decrease in first phase insulin secretion indicates that marked β-cell destruction has already occurred, if susceptible individuals can be identified earlier, based on their complement of susceptibility genes, and screening can be extended beyond those with a positive family history, it may be possible to intervene earlier, before the onset of β-cell destruction and, thus, have a much greater impact on delaying or preventing the onset of type 1 diabetes. Second, as the pathways that are responsible for initiating the autoimmune process are identified, new therapies designed to interfere specifically with these pathways and prevent β-cell destruction can be developed. These therapies will likely be more efficacious in preventing the onset of diabetes.

GENETICS OF WOLFRAM SYNDROME

Wolfram and Wagener described a syndrome consisting of diabetes mellitus and optic atrophy in 1938. Since then, the clinical spectrum and genetic basis of the syndrome have been described. Wolfram Syndrome is inherited in an autosomal-recessive fashion. Early onset (generally age <15 yr) of diabetes and optic atrophy are necessary for the diagnosis. The recognition of additional manifestations of the disease resulted in the acronym DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness). Wolfram Syndrome is a progressive neurodegenerative disease. Additional neurological features present in some affected individuals include psychiatric illness, urinary tract atrophy, peripheral neuropathy, ataxia, dementia, and mental retardation. Consistent with its neurodegenerative nature, MRI studies have revealed atrophy of the optic nerves and neurodegeneration in the lateral

Table 32-1
Susceptibility Loci for Type 1 Diabetes Mellitus

Susceptibility locus	*Chromosome*	*Linked markers*	*Candidate genes*

geniculate nucleus, basis pontis, and hypothalamic nuclei, including the paraventricular and supraoptic nuclei.

Diabetes mellitus is typically, although not invariably, the initial manifestation of the disease, with the mean of age of onset being 6–8 yr in one study. The mean age of optic atrophy was 11 yr, whereas diabetes insipidus and deafness presented in the second decade of life. Affected individuals are insulin deficient, with pathological specimens demonstrating islet atrophy with loss of β-cells, but relative sparing of the α- and δ-cells. Unlike type 1 diabetes, no HLA association or evidence for autoimmunity has been identified. Interestingly, for reasons that are unclear, microvascular complications are relatively unusual and, when present, develop more slowly than is typical in type 1 diabetes.

Linkage studies localized the gene responsible for Wolfram Syndrome to the short arm of chromosome 4 (4p16.3). Subsequently, the responsible gene, *WFS1*, was identified. *WFS1* consists of 8 exons spanning 33.4 kbp of DNA and is expressed in a variety of tissues, including adult human heart, brain, lung, pancreas, and placenta. *WFS1* encodes a novel approx 100-kDa protein, wolframin, which is predicted to have nine transmembrane domains. Wolframin is an integral membrane glycoprotein that is located primarily in the endoplasmic reticulum and is associated with ion channel activity. It likely serves either as a calcium channel or as a regulator of calcium channel activity. In the pancreas, wolframin is present in β-cells and, to a much lesser extent, α-cells. Mutations in *WFS1* have been demonstrated in 90% of patients with Wolfram Syndrome, with the majority of patients being compound heterozygotes. Linkage to chromosome 4p16.3 was excluded in three families and linkage to a second locus, 4q22-q24, was established. The disease gene at this locus awaits identification.

GENETICS OF TYPE 2 DIABETES MELLITUS

Type 2 diabetes mellitus is a heterogeneous disorder that develops in response to both genetic and environmental factors (Fig. 32-1). In contrast to type 1 diabetes, type 2 diabetes is often diagnosed during routine screening by the detection of hyperglycemia or because of mild symptoms of hyperglycemia, for example, polyuria. Much like type 1 diabetes, individuals with type 2 diabetes pass through a series of phases before the onset of diabetes. Initially, plasma insulin levels are increased because of insulin resistance, but euglycemia is maintained. In the second phase, postprandial hyperglycemia is present despite persistent hyperinsulinemia. Finally, insulin secretion declines in the face of persistent insulin resistance, which results in diabetes. Thus, affected individuals demonstrate both insulin resistance, manifested as hyperinsulinemia and decreased insulin-stimulated glucose uptake into tissues, and abnormal β-cell function, manifested as altered glucose-induced insulin secretion. Obesity, via its effects on insulin sensitivity, also contributes to type 2 diabetes. Obesity, in turn, is affected by both energy expenditure and intake. Energy expenditure is dependent to

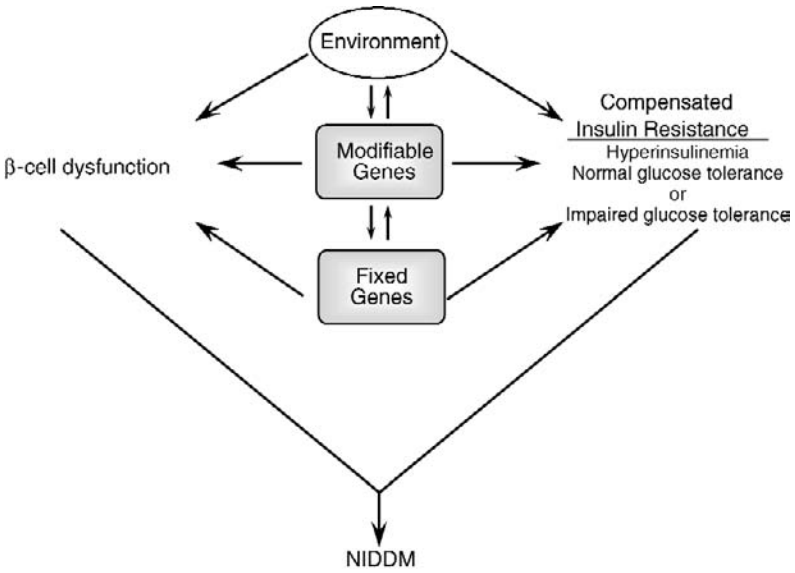

Figure 32-1 Schematic model of the etiology of type 2 diabetes mellitus. Type 2 diabetes is secondary to both insulin resistance and inadequate insulin secretion secondary to β-cell dysfunction. With sufficient β-cell function, euglycemia or impaired glucose tolerance is maintained in the presence of insulin resistance at the expense of hyperinsulinemia (compensated insulin resistance). With concomitant β-cell dysfunction, however, inadequate insulin secretion to compensate for the insulin resistance results in the onset of type 2 diabetes. Similarly, a primary defect in β-cell function may result in type 2 diabetes in the presence of some degree of insulin resistance. Both insulin resistance and β-cell dysfunction are influenced by genetic and environmental factors. Type 2 diabetes is multigenic, and its penetrance is secondary to the expression of several different genes, some of which are likely fixed and act independently of environmental factors. Other predisposing genes might be modifiable in that their expression or action is influenced by environmental factors. Interactions between genes are also likely to contribute to insulin resistance and β-cell dysfunction.

a large degree on resting metabolic rate, whereas energy intake is regulated by central nervous system and behavioral regulation of eating and satiety. All of the previously mentioned processes are in part heritable, but complex, and dependent on a variety of different gene products, each of which may have the potential to contribute to the genetic predisposition to type 2 diabetes.

Consistent with the heterogeneity of type 2 diabetes and the multiple contributing factors described, mathematical modeling has suggested that type 2 diabetes is a polygenic disease. Consequently, onset of the disease likely requires the simultaneous presence of a subset of genes that affect the above processes. Because different subsets of genes are probably sufficient to confer susceptibility to type 2 diabetes, susceptibility genes likely vary between, and possibly within, populations. Moreover, environmental factors that have not been fully defined contribute to the development of type 2 diabetes. Thus, disease susceptibility genes may be present in unaffected individuals because they lack a required complement of disease susceptibility genes or needed environmental factors to induce diabetes. This has and will continue to complicate attempts to define susceptibility genes for type 2 diabetes. An additional complication in defining the genetics of type 2 diabetes is its late onset. Typically, parents, especially affected parents who may have succumbed to the complications of diabetes, are not available for study, and offspring are unlikely to be affected. Thus, family studies of type 2 diabetes are difficult.

Despite the previously mentioned challenges, progress has been made in defining the genetics of late-onset type 2 diabetes. As with type 1 diabetes, the candidate gene approach and genome scanning have been used to identify genes that confer susceptibility to type 2 diabetes.

GENETICALLY DEFINED FORMS OF TYPE 2 DIABETES

Given the complexities of the genetics of type 2 diabetes, substantial effort has been applied using both candidate gene and positional cloning approaches to define the genetics of rare, but monogenic, forms of diabetes with the hope that this will provide insight into the genetics of type 2 diabetes.

Mitochondrial Diabetes Mellitus The role of mutations in mitochondrial DNA in disease etiology is becoming increasingly appreciated. Mitochondrial DNA is inherited maternally and encodes 13 polypeptide subunits involved in oxidative phosphorylation and the respiratory pathway, 22 transfer RNAs (tRNAs), and 2 ribosomal RNAs. Mitochondrial DNA is vulnerable to mutation because it is made up almost exclusively of coding sequences, lacks protection by histones, has inefficient repair mechanisms, and is exposed to reactive oxygen species produced during oxidative phosphorylation. Mitochondrial DNA undergoes mutation 5–10 times faster than nuclear DNA. The possibility that mitochondrial DNA mutations might contribute to the pathogenesis of diabetes mellitus was suggested by the association of diabetes with several mitochondrial diseases and by the maternal inheritance of mitochondrial DNA, given the slight preference for maternal transmission of type 2 diabetes.

Initially, a syndrome of diabetes mellitus and deafness caused by sensorineural hearing loss was identified in two pedigrees. In both, an A/G exchange at nucleotide 3243 in the mitochondrial $tRNA^{Leu(UUR)}$ gene was noted. This particular mutation was located within a mitochondrial DNA binding site for a protein that contributes to the termination of transcription at the boundary between the 16S ribosomal RNA and $tRNA^{Leu(UUR)}$ genes. Thus, this mutation alters both $tRNA^{Leu(UUR)}$ synthesis and mitochondrial protein stability. Interestingly, $tRNA^{Leu(UUR)}$ is a hot spot for mutations;

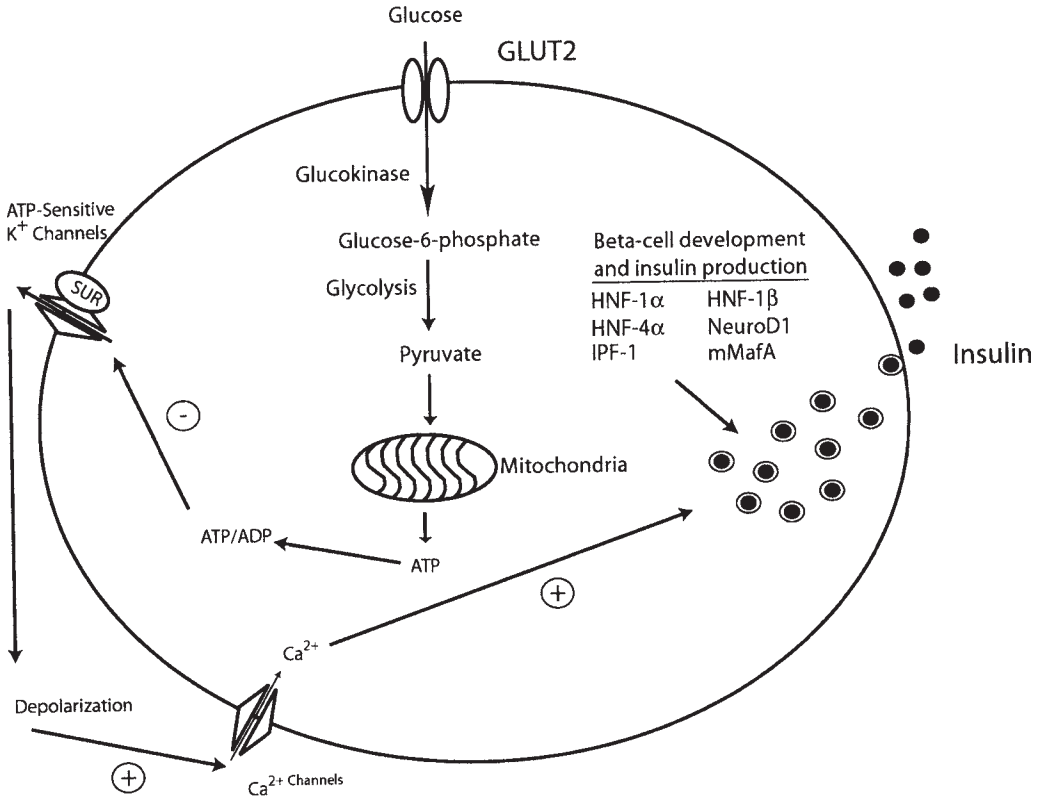

Figure 32-2 Schematic representation of glucose-stimulated insulin secretion by the pancreatic β-cell. Glucose uptake is mediated by GLUT2, and glucose is phosphorylated by glucokinase to generate glucose-6-phosphate. Metabolism of glucose-6-phosphate via glycolysis yields pyruvate, which enters the tricarboxylic acid cycle in the mitochondria to generate ATP. The generation of ATP increases the ATP/adenosine 5′ diphosphate ratio in the cytoplasm, which inhibits activity of the ATP-sensitive K^+ channel. The ATP-sensitive K^+ channel is a complex of the sulfonylurea receptor and an inward rectifying K^+-channel protein (KIR6.2). Inhibition of this channel results in membrane depolarization and opening of voltage-dependent Ca^{2+} channels. The resulting increase in the intracellular concentration of Ca^{2+} stimulates insulin secretion. β-cell development and insulin production are regulated by many factors, including several different transcription factors, some of which are listed.

11 disease-related mutations have been identified within this gene, 5 of which are associated with diabetes mellitus. The association of diabetes with point mutations and deletions in other mitochondrial genes has also been described.

Identification of these syndromes raised the question regarding the role of mitochondrial DNA mutations in the pathogenesis of diabetes mellitus. Of patients with type 1 and 2 diabetes mellitus, the A/G exchange in the $tRNA^{Leu(UUR)}$ gene is present in 0.5–1.5% of patients. If only those patients with a family history of diabetes are considered, the prevalence of the mutation is two to five times higher. Patients with the A/G exchange at nucleotide 3243 typically present with diabetes around age 35. Most also exhibit some degree of hearing loss because of reduced detection of high frequency tones. Detailed characterization of affected individuals and their siblings demonstrated that 48% presented with diabetes and deafness, 21% had diabetes alone, 15% had deafness alone, 3% had deafness associated with some neurological changes, and 13% had diabetes, deafness and the findings of the MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes). The phenotypic variation presumably results from variable numbers of mitochondria containing normal compared with abnormal mitochondrial DNA (heteroplasmy) between tissues. Heteroplasmy results from unequal separation of mitochondrial populations during meiosis or mitosis and differential accumulation of subsequent mitochondrial mutations.

Although patients with mitochondrial DNA mutations were initially diagnosed as having either type 1 or 2 diabetes mellitus, there are differences between these patients and those with "typical" type 1 or 2 diabetes. Those diagnosed initially as having type 1 diabetes in general lack anti-islet cell antibodies and do not typically have a history of diabetic ketoacidosis, whereas those initially diagnosed as having type 2 diabetes tend to be leaner and more likely to be treated with insulin compared with general populations with type 2 diabetes. Subsequent studies to define the etiology of diabetes in patients with mitochondrial mutations demonstrated decreased insulin secretion in response to an oral glucose tolerance test, whereas measures of glucose utilization demonstrated essentially normal insulin sensitivity. The above findings suggest that the primary defect in patients with mitochondrial mutations is in the pancreatic β-cell. Oxidative phosphorylation and ATP generation play an important role in insulin secretion (Fig. 32-2), so mutations in β-cell mitochondrial DNA would likely interfere with insulin secretion because of insufficient ATP generation.

In patients with diabetes accompanied by hearing loss, a diagnosis of mitochondrial DNA mutations as the cause of the diabetes should be considered. Patients with these mutations should be advised that they will be much more likely to require insulin therapy because of the insulin deficiency that develops. Moreover, family members need to be carefully screened for both diabetes and evidence of sensorineural hearing. Frequently, the hearing loss develops

Table 32-2
MODY Genes

Condition	*Gene*	*Chromosomal location*	*Function*	*Characteristics*
MODY1	*HNF4α*	20q12-q13.1	Transcription factor	Onset in adolescence or early adulthood, microvascular complications frequent, rare cause of MODY
MODY2	Glucokinase	7p15.3-15.1	Glycolysis, glucose sensing	Onset at birth, mild hyperglycemia with minor deterioration with age, microvascular complications rare
MODY3	*HNF1α*	12q24.3	Transcription factor	Onset in adolescence or early adulthood, microvascular complications frequent, most common cause of MODY in most populations
MODY4	*IPF1*	13q12.1	Transcription factor	Onset in early adulthood, only one family described, homozygous mutation causes pancreatic agenesis
MODY5	*HNF1β*	17cenq21.3	Transcription factor	Onset in adolescence or early adulthood, rare cause of MODY, associated with renal cysts, proteinuria, renal failure and genital malformations
MODY6	*NeuroD1*	2q32	Transcription factor	Onset in adolescence or early adulthood, rare cause of MODY

HNF, hepatocyte nuclear factor; MODY, maturity onset diabetes of the young. Adapted with permission from Mitchell SMS, Frayling TM. The role of transcription factors in maturity-onset diabetes of the young. Mol Genet Metab 2002;77:35–43.

after the onset of diabetes, so those patients with diabetes need to be examined over time for hearing loss.

Maturity Onset Diabetes of the Young Maturity onset diabetes of the young (MODY) is a subtype of diabetes that is monogenic and provides a model for studying the molecular genetics of type 2 diabetes. MODY is characterized by an early age of onset of diabetes and an autosomal-dominant mode of inheritance that is based on the demonstration of a positive family history in three successive generations. Disease onset often occurs between ages 9 and 13 and typically, although not universally, occurs before age 25.

Characterization of MODY patients from different kindreds revealed phenotypic differences between patients suggesting heterogeneity, which molecular genetic analyses confirmed. Six variants of MODY, MODY1–6, have been characterized and are the result of mutations in different genes (Table 32-2). Initially, linkage to polymorphisms in the glucokinase gene on chromosome 7p was demonstrated in some patients, whereas in other patients analyses demonstrated linkage to markers on either chromosome 20q or 12q. Mutations in the glucokinase gene on chromosome 7p were shown to cause diabetes in kindreds with MODY2. Subsequent genetic analyses demonstrated that the kindred described as having MODY1 had a mutation in the hepatocyte nuclear factor (HNF)-4α gene on chromosome 20q, whereas kindreds with MODY3 had mutations in the *HNF1α* gene on chromosome 12q. As HNF-1β heterodimerizes with HNF-1α, it was examined as a candidate MODY gene. Mutations were identified, and *HNF1β* was designated as MODY5. Because of its role in kidney development and function, subjects with HNF-1β mutations frequently demonstrate nondiabetic renal disease, especially cystic renal disease, in addition to diabetes. Early onset diabetes was shown to segregate with heterozygous mutations in the insulin promoter factor (IPF)-1 gene in family members of a proband with pancreatic agenesis secondary to a homozygous frameshift mutation in the *IPF1* gene. Thus, *IPF1* was identified as MODY4. Two families in which mutations in NeuroD1, a helix–loop–helix transcription factor, cosegregate with diabetes have also been described. This has led to its designation as MODY6. Importantly, 10–20% of families meeting criteria for MODY do not have mutations in any of the known MODY genes, suggesting that additional, unidentified MODY genes exist.

MODY genes play a critical role in pancreatic β-cell function and/or development. Glucokinase is a key enzyme in glucose metabolism in β-cells and hepatocytes which catalyzes the formation of glucose-6-phosphate from glucose and participates in glucose-sensing. It is important for linking glucose to insulin secretion. In patients with glucokinase mutations, the severity of enzyme impairment is correlated with the degree of hyperglycemia. Because of the decreased sensitivity of the β-cells to glucose in these patients, the dose–response curve for glucose-induced insulin secretion is shifted to the right, although increased insulin secretion is observed with increasing degrees of hyperglycemia. Whether altered glucose metabolism in hepatocytes contributes to the hyperglycemia is not known.

The genes responsible for MODY1 and 3–6 are transcription factors. HNF-4α is a transcription factor that is a member of the steroid/thyroid superfamily of nuclear receptors. Members of this receptor family are typically ligand-activated, but whether there is a ligand that activates HNF-4α is unknown. HNF-1α is a homeodomain transcription factor that functions as either a homodimer or heterodimer with the structurally related transcription factor HNF-1β. As their names imply, these factors are important for hepatic gene expression, but they are expressed in other tissues, including pancreatic islets. In pancreatic β-cells, HNF-1α and HNF-4α are part of an integrated network of transcription factors in which altered expression of one affects expression of the other. Although some of the identified mutations in HNF-1α and HNF-4α exert a dominant negative effect, the accumulated data suggest that MODY1 and 3 occur secondary to loss of a functional allele and a decreased level of active transcription factor (haploinsufficiency). In animal models, deficiency of HNF-1α directly or indirectly decreases expression of genes encoding proteins important for β-cell function, for example the pancreatic β-cell glucose transporter GLUT2, pyruvate kinase, and insulin, as well as genes encoding transcription factors important for pancreatic β-cell development and function, for example, Pdx-1 (the mouse homologue

of IPF-1), HNF-4α and NeuroD1. HNF-4α also plays a key role in β-cell function, as over 40% of the active promoters in the pancreas are bound by HNF-4α. IPF-1, in turn, plays a critical role in pancreatic development. In both humans and mice the absence of functional IPF-1 results in pancreatic agenesis. IPF-1 is also important in differentiated β-cell function in that it controls the expression of a variety of genes, including insulin, GLUT2, and glucokinase. NeuroD1 also controls islet development and function. Mice lacking NeuroD1 exhibit a marked reduction in β-cells and fail to develop mature islets, whereas in differentiated β-cells, NeuroD1 regulates insulin gene expression.

Because altered glucose sensing results in an increase in the blood glucose threshold that stimulates insulin secretion, patients with MODY2 typically present early in life, usually before puberty, with mild fasting hyperglycemia that does not worsen over time. Commensurate with the mild hyperglycemia, these patients are much less susceptible to the microvascular and macrovascular complications of diabetes compared with patients with type 2 diabetes. Patients with MODY1 and 3 also have a defect in β-cell function manifested as decreased insulin secretion in response to glucose and arginine. Unlike patients with MODY2, a progressive increase in insulin secretion with increasing hyperglycemia is not observed, suggesting a reduced capacity for insulin secretion. Similar defects, albeit not as severe, are present in individuals who have mutations in HNF-1α but are not, as yet, diabetic. Given the progressive hyperglycemia characteristic of MODY1 and 3, these patients exhibit the micro- and macrovascular complications associated with diabetes. As noted, one of the prominent features of MODY5 is renal disease. Indeed, kidney disease may be the initial manifestation of MODY5. Families with MODY4 and 6 are rare and, thus, little information about the phenotype or natural history of the disease is available.

Given the impact of the MODY genes on β-cell function, the issue of their potential contribution to the etiology of late-onset type 2 diabetes has been raised. Of women with gestational diabetes mellitus and a first degree relative with diabetes, 2–5% have mutations in the glucokinase gene. A common polymorphism in the promoter of the glucokinase gene is present in about 30% of Caucasians in the United Kingdom and is associated with a small increase in fasting glucose. However, this polymorphism has not been clearly shown to be associated with type 2 diabetes. Thus, there is no evidence to suggest that variation in the glucokinase gene contributes significantly to the development of late-onset type 2 diabetes. Recent association studies in several populations, including Japanese, European Caucasians, and Ashekenazi Jews, have suggested that polymorphisms in the *HNF-4α* gene increase the risk of type 2 diabetes. Mutations in the *IPF-1* gene have been found with an increased albeit low frequency in Caucasian subjects with type 2 diabetes, whereas a mutation in HNF-1α, substitution of serine for glycine at codon 319, that is unique to the Oji-Cree population in Canada is associated with early-onset of type 2 diabetes.

Now that the MODY genes have been defined, genetic testing is available to patients and family members from MODY kindreds. This will have important implications for therapy, for example patients with MODY3 exhibit sensitivity to sulfonylureas, and disease screening in family members. Also, as the role of the different transcription factors in pancreatic development and function is elucidated, new therapeutic targets to enhance β-cell function may become available.

Insulin Gene Insulin is a primary hormone in the regulation of glucose homeostasis and, thus, represents a natural candidate gene for type 2 diabetes. Six different mutations that affect insulin processing and action have been described, but these mutations are rare. Three of these mutations alter the primary sequence of the A- or B-chain of insulin. These mutations affect insulin binding to its receptor and, thus, decrease the efficacy of insulin. Individuals with these mutations typically have mild hyperglycemia in association with hyperinsulinemia. Three mutations that affect proinsulin processing have also been described. These mutations have only a minimal effect on glucose homeostasis but result in hyperproinsulinemia. Because of their rarity, most individuals who bear insulin gene mutations are heterozygotes who have minimal impairment of glucose homeostasis, although this can be modified by obesity and increasing age. Insulin gene mutations are rare in type 2 diabetes suggesting that they do not make a major contribution to the disease.

Because insufficient insulin secretion to compensate for insulin resistance contributes to the etiology of type 2 diabetes, the role of mutations in the insulin gene promoter has also been examined. Promoter variants, including an 8-bp insertion in the promoter of some African Americans, have been described, but there is no evidence to suggest that insulin gene promoter variants contribute significantly to type 2 diabetes. Because the class-III allele of the insulin VNTR is associated with decreased insulin gene expression in the pancreas, its role in susceptibility to type 2 diabetes has also been examined. Several studies have demonstrated an association of the class-III allele with increased risk for type 2 diabetes, including one suggesting that transmission of paternal but not maternal alleles increased the risk for type 2 diabetes. Other studies have failed to reproduce these findings, so the role of the insulin VNTR remains unclear.

Insulin Receptor Gene As the most proximal site of insulin action, the insulin receptor is a second candidate gene for type 2 diabetes. The insulin receptor is a transmembrane receptor with tyrosine kinase activity that is activated on insulin binding (*see* Chapter 31 for details of signal transduction). Normal tyrosine kinase activity is critical for transmission of a signal via the insulin receptor.

The potential roles of insulin receptor mutations in diabetes mellitus were revealed by the demonstration that insulin receptor mutations were associated with specific syndromes of extreme insulin resistance, including leprechaunism, Rabson–Mendenhall syndrome, and type-A extreme insulin resistance. These syndromes differ phenotypically because of different degrees of insulin resistance. Leprechaunism is associated with the greatest degree of insulin resistance and is characterized by intrauterine and postnatal growth retardation, dysmorphic facies, lipoatrophy, acanthosis nigricans (a cutaneous manifestation of insulin resistance), and death in early infancy. Rabson–Mendenhall presents in early childhood and is characterized by insulin-resistant diabetes mellitus, abnormal facies, dental dysplasia, thickened nails, hirsutism, precocious puberty, and acanthosis nigricans. Although these patients exhibit severe insulin resistance, they have a lesser degree of insulin resistance than patients with leprechaunism. Finally, type-A insulin resistance is characterized by extreme insulin resistance, albeit of lesser degree than that seen in the above two syndromes, and is often associated with normal or only mildly impaired glucose homeostasis and acanthosis nigricans. Women with this syndrome typically exhibit hyperandrogenism, hirsutism, and polycystic ovaries. The varying degree of insulin resistance present in these different syndromes is determined both by the number of mutant alleles inherited as well as the severity of the mutations. Patients with leprechaunism typically inherit two mutant alleles, whereas patients with the Rabson–Mendenhall

syndrome and type-A insulin resistance inherit one or two alleles with mutations that confer different degrees of receptor dysfunction. More than 40 mutations in the insulin receptor have been described. These mutations occur throughout the receptor with effects on receptor synthesis or processing, insulin binding, or tyrosine kinase activity.

The role of insulin receptor mutations as an etiological factor in type 2 diabetes is not as clear. Receptor mutations that induce more subtle defects in receptor activity than those described above have been identified but are rare. It has been estimated that no more than 1–2% of patients with type 2 diabetes have mutations in the tyrosine kinase domain of the insulin receptor that affect receptor function. Studies designed to demonstrate association of restriction fragment length polymorphisms in the insulin receptor with type 2 diabetes have been largely negative, and linkage of the insulin receptor to type 2 diabetes has not been demonstrated. Thus, there is no evidence to suggest that insulin receptor mutations contribute significantly to the pathogenesis of type 2 diabetes.

GENETICS OF LATE-ONSET TYPE 2 DIABETES Despite significant progress in defining the genetics of monogenic forms of diabetes, genetic abnormalities that contribute to most cases of late-onset type 2 diabetes have not been identified using this approach. For that reason, both candidate gene and genome scanning/positional cloning approaches have been used to define the genetics of type 2 diabetes.

Candidate Genes for Late-Onset Type 2 Diabetes The candidate gene approach is dependent on the use of educated guesses to choose gene products that may have an effect on glucose homeostasis and, thus, predispose an individual to the development of type 2 diabetes. Logical candidates would include genes that affect insulin production, glucose metabolism in pancreatic β-cells, insulin processing and secretion, insulin action and glucose metabolism in peripheral tissues, or obesity/eating behavior/satiety, and genes that encode inhibitors of insulin action (Figs. 32-2 and 32-3). Many studies have examined the association of potential candidate genes with type 2 diabetes or related traits. Although many are either negative or have failed to be replicated, critical review of the literature suggests a few genes in which variants may confer an increased risk for type 2 diabetes.

Sulfonylureas, a common treatment for type 2 diabetes, increase insulin secretion by inhibiting an ATP-sensitive potassium channel through an interaction with the sulfonylurea receptor (SUR1) that is associated with a member of the inwardly rectifying K^+ channel subfamily 6.0, which is encoded by the *KIR6.2* gene. The *SUR1* and *KIR6.2* genes are located 4.5 kb apart on chromosome 11p15.1, and multiple polymorphisms have been identified in both genes. In the *SUR1* gene, a nucleotide transition in intron 16 (-3c to t) is associated with increased susceptibility to type 2 diabetes in various Caucasian populations, although this finding was not replicated in all Caucasian populations. This polymorphism was also associated with impaired second phase insulin secretion during a hyperglycemic clamp in Dutch Caucasians, but in some studies, an association of this variant with altered β-cell function could not be demonstrated. This variant is present within the context of a splice acceptor site, but it does not affect SUR1 messenger RNA splicing. This has led to speculation that the variant is in linkage disequilibrium with another variant in the *SUR1* gene or another nearby gene that accounts for the increase in risk.

Like the *SUR1* gene, several missense and silent mutations have been identified in the *KIR6.2* gene. One of these variants, a glutamic acid to lysine substitution at codon 23 (E23K), has been shown in several large studies of distinct populations to be associated with an increased risk of type 2 diabetes. Importantly, this missense mutation is not in linkage disequilibrium with the intron 16 -3t to c polymorphism in the *SUR1* gene, suggesting that the association between this polymorphism and type 2 diabetes is independent of this *SUR*1 gene variant. Studies of the impact of the E23K mutation on KIR6.2 function demonstrated that the variant protein altered the probability of the channel being in the open vs closed state and the ATP sensitivity of the channel. The functional consequence of this is to shift the physiological glucose dependence of channel activity to a higher glucose concentration and inhibit insulin secretion. In subjects with normal glucose tolerance, the E23K variant is associated with decreased insulin secretion. Thus, the E23K variant of Kir6.2 is now generally accepted as conferring a small increase in risk for type 2 diabetes, although the presence of other variants in the *SUR1*/*KIR6.2* locus that increase susceptibility to type 2 diabetes has not been excluded.

Thiazolidinediones, a class of drugs used to treat diabetes, enhance insulin sensitivity via ligand-induced activation of the transcription factor peroxisome proliferator-activated receptor (PPAR)-γ. The potential impact of genetic variants of the *PPAR*-γ gene on diabetes risk was made evident by the identification of two different missense mutations in the ligand-binding domain of the protein, substitution of leucine for proline at codon 467 and methionine for valine at codon 290, in a few patients. Both of these mutations abrogate ligand-induced transactivation of PPAR-γ and result in insulin resistance with early-onset diabetes and hypertension and low high-density lipoprotein levels in association with elevated triglyceride levels. Interestingly, affected individuals tended to be lean, although they did have an increased waist to hip ratio. Both of these mutations were present in the heterozygous state, suggesting they act in a dominant negative fashion.

Inactivating mutations in the *PPAR*γ gene are rare, but an intriguing finding related to the *PPAR*γ gene was identification of a variant with substitution of alanine for proline at codon 12 (Pro12Ala). This genetic variant appears to have an important impact on diabetes risk in the general population. The Ala^{12} variant of PPAR-γ binds with decreased affinity to the PPAR-γ DNA binding site and exhibits decreased ligand-induced transactivation, although this effect was relatively mild compared with the impact of the mutations described above. Interestingly, despite this effect, the Ala^{12} variant is associated with enhanced insulin sensitivity in humans. An initial study reported that the Ala^{12} variant protected against type 2 diabetes in Caucasian and Japanese populations. Subsequent studies replicated this finding, whereas others, many with reduced power because of a limited number of subjects, failed to do so. When all available data were pooled, a highly significant association between the Pro12Ala variant and type 2 diabetes was evident, with the Ala^{12} variant conferring protection against diabetes. The impact of this variant on disease risk was modest, as the increment in diabetes risk conferred by the proline allele is only approx 25%. Although the increase in diabetes risk for an individual with this allele is small, the proline allele is common in the population (frequency of 83–87%). Thus, its impact on diabetes risk in the population as whole is large. Indeed, the population attributable risk, which is the fraction by which a disease would be reduced if the risk factor was absent from the population, for the Pro12Ala variant is 25%.

Beyond these two loci, variation in the gene encoding HNF-4α may also contribute to susceptibility to type 2 diabetes, as described earlier. Otherwise, hundreds of studies in the literature have examined the potential association of other candidate genes

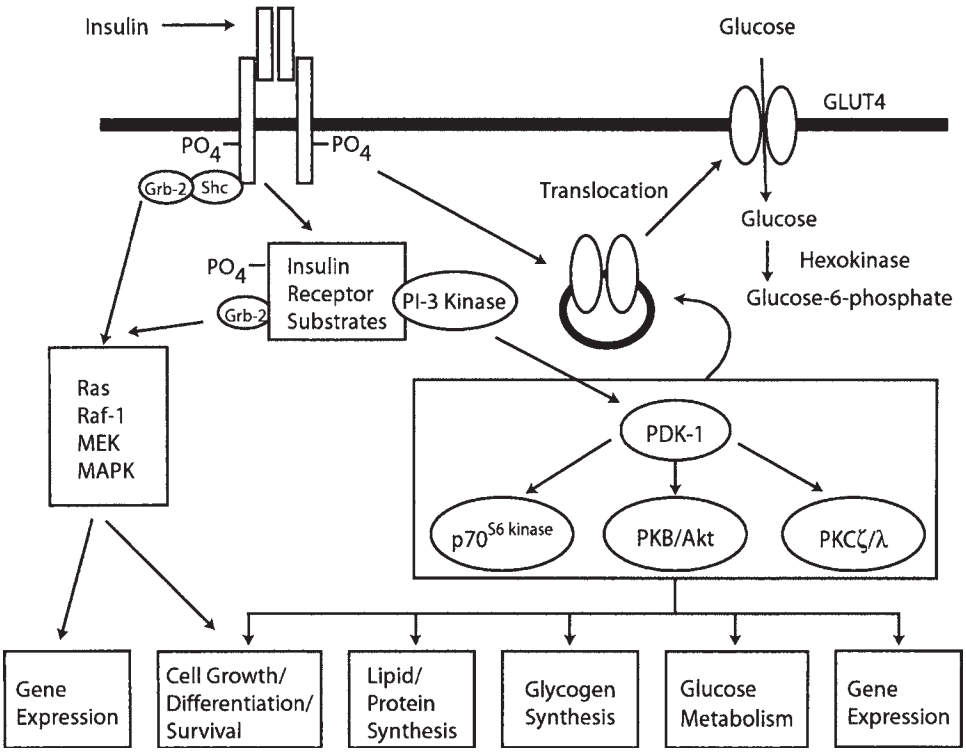

Figure 32-3 Schematic representation of insulin-induced signaling. Insulin signaling is initiated by insulin binding to the insulin receptor, which increases the activity of the receptor's intrinsic tyrosine kinase activity. This results in tyrosine phosphorylation of a series of substrate proteins, including members of the insulin receptor substrate family (IRS1-4) and Shc as well as Gab-1 and Cbl (not shown). This leads ultimately to activation of two major signaling pathways, the phosphatidylinositol 3-kinase (PI 3-kinase) and mitogen-activated protein kinase (MAPK) pathways and increased glucose transport via recruitment of the insulin-responsive glucose transporter, GLUT4, to the plasma membrane. Activation of PI 3-kinase results in generation of phosphatidylinositol 3,4,5-trisphosphate, which, in turn, leads to activation of the serine/threonine kinases protein kinase B (PKB)/Akt and $p70^{S6\ kinase}$ and the atypical protein kinase C isoforms PKCζ and λ via phosphoinositide-dependent kinase (PDK). Activation of PKB, $p70^{S6\ kinase}$, and the atypical PKC isoforms results in a variety of metabolic effects, including glycogen, protein, and lipid synthesis and the expression of specific genes. These pathways also contribute to effects of insulin on cell survival, growth, and differentiation. Activation of the MAPK pathway regulates the expression of a variety of genes, many of which contribute to cell growth and differentiation. The relative contribution of these different pathways to the various effects probably varies in different cell types, and it is likely that additional pathways not shown here also contribute to insulin-induced effects. Alteration of any of the molecules in these different signaling pathways would be expected to have an effect on insulin sensitivity and contribute to the development of insulin resistance.

with type 2 diabetes or related traits. Although the accumulated data suggest a positive, albeit still inconclusive, association for some candidate genes, progress identifying additional clear susceptibility genes for type 2 diabetes has been limited. Several factors have contributed to this problem. First, as is evident with the Pro12Ala variant of the *PPARγ* gene, the effect of any gene on disease risk may be small, thus making it unlikely that studies with limited number of subjects will demonstrate or replicate a previous positive finding. Second, the contribution of diet and physical activity to disease risk suggests that gene–environment interactions will be important for disease risk. Such interactions will further confound the ability to demonstrate the impact of genetic variants with a modest effect. Finally, the majority of candidate gene analyses have been performed in the context of case–control analyses. These types of studies, especially those with limited numbers of subjects, are susceptible to either false-positive or -negative studies. An alternative strategy is to identify and study positional candidate genes, i.e., genes with a function important for insulin secretion or glucose metabolism that are located within chromosomal loci demonstrating linkage to type 2 diabetes.

Identification of Susceptibility Loci for Late-Onset Type 2 Diabetes Multiple genome scans for type 2 diabetes or diabetes-related traits in diverse populations have provided several conclusions. First, unlike *IDDM1* in type 1 diabetes, there is no single locus with a major effect on susceptibility to type 2 diabetes. Second, few loci with evidence for significant linkage (i.e., lod score >3.6) have been identified. This is not surprising, because in the absence of a single locus with a major effect, it is likely that many loci that confer a modest increase in relative risk exist. Identification of these loci will require a large number of subjects. Finally, replication of findings between scans has been infrequent. This may be secondary, in part, to differences in susceptibility genes between populations. Also, because of the modest increase in risk conferred by loci and the limited number of subjects present in most studies, this lack of replication is not surprising. Despite these limitations, several loci that exhibit at least suggestive evidence for linkage to type 2 diabetes have been replicated by additional studies after the initial identification. A type 2 diabetes susceptibility locus that was mapped to chromosome 1q21-q24 was initially identified in Pima Indians and families of Northern European descent. Evidence for linkage of this locus to type 2 diabetes has now been observed in six different populations. Linkage to chromosome 12q24 in the region of the *HNF1α* gene was found in Finns with three other groups also finding evidence for linkage in this region in Caucasian populations. Interestingly, the *HNF1α* gene does not appear to be the source of linkage to this region.

Linkage of type 2 diabetes and the metabolic syndrome to chromosome 3q27 has been demonstrated in Caucasian populations and Australian Aborigines. A potential candidate gene in this region is the adipocyte-derived hormone adiponectin. Adiponectin enhances insulin sensitivity, and some studies have shown the association of variants in the adiponectin gene with insulin sensitivity and adiponectin levels. Finally, several groups have reported evidence for linkage of loci on chromosome 20 to type 2 diabetes, although the region identified by the different studies is large and encompasses much of the chromosome.

The first type 2 diabetes locus, referred to as *NIDDM1*, was identified in Mexican Americans and mapped to the telomere of chromosome 2q. Detailed analyses of this region of chromosome 2 failed to identify obvious candidate genes, so positional cloning was used to map the locus conferring susceptibility to the gene encoding calpain-10. Calpain-10 is a relatively ubiquitously expressed member of the calpain (calcium-activated neutral proteases) family of nonlysosomal cysteine proteases. The specific functional role of calpain-10 has not been determined, but it is expressed in tissues important for the pathogenesis of type 2 diabetes, including muscle, fat, and pancreatic β-cells. Through a series of linkage and association studies, a specific heterozygous haplotype combination of three single-nucleotide polymorphisms was shown to confer a threefold increase in risk for type 2 diabetes in Mexican Americans. Interestingly, all of these single-nucleotide polymorphisms occur in introns. Exhaustive studies have failed to demonstrate that these variants are in linkage disequilibrium with other genetic variants with the potential to alter protein function, leading to the tentative conclusion that these variants may confer the increased risk for type 2 diabetes. Evidence for linkage of type 2 diabetes to chromosome 2q has not been found in Pima Indians, Caucasians, or Japanese, but studies have demonstrated association of the at-risk genotype or other sequence variations in the calpain-10 gene with type 2 diabetes or metabolic phenotypes, including impaired fasting glucose, impaired glucose tolerance, and insulin resistance, in various populations. Others, however, have failed to demonstrate similar associations. Thus, the specific role of calpain-10 and variations in the calpain-10 gene in the pathogenesis of and susceptibility to type 2 diabetes remains to be determined. Hopefully, the ability to identify specific genetic variants that confer increased susceptibility to type 2 diabetes will improve with the availability of the sequence of the human genome and haplotype maps, and improved methods of analysis and understanding of linkage disequilibrium in humans.

CLINICAL IMPLICATIONS Defining the genetics of type 2 diabetes will elucidate the molecular basis for the disease and have important clinical implications. Understanding the molecular basis of type 2 diabetes will facilitate the development of new therapeutic modalities. As susceptibility genes are defined, the genetic burden of a given individual can be determined. In appropriate individuals, aggressive preventive measures might be instituted. Moreover, type 2 diabetes can be subclassified based on the predisposing genes present in a patient, and that subclassification can be used to direct therapeutic interventions based on the probable underlying pathophysiology.

33 Pituitary Function and Neoplasia

SHLOMO MELMED

SUMMARY

The molecular pathogenesis of pituitary adenomas appears multifactorial. Clearly early proximal DNA-altering events might occur that may involve transcription factor dysregulation or hereditary mutations. Multiple promoting influences might subsequently impinge on the previously "initiated" cell and determine clonal expansion. These factors include disordered hypothalamic hormone receptor signaling, overstimulation by ectopic hypothalamic hormones, disordered paracrine growth factor action, disordered signal transduction, loss of negative feedback inhibition leading to pituitary hyperplasia, estrogen-mediated or paracrine angiogenesis, and loss of tumor suppressor activity. Once the cell has been transformed, its ultimate growth characteristics and neoplastic behavior appear to be determined by several genes acting relatively distally, including ras and nm23.

Key Words: Acromegaly; adrenocorticotropic hormone; corticotrophin-releasing hormone; Cushing's syndrome; gonadotropin-releasing hormone; hypothalamic; neoplasia; pituitary.

INTRODUCTION

The cell types of the mature adenohypophysis are derived embryologically from somatic ectoderm associated with Rathke's pouch. Highly specific trophic factors determine a precise temporal and spatial development of cells expressing unique gene products. The six hormones of the anterior pituitary gland are expressed by at least five distinct hormone-producing cell populations, including corticotrophs (pro-opiomelanocortin, POMC), somatotrophs (growth hormone, GH), lactotrophs (prolactin, PRL), thyrotrophs (thyroid-stimulating hormone, TSH), and gonadotrophs (follicle-stimulating hormone, FSH and luteinizing hormone, LH) (Table 33-1). Each of these cells is identified by specific assays of polypeptide gene expression, including single-cell mRNA, immunoelectron microscopy, and immunocytochemical assays. The temporal ontogeny of these gene products is initially adrenocorticotropic hormone (ACTH) and α-subunit. Distinct GH- and PRL-expressing cells follow and TSH, LH, and FSH are the final cell types to mature at 12 wk.

Each of the anterior pituitary trophic hormones is induced by a respective hypothalamic-releasing hormone, and their transcription is regulated by negative feedback inhibition of their respective target hormone (Table 33-2).

CORTICOTROPH CELLS

Corticotrophs constitute about 15–20% of the adenohypophyseal-cell population, and express strong granular cytoplasmic immunopositivity for ACTH and other POMC fragments.

Corticotrophin-releasing hormone (CRH) and glucocorticoids exert opposite effects on *POMC* gene transcription; CRH increases POMC mRNA and protein content through cAMP, whereas the glucocorticoid negative feedback effect is probably mediated through binding of the glucocorticoid receptor complex to *cis*-active POMC promoter sequences. Several enhancer elements have been identified on the *POMC* gene promoter. These appear to act synergistically in regulating POMC transcription. POMC transcription is also induced by β-adrenergic activation and insulin-induced hypoglycemia as well as by proinflammatory cytokines.

REGULATION OF ACTH

Ligand activation of the CRH receptor (Gs protein containing seven transmembrane domains) on the corticotroph stimulates ACTH synthesis and release. POMC transcriptional regulation is mediated by cAMP as well as indirectly by c-fos activation. Arginine vasopressin, physical stress, exercise, acute illness, and hypoglycemia all increase ACTH levels. Several cytokines mediating inflammatory and or immune responses, including tumor necrosis factor-α, interleukin (IL)-1, IL-6, and leukemia-inhibitory factor (LIF), also stimulate ACTH, whereas glucocorticoids and opiates inhibit ACTH transcription and release. This neuroimmune endocrine interface appears to occur both centrally and directly at the level of *POMC* gene expression. ACTH secretion is pulsatile, with an endogenous circadian rhythm associated with a parallel diurnal pattern of glucocorticoid secretion. Both ACTH and cortisol are higher in the early morning and decline at night.

Hypercortisolism might be caused by pituitary corticotroph adenomas (Cushing's disease) (70%) ectopic ACTH production (12%), cortisol-producing adrenal adenomas, carcinoma and hyperplasia (18%), and, rarely, ectopic CRH production. Iatrogenic hypercortisolism caused by prolonged administration of glucocorticoids produces a similar clinical syndrome.

ACTH-CELL ADENOMA Of all pituitary adenomas, approx 10–15% are ACTH producing tumors that are usually well-differentiated microadenomas. About 5% are silent corticotroph adenomas. Secretory granules in tumor cells immunostain positively for ACTH, β-endorphin, β-LPH, and N-terminal peptide. Although these adenomas exhibit unrestrained ACTH secretion with resultant

hypercortisolemia, they often retain suppressibility during high doses of administered glucocorticoids.

ECTOPIC ACTH SECRETION ACTH production by small cell lung carcinomas and bronchial and thymic carcinoids might result in florid manifestations of Cushing's syndrome. The POMC mRNA transcript derived from nonpituitary ACTH-secreting tumors might be longer than the normal transcript or that detected in pituitary tumors. Corticotrophin-like intermediary peptide and β-melanocyte-stimulating hormone fragments might also be detected in ectopic tumors, indicating alternative POMC processing. Glucocorticoids do not suppress POMC mRNA expression in small cell lung cell lines, thus highlighting their unrestrained gene expression.

CUSHING'S SYNDROME Patients typically present with truncal obesity, hirsutism (also associated with a "moon facies" and "buffalo hump"), cutaneous striae, muscle weakness, osteoporosis, acne, hypertension, depression, and ovarian dysfunction. Because hypercortisolemia is associated with insulin resistance, patients might also have impaired glucose tolerance. Ectopic Cushing's syndrome associated with small cell lung carcinoma is usually more acute with relatively rapid onset of hypertension, edema, hypokalemia, glucose intolerance, and hyperpigmentation. The most direct way to demonstrate ACTH hypersecretion of pituitary origin is by catheterization of the inferior petrosal venous sinuses. ACTH measurements in petrosal and peripheral venous plasma before and after CRH stimulation might document a central-to-peripheral venous gradient of ACTH concentrations.

ACTH hypersecretion by a corticotroph adenoma is usually suppressible by high doses of dexamethasone, whereas ectopic ACTH secretion persists despite high doses of dexamethasone. High-resolution pituitary MRI with gadolinium enhancement with a sensitivity of 2 mm is useful in determining the location of corticotroph adenomas. The treatment of choice is transsphenoidal adenomectomy, with a cure rate as high as 80% in experienced centers.

GROWTH HORMONE

Somatotrophs comprise more than 40% of pituitary cells and reveal intense cytoplasmic immunopositivity for GH. The GH genomic locus consists of five highly conserved genes, including human GH (exclusively expressed in somatotrophs), whereas the others are also expressed in placental tissue. Cis-elements within 300 bp of 5′ flanking DNA of the GH promoter mediate both pituitary-specific and hormone-specific signaling. These include Pit-1, a 33-kDa tissue-specific transcription factor, which binds to specific promoter sites on the *GH*, *PRL*, and *TSH*-β genes regulating their respective transcription. The tri-iodothyronine (T3) receptor might synergize with Pit-1 in stimulating GH transcription, although this effect might be species specific. Pit-1 also appears to be a determinant of growth hormone-releasing hormone (GHRH) receptor function, in as much as Pit-1 mutations might block GHRH-induced somatotroph proliferation.

Pulsatile GH secretion is associated with low or undetectable basal levels between peaks. Maximum GH secretory peaks occur

within an hour of sleep onset. Somatostatin (SRIF) and GHRH interact to generate pulsatile GH release. GHRH stimulates GH synthesis and secretion, whereas SRIF, as well as the target hormone insulin-like growth factor (IGF)-I, inhibit GH secretion. GHRH signaling is mediated by cAMP, and several additional signals regulate *GH* gene expression, including glucocorticoids, IGF-I, activin, T3, and phorbol esters. The somatotroph expresses GH-secretory receptors, and ghrelin, a ligand for this receptor, is synthesized mainly in the gastrointestinal tract and induces GH by central mechanisms.

The GH receptor is expressed mainly in the liver and in other tissues. GH binding proteins are soluble short forms of the hepatic GH receptor and are identical to its cleaved extracellular domain. These proteins might prolong circulating GH half-life and might also competitively inhibit GH binding to peripheral surface receptors.

ACROMEGALY Of patients with acromegaly, >95% harbor a GH-secreting pituitary adenoma, two-thirds have pure GH-cell tumors, and the others have plurihormonal tumors, usually expressing PRL in addition to GH. Tumor-derived GH hypersecretion leading to acromegaly might be caused by excess GHRH or excess GH elaboration.

Ectopic acromegaly might be central as a result of excess GHRH production by functional hypothalamic tumors, or peripheral as a result of rare extrapituitary GH-secreting tumors (pancreas) and the more common tumors secreting GHRH (carcinoid, pancreas, small cell lung cancer). Patients with ectopic acromegaly exhibit normal (central) or elevated (peripheral) GHRH levels. Interestingly, somatotroph hyperplasia and ultimately true GH-cell adenomas might develop in these latter patients.

The clinical manifestations of acromegaly include acral enlargement and visceromegaly. Tongue, salivary glands, thyroid, heart, and soft organs all enlarge. Skeletal overgrowth leads to mandibular prognathism, frontal bossing, increased hand, foot and hat size, and wide incisor spacing. These features result in voice deepening, headaches, painful arthropathy and carpal tunnel syndrome, muscle weakness and fatigue, oily skin and hyperhidrosis, hypertension and left ventricular hypertrophy, and sleep apnea. Glucose intolerance because of insulin antagonism by GH commonly occurs. Overall mortality is increased in acromegaly because of an increased incidence of cardiovascular disorders, malignancy, and respiratory disease. Mortality rates correlate well with GH levels, and effective therapeutic suppression of GH might normalize mortality outcomes. Transsphenoidal adenoma resection is the indicated treatment for GH-secreting pituitary adenoma. Octreotide, a long-acting SRIF analog, significantly attenuates GH and IGF-I levels and blocks tumor growth in most patients; long-term administration of the long-acting octapeptide is also accompanied by marked clinical improvement. Pegvisomant, a GH receptor antagonist, prevents GH-receptor dimerization and normalized IGF-1 levels in >90% of patients. GH levels, albeit bioinactivated, are persistently elevated and long-term effects on tumor growth are still unclear.

PROLACTIN

The acidophilic lactotrophs contain PRL-immunostaining secretory granules and constitute 15% of adenohypophyseal cells. PRL is highly homologous to GH and placental lactogen, which might all have originally arisen from a common ancestral gene. The *PRL* gene has two lactotroph-specific transcription activation regions, a proximal promoter (–422 to +33) and a distal enhancer element (–1831 to –1530), both containing specific binding sites for Pit-1. Dopamine, a potent inhibitor of PRL, acts through the D2 dopamine receptor to decrease intracellular cAMP and *PRL* gene transcription, synthesis, and release. Dopamine effects are mediated by the phosphoinositide–calcium pathway. Vasoactive intestinal polypeptide induces, whereas glucocorticoids and thyroid hormones suppress, PRL transcription and secretion. Estrogens and thyrotropin-releasing hormone (TRH) induce PRL transcription and secretion by either transactivating an estrogen-responsive PRL enhancer element or by inducing the phosphoinositide–protein kinase C pathway. The estrogen receptor might directly synergize with Pit-1 to induce PRL transcription.

Although PRL receptors are widely distributed, their hormonal regulation is tissue specific. High progesterone levels during pregnancy limit breast PRL receptor number, but early in lactation their numbers increase markedly. Prostatic PRL receptor levels are increased by testosterone and decreased by estrogens.

Prolactinomas are the most common hormone-secreting pituitary adenomas and, depending on their size, are classified as microprolactinomas (<10 mm, 90% of which affect women), or macroprolactinomas (>10 mm, 60% of which affect men). PRL serum levels >200 μg/L are usually associated with a prolactinoma. Hyperprolactinemia presents as hypogonadism with amenorrhea and galactorrhea in women, and impotence and infertility in men. Patients harboring macroadenomas are usually males, and their clinical presentation might be associated with local mass effect signs of headaches and visual field disturbances. Most patients are successfully treated with dopamine agonists whereas transsphenoidal surgery is reserved for drug-resistant tumors, which comprise approx 5–10% of patients.

THYROID-STIMULATING HORMONE

Thyrotrophs comprise 5% of the anterior pituitary cell population. TSH and the glycoproteins, LH, FSH, and human chorionic gonadotropin, are made up of two noncovalently linked subunits, a common α and a specific β. Although the α-subunit is expressed in pituitary thyrotrophs and gonadotrophs and in placental cells, cell-specific expression depends on different promoter regions. Tissue specificity is determined by the β-subunit despite their 75% structural homology. Both α- and β-subunit transcriptions are induced by TRH and inhibited by T3 and dopamine. TSH secretion is stimulated by TRH, whereas thyroid hormones, dopamine, SRIF, and glucocorticoids suppress TSH.

TSH-producing pituitary adenomas made up of <1% of pituitary tumors and secrete both TSH α- and β-subunits. The tumor-derived α-subunit is synthesized in excess of the β-subunit, a characteristic useful for differential diagnosis. TSH-secreting tumors fail to respond to thyroid hormone-negative feedback but are suppressed by SRIF. Clinical presentation usually includes hyperthyroidism and diffuse goiter, with elevated or inappropriately normal TSH levels in the presence of elevated thyroid hormones. Tumors are usually large and often invasive with commonly observed local mass effects. Transsphenoidal pituitary surgery is the preferred initial therapeutic approach, but surgical cure is elusive and most patients require adjuvant medical or radiation therapy. The SRIF analog, octreotide, suppresses TSH and might attenuate further tumor growth. Thyroid ablation to cure hyperthyroxinemia is not recommended because of the potential risk of pituitary tumor expansion as a result of disinhibition of the thyrotroph cells from negative feedback.

FOLLICLE-STIMULATING HORMONE AND LUTEINIZING HORMONE

Gonadotrophs comprise up to 10% of anterior pituitary cells and express both FSH and LH-β-subunits. Gonadotropin-releasing hormone (GnRH) induces the transcription of all three gonadotropin subunits, whereas estrogen attenuates their transcription, in part by inhibiting hypothalamic GnRH. However, estrogen might exert positive pituitary feedback and might actually increase LH-β mRNA under several physiological conditions. A gonadotroph-specific protein (SF-1) regulates pituitary α-subunit gene expression distinct from placental regulation of this gene.

GONADOTROPH CELL TUMORS Gonadotroph adenomas are among the most common pituitary adenomas. These "nonsecreting" or "incidental" adenomas are clinically nonfunctional because the gonadotropins and their subunits are either not released or are inefficiently secreted and usually do not produce a distinct clinical syndrome. These tumors result in elevated α- and FSH-β-subunit and, rarely, LH-β serum levels. Some adenomas secrete α-subunits but not intact FSH or LH. TRH administration usually induces secretion of gonadotropins or their subunits in patients harboring these nonfunctional adenomas, unlike the absent TRH response seen in normal subjects. Most nonsecreting adenomas immunostain positively for intact FSH and LH, or α-, FSH-β-, and LH-β-subunits. Excessive secretion of FSH or LH might occasionally downregulate the reproductive axis resulting in clinical hypogonadism. Mass effects, including optic chiasm pressure and other neurological symptoms, might be the initial symptoms of large gonadotroph tumors. Surgical excision is the most effective therapy and pharmacological agents are largely ineffective in shrinking these tumor masses.

ANTERIOR PITUITARY FAILURE

Hormone-specific anterior pituicytes are embryologically derived from a pluripotent precursor, and arise as a consequence of temporal and spatial control of homeodomain repressor and activator transcription factor expression. Mutations of early developmental genes (including *Rpx*, *Lhx3*, *Lhx4*, and *Pitx2*) pleiotropically affect adjacent midline structures, resulting in pituitary hypoplasia and multiple pituitary hormone deficits whereas mutations in genes determining specific pituitary lineages (including *Prop1*, *Pit1*, *Tpit*) are involved in single or combined pituitary hormone deficiencies with hypoplasia. Developmental *PROP-1* defects produce variable phenotypes. GH, PRL, and TSH expressing cells share a common developmental pathway, and *Pit-1* mutations can affect all three cell types. Ames dwarf (Prop1 df/df) and Pit-1 dw/dw mice display growth deficiency, hypothyroidism and infertility. Persistent transgenic murine pituitary Prop-1 expression results in delayed murine gonadotrope differentiation, persistent Rathke's cleft cysts, pituitary enlargement, and null cell nonsecreting pituitary adenomas. Several transgenic mice models expressing dysfunctional GH transcriptional regulation exhibit markedly attenuated or absent *GH* gene expression. For example, the Snell dwarf mouse has a *Pit-1* point mutation. In humans, sporadic and familial cases of *Pit-1* mutation exhibit varying degrees of combined GH, PRL, and TSH basal deficiency, or impaired reserve. Some of those patients might exhibit a hypoplastic pituitary gland (Tables 33-3 and 33-4). Autosomal-dominant or -recessive *Pit-1* mutations associated with this heterogeneous clinical syndrome include dysfunctional point mutations with defective binding to pituitary gene promoters (e.g., 158 A to P), and dominant negative missense mutations (e.g., 271 Arg to Trp).

Table 33-3
Pituitary Failure Associated With Pit-1 Mutations

Mutation	*Clinical phenotype*	*Autosomal inheritance*
DNA binding domain		
143Arg → Gln	Growth retardation	Recessive
158Ala → Pro	Hypothyroid; growth retardation	Recessive
172Arg → Stop	Hypothyroid	Recessive
271Arg → Trp	Growth retardation; impaired thyroid reserve	Dominant
135Phe → Cys	Growth retardation; hypothyroidism	Recessive
Activation domain		
^{24}Pro → Leu	Growth retardation	Dominant

A missense mutation (77 Cys → Arg) in the GH molecule also leads to short stature. This mutant GH has weakened signal-transducing capacity, and might also function as a dominant negative inhibitor of wild-type GH.

PATHOGENESIS OF PITUITARY TUMORS

Each anterior pituitary cell type might give rise to monoclonal benign neoplasms that are hormonally functional or nonfunctional (Tables 33-5 and 33-6). Functional tumors are characterized by autonomous trophic hormone secretion, leading to clinical hormone excess syndromes, including hyperprolactinemia, acromegaly or Cushing's disease. Nonfunctioning pituitary adenomas secrete clinically inactive glycoprotein hormones or their free subunits. True pituitary carcinomas are extremely rare, and less than 40 cases have been unequivocally documented.

CLONAL ORIGIN OF PITUITARY ADENOMAS Complete resection of well-circumscribed pituitary adenomas often results in a cure of unrestrained or paradoxic hormone hypersecretion. This observation prompted the question regarding whether these tumors were clonal expansions of a single disordered cell. Disordered hypothalamic regulation would likely give rise to a generalized polyclonal cellular hyperplasia, as seen in patients harboring extrapituitary tumors elaborating hypothalamic-releasing hormones (e.g., GnRH, CRH). Alternatively, an intrinsic genetic defect within the pituitary would likely be associated with clonal proliferation.

Using X-chromosomal inactivation analysis of female patients heterozygous for sex-linked genes, several groups have confirmed the monoclonal origin of functional and nonfunctional pituitary tumors. When clonal analysis was performed on tumor DNA for hypoxanthine phosphoribosyl transferase or phosphoglycerate kinase in heterozygous patients with acromegaly, Cushing's disease, prolactinomas, and nonfunctioning tumors, a preferential loss of the inactive X-chromosome allele was observed after digestion with methylation-sensitive enzymes. These observations have prompted the quest for unraveling an intrinsic pituitary genetic defect resulting in either activation of a cell stimulator or inactivation of an inhibitor of cell proliferation.

HYPOTHALAMIC ORIGIN OF PITUITARY ADENOMAS Hypothalamic hormones regulate expression of the respective pituitary hormone genes by binding to specific cell surface receptors.

Table 33-4
Human Pituitary Transcription Factor Mutations

Factor	*Hormone deficiency*	*Pituitary size*	*Associated phenotype*
Early (pituitary commitment and progression)			
Hesx 1	Isolated GH: panhypopituitarism	Hypoplastic, hyperplastic	Septo-optic dysplasia
LHX 3	GH, TSH, PRL, LH, FSH	Hypoplastic	Rigid cervical spine
LHX 4	GH, TSH, ACTH	Hypoplastic	Chiari cerebellar deformity
PITX 2	GH	Hypoplastic	Reiger syndrome
Intermediate (pituitary patterning and cell type determination)			
Prop-1	GH, TSH, PRL Later: FSH, LH, ACTH	Hypoplastic Hyperplastic	
Late (cell type differentiation)			
Pit 1	GH, TSH, PRL	Hypoplastic	
T-Pit	ACTH	Hypoplastic	

Table 33-5
Classification of Pituitary Adenomas

Adenoma cell origin	*Hormone product*	*Clinical syndrome*
Lactotroph	PRL	Hypogonadism, galactorrhea[a]
Gonadotroph	RSH, LH, subunits	Silent or hypogonadism
Somatotroph	GH	Acromegaly, gigantism
Corticotroph	ACTH	Cushing's disease
Mixed growth hormone and prolactin cell	GH, PRL	Acromegaly, hypogonadism
Other plurihormonal cell	Any	
Acidophil stem cell	PRL, GH	Hypogonadism, acromegaly
Mammosomatotroph	PRL, GH	Hypogonadism, acromegaly
Thyrotroph	TSH	Hyperthyroidism
Null cell	None	Pituitary failure
Oncocytoma	None	Pituitary failure

[a]Females present with amenorrhea and infertility and males present with impotence or infertility.

Hormone-secreting tumors are listed in decreasing order of frequency. All tumors may cause local pressure effects, including visual disturbances, cranial nerve palsy, and headache.

In addition, these peptides might also induce DNA synthesis and enhanced mitotic activity in their target pituitary cells. Thus, mice expressing a GHRH transgene will exhibit somatotroph hyperplasia and ultimately adenoma. Patients harboring tumors elaborating ectopic GHRH or CRH might also present with GH-cell or ACTH-cell hyperplasia or adenomas, in addition to the hormone hypersecretory syndrome. Pituitary tumor-derived GHRH, SRIF, and TRH have been characterized by *in situ* or reverse transcriptase PCR techniques. These observations of intrapituitary peptide expression might imply a paracrine role for the hypothalamic peptides in pituitary tumorigenesis.

***gsp* MUTATIONS** Peptide hormone signal transduction involves coupling of activated cell surface receptors with membrane G proteins, consisting of three polypeptides: an α-chain that binds to guanine nucleotide, and a β- and γ-chain. Ligand-induced activation of the receptor induces GTP binding, which causes a conformational change in G protein, releasing the α-subunit from βγ, allowing it to interact with target proteins. Hydrolysis of bound GTP to GDP by the intrinsic guanosine 5′-triphosphatase (GTPase) activity of the α-subunit terminates the ligand-induced signal (Fig. 33-1). GHRH, by binding to its somatotroph receptor coupled to G proteins, uses cAMP as a second messenger to stimulate GH secretion and somatotroph proliferation. A subset of GH-secreting pituitary tumors contains elevated intracellular cAMP levels and increased in vitro GH secretion, and is not responsive to further GHRH stimulation. Intratumoral adenylyl cyclase levels are constitutively enhanced approx 10-fold compared with levels in unaffected patients. The GHRH-independent induction of cAMP in these tumors could conceivably occur as a result of constitutive activation of GHRH receptor or the catalytic domain of adenylyl cyclase or the stimulatory subunit of G protein. Point mutations of Gsα were identified in approximately one-third of these tumors. These missense mutations occur either in Arg-201 (Arg → Cys or His) or in Gln-227 (Gln → Arg), in a region of the Gsα that is involved in GTP hydrolysis. Thus, these *gsp* mutations activate Gsα by inhibiting its intrinsic GTPase activity. In the cAMP-responsive somatotroph cells, therefore, conversion of Gs-α into an activating oncogene, *gsp*, might explain the pathogenesis of unrestrained cell proliferation and GH hypersecretion in these tumors. Gs-α activation also induces both the *Pit-1* promoter and serine phosphorylation of the cAMP response-protein (CREB) in acromegalic tissue, thus promoting somatotroph cell proliferation. In fact, CREB phosphorylation appears to be a universal finding in GH-cell adenomas, and is significantly lower in clinically silent gonadotroph cell adenomas.

Interestingly, the *gsp* mutation is detected at a negligible frequency in Japanese patients, implying a geographic selection for the mutation. No significant clinical phenotype is associated with *gsp* mutations, and ultimate tumor behavior and response to therapy is not altered in these patients. It would therefore appear that additional cAMP-associated signaling genes are involved in GH-cell tumorigenesis.

***Ras* MUTATIONS** Transduction of intrapituitary hypothalamic, peripheral hormonal, and paracrine growth factor signals uses pathways other than those coupled to G proteins. The product of the proto-oncogene *ras* plays an important role in growth factor signal transduction. There are three functional *ras* genes, H-, N-, and K-*ras*, that encode a 21-kDa protein, p21ras. The guanine

Table 33-6
Gene Defects in Pituitary Tumors

Activating			*Mechanism of overexpression/*	
Gene	*Protein*	*Tumor type*	*inactivation*	*Function/defect*
Gsp	GNAS1	40% GH-secreting tumors McCune-Albright syndrome	Point mutation	Signal transduction/ Elevated cAMP

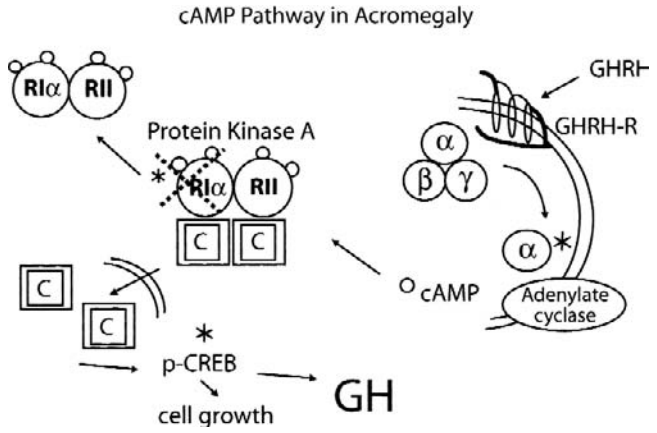

Figure 33-1 Cascade of events leading to GH gene regulation by activation of GHRH receptor and cAMP pathway. Lesions leading to acromegaly might occur at the level of GTPase, leading to elevated cAMP levels, PKA (Carney Complex) or at level of activated CREB. The genetic etiology of most sporadic GH-secreting tumors, however, remains elusive.

nucleotide-binding protein p21ras possesses intrinsic GTPase activity and is associated with the plasma membrane. Downstream ras signaling involves protein kinase cascades that transduce the incoming signal to the nucleus. Point mutations of the *ras* gene can convert it to a constitutively active oncogene that has been implicated in the development of a variety of tumors, and represents one of the most common mutations detected in human neoplasia. *Ras* gene mutations, however, occur rarely in pituitary tumors. Only a single invasive prolactinoma was found to harbor a missense *ras* mutation. Ras mutations were also detected in metastatic deposits of pituitary carcinomas, but not in the respective primary pituitary tumors. An activating transforming gene *(PTTG)* was isolated from rat and human pituitary tumors and is located on chromosome 5q33. These findings suggest that activation of ras is not an initial event in pituitary tumorigenesis; however, point mutations of *ras* might be important for the development or growth of metastases originating from rarely occurring pituitary carcinomas.

TUMOR SUPPRESSOR GENES Studies of the multiple endocrine neoplasia type (MEN) 1 gene locus surprisingly yielded evidence for tumor suppressor gene participation in pituitary

tumorigenesis. Loss of heterozygosity (LOH) of chromosome 11q13 is present in hereditary pituitary tumors associated with MEN1, and in up to 20% of sporadically occurring pituitary adenomas, including GH-, PRL-, and ACTH-cell adenomas, as well as some nonfunctional tumors. Several of these tumors exhibiting 11q13 LOH concurrently were shown to harbor a gsp mutation, lending further credence to a multistep cause of pituitary tumors. The gene for MEN1 (menin) has been cloned; menin mutations in mice recapitulate the syndrome of parathyroid, pancreatic, and pituitary neoplasms. Sporadic pituitary tumors do not manifest menin mutations, even in the presence of chromosome II LOH.

The retinoblastoma susceptibility gene *(RB)* is inactivated in a variety of human tumors. Individuals with germline mutations on one *RB* allele have >90% chance of developing a childhood retinoblastoma. The *RB* gene maps to chromosome 13ql4, and LOH at this locus is seen in retinoblastoma cells. The *RB* gene product is a major determinant of cell cycle control and acts as a signal transducer interfacing the cell cycle with specific transcriptional activation. The RB protein is phosphorylated in a cell cycle-dependent manner, being maximal at the start of the S phase and low after mitosis and entry into G1, and its activity appears regulated by the state of phosphorylation. Loss of RB protein function deprives the cell of an important mechanism for restraining cell proliferation.

The role of the *RB* gene in pituitary tumor formation was initially suggested by observations made in transgenic mice, in which one allele of the *RB* gene was disrupted. Although homozygous RB mutations are lethal early in fetal life, mice heterozygous for the *RB* gene mutation are not predisposed to retinoblastoma, but interestingly demonstrate pituitary tumors at a high frequency. These tumors originate from the pars intermedia of the pituitary, and express POMC immunoreactive products. The wild-type *RB* allele is absent in these pituitary tumors, whereas the mutant allele is retained. Pituitary tumor tissue derived from these mice also expresses a truncated dysfunctional RB protein.

In benign human pituitary microadenomas, no LOH at the *RB* locus has been detected. However, in invasive pituitary macroadenomas and in pituitary carcinomas, allelic deletions at the RB locus were observed. Therefore, LOH at the *RB* locus is unlikely to be an initiating event in pituitary tumorigenesis, but rather *RB* or an associated tumor suppressor gene might play a role in progression of benign tumors to more invasive and malignant phenotypes. Because immunoreactive RB protein appears to be present in these tumors, it is likely that another tumor suppressor gene is located on chromosome 13 in close proximity to the *RB* locus and might be involved in pituitary tumor progression.

nM23, a nucleoside diphosphate kinase gene associated with suppression of breast cancer and melanoma metastases, is highly expressed in small noninvasive pituitary adenomas. Pituitary nM23 expression correlates inversely with cavernous sinus invasiveness and is markedly attenuated in large invasive tumors. Interestingly, although *p53* tumor suppressor gene mutations have been detected in a variety of human tumors, no *p53* mutation has been detected in a comprehensive screening of pituitary tumors.

INTRAPITUITARY PARACRINE GROWTH FACTORS

Several intrapituitary growth factors and cytokines are expressed in normal and tumorous tissue. Their paracrine or autocrine regulation of specific pituitary function involves several trophic hormones either singly or in combination. These factors include epidermal growth factor, nerve growth factor, IGF-I, activin, and endothelin. Cytokines, including IL-6, IL-2, and LIF, also participate in paracrine regulation of trophic hormones. Although several in vitro and in vivo rat models have demonstrated growth factor-mediated pituitary mitogenesis, most of the information yielded from studies of human pituitary tumors is largely descriptive. The paucity of human tissue, as well as the failure of human pituitary cells to proliferate in vitro, has largely limited the subcellular regulatory studies required to establish a direct tumorigenic link for these growth factors.

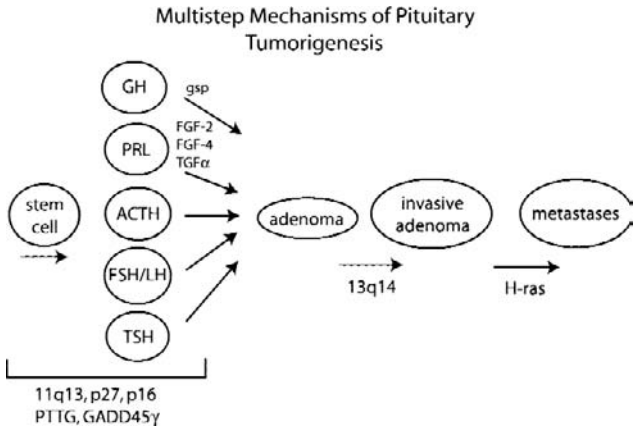

Figure 33-2 Depiction of known molecular mutations associated with pituitary tumorigenesis. Both activating and inactivating mutations have been observed in the pathogenesis of experimental animal tumors, or in human tumors. True pituitary malignant transformation is exceedingly rare, and might reflect unique endocrine cell cycle control. Cellular origin of tumors, in decreasing order of frequency is gonadotroph (nonfunctioning), lactotroph, somatotroph, corticotroph, and thyrotroph.

The most compelling evidence in favor of a growth factor role in pituitary pathogenesis is that derived from studying the fibroblast growth factor (FGF) family. Basic FGF (bFGF) is abundantly expressed in the pituitary, regulates PRL and TSH secretion, and also might stimulate human pituitary cell mitogenesis in vitro. Interestingly, circulating bFGF, as well as bFGF autoantibodies, is detectable before pituitary tumor resection in patients with MEN1, and bFGF levels fall after surgery. These observations imply that at least in MEN1, the pituitary adenoma might be a source of this mitogen. FGF-4, which might behave as a transforming proto-oncogene is expressed in human prolactinomas and induces PRL transcription. *PTTG* pituitary tumor transforming gene was isolated by differential mRNA display of rat pituitary tumors and is abundantly expressed in human pituitary adenomas. Disrupted *PTTG* also blocks experimental pituitary tumor growth and PRL secretion. PTTG is the index mammalian securin protein, involved in regulating faithful sister chromatid separation. Overexpressed PTTG leads to cell cycle disruption and aneuploidy. A truncated FGF4 receptor is also mitogenic for pituitary tissue in vivo.

Other paracrine growth factors that have been implicated in pituitary tumorigenesis include epidermal growth factor, transforming growth factor-α and -β and IGF-I. The gp-130 family of cytokines, including IL-6 and LIF, are expressed in functional pituitary adenomas, regulate POMC transcription, and might be inhibitory for pituicyte mitogenesis.

Table 33-7
Protein Products and Chromosomal Loci Associated with Hereditary Pituitary Tumor Syndromes

Familial GH-secreting tumors		
Syndrome	*Protein product*	*Chromosomal loci*
Multiple endocrine neoplasia type I	Menin	11q13
Carney complex	CNC1	17q24
	CNC2	2p16
McCune-Albright syndrome	Gsp	20q13
Isolated familial acromegaly	?	11q13

CONCLUSION

The molecular pathogenesis of pituitary adenomas appears multifactorial (Fig. 33-2). Clearly early proximal DNA-altering events might occur that might involve transcription factor dysregulation (e.g., Pit-1) or hereditary mutations (e.g., MEN, Carney complex) (Table 33-7). Multiple promoting influences might subsequently impinge on the previously "initiated" cell and determine clonal expansion. These factors include disordered hypothalamic hormone receptor signaling (e.g., gsp); overstimulation by ectopic (or paracrine?) hypothalamic hormones (e.g., GnRH, CRH); disordered paracrine growth factor action (e.g., FGF-4, bFGF); disordered signal transduction (e.g., CREB); loss of negative feedback inhibition leading to pituitary hyperplasia (e.g., hypothyroidism or hypogonadism); estrogen-mediated or paracrine angiogenesis (e.g., vascular endothelial growth factor); and loss of tumor suppressor activity (e.g., chromosomes 11 and 13). Once the cell has been transformed, its ultimate growth characteristics and neoplastic behavior appear to be determined by several genes acting relatively distally, including *ras* and *nm23*.

34 Growth Hormone Deficiency Disorders

Amy Potter and John A. Phillips, III

SUMMARY

Growth hormone (GH) is a multifunctional hormone produced in the pituitary that promotes postnatal growth of skeletal and soft tissues through a variety of effects. In addition to promoting growth of tissues, GH also exerts a variety of other biological effects, including lactogenic, diabetogenic, lipolytic, and protein anabolic effects, as well as sodium and water retention. The frequency of GH deficiency has been estimated at 1/4000–1/10,000 in various studies. Estimates of the proportion of GH-deficient cases having an affected parent, sib, or child range from 3 to 30% in different studies. This occurrence of familial clustering suggests that a significant proportion of cases might have a genetic basis. This chapter discusses the genetics and molecular pathophysiology of familial isolated growth hormone deficiency and combined pituitary hormone deficiency.

Key Words: Combined pituitary hormone deficiency; growth hormone; growth hormone releasing hormone receptor; isolated growth hormone deficiency; Laron syndrome; pituitary.

INTRODUCTION

Growth hormone (GH) is a multifunctional hormone produced in the pituitary that promotes postnatal growth of skeletal and soft tissues through a variety of effects. The GH gene, *GH1*, is part of a gene cluster that likely originated through duplication events during evolution (Fig. 34-1). Controversy remains about the relative contribution of direct and indirect actions of GH. The direct effects of GH have been demonstrated in many tissues and organs and growth hormone receptors (GHRs) have been documented in a number of cell types. However, a substantial amount of data indicates that a major portion of the effects of GH are mediated through the actions of GH-dependent insulin-like growth factor-1 (IGF-I). IGF-I is produced in many tissues, primarily the liver, and acts through its own receptor to enhance the proliferation and maturation of many tissues, including bone, cartilage, and skeletal muscle. In addition to promoting growth of tissues, GH also exerts a variety of other biological effects, including lactogenic, diabetogenic, lipolytic, and protein anabolic effects, as well as sodium and water retention.

At the cellular level, a single GH molecule binds two GHR molecules, causing them to dimerize (Chapter 31). Dimerization of the two GH-bound GHR molecules is thought to be necessary for signal transduction, which is associated with the tyrosine kinase JAK-2. The diverse effects of GH might be mediated by a single type of GHR molecule that can possess different cytoplasmic domains or phosphorylation sites in different tissues. When activated by JAK-2, these differing cytoplasmic domains can lead to distinct phosphorylation pathways, one for growth effects and others for various metabolic effects. GHR is localized on the cell surface, and contains extracellular, transmembrane, and cytoplasmic domains (Fig. 34-2). The extracellular domain is cleaved, releasing the extracellular portion of GHR into the circulation as growth hormone-binding protein (GHBP). GHBP functions as a reservoir for GH in the plasma.

The frequency of GH deficiency (either isolated or concomitant with other pituitary hormone deficiencies) has been estimated at 1/4000–1/10,000 in various studies. Most cases are sporadic and assumed to arise from cerebral insults or defects that include cerebral edema, chromosomal anomalies, histiocytosis, infections, radiation, septo-optic dysplasia (SOD), trauma, or tumors affecting the hypothalamus or pituitary. MRI examinations detect hypothalamic or pituitary anomalies in approx 12% of patients who have isolated growth hormone deficiency (IGHD).

Estimates of the proportion of GH-deficient cases having an affected parent, sib, or child range from 3 to 30% in different studies. This occurrence of familial clustering suggests that a significant proportion of cases might have a genetic basis. The genetics and molecular pathophysiology of familial IGHD and combined pituitary hormone deficiency (CPHD) is discussed next. Table 34-1 shows an overview of the genetic disorders associated with GH deficiency or defective GH function.

CLINICAL FEATURES

Adequate amounts of GH are needed throughout childhood to maintain normal growth. Newborns with GH deficiency are usually of normal length and weight. Infants with CPHD might have signs of other pituitary hormone deficiencies, such as micropenis (gonadotropin deficiency) or fasting hypoglycemia (adrenocorticotropin deficiency, GH deficiency) in addition to their low linear growth, which becomes progressively retarded with age. In those with IGHD, skeletal maturation is usually delayed in proportion to their retardation in height. Truncal obesity, facial appearance younger than expected for chronological age, delayed secondary dentition, and high-pitched voice are often present. Puberty might be delayed until the late teens but normal fertility usually occurs.

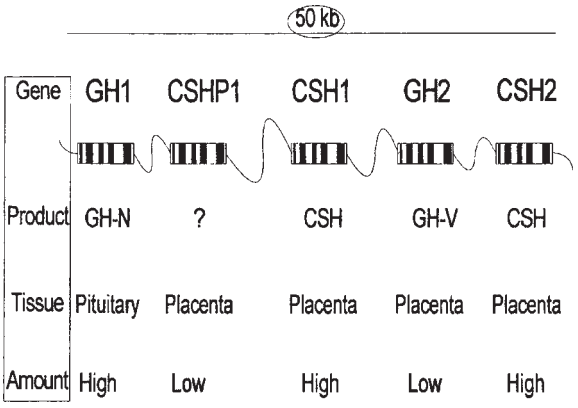

Figure 34-1 Schematic overview of the GH gene cluster, including the protein products and expression patterns of its component genes. *GH1* encodes the pituitary growth hormone; all of the other genes are expressed in the placenta. As the nomenclature of this gene cluster has been somewhat confusing, alternative names and abbreviations are given in parentheses where ever appropriate. *GH1*, the growth hormone gene; *GH-N*, the active form of growth hormone; *CSHP1*, chorionic somatomammotropin pseudogene 1 (CSHL1, chorionic somatomammotropin hormone like 1; CSL, chorionic somatomammotropin like); *CSH1*, chorionic somatomammotropin hormone 1 gene (CSA, chorionic somatomammotropin A); CSH, chorionic somatomammotropin hormone; *GH2*, growth hormone 2 gene; GH-V, growth hormone variant (produced only in the placenta); *CSH2*, chorionic somatomammotropin hormone 2 gene (CSB, chorionic somatomammotropin B). "?" denotes uncertainty concerning the presence or functionality of any protein product of this gene. Evidence suggests that most transcripts result in nonfunctional protein products, although some functional product might be present in low amounts.

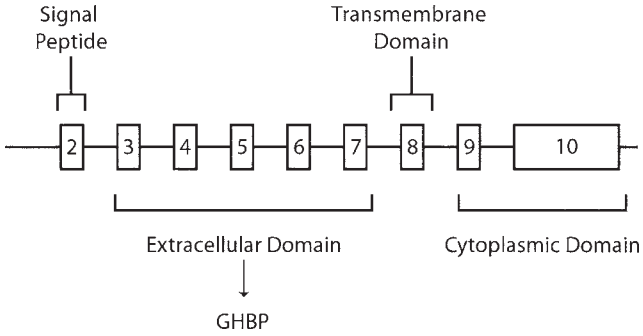

Figure 34-2 Structure of the coding region of the growth hormone receptor (GHR), demonstrating the signal peptide and extracellular, transmembrane, and cytoplasmic domains. Numbered boxes represent exons. GHR is cleaved by tumor necrosis factor-α converting enzyme (TACE, a metalloprotease) to form GHBP. In humans the cleavage site localizes to residues 240–247, close to the transmembrane domain.

Fine, wrinkled skin appearing similar to that of premature aging is seen in affected adults. Concomitant deficiency of other pituitary hormones—for example, luteinizing hormone (LH), follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and adrenocorticotropic hormone (ACTH)—in addition to GH, is called panhypopituitary dwarfism or CPHD. With these additional hormone deficiencies, the retardation of growth and skeletal maturation is often more severe and spontaneous puberty might not occur.

Laron syndrome (*see* Laron Syndrome) is an autosomal-recessive disorder-caused by target organ resistance to the action of GH. Patients with Laron syndrome are similar in clinical appearance to those with severe IGHD. At the biochemical level, Laron syndrome subjects have low levels of IGF-I, despite increased circulating levels of GH. This contrasts with the low levels of both IGF-I and GH that are seen in GH deficiency. Patients with Laron syndrome do not respond to exogenous GH therapy, but replacement therapy with recombinant IGF-I (thus bypassing the dysfunctional GHR) is effective. Laron syndrome is caused by defects in GHR (*see* molecular pathology details in Laron Syndrome).

DIAGNOSIS

Although short stature, delayed growth velocity, and delayed skeletal maturation are all seen with GH deficiency, none of these signs is specific for this disorder. Patients should be evaluated for other systemic diseases causing growth failure (such as thyroid disease, occult renal disease, malabsorption syndromes, anemia, and others). IGF-I levels might be used as a screening test for GH deficiency. For patients with low IGF-I levels compared with age norms (or low-normal levels in a suggestive clinical setting), provocative testing to definitively prove GH deficiency is necessary. The most commonly used provocative tests include exercise, levodopa, insulin tolerance test, arginine, clonidine, and growth hormone releasing hormone (GHRH); typically, two tests are performed in combination, for example, insulin tolerance testing and arginine stimulation. Glucagon and propranolol have also been used for stimulation testing but are not commonly used currently. Inadequate GH peak responses (usually <7–10 ng/mL) differ from test to test. Patients whose stimulation tests confirm GH deficiency should undergo an MRI to rule out mass lesions or congenital anomalies (e.g., SOD) as the cause of the deficiency. Testing of the LH, FSH, TSH, and ACTH axes should be performed to identify any additional pituitary hormone deficiencies.

FAMILIAL ISOLATED GH DEFICIENCY

GENETIC BASIS AND MOLECULAR PATHOLOGY OF DISEASE Familial IGHD is associated with at least four Mendelian disorders. These include two forms that have autosomal-recessive inheritance (IGHD IA and IB), as well as autosomal-dominant (IGHD II) and X-linked (IGHD III) forms. A variety of molecular defects have been detected which cause these disorders (Table 34-2). These defects are reviewed on the basis of the type of inheritance (IGHD I–III) that they cause.

ISOLATED GROWTH HORMONE DEFICIENCY IA The most severe form of IGHD, called IGHD IA, has an autosomal-recessive mode of inheritance. Affected individuals occasionally have short lengths at birth and hypoglycemia in infancy, but uniformly develop severe dwarfism by 6 mo. In response to replacement therapy with exogenous GH, IGHD IA subjects have a strong initial anabolic and growth response that is frequently followed by the development of anti-GH antibodies in sufficient titer to block the response to GH replacement.

GH1 Gene Deletions Initially, all individuals with IGHD IA were homozygous for *GH1* gene deletions and developed anti-GH antibodies with treatment. Subsequently, additional patients with *GH1* gene deletions have been described who also have complete GH deficiency, but respond well to GH replacement. Thus, the clinical outcomes of subjects with the same molecular findings vary, making the presence of anti-GH antibodies an inconsistent finding in IGHD IA cases.

At a molecular level, Southern blot analysis showed deletions of approx 6.7, 7, or 7.6 kb, with most (~ 75%) being 6.7 kb. DNA

Table 34-1
Overview of Disorders Causing Growth Hormone Deficiency

Level of disorder	*Type of deficiency*	*Gene involved*	*Inheritance*	*Defect*
Pituitary	MPHD	*POU1F1*	R, DN	All cause defects in pituitary development with varying degrees of pituitary hypoplasia
		PROP1	R	
		HESX1	R	
	IGHD III	*SOX3*	X	Likely pituitary hypoplasia, syndrome includes mental retardation
Growth hormone releasing hormone receptor (GHRHR)	IGHD IB	*GHRHR*	R	Failure to respond to GHRH
Growth hormone	IGHD IA	*GH1*	R	Absent GH resulting from gene deletions, frameshifts, and nonsense mutations
	IGHD IB	*GH1*	R	Splicing defects
	IGHD II	*GH1*	DN	Splicing defects leading to defective processing/secretion of GH
	Biodefective growth hormone	*GH1*	?	Nonfunctional growth hormone molecule
Growth hormone receptor	Laron syndrome	*GHR*	R (most common), DN (rare)	Nonfunctional GHR causes resistance to growth hormone and deficiency of growth hormone effect

MPHD, multiple pituitary hormone deficiencies; IGHD, isolated growth hormone deficiency; R, recessive; DN, dominant negative; X, X-linked.

	Exon IV	6191 G → T	Val110Phe, possible altered protein folding	Binder et al. (2001)
	Exon V	6664 G → A	Arg183His, altered secretory granules	Deladoëy et al. (2001)

[a]Nucleotide numbering according to Chen EY, Liao Y, Smith DH, et al. The human growth hormone locus: nucleotide sequence, biology, and evolution. Genomics 1989;4:479–497.

GH, growth hormone; IGHD, isolated growth hormone deficiency.

sequence analysis of the fusion fragments associated with *GH1* gene deletions has shown that homologous recombination between sequences flanking the *GH1* gene causes these deletions (Fig. 34-3). *GH1* gene deletions are detected using PCR amplification of the homologous regions flanking the *GH1* gene and the fusion fragments associated with *GH1* gene deletions. Because the fusion fragments associated with 6.7-kb deletions differ in the size of fragments produced by certain restriction enzymes (*see Sma*I sites indicated by solid circle in Fig. 34-3), homozygosity or heterozygosity for these deletions can easily be detected by enzyme digestion of PCR

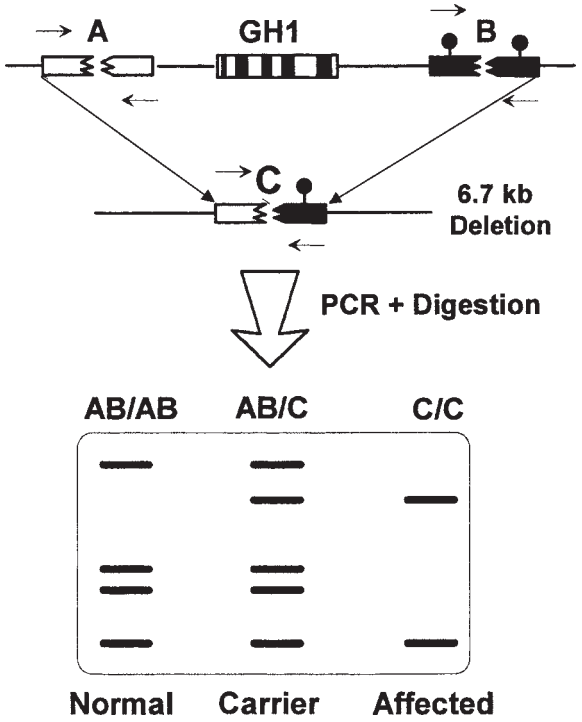

Figure 34-3 PCR amplification of homologous sequences flanking the GH1 gene. Flanking sequences are distinguished from GH-deletion fusion fragments by restriction enzyme digestion (•), shown above, and gel electrophoresis, shown below.

products. A variety of studies suggest that 13–15% of subjects with severe IGHD (>–4.5 standard deviations [SD] in height) have *GH1* gene deletions. Frameshift and nonsense mutations have also been found in subjects with the IGHD IA phenotype, such that this disorder might best be described as complete GH deficiency as a result of *GH1* gene defects, rather than gene deletions alone.

GH1 Deletion and Frameshift Mutations Two affected siblings diagnosed with IGHD IA have been reported who are compound heterozygotes for deletion and frameshift mutations of the *GH1* gene. Southern blot analysis showed the patients to be heterozygous for the 6.7 kb GH gene deletion. DNA sequence analysis of the retained *GH1* gene showed it had a cytosine deleted in the 18th codon of the prohormone sequence. This single-base deletion results in a frameshift within the signal peptide coding region that prevents the synthesis of any mature GH protein. These patients presented with severe growth failure, and after an initial growth response to treatment with exogenous GH, had high titers of anti-GH antibodies.

GH1 Nonsense Mutations A G → A transition in codon 20 (Trp20Ter) of the *GH1* signal peptide has been reported in a consanguineous Turkish family with IGHD IA. This results in the termination of translation after residue 19 of the signal peptide and no production of mature GH. Patients homozygous for this mutation have no detectable GH and produce anti-GH antibodies in response to exogenous GH treatment. Interestingly, this mutation generates a new *Alu*I site that can be readily screened for by PCR amplification of the GH gene followed by *Alu*I digestion and gel electrophoresis (Fig. 34-4).

IGHD IB CAUSED BY GH1 MUTATIONS Patients with IGHD IB are characterized by low, but detectable levels of GH, stature more than 2 SD below the mean for age and sex, autosomal-recessive inheritance, and a positive response and immunological

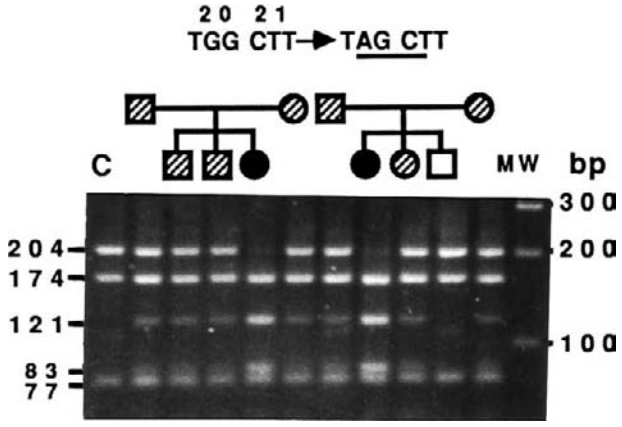

Figure 34-4 Detection of the GH G → A codon 20 (Trp → Stop) mutation by restriction enzyme digestion with *Alu*I and gel electrophoresis. Note when this mutation is present a new *Alu*I recognition site occurs and the normal 204 bp fragments are cleaved to 121 and 83 bp.

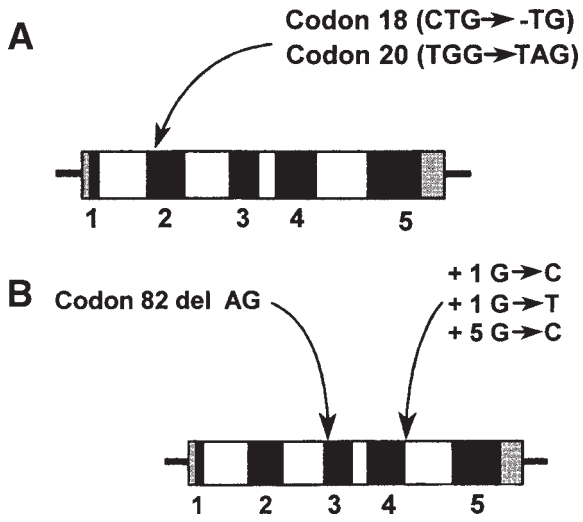

Figure 34-5 Schematic representation of the GH1 gene showing the locations of various isolated growth hormone deficiency (IGHD) IA **(A)** and IB **(B)** mutations. Shaded areas represent exons; clear areas represent introns. A +1 indicates position within the donor splice site.

tolerance to treatment with exogenous GH. Some patients clinically diagnosed as IGHD IA because of an apparent lack of endogenous GH are actually type IB. In these patients, *GH1* gene defects result in mutant GH protein that cannot be effectively measured by radioimmunoassay. The presence of this protein might explain their good response to GH therapy and lack of anti-GH antibodies. Figure 34-5 shows selected *GH1* mutations causing IGHD IA and IB. IGHD IB is also caused by defects in the growth hormone releasing hormone receptor (*GHRHR*) gene. Lack of signaling through GHRHR leads to very low level or absent GH production.

GH1 Splicing Mutations A G → C transversion in the first base of the donor splice site of intron 4 has been detected in a consanguineous Saudi Arabian family. The mutation causes the activation of a cryptic splice site 73 bases upstream of the exon 4 donor splice site. This altered splicing results in the loss

of amino acids 103–126 of exon 4 and creates a frameshift that alters the amino acids encoded by exon 5. Such changes in the amino acids encoded by exons 4 and 5 affect the stability and biologic activity of the mutant GH protein, and bovine GH mutants also derange intracellular targeting of GH protein products to the secretory granule.

A G → T transversion has been identified at the same site in another consanguineous Saudi family. This G → T transversion had the same effect on splicing as the G → C transversion. Both of these mutations destroy an HphI site that enables their detection by restriction digestion of *GH1* gene PCR products followed by gel electrophoresis. Patients homozygous for these defects responded well to exogenous GH treatment and did not make anti-GH antibodies.

A G → C transversion of the fifth base of intron IV was identified in a highly consanguineous family diagnosed with IGHD I. This mutation created a new MaeII site that was used to screen all family members for the mutation. Reverse transcriptase-PCR analysis of GH mRNA transcripts from the lymphoblastoid cells of an affected patient demonstrated that the mutation destroyed the intron IV donor splice site and had the same overall effect on splicing as the +1G → C transversion previously described. Interestingly, heterozygous carriers of this mutation were later reported to have a higher frequency of short stature than homozygous wild type family members.

GH1 Deletions and Frameshifts An IGHD patient with severe growth retardation was found to have two GH gene defects. The first GH allele was a 6.7-kb deletion and the second had a 2-bp deletion in exon 3. This 2-bp deletion results in a frameshift within exon 3 and generates a premature stop codon at the position of amino acid residue 132 in exon 4. The patient had a positive response to GH replacement therapy and did not produce anti-GH antibodies, again suggesting that some GH-related protein was produced.

IGHD IB CAUSED BY GHRHR MUTATIONS The molecular basis for the "little" (lit) mouse phenotype, characterized by dwarfism and hypoplasia of the anterior pituitary gland, is a point mutation in the *GHRHR* gene that results in an Asp→Gly substitution at residue 60 (Asp60Gly). Anterior pituitaries of mutant mice showed spatially distinct proliferative zones of GH producing stem cells and mature somatotropes, each regulated by a different trophic factor. Subsequent studies have shown that the Asp60Gly mutant does not bind GHRH.

A nonsense mutation in the human *GHRHR* gene was found in two first cousins, a boy, and a girl, of a consanguineous Indian family with profound GH deficiency. Both the 3.5-yr-old girl and her 16-yr-old cousin showed poor growth since infancy and were extremely short. They were prepubertal with frontal bossing and predominantly truncal obesity. Although both failed to produce GH in response to standard provocative tests and to repetitive stimulation with GHRH, they responded to administration of exogenous GH. The affected individuals were homozygous for a G → T transversion at position 265 of their *GHRHR* genes, resulting in a premature termination mutation (Glu72Stop). Because both GH releasing peptide (a synthetic heptapeptide) and nonpeptidyl benzamines can stimulate GH release without involvement of the GHRH receptor, they might be useful in therapy of this disorder. Subsequently, the same *GHRHR* mutation was found in an isolate from the Indus valley of Pakistan. A splice mutation of the *GHRHR* gene was found in a large consanguineous kindred in Brazil. The mutation was a G → A transition at the +1 position of IVS1. A mutation that affects the PIT-1 binding site in the *GHRHR* promoter (–124 A → C) and thereby decreases *GHRHR* expression has also been described.

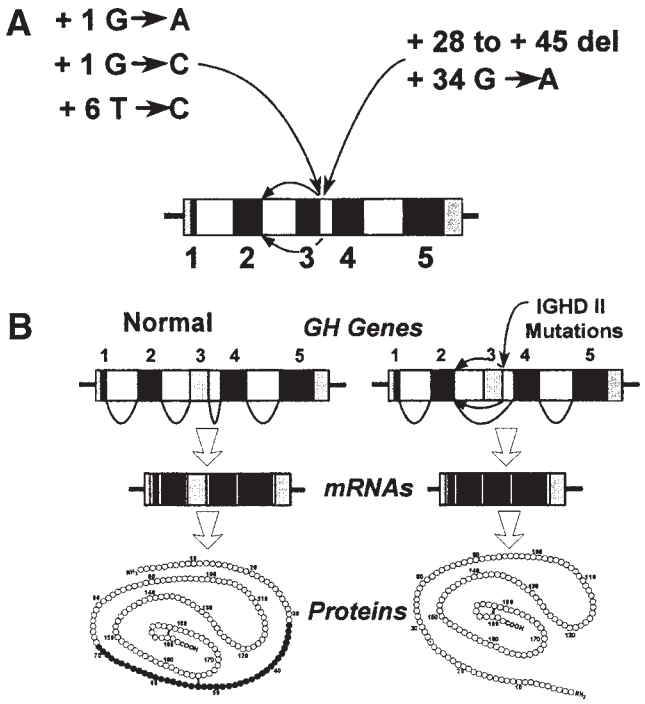

Figure 34-6 Schematic representation of **(A)** the GH1 gene showing the locations of various isolated growth hormone deficiency (IGHD) II mutations and **(B)** the mRNA splicing patterns of the normal growth hormone (GH) and IGHD II mutant GH genes. Note that the deleted amino acids corresponding to exon III are shaded in the normal peptide (left) and absent in the mutant peptide (right). Shaded areas represent exons; clear areas represent introns. A+ sign indicates position within the intron.

IGHD II IGHD II has an autosomal-dominant mode of inheritance. Patients diagnosed with IGHD II have a single affected parent, vary in clinical severity between kindreds, and respond well to GH treatment. The majority of IGHD II patients with GH1 gene defects have mutations in intron 3 that alter splicing of GH transcripts, resulting in skipping of exon 3 (Fig. 34-6). The mechanism by which the mutant, truncated GH protein inactivates the normal GH protein appears to be related to altered intracellular processing of the GH protein product (*see* Dominant-Negative Mutations).

Dominant-Negative Mutations A T → C transition of the sixth base of the donor splice site of intron 3 was the first mutation associated with IGHD II. The mutation inactivates the intron 3 donor splice site causing deletion or skipping of exon 3 and loss of amino acids 32–71 from the corresponding mature GH protein products. All of the affected patients in this family were heterozygous for the intron 3 +6 T → C change and had low, but measurable, GH levels after provocative stimulation. Affected subjects responded well to treatment with exogenous GH without forming significant levels of anti-GH antibodies.

Many additional mutations causing altered splicing leading to IGHD II mutations have been identified (*see* Table 34-2). The intron 3 donor splice site appears to be a mutational "hot spot," with a recurring G → A transition at the first base of the donor splice site as well as other mutations. The G → A transition has been identified in nonrelated kindreds and is thought to arise because of the high mutation frequency of CpG dinucleotides. All of these donor splice site mutations cause exon 3 skipping in vitro.

Intron 3 mutations that alter splicing but do not occur within the consensus branch, donor, or acceptor sites have also been identified. One deletes 18 bp (del+28–45), and the second is a G → A transition of the 28th base of intron 3. Both of these mutations in vitro lead to exon 3 skipping. These mutations disrupt an intron splice enhancer sequence with the motif $G_2X_{1-4}G_3$, which normally regulates splicing. An exon 3 +5 A → G mutation has also been described that it disrupts an exon splice enhancer and causes partial or complete exon 3 skipping.

The mechanism for the autosomal-dominant inheritance pattern of these mutations was previously unknown, although it was hypothesized that the mutant protein somehow interfered with the function or secretion of the wild type protein translated from the normal allele. In 1999, it was demonstrated that *GH1* constructs with intron 3 donor splice site mutations (causing exon 3 skipping) caused significant inhibition of wild type GH secretion in neuroendocrine cell lines. In 2002, it was shown that a different mutation associated with IGHD II (R183H) was retained in cells after packaging into secretory granules for a longer period than wild type protein. Studies in mice transgenic for the intron 3 + 1 G → A mutation (Δexon3hGH) have clearly demonstrated that the mutated protein aggregates in the cytoplasm of the pituitary somatotropes. Few secretory vesicles were visible in these cells, and abnormal histology was seen. Mouse lines with the highest transgene copy numbers were most severely affected, with destruction not only of somatotropes but eventually other pituitary cell lines as well, leading to multiple pituitary hormone deficiencies.

In addition to the R183H mutation discussed earlier, other mutations causing IGHD II through amino acid changes rather than splicing changes have been found. Patients with IGHD II on the basis of an amino acid change tend to have a milder phenotype than those with splicing changes, but there is considerable interindividual variation. It is likely that these other missense mutations cause IGHD II by affecting protein packaging and/or secretion in a manner similar to that described for R183H.

IGHD III IGHD III has an X-linked mode of inheritance, but distinct clinical findings in different families. Affected individuals in some kindreds have γ-globulinemia associated with their IGHD, but others do not, suggesting that contiguous gene defects of Xq21.3–q22 might occur in some cases. Interestingly, other cases of IGHD have an interstitial deletion of Xp22.3 or duplication of Xq13.3–q 21.2 suggesting that multiple loci might cause IGHD III.

SOX3, located on the X chromosome, is a member of the SRY-related high-mobility group box family of transcription factors. It has been associated with an X-linked syndrome of short stature, mental retardation, characteristic facies, and IGHD in one family. Analysis of the *SOX3* gene in that family showed an in-frame 33 bp duplication occurring within a poly-alanine tract. Mouse studies have shown that *SOX3* is widely expressed in the developing CNS and pituitary. Duplications of the X chromosome spanning the region Xq26.1–q27.3, which includes *SOX3*, have been associated with pituitary hypoplasia. This evidence suggests that overexpression of *SOX3* might lead to abnormalities of both the pituitary and other elements of the CNS; however, the exact mechanism remains to be confirmed.

BIODEFECTIVE GH

Treatment with exogenous human GH induced normal levels of IGF-I and a significant increase in growth rate in two unrelated boys with growth retardation, delayed bone ages, low levels of IGF-I, and normal GH levels after stimulation. Although the family data did not support a specific mode of inheritance, a mutation resulting in a biologically ineffective GH molecule was speculated. A similar case confirmed a structural abnormality of the GH molecule: 60–90% of circulating GH was in the form of tetramers and dimers (normal, 14–39% in plasma) and the patients' GH polymers were abnormally resistant to conversion into monomers by urea.

Subsequently, a boy was reported who was short at birth (39 cm at 41 wk gestation) and at the age of 4.9 yr had a height that was –6.1 SD below the mean and a bone age of 2 yr. He had normal body proportions, with a prominent forehead and saddle nose. His IGF-I was 34 ng/mL (normal 35–293). Basal GH levels were 7–14 ng/mL and peak levels after insulin-induced hypoglycemia, arginine, and levodopa administration were 38, 15, and 35 ng/mL, respectively. Serum IGF-I was unchanged after 3 d of daily subcutaneous injections of 0.1 U of recombinant human GH/kg body weight (0.035 mg/kg). During prolonged treatment with GH (0.18 mg/kg/wk), his serum IGF-I was 200 ng/mL and his rate of linear growth increased to 6 cm/yr from 3.9 cm/yr before treatment. Assay of the bioactivity of his GH was below the normal range, and isoelectric focusing of his serum showed an abnormal GH peak in addition to a normal peak, whereas serum from his father and normal controls contained only one peak. The affected son was heterozygous for a C→T transition encoding an Arg→Cys substitution at codon 77 (Arg77Cys) of his GH1 gene. Inexplicably, his father, also heterozygous for this mutation, was of normal height, had a peak GH level of 23.7, and normal isoelectric focusing results. The same researchers have also reported a different mutation, Asp112Gly, in a 3-yr-old girl with short stature and high circulating GH levels as well as good response to exogenous GH therapy. This mutation is associated with GHR in a 1/1 ratio instead of 1/2, resulting in decreased intracellular signaling in vitro.

LARON SYNDROME: GROWTH HORMONE RESISTANCE

As mentioned, Laron syndrome is caused by defects in *GHR*. Most cases display autosomal-recessive inheritance, but at least two instances of autosomal-dominant (dominant negative) inheritance have been described.

AUTOSOMAL-RECESSIVE GH RESISTANCE The first *GHR* mutations causing autosomal-recessive Laron syndrome were described in 1989, when both a partial *GHR* gene deletion and a missense mutation (Phe96Ser) in the extracellular portion of the receptor were discovered. Since then, many different mutations have been reported. The majority occurs in the extracellular portion of the receptor, causing the phenotype of Laron syndrome with normal-to-elevated GH levels, low-to-absent GHBP levels, and low IGF-I levels with poor growth. GHBP consists of the extracellular portions of *GHR* that have been proteolytically cleaved from the cell surface. Mutations that affect the extracellular portion of *GHR* lead to low GHBP levels. Such mutations are heterogeneous. For example, nine novel mutations were reported occurring in 13 unrelated patients: three were nonsense mutations, one caused a frameshift, two were splice site mutations, and three were missense mutations. All affected the extracellular domain of the receptor, and all 13 patients had undetectable GHBP. Exon 4 was also noted as a "hot spot" for mutations, with five out of the nine mutations occurring in exon 4.

Table 34-3
Selected Mutations in the POU1F1 Genes of Subjects with CPHD

Mode	*Codon*	*Nucleotide change*	*Effect of mutation*	*References*
AR		Deletion	Deletion of POU1F1 gene	Wit et al. (1989)
	135	T → G	Amino acid change (Phe → Cys)	Pelligrini et al. (1996)
	143	G → A	Amino acid change (Arg → Gln)	Ohta et al. (1992)
	158	G → C	Amino acid change (Ala → Pro)	Wit et al. (1989)
	172	C → T	Generates a stop codon	Tatsumi et al. (1992)
	230	G → A	Amino acid change (Lys → Glu)	Gat-Yablonski et al. (2002)
	239	T → C	Amino acid change (Pro → Ser)	Pernasetti et al. (1998)
	250	G → T	Generates a stop codon	Irie et al. (1995)
AD	24	C → T	Amino acid change (Pro → Leu)	Ohta et al. (1992)
	271	C → T	Amino acid change (Arg → Trp)	Radovick et al. (1992) Cohen et al. (1995)

AD, autosomal-dominant; AR, autosomal-recessive.

Mutations associated with elevated GHBP levels have also been reported. One patient with Laron syndrome had a marked elevated of GHBP. Investigation revealed a G → T transversion at exon 8 –1, causing skipping of exon 8 (which encodes the transmembrane domain) and a frameshift leading to a premature stop codon. The truncated protein is thus unable to be appropriately anchored in the cell membrane, and appears in the serum as GHBP. The patient was homozygous for the mutation, suggesting autosomal-recessive inheritance; the patient's mother was heterozygous for the mutation and of normal height with elevated serum GHBP levels.

DOMINANT-NEGATIVE GH RESISTANCE A patient with Laron syndrome and normal GHBP levels has been described. The patient and her mother had a heterozygous G → C transversion of the 3′ splice acceptor site before exon 9. This splice site mutation resulted in deletion of exon 9 with a frameshift and premature stop codon, resulting in reduction of the intracellular portion of the receptor to only seven amino acids. In vitro studies of this mutant showed that it was unable to initiate JAK/STAT signaling. Lack of the intracellular portion of the receptor would also be expected to reduce internalization and degradation of the receptor. The resulting accumulation of abnormal receptors on the cell surface would then competitively inhibit the normal receptor, accounting for the dominant negative phenotype. A mutation of the donor splice of intron 9 produced a truncated receptor structurally identical to that produced by the G → C transversion of the 3′ splice acceptor site prior to exon 9.

GHR DEFECTS IN IDIOPATHIC SHORT STATURE Idiopathic short stature (ISS) is the name given to short stature once systemic disorders and other known causes have been excluded. By definition, ISS patients have normal responses to GH stimulation testing. Some ISS patients might have low IGF-I and GHBP levels, and it has been theorized that at least some cases of ISS might be because of less severe or heterozygous mutations of *GHR*. Results of investigations suggest that *GHR* mutations account for a small but significant percentage of ISS cases.

FAMILIAL COMBINED PITUITARY HORMONE DEFICIENCY

GENETIC BASIS AND MOLECULAR PATHOPHYSIOLOGY OF DISEASE Familial CPHD is characterized by deficiency of one or more of the other pituitary trophic hormones (ACTH, FSH, LH, or TSH) in addition to GH deficiency. Whereas the great majority of cases are sporadic, there are Mendelian forms with autosomal-recessive, autosomal-dominant, or X-linked modes of inheritance. Mutations in several transcription factors, including *POU1F1* (also called *PIT1*), *PROP1*, and *HESX1* have been associated with CPHD in humans. *POU1F1* and *PROP1* are both members of the POU (for Pit-1, Oct-1, and Unc-86) homeodomain family of transcription factors and play an important role in pituitary development.

POU1F1 *POU1F1* (or *PIT1*) encodes a protein that binds to and transactivates promoters of the *GH1* and prolactin genes. It is required for differentiation and proliferation of somatotropes, lactotropes, and thyrotropes. At least 10 different *POU1F1* mutations have been found in humans in a subtype of CPHD associated with GH, prolactin, and TSH deficiency (Table 34-3).

Autosomal-Recessive *POU1F1* Mutations The first and second *POU1F1* mutations reported were found in two consanguineous Japanese families. One family had a C → T transition in codon 172 (Arg172Ter). Both parents were heterozygous and the affected child was homozygous for the mutation. In the second family, a missense mutation (Arg143Gln) was found. The patient was homozygous for this mutation, whereas the parents and two unaffected siblings were heterozygous. Both mutations occur in the POU-specific domain and are thought to affect binding of the POU1F1 protein to the DNA.

The third and fourth *POU1F1* mutations were found in two Dutch families who had postnatal growth failure with complete deficiencies of GH and prolactin, whereas the thyroxine (T4) levels were low or normal before or following GH replacement. Subjects in one family who had normal T4 levels were homozygous for a G → C substitution in codon 158 (Ala158Pro). This mutation interferes with formation of POU1F1 homodimers and dramatically reduces the altered POU1F1's ability to activate transcription. Subjects in the second family with low T4 levels had one deleted *POU1F1* gene and one *POU1F1* gene with the previous mutation. These cases emphasize the importance of determining prolactin levels and TSH responses to thyrotropin-releasing hormone (TRH) in evaluating CPHD. Because GH and TSH deficiency often occur together, finding a low prolactin level and absent TSH response should raise the question of a *POU1F1* gene defect.

A fifth *POU1F1* mutation was identified in a Thai patient with deficiency of GH, TSH, and prolactin. Both parents were healthy and heterozygous for a G →T transversion in codon 250 (Glu250Ter). The CPHD patient was homozygous for the mutation. This mutation resulted in complete loss of the POU-homeodomain that is necessary for DNA binding.

Table 34-4
Selected Mutations in the *PROP1* Genes of Subjects With CPHD

Mode	*Codon*	*Nucleotide change*	*Effect of mutation*	*References*
AR	101	Deletion	Two base pair deletion causes frameshift, premature stop at codon 109	Wu et al. (1998)
	117	T → A	Amino acid change (Phe → Ile)	Wu et al. (1998)
	120	C → T	Amino acid change (Arg → Cys)	Wu et al. (1998)

AR, autosomal-recessive.

A sixth *POU1F1* mutation has been reported in a consanguineous family of Tunisian descent. All four affected sibs were homozygous for a T → G transversion in codon 135 (Phe135Cys) in the POU-specific domain of *POU1F1*. The patients had pituitary hypoplasia and deficiencies of GH, TSH, and prolactin.

Autosomal-Dominant POU1F1 Mutations The first dominant-negative mutation identified in the *POU1F1* gene was a G → T substitution in codon 271 (Arg271Trp). This mutation is located in the POU-homeodomain and does not affect binding of the mutant POU1F1 protein to DNA but functions as a dominant inhibitor of POU1F1 action by an unknown mechanism. Three unrelated patients have been reported to be heterozygous for this mutation. Two of the patients were evaluated as adults and had pituitary hypoplasia and deficiencies of GH, prolactin, and TSH. The third patient was identified at only 2 mo of age and had a normal pituitary and normal basal levels of TSH but a delayed TSH response in a TRH stimulation test. The authors suggest that, because POU1F1 might be necessary for anterior pituitary cell survival, the affected patient will develop hypoplasia and TSH deficiencies with age.

The second dominant-negative *POU1F1* gene mutation was a T → C transition in codon 24 (Pro24Leu). This proline residue resides within the major transactivating domain of *POU1F1* and is highly conserved in different species. The mechanism by which this mutation exerts its dominant-negative effect is also not known.

PROP1 Ames dwarf (df/df) mice have CPHD and hypocellular anterior pituitaries that lack somatotropes, lactotropes, thyrotropes, and GH transcripts. The genetic defect associated with the Ames dwarf phenotype has been found in the gene called Prophet of Pit-1 (*Prop-1*), which encodes a pituitary-specific homeodomain factor. Sequence analysis of the Prop-1 cDNA in the df/df mouse revealed a T → C transition in codon 83 that causes a Ser → Pro amino acid change in the first helix of its homeodomain. Although *Prop-1* is required for expression of *Pit-1*, the mechanism of its action remains uncertain.

Three human *PROP1* gene defects were found in studies of four families with familial autosomal-recessive CPHD (Table 34-4). In addition to the GH, prolactin, and TSH deficiency seen with *POU1F1* defects, *PROP1*-deficient subjects also have LH and FSH deficiency, which prevents the onset of spontaneous puberty. Family I had three affected sibs, all homozygous for a C → T transition in codon 120 of the *PROP1* gene (Arg120Cys). This Arg → Cys substitution in the third helix of the homeodomain greatly reduced the protein's DNA-binding and transactivating abilities. Families II and III had the same 2-bp AG deletion in codon 101 that causes a frameshift that results in a premature stop at codon 109. The truncated protein product had no DNA binding or transactivating abilities. The patient in family IV had two different *PROP1* gene mutations (compound heterozygosity). One allele had the 2-bp AG deletion described earlier and the second allele had a T → A transversion (Phe117Ile) that resulted in greatly reduced DNA-binding and transactivating abilities.

Although the typical phenotype of *PROP1* mutations is panhypopituitary dwarfism with short stature occurring early in childhood, one patient has been described who reached a normal adult height without intervention. This patient had the expected hypogonadotropic hypogonadism with delayed puberty, and investigators theorized that the lack of estrogen allowed this female to continue growing until age 20, thus eventually reaching an adult height. The patient was deficient in GH, FSH, LH, prolactin, TSH, and ACTH.

HESX1 *HESX1* (mouse homologue, *Hesx1*) is a member of the paired-like homeobox gene class, which is important in the development of the pituitary gland as well as other midline brain structures in both the mouse and human. Mice homozygous null for *Hesx1* are severely affected, with reduced or absent eyes, olfactory placodes, and telencephalic derivatives. Rathke's pouch is absent in these mice and the anterior pituitary is small. Because these features are similar to the findings in the human syndrome of SOD, researchers sought mutations within the homologous human gene, *HESX1*. A homozygous C → T substitution at nucleotide position 478 (Arg53Cys) was demonstrated in two siblings with SOD and panhypopituitarism. Subsequently, the same group found that heterozygous *HESX1* mutations led to less severe phenotypes in humans (ranging from mild SOD with pituitary insufficiency, to CPHD without SOD, to IGHD).

TREATMENT

Recombinant GH is available worldwide and is administered by subcutaneous injection. To obtain an optimal outcome, children with GHD should be started on replacement therapy as soon as their diagnosis is established. The initial dosage of recombinant GH is based on body weight, but the exact amount used and the frequency of administration vary among protocols. The dosage increases with increasing body weight to a maximum during puberty and is usually discontinued by approx 17 yr.

Conditions that are treated with GH include those in which it has proven efficacy (and for which it is approved) and others in which its use has been reported but is not accepted as standard practice. Disorders in which GH treatment has been approved include the following: GHD (in isolation or associated with CPHD) in children and adults; Turner's syndrome; growth failure associated with chronic renal insufficiency in children; small for gestational-age children who have not caught up their linear growth by the age of 2; and the Prader–Willi syndrome; and ISS. The clinical responses of individuals with IGHD or CPHD to GH therapy varies depending on the severity and age at which, treatment is begun, recognition and response to treatment of associated deficiencies such as thyroid hormone deficiency, and whether treatment is complicated by the development of anti-GH antibodies. The outcome of

Turner's syndrome subjects varies with the severity of their short stature, chromosomal complement, and age at which treatment was begun. In Prader–Willi syndrome, improvements in body composition are an important outcome of treatment.

Additional disorders in which the use of GH has been reported but for which its efficacy is not accepted as standard practice include treatment of selected skeletal dysplasias such as achondroplasia, growth suppression secondary to exogenous steroids (as in chronic autoimmune diseases), and the Silver–Russell syndrome. There is, in general, insufficient data to establish the efficacy of GH replacement therapy in treating these disorders because of the limited number of subjects and lack of use of standardized protocols.

FUTURE DIRECTIONS

Several problems contribute to incomplete ascertainment of affected individuals, which in turn can result in less than optimal outcomes. Such problems include the spectrum of severity, lack of a single provocative test that is both very sensitive and specific, and lack of an assay to test for qualitative changes in endogenous GH. Improvements in techniques that address these problems could facilitate the detection of and improve the outcome for treated patients in the future.

A number of genetic defects in GH biosynthesis have been documented that prevent some affected individuals from secreting GH. These include defects that result in the synthesis of truncated GH molecules, lack of GHRH receptor function, and mutant GH products that have dominant-negative effects on the normal GH products that are present. In the future, agonists of GH secretion, for example, that complement the function of GHRH, might be found that can enhance release of the stored GH found in some of these cases. The efficacy of IGF-I in treating Laron dwarfism and IGHD IA patients who are resistant to exogenous GH because of anti-GH antibodies has been proven. Additional uses of IGF-I or perhaps isoforms of IGF-I that have prolonged half-lives might provide improved efficacy in the future.

Although potential applications of gene therapy to somatic cells are feasible, targeted and regulated expression that is pituitary specific remains impractical. Thus, potential applications of gene therapy to achieve appropriate hormonal regulation seem remote.

35 Thyroid Disorders

PETER KOPP

SUMMARY

The thyroid is controlled by a classic hypothalamic-pituitary axis. The thyroid gland evolves from two distinct embryological structures. Thyroid disorders can broadly be divided into disorders of function or growth. The two alterations may occur independently or in combination. For example, in patients with Graves' disease, the thyroid is typically diffusely enlarged and secretes excessive amounts of thyroid hormone. This chapter gives an overview on the variety of defects affecting thyroid function and growth at all levels of the axis.

Key Words: Autoimmune thyroid disorders; Graves' disease; human chorionic gonadotropin; iodide; thyroid cancer; medullary thyroid cancer; multiple endocrine neoplasia type 2; pendred syndrome; thyroid disorders; thyrotropin-releasing hormone; thyroperoxidase.

INTRODUCTION

Insights into the molecular basis of numerous thyroid disorders have grown impressively. Careful clinical and biochemical phenotyping continues to be the essential first step in all attempts to unravel the underlying pathogenic mechanisms. Elucidation of the molecular basis has been enormously facilitated by the increasingly complete information on the human genome, growing knowledge about developmental processes, the complexity of signaling pathways, and mechanisms of hormone action. Aside from deepening the understanding of the mechanisms governing physiology and pathology of the hypothalamic-pituitary-thyroid axis, this increasingly dense knowledge has growing impact on diagnostic and therapeutic modalities.

THE HYPOTHALAMIC-PITUITARY-THYROID AXIS

The thyroid is controlled by a classic hypothalamic-pituitary axis (Fig. 35-1). The tripeptide thyrotropin-releasing hormone (TRH), synthesized in the paraventricular nucleus of the hypothalamus, stimulates the production and secretion of the glycoprotein thyrotropin (thyroid stimulating hormone [TSH]) in the pituitary. TSH in turn stimulates growth and function of thyroid follicular cells resulting in the production of the thyroid hormones thyroxine (T4) and triiododothyronine (T3) (Figs. 35-2 and 35-3). In the bloodstream, only a minute fraction of T4 and T3 is found as free hormone whereas the majority is protein-bound to thyroxine-binding globulin (TBG), transthyretin (TTR), and albumin.

After uptake into peripheral cells, a process that is at least partially mediated by amino acid channels, T4 is either 5′-deiodinated by deiodinase I or II, a process that produces the more active T3, or it is modified into the inactive reverse triiododothyronine (rT3) by deiodination of the inner ring (*see* Fig. 35-3). At the cellular level, thyroid hormones have multiple effects on differentiation, growth, and metabolism. Thyroid hormone action is primarily mediated by nuclear receptors regulating gene transcription (Fig. 35-4). Albeit less well characterized, several nongenomic actions are a focus of growing interest. Negative regulation of the hypothalamic-pituitary-thyroid axis is exerted by T3, somatostatin and dopamine. At least in rodents, the transition from the fed to starved state is associated with a reduction in thyroid hormone levels, an adaptive response caused by a reduction in TRH and regulated by a decrease in leptin, a finding that emphasizes the intricate relationship between the thyroid axis and fuel homeostasis.

NORMAL DEVELOPMENT OF THE THYROID GLAND

The thyroid gland evolves from two distinct embryological structures. In humans, the thyroid *anlage* is first visible at embryonic day 20 (E20). It derives from the endodermal floor of the primitive pharynx and gives rise to thyroid follicular cells. These cells evolve into a diverticulum that expands caudally to form the thyroglossal duct. After rapid proliferation, they then expand laterally and by E30 the gland becomes bilobated. As the gland continues to descend and grow, the thyroglossal duct thins and elongates, eventually fragmenting and degenerating by E40. The ultimobranchial bodies, located in the fourth pharyngeal pouch, are of neural crest origin and, after undergoing a similar descent, differentiate into the parafollicular calcitonin-producing C cells. After migration and fusion of the two cell populations, thyroid follicular cells undergo further differentiation. This is marked by the expression of genes that are essential for thyroid hormone synthesis such as the TSH receptor, the sodium–iodide symporter (NIS), thyroperoxidase (TPO), and thyroglobulin (TG) (*see* Fig. 35-2). Thyroid hormone is detectable in the fetus at about gestational week 11.

OVERVIEW OF THYROID DISORDERS

Thyroid disorders can broadly be divided into disorders of function or growth. The two alterations may occur independently or in combination. For example, in patients with Graves' disease,

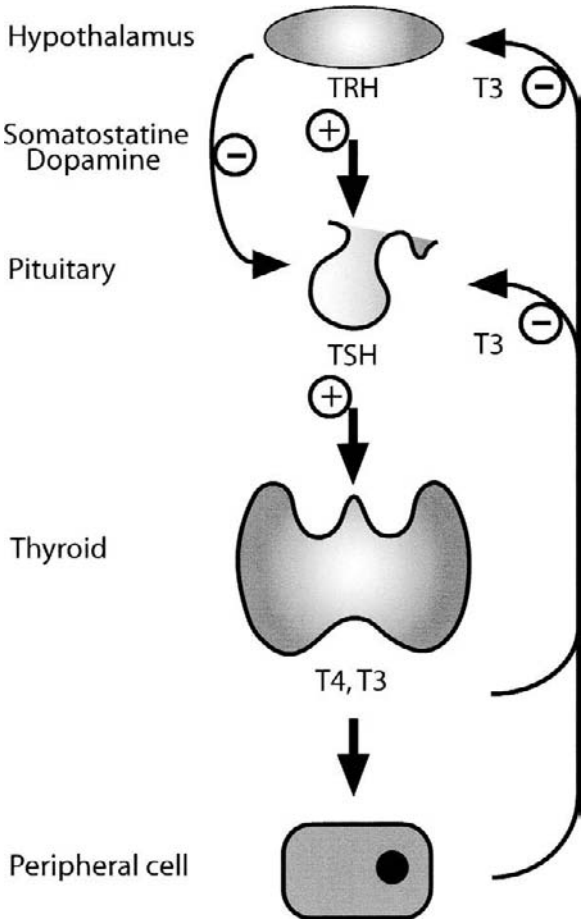

Figure 35-1 The hypothalamo-pituitary-thyroid axis. The hypothalamic thyrotropin-releasing hormone (TRH) enhances production and secretion of the pituitary hormone thyrotropin (TSH), which then stimulates thyroid hormone synthesis in follicular cells. Thyroid hormones act on multiple target genes in peripheral cells through nuclear receptors that regulate gene transcription. Triiododothyronine (T3) regulates TSH and TRH through a negative feedback mechanism. T4, thyroxine.

the thyroid is typically diffusely enlarged and secretes excessive amounts of thyroid hormone.

Disorders affecting thyroid function result either in hypothyroidism or in hyperthyroidism. Cardinal clinical characteristics are summarized in Table 35-1. Hypothyroidism is the most common disorder of thyroid function and most frequently caused by chronic autoimmune inflammation, Hashimoto's thyroiditis. The most frequent form of hyperthyroidism is Graves' disease, also an autoimmune disorder, followed by toxic multinodular goiters and toxic adenomas.

Congenital hypothyroidism affects approximately 1/3000–4000 infants. Screening programs introduced decades ago led to its early recognition and treatment, thus avoiding the disastrous consequences of thyroid hormone deficiency on brain development. In approximately 85% of all affected infants, congenital hypothyroidism is sporadic and associated with developmental defects referred to as thyroid dysgenesis. They include thyroid (hemi)agenesis, ectopic tissue and thyroid hypoplasia. Defects in one of the multiple steps required for normal hormone synthesis, dyshormonogenesis, account for approximately 10–15% of congenital hypothyroidism. Dyshormonogenesis is typically recessive and thus more common in families with consanguinity. Advances in molecular genetics led to the characterization of numerous genes that are essential for normal development and hormone production of the hypothalamic-pituitary-thyroid axis. A wide spectrum of defects in these genes provide a molecular explanation for a subset of the sporadic and familial defects in pituitary and thyroid development, or TSH and thyroid hormone synthesis (Tables 35-2 to 35-4).

The transport of T4 is altered by a variety of defects in binding proteins (Table 35-5). Cellular uptake of thyroid hormones appears to be mediated by amino acid channels, and mutations in monocarboxylate transporter 8 (MCT8) lead to alterations in brain function and thyroid function tests (Table 35-6). Mutations in the nuclear thyroid hormone receptors (TR) may cause profound alterations in thyroid hormone action in the syndrome of resistance to thyroid hormones (RTH) (Table 35-7).

Abnormal growth of the thyroid may be associated with developmental malformations or hypoplasia, involutional changes associated with chronic inflammation, or goitrous enlargement. Goiters can be diffuse or nodular. The enlargement might be induced by chronic exogenous stimulation by TSH, for example because of iodine deficiency.

Worldwide, the most common cause of thyroid disorders is iodine deficiency. Insufficient iodine supply causes endemic goiter, the compensatory growth of the thyroid gland. If more severe, iodine deficiency can result in hypothyroidism and severe developmental retardation, endemic cretinism. Although eradicated in many parts of the world, iodine deficiency is still a major health problem affecting a substantial part of the world population.

Other causes for goitrous enlargement include stimulatory antibodies, or benign and malignant neoplasias. Benign thyroid nodules are common and found in >20% of individuals evaluated by ultrasonography. In contrast, thyroid cancers only account for approx 1% of malignancies. Although the molecular defects underlying the pathogenesis of thyroid nodules and adenomas as well as papillary, follicular, and anaplastic thyroid cancers are far from being completely understood, new insights have been obtained with the tools of molecular biology (Table 35-8). A majority of thyroid nodules are of monoclonal origin making somatic mutations in growth-controlling gene a likely cause for their development. Two large groups of genes have been implicated in uncontrolled cell proliferation and clonal expansion of mutated cells. Protooncogenes are activated through gain-of-function mutations in the regulatory or coding sequence thus creating the oncogene. This results in overexpression of the normal product or an abnormal form of the protein. Tumor suppressor genes control cell proliferation under normal conditions. Unrestrained growth of cells and thus formation of tumors can occur through loss-of-function of these genes. Among other important insights, the detection of certain molecular defects has modified diagnostic and therapeutic procedures. For example, mutations in the *RET* gene, which encodes the RET tyrosine kinase, are the molecular alterations found in medullary thyroid cancer (MTC) and the multiple endocrine neoplasia type 2 (MEN2) syndromes (Chapter 40). It is now possible to precisely detect carriers of the disease in early childhood and thus treat these patients accordingly.

This chapter gives an overview on the variety of defects affecting thyroid function and growth at all levels of the axis.

THYROTROPIN-RELEASING HORMONE DEFICIENCY

TRH is a hypothalamic tripeptide (Glu-His-Pro) generated from a large prohormone of 27 kDa. Besides its role as a stimulator

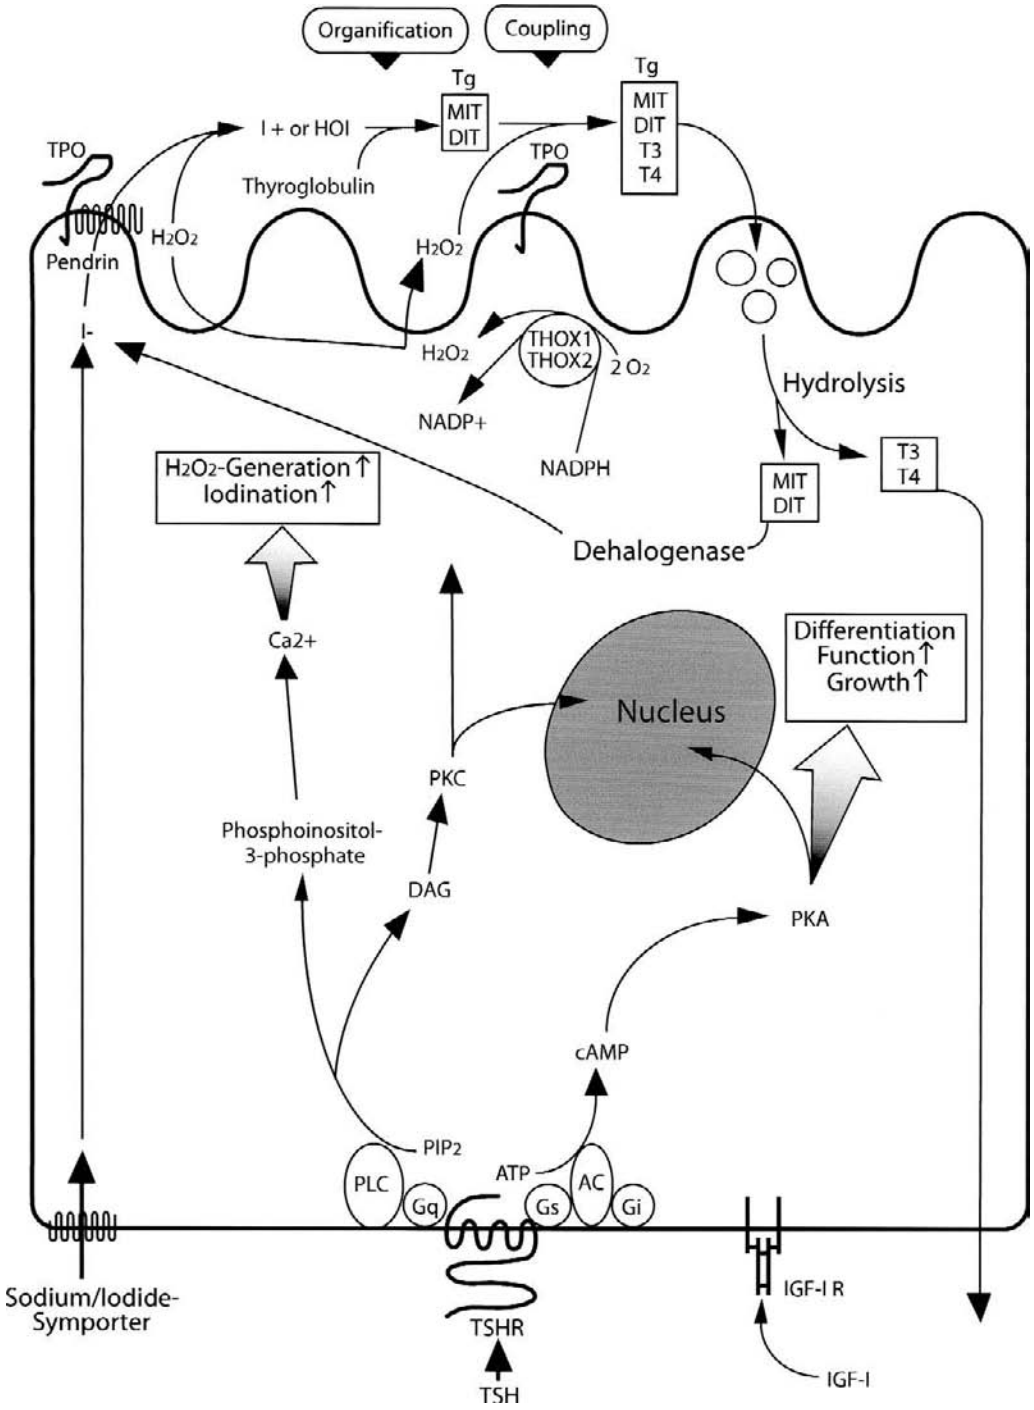

Figure 35-2 Thyroid hormone synthesis in a follicular cell. For details *see* text. AC, adenylyl cyclase; IGF-I, IGF-I R, insulin-like growth factor I (receptor); MIT, DIT, mono- and diiodotyrosine; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; TG, thyroglobulin; TPO, thyroperoxidase.

of the pituitary gland in which it releases TSH and prolactin, TRH is a neurotransmitter in numerous areas of the brain and is also found in some peripheral organs.

A few patients with congenital hypothyroidism and isolated TRH deficiency without destructive hypothalamic lesions have been reported. The diagnosis of central hypothalamic hypothyroidism is made based on the constellation of low TSH and an increase thereof after administration of exogenous TRH. The molecular defect underlying these cases remains elusive and could affect synthesis or secretion of TRH. Targeted disruption of the TRH gene in mice led to an overtly hypothyroid phenotype. Remarkably, the TSH levels were elevated in these mice but displayed diminished biological activity. Similar biochemical constellations with elevated TSH with reduced bioactivity have been found in some individuals with central hypothyroidism.

RESISTANCE TO TRH

Resistance to TRH in pituitary thyrotrophs was discovered in a boy with isolated central hypothyroidism. His T4 was decreased, the TSH was normal, and there was no increase of TSH and prolactin

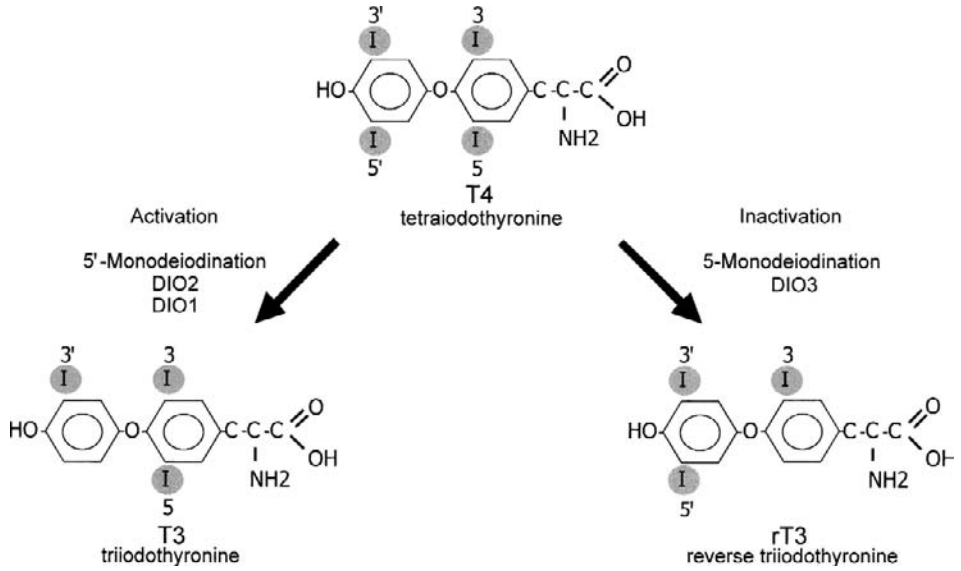

Figure 35-3 Structure of thyroxine (T4), triiododothyronine (T3) and reverse triiododothyronine (rT3). T4 is activated to T3 by deiodinase 1 and 2. T4 is inactivated into rT3 by deiodinase 3.

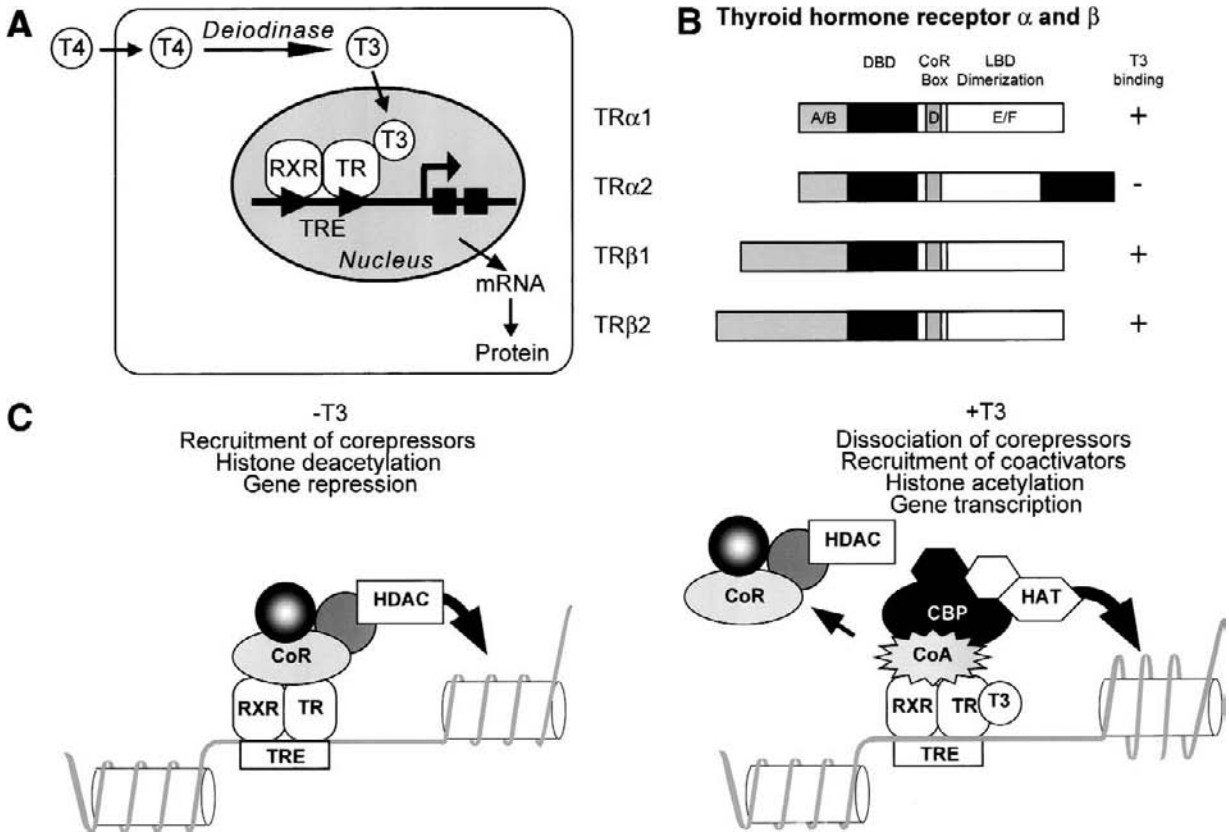

Figure 35-4 **(A)** Nuclear thyroid hormone action. Thyroxine (T4) enters the cell in which it is converted into triiododothyronine (T3) by 5′-monodeiodinases. In the nucleus, T3 interacts with thyroid hormone receptors. Thyroid hormone receptors bind to specific sequences, thyroid response elements (TRE) in the promoter regions of target genes in conjunction with other nuclear receptors such as the retinoid X receptor (RXR). **(B)** Schematic structure of the most abundant thyroid hormone receptor isoforms and their functional domains. The DNA binding domain consists of two zinc fingers. TRβ2 is most abundant in the pituitary gland in which it mediates negative regulation of thyrotropin (TSH). TRα2 does not bind T3; its exact physiological role is unknown. DBD, DNA binding domain; CoR box, interaction with corepressors; LBD, ligand binding domain; AF2, activation domain 2. **(C)** Model of thyroid hormone action on a positively regulated gene. In the absence of thyroid hormone, corepressors interact with thyroid hormone receptor homo- or heterodimers and silence transcription. Deacetylation of histones is associated with silenced transcription. Thyroid hormone relieves the interaction with corepressors and after binding of coactivators and factors of the basal transcription apparatus, gene expression is started, a process that involves chromatin remodeling through histone acetylation. RXR, retinoid X receptor; TR, thyroid hormone receptor; HDAC, histone deacetylase; CoR,Corepressor; CoA, Coactivator; CBP, CREB binding protein; HAT, histone acetyltransferase.

in response to TRH. Mutational analysis of the TRH receptor gene revealed compound heterozygous point mutations that inactivate the TRH receptor.

AUTONOMOUS PRODUCTION OF TSH

TSH is a heterodimeric glycoprotein hormone. It shares a common α-chain with the pituitary follicle-stimulating hormone (FSH) and luteinizing hormone (LH) as well as the placental hormone choriogonadotropin (CG). Each of these hormones has a unique β-chain. Two novel human glycoprotein hormone-like genes α2 (A2) and β5 (B5) have been cloned. The heterodimer formed by these subunits, referred to as thyrostimulin, activates the human TSH receptor, but not the LH and FSH receptors. Thyrostimulin is expressed in the pituitary and, given that TSH receptors are also found in a subset of anterior pituitary cells, it has been proposed that it may act as a paracrine hormone. Its physiological role and relevance remain, however, unresolved.

Hypersecretion of TSH by thyrotrope pituitary adenomas is a rare cause of hyperthyroidism. Biochemically, these patients are characterized by an inappropriate secretion of TSH and hyperthyroxinemia. Typically the secretion of free α subunit is excessive. Rarely, there is cosecretion of growth hormone. MRI and or CT-scan confirm the diagnosis. The molecular defect in the thyrotropes resulting in autonomous growth and function remains unclear. Clonal analysis using the X-inactivation technique in a very small number of tumors showed that they are of monoclonal origin suggesting that a somatic mutation or the loss of a tumor suppressor is at the onset of their development. Screening of several candidate genes (Gsα, Gqα, G11α, TRH receptor) in a small number of such tumors did not show alterations in these candidate genes. In a single TSHoma, a somatic mutation in the TRβ gene was identified (H435Y). This mutant TRβ has impaired T3 binding, and the T3-mediated negative regulation of the glycoprotein hormone α subunit and TSHβ genes is impaired suggesting that it may be responsible for the defect in negative regulation of TSH by thyroid hormone in the tumor.

Table 35-2
Hypothalamic and Pituitary Defects

Gene/protein	*Phenotype*	*Molecular defect*	*Inheritance*	*Chromosome*
TRH	Hypothalamic hypothyroidism	Unknown	AR	3q13.3-q21
TRH receptor	Pituitary hypothyroidism No increase of TSH and prolactin in response to TRH	Inactivating mutations	AR	8q23
TSH	TSH-deficient hypothyroidism Prolactin increase to TRH	Mutations in TSHβ-chain	AR	β-chain 1p22
	TSH-secreting adenomas with hyperthyroidism	Unknown TRβ mutation (1 case)	Sporadic

	Hypothyroidism			
GNAS1/Gsα	Toxic adenoma	Somatic activating point mutations	Sporadic	20q.13.2
	McCune-Albright syndrome	Mosaicism for gain of function mutations	Sporadic	
	Pseudohypoparathyroidism Ia: Hypothyroidism, hypogonadism, AHO	Inactivating point mutations on maternal allele	AD	
NIS (SLC5A5) Sodium-iodide symporter	Hypothyroidism with defective iodide uptake	Inactivating point mutations	AR	19p13.2-p12
Thyroperoxidase	Congenital hypothyroidism, goiter Iodide organification defect	Inactivating point mutations	AR	2p25
PDS (SLC26A4)	Pendred's syndrome: Sensoneurinal deafness, goiter, partial organification defect	Inactivating mutations, small deletions	AR	7q31
Thyroglobulin	Goiter with compensated or overt hypothyroidism	Point mutations and splice site mutations	AR	8q24.2-q24.3
	Classic endoplasmic reticulum storage disease with retention of mutated protein			
THOX2	Transient or permanent hypothyroidism Iodide organification defect because of deficient H_2O_2 generation	Monoallelic or biallelic mutations	Sporadic	15q15.3
Dehalogenase	Congenital hypothyroidism, goiter, loss of iodide through secretion of DIT, MIT	Point mutations	AR	6q25.1

AD, autosomal-dominant; AR, autosomal-recessive; DIT, diiodotyrosine, MIT, monoiodotyrosine; NIS, sodium-iodide symporter; TSH, thyrotropin.

Therapy consists in most cases in transsphenoidal removal of the pituitary adenoma. The somatostatin analog octreotide is useful in some patients unable to undergo surgery or with invasive tumors. Preoperatively, hyperthyroid patients should be controlled with thyreostatic drugs.

COMBINED PITUITARY HORMONE DEFICIENCY AND ISOLATED TSH DEFICIENCY

TSH deficiency may occur in the setting of panhypopituitarism, most commonly owing to a pituitary adenoma. Genetic defects in the development and function of the pituitary gland can result in various forms of combined pituitary hormone deficiency (CPHD) (Table 35-2). Patients with CPHD present with impaired production and secretion of one or several anterior pituitary hormones that may include TSH. Some patients also display midline malformations. Mutations in the TSHβ gene can result in isolated TSH deficiency. Therapy aims at substituting T4, and, if deficient, other hormones.

POU1F1 POU1F1 (traditionally referred to as PIT1) is a pituitary-specific transcription factor regulating the development of somatotropes, lactotropes, and thyrotropes as well as gene expression of growth hormone, prolactin and the β-subunit of TSH. It is a member of the POU family of transcription factors, an eponym that was created after the identification of the first three members of this group, Pit-1, Oct-1, and Unc-86. POU1F1 contains two main functional domains, an activation domain and a DNA binding domain formed of a POU-specific and a homeodomain. The homeodomain is highly similar to the homeobox containing genes in Drosophila that control development of specific body segments, whereas the POU-domain is necessary for high affinity DNA binding. DNA sequences, which bind the transcription factor, are found in the promoters of the GH, prolactin, TSH-β, and POU1F1 genes. Several splice variants with variable activation domains have been reported and may define promoter specificity.

Mutations in the murine homolog Pit1 have been identified in the Snell and Jackson dwarf mice, which have deficiencies in GH, prolactin, and TSH. Patients with identical hormone deficiencies have mutations in the human homolog POU1F1. POU1F1 mutations can be inherited in an autosomal-dominant or -recessive manner. Recessive mutations alter the transactivation or DNA binding properties of the transcription factor. The dominant mutations bind to DNA, but impair transcription by the wild-type allele by altering dimerization and or interaction with other nuclear transcription factors.

A case of fetomaternal POU1F1 deficiency resulting from a heterozygous, dominant negative point mutation led to absolute fetal hypothyroidism in the fetus with dramatic delay in respiratory, cardiovascular, neurologic, and bone maturation. The absence of Pit-1 and the ensuing hypoprolactinemia in the mother resulted in puerperal alactogenesis. This case impressively illustrates the importance

Table 35-4
Developmental Defects

Gene/protein	*Phenotype*	*Molecular defect*	*Inheritance*	*Chromosome*
PAX8	Thyroid hypoplasia or ectopy Hypothyroidism	Point mutations (Haploinsufficiency?)	Sporadic AD	2q12-q14
TTF-1 (NKX2.1)	Mild hypothyroidism Respiratory distress Choreoathetosis Mental retardation	Chromosomal deletions and point mutations: Haploinsufficiency	Sporadic	14q13
TTF-2 (FOXE1)	Bamforth-Lazarus syndrome: Thyroid agenesis Cleft palate Choanal atresia Bifid epiglottis Spiky hair	Inactivating point mutations	AR	9q22

AD, autosomal-dominant; AR, autosomal-recessive; TTF, thyroid transcription factor.

Table 35-5
Binding Proteins Defects

Gene/protein	*Phenotype*	*Molecular defect*	*Inheritance*	*Chromosome*
TBG Thyroxine-binding globulin	Decreased total T4 levels, euthyroidism	Deletions, point mutations	X-linked recessive	Xq22.2
	Increased total T4 levels, euthyroidism	Gene amplification	Sporadic *de novo* germline mutations	
TTR Transthyretin	Hyperthyroxinemia Familial amyloidotic polyneuropathy	Point mutations	AD	18q11.2-q12.1
Albumin	Familial dysalbuminemic hyperthyroxinemia	Point mutations	AD	4q11-13
	Familial dysalbuminemic hypertriiodothyroninemia	Point mutations	AD	

AD, autosomal-dominant; T4, thyroxine.

Table 35-6
Other Genetic Defects Associated With Thyroid Dysfunction

Gene/protein	*Phenotype*	*Molecular defect*	*Inheritance*	*Chromosome*
MCT8 (SCL16A2)	Hemizygous males: Elevated T3 and TSH Severe mental retardation Spastic quadriplegia Rotary nystagmus Impaired gaze and hearing Heterozygous females: only thyroid function abnormalities	Deletions, point mutations	AR, sporadic	Xq13.2
Deiodinase 3	Consumptive hypothyroidism because of increased degradation of T4 and T3 in hemangiomas and other vascular tumors	Overexpression	Sporadic	14q32
KCNE3	Thyrotoxic periodic hypokalemic paralysis	Monoallelic point mutations	Sporadic?	11q13-q14

AR, autosomal-recessive; T3, triiododothyronine; T4, thyroxine; TSH, thyrotropin.

of POU1F1 in the control of different endocrine axes and the importance of prenatal thyroid hormone for fetal maturation.

PROP1 Characterization of the Ames dwarf mouse led to the cloning of the paired-like homeodomain factor Prop-1 (Prophet of pit1). PROP-1 is necessary for the expression of POU1F1 and is involved in ontogenesis, differentiation, and function of somatotropes, lactotropes, thyrotropes, and possibly gonadotropes. Inactivating mutations in the human *PROP-1* gene have been identified as a cause of an autosomal-recessive CPHD phenotype affecting these cell lineages. Of note, there is variability in the phenotypic expression among CPHD patients with PROP-1 mutations.

Table 35-7
Resistance to Thyroid Hormone

Gene/protein	*Phenotype*	*Molecular defect*	*Inheritance*	*Chromosome*
TRβ	Resistance to thyroid hormone. Goiter, variable degrees of hypo- and or hyperthyroidism	Heterozygous point mutations: Dominant negative activity of mutated allele	AD, sporadic	3p24.3
		One kindred with total deletion of coding region of TRβ locus	AR	
Unknown	Resistance to thyroid hormone without mutations in TRβ	Unknown	AD	unknown

AD, autosomal-dominant; AR, autosomal-recessive.

Table 35-8
Molecular Alterations in Benign and Malignant Thyroid Tumors

Gene	*Chromosomal location*	*Lesion*	*Tumor*
TSHR	14q31	Point mutations	Toxic adenoma Differentiated carcinoma

p53	17p13	Point mutations Deletion, Insertion	Differentiated carcinoma Anaplastic adenoma
Rb	13q14.1-14	mRNA variants	Differentiated carcinoma Anaplastic adenoma
p16 (MITS)	9p21	Deletion of coding region	Differentiated carcinomas cell lines
p21/WAF	6p21.2	Reduced expression	Differentiated and anaplastic carcinomas
MET	7q31	Overexpression	FTC
C-MYC	8q24.12-q24	Overexpression	Differentiated carcinoma
LOH	3p, 11q13 and multiple other loci	LOH	FTC
APC	5q21-q22	Autosomal-dominant inheritance with somatic second hit	PTC in Gardner syndrome
PTEN	10q23.31	Autosomal-dominant inheritance with somatic second hit	PTC in Cowden syndrome
PRKAR1A	17q23-q24	Autosomal-dominant inheritance with somatic second hit	FTC in Carney complex type 1

FTC, follicular thyroid carcinomas; LOH, loss of heterozygosity; PPAR, peroxisome proliferators-activated receptor; PTC, papillary thyroid carcinomas; Rb, retinoblastoma susceptibility gene.

LHX3 Recessive mutations in LHX3, a LIM homeodomain transcription factor, also cause CPHD of all anterior pituitary hormones with the exception of adrenocorticotrophic hormone. In addition, these patients have a rigid cervical spine and a limited ability to rotate the head. In Lhx3–/– mice, the primordium of the anterior pituitary is present, but with the exception of the corticotroph cells, there is no further growth and differentiation of the rostral part of the gland.

LHX4 Heterozygous mutations in the human LIM homeobox transcription factor LHX4 lead to an autosomal-dominant pheno-

type characterized by short stature, pituitary and cerebellar hindbrain defects, and abnormalities of the sella turcica.

HESX1 HESX1, also referred to as RPX, is a member of the paired-like class of homeobox transcription factors. Familial septo-optic dysplasia (SOD), a syndromic form of CPHD associated with optic nerve hypoplasia and agenesis of midline structures in the brain, can be caused by homozygous mutations in HESX1. A similar phenotype was observed in Hesx1–/– mice. Interestingly, a small proportion of the mice heterozygous for a Hesx1 null allele also had a milder form of SOD. This discovery prompted further screening of patients presenting with a wide spectrum of congenital pituitary dysfunctions. A subset of these patients was heterozygous for HESX1 mutations. Phenotypically, heterozygous HESX1 mutations result in various constellations of pituitary hormone deficiencies and the phenotype is variable among family members with the same mutation.

TSHβ MUTATIONS Congenital hypothyroidism caused by isolated hereditary TSH deficiency is a rare autosomal-recessive disease caused by mutations in the TSH β-chain. In these patients, TSH is unmeasurable or very low, and the administration of TRH does not result in a rise in serum TSH. The levels and the function of the other pituitary hormones are normal, including an adequate rise of prolactin in response to TRH. The first familial incidence was described in a Japanese family in two sisters with cretinism. Two other families from the same island were reported to harbor the same defect and it is thus likely that they originate from a common founder.

Several independently recurrent mutations have now been reported in 18 families that are, in part, of distinct ethnic origin. They include point mutations, frame shift mutations and a splice site mutation. The C105V/114X frameshift mutation destroys a disulfide bond essential for normal protein conformation and bioactivity, other mutations lead to disruption of heterodimer formation with the β-chain (e.g., G29R), and the reported splice site mutation results in skipping of exon 2.

AUTONOMOUS FUNCTION OF THE TSH RECEPTOR

TSH exerts its effects on thyroid follicular cells through the TSH receptor, a member of the G protein coupled seven transmembrane receptors. Together with the receptors for FSH and LH it forms a distinct subfamily defined by a large amino-terminal extracellular domain involved in binding of the hormone. The 744 amino acid receptor is encoded by a gene containing 10 exons and localized on chromosome 14q31. The TSH receptor is coupled to Gs and thus to the adenylyl cyclase cascade, which is the predominant signaling pathway for growth and function of the thyrocyte (*see* Fig. 35-2). It is, however, also coupled to Gq and activates the inositol phosphate pathway.

Mutations in several G protein coupled seven transmembrane receptors confer constitutive activation to these receptors, a mechanism characterizing an important pathophysiological entity. For example, they have been found in rhodopsin as a cause of retinitis pigmentosa, in the LH/CG receptor in male limited precocious puberty, and in the TSH receptor they cause hyperthyroidism. Point mutations in the Ca^{2+}-sensing receptor lead to autosomal-dominant hypocalcemia with hypercalcuric hypocalcemia, and in the parathyroid hormone receptor to metaphyseal chondrodysplasia.

ACTIVATING SOMATIC TSH RECEPTOR MUTATIONS IN TOXIC ADENOMAS AND THYROID CARCINOMAS Somatic mutations in the TSH receptor are the main molecular cause of toxic adenomas. Functionally, these mutations increase basal cAMP levels; some of the mutants also activate the phospholipase C cascade. In contrast to activating mutations in other seven transmembrane receptors, there is a striking diversity in the affected residues that are scattered over almost the entire transmembrane domain of the TSH receptor.

Activating mutations in the TSH receptor have also been found in a small number of thyroid carcinomas with the unusual finding of increased hormone secretion. Remarkably, the mutations found in these tumors activate the cAMP cascade as well as the inositol triphosphate pathway. This supports the concept that concomitant activation of these two signaling cascades may promote transformation.

ACTIVATING GERMLINE TSH RECEPTOR MUTATIONS IN FAMILIAL NONAUTOIMMUNE HYPERTHYROIDISM Activating mutations occurring in the germline give rise to familial nonautoimmune hyperthyroidism. Gain of function mutations are by definition dominant and one mutated allele is thus sufficient to result in disease. The subsequent activation of the adenylyl cyclase pathway increases function and growth of thyroid follicular cells resulting in hyperplasia and hyperthyroidism. The typical signs associated with autoimmune hyperthyroidism, i.e., exophthalmos, myxedema, stimulating autoantibodies, and lymphocytic infiltration of the thyroid gland are absent. Several families with nonautoimmune familial hyperthyroidism and documented TSH receptor mutation have been reported. The onset of hyperthyroidism may vary in carriers of the same mutation in a given kindred, suggesting that other factors such as genetic background and or iodine intake are modulating the phenotypic expression of the activated receptor.

ACTIVATING GERMLINE TSH RECEPTOR MUTATIONS IN NEONATAL NONAUTOIMMUNE HYPERTHYROIDISM Congenital hyperthyroidism is usually caused by transplacental transfer of maternal antibodies in offspring of a mother with autoimmune thyroid disease. In this instance, the disease is transient and resolves within several weeks to months on clearance of the antibodies. However, a few cases show a persistent course with severe hyperthyroidism. *De novo* germline mutations in the TSH receptor have been found as cause of this unusual form of hyperthyroidism. The recognition of this entity of hyperthyroidism has clinical implications. In certain patients a more aggressive therapeutic approach (surgery, ablative radiotherapy) is indicated and, in families with nonautoimmune hyperthyroidism, molecular diagnostics allow an early diagnosis and treatment.

TSH RECEPTOR MUTATIONS CONFERRING HYPERSENSITIVITY TO HUMAN CHORIONIC GONADOTROPIN A remarkable form of familial gestational hyperthyroidism is caused by a mutant TSH receptor displaying hypersensitivity to normal levels of human chorionic gonadotropin (hCG). The proband and her mother had a history of two miscarriages that were accompanied by hyperemesis. Subsequently, she had two pregnancies that were complicated by hyperthyroidism, severe nausea and vomiting. Analysis of the TSH receptor gene in the proband and her mother revealed a heterozygous point mutation resulting in the substitution of K183R in the extracellular domain of the TSH receptor. Functional studies in cells transfected with the mutated receptor documented hypersensitivity to hCG. Although the wild-type TSH receptor reacts only minimally to high doses of hCG, the K183R mutant is hypersensitive to hCG, although it is still 1000 times less

responsive to hCG than the LH/CG receptor. The K183R mutant does not differ from the wild-type in terms of membrane expression, or basal and TSH stimulated cAMP accumulation. Aside from explaining the recurrent hyperthyroidism in these two patients, the K183R TSH receptor mutation is unique because the sensitivity is only increased for hCG but remains unaltered for the cognate ligand TSH. Reduction of ligand specificity by naturally occurring mutations is not limited to the TSH receptor. Heterozygous mutations in the FSH receptor permitting stimulation by hCG have been identified in women with pregnancy-associated ovarian hyperstimulation syndrome.

INSENSITIVITY TO TSH AND INACTIVATING MUTATIONS OF THE TSH RECEPTOR

TSH insensitivity results in a decrease in function and thus reduced synthesis and secretion of thyroid hormones and hypoplasia of the gland. Resistance to TSH may be caused by various molecular mechanisms, among them inactivating mutations in the TSH receptor that are partially or completely inactivating. The mode of inheritance is recessive and affected individuals are homozygous or compound heterozygous for inactivating mutations. Among these patients the phenotype encompasses a wide spectrum ranging from isolated TSH elevation to severe hypothyroidism, and there is a clear correlation between genotype and phenotype.

The first human case with TSH resistance resulting from a defect in the TSH receptor was documented in three sisters, offspring of unrelated parents, who were found to have normal peripheral thyroid hormone but high TSH levels, a constellation referred to as *euthyroid hyperthyrotropinemia*. Both parents only showed discrete TSH elevations. None of the family members had clinical signs of hypothyroidism. The three affected siblings were found to be compound heterozygous for mutations in the extracellular TSH-binding domain of the receptor (P162A and I167N). In vitro studies documented that the I167N mutation had almost no biological activity, whereas P162A displayed reduced activity. Euthyroid hyperthyrotropinemia resulting from mutations in the TSH receptor gene has subsequently been reported in several other families. More pronounced or complete inactivation of both TSH receptor alleles leads to mild or severe congenital hypothyroidism. Because of absent uptake of the radioisotope, scintigraphic studies often do not reveal any thyroid tissue. However, ultrasound of the neck reveals a normally located hypoplastic gland. Intriguingly, many of these patients have normal or elevated TG levels.

A loss of function mutation in the TSH receptor gene as a cause of TSH resistance was also discovered in the thoroughly studied hypothyroid *hyt*/*hyt* mouse. The phenotype of this inbred mouse strain is defined by congenital hypothyroidism, retarded growth, mild anemia, hearing loss, and infertility. The hypoplastic thyroids of these mutant mice are located in the proper position. Histologically, the thyroid follicular cells are developed, but incompletely differentiated, and the epithelial cells are not organized into structures recognizable as follicles.

The *hyt/hyt* mouse and patients with TSH-resistant congenital hypothyroidism with correctly located hypoplastic glands confirm that development and migration of the thyroid is independent of TSH stimulation. This is consistent with the observation that the genes for TPO, TG, and the TSH receptor are only expressed once the gland has reached its pretracheal location. Although early events of thyroid development are not dependent on TSH and its signaling pathway, this cascade is essential for complete differentiation, growth and function of thyroid follicular cells. These findings have been corroborated in the TSH receptor knock-out mouse, or mice overexpressing a dominant negative cAMP response element binding protein (CREB) in the thyroid. These studies exemplify how careful phenotyping of several naturally occurring mutants and genetically modified mice provide fundamental insights into the molecular mechanisms controlling organogenesis, differentiation and function in vivo.

In other patients with sporadic or familial resistance to TSH, the TSH receptor gene was normal indicating locus heterogeneity owing to defects in other genes. Obvious candidate genes include genes encoding elements of the TSH-dependent signaling cascades or regulators of thyroid development and gene expression.

ACTIVATING AND INACTIVATING MUTATIONS IN GSA

Analogous to the mutations in the TSH receptor, gain of function mutations in the *GNAS1* gene encoding the α subunit of the stimulatory G protein (gsp mutations) lead to a constitutive activation of the cAMP pathway and subsequently to an increase of function and growth of cell types like the pituitary somatotropes or thyroid follicular cells.

In the thyroid, somatic gsp mutations have been found with variable frequencies in nontoxic and toxic adenomas, as well as in differentiated thyroid carcinomas. The most commonly affected amino acids are arginine 201 and glutamine 227. The ensuing substitutions (R201C or R201H; Q227R or Q227K) impair the hydrolysis of GTP to GDP, resulting in an ongoing activation of adenylyl cyclase. The same molecular defect is found as somatic mutation in 35–40% of somatotrope tumors in acromegalic patients.

Sporadic mutations in Gsα that occur early in development lead to the McCune-Albright syndrome. These patients are mosaic for the mutation and the clinical phenotype varies depending on its tissue distribution. The clinical manifestations include ovarian cysts that secrete sex steroids and cause precocious puberty, polyostotic fibrous dysplasia, café au lait skin pigmentation, GH-secreting pituitary adenomas, and hypersecreting autonomous thyroid nodules.

In pseudohypoparathyroidism type Ia, the affected subjects show resistance not only to parathyroid hormone, but also to TSH and gonadotropins, in combination with the features of Albright's hereditary osteodystrophy. The molecular cause is a reduction of expression of the stimulatory Gsα subunit by a variety of loss of function mutations. The disorder affects many cell types with the cardinal signs being stunted growth, obesity, skeletal abnormalities, and hypogonadism. At the level of the thyroid, it is typically associated with mild hypothyroidism. The GNAS1 gene is imprinted in a tissue-specific manner. Most tissues express both alleles, but the paternal allele is imprinted and thus inactivated in tissues displaying hormone resistance. In pseudohypoparathyroidism type Ia, the mutation disrupts the active maternal allele that subsequently results in a decrease in signaling and partial hormone resistance to the trophic hormone in tissues such as the proximal renal tubule, the thyroid and the gonads.

DEFECTIVE THYROID HORMONE SYNTHESIS

The major steps involved in thyroid hormone synthesis are summarized in Fig. 35-2. After active transport of iodide into the thyroid follicular cell by the NIS, iodide is brought to the apical pole of the cells oriented toward the follicular lumen. At the apical membrane, pendrin, probably in conjunction with one or several other unidentified channels, is involved in transport of iodide into the follicular lumen. TG is secreted by exocytosis into the follicu-

lar lumen. TPO, localized in the apical membrane, oxidizes iodide, and subsequently iodinates tyrosyl residues of the intrafollicular TG (organification or iodination) in the presence of hydrogen peroxide. Two elements of the NADPH-dependent H_2O_2-generating, system, THOX1, and THOX2, have been been identified. The iodotyrosines, mono- and diiodotyrosyl (MIT, DIT), are coupled to T4 or T3, a reaction that is also catalyzed by TPO (coupling). TG carrying T4, T3, and iodotyrosines is internalized into the follicular cell by fluid phase or receptor-mediated endocytosis and digested in lysosomes. Although the thyronines T4 and T3 are released into the bloodstream, MIT, and DIT are deiodinated by dehalogenase in the cell and the released iodide is recycled. A dehalogenase referred to as DEHAL1 has been cloned very recently. In patients with congenital hypothyroidism, defects have been identified at all major steps involved in hormonogenesis (Table 35-3).

DEFECTS OF IODIDE TRANSPORT Normal iodide uptake at the basolateral membrane by the perchlorate-sensitive NIS is a rate-limiting step in thyroid hormone synthesis (*see* Fig. 35-2). Following the cloning of the *NIS* gene, several homozygous, or compound heterozygous mutations have been identified in individuals with hypothyroidism with iodine trapping defects. Most patients with iodide trapping defects have a diffuse or nodular goiter, little or no uptake of radioiodide, and a decreased saliva/serum radioiodine ratio. In children, the thyroid might be initially of normal size and often enlarges later in life.

The precise molecular mechanisms by which NIS mutations directly cause iodide transport defects have been identified in a subset of cases. The T354P mutation, an alteration found in several patients from Japan, causes NIS to lose its functional ability to transport iodide. In contrast, the functional defects of two other NIS mutations (Q267E, S515X) are the consequence of defective cellular trafficking and failure of the mutant proteins to reach the plasma membrane.

THYROPEROXIDASE TPO is a glycosylated hemoprotein that catalyzes several essential reactions of thyroid hormone synthesis: oxidation of iodide, the iodination of tyrosine residues in TG and the coupling of iodinated tyrosines to generate T4 and T3 (*see* Fig. 35-2). TPO is the protein historically referred to as microsomal antigen in autoimmune thyroid disease. It is anchored in the membrane and has its catalytic site in the follicular lumen. The enzyme is closely related to myeloperoxidase and it is thought that they share a common ancestor; their chromosomal localizations are, however, distinct.

TPO defects are among the most frequent causes of inborn abnormalities of thyroid hormone synthesis. Because of the defective organification of iodide, these patients typically have a significant discharge of radioiodine after the administration of perchlorate. Mutations in the *TPO* gene have been reported in numerous families with a partial or total iodide organification defect. The overall incidence of congenital hypothyroidism is on average 1/3000, total iodide organification defect is thought to occur in approximately 1/66,000 of all infants with congenital hypothyroidism and almost all of these patients have homozygous or compound heterozygous mutations in the *TPO* gene.

PENDRED SYNDROME Pendred syndrome is an autosomal-recessive disorder characterized by sensorineural deafness, goiter, and a positive perchlorate test. This disorder represents one of the most common forms of syndromic deafness, with an incidence estimated at 7.5–10/100,000 individuals. Although the classic presentation of the syndrome consists of the triad of deafness, goiter, and partial organification defect, the phenotypic expression of these components is highly variable among families and even within the same family. Sensorineural hearing loss, in most instances profound prelingual deafness, is the hallmark of Pendred syndrome. More rarely, the hearing impairment manifests itself later in life as a progressive hearing loss. High resolution MRI of the inner ear reveals malformations of the vestibular aqueduct, endolymphatic duct, and endolymphatic sac in nearly 100% of individuals with a clinical diagnosis of Pendred syndrome. Goiter is the most variable component of the disorder, with some individuals developing very large goiters, whereas others present with minimal to no enlargement. Although many patients with Pendred syndrome are euthyroid, others have subclinical or overt hypothyroidism.

Pendred syndrome is caused by mutations in the *PDS* gene, now officially designated *SLC26A4*. It encodes pendrin, a member of the solute carrier family 26A, which contains several anion transporters and the motor protein prestin. Pendrin is predominantly expressed in the thyroid, inner ear, and the kidney. In thyroid follicular cells, pendrin is inserted into the apical membrane and functional studies suggest that it is involved in apical iodide efflux from thyrocytes. These observations are consistent with the clinical phenotype, which is characterized by impaired iodide organification. In the kidney, pendrin is thought to act as a chloride-bicarbonate exchanger in β-intercalated cells of the cortical collecting duct, a subpopulation of cells that mediate bicarbonate secretion. The critical role of pendrin in the inner ear has been corroborated by targeted disruption of the *Pds* gene in mice. *Pds–/–* mice develop early onset deafness and exhibit signs of vestibular dysfunction. In line with the enlargement of the endolymphatic system observed in human patients, analysis of the inner ear in these mice reveals dilated endolymphatic ducts and sacs beyond E15, presumably as a consequence of defects in anion and fluid transport.

During the last few years, more than 95 *PDS* gene mutations have been described, indicating marked allelic heterogeneity. The majority of *PDS* mutations are missense mutations and some of these mutants appear to be retained in the endoplasmic reticulum. A smaller number of mutations result in premature truncations or in alterations of splice donor or acceptor sites. Individuals with Pendred syndrome from consanguineous families are homozygous for *PDS* mutations, whereas sporadic cases typically harbor compound heterozygous mutations. Mutations in the *PDS* gene are not only found in patients with classic Pendred Syndrome, but also in individuals afflicted with familial enlarged vestibular aqueduct. The diagnosis of Pendred syndrome based on the clinical findings of deafness and goiter is not sufficient; it requires confirmation by imaging studies of the inner ear or/and molecular analysis of the *PDS* gene.

HYDROGEN PEROXIDE GENERATION H_2O_2 is an essential factor in the iodination and coupling reactions. Although the ability of follicular cells to produce H_2O_2 has been known for more than three decades, the enzyme system remains only partially characterized. Two NADPH oxidases, THOX1 and THOX2 (also called LNOX or DUOX) that are part of this system have been cloned. Structurally, these proteins contain seven putative transmembrane domains, four NADPH binding sites, 1 FAD binding site, and in line with the predicted regulation by calcium, an everted finger motif.

Heterozygous loss of function mutations in the *THOX2* gene result in mild transient congenital hypothyroidism. Biallelic THOX2 mutations are associated with a severe phenotype and confirm that H_2O_2 is essential for iodide organification. There are no reported mutations in THOX1.

Deficient H_2O_2 generation has been proposed to explain the phenotype in a few sporadic patients with euthyroid goiter and

abnormal iodide organification, and a family with two siblings presenting with hypothyroidism, goiter, and an iodide organification defect. The molecular defect in these patients remains unknown.

THYROGLOBULIN TG is produced by thyroid follicular cells and secreted into the follicular lumen. Some of its tyrosine residues are iodinated by TPO (organification/iodination), and the tyrosines MIT and DIT are subsequently coupled to form T3 and T4 (coupling). TG is therefore considered to be a thyroid hormone precursor. Besides its importance for hormone synthesis, it allows storage of iodine and thyroid hormone and thus to adapt to scarce iodine supply.

The monomer of TG is made up of a 19-amino acid signal peptide followed by 2749 residues containing 66 tyrosines. TG contains an average number of tyrosine residues, altogether 67, but only a minority of these residues localized in the carboxy- and amino-terminus are hormonogenic sites. Complete hydrolysis of iodinated TG yields only two to four molecules of the iodothyroxines T4 and T3. The mature protein is formed by two units in noncovalent linkage (19 S TG). Of the total weight, 10% are formed by carbohydrates, and glycosylation plays an important role in the structure of the protein. The TG monomer contains 20 glycosylation sites and extensive microheterogeneity has been reported in their use. The primary structure of the TG protein contains three regions with repetitive sequences with internal homology, and the carboxy-terminal part shares remarkable homology with acetylcholinesterase. This structure suggests the possibility of a convergent origin of the *TG* gene from two different ancestral DNA sequences.

The human *TG* gene is large, spans approximately 270 kb and contains 48 exons. The transcription of the *TG* gene is controlled by transcription factors such as thyroid transcription factor (TTF)-1 (NKX2.1), TTF-2 (FOXE1), and PAX 8. The full-length 8.5 kB mRNA sequence shows a 41-nucleotide 5′-untranslated segment preceding an open reading frame of 8307 bases and a 3′-untranslated segment ranging from 101 to 120 bp. There are numerous alternatively spliced RNA transcripts and the gene contains multiple polymorphisms, some of them silent, others with impact on the primary amino acid sequence.

Defects of TG synthesis or secretion have been studied in several animal strains and human patients. TG gene defects are inherited in an autosomal-recessive manner. The phenotype is typically characterized by goitrous enlargement of the thyroid. The metabolic status is variable and, depending on the severity of the defect, patients are hypothyroid, subclinically hypothyroid, or euthyroid. Unless treated with levothyroxine, goiters are often remarkably large and display continuous growth. Symptoms can result from compression of adjacent neck structures. The radioiodine uptake is elevated indicating an activation of the iodine concentration mechanism, because of chronic stimulation of TSH. In patients evaluated with a perchlorate discharge test, there is no increased release of radioiodine after administration of the competitor, indicating that the organification process itself is not affected. Serum TG levels can vary from low to low normal, and the presence of an abnormal TG level in a goitrous individual may suggest a defective TG synthesis. An abnormal TG synthesis may also be suggested by the presence of abnormal iodoproteins in the serum. Because there is no normal intrathyroidal TG, albumin as well as other proteins are iodinated, generating iodotyrosines and iodohistidines. This is, however, an unspecific sign and also found in endemic and sporadic goiters and thyroids affected by autoimmune Hashimoto's thyroiditis. Increased secretion of low-molecular weight iodinated material (>5%) in the urine may also be helpful in establishing the diagnosis. Histological analysis often demonstrates scarce colloid, large follicular lumina, and cuboidal epithelial cells. In instances with-impaired TG export, TG-immunopositivity is found predominantly inside the cytoplasm. Although it is possible to diagnose TG defects at the molecular level, this is not a trivial task considering the large size of the gene; thus the data on molecular alterations are still relatively scarce. Further studies of patients with TG abnormalities may reveal a more detailed understanding of the structure-function relationship of TG.

The first models with abnormal TG to be studied in detail at the molecular level were the Afrikaander cattle and the Dutch goat. The Afrikaander cattle is characterized by large goiters and an euthyroid metabolic status. A recessive point mutation in exon 9 leads to a premature stop. Interestingly, alternative splicing allows rescuing the transcription to some degree by producing a misspliced 7.3-kb message missing exon 9, a mechanism referred to as *exon skipping*. The original reading frame is maintained in this transcript and it is translated into a functional protein missing the part encoded by exon 9. Both transcripts are, however, only present at low levels. The Dutch goat is goitrous as well and, provided that iodine intake is high, euthyroidism can be maintained. A nonsense mutation (Y296X) in exon 8 results in a truncated protein. The fact that the animal may remain euthyroid despite this truncation is indirect evidence that the amino-terminal part contains a major hormonogenic site.

Molecular analysis of several TG point mutations found in patients with congenital hypothyroidism and in the *cog*/*cog* mouse, which all present with goiters, reveal that at least some of these alterations result in a secretory defect and thus an endoplasmic reticulum storage disease. In contrast to these TG defects associated with goiter development, the recessive dwarf *rdw*/*rdw* rat displays a nongoitrous form of congenital primary hypothyroidism caused by a *Tg* gene mutation. The identification of a mutation in the *Tg* gene as a cause of nongoitrous hypothyroidism in the *rdw*/*rdw* rat challenges the previously held generalization that nongoitrous congenital hypothyroidism is caused by thyroid dysgenesis or defects in TSH-signaling.

It has been proposed that TG mutations may be associated with nonendemic simple goiter. These results await, however, further confirmation; the TG gene contains multiple polymorphisms, and in the absence of functional data it remains unclear whether these reported alterations are causally involved in the abnormal phenotype.

DEHALOGENASE DEFECT After entering the follicular cell, TG is hydrolyzed and T4 and T3 are secreted into the blood (*see* Fig. 35-2). The iodotyrosines, MIT and DIT, which are much more abundant in the TG molecule than in T4 and T3, are deiodinated by an intrathyroidal dehalogenase and recycled for hormone synthesis. An intrathyroidal dehalogenase referred to as DEHAL1, which may exert this function, has been cloned. Very recently, mutations in *DEHAL1* have been reported in patients with a dehalogenase defect. In case of a defective dehalogenase system, MIT and DIT leak into the circulation and are excreted in the urine. This leads, especially if iodine is scarce, to a severe iodine loss and thus to hypothyroidism and goiter. Very recently, mutations in *DEHAL1* have been reported in patients with a dehalogenase defect.

Clinically, patients with a deiodinase defect present with congenital hypothyroidism and a goitrous gland. The diagnosis is established by administration of radiolabeled DIT. Normally, DIT will be deiodinated, whereas in the case of a defective dehalogenase, the majority will be secreted unaltered as DIT in the urine.

Furthermore, administration of iodide in sufficient amounts to compensate for the increased loss will reestablish a euthyroid metabolic state. The disorder is inherited in an autosomal-recessive fashion. Although only homozygotes are clinically affected, biochemical testing in heterozygotes demonstrates an increased secretion of labeled DIT in the urine. The clinical and biochemical phenotype of several kindreds have been studied in detail. The classic report traces the family history of an inbred kindred originating from the marriage of first cousins through 160 yr.

DEVELOPMENTAL THYROID DEFECTS ASSOCIATED WITH MUTATIONS IN TRANSCRIPTION FACTORS

In approximately 85% of all affected infants, congenital hypothyroidism is sporadic and associated with developmental defects referred to as thyroid dysgenesis. They include thyroid (hemi)agenesis, ectopic tissue, and thyroid hypoplasia.

Molecular defects only explain a minority of cases of thyroid dysgenesis (Table 35-4). It is likely that a further subset of patients with thyroid dysgenesis have defects in other transacting proteins or elements of the signaling pathways controlling growth and function. In other instances, thyroid dysgenesis might be a polygenic disease or have a multifactorial basis. With further characterization of the molecular basis of congenital hypothyroidism, genetic testing, and counseling may become increasingly important in the future.

PAX8

PAX8 is a paired domain thyroid-specific transcription factor responsible for thyroid development and for *TG* and *TPO* gene expression. PAX8 binds predominantly to the TPO promoter and with less affinity to the TG promoter.

Heterozygous mutations in PAX8 have been documented and characterized in sporadic and familial patients with thyroid hypoplasia or ectopy.

In humans, the biochemical and morphological phenotype may vary among patients with the same PAX8 mutation. Underlying mechanisms may include incomplete penetrance, a phenomenon associated with mutations in other *PAX* genes. Alternatively, the phenotypic expression might be modulated by modifier genes.

It is unclear why mutation of a single PAX8 allele is sufficient to result in congenital hypothyroidism in humans, a finding that contrasts with the observation that mice heterozygous for a disrupted *Pax8* gene do not display a pathological phenotype. Proposed mechanisms explaining that one mutated allele is sufficient to cause disease in humans include haploinsufficiency, allele-specific expression in the thyroid and, less likely, a dominant negative effect.

THYROID TRANSCRIPTION FACTOR-1 (TTF-1, NKX2.1) TTF-1 (NKX2.1, TITF-1, or thyroid specific enhancer-binding protein T/ebp), is a homeobox domain transcription factor of the NKX2 family involved in the development of the gland and in transcriptional control of the *TG*, *TPO*, and *TSH receptor* genes. It is expressed in the lung, forebrain, pituitary gland, and the thyroid. In the lung, TTF1 activates transcription of surfactant protein B.

Mice with targeted disruption of both *TTF1* alleles survive throughout gestation, but die at birth from respiratory failure. The lung is severely hypoplastic and consists of a sac-like structure without bronchioli, alveoli, or lung parenchyma. Both the thyroid gland and pituitary gland are completely absent, and the hypothalamus is severely malformed.

The observation of a newborn with severe respiratory distress, a normally located thyroid gland, elevated TSH levels and a heterozygous deletion on chromosome 14q13 encompassing the *TTF1* locus suggested that haploinsufficiency for TTF1 could be associated with impaired lung maturation and thyroid function. Haploinsufficiency, i.e., inability of a single functional allele to maintain normal function, is a frequently observed pathogenetic mechanism associated with mutations in transcription factors. The detection of a similar heterozygous deletion of chromosome 14q12-13.3 in two female siblings with congenital thyroid dysfunction and recurrent acute respiratory distress gave further support to this concept. A few additional patients with hyperthyrotropinemia, neonatal respiratory distress, and ataxia associated with missense or frameshift mutations, or chromosomal deletions of the TTF-1 gene have been reported. The TSH levels were only mildly elevated and the thyroid was normal in size and position. The hallmark of this phenotype is the neurological deficit, which includes ataxia or choreoathetosis, truncal apraxia, and mental retardation, in combination with neonatal respiratory distress. Heterozygous TTF-1 mutations have also been identified as the molecular cause of hereditary chorea.

THYROID TRANSCRIPTION FACTOR-2 (TTF-2, FOXE1) TTF-2, official designation FOXE1, is a forkhead/winged-helix domain transcription factor activating the *TG* and the *TPO* gene promoters. Homozygosity for recessive mutations in TTF-2 results in a syndromic form of thyroid dysgenesis with the eponym Bamforth-Lazarus syndrome. This phenotype, first described in two brothers from a consanguineous family, includes thyroid agenesis, cleft palate, choanal atresia, bifid epiglottis, and spiky hair. Mice homozygous for a disrupted *Ttf2* gene die shortly after birth, and are profoundly hypothyroid. They exhibit either small lingual thyroid remnants or have complete thyroid agenesis, findings that support the important role of TTF-2 in thyroid development, and they also have cleft palates.

SERUM BINDING PROTEIN DEFECTS

Thyroid hormones circulate bound to plasma proteins, the three major proteins being TBG, TTR (formerly referred to as T4-binding prealbumin) and albumin. To a minor degree, α and β lipoproteins bind T4. Under physiological conditions, only 0.03% of T4 and 0.3% of T3 circulate as free hormone.

Abnormalities in transport proteins lead to a decrease or increase in total T4 or T3 levels; free hormone levels are within the normal range and patients are clinically euthyroid (Table 35-5). Failure to recognize these entities results in inappropriate treatment aimed at normalizing the thyroid hormone levels. TTR variants are of clinical importance because they are associated with various forms of amyloidosis.

THYROXIN-BINDING GLOBULIN TBG is an acidic glycoprotein with a single binding site for T4 or T3. The TBG concentration is low (1–2 mg/dL), but the protein has a high affinity for thyroid hormones (T4 > T3) and it carries approx 75–80% of the bound thyroid hormones. The mature protein contains 395 amino acids with four heterosaccharide chains with 5–9 sialic acids. Like corticosteroid-binding globulin it shows a high homology with the proteases α_1-antichymotrypsin and α_1-antitrypsin and it is a member of the serine protease inhibitor (serpin) family of proteins, although it is not a protease inhibitor. The carbohydrates play a minor role in T4 binding, but loss of carbohydrates decreases its stability and elevates the hepatic clearance rate. An increase in sialylation, for example, induced by estrogens, lowers the hepatic clearance and thus increases the TBG levels. Multiple other drugs increase or

decrease TBG concentrations either by alteration of the synthesis rate and or the degree of sialylation. The single copy gene encoding TBG is localized on the X-chromosome (Xq11-q23).

TBG abnormalities are classified according to the levels of TBG into complete or partial deficiencies or TBG excess. Besides their biochemical classification, several TBG variants have been characterized at the molecular level. Complete TBG-deficiency is defined as absence of TBG in the serum of hemizygous (XY) individuals. The heterozygote females in these kindreds have TBG levels of about half the normal amount because random X-inactivation results on average in a 50% reduction of the protein. The prevalence of complete deficiency has been estimated at 1/15,000. Partial deficiency is the most common form of TBG deficiency. In white and mixed populations it is found with a frequency of 1/4000, roughly 50% of Australian Aborigines have an abnormal TBG (TBG-A), and a TBG migrating slowly on electrophoresis (TBG-S) is found in African and Pacific Islands populations. Some of these TBG-variants have a reduced affinity for T4 (TBG-A, TBG San Diego). In some variants, an accelerated rate of degradation is responsible for their low serum concentration. The identified mutations in the *TBG* gene that result in complete or partial deficiency consist of point mutations, deletions, frameshift mutations, and splice site mutations.

TBG excess is not as frequent as TBG deficiency with an incidence of approximately 1 in 25,000 births. TBG and T4 levels are elevated three- to fivefold in hemizygotes and two- to threefold in heterozygote females. The TBG increase is explained by overexpression of the protein because of gene amplification.

TRANSTHYRETIN TTR is a homotetramer formed of subunits containing 127 amino acids and two T4 binding sites. Negative cooperativity allows only one site to be occupied at a given time. TTR has a substantially lower affinity for T4, but it is present in higher amounts than TBG (approx 25 mg/dL). TTR also binds retinol-binding protein and takes part in the transport of vitamin A. Binding of retinol does not influence T4 transport. The TTR gene contains four exons and is localized on chromosome 18. TTR is predominantly synthesized in the liver, but also in the plexus chorioideus. Although the exact role of TTR in the brain is not known, it has been postulated that T4 binds to TTR in the epithelial cells of the plexus chorioideus, is then secreted into the cerebrospinal fluid and subsequently distributed in the brain. More than 80 disease-causing mutations in TTR have been reported. Their impact on T4 affinity varies and may result in unchanged, increased or reduced affinity. Many of the point mutations have been related to distinct forms of amyloidosis. The inheritance is autosomal-dominant in most instances. Although the clinical manifestations vary, most have polyneuropathy, thus the eponym familial amyloidotic polyneuropathy, and amyloid depositions in the heart.

ALBUMIN Albumin is a monomer of 69 kDa associated with the transport of various endogenous and exogenous hydrophobic compounds. Albumin has a relatively low affinity for T4 and T3, but because of its high concentration (approx 3.5 g/dL) it binds up to 10% of T4 and 30% of T3.

Familial dysalbuminemic hyperthyroxinemia is the most common cause of euthyroid hyperthyroxinemia. Familial dysalbuminemic hyperthyroxinemia is characterized by increased binding of T4 and thus elevated total T4, but normal free T4 levels. It is inherited in an autosomal-dominant manner. Studies of several families have led to the identification of two independently recurring point mutations in the albumin gene that lead to substitutions of arginine at position 218 (R218H, R218P). Crystallographic analyses revealed that the two mutations result in conformational changes that favor binding of T4 on one of the four T4-binding sites on albumin.

In a family presenting with high serum total T3, but not T4, an albumin mutation L66P was identified. The L66P albumin leads thus to *familial dysalbuminemic hypertriiodothyroninemia* with an affinity for T3 that is approximately 40 times higher than wild-type albumin. In contrast, the affinity for T4 is barely changed.

UPTAKE OF THYROID HORMONE INTO CELLS

Cellular uptake of thyroid hormones appears to be mediated by amino acid channels. Point mutations and deletions in the X-chromosomal *MCT8* gene have been identified in several male patients presenting with elevated T3 and TSH levels and a remarkable neurological phenotype that includes severe mental retardation, spastic quadriplegia, rotary nystagmus, and impaired gaze, and hearing. In one instance, the disorder was found in several males of a consanguineous mating, in the other cases, it was sporatic. Heterozygous females have discrete thyroid hormone abnormalities, but no neurological alterations. The abnormal T3 elevation may be due to impaired uptake into cells such as neurons and resembles in many aspects to the phenotype in neurological cretinism. It remains unclear whether MCT8 transports other amino acid derivatives that could be involved in the development of the complex phenotype. The observations indicate, however, that the uptake of thyroid hormones is, at least in part, mediated by channels. Of note, studies have revealed that the Allan-Herndon-Dudley syndrome, a recognized cause of X-linked mental retardation with a wide spectrum of neurological alterations, is caused by mutations in MCT8.

PERIPHERAL MONODEIODINATION

In target tissues, T4 is metabolized into the more active compound T3 by intracellular 5′-monodeiodination or into the inactive metabolite rT3 by 5-monodeiodination (*see* Fig. 35-3). Because roughly 80% of T3 is generated by monodeiodination of T3, T4 is sometimes considered a prohormone. Monodeiodination of the outer and inner ring is catalyzed by three well-characterized deiodinases, which are unusual because they are selenoproteins. They contain the rare amino acid selenocysteine (Sec), which is encoded by UGA, a triplet that usually encodes a stop codon. The translation of the Sec codon requires specific stem loop sequences that are located in the 3′ untranslated region (SECIS element) of the mRNA.

Type 1 iodothyronine deiodinase (DIO1) primarily converts T4 to T3 and is sensitive to propylthiouracil. In humans, it is expressed in many tissues, including liver, kidney, thyroid, and pituitary. DIO2 deiodinates exclusively the outer ring. Its expression is abundant in the human pituitary, brain, thyroid, and skeletal muscle; high levels are found in the brown adipose tissue of rodents in which it plays an important role in adaptive thermogenesis. DIO3 is the major enzyme inactivating T4 and T3 (*see* Fig. 35-3). In addition to its expression in tissues such as the central nervous system and skin, DIO3 is particularly abundant in the placenta and regulates circulating fetal thyroid hormone concentrations during gestation.

Overexpression of DIO3 in infantile hemangiomas and other vascular tumors leads to *consumptive hypothyroidism* through inactivation of thyroid hormone at a rate that exceeds the maximal thyroid hormone synthesis.

THYROID HORMONE ACTION

Thyroid hormones exert their multiple cellular effects through nuclear TR, transcription factors that act by altering patterns of gene expression both as activators and repressors (*see* Fig. 35-4). The two TR genes, TRα and TRβ, cellular homologs of the viral erythroblastic leukemia oncogene v-erbA, were cloned based on their relationship to other members of the steroid receptor superfamily of nuclear receptors that share a characteristic modular domain structure with a central DNA binding domain and a carboxy-terminal ligand binding domain. In the TR, the carboxy-terminus of the receptor also contains nuclear localization signals, dimerization domains, and transactivation functions. The functional properties of the amino-terminal region of the receptor are less well characterized but seem also to be involved in transactivation.

The two TRs, TRα and TRβ, are encoded by separate genes located on chromosomes 17 and 3, respectively. Although they bind thyroid hormones with high affinity, TRα and TRβ differ in their developmental patterns of expression, tissue distribution and the patterns of splicing to create additional isoforms. The TR can bind as monomer or with greater affinity as homodimers and heterodimers, particularly with retinoid X receptors to thyroid hormone response elements (TREs) in specific target genes.

In most instances, unliganded TR represses transcription by recruiting corepressors, some of which have histone deacetylase activity (*see* Fig. 35-4C). Binding of T3 alters the conformation of the receptor resulting in release of the corepressor complex and recruitment of a coactivator complex that includes multiple histone acetyltransferases. The modification of histones is an important mechanism controlling chromatin structure and transcriptional events. Several TR-interacting coregulators act more directly on the basal transcriptional machinery suggesting that mechanisms independent of histone acetylation and deacetylation are also involved in TR action.

Although there is considerable heterogeneity in the TREs of different target genes, most TREs contain two or more "half sites" that correspond to the minimal recognition motif for a receptor monomer. The consensus TRE half-site consists of the DNA sequence AGGTCA. These half-sites can be arranged as a palindrome, a direct repeat spaced by four nucleotides, or as an inverted repeat, also called lap (an eponym created by inversion of *pal*indrome). Remarkably, TRs can bind to these TREs with different orientations as homodimers or heterodimers with cofactors, indicating flexibility in the determinants of the protein–protein interface. Receptor binding to these repeats is importantly influenced by neighboring nucleotides and by the spacing between the elements that provide one of the primary determinants of receptor specificity for different nuclear receptors like TRs, retinoid receptors and vitamin D receptors. Changes in gene transcription are reflected in alterations in mRNA levels followed by changes in protein biosynthesis. A large number of genes that respond to thyroid hormone have been identified.

The crystal structure of the rat TRα1 ligand-binding domain bound to T3 has been solved and permits a better understanding of structure-function relationship. Knowledge about the structure may also permit the design of novel agonists and antagonists that may have differential effects on TRs and of use in conditions such as hyperthyroidism, lipid disorders, and obesity.

Important insights into thyroid hormone action have been gained through systematic disruption of the TRα and TRβ genes and isoforms, independently or in combination. More than ten mutant strains have been characterized. These studies reveal that TRβ is essential for the development of the inner ear, color vision, and liver function. TRα, abundantly expressed in the heart, is essential for normal cardiac function. Moreover, it is important for maintaining basal energy metabolism and regulating enchondral bone formation. Evaluation of the combined TR knock-out indicates that hypothyroidism is associated with more significant abnormalities than receptor deficiency. This supports that the unliganded receptors have a repressive function of physiological relevance. Knock-in experiments have also been successfully used to model the syndrome of RTH and continue to reveal fundamental insights into TR-mediated gene regulation. For example, mice heterozygous for a knock-in of a dominant negative mutation into the TRα1 gene display a phenotype with marked visceral adiposity and insulin resistance, increased TSH levels and minimally elevated T4 and T3 levels suggesting that TRα plays an important role in regulating both lipogenesis and lipolysis by modulating adrenergic activity.

Lastly, some thyroid hormone-mediated effects are rapid and not mediated by genomic actions. They involve effects on the cell membrane, mitochondria, and stimulation of signaling pathways. Of growing interest, these nongenomic effects await more thorough characterization.

RESISTANCE TO THYROID HORMONE

RTH was first recognized in 1967 in two sibs of a consanguineous marriage presenting with goiter, high levels of protein-bound iodine, deaf-mutism, delayed bone age, and stippled epiphyses, but without signs of hyperthyroidism. Abnormalities in thyroid hormone itself or its transport into tissues were excluded, and it was thus postulated that resistance in peripheral tissues was the explanation for the absence of signs and symptoms of thyrotoxicosis. Following the cloning of the TRs, linkage analysis demonstrated that TRβ is tightly linked to RTH, whereas no association could be demonstrated to TRα. The ultimate proof that a defect in the receptor is the cause of RTH was provided in 1989 by the demonstration of mutations in the TRβ gene, a finding that has been confirmed in multiple reports. RTH is a rare disorder, but because of growing awareness of its existence more than 400 familial and sporadic patients have been studied.

Biochemically, RTH is defined by elevated circulating levels of free thyroid hormones because of reduced target tissue responsiveness and normal, or elevated, levels of TSH. This "inappropriate" TSH elevation contrasts with the situation in hyperthyroidism, in which the pituitary secretion of TSH is suppressed. Patients with RTH typically present with goiter and signs of hypothyroidism in tissues expressing predominantly TRβ, but hyperthyroidism in organs with predominant TRα expression such as the heart. They can include short stature, delayed bone maturation, hyperactivity and learning disabilities, hearing defects and tachycardia. There is a striking clinical heterogeneity in patients with RTH, a phenomenon presumably caused by genetic background or nongenetic factors modulating thyroid hormone action.

With the exception of the first studied kindred, a single sibship harboring a deletion of the entire coding sequence of the entire TRβ gene and a recessive pattern of inheritance, RTH is most commonly caused by heterozygous mutations of the TRβ gene. They can be inherited in an autosomal-dominant manner or occur as *de novo* mutations. The mutant receptors act in a dominant

negative fashion to block the activity of normal TRα and TRβ receptors. The mutations are clustered in three domains in the carboxy-terminal region of the receptor. Many mutations occur in CpG dinucleotide sequences, and consist in most cases of nucleotide substitutions that result in single amino acid substitutions. In a few cases, the mutations cause frameshifts, either altering the reading frame, or causing premature stop codons. No mutations have been found within the DNA binding domain or in the amino-terminus. In general, the mutations preserve some critical receptor functions such as dimerization and DNA binding, whereas inactivating other activities such as T3 binding and transcriptional activation.

The dominant negative activity of mutant TRs involves several mechanisms. Mutant TRs, which have lost their transcriptional activity, can block wild-type TR from binding to TREs. Given the decreased or impaired T3 binding, this will favor interactions with corepressors (*see* Fig. 35-4C). Some mutations may also have altered dimerization properties that may disrupt interaction with coactivators. These naturally occurring mutations continue to provide important insights into the mechanisms of thyroid hormone action, molecular mechanisms of dominant negative activity, and structure-function relationship of the TRs, which is now facilitated by the available crystal structure for TRα.

Several kindreds with a RTH phenotype without mutations in the TR and autosomal-dominant transmission of the disorder have been reported. It is likely that mutations in cofactors that are required for normal TR function are involved in the pathogenesis of RTH in these patients.

Somatic mutations in the TRs have been identified in a subset of thyroid cancers, a TSH-secreting pituitary adenoma, renal cell cancers, and hepatomas. Their exact role in the development of these neoplasias is unknown.

AUTOIMMUNE DISORDERS

Autoimmune thyroid disorders (AITD), Hashimoto thyroiditis and Graves' disease, are by far the most common diseases affecting the thyroid gland. They are characterized by an immune response to thyroidal antigens, infiltration by T cells and production of antibodies. In Graves' disease, thyroid-stimulating antibodies lead to activation of the TSH receptor and hyperthyroidism, a process involving mainly a Th2 cell response. In Hashimoto's thyroiditis, a predominantly Th1-mediated chronic inflammation leads to progressive destruction and hypothyroidism. Both disorders are found more frequently in women than in men (4–10/1), a difference that is most commonly explained by influences of sex steroids on immunoregulatory mechanisms. The incidence of Graves' disease in the general population has been estimated at 0.2–1%. Hashimoto's thyroiditis has been reported to occur in up to 3–4.5%, and approx 15% of elderly women have thyroid autoantibodies although there is not necessarily a clinical correlate.

Thought to be multifactorial, the AITD require a genetic predisposition in combination with environmental triggers. Epidemiological data support a strong genetic component in the development of AITD, further supported by twin studies. Graves' disease occurs in approximately 3–9% of dizygotic and 30–60% of monozygotic twins. For Hashimoto's thyroiditis, the concordance rate for monozygotic twins is approximately 40%, but very low for dizygotic twins. Of note, monozygotic twins are not identical in terms of their immune repertoire, which may explain that perfect concordance is absent. Genetic and molecular analyses have allowed a partial understanding of the pathophysiological mechanisms underlying the two disorders, but their precise elucidation continues to form a major challenge.

As in other autoimmune diseases, associations have been established between the disease and the presence of certain human leukocyte antigens (HLA) constellations. Graves' disease is associated with HLA-DR3. However, most linkage studies have been negative. HLA correlations for Hashimoto's thyroiditis differ from the ones reported for Graves' disease and appear to include HLA-DR3, DR4, and DR5 haplotypes.

Candidate gene analyses aiming at investigating associations between variants in genes such as the TSH receptor, TPO, and the T-cell receptor with AITD have been negative. In contrast, the TG and cytotoxic T-lymphocyte antigen, four genes appear to be important susceptibility genes for AITD. Whole genome screens using AITD families identified several loci or genes with evidence for linkage to AITD (GD-1 on chromosome 14; GD-2 on chromosome 20; HT-2 on chromosome 12; Tab-1 on chromosome 2; the TG gene on chromosome 8). It also became apparent that gene–gene interactions occur between some of these genes. The identified loci show, in part, linkage to Graves' and Hashimoto's disease suggesting that certain genes underlie the development of AITD, but that additional genetic and or nongenetic factors are required for the expression of the specific phenotype.

ANTIBODIES AND AUTOIMMUNE THYROID DISEASE

Because stimulating autoantibodies against the TSH receptor (TSAb) are the cause of Graves' disease, their assessment can help establish the diagnosis. Most tests rely on measurement of the binding of these antibodies to the receptor but this test does not assess their bioactivity. Cloning of the TSH receptor led to the development of new bioassays that allow measurement of TSAb. They allow reliable distinction of TBAb; these blocking antibodies may also be present in other forms of AITD. For these new assay systems, the TSH receptor has been stably transfected into cell lines. Measurement of cAMP in response to a patient serum allows assessment of the presence and bioactivity of thyroid autoantibodies.

Molecular biology established that the microsomal antigen in autoimmune thyroiditis is in fact TPO. The epitopes within the TPO enzyme, which are the targets of autoantibodies, are still a matter of debate, however. Recombinant TPO can now also be produced for the assay of autoantibodies.

THYROTOXIC HYPOKALEMIC PERIODIC PARALYSIS

Periodic paralysis with hypokalemia can occur in patients with thyrotoxicosis. The clinical presentation is indistinguishable from familial hereditary hypokalemic paralysis without hyperthyroidism. Analysis of several genes encoding channels that are mutated in the familial form in patients with the thyrotoxic form led to the identification of a mutation in the KCNE3 potassium channel gene. No mutations could be found in other candidates such as the calcium channel CACN1AS or the sodium channel SCN4A.

THYROID CANCER

Thyroid cancers are relatively infrequent neoplasms and account for approx 0.6–1.6% of all malignancies. The incidence of thyroid cancer is 1–10/100,000 in most countries. In the United States, this results in approximately 20,000 new cases and 1200 deaths per year. Thyroid cancer is about three times more frequent in females. Remarkably, thyroid cancer has shown the highest increase in

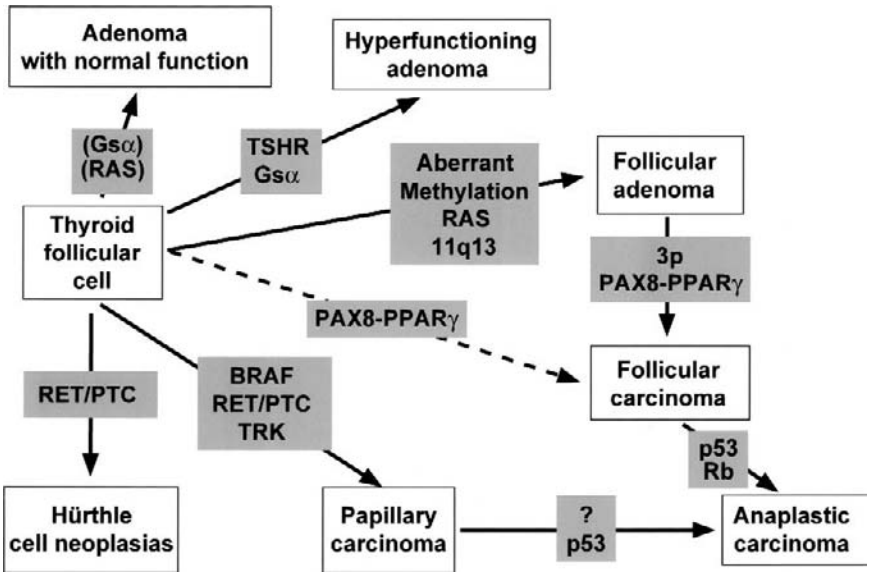

Figure 35-5 Molecular alterations involved in the pathogenesis of benign and malignant thyroid tumors. (Redrawn and modified after Fagin JA.)

cancer incidence (+4.3/100,000) during the 1992–2002 survey period of the Surveillance, Epidemiology, and End Results of the National cancer institute (http://seer.cancer.gov/).

Most thyroid malignancies are papillary thyroid carcinomas (PTC) or follicular thyroid carcinomas (FTC), both originating from follicular cells. PTC is by far the most common thyroid cancer (approximately 90%) in countries with sufficient iodine intake, FTC is comparatively uncommon. Their relative distribution is, however, variable and the incidence of FTC increases in regions with iodine deficiency. TG, only expressed in thyroid follicular cells, serves as an excellent tumor marker in patient follow-up. TG mRNA can be detected by reverse transcriptase PCR in serum samples and is being evaluated as a potential diagnostic tool for residual cancer. Besides the clinically relevant forms of PTC, occult PTC (<1 cm) are found in up to 36% of autopsies. The highly malignant anaplastic carcinoma (ATC) and several unusual variants of thyroid cancers (Hürthle cell carcinoma, insular thyroid carcinoma, primary squamous carcinoma, and lymphoma of the thyroid) are much rarer forms of thyroid malignancies. ATC is thought to arise from preexisting well-differentiated carcinomas in some cases. Hürthle cell carcinomas and insular carcinomas are both traditionally classified as variants of FTC, but are now considered to form distinct entities by many authors. This separate classification can be justified based on their greater tendency to recur and, particularly in the case of the insular carcinoma, a significantly compromised prognosis.

A major risk factor for the development of benign and malignant thyroid neoplasms is radiation. This has been recognized after use of external radiation for medical treatment of benign and malignant conditions in the neck and more dramatically after accidental releases of ionizing radiation from atomic explosions and accidents in nuclear facilities.

PTC, which presents with several distinct histological subtypes, may occur in the setting of some rare autosomal-dominant syndromes with disseminated neoplasias: familial adenomatous polyposis (Gardner's syndrome; APC gene mutations), as well as Cowden's syndrome (PTEN gene mutations), a condition characterized by multiple hamartomas with benign and malignant breast tumors, gastrointestinal polyps, ovarian cysts and mucocutaneous papulae. The Carney complex, an autosomal-dominant disorder defined by cardiac myxomas, benign endocrine neoplasms and, more rarely, follicular cancers, is associated with activating mutations in the regulatory subunit 1A of the cAMP-dependent PKA (PRKAR1A). Nonsyndromic familial PTC has been reported repeatedly; in some instances the familial accumulation may, however, be the result of exposure to a shared risk factor than a familial disease in the strict sense. Familial aggregation of FTC seems to occur in families with dyshormonogenesis.

Several molecular mechanisms involved in the development of thyroid neoplasms have been elucidated during the last decade (Fig. 35-5; *see* Table 35-8). None of these markers has been used as a routine clinical test. New markers would be particularly desirable for the distinction of follicular adenomas and follicular carcinomas, two entities that cannot be discriminated by cytology.

CLONAL ANALYSIS Clonal analysis was performed in thyroid nodules, adenomas and cancers with the X-inactivation technique in females. Studies on clonality of thyroid neoplasms revealed that most thyroid nodules are monoclonal in origin, i.e., true adenomas. In multinodular goiters, polyclonal nodules coexist with nodules of monoclonal origin, and the latter may have distinct clonal origins in the same gland. As in the parathyroid gland, the diagnosis of a monoclonal lesion can often only be made with X-inactivation analysis because of marked histological heterogeneity even in monoclonal tissues. As expected, cancers are of monoclonal origin; the few reported exceptions are probably because of PTC with important amounts of stromal tissue.

Besides clonal analysis by means of the X-inactivation approach, loss of heterozygosity has been detected at multiple loci. Taken together, these results suggest that somatic mutations in growth-controlling genes or loss of tumor suppressors are involved in the development and or progression of most of these tumors.

GROWTH FACTORS AND ONCOGENES Studies on expression of growth factors and their receptors at the mRNA and protein level reported partially contradicting observations and it is difficult to draw definite conclusions concerning their exact role in the development of thyroid malignancies. Many of these proteins

are abnormally expressed in benign and malignant thyroid tumors. In part, these alterations are secondary events because no structural abnormalities could be detected in the involved genes or the respective chromosomal location.

Amplification of the *MET* gene, encoding a heterodimeric tyrosine kinase whose ligand is the hepatic growth factor, has been reported in 70% of PTC and undifferentiated thyroid cancer, and in 25% of FTC; it was associated with aggressive clinical and histological phenotype. MET oncogene amplification has also been reported in a number of gastrointestinal, hepatocelllular, meningeal, and neuronal carcinomas. The abundance of transcripts for the transcription factor c-*myc* increases in less differentiated thyroid tumors and c-*myc* mRNA correlated negatively with that of the TSH receptor in one study.

Somatic mutations in oncogenes and or loss of tumor suppressors may result in loss of growth control and have been identified in several genes in benign and malignant thyroid tumors. Analogous to mutations in the α-subunit of Gs, mutations in the RAS oncogene can lead to a reduction of the guanosine 5′-triphosphatase activity resulting in continuous activation of the protein. Mutations in the three *RAS* genes, Ha-RAS, K-RAS, and N-RAS, which encode closely related 21-kDa proteins involved in signal transduction, have been found in numerous human tumors. The most frequently mutated codons are 12, 13, and 61 (corresponding to residue 227 of Gsα). Although mutations have been detected in both benign and malignant thyroid tumors in all three RAS genes, there is considerable variation in the reported prevalence of these mutations among several studies. The prevalence of activating mutations of all three RAS genes is higher in follicular adenomas and carcinomas than in PTC, suggesting that the different histological entities develop in response to distinct oncogenic pathways.

Somatic gsp mutations, activating mutations in the α subunit of the stimulatory G protein, occur in up to 38% of toxic adenomas (*see* above), but are relatively uncommon in PTC and FTC. Some of the amino acid substitutions at arginine 201 and glutamine 227, the most frequently involved residues, are rather unusual in differentiated carcinomas. As for other mutations in oncogenes, for example, RAS, the reported frequency is highly variable.

RET is a transmembrane tyrosine kinase for several ligands, among them glial cell-derived neurotropic growth factor, and is involved in neuronal differentiation. It is made up of five domains: a cadherin-like extracellular domain, a cysteine-rich domain involved in dimerization, a transmembrane domain and two intracellular tyrosine kinase domains. Normally, the RET protooncogene is not expressed in thyroid follicular cells but it is found in C-cells. Point mutations in the *RET* gene are at the onset of the MEN2 syndromes and familial medullary thyroid cancer (FMTC) (*see* FMTC and MEN2).

Rearrangements of the RET locus were detected after the observation of structural alterations in chromosome 10 in PTC and are referred to as RET/PTC rearrangements. There are several distinct types of translocations. A breakpoint in intron 11 upstream of the tyrosine kinase domains places different promoters upstream of the respective sequences. The tyrosine kinase domains are thereby under control of constitutive promoters resulting in continuous activity. RET/PTC1 is defined by a paracentric inversion of the long arm of chromosome 10 [inv(10)q11.2q21] recognized by the probe H4 (D10S170). RET/PTC2 is a recombination between chromosomes 10 and 17 [t(10;17)(q11.2;q23)] placing the R1α regulatory subunit of protein kinase A upstream of the RET tyrosine kinase domains. The RET/PTC3 rearrangement puts the *ELE1* gene of chromosome 10, which is capable of transforming fibroblasts, adjacent to the tyrosine kinase sequences. RET/PTC rearrangements occur in approx 10–40% of all PTC. Some studies suggest a higher incidence of local invasion and distant metastases in PTC with RET/PTC rearrangements. RET rearrangements are particularly common in pediatric PTC; in children developing PTC as a consequence of the nuclear accident of Chernobyl, the incidence is even higher. PTC is frequently multicentric. Molecular analyses suggest that the tumor foci develop independently given that they often harbor distinct RET/PTC rearrangements. This could be explained by widespread DNA damage or, alternatively, genetic susceptibility, for example, associated with defects in DNA repair enzymes. Remarkably, RET/PTC rearrangements are not limited to PTC and are also found in Hürthle cell adenomas and carcinomas. This led to the reclassification of Hürthle cell tumors as variants of papillary carcinoma, a controversial concept.
