Furthermore, inactivating mutations of tumor suppressor genes including p53, $p19^{ARF}$, ATM, ChK2, and Rb also prevent cell-cycle inhibition and promote survival of cancer cells. Of particular note, p53 apparently can play a dual role in regulating apoptosis. Although an inactivating mutation of p53 not only inhibits its transcriptional activity and upregulation of proapoptotic genes like BAX, NOXA, PUMA, it may also block its newly described function to directly bind and prevent Bcl_{XL} (or BCL-2) from neutralizing BAX's proapoptotic activity.

Moreover, mutations in transcriptional silencing of some of the positive regulators of the extrinsic (e.g., FAS Antigen/CD95, TRAIL-R1/R2, or proCaspase 8) or intrinsic (e.g., Apaf-1) apoptotic pathways have been reported in various cancers. Therefore, therapeutic targeting with the intent of inhibiting these proapoptotic regulators has the potential for enhancing cell death in cancer cells. This concept represents an active field of research among oncologists and has the potential to add a therapeutic approach to the anticancer armamentarium.

Finally, patients with a heterozygous mutation in the FAS antigen or those with initiator caspase-10 deficiency may develop an autoimmune lymphoproliferative syndrome characterized by ineffective lymphocyte apoptosis. In addition, mutation of caspase-8, another initiator caspase, can result in autoimmunity characterized by a developmental immunodeficiency resulting from defects in T-, B-, and NK-cell activation.

APOPTOSIS IN NONMALIGNANT DISEASES Neurodegenerative disorders, including Alzheimer's, Parkinson's, Huntington's, and the prion disease, scrapie, represent diseases in which inappropriately enhanced apoptosis has been observed and may be causative. For example, in Alzheimer's and Huntington's disease, failure of proper folding of proteins within the endoplasmic reticulum that results from defects in chaperone protein partner binding, appears to lead to a misfolded or "unfolded" protein. This constitutes a form of organelle stress and stimulates the unfolded protein response, which is a normal, compensatory response leading to degradation of the misfolded products in an attempt to restore proper "protein homeostasis." However, when overwhelmed by too many "misfolded" proteins, the normal unfolded protein response may itself lead to cell damage of the endoplasmic reticulum and trigger endoplasmic reticulum-initiated apoptosis. For example, in Alzheimer's disease, neurotoxicity is associated with an abnormal accumulation of amyloid-β-peptides owing to a failure of appropriate cleavage of the normal amyloid precursor protein. This buildup results in local endoplasmic reticulum-lipid peroxidation, leads to increased Ca^{2+} release from the endoplasmic reticulum, and triggers activation of caspase-12, leading to mitochondrial dysregulation and neuronal cell death by activation of the intrinsic pathway. In Huntington's disease, a mutant Huntingtin protein fails to function normally in the formation of a clathrin complex involved in normal vesicular transport during neurotransmitter release from neurons. Malfunction of this protein appears to result in the activation of both the initiator caspase-8 and effector caspase-3 and is linked to the neurotoxic properties of mutant Huntingtin protein cleavage products. Finally, for at least one form of Parkinson's disease, the autosomal-recessive juvenile Parkinson's disease, protein homeostasis in the endoplasmic reticulum may be disrupted in a different way by utilizing the process of endoplasmic reticulum-associated protein degradation of ubiquitinated proteins by the proteosome pathway.

Activation of this pathway may result in the death of dopaminergic neurons characteristic of Parkinson's disease.

Neuronal cell death may also play a role in another neurodegenerative disorder, the prion disease scrapie. Although cellular prion protein, PrP^{c}, is ubiquitously expressed on the cell membrane as a glycosylphosphotidyl-inositol-linked glycoprotein, when misassembled into an abnormal conformer, PrP^{sc}, it is associated with prion-mediated apoptosis. Thus, although apoptosis appears to play a critical role in neurodegenerative diseases, whether it is causative or merely an effect of the disease is not clear. Nonetheless, blocking activation of caspases and apoptosis in such diseased tissues is an active strategy that, if successful, may at least slow the degenerative process.

73 Colorectal Cancer

SATYA NARAYAN

SUMMARY

Colorectal cancer is the third most common death-causing disease in the developed countries. It arises after a series of mutations in various tumor suppressor and proto-oncogenes, each of which are accompanied by specific alterations and pathological conditions. Recent advances have contributed a great deal of understanding of the molecular basis of events that lead to colorectal tumorigenesis. Mutation in the *adenomatous polyposis coli (APC)* gene is considered to be one of the earliest events in the development of colon cancer. The familial adenomatous polyposis and hereditary nonpolyposis colorectal cancer (HNPCC) are the most commonly inherited colorectal cancers. Familial adenomatous polyposis and HNPCC develop owing to mutations in *APC* and DNA mismatch repair (MMR) genes, respectively. The main functions of APC are known to regulate β-catenin protein levels through Wnt-signaling pathway, involved in cell migration and cell–cell adhesion, and chromosomal stability. Mutations in the *APC* gene disrupt the normal functioning of these pathways and thus are involved in the development of colon cancer. Colorectal cancer also develops owing to alterations in the transforming growth factor-β-signaling pathway. Mutations in the pro-apoptotic gene *Bax* is found in many colon tumors from HNPCC patients. A summary of the molecular genetics of the development of colorectal cancer is briefly discussed here.

Key Words: *Adenomatous polyposis coli*; chromosomal instability; colorectal cancer; familial adenomatous polyposis; hereditary nonpolyposis colorectal cancers; heterozygosity; microsatellite instability; mismatch repair; mutation cluster region; transforming growth factor-β.

INTRODUCTION

Prognosis of colorectal cancer depends on the tumor stage at the time of diagnosis with surgery being the most effective treatment. Colorectal cancers develop through a series of histologically distinct stages from "adenoma to carcinoma." The temporal order in which mutations occur in different genes relates to the progression through the histological stages of cancer from adenoma to carcinoma. Genes that are mutated at different stages of colorectal cancer development include tumor suppressor genes, proto-oncogenes, DNA repair genes, growth factors and their receptor genes, cell-cycle checkpoint genes, and apoptosis-related genes (Fig. 73-1). It is thought that mutations in one of these genes set the stage for initiation and transformation of the normal colonic epithelial cells. Further accumulation of mutations in other genes then contributes to the progression of cancer through the adenoma-carcinoma-metastasis stages. During accumulation of genetic changes, a complex signaling network is established among inactivated and activated cellular pathways. Many cells bearing defective signaling pathways may go through programmed cell death or apoptosis and be removed from the normal population of cells; however, one of the target cells can go through the selection process and survive among other cells by overruling cell-cycle checkpoints and abrogating apoptosis pathways. After clonal expansion, the genetically modified single cell becomes a full-grown tumor.

Many colon cancer syndromes have been characterized based on their phenotypic, histological, and genetic changes. Among them, the most common and highly studied colon cancer syndromes are familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancers (HNPCC), which are caused by mutations in the *adenomatous polyposis coli (APC)* and mismatch repair (MMR) genes, respectively. Other colon cancer syndromes include Peutz-Jeghers syndrome, juvenile polyposis syndrome, hereditary mixed polyposis syndrome, and Cowden's syndrome. These syndromes contain hamartomatous polyps and are inherited in an autosomal-dominant fashion. Mutations in serine-threonine kinase II, *STKII*, gene, Sma and Mad-related protein 4/deleted in pancreatic carcinoma 4, *Smad4/DPC4*, gene, and phosphatase and tensin homolog deleted on chromosome 10 *(pten)* gene, and *pten* gene are linked with Peutz-Jeghers syndrome, juvenile polyposis syndrome, and Cowden's syndromes, respectively. The inherited syndromes account for only 3–5% of all colon cancers, and the rest are the somatic colon cancers in which both alleles of the tumor suppressor genes are inactivated somatically. This chapter mainly discusses the functions of *apc* and *mmr* genes.

APC GENE MUTATIONS

Mutations in the *APC* gene on chromosome 5q21 locus are considered one of the earliest events in the initiation and progression of colorectal cancer. In FAP patients, allelic mutation of the *APC* gene followed by a loss of heterozygosity is a common feature. Notably, mutations in the *APC* gene also are found in 60–80% of sporadic colorectal cancers and adenomas. Patients with *APC* mutations are prone to hundreds to thousands of colorectal adenomas and early onset carcinoma. FAP patients also are prone to small intestinal adenomas (and carcinomas), intra-abdominal

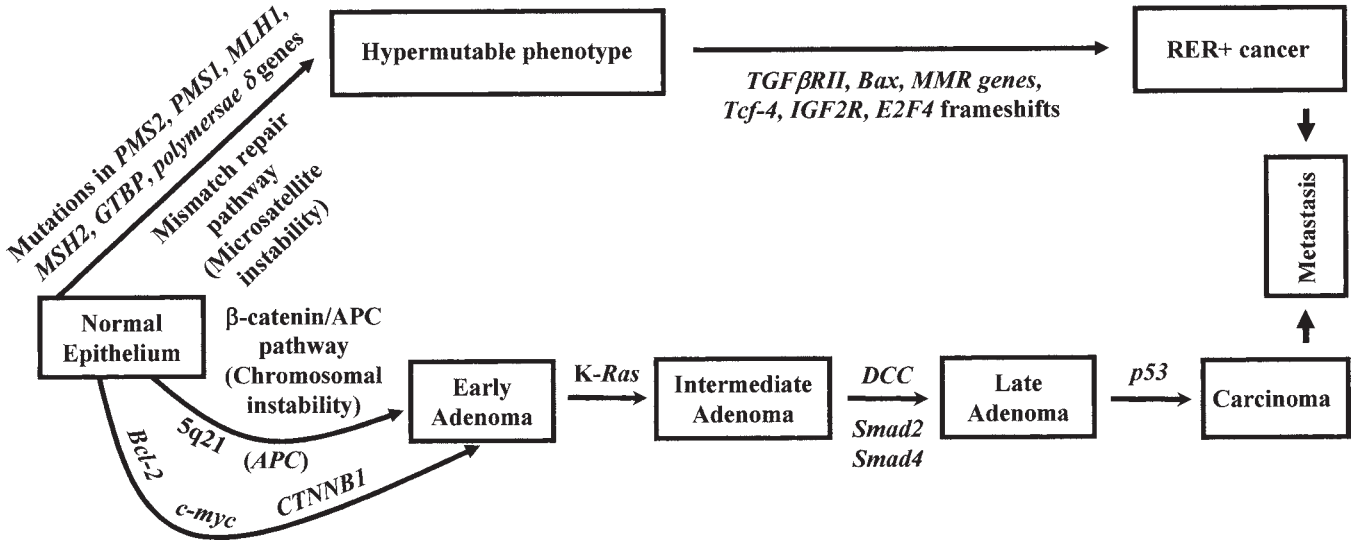

Figure 73-1 Model for genetic alterations in the development of colorectal cancer. Based on genetic analysis, at least two pathways are characterized in detail, which lead to colon cancer development. One pathway initiates with mutations in the adenomatous polyposis coli gene and CI followed by mutations in K-*ras*, deleted in colorectal cancer and *p53* genes. The second pathway is initiated by the mutations in the MMR genes and MSI followed by mutations in *TGF*β*IIR, Bax, Tcf-4, insulin-like growth factor 2 receptor,* and *E2F4* genes. Other pathways are less characterized but a high degree of overlap is expected among them. At least seven gene mutations are needed to develop a normal epithelial cell into carcinoma. However, a cluster of gene mutations is observed in carcinoma and metastatic tumors. Bcl-2, B-cell leukemia/lymphoma 2; CTNNB1, β-catenin; GTBP, G/T mismatch-binding protein; MLH1, mutL homolog1; MSH2, mutS homolog2; PMS, postmeiotic segregation increased; RER, replication error (+).

desmoids and osteomas (Gardner's syndrome), congenital hypertrophy of retinal pigment epithelium, fundic gland polyps in the stomach, pancreas and thyroid, dental abnormalities, and epidermal cysts.

APC is expressed constitutively within the normal colonic epithelium. The *APC* gene product is a 310-kDa-homodimeric protein localized in both the cytoplasm and the nucleus. The *APC* gene is inducible, which is transcriptionally upregulated by p53 in response to DNA damage. p53 is a negative regulator of normal cell growth and division. Although mutation in the *p53* gene is also widely present in colorectal cancers, its consequence on the expression of the wild-type or mutant *APC* gene is not clear. In the $Apc^{Min/+}$ (Min, multiple intestinal neoplasia) mice model, an increased multiplicity and invasiveness of intestinal adenomas is often associated with deficiency for *p53*. Also, the occurrence of desmoid fibromas in these mice was strongly enhanced by *p53* deficiency. The structure of the APC protein with different protein interaction domains is given in Fig. 73-2. At the N-terminal site, the APC protein contains oligomerization and armadillo repeat-binding domains; at the C-terminal site there are EB1 and tumor suppressor protein DLG-binding domains. APC protein also contains three 15-amino acids and seven 20-amino acids repeat regions in which the latter is involved in the negative regulation of β-catenin protein levels in cells. APC functions as a nuclear-cytoplasmic shuttling protein and as a β-catenin chaperone. There are three APC nuclear export signals located in the 20-amino acid repeat region of 3, 4, and 7. The first 20-amino acid repeat in the *APC* gene is located at the 5′-end of the mutation cluster region (MCR) and often produces truncated proteins. An association exists between severe polyposis phenotype and germline mutations in the MCR. Selective pressure for an MCR mutant has been proposed based on the germline mutation in FAP. These findings suggest that a truncation mutation in MCR is necessary for APC to lose β-catenin-binding and nuclear localization signals. These mutations produce loss of function and tumor progression.

APC REGULATION OF β-CATENIN LEVELS THROUGH Wnt-SIGNALING APC acts as a negative regulator of β-catenin signaling in the transformation of colonic epithelial cells and in melanoma progression. The role of the Wingless/Wnt signaling pathway has been described in *Drosophila*, *Xenopus*, and in vertebrates. This pathway is important in organ development, cellular proliferation, morphology, motility, and the fate of embryonic cells. In a simple model shown in Fig. 73-3, Wingless/Wnt signaling regulates the assembly of a complex consisting of axin (and its homologs Axinl and conductin), APC, β-catenin, and glycogen synthase-3β kinase (GSK3β). Axin (Axil/conductin) binds to form a complex with APC, β-catenin, and GSK3β to promote β-catenin phosphorylation and subsequent binding with slim (β-TrCP), which mediates its ubiquitination and degradation in the proteasome. GSK3β regulates this process by phosphorylating β-catenin, APC, and Axin (Axil/conductin) complex. Activation of the Wingless/Wnt signaling pathway inhibits GSK3β and stabilizes β-catenin. Mutations of β-catenin or truncation of APC, which occur both in colon cancer and melanoma cells, increases the stability and transcriptional activity of β-catenin. The stabilized pool of β-catenin associates with members of the T-cell factor (Tcf)–lymphoid enhancer factor (Lef) family of transcription factors. There are four known members of the Tcf and Lef family in mammals, one of which, the human *Tcf4* gene, is expressed specifically in colon cancer cells. The β-catenin/Tcf4 complex regulates the proto-oncogene and cell-cycle regulator *c-myc*, the G_1/S-regulating *cyclin D1*, the gene encoding the matrix-degrading metalloproteinase, *matrysin*, the AP-1 transcription factors *c-jun* and *fra-1*; and the urokinase-type plasminogen activator (uPA) receptor gene. From this discussion, it is clear that the inactivation of APC causes activation of β-catenin, which results in the constitutive activation of Tcf/Lef response genes.

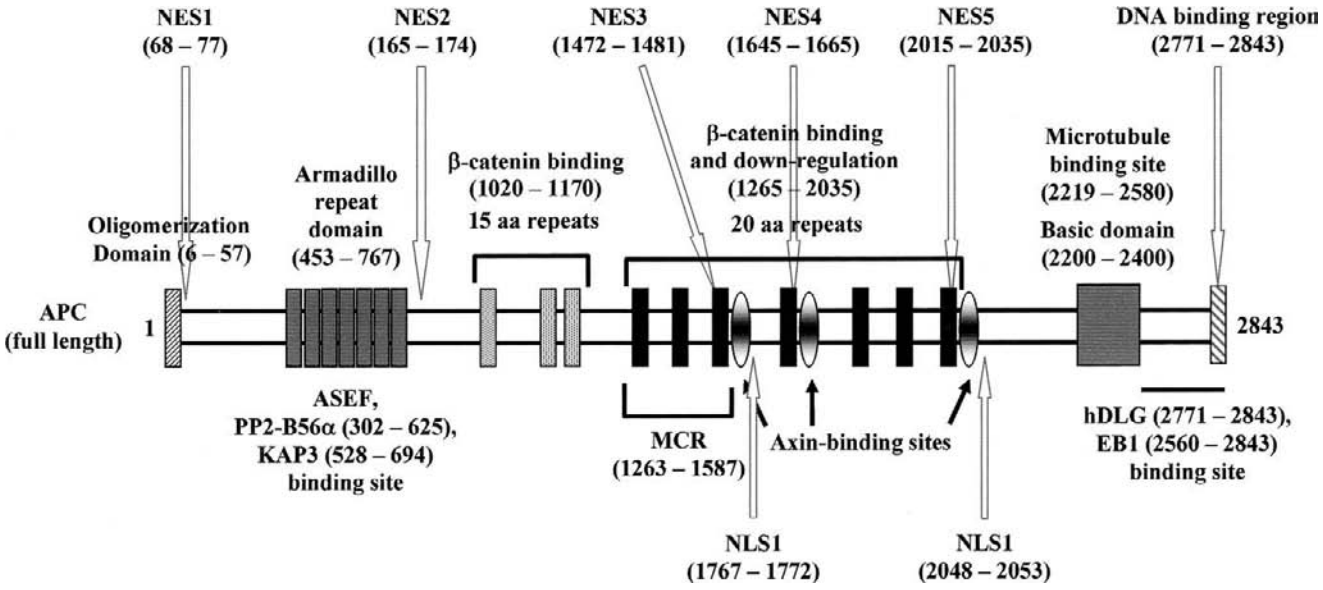

Figure 73-2 Structural features of the adenomatous polyposis coli protein. Most of the mutations in APC occur in the mutator cluster region and create truncated proteins. The truncated proteins contain APC-stimulated guanine nucleotide exchange factor and β-catenin-binding sites in the armadillo repeat domain but lose the β-catenin regulatory activity that is located in the 20-amino acids repeat domain. Somatic mutations are selected more frequently in FAP patients with germline mutations outside of the MCR. aa, amino acid; EB1, end-binding protein 1; hDLG, human disks large; KAP, kinesin superfamily associated protein; NES, nuclear export signal; NLS, nuclear localization signal; PP2-B56α, protein phosphatase 2 B56α-subunit.

In many cases colon tumors carrying mutations in the *APC* gene also carried increased levels of c-Myc, a known factor for cellular proliferation. A direct link has been established between *APC* gene mutation, β-catenin activation, and *c-myc* gene upregulation in colon cancer development. The increased expression of c-Myc through Wnt-signaling pathway upregulates the expression of *Cdk4* gene, whose product is responsible for cell-cycle regulation in G_1 phase. The *c-myc* gene encodes a transcription factor of helix-loop-helix leucine zipper family that binds as a heterodimer with Max to E boxes (CACGTG) on target promoters, for example *Cdk4* gene, and activates its expression. Max can also interact with Mad and Mxi1 and downregulate c-Myc target gene expression. It has been suggested that the increased levels of Cdk4 protein can phosphorylate pRB. The E2F/DP transcription factor then dissociates from the hyperphosphorylated pRB, which actively transcribes genes involved in cell-cycle progression through G_1 phase. It is also suggested that the increased levels of Cdk4 may sequester cell-cycle kinase inhibitor p21, p27, and p16. This sequestration may account for the ability of c-Myc overexpression to substitute for p16 deficiency as noted in mouse fibroblast transformation. Thus there is a link among *APC* gene mutation, β-catenin stabilization, *c-myc* gene activation, and Cdk4/cyclin D1/pRB/p16 pathway in colorectal cancer development.

APC INVOLVEMENT IN ACTIN CYTOSKELETAL INTEGRITY, CELL–CELL ADHESION, AND CELL MIGRATION Actin cytoskeletal integrity is necessary to maintain the shape and adherence junctions of cells. The imbalance in actin cytoskeletal integrity can cause disturbance in cell–cell adhesion and cell migration. The role of APC in actin cytoskeletal maintenance is predicted through its interaction with β-catenin. β-catenin establishes a link between APC and actin by providing a bridge to β-catenin. In *Drosophila*, mutations in E-APC affect the organization of adherence junctions. Another link of APC with actin is shown through its interaction with PDZ domain of DLG protein. Because APC colocalizes with DLG at the lateral cytoplasm in rat colon epithelial cells, the APC–DLG complex may participate in regulation of cell-cycle progression. Mutant APC lacking the S/TXV motif for DLG-binding exhibits weaker cell-cycle blocking activity at G_0/G_1 phase than the intact APC.

Interaction of APC with β-catenin and the members of the cadherin family of proteins have been implicated in cell–cell adhesion. The C-terminal domain of E-cadherin interacts with β- and γ-catenin, which associate with α-catenin and form an E-cadherin complex with actin cytoskeleton. This complex maintains the stable cell–cell adhesion. APC becomes a part of the cell–cell adhesion complex linked with E-cadherin, because it directly binds with β-catenin, γ-catenin, and actin filament. The tyrosine phosphorylation of β-catenin by epidermal growth factor, hepatocyte growth factor, and c-Met receptors is important in modulating cadherin-catenin complexes from membrane bound form to free cytosolic form. The phosphorylation of β-catenin at tyrosine residue, which is blocked by tyrosine phosphatase Pez, is involved in epithelial cell migration. If the Wnt-pathway and the epidermal growth factor receptor or c-Met receptors pathway are activated at the same time, then the degradation of β-catenin can be inhibited and it may translocate to the nucleus, bind to the Lef–Tcf transcription factor, and downregulate the transcription of E-cadherin gene, *CDH1*, expression. These complex interactions may finally result in the reduction in E-cadherin-mediated cell–cell adhesion and proliferation of cells.

Another important role for APC is in cell migration. Colonic epithelial cells, derived from a committed stem cell, divide in the lower two-thirds of the crypts and migrate rapidly to the surface to form a single layer. During migration, they differentiate into absorptive, secretory, Paneth, and endocrine cells. The function of a wild-type APC is necessary in maintaining the direction of

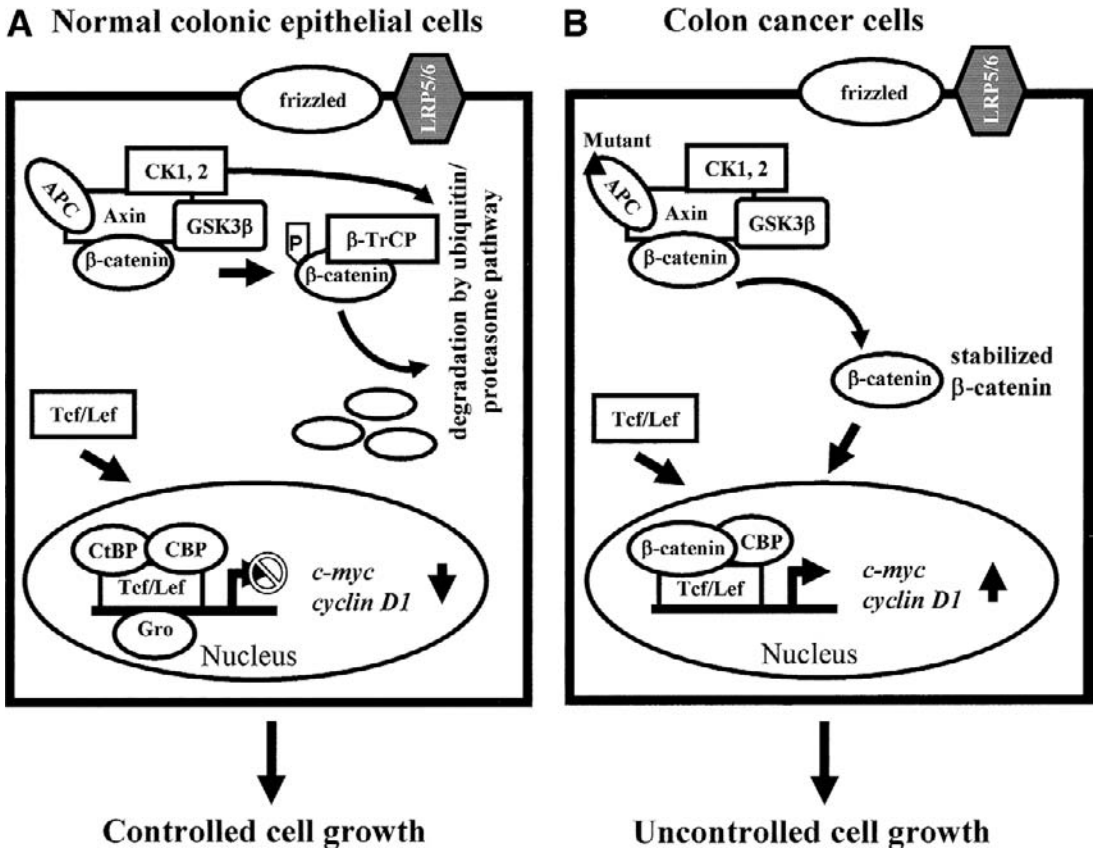

Figure 73-3 A model for the Wnt-signaling pathway. **(A)** downregulation of β-catenin transactivation activity in normal colonic epithelial cells. β-Catenin remains in a complex of Axin/Axil/conductin, adenomatous polyposis coli, GSK3β and casein kinase 1 or 2 (CK1 or 2). In the absence of Wnt-signaling, GSK3β and CK1 or 2 kinases become active and phosphorylate β-catenin at serine and threonine residues in the N-terminal domain. Axin and APC promote phosphorylation of β-catenin by acting as a scaffold protein and bringing together enzyme(s) and substrate(s). The phosphorylated β-catenin then binds with F-box protein β-transducin repeat-containing protein of the Skp1-Cullin-F-box complex of ubiquitin ligases and undergoes proteasomal degradation. Even though Tcf–Lef transcription factor without β-catenin may bind to DNA in the absence of β-catenin, the repressors and corepressors such as carboxy-terminal-binding protein, CREB-binding protein, Groucho, and LDL receptor-related protein bind with Tcf–Lef and repress *c-myc* or *cyclin D1* gene expression to control cell-cycle progression. Some other known genes that are regulated by β-catenin/Tcf–Lef pathway include *Cyclin D1, CDH1, Tcf-1, c-jun, Fra-1, PPARd, Gastrin, uPAR, MMP7, Conductin, CD44, Id2, Siamois, Xbra, Twin,* and *Ubx*. **(B)** The role of mutations in the APC or β-catenin protein in the regulation of β-catenin level and its transactivation property in colon cancer cells. The mutant β-catenin escapes its degradation through the Wnt-pathway and becomes stabilized in the cytoplasm. The stabilized level of β-catenin then heterodimerizes with Tcf–Lef transcription factor and moves into the nucleus, where it actively transcribes cell-cycle-related genes causing cellular proliferation. The binding of β-catenin with Tcf–Lef inhibits the binding of carboxy-terminal-binding protein, CREB-binding protein, Groucho or LDL receptor-related protein and potentiates its transcriptional activity.

upward movement of these cells along the crypt-villus axis. Loss of wild-type APC functions resulting from loss of expression or mutations affects cell migration. Instead of migrating upward toward the gut lumen, these cells migrate aberrantly or less efficiently toward the crypt base in which they accumulate and form polyps. In time, they become aneuploid because of defects in chromosome segregation as well as acquire β-catenin stabilization and activation of genes for cell proliferation. The mechanisms by which APC might be involved in cell migration can be understood by its association with the kinesin superfamily associated protein KAP3 that has been established in cell–cell adhesion and migration. APC, mediated by KAP3, interacts with kinesin motor proteins that transport it as well as β-catenin along the microtubules to the growing ends of the cytoskeleton protruding into motile cell membranes. At the tip of microtubule, APC interacts with the end-binding protein, EB1, and protein tyrosine phosphatase (PTP)-BL. PTP-BL modulates the steady state levels of tyrosine phosphorylations of APC-associated proteins such as β-catenin and GSK3β. In fact, GSK3β kinase activity has been implicated in microtubule dynamics. The mechanism by which mutated APC might play a role in the migration of colorectal tumor cells is predicted through its interaction with Rac-specific guanine nucleotide exchange factor ASEF. APC binds with ASEF and controls its activity. ASEF is activated in colorectal cancer cells containing truncated APC. Active ASEF decreases E-cadherin-mediated cell–cell adhesion and promotes cell migration. Thus, the dynamic association of APC, EB1, ASEF, catenins, EGFR or c-Met receptor, PTP-BL, and E-cadherin proteins at cell–cell adherence junctions and microtubule ends play an important role in cell–cell communication, cell migration, and carcinogenesis.

GENETIC INSTABILITY IN COLON CANCER PROGRESSION

Both sporadic and hereditary colorectal cancers exhibit a defined set of biological and genetic cell heterogeneity through a series of molecular events. Two specific pathologically distinct

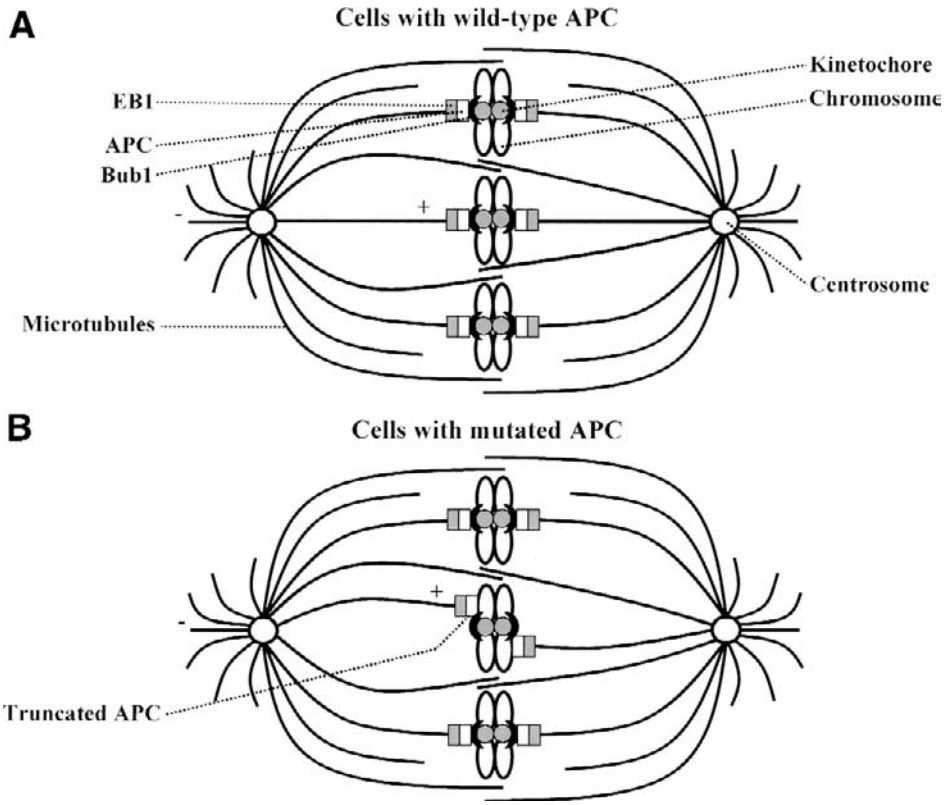

Figure 73-4 CI in cells carrying mutations in adenomatous polyposis coli gene. **(A)** A model for the interaction of APC with plus-end of microtubule through end-binding protein and with kinetochore of chromosome through budding uninhibited by benzimidazole 1 in normal colonic epithelial cells. APC can also bind microtubules directly via the C-terminal basic domain. **(B)** A disruption in the interaction between spindle microtubules and kinetochores because of expression of truncated form of APC in colon cancer cells.

genetic pathways for colorectal cancer have been identified—the chromosomal instability (CI) pathway and the microsatellite instability (MSI) pathway. The CI and MSI are associated with two major inherited syndromes, FAP and HNPCC, respectively. The MSI leads to a 1000-fold increase in the rate of subtle DNA changes, whereas CI enhances the rate at which gross chromosomal changes occur during cell division such as chromosome breaks, duplication, rearrangements, and deletions. Findings describing these two pathways are discussed below.

***APC* GENE MUTATION ASSOCIATED WITH CI** Aneuploidy, the abnormal number of chromosomes both quantitatively and qualitatively, is a common characteristic of colon cancer cells. It is thought that the aneuploidy in colon cancer cells arises during mitosis through a defective cell division leading to CI. CI is a common feature of approx 85% colorectal cancers, and it has been detected in the smallest adenoma, suggesting that CI may occur at very early stages of colorectal cancer development. The mechanism(s) by which CI is generated in colon cancer cells is largely unclear. Because the main feature of CI is aneuploidy, it has been suggested that it may arise because of structural changes to the chromosomes and abnormal mitosis. In this scenario, the wild-type APC is involved in maintaining the proper connection of microtubules with chromosomes. APC performs a bridging function between microtubules and chromosomes. APC binds at the plus end of the microtubule through EB1, stretches it to the chromosomes, and inserts them into kinetochores after binding with benzimidazole 1 (Bub1). APC colocalizes to kinetochores and forms complexes with Bub1 and Bub3, the two mitotic checkpoint proteins. The successful complex formation facilitates proper growth of spindle formation and helps in maintaining euploidy (Fig. 73-4A). Once the *APC* gene is mutated, the truncated APC protein loses its ability to bind with Bub1 and it is unable to properly maintain the attachment of microtubules at kinetochores, resulting in defect in segregation of chromosomes (Fig. 73-4B).

Another observation noted with CI was that after blocking apoptosis in either $Apc^{Min/+}$ or *Apc1638T* ES cells, the number of aberrant chromosomes were much greater than in control ES cells that were unable to undergo apoptosis. From these findings, a multiple-hit hypothesis of colorectal cancer development has been suggested. The chromosome segregation defect in colon cancer cells with mutated *APC* gene could lie dormant until an additional genetic-hit suppresses the mitotic checkpoint or the apoptosis of defective cells. In this regard, the proper functioning of the hSecurin, a protein necessary for the completion of the anaphase portion of mitosis, is critical to maintain euploidy, because the loss of hSecurin is often associated with the loss of chromosomes at a high frequency. Furthermore, telomere dysfunction promotes CI that triggered early carcinogenesis in the $Apc^{Min/+}$ $Terc^{-/-}$ mouse models, whereas telomerase activation restored genomic stability to a level permissive for tumor progression, suggesting that early and transient telomere dysfunction is a major mechanism underlying CI of human cancers. Thus, multiple factors may influence colorectal cancer development from normal epithelial cells to adenoma to carcinoma stages.

MMR GENE MUTATIONS ASSOCIATED WITH MSI MSI is characterized by the size variation of microsatellites in tumor DNA as compared to matching normal DNA because of defects in

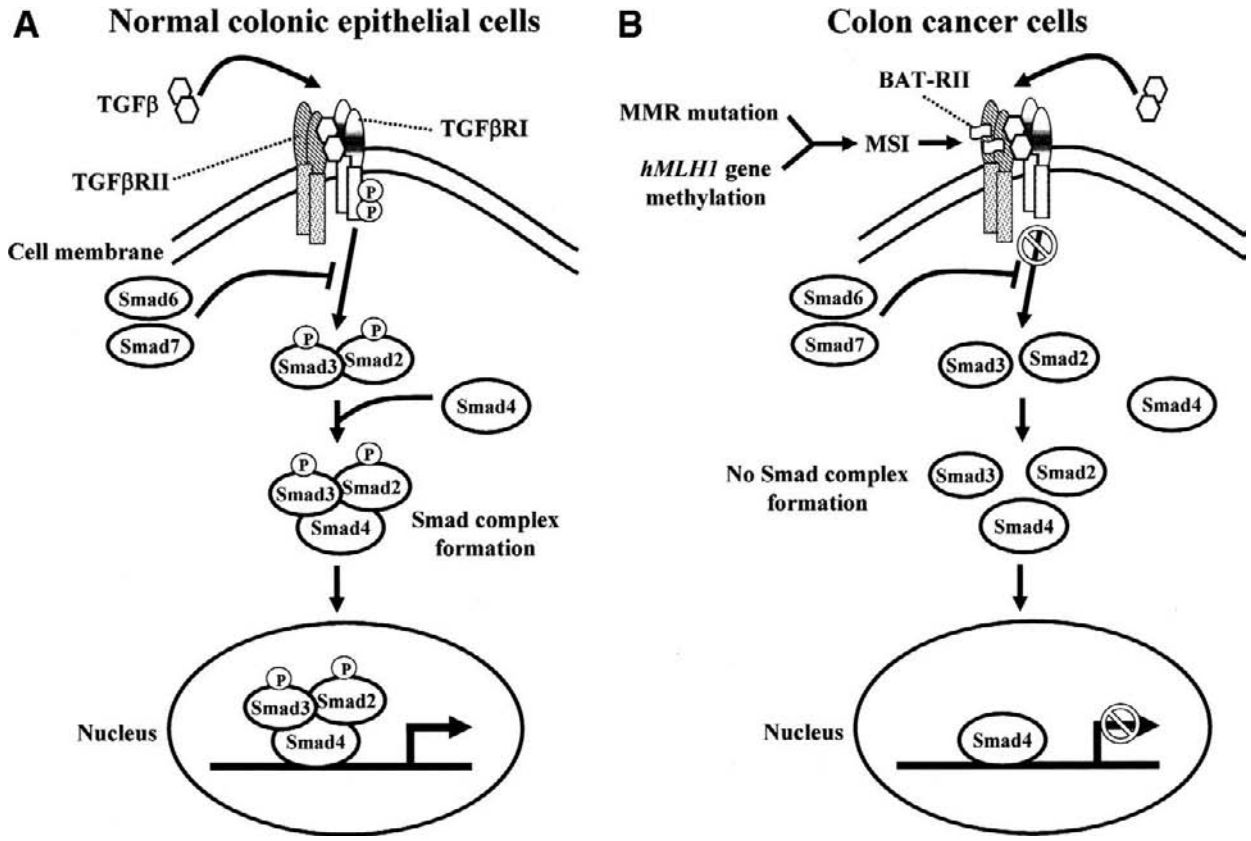

Figure 73-5 TGF-β signaling in normal colonic epithelium and cancer cells. **(A)** The functional pathway of TGF-β signaling in normal colonic epithelial cells. TGF-β ligand-binding with TGF-β receptor II recruits TGFβRI into a tetrameric receptor complex resulting in transphosphorylation and activation of TGFβRI. After phosphorylation, the TGFβRI becomes an active kinase that phosphorylates Smad2 and Smad3. Smad anchor for receptor activation (SARA), a scaffolding protein, facilitates interaction between Smad2, Smad3, and TGFβRI. Phosphorylated Smad2 and Smad3 allow the formation of homo- and heterodimerization complex, including Smad4. The Smad complex then translocates into nucleus, binds with DNA, and stimulates the expression of target genes including *p15* (inhibitor of cell-cycle kinase that controls cell cycle into G_1 phase) and *PAI-1* (inhibitor of protease 1 that degrades extracellular matrix proteins during metastasis). **(B)** The abnormal pathway of TGF-β signaling in colon cancer cells. Many colon cancer cells with MSI because of defective MMR activity induce mutations in *TGFβRII* gene. Often these are frameshift mutations that insert or delete one or two adenine bases located within a 10 bp polyadenine repeat region (base pairs 709–718, codons 125–128; referred to as BAT-RII) of *TGFβRII* gene. These mutations encode TGFβRII proteins that are truncated between 129 and 161 amino acids of the cytoplasmic domain, which causes functional inactivation of these proteins. Thus, the loss of TGF-β signaling may abolish cell-cycle control and induce metastasis of colon cancer cells by inhibiting *p15* and *PAI-1* gene expression, respectively. hMLH1, human mutL homolog1.

the MMR system. MMR system is critical for the maintenance of genomic stability. MMR increases the fidelity of DNA replication by identifying and excising single-base mismatches and insertion–deletion loops that may arise during DNA replication. Thus, the MMR system serves a DNA damage surveillance function by preventing incorrect base pairing or avoiding insertion–deletion loops by slippage of DNA polymerase. Once cells compromise with these functions, it may lead to accumulation of mutations resulting in the initiation of cancer. The MMR genes are involved in one of the most prevalent cancer syndromes in humans known as HNPCC or Lynch syndrome. HNPCC is characterized as an autosomal-dominant inherited disease with 85–90% gene penetrance for early onset of colorectal carcinoma. HNPCC accounts for approx 5–7% of cases of colorectal carcinoma. The molecular diagnosis of HNPCC is based on determining MMR genes for germline mutations. There are at least six different proteins required for the complete MMR system: hMSH2, hMLH1, hPMS1, hPMS2, hMSH3, and hMSH6 (GTBP). hMSH2 forms a heterodimer with either hMSH6 or hMSH3 (depending on the type of lesion to be repaired) and binds to the mismatch site. The complex of hMSH2 with hMSH6 is called hMutSα, and it is required for the correction of single-base mispairs. The complex of hMSH2 with hMSH3 is called hMutSβ, and it is required for the correction of insertion–deletion loops. Subsequently, a heterodimer of hMLH1 and hPMS2 proteins are recruited by hMutSα or hMutSβ proteins to the mismatch recognition complex, which with other proteins are involved in excision, resynthesis, and ligation of DNA. Mutations in the hMLH1 and hPMS2 have been found in approx 90% of HNPCC cases. Mutations in other MMR genes have been less frequent in HNPCC patients. In many sporadic colon cancers, hypermethylation of the *hMLH1* gene promoter resulting in its transcriptional silencing has been observed more than mutations. Both mutations and methylation of *hMLH1* gene have been linked with MSI playing a causal role in the initiation of colorectal cancer. The CpG island methylator phenotype pathway has been suggested as a novel mutator pathway that predisposes to colonic tumorigenesis. In many cases of the sporadic colon cancers, the MSI can be induced by CpG island methylator phenotype, followed by *hMLH1* gene's promoter methylation, loss of *hMLH1* gene expression, and resultant MMR deficiency.

Mutation rate in cells with MMR deficiency are 100- to 1000-fold greater than in normal cells. There are many targets of MMR gene inactivation; however, the precise stage of tumorigenesis in which mutation of the wild-type MMR gene occurs is not clear. There are four well-studied gene targets of MMR, whose mutations in the microsatellite region have been found in colorectal cancers carrying a mutated *hMLH1* gene. These gene targets are the transforming growth factor-β receptor-II (*TGF-II*β), insulin-like growth factor II receptor, antiapoptotic gene *Bax*, *Tcf-4*, and the cell-cycle regulator *E2F4*.

Altered TGF-β Signaling in MSI Cells In colon cancers, TGF-β signaling potently inhibits the growth of normal epithelial cells; because the tumor cells are frequently resistant to TGF-β, they cause preneoplastic lesions, increase motility and spread cancer. The structural basis for TGF-β resistance in colon cancers is defined resulting from somatic mutations that inactivate TGF-β receptor II (TGFβRII). In human colon cancer cell lines with high rates of MSI, mutations in the *TGF*β*RII* gene were found. These are primarily frameshift mutations that add or delete one or two adenine bases within or from a 10 bp polyadenine repeat in the cysteine-rich coding region (codons 125–128) of the *TGF*β*RII* gene. These mutations produce truncated proteins that lack the cytoplasmic domain. As much as 90% of the colorectal cancers with MSI have a mutated *TGF*β*RII* gene. TGFβIIR responses are connected with Smads, tumor suppressor gene products, which help to initiate TGFβ-mediated gene transcription (Fig. 73-5). The transcriptional regulation of type-1 plasminogen inhibitor (*PAI-1*) and cyclin-dependent kinase inhibitor *p15* genes are controlled by TGFβ signaling. PAI-1 is the primary inhibitor of tissue-type plasminogen activator and uPA. TGFβ inhibits cell proliferation by inducing a G_1-phase cell-cycle arrest acting through increased expression of *p15*. Thus, the loss of TGFβIIR or Smad4 can abolish TGFβ-signaling and advocate cell proliferation and development of colorectal cancer.

Mutations in Proapoptotic Gene BAX in MSI Cells Of tumors with MSI, approx 50% are found with mutations in the *Bax* gene. These mutations produce frameshift mutations within a coding region of eight nucleotide stretch of guanine residues, G_8. Bax heterodimerizes with antiapoptotic protein Bcl2 and induces apoptosis. In the presence of apoptotic signals, BH3 domain proteins tBid are activated and bound with Bax. The interaction of tBid with Bax brings conformational changes in Bax, and this promotes its translocation to the mitochondria. Bax oligomerizes and inserts into the outer mitochondrial membrane in which it forms channels to release cytochrome *c* (Cyt c) into the cytoplasm. The released Cyt c forms a complex called apoptosome with Apaf-1, dATP, and procaspase 9. The apoptosome recruits and processes procaspase 9 to form a holoenzyme complex, which in turn recruits and activates the effector caspases leading to apoptosis. Thus, the expression of mutated Bax protein may fail to release Cyt c and increase the Bax-Bcl2 ratio resulting in the escape from apoptosis and inducing initiation of colorectal carcinogenesis.

CONCLUSIONS

Development of colorectal cancer is a complex, multistep process in which several gene defects coordinate in genotypic and phenotypic outcome. Mutations in many tumor suppressor and protooncogenes in the development of sporadic and hereditary colorectal cancers are well established; however, their precise role in this process is unclear. For example, it is established that mutations in *APC* gene may be necessary for the early onset of FAP. Mutations in the *APC* gene perhaps set a stage for mutations in other genes such as K-*ras*, deleted in colorectal cancer, and *p53*. However, the mechanism(s) by which *APC* gene mutations may contribute to the accumulation of mutations in the genes associated with the colon cancer progression remain unclear. Mutations in the MMR genes can be linked to an increased rate of mutations; however, MMR negative cells develop resistance to apoptosis rather than accumulation of mutations. Thus, MMR gene mutations and their role in MSI and apoptosis need further investigation in context with apoptosis and cell-cycle-related genes. These studies will provide a better understanding of colorectal cancer development and its intervention by genetic or chemotherapeutic means.

74 Breast Cancer

Yi Huang and Nancy E. Davidson

SUMMARY

Breast cancer is the most common malignancy among Western women. Like other human cancers, breast cancer results from the accumulation of a series of genetic and/or epigenetic changes to genes with diverse functions, ultimately evolving to a malignant state. Recent scientific advances have offered many new approaches to identify and target a growing number of these genetic and epigenetic alterations in breast cancer. It is expected that this improved understanding of breast cancer biology will enhance risk assessment, prevention, diagnosis, and treatment of this disease.

Key Words: Breast cancer; breast cancer susceptibility genes; ductal carcinoma *in situ* (DCIS); endocrine therapies; epigenetic alterations; growth factor receptors; hormone regulation; hormone resistance; invasive breast cancer; oncogenes; steroid hormone receptors; tumor suppressor genes.

INTRODUCTION

Breast cancer is the most common malignancy and a leading cause of mortality in women in the Western world. More than 200,000 American women were diagnosed with breast cancer in 2004. The incidence of breast cancer varies with multiple factors including gender, age, ethnicity, family history, reproductive factors, socioeconomic class, exogenous and endogenous hormones, radiation exposure, genetic susceptibility, and so on. Like other human cancers, breast cancer is recognized as a genetic disease in that it is thought to result from a progressive accumulation of genetic changes. Initiation of breast cancer results from uncontrolled cell proliferation and/or aberrant programmed cell death as a consequence of cumulative alterations of tumor suppressor gene and/or protooncogene expression. Epigenetic changes such as DNA methylation or chromatin modeling can also contribute to modified gene expression. These changes can modulate expression of a variety of critical genes with diverse functions. Previously, the only biological factor of clinical import in breast cancer was steroid receptor expression because it has been an important predictive factor of response to endocrine therapy. But over the last two decades, enormous advances have been made in the understanding of breast cancer at the molecular level. This understanding has revealed a large number of new targets that may play a role as risk, prognostic, or predictive factors and/or aid in the development of new effective therapies of breast cancer.

BREAST CANCER PATHOLOGY AND DEVELOPMENT

The natural history of breast cancer involves a sequential progression of epithelial changes. Epithelial hyperplasia may be one of the first steps in breast carcinoma development. Hyperplasia without atypia (also termed usual or typical hyperplasia) is characterized by myoepithelial and epithelial growth, resulting in increased cellularity of the terminal duct lobular unit. Atypical ductal hyperplasia is associated with an increased risk of breast cancer progression and could represent the next step toward breast carcinoma. Ductal carcinoma *in situ* (DCIS) is a malignant proliferation of a subgroup of epithelial cells without invasion through basement membrane into stroma. DCIS is thought to be a precursor of invasive ductal carcinoma in some cases. Different histological patterns of DCIS have been described and differences in biological behavior have been ascribed to these patterns. For example, comedo DCIS is generally a high-grade lesion characterized by clusters of large epithelial cells with central necrosis, reflecting cell death because of the deprivation of essential metabolites, and is thought to be associated with poorer outcome. The noncomedo DCIS, like cribriform and micropapillary DCIS, are usually low grade with a relatively low mitotic rate. Histological grade is judged to be a more important determinant of outcome than the particular pattern of DCIS. In some cases, extended growth of DCIS into a breast lobule makes it difficult to distinguish DCIS from lobular carcinoma *in situ* (LCIS), a neoplastic proliferation of epithelial cells in the terminal duct lobular unit. In contrast to DCIS, cells of LCIS are usually regular with small, rounded nuclei and defined border. LCIS is felt to be a marker for the propensity to develop invasive breast cancer in the future.

Accumulated genetic changes combined with other factors may lead to the development of invasive carcinoma. Infiltrating duct carcinomas are the most common type of invasive breast cancer, accounting for 60–80% of all breast cancers. The second most common type of invasive breast cancer (approx 10% of breast cancers) is invasive lobular carcinoma. Classic lobular carcinoma cells are small with rounded nuclei and dense chromatin. Generally, lobular carcinoma has slightly better overall survival rate than ductal tumors. Medullary carcinoma, comprising 5–7% of breast malignancies, is a circumscribed entity with extensive infiltration of lymphocytes and plasma cells. Other types of uncommon invasive breast carcinomas include tubular, adenoid cystic, mucinous, papillary, and metaplastic carcinomas. A hallmark of all invasive breast carcinomas is disruption of the basement membrane, which suggests that cancer cells

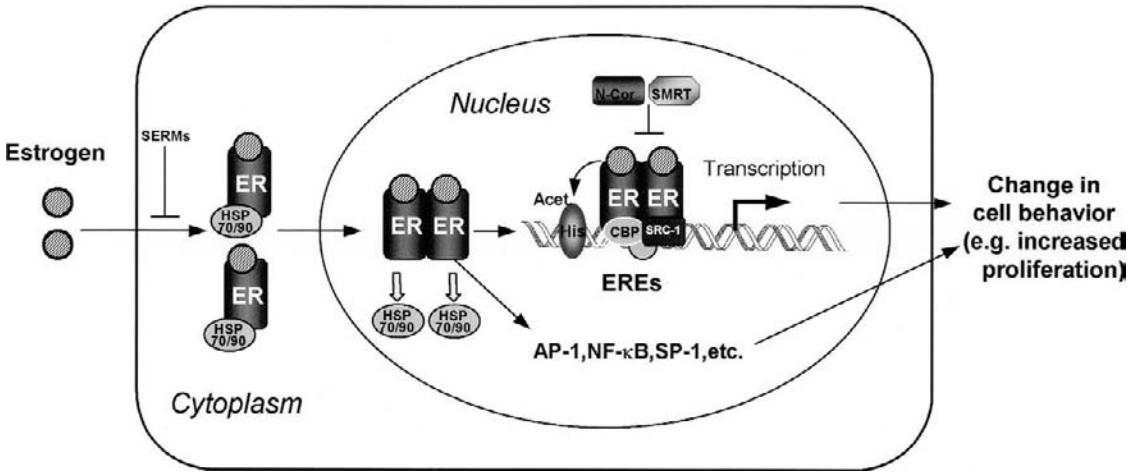

Figure 74-1 Mechanisms of ligand-dependent activation of ERs. Binding of agonist to ER complex can induce ER-conformational change, which results in the disassociation of chaperones (hsp90 or hsp70) and ER dimerization. Coactivators of ER such as steroid receptor coactivator-1 and CREB-binding protein can form a complex with receptor dimers, which in turn binds to EREs of target genes. The coactivator complex activates gene transcription via interaction with basal transcription factors and stimulation of histone (His) acetylation (Acet.). ER corepressors N-Cor and silencing mediator of retinoid and thyroid receptors can suppress transcription of ER target genes by interacting with ER dimers and forming a complex with histone deacetylase. Ligand-bound ER may also activate genes without EREs ("nonclassic" activation) via the interaction of ER with other transcription factors such as activating protein-1 (AP-1) NF-κB, or SP1, which subsequently activates target genes that do not contain EREs but encompass specific binding sites for AP-1, NF-κB, or SP1. ER-mediated gene expression usually promotes the breast cell proliferation that may ultimately lead to breast tumorigenesis. Selective ER modulators can selectively inhibit the ligand–receptor interaction, thereby preventing estrogen molecules from binding to these receptors. CBP, CREB-binding protein; HSP, heat shock protein; N-CoR, nuclear receptor corepressor.

may have acquired the ability to metastasize to distant sites. Metastatic tumors can become fatal when they disrupt the function of vital organs.

HORMONE REGULATION

ESTROGEN RECEPTOR Estrogen receptors (ER) are members of the steroid receptor superfamily. Two isoforms of ER (ERα and ERβ) have been identified. Although ERα and ERβ have only 30% overall sequence similarity, their DNA-binding and ligand-binding domains are highly homologous, suggesting that the two receptors likely share similar ligands and DNA-binding activity. Most of the knowledge about ER activity and function in breast cancer has been obtained from studies on ERα; much less is known about ERβ.

The ER is a nuclear transcription factor that regulates the expression of a number of genes involved in regulation of cell proliferation and differentiation. Binding of a ligand to ER results in a ligand–ER complex that subsequently induces an ER-conformational change, disassociation of chaperones such as hsp90 or hsp70, and receptor dimerization (Fig. 74-1). Activated ER dimers can bind to the estrogen response elements (EREs) of target genes and regulate their transcription. Some nuclear proteins interact with ER and function as coactivators or corepressors of ER. Identified coactivators include SRC-1, SRC-2, SRC-3 (AIB-1), CREB-binding protein/p300, TRIP-1, TIF-2, and others. N-Cor and silencing mediator of retinoid and thyroid receptors are corepressors that can interact with ER and inhibit ER-activated transcription. Coactivators may either directly acetylate histones or recruit other molecules containing such activity, whereas corepressors have the opposite function by forming complexes with histone deacetylases (HDACs). Ligand-bound ER may also activate genes without EREs in their promoter region ("nonclassic" activation). In that situation, ligand binding to ER leads to its interaction with other transcription factors such as AP-1, nuclear factor (NF)-κB, or SP1, which subsequently activate target genes that do not contain EREs but rather encompass specific binding sites for AP-1, NF-κB, or SP1. Finally, some signaling in the estrogen pathway may take place through the membrane.

Because of the pivotal role that ER plays in breast cancer progression, development of specific agents targeting ER or its ligands has become an important strategy for breast cancer treatment. Applied endocrine therapies include depletion of the ligand, estrogen, (by oophorectomy or luteinizing hormone releasing hormone analogs in premenopausal women or aromatase inhibitors in postmenopausal women), steroidal antiestrogens that destroy ER such as fulvestrant (also known as ICI 182,780), and selective ER modulators (SERMs) like tamoxifen. SERMs selectively stimulate or inhibit the ER in different target tissues. A SERM may interfere with ER activity in breast cells but activate the ER in other target tissues like uterus, bone, and liver. The most widely used SERM is tamoxifen, which can selectively inhibit the ligand–ER interaction in breast, thereby preventing estrogen molecules from binding to these receptors. But unlike estrogen, the binding of tamoxifen to ER does not cause the ER to acquire the altered conformation that allows it to bind properly to coactivators. As a result, ER target genes that stimulate cell proliferation cannot be activated. Most studies show that early-stage breast cancer patients with ER-expressing tumors benefit from tamoxifen treatment with longer disease-free and overall survival. However, tamoxifen has no obvious impact on the outcome of ER-poor tumors. Thus assessment of ER status in breast cancer patients has been of major utility to predict the potential response to hormonal therapy.

Unfortunately *de novo* or acquired hormone resistance is a feature of some breast cancers. Approximately 30% of breast cancers lack ER-gene expression (ER-negative). Tumors lacking ER protein are usually associated with higher growth rate, poorer differentiation, and worse clinical outcome. Thus, ER expression has been a possible prognostic factor for early breast cancer patients. Genetic changes that could account for the loss of ER in breast cancer include

deletions, insertions, point mutations, or rearrangements of ER gene. However, these alterations do not occur frequently enough to explain the loss of ER expression in a substantial fraction of breast cancers. As discussed later, inactivation of ER-gene expression may result from hypermethylation of the ER-CpG island in promoter region or other epigenetic mechanisms. Support for this possibility comes from in vitro studies showing re-expression of the ER gene in ER-negative human breast cancer cell lines by using inhibitors of DNA methyltransferase or HDAC. In addition, studies using sensitive PCR-based assays have shown that CpG island methylation is a common feature of primary breast cancers that lack ER-protein expression by immunohistochemistry and ligand-binding assays. A number of mechanisms may account for hormone resistance in the presence of ER: a shift to dependence on other growth regulatory pathways, inappropriate balance of coactivators and corepressors, or other defects in the ER-transcriptional pathway.

PROGESTERONE RECEPTOR The progesterone receptor (PR) gene also belongs to the nuclear receptor superfamily. Two isoforms of PR, PRA, and PRB, arise from two different transcription initiation sites within the same gene. Like ER, PR can also bind to ligand and target DNA to function as a transcription factor. About half of ER-positive tumors are reported to express both ER and PR genes (ER-positive/PR-positive) and these tumors are more differentiated and more responsive to hormonal therapy. About 25–30% of primary breast tumors are negative for both ER and PR. These tumors are generally associated with poorer differentiation and worse clinical outcome than ER-positive/PR-positive tumors (Table 74-1). Clinical trials have confirmed the value of PR gene expression in predicting the response of breast tumors to hormonal therapy. Elevated PR levels significantly correlate with increased response to tamoxifen in patients with ER-positive metastatic breast cancer. In ER-negative/PR-positive tumors, response to hormonal therapy is commonly observed, although responses are not as frequent as with tumors expressing both ER and PR (Table 74-1). As the ER gene is a critical regulator of PR expression, loss of ER or abrogation of the ER pathway is one mechanism for loss of PR expression. As with ER, the inactivation of PR gene in some breast tumors may also be a consequence of genetic changes or epigenetic modifications like CpG island methylation in the PR promoter region. The mechanism of methylation is of potential interest in accounting for the differential loss of PR in ER-positive/PR-negative phenotype.

Table 74-1
Frequency of ER and PR Expression in Breast Cancer and Response to Hormonal Therapy

Tumor phenotype	*Frequency of phenotype*	*Response rate to hormonal therapy*
ER+/PR+	40%	75–80%
ER+/PR–	30%	20–30%
ER–/PR+	Less than 5%	40–50%
ER–/PR–	25–30%	Less than 10%

ONCOGENES AND GROWTH FACTOR RECEPTORS

The identification of alterations to a number of protooncogenes and growth factor receptors in breast carcinoma has highlighted a number of signal transduction cascades that have important roles in normal mammary growth and mammary tumorigenesis.

THE HER FAMILY The members of the *erb*-B/epidermal growth factor receptor (EGFR)/class I family of receptor tyrosine kinases include HER1 (EGFR/*c-erb*-B1), HER2 (*c-erb*-B2/neu), HER3 (*c-erb*-B3), and HER4 (*c-erb*-B4) and share significant sequence homology to each other. HER2/*neu* has emerged as one of the most important oncogenes in breast cancer. The molecular mechanisms by which overexpression of HER2/*neu* induces cell transformation are not completely understood but may involve the formation of heterodimers of HER2/*neu* with other members of HER family and subsequent activation of several signaling pathways leading to cell proliferation. Although various ligands with selectivity for one of the HER receptors have been recognized, no ligand has been identified that directly binds to HER2/*neu*. The major HER2/*neu* activated signaling pathways are summarized in Fig. 74-2. Several downstream substrates such as the adaptor molecules, Grb2, and/or Shc, can complex with activated HER dimer via src homology-2 domains. Interaction between the guanine-nucleotide exchange factor, son of sevenless, and Shc/grb2 catalyzes the activation of the ras-GTP complex that subsequently activates the serine-threonine kinase *Raf-1* and mitogen-activated protein kinase (MAPK) pathways. HER2/HER3 heterodimer can phosphorylate and activate the p85 unit of phosphoinositide 3-kinase (PI3K), an important enzyme for generation of an intracellular second message. MAPK and PI3K activation by HER2/*neu* leads to enhanced cell proliferation through the activation of a number of nuclear targets, including c-fos, c-jun, c-*myc*, cyclin D1, and so on. The direct activation of phospholipase C-γ (PLC-γ) by HER2/*neu* also appears to mediate the transforming potential of HER2/*neu* although the exact role of PLC-γ is not clear. The induced activity of these pathways may reflect the most important cellular effects of HER2/*neu* receptor activation in breast cancer cells.

Amplification of the HER2/*neu* gene occurs in approx 20–30% breast carcinomas. Since the first report in 1987 of the correlation of HER2/*neu* gene amplification with poorer clinical outcome in a multivariate analysis in node-positive breast cancer patients, a number of prognostic studies have given mixed results on this finding. Others have addressed the possibility that HER2 overexpression correlates with absence of ER expression or tamoxifen resistance in an ER-expressing tumor. A possible mechanism for the latter is that HER2/*neu* overexpression can upregulate MAPK. MAPK then phosphorylates ER, leading to ligand-independent activation of ER and loss of the inhibitory effect of tamoxifen on ER-mediated transcription. These findings imply a role for HER2/*neu* overexpression as a potential predictive marker for hormone therapy and suggest that the possible utility of combinations of anti-HER2/*neu* and endocrine therapy in clinical practice.

Increasing attention has been given to the HER2/*neu* receptor as a direct therapeutic target in breast cancer overexpressing HER2/*neu*. One such approach, use of the anti-HER2 monoclonal antibody, trastuzamab, is effective in the treatment of HER2-positive metastatic breast cancer. Trastuzamab can inhibit both PI3K and MAPK activation induced by HER2/*neu* and arrest cells at G_1 phase. Preclinical and clinical studies suggest that the combination of trastuzamab with certain chemotherapeutic agents such as paclitaxel may significantly improve the therapeutic efficacy over chemotherapy alone.

Other studies have focused on the role of the EGFR/HER1 gene in breast cancer. HER1 overexpression is associated with loss of ER expression and, like HER2/*neu*, HER1 expression may

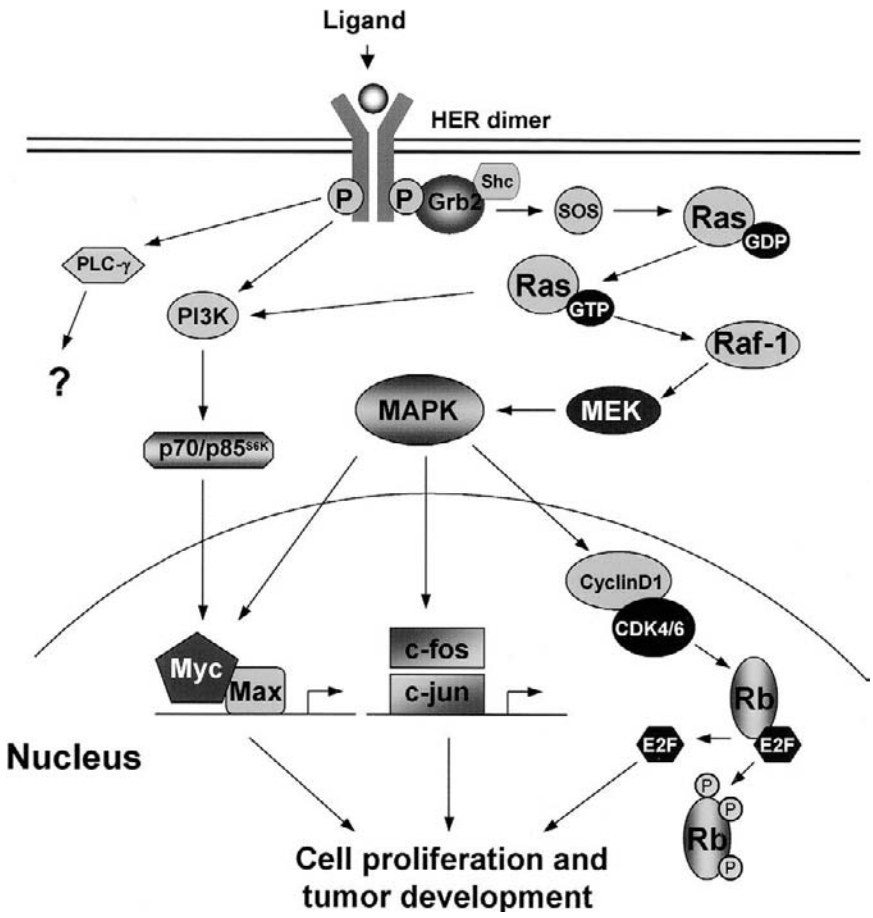

Figure 74-2 The major signal transduction pathways activated by HER2/*neu* heterodimers. Ligand induction of HER2/*neu*-containing dimerization induces phosphorylation on specific tyrosine residues in the C-terminus of the dimer. Downstream signaling substrates grb2 and/or Shc can complex with activated receptor tyrosine kinases via src homology-2 domains. Interaction between SOS and Shc/grb2 catalyzes the activation of ras-GTP complex. Subsequent activation of *Raf-1* and MAP kinase pathways by ras leads to cell proliferation and breast tumor progression through activation of a number of nuclear targets, including *c-fos*, *c-jun*, *myc*, cyclin D1, E2F, and so on. Another pathway is the PI3K, whose activation results in increased pro-survival signals. In addition, PLC-γ mediates the transforming potential of HER2 via uncertain pathways. CDK, cyclin-dependent kinase; HER, Hercgulin; MEK, MAPK/ERK kinase; Rb, retinoblastoma protein; P, phosphate; PI3K, phosphoinositide 3-kinase; SOS, son of sevenless.

also be associated with endocrine resistance. Attempts to target HER1 by the small molecule tyrosine kinase inhibitor, gefitinib, have shown modest effects in heavily pretreated advanced breast cancer patients. Combined approaches with trastuzamab, endocrine therapy, or cytotoxics are under evaluation.

C-MYC The proto-oncogene c-*myc* belongs to the *myc* gene family that also includes B-*myc*, L-*myc*, N-*myc*, and S-*myc*. c-*myc* is a nuclear transcription factor that, when dimerized with Max, binds to a specific DNA sequence in the promoter region of target genes that are involved in regulating cell proliferation and apoptosis. Cell transformation may occur when c-*myc* is aberrantly expressed or genetically altered.

c-*myc* amplification has been found in approx 20% of primary human breast cancers and occurs more frequently in tumors that lack ER and/or PR expression. The transformation of normal cells by c-*myc* generally requires the coactivation and/or amplification of other important oncogenes like HER2/*neu*, cyclin D1 gene (*ccnd1*), and *ras*, and so on. The tumor suppressor *BRCA1* can also physically interact with c-*myc* and repress c-*myc*-mediated transcription. However, loss of p53 in breast cells seems to have negligible effect on c-*myc*-induced mammary carcinogenesis. Although several studies have indicated a relationship between c-*myc* gene amplification and poor prognosis, other studies did not find such a correlation. This may reflect complex and differential effects of c-*myc* on different proteins and signaling pathways that may ultimately have divergent, even opposite functions.

RAS The *Ras* proto-oncogene family, including the N-, H- and K-*Ras* genes, encodes small GTP binding proteins that regulate many cellular processes, including proliferation, differentiation, cytoskeleton organization, and membrane trafficking. The *Ras* protein interacts with a variety of factors, including *Raf*, PI3-kinase, and Ral-GDS and can activate several important proproliferation pathways like MEK/Erk, Akt/PKB, and so on. The role of *Ras* genes in human breast carcinogenesis is not completely clear. Although alteration of *Ras* gene expression has been reported to be associated with aggressive features of breast carcinoma, the incidence of significant *Ras* oncogenic mutations in human breast cancer is rare. Increased *Ras* activity in breast cancer cells has also been reported to occur through HER2/*neu* signaling mediation. Expression of activated *Ras* in ER-positive breast cancer cells results in increased estrogen-independent growth of cells in vitro. This might be caused by *Ras*-induced Erk activity and the

activation of Erk-regulated ER coactivator, AIB1. *Ras* signaling is a potential target in breast cancer treatment as *Ras* protein processing farnesyltransferase inhibitors inhibit growth of breast tumor cells in vitro and are under evaluation in advanced breast cancer clinical trials.

CYCLIN D1 Cyclin D1 protein is encoded by *CCND1* gene and was first implicated in tumorigenesis following localization to chromosome 11q13, a region that is commonly amplified in human breast cancer. Cyclin D1, complexed with either cyclin-dependent kinase (CDK)4 or CDK6, controls cell cycle progression in the G1 phase by enabling the enzymes to phosphorylate retinoblastoma protein (Rb), a pivotal factor in cell-cycle regulation (*see* Fig. 74-2). Knockout studies have shown the important role of cyclin D1 in normal mammary gland physiology. Overexpression of *CCND1* gene has been found in approx 50% of human mammary carcinomas. Preliminary studies on primary breast cancers indicate that lobular carcinomas universally overexpress *CCND1*, whereas overexpression in ductal carcinomas is confined to ER-positive cases.

TUMOR SUPPRESSOR GENES AND BREAST CANCER SUSCEPTIBILITY GENES

Although activation of oncogenes is accepted as one essential mechanism to transform normal breast cells, it is clear that inactivation or alteration of tumor suppressor genes may also play an important role in breast cancer progression. Dozens of tumor suppressor genes have been identified and the investigation into the function of tumor suppressor genes in breast cancer has provided invaluable information.

p53 The most commonly mutated tumor suppressor gene in human tumors is p53. Wild-type p53 functions to maintain the genomic stability and has been called "guardian of the genome." When DNA damage occurs, p53 acts as a cell-cycle checkpoint to arrest the cells in the G_1 phase for damage repair or to eliminate the damaged cells by triggering apoptotic pathways. Several independent pathways activate p53 under certain circumstances, including an ataxia-telangectasia mutated/human homolog of the Rad53 (Chk2)-dependent pathway activated by DNA double-strand breaks, an INK4 and $p14^{ARF}$ dependent pathway, and a pathway activated by ultraviolet light or cytotoxic antitumor agents. Increased protein levels and DNA binding affinity of p53 may be caused by reduced mouse double minute 2-dependent proteolytic degradation.

Involvement of p53 in breast cancer development was first reported when germline mutations in this gene were revealed to be responsible for Li–Fraumeni syndrome, a hereditary cancer syndrome that includes elevated risk of breast cancer. This clinical finding implies an important role for p53 in mammary carcinogenesis. However, comprehensive meta-analysis showed that only approx 20% of primary breast cancers express mutant p53 protein. Although loss of heterozygosity (LOH) in the p53 gene is a common phenomenon in primary breast cancer, the majority of cases with LOH retain one wild-type p53 allele. Several studies indicate that p53 mutations are rare in low-grade DCIS, but more frequent in high-grade DCIS. An increased rate of p53 mutations has been observed in cancers with germline *BRCA1/BRCA2* mutations, suggesting that the distribution and type of p53 changes may be affected by *BRCA1/BRCA2* status in breast cancer. Moreover, certain types of breast carcinoma like typical medullary carcinoma are associated with higher frequencies of p53 mutation.

Many studies support the prognostic significance of p53 mutations in breast cancer. There is evidence that tumors with missense p53 mutations affecting amino acids critical for DNA binding are associated with very aggressive phenotype and a short survival, whereas null mutations or other kinds of missense mutation display an intermediate clinical phenotype. Preclinical studies also suggest that analysis of p53 mutation status can provide valuable information to predict the response to DNA damaging chemotherapeutic drugs in breast cancer patients. It is hoped that molecular analysis of specific components in p53 signaling pathway may ultimately provide greater impact on the diagnosis, prognostication, and selection of optimal treatment for breast cancer patients.

RETINOBLASTOMA GENE The Rb gene, the classic example of a tumor suppressor gene, is located on chromosomal band 13q14 and encodes for a 105 kDa protein. Hyperphosphorylation of Rb by cyclin-dependent kinases allows cells to progress from G_1 to S-phase. Unphosphorylated Rb restricts cell-cycle progression in G_1 by interacting with various proteins including the growth-stimulatory protein, E2F. Loss of Rb activity has been implicated in breast cancer progression. Structural abnormalities of the Rb gene including chromosomal loss and mutations have been reported in approx 20–30% of breast cancers. Other mechanisms like methylation of the Rb promoter may also result in down-regulation of Rb gene expression. Estrogen may not only lead to the phosphorylation of Rb but also increase Rb mRNA and protein levels in estrogen-dependent breast cancer cells, suggesting that regulation of Rb by estrogen may contribute to breast tumorigenesis.

BRCA1/BRCA2 It has been estimated that 5–10% of all breast cancers are linked to hereditary genetic predisposition. In the early 1990s, two breast cancer susceptibility genes, *BRCA1* and *BRCA2*, were identified. Germline mutation of either of these two genes followed by somatic inactivation of the remaining wild type allele may lead to the cancer phenotype that accounts for some inherited breast cancer cases. Although *BRCA* mutations are rare, women who carry these mutations have a very high lifetime risk of developing breast cancer. Clinical features that imply a genetic alteration of *BRCA1* and *BRCA2* include bilateral breast cancer, breast cancer development at an unusually young age, and ovarian cancer. It is not clear why germline mutations of *BRCA1* and *BRCA2* genes, which are transmitted in an autosomal-dominant fashion, predispose particularly to breast or ovarian cancer. It is possible that other factors or exposures like reproductive factors and hormonal influences play a role.

The *BRCA1* and *BRCA2* genes are located on chromosome 17q21 and 13q12-q13, respectively. *BRCA1/2* proteins are thought to function as tumor suppressors and are involved in repair of DNA damage and maintenance of chromosome integrity. The understanding of the role of *BRCA1* and *BRCA2* in DNA repair is summarized in Fig. 74-3. When DNA damage occurs, *BRCA1* is phosphorylated by ataxia-telangiectasia (ATM) mutated protein kinase. Phosphorylated *BRCA1* in turn activates DNA repair machinery through formation of a complex with *BRCA2*, *BRCA1*-associated RING domain, *Rad51* and/or *Rad50*, which are key proteins for mitotic recombination and DNA break repair. Loss of *BRCA1* or *BRCA2* function in breast cells leads to chromosomal instability and triggers checkpoint activation. If the checkpoint function is intact, critical checkpoint genes like p53 and p21 may be activated and induce cell-cycle arrest. However, mutation of *BRCA* genes frequently results in an accelerated accumulation of secondary genetic changes. When such secondary genetic changes occur to critical checkpoint genes like p53, the checkpoint cannot be activated and

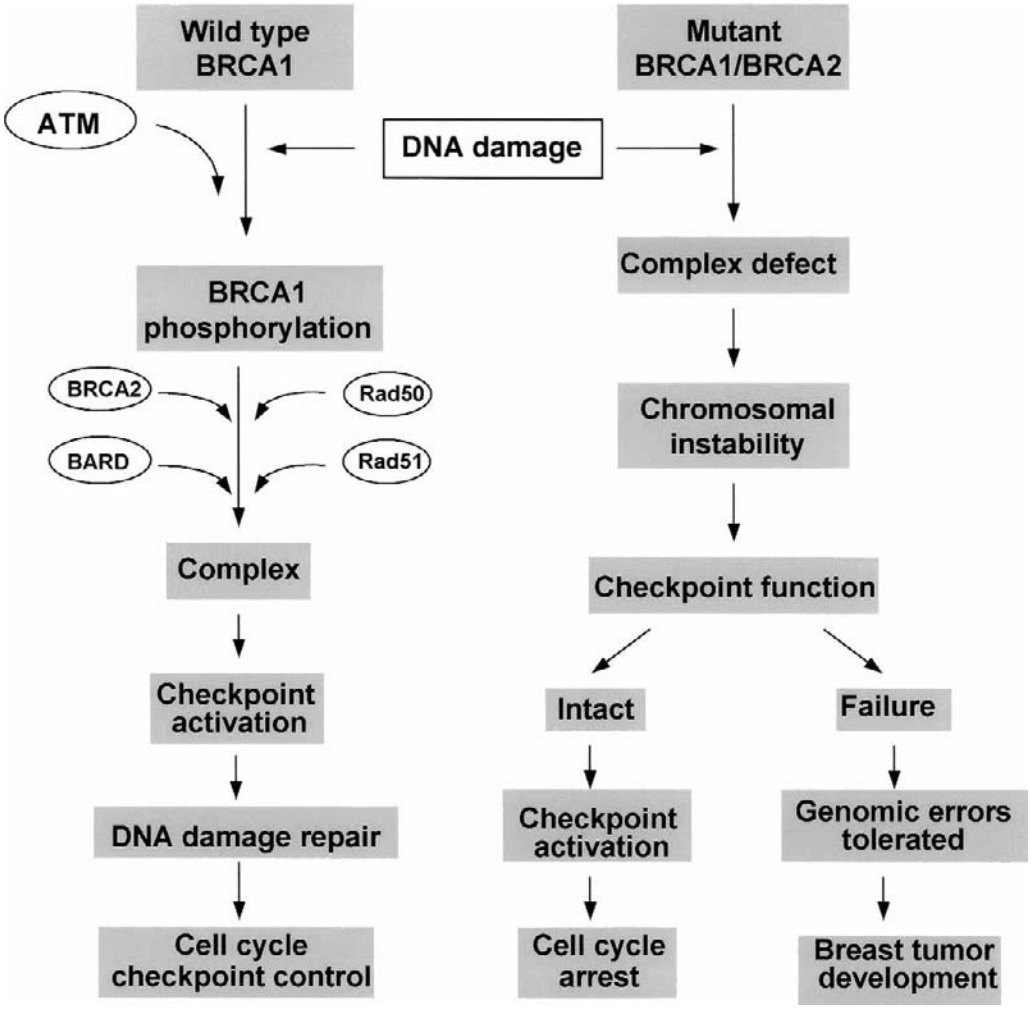

Figure 74-3 Function of breast cancer susceptibility genes *BRCA1* and *BRCA2* in DNA repair. In response to DNA damage, *BRCA1* is phosphorylated by ataxia-telangectasia mutated protein kinase. Phosphorylated *BRCA1* activates DNA damage repair by recombination with *BRCA2*, BRCA1-associated RING domain, Rad50 and/or Rad51. The complex might be involved in DNA-damage cell-cycle checkpoint. Mutations in *BRCA1* and/or *BRCA2* may cause a complex recombination defect in response to DNA damage and would lead to chromosomal instability. If the checkpoint function is intact, important checkpoint genes such as p53 and p21 can be activated and induce cell-cycle arrest. When such a checkpoint has already been disabled (e.g., p53 mutation), the chromosomal errors may be tolerated and lead to uncontrolled neoplastic progression.

uncontrolled cell growth may result. In support of this, an increased frequency and accelerated onset of breast tumors accompanying p53 inactivation has been observed in *BRCA1* knockout mice.

The identification of *BRCA1* and *BRCA2* makes predictive genetic testing possible for individuals in families where a disease-associated mutation is identified. However, *BRCA1* and *BRCA2* mutations are found in a limited proportion (<50%) of inherited breast cancer families, suggesting that *BRCA1/2* mutations are unlikely to be the only genetic change in inherited breast cancer. In addition, somatic mutations of *BRCA1* and *BRCA2* are absent in sporadic breast cancer. To better understand the genetics of inherited breast cancer as well as the development of sporadic breast cancer, it is important to identify other potential breast cancer susceptibility genes or nongenetic factors, whose activities may contribute to the greater burden of breast cancer.

GENETIC CHANGES IN BREAST CANCER ADHESION, INVASION, AND METASTASIS

Normal breast epithelial cells are arrayed in a very orderly manner and are cemented in position by a number of cell adhesion and basement proteins; the development of invasive breast cancer requires loss of adhesive properties and the acquisition of a motile and invasive phenotype. Mutations in the cognate genes may lead to the malfunction of adhesion proteins. Two types of cell adhesion proteins related to breast cancer invasion are the cadherins and integrins. E-cadherin (E-Cad) is a member of the cadherin superfamily and plays a critical role in initiating and maintaining cell–cell contacts and suppressing invasion. The E-Cad gene is located on chromosome 16q22.1, a region frequently associated with LOH in sporadic breast cancer. Loss of E-Cad resulting from inactivating mutations has been detected in early breast carcinomas. CpG hypermethylation of the E-Cad gene correlates with loss of E-Cad expression in breast cancers that lack E-Cad mutations. Re-expression of E-Cad in E-Cad-negative breast cancer cells in laboratory models decreases motility and invasiveness, suggesting a metastasis suppressor role of this protein in breast cancer development. Another important class of cell adhesion molecules is integrin receptors that are actively involved in regulation of cell–cell and cell–stromal interactions. Integrins form heterodimers that provide a transmembrane link between cytoskeleton

and specific extracellular matrix proteins. Among these dimers, $\alpha_2\beta_1$ and α_6 integrins (especially $\alpha_6\beta_1$ and $\alpha_6\beta_4$) have been most clearly implicated in breast cancer progression. The cross-talk between integrins and receptors for some important growth factors, hormones, and cytokines may contribute to breast cancer invasion and metastasis. In particular, findings show that the integrins activate the PI3-K/Akt/PKB signaling pathway, which plays a pivotal role in invasive breast carcinoma development.

Enzymatic proteolysis degrades extracellular matrix, permitting cells to traverse the basement membrane, a critical step in breast cancer invasion and metastasis. Three major groups of proteolytic enzymes implicated in breast invasion and metastasis include cathepsins, serine proteinases, and matrix metalloproteinases. In addition, several factors may affect tumor cell motility, including autocrine mobility factor, hepatocyte growth factor, chemoattractants and their receptors, and so on. Research has demonstrated that protein kinase C is also activated in metastatic breast carcinomas. Further understanding of the molecular mechanisms underlying the metastatic process of invasive breast carcinoma will be important for therapy development.

EPIGENETIC ALTERATIONS

Although much work has focused on genetic alterations as previously outlined, more attention has been focused on the contribution of epigenetic modifications to breast tumorigenesis. Indeed epigenetic changes such as DNA hypermethylation and histone modifications may modify gene expression with a higher frequency than genetic changes. Although both genetic and epigenetic changes are heritable, a critical difference between genetic and epigenetic changes is that epigenetic changes are potentially reversible. The role of DNA hypermethylation as an epigenetic regulator of gene expression is the most studied. In the promoter region of many genes, CpG dinucleotides are frequently found to cluster into CpG islands, which extend about 500–3000 bp. Cytosines in these CpG islands may be methylated through the actions of three active DNA methyltransferases (DNMT). DNMT1 is highly conserved in human cells and is mainly responsible for maintenance of DNA methylation. DNMT 3a and 3b are active in *de novo* DNA methylation rather than methylation maintenance. CpG methylation is frequently associated with transcription repression through several possible mechanisms. First, methylation may directly interfere with the transcription initiation at the promoter area of a gene by reducing the binding affinity of sequence-specific transcription factors such as AP-1, NF-κB, and E2F. Also CpG methylation recruits transcriptional corepressors like mSin3A, DMAP1, TSG101, and Mi2. In addition, sequence-independent changes in chromatin structure and histone acetylation and methylation have emerged as an important mechanism to mediate silencing of gene expression. Several methyl-CpG-binding proteins including MeCP2 and MBD1/2a/2b/3 have been identified to function as transcriptional repressors through association with members of HDACs family.

As shown in Table 74-2, studies of DNA hypermethylation alterations in human breast cancer specimens have identified many key breast tumorigenesis-related genes as targets for epigenetic downregulation. Altered cell proliferation is fundamental to breast cancer cell growth and expression of some growth control genes may be epigenetically regulated. For example, loss of tumor suppressor gene p16 expression resulting from methylation of its promoter has been observed in approx 20–30% of primary breast cancers. Progressive methylation of p16 gene may cause human mammary epithelial cells to escape from block of transient growth plateau (M0), leading ultimately to breast tumorigenesis. *Cyclin D2* is involved in regulation of transition from G1 to S during cell cycle. Hypermethylation of the CpG island in *cyclin D2* promoter has been detected in DCIS, suggesting that loss of *cyclin D2* expression is an early event in breast tumorigenesis. In sporadic breast cancer, DNA methylation has been proposed as an alternative mechanism to inactivate the *BRCA1* gene. One study showed that *BRCA1* promoter hypermethylation was present in approx 13% of unselected primary breast carcinomas.

Table 74-2
Some Epigenetically Regulated Breast Tumor Genes

Gene	*Function*
Breast cancer type 1 (BRCA1)	DNA damage repair, cell-cycle checkpoint control
p53	Regulation of cell-cycle and apoptosis
p16	Regulation of cell-cycle and senescence, tumor suppressor
Homeo box A5	Regulation of apoptosis
Cyclin D2 (CCND2)	Cell-cycle regulation
Stratifin (14-3-3σ)	Cell-cycle regulation
Estrogen receptor-α and -β	Cell-growth regulation, hormonal therapy predictor
Progesterone receptor	Cell-growth regulation
RARβ	Apoptosis, growth inhibition
Transforming growth factor β receptor II	Regulation of proliferation and cell cycle
E-cadherin	Epithelial cell–cell adhesion
Tissue inhibitor of metalloproteinase-3	Inhibits tumor growth, angiogenesis, and invasion
Glutathione S-transferase PI	Carcinogen detoxification

As noted, steroid hormone receptors may also be epigenetically regulated. Both the ER and PR can be methylated in breast cancer specimens and methylation appears to correlate with gene expression. Use of methyltransferase inhibitors (5-aza-cytidine or 5-aza-2′-deoxycytidine) and HDAC inhibitors may lead to reexpression of ER mRNA in ER-negative breast cancer cells, suggesting that both DNA methylation and histone acetylation are actively involved in regulation of ER-gene transcription. The methylation of the PR has been demonstrated in approx 40% of PR-negative breast cancers. Also expression of retinoic acid receptor (RAR)-β is frequently reduced in breast cancer cells, and RAR-β promoter methylation is thought to be one of the major mechanisms leading to RAR downregulation and loss of response to retinoids.

A number of other critical genes related to breast tumorigenesis are also methylation targets. These include 14-3-3σ, p53, homeo box A5, E-Cad, Tissue inhibitor of metalloproteinase-3, transforming growth factor β receptor II, glutathione *S*-transferase PI, and so on. (Table 74-2). Knowledge of these methylated markers may provide a useful tool for risk assessment or breast cancer detection as aberrant methylation is felt to be a hallmark of malignancy and CpG island hypermethylation might be detected with higher specificity, sensitivity, and frequency. Also, because epigenetic changes are potentially reversible, strategies to reverse these changes in breast cancer could be a novel approach to treatment.

CONCLUSIONS

As with all cancers, the molecular mechanisms underlying the development of breast cancer are extremely complex. Breast cancer

development is a sequential process whereby normal cells accumulate a series of genetic and/or epigenetic changes to genes with diverse functions, ultimately evolving to a malignant state. Damage to proto-oncogenes or tumor suppressor genes such as p53, *BRCA1/2*, *Myc*, and so on, may significantly increase the risk of developing breast carcinoma. Development of invasive and metastatic breast carcinoma may stem from altered expression of genes that regulate cell growth, death, adhesion, motility, and invasion. The management of breast cancer in the clinic is already dependent on the understanding of breast cancer biology. For example, detection of germline mutations in *BRCA1, BRCA2*, or p53 permits identification of high risk individuals who may wish to undertake surveillance or prevention strategies. Knowledge of the expression of the ER, PR, and HER2/*neu* proteins is a prerequisite for effective counseling about the use of targeted endocrine therapies or trastuzamab for breast cancer treatment. It is hoped that enhanced understanding of breast cancer biology will enhance risk assessment, prevention, diagnosis, and treatment. Finally, it is likely that new techniques such as cDNA microarray and proteomic analysis will permit refocusing from the assessment of a handful of genes and proteins to simultaneous consideration of multiple targets, deepening the understanding of breast cancer biology and its clinical implications.

75 Lung Cancer

LEI XIAO

SUMMARY

Lung cancer is the leading cause of cancer-related deaths worldwide today. An increasing understanding of the pathogenesis of lung cancer at the cellular and molecular levels has revealed that lung cancer arises as the result of the accumulation of multiple genetic and epigenetic alterations. These include chromosomal abnormalities, aberrant DNA methylation, the activation of proto-oncogenes, the inactivation of tumor suppressor genes, and changes in signal transduction pathways. This chapter provides a brief summary of the recent advances in understanding the molecular biology of human lung cancer with emphasis on tumor-acquired deregulation of cell proliferation and survival.

Key Words: Apoptosis; chromosomal abnormality; epigenetic alternation; lung cancer; oncogene; proliferation; signal transduction; telomerase; tumor suppressor gene; tumorigenesis.

INTRODUCTION

Lung cancer is the leading cause of cancer-related deaths worldwide today, with an estimated 169,500 new cases and 157,400 deaths predicted for 2001 in the United States. Human lung cancer is a disease of heterogeneous histology that can be divided into two major categories: small-cell lung cancer (SCLC) and non-small-cell lung cancer (NSCLC). SCLC represents approx 25% of all lung cancer worldwide. The remaining 75% of lung cancers fall into one of three major subtypes of NSCLC carcinomas: squamous cell carcinoma (SCC), adenocarcinoma, and large cell carcinoma. Tobacco smoking is the most important cause of lung cancer with 80–90% of the disease arising in cigarette smokers. Early epidemiological studies of the smoking-caused lung cancer indicated that SCC was the most frequently diagnosed type of lung cancer, followed by small cell carcinoma. Adenocarcinoma of the lung is the most common histological type of lung cancer in the world, and is the most frequent type of lung cancer in women, nonsmokers, and in young people.

SCLC is distinct from NSCLC in biology, response to therapy, and prognosis. SCLCs are neuroendocrine (NE) tumors that are strongly smoking associated and characterized by early metastasis and initial marked responsiveness to chemotherapy and radiation. However, nearly all patients with SCLC relapse develop resistance to cytotoxic therapies. The overall 5-yr survival rate is only 3–4%. NSCLCs, at large, lack NE features. They respond poorly to chemotherapy as compared with SCLCs. The treatment strategies of NSCLCs are based on the stage of diseases at the time of diagnosis, which include surgery, chemotherapy, radiotherapy, or combined therapy. Although great efforts have been made to improve patient survival, the overall treatment results have not changed significantly in the past 30 yr. The 5-yr lung cancer survival rate remains between 8 and 14%.

In the past decade an increasing understanding of the pathogenesis of lung cancer at the cellular and molecular levels has provided insight into the molecular process underlying lung tumorigenesis and progression. Lung cancer arises as the result of multiple genetic lesions because of exposure to cigarette smoke or other environmental carcinogens as well as inherited predisposition(s). It is becoming clear that genetic changes acquired by lung cancer are multiple, complex, and heterogeneous. These genetic abnormalities include chromosomal deletion and/or amplification, epigenetic changes in DNA methylation, the activation of proto-oncogenes and other growth promoting genes, and the inactivation of tumor suppressor genes (TSGs). NSCLC and SCLC exhibit distinct but overlapping patterns of genetic alterations. This chapter briefly reviews advances in the understanding of the molecular biology of human lung cancer with emphasis on tumor-acquired deregulation in cell growth and apoptosis.

ONCOGENES AND TSGS

Oncogenes are derived from the activation of proto-oncogenes through a variety of mechanisms, including DNA rearrangement, chromosomal translocation, point mutation, gene amplification, and overexpression, whereas TSGs are inactivated through biallelic alterations that are combinations of point mutation, deletion, epigenetic changes, and loss of heterozygosity (LOH). Activation of proto-oncogenes usually results in a dominant phenotype, leading to cellular transformation. In contrast, loss of function of TSGs leads to abrogation of the normal growth control. Alterations of either type of genes could result in dysregulated growth, which eventually can lead to malignancy along with other genetic changes.

ONCOGENES

The Ras Family The Ras family of genes (N-*ras*, K-*ras*, and H-*ras*) encodes three GTP-binding proteins, which function as molecular switches that cycle between an active GTP-bound and an inactive GDP-bound form, and play a pivotal role in signal transduction. The critical difference between the oncogene and the proto-oncogene is a point mutation resulting in a single amino

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

acid substitution in codon 12, 13, or 61 of the Ras protein. Compared with normal Ras, mutant (oncogenic) Ras has impaired intrinsic guanosine triphosphatase activity, which catalyzes the hydrolysis of the bound GTP. Consequently, a higher proportion of oncogenic Ras exists in the cell as the active GTP-bound form, whereas normal Ras is usually in the inactive GDP-bound form. Thus, oncogenic Ras acts as a signal transducer that causes persistent activation of multiple effector-mediated signaling pathways, leading to cell proliferation, transformation, and other abnormal biological effects in the cell.

Activating mutations of the Ras gene family (major K-*ras*2) have been detected in >30% of NSCLCs, particularly adenocarcinomas. In contrast, *ras* mutations have never been detected in SCLC. The presence of a K-*ras* mutation seems to be an unfavorable prognostic factor and may be associated with tumor progression of NSCLC. This is probably, at least in part, because cells harboring Ras oncogenes become more resistant to radiotherapy and chemotherapy, suggesting that an abnormal Ras signaling may lead to certain cellular changes that are required for developing a resistance to treatment.

Given the relevance of *ras* oncogenes in lung cancer, the activated Ras proteins and/or their downstream signaling components have become attractive targets for therapeutic intervention. The major downstream targets activated by oncogenic Ras include the Raf-1/MEK (ERK-activating kinase)/ERK (extracellular signal-regulated kinase) pathway and the Raf-independent pathways such as the JNK/stress-activated protein kinase pathway. Activation of the Raf-1/MEK/ERK pathway is frequently associated with transformation of primary cells by Ras. However, the Raf-independent pathways seem particularly important for transformation of epithelial cells. This is important because all carcinomas including lung cancer are derived from their epithelial origin. Studies have pinpointed the importance of the JNK pathway in the growth control of lung cancer cells. The JNK/c-Jun/AP-1 pathway plays an essential role in mediating oncogenic Ras transforming function in lung cancer cells, and a significant growth-promoting role of JNK has also been demonstrated in human lung cancer cells. A major target of the JNK pathway is the AP-1 transcriptional activator, which is made up of homo- or heterodimers of the Jun and Fos family proteins. AP-1 activity is abundantly present in NSCLC cells but not in SCLC cells. The induction of AP-1 activity is associated with a transition from SCLC to NSCLC phenotype in an in vitro SCLC progression model. These data suggest that AP-1 is an important mediator of oncogenic Ras signaling and plays a role during lung cancer progression. It is hoped that a detailed understanding of the Raf-independent signal transduction pathways will serve to identify novel targets for therapeutic intervention.

The Myc Family Members of the *myc* gene family, c-*myc*, N-*myc*, and L-*myc*, are sequence-specific DNA-binding transcription factors that play important roles in cell cycle regulation, apoptosis, and differentiation. Myc proteins heterodimerize with other cellular proteins such as Max. The Myc–Max heterodimers bind to specific DNA sequences, leading to transcriptional activation of the targeted genes. The general mechanism of *myc* oncogene activation is gene amplification or genetic alterations that lead to increased transcription, which results in protein overexpression. Amplification of *myc* family genes is more frequently observed in SCLC than NSCLC, and has been associated with an adverse effect in survival of SCLC. High levels of c-*myc* mRNA have been detected in 58% of primary NSCLCs in comparison to nontumor lung epithelium, suggesting that *myc* gene expression may significantly affect the development of NSCLCs. Moreover, studies have suggested that L-*myc* polymorphism may play a role in the progression of NSCLC and in determining the different susceptibility to lung cancer in smokers.

Bcl-2 The Bcl-2 family of proteins are key regulators in programmed cell death, or apoptosis. The Bcl-2 family consists of proapoptotic and antiapoptotic subfamilies. The interactions between the pro- and antiapoptotic Bcl-2 members help determine cell fate during apoptosis. Bcl-2 is an antiapoptotic member that forms heterodimers with several proapoptotic Bcl-2 members such as Bax and Bak. The mechanisms by which Bcl-2 prevents apoptosis are not fully understood, but stabilizing the mitochondrial membrane and preventing the release of the proapoptotic proteins are possibilities.

Bcl-2 is expressed in the early stage of bronchial preneoplasia and is related to smoke exposure. Bcl-2 expression is more common in SCLCs (75%) than NSCLCs, whereas SCCs show a higher level of Bcl-2 expression than adenocarcinomas. There is no clear conclusion regarding the Bcl-2 status and a survival benefit for patients. However, an inverse correlation between Bcl-2 and Bax expression in low grade (high in Bax) and high grade (high in Bcl-2) of NE lung tumors suggests that Bcl-2 may be linked to the disease progression.

TUMOR SUPPRESSOR GENES

p53 and p14/ARF The p53 gene, located at chromosome 17p13.1, encodes a transcription factor that plays important roles in cell cycle control, DNA damage response, genome stability, and apoptosis. In response to DNA damage, p53 is phosphorylated and functions as a sequence-specific DNA-binding transcription factor that regulates the expression of several downstream genes including p21/Cip1/WAF1, MDM2, GADD45, Bax, and cyclin G, thereby leading to cell cycle arrest or apoptosis. Most p53 mutations identified in human cancers including lung cancer are missense and occur frequently in the DNA-binding domain. Many of these mutations completely abrogate the DNA binding and transactivation function of p53. Thus, transactivation of gene expression by p53 is thought to significantly influence its tumor suppressing activity.

Inactivation of p53 in lung cancer mainly occurs through point mutations or by small chromosomal deletions of the region containing the p53 gene. p53 mutations are present in approx 50% of NSCLCs and more than 90% of SCLCs. A significantly higher frequency of p53 mutations was observed in smokers compared with nonsmokers. Loss of p53 function is viewed as an early event in lung tumorigenesis. This is supported by the presence of p53 mutations and/or the accumulation of the p53 protein in preneoplastic lesions, such as bronchial epithelial dysplasia.

p14/ARF, encoded by the p16/INK4A locus via an alternative reading frame, is one of the major upstream regulators in the p53 growth-control pathway. As an inhibitor of HDM2 (Mdm2 in mice) that reduces p53 levels through proteasome-dependent degradation, p14/ARF prevents p53 degradation by binding to HDM2 and sequestering it in nucleoli, resulting in p53 activation/stabilization. Thus, dysregulation of p14/ARF in cancer provides an additional means of disrupting the p53 growth-control pathway. p14/ARF mutations were found in 19–37% of NSCLCs; the absence of p14/ARF protein was observed in 65% of SCLCs. However, mutations in the p53 gene and loss of p14/ARF expression

are not always mutually exclusive suggesting the tumor suppressing function of p14/ARF may be p53 independent.

p16/INK4A and Rb p16/INK4A and retinoblastoma (Rb) are key components of the cell cycle pathway of p16/INK4A-cyclin D1-CDK4-Rb, which plays an essential role in controlling G1 to S phase transition of the cell cycle. p16/INK4A is a member of a family of cyclin-dependent kinase (CDK) inhibitory proteins and functions by inhibiting the kinase activity of the CDK4/cyclin D1 complex. The cyclin D1-associated CDK4 and CDK6 can phosphorylate Rb, which inactivates Rb's ability to bind to a number of cellular proteins, including the E2F family of transcription factors, thereby releasing cells from the growth inhibitory stage (G0/G1) and promoting G1/S transition.

Inactivation of p16/INK4A has been observed in 30–70% of NSCLCs, whereas Rb inactivation is much more common in SCLCs (approx 90%) than in NSCLCs (15–30%). These findings suggest that the p16/INK4A-cyclin D1-CDK4-Rb pathway is inactivated predominantly through p16/ARF4A inactivation in NSCLC, whereas Rb inactivation appears to be the preferred mechanism in SCLC. Homozygous deletion and epigenetic alterations of promoter hypermethylation are the most common mechanisms for p16/INK4A inactivation. Deletion, nonsense mutations, and splicing abnormalities that lead to truncated (mutant) Rb proteins are responsible for alterations of the Rb gene. A reciprocal relationship between Rb inactivation and p16/INK4A expression has been observed in primary lung cancers, suggesting the inactivation of p16/INK4A and Rb are mutually exclusive.

Tumor Suppressor Genes at Chromosome 3p Homozygous deletions in specific chromosomal regions may imply the presence of putative TSGs. Chromosome 3p contains several distinct deletion regions including 3p25-26, 3p21-22, and 3p14, which are frequently deleted in lung cancer. Homozygous deletions at 3p14.2 in lung cancer led to the discovery of the fragile histidine triad (*FHIT*) gene that encodes the protein diadenosine 5′,5′-P^1, P^3-triphosphate (Ap_3A) hydrolase. When introduced into cancer cells with a *FHIT* gene alteration, FHIT inhibits tumor growth through the induction of apoptosis and/or cell cycle arrest. This links the tumor-suppressor activity of FHIT to its proapoptotic function. Abnormal transcripts of *FHIT* were found in 40% of NSCLCs and 80% of SCLCs. In addition, approx 50% of primary lung tumors fail to express the FHIT protein, mainly owing to tumor-acquired promoter methylation. LOH of the *FHIT* gene is more common in smokers (80%) than in nonsmokers (approx 22%), indicating that the *FHIT* gene is a target for tobacco carcinogens and may occur early in lung tumorigenesis.

The RASSF1 (the Ras association domain family 1) gene, located at the lung tumor suppressor locus 3p21.3, consists of two major alternative transcripts, *RASSF1A* and *RASSF1C*. *RASSF1A* is epigenetically inactivated in >90% of SCLCs and 40% of NSCLCs. Reexpression of *RASSF1A* reduced the growth of human lung cancer cells in vitro and in vivo, supporting a role for *RASSF1A* as a TSG. RASSF1A binds Ras in a GTP-dependent manner and may serve as a novel Ras effector that mediates the apoptotic effects of oncogenic Ras. *RASSF1A* inactivation and K-*ras* activation are mutually exclusive events in the development of certain carcinomas. This observation further pinpoints the function of RASSF1A as a negative effector of Ras. Importantly, a significant correlation between *RASSF1A* promoter methylation and impaired lung cancer patient survival was reported, and *RASSF1A* silencing was correlated with several parameters of poor prognosis and advanced tumor stage (e.g., poor differentiation, aggressiveness, and invasion). Thus, RASSF1A may serve as a useful marker for the prognosis of lung cancer patients.

In addition to *RASSF1A*, several candidate TSGs including *FUS1*, *SEMA3B*, *101F6*, and *NPRL2* are all located within 100 kb of *RASSF1A* in the 3p21.3 region. Data indicate that LOH at 3p, in particular the 3p21.3 region, is one of the earliest changes occurring in smoking-damaged, but histologically normal lung epithelium, suggesting that alterations in the expression of these putative TSGs are a critical early step in the development of lung cancer.

CHROMOSOME ABNORMALITIES

Numerous chromosomal abnormalities including common regions of chromosomal loss and LOH have been found in lung cancer. The chromosomal arms with the most frequent LOH are 1p, 3p, 4p, 4q, 5q, 8p, 9p (p16/INK4A), 9q, 10p, 10q, 13q (Rb), 15q, 17p (p53), 18q, 19p, Xp, and Xq. SCLC and NSCLC show distinct regions of frequent LOH, suggesting that SCLC and NSCLC frequently undergo different genetic alterations. Additionally, a much higher frequency of widespread chromosomal abnormalities has been found in lung adenocarcinoma from smokers than such tumors arising in nonsmokers. This observation supports the idea that lung cancers in nonsmokers arise through genetic alterations distinct from the common events in tumors from smokers.

The most consistent chromosomal abnormality in lung cancer has been the allele loss of chromosome 3p (3p12-26), found in more than 90% of SCLCs and more than 80% of NSCLCs. Several distinct regions on 3p show frequent allele loss or independent homozygous deletions in lung cancer, which represent strong evidence for the presence of potential TSGs. A number of putative TSGs including *RASSF1A* and *FHIT* have been cloned from these 3p deletion regions. It should be noted that 3p allele loss also occurs in the normal epithelium of smokers without lung cancer as well as preneoplastic lesions of the lung. A progressive increase in the frequency and the size of 3p allele loss was correlated with the increasing severity of histopathological preneoplastic/preinvasive changes. These observations suggest that 3p allele loss is an early event involved in the pathogenesis of lung cancer.

EPIGENETIC CHANGES (ABERRANT PROMOTER METHYLATION)

Epigenetic alterations in general and gene silencing events in particular are viewed as fundamental aspects of tumorigenesis. Tumor cells generally exhibit a global DNA hypomethylation and regional promoter hypermethylation that is associated with gene silencing. Aberrant methylation of CpG islands in promoter regions is one of the major mechanisms for silencing of TSGs in cancer cells. Methylation serves as an alternative to the genetic loss of a TSG function by deletion or mutation. TSGs that are frequently methylated in primary lung tumors include adenomatous polyposis coli, retinoic acid receptor beta, *CDH13* (H-cadherin), *FHIT*, *RASSF1A*, *p16/INK4A*, death-associated protein kinase (DAPK), and others. The profile of methylated genes in NE tumors (SCLC and carcinoids) was very different from that of NSCLC, and significant differences in the methylation patterns also exist between the two major types of NSCLC (adenocarcinoma and SCC), indicating that distinct epigenetic alterations may contribute to the development of different subtypes of lung cancer.

A significantly reduced overall, and/or disease-free survival has been linked to the promoter hypermethylation of *DAPK* and *RASSF1A*. Methylated DNA sequences can be detected in primary tumors, circulating in serum DNA from lung cancer patients, in sputum samples before the onset of invasive lung cancer, in preneoplastic lesions of lung carcinomas, as well as in the smoking-damaged bronchial epithelium from cancer-free heavy smokers. Thus, an assessment of promoter hypermethylation of certain TSGs may be useful biomarkers for early diagnosis and risk assessment of lung cancer.

TELOMERASE

Telomerase is a specialized ribonucleoprotein polymerase that adds TTAGGG repeats at the ends of vertebrate chromosomal DNA called telomeres. Telomeres are important in maintaining stability of the chromosome, which undergo progressive shortening with cell division through replication-dependent sequence loss at DNA termini. Telomerase is thought to compensate for the loss of telomeric repeats and is associated with the acquisition of the immortal phenotype. Telomerase activity is detected in many types of human cancers. Almost all SCLCs and approx 80% of NSCLCs are telomerase positive. Telomerase activity has been directly correlated with malignant and metastatic phenotypes of human lung cancer. Telomerase RNA expression was present in 20% of hyperplasia, 53% of dysplasia, and 100% of microinvasion and carcinoma *in situ*. Lower levels of telomerase activity were detected in preneoplastic lung cancer lesions compared with invasive cancer. These findings indicate that dysregulation of telomerase expression increases along with lung tumor progression.

GROWTH FACTORS/RECEPTORS

Many growth factors or neuropeptides and their receptors are expressed and/or mutated in human lung cancer cells or in the adjacent stroma. This results in multiple autocrine and/or paracrine circuits that activate the positive growth signaling pathways and promote tumor cell growth. Neuropeptides and their specific G protein-coupled receptors (GPCR) play a key role in the regulation of SCLC growth, whereas peptide growth factors and receptor tyrosine kinases (RTKs) are more important for stimulating NSCLC growth. In the context of the multistage evolution of cancer, these autocrine and/or paracrine mitogens may play a role as tumor promoters in the early stages of lung tumorigenesis and/or later as growth stimulators in the unrestrained growth of the fully developed lung tumor.

NEUROPEPTIDE GROWTH FACTORS Neuropeptide growth factors include gastrin-releasing peptide (GRP) and bombesin-like peptides that have been extensively studied as neuropeptide mitogens in SCLC. Expression of GRP was demonstrated in 20–60% of SCLCs but less frequently in NSCLCs by immunohistochemical analysis. Neutralizing antibodies against GRP/bombesin and bombesin antagonists inhibit both in vitro and in vivo growth of SCLC cells. In addition, a high frequency (>50%) of coexpression of gastrin and its receptor CCK-B in SCLCs suggests that the neuropeptide autocrine signaling is a prominent driving force for SCLC proliferation.

GRP and bombesin-like peptides function as autocrine growth factors, which signal through the GPCRs. GRP and bombesin-like peptides bind to at least three GPCRs, including the GRP receptor, the bombesin receptor, and the neuromedin B receptor, which lead to the activation of multiple intracellular protein kinase pathways that ultimately converge on the regulation of some important cell cycle proteins. In particular, activation of protein kinase C (PKC) and the mitogen-activated protein kinase cascade play important roles in regulating neuropeptide autocrine growth signaling in SCLC cells.

RECEPTOR TYROSINE KINASES RTKs are key components of signaling pathways that regulate cell growth, differentiation, and survival. RTKs consist of an extracellular-, transmembrane-, and intracytoplasmic-domain and are activated through appropriate ligand binding. Ligand binding of the receptor results in dimerization and activation of tyrosine kinase activity through autophosphorylation of the intracellular tyrosine kinase domain of the receptor itself. The phosphotyrosine residues of activated RTKs play a crucial role in transducing extracellular signals to intracellular signaling molecules. Oncogenic activation of RTKs occurs through deletion, point mutations, as well as overexpression, which lead to persistent activation of the receptor-mediated signaling pathways independent of ligand binding, resulting in uncontrolled cell growth. A number of RTKs are overexpressed or mutated in human lung cancer cells. These RTKs are attractive targets for therapeutic intervention against lung cancer.

Epidermal Growth Factor Receptor Epidermal growth factor receptor (EGFR, also called *erBB1*) and heregulin receptor (*HER2/neu*) belong to the type-I EGFR family that regulates epithelial proliferation and differentiation. The EGFR is activated by binding the extracellular domain to one of several ligands, including EGF (betacellulin), transforming growth factor-α (epiregulin), and HB-EGF (amphiregulin). NSCLC tumors have been demonstrated to synthesize transforming growth factor-α and HB-EGF, and these growth factors seem to form an autocrine feedback loop with EGFR and, as a result, play an important role in the tumorigenesis.

The EGFR expression varies according to histological subtypes. Overexpression of EGFR was found frequently in 60–80% of NSCLCs but rarely in SCLCs. Overexpression of EGFR is one of the earliest and most consistent abnormalities in bronchial epithelium of high-risk smokers. It is present at the stage of basal cell hyperplasia and persists through squamous metaplasia, dysplasia, and carcinoma *in situ*. The prognostic significance of EGFR overexpression in NSCLC is unclear. However, patients with strong EGFR-expressing tumors tended to have shorter survival than the patients with slight- or nonexpressing tumors.

HER2/neu is highly expressed in approx 30% of NSCLC, particularly adenocarcinomas. High levels of HER2/neu expression are associated with a shortened survival time and with an intrinsic chemoresistance to three commonly used chemotherapeutic drugs (doxorubicin, etoposide, and cisplatin) in NSCLC. Coexpression of EGFR and HER2/neu also occurs in NSCLC tumors. HER2/neu and EGFR coexpression appears to have an additive effect on survival. High HER2/neu expression and high EGFR/HER2 coexpression gave unfavorable prognosis, indicating that HER2/neu and EGFR play a critical role in the biological behavior of NSCLCs.

Proto-Oncogene c-Kit c-Kit RTK is a class III receptor similar to platelet-derived growth factor receptor. c-Kit and its natural ligand, stem cell factor, form an autocrine loop that is implicated in the development of SCLC. Coexpression of c-Kit and stem cell factor was reported in up to 70% of SCLC tumor specimens and cell lines. Inhibition of c-Kit activation by several tyrosine kinase inhibitors led to growth suppression and cell death in SCLC cell lines.

Several additional growth factor/RTK autocrine loops that have been implicated in the growth regulation of lung cancer include insulin-like growth factors and their receptor IGF-R_s as well as hepatocyte growth factor and its receptor c-Met.

DYSREGULATION OF APOPTOSIS

Apoptosis, or programmed cell death, is a highly specific and regulated process that plays an important role in the development and homeostasis of multicellular organisms as well as tumorigenesis. There is an increasing evidence that the control of apoptosis is disrupted in many tumor cells. The dysregulated apoptosis is thought to contribute to enhanced tumor progression and metastasis. Furthermore, it has become evident that resistance to apoptosis is one potential mechanism whereby tumor cells escape from chemotherapy-induced cytotoxicity, leading to cell survival. Development of drug resistance (intrinsic or *de novo*) in cancer cells may be because of their selective alterations in the expression and/or function of genes important to the apoptotic response. These changes may provide a selective advantage for tumor cells, thereby rendering them resistant to chemotherapy.

CASPASES-8 Apoptotic cell death is controlled by the activation of caspases, a family of aspartate-specific cysteine proteases. Caspases are normally expressed as latent zymogens and are activated by proteolytic cleavage at the onset of apoptosis. There are two well-characterized caspase-activating cascades that regulate apoptosis: one is mediated by cell surface death receptors and the other is regulated by the mitochondria. Chemotherapeutic drug-induced apoptosis is, in general, regulated via the mitochondrial pathway.

Caspase-8 is a so-called initiator caspase and plays an essential role in the death receptor-mediated apoptosis. However, studies indicate that activation of caspase-8 is also involved in drug-induced apoptosis. Caspase-8 mRNA expression is absent in most (79%) of SCLC cell lines, but retained in all NSCLC cell lines tested. Loss of caspase-8 gene expression is correlated with the absence of the protein. In addition, the absence of caspase-8 expression was also found in a subset of SCLC tumors but in none of NSCLC tumors. These observations suggest that inhibition of caspase-8 activity represents one potential mechanism by which lung tumor cells, especially SCLC cells, develop resistance to drug-induced apoptosis.

SERINE/THREONINE KINASES

Akt/PKB The serine/threonine kinase Akt (or protein kinase B) is the cellular homolog of a retroviral oncogene product, v-Akt. Akt is commonly activated in response to growth factor stimulation and plays a key role in cancer progression by stimulating cell proliferation and inhibiting apoptosis. Constitutively activated Akt can contribute to tumorigenesis in vivo in a variety of tissues. The antiapoptotic function of Akt is mediated by phosphorylating various proteins involved in apoptosis, including proapoptotic Bcl-2 family member Bad, the forkhead transcription factor, and glycogen synthase kinase 3. Akt activation might inhibit apoptosis by promoting the increased expression of survival molecules or the degradation of proapoptotic molecules.

Constitutive Akt activity was found in premalignant and malignant human bronchial epithelial cells, but not in nonmalignant human bronchial epithelial cells. Furthermore, Akt is activated in primary human lung epithelial cells in vitro and in vivo by exposure to nicotine and to a tobacco-specific carcinogen, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone. Nicotine activation of Akt also promotes the survival of human lung epithelial cells by suppressing apoptosis. The fact that phosphorylated Akt (an activated form) was detectable in 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone-induced murine lung tumors and in human lung cancers derived from smokers suggests that nicotine activation of Akt plays a role in lung tumorigenesis, and sustained Akt activation might be necessary for tumor maintenance. Thus, Akt and the PI3K/Akt pathway might be important molecular targets for lung cancer prevention and treatment.

Protein Kinase C PKC is a family of at least 11 structurally related serine/threonine protein kinases that play crucial roles in transducing signals that regulate diversified biological functions, including proliferation, differentiation, and apoptosis. PKC is known to play a role in the regulation of two survival pathways, the PI3K/Akt and MEK/ERK pathways, and has been implicated in regulating drug resistance in cancer cells. Alterations in expression and/or activity of PKCs have been linked to the drug resistant phenotype in lung cancer cell lines and primary lung tumors. Studies suggest that the antiapoptotic effect of specific PKC isoforms, in particular the novel PKC isoforms (PKC-ε and PKC-δ), may contribute to chemoresistance in lung cancer cells. Forced expression of PKC-ε in SCLC cells conferred chemoresistance by effectively blocking drug-induced apoptosis, which was accompanied by the inhibition of cytochrome-*c* release from mitochondria and caspase activation, indicating that dysregulation of the mitochondrial pathway may be involved in PKC-ε-mediated survival. In contrast, inhibition of PKC-δ function with rottlerin, a PKC-δ specific inhibitor, or by a dominant negative mutant, increased apoptosis and dramatically sensitized NSCLC cells to chemotherapeutic drugs. These findings suggest that specific PKC isoforms may be targeted for the novel therapeutic intervention in order to overcome drug resistance in lung cancer.

Death-Associated Protein Kinase The DAPK is a family of calmodulin-regulated serine/threonine protein kinases that functions as a positive mediator of programmed cell death and is ubiquitously expressed in various tissues. A unique autoinhibiting mechanism is thought to keep these death-promoting kinases silent in healthy cells and ensures their activation only in response to apoptotic signals. DAPK is involved in both death receptor and mitochondrial pathways of apoptosis. *DAPK* is located on chromosome 9q34.1, a region of frequent allelic loss in 50–64% of lung cancer, and is inactivated in a large fraction of lung cancer via aberrant promoter methylation. Promoter methylation of the DAPK gene in NSCLCs is associated with poor prognosis and an advanced pathological stage, but not with exposure to tobacco or asbestos, suggesting that DAPK may be important in the progression of NSCLC from early to late stage disease.

CONCLUSION

It is becoming clear that the development of lung cancer and its progression is the result of accumulations of multiple and complex genetic defects. Modern molecular and genetic techniques have identified numerous genes and proteins whose expression is altered in lung cancer and/or preneoplastic lesions. These molecular abnormalities have provided novel possibilities for translational research into the diagnosis, prognosis, and the treatment of the disease. Certainly, knowledge of the fundamental cellular and molecular biology of lung cancer will significantly advance with the information from the human genome project and the use of genome-wide techniques such as microarrays and proteinomics. One major challenge is to successfully translate knowledge into clinical practice.

76 Discoveries and Frontiers in Prostate Cancer Translational Sciences

JONATHAN W. SIMONS

SUMMARY

With the application of molecular biology and biotechnologies to human prostate cancer research, new targets in the lethal phenotypes of prostate cancer have been rapidly ascertained. How many are pharmacologically amenable and can be blocked with clinical relevance remains to be discovered. For all the emergent genetic and protein target insights, perhaps the greatest challenges will be the participation of more men with prostate cancer in translational research clinical trials that evaluate the new science of therapeutics designed specifically for prostate cancer.

Key Words: Androgen receptor; benign prostatic hyperplasia; glutathione *S*-transferase; hereditary prostate cancer; polycyclic aromatic hydrocarbons; proliferative inflammatory atrophy; prostate cancer; prostatic intraepithelial neoplasia.

OVERVIEW

Prostate cancer is among the most common human neoplasias. In 1990, prostate cancer overtook lung cancer as the most common noncutaneous cancer diagnosed in US men. More than 30,000 US men were projected to die from prostate cancer in 2004; this is an estimated annual loss of 300,000 yr of life. Prostate cancer is truly a medical burden created from successful increases in *Homo sapiens'* life expectancy in the 20th century; less than 1% of cases are diagnosed under the age of 40. Specific genetic alterations in pathogenesis are reviewed later, but a key factor in human prostate cancer biology is time. Time is required to acquire the specific genetic alterations in the prostate epithelium to confer an invasive metastatic phenotype for human prostate cancer. Despite the decades it takes to emerge, prostate carcinogenesis begins early. Undiagnosed, microscopic foci of prostate cancer have been identified in autopsy series in men younger than 30 yr. The latency of most prostate cancer suggests very important gene–environment interactions may influence later steps in the development of the lethal phenotypes of prostate cancer. Prostate cancer initiation—manifested by a histologically identifiable lesion—is frequent, being detected at autopsy series in nearly one-third of men over age 45. The majority of these microscopic adenocarcinomas do not progress to clinically detectable tumors within the lifetime of these men. A critical question is: why not? Epigenetic and genetic factors that create clinically aggressive cancers from incidentally diagnosed ones are at the heart of investigation. The long latency period of prostate cancer affords a new opportunity for chemoprevention, and potentially dietary interventions as described later.

Despite its incidence and mortality in the developed world, prostate cancer has historically lagged behind others in molecular understanding of pathogenesis. With a significant push from the activism of national nonprofit organizations of prostate cancer survivors in the United States, federal funding has increased over 500% from its 1993 baseline to 2000. By 2003, a concomitant increase in new research models and basic understanding has affected the field and defined treatment targets for the future. Described later are discoveries that have generated new opportunities for translational research to reduce the morbidity and mortality of prostate cancer. A special emphasis is placed on implications for therapy in chemoprevention and the development of systemic therapies for advanced disease.

NEW CONCEPTS IN CARCINOGENESIS AND CHEMOPREVENTION

Prostate neoplasia develops in two different regions of the gland, with most lesions (approx 80%) found in the periphery that can be palpated, and most of the remaining cancers found in a periurethral region transition zone. Benign prostatic hyperplasia (BPH) originates in the transition zone of the prostate. Based primarily on this tissue difference in the incidence of benign growth and adenocarcioma formation, and the finding that stromal cell proliferation is typically a major component of BPH. BPH is not the precursor of prostate cancer. Rather, prostatic intraepithelial neoplasia (PIN) containing foci of dysplastic ductal and acinar cells is thought to be the precursor lesion of prostate cancer. PIN lesions have become critical for application of molecular probes to define the earliest changes in malignant transformation at the level of DNA and RNA alterations and protein expression.

The incidence of prostate cancer shows clear age, racial, and geographic dependencies. Prostate cancer is relatively uncommon in Asian populations and prevalent in Scandinavian countries, and the highest incidence (and mortality) rates known are in African Americans, being nearly twice higher than in white Americans.

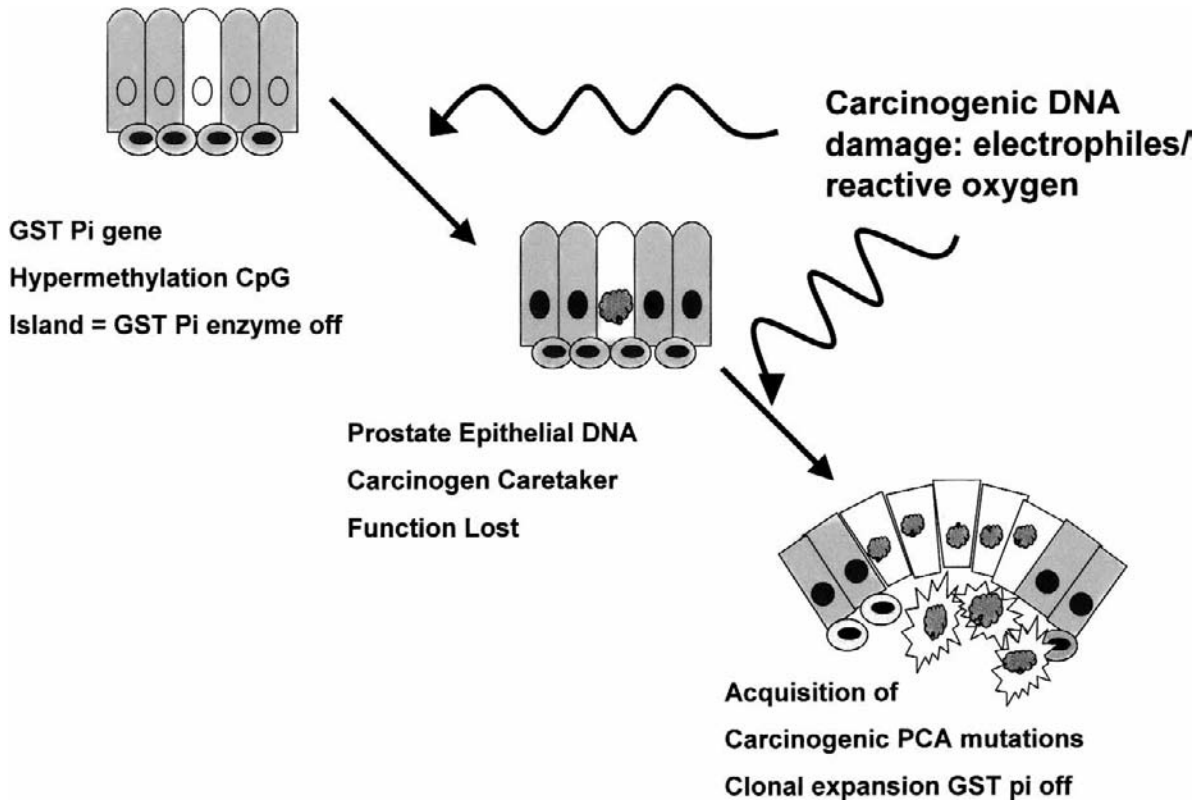

Figure 76-1 GST-π inactivation is the earliest known and essential step in prostate cancer carcinogenesis. Loss of "caretaker" function permits electrophilic attack and mutations to be introduced into prostate epithelial cell DNA. Chemoprevention strategies are oriented to restoring this protective function of GST-π.

Mortality rates vary significantly by country, ranging from the highest reported rates in Trinidad, to 23/100,000 in the United States, to less than one-fifth US rates in Japan.

Significant focus has been placed on interactions of diet and lifestyle and genes critical to prostate cancer tumorigenesis in the developed world. There is also species specificity to human prostate cancer risk. Despite the presence of a prostate in all male mammals, there is no reported high risk for prostate cancer in any other aging mammal in veterinary medicine except for the *Canis familiaris* (dog). Human lineage departed from other higher primates eight million years ago. *Homo sapiens* emerged only about 200,000 yr ago, and only in the past 15,000 yr have humans and dogs experienced dietary changes that might affect prostate cancer carcinogenesis. With civilization and departure from agrarian to urban dietary habits, cooked, smoked, processed, and stored meats became predominant dietary components during this time for man and, via leftovers, for dog. Polycyclic aromatic hydrocarbons and other components of burned red meat in particular are implicated as potential prostate cancer carcinogens; these are created in charbroiling fish and meat. As Asians cultures do not char meats in cooking, the reduced incidence of prostate cancer in Asian men has been speculated to be because of lesser lifetime exposure to intraprostatic polycyclic aromatic hydrocarbons. This would also help account for the increasing rates of prostate cancer in Asian Americans who immigrated to the United States and Western diets one generation ago.

Genetic alterations in prostate cancer tumorigenesis suggest a specific pattern for carcinogenesis in the prostate epithelium (Fig. 76-1). The most common genomic alteration in prostate cancer—and the first identified molecular event in prostate cancer—is the inactivation of the glutathione *S*-transferase (GST)-π gene. GSTs are enzymes that catalyze conjugation reactions between glutathione and various reactive chemical species. GSTs detoxify carcinogens, acting as "caretaker" genes to prevent carcinogen-induced DNA mutations and cancer development. The π-family of GSTs are ubiquitous, and have a critical role in genomic DNA damage defense. For example, GST-π knockout mice carrying disrupted genes exhibit increased skin cancers on cutaneous treatment with 7,12-dimethylbenzanthracene. Somatic inactivation of GST-π by transcriptional silencing associated with *de novo* CpG island hypermethylation occurs in more than 90% of prostate cancers. The loss of GSTP1 in PIN and prostate cancer exposes the cell to genomic damage inflicted by heterocyclic amine carcinogens, such as those present in "well-done" meats, and perhaps more importantly by reactive oxygen species produced by inflammatory cells in prostatitis (discussed later). Thus a unique feature of the prostate epithelium compared with other human cancers is how early in malignant transformation it loses a defined enzyme in detoxifying carcinogens.

Some high-grade PINs and early adenocarcinomas appear to arise from areas of proliferative inflammatory atrophy (PIA). PIA has been recognized as the lesion creating genetically damaged clones that form PIN. PIA has become a focus for carcinogenesis research in prostate cancer. Inflammation and other environmental factors may (1) lead to the destruction of prostate epithelial cells, (2) increase epithelial turnover, and (3) drive the increased prostate epithelial proliferation that occurs in PIA. Decreased G1/S checkpoint control protein p27(Kip1) has been found in PIA

lesions. Increased oxidant and electrophile stress in the setting of increased proliferation rates in PIA lesions may be the presumed source for expanding clones that have accumulated new DNA mutations. Epithelial cells in PIA lesions characteristically exhibit several molecular signs of stress, including induced expression of GSTP1, GSTA1, and COX-2. Loss of GSTP1 expression via *de novo* GSTP1 CpG island hypermethylation seems to demarcate the switch from PIA to clonal, GSTP1-inactivated neoplasia in PIN or prostate adenocarcinoma. A major effort in ultimate chemoprevention of prostate cancer will be to block the epigenetic processes that drive PIA into PIN foci.

TRANSLATIONAL RESEARCH IMPLICATIONS: CHEMOPREVENTION

Significant implications for chemoprevention of prostate cancer have arisen from the finding that human prostate cancer is characterized by an early and near-universal loss of expression of the phase 2 enzyme GST-π. First, on prostate biopsies that are negative for adenocarcinoma, diagnostic loss of GST-π expression in high frequency of normal appearing cells may indicate epithelium at lifetime higher risk for developing prostate cancer. Second, investigators are pursuing a mechanism-based prostate cancer preventive strategy that involves induction of phase 2 enzymes within the prostate to compensate for the loss of GSTP1 expression via dietary supplementation. NAD[P]H: (quinone-acceptor) oxidoreductase/quinone reductase enzymatic activity can be measured after treating the human prostate cancer cell lines with known phase 2 enzyme-inducing agents from distinct chemical classes. The search for antioxidant micronutrients in tomatoes and cruciferous vegetables in high throughput screening is ongoing.

Given the interest in Cox-2 in chemoprevention of bowel and other tumors, the role of prostate cancer cell lines do not express basal levels of Cox-2 protein. Analysis of multiple primary human prostate cancer specimens by immunohistochemistry indicates there is no consistent overexpression of COX-2 in established prostate cancer or high-grade PIN, as compared with adjacent normal prostate tissue. Positive staining is observed only in scattered cells (<1%) in both tumor and normal tissue regions but was much more consistently observed in areas of PIA, lesions that have been implicated in prostatic carcinogenesis. Staining was also seen at times in macrophages. Western blotting and quantitative reverse transcriptase PCR analyses confirmed these patterns of expression. The chemoprevention effects—if any—of COX-2 inhibitors are likely to be mediated by modulating COX-2 activity in non-prostate cancer cells (either inflammatory cells or atrophic epithelial cells) or by affecting now recognized COX-2-independent pathways of NSAID action.

MOLECULAR GENETICS OF PROSTATE CANCER: RNASEL, MSR1

Inherited genes are estimated to account for perhaps 10% or more of the risk of prostate cancer. Its heterogeneous nature suggests that the predisposition to prostate cancer may involve multiple genes and variable phenotypic expression. Mendelian inheritance of prostate cancer has allowed genome wide searches for hereditary prostate cancer (HPC) genes. The high prevalence of sporadic cases of prostate cancer has made it very difficult to identify tumor suppressor genes that are involved in familial prostate cancer. Previously, there has been limited success in identifying high-risk susceptibility genes in prostate cancer analogous to BRCA1 or BRCA2 for breast and ovarian cancer. Linkage studies have identified at least two genes in familial clusters of HPC. The discovery of these genes within the human genome could have broad implications for understanding sporadic prostate cancers. Germline mutations in the gene encoding 2′-5′-oligoadenylate (2-5A)-dependent RNase L gene (RNASEL) segregate in prostate cancer families with autosomal-recessive HPC1 (hereditary prostate cancer 1) region at 1q24-25. The RNASEL gene maps to the HPC-predisposition locus at 1q24-q25 (HPC1). RNASEL has inactivating truncation mutations in two families with linkage to HPC1. Inactive RNASEL alleles are present at a low frequency in the general population. Microdissected tumors with a germline mutation of RNASEL had loss of RNase L protein, and RNASEL activity was reduced in lymphoblasts from heterozygotes.

In addition to the 1q24-25 locus, deletions on human chromosome 8p22-23 in prostate cancer cells and linkage studies in families affected with HPC suggested this region is involved in prostate tumorigenesis. The macrophage scavenger receptor 1 gene (MSR1) is located at 8p22, and in families affected with HPC, six rare missense mutations and one nonsense mutation in MSR1 have been identified. Furthermore, in whites of European descent, MSR1 mutations were identified in 4% of individuals affected with non-HPC compared with 0.8% of unaffected men. Among African American men, these values were 12.5% and 1.8%, respectively. MSR1 genotype may confer major risk for prostate cancer in men from both African American and European descent. Pilot genetic testing with biotechnologies for allelotyping MSR1 and RNASEL are under development.

TRANSLATIONAL RESEARCH IMPLICATIONS OF GENETICS MOLECULAR EPIDEMIOLOGY OF HEREDITY AND PROSTATITIS

Both RNASEL and MSR1 created fascinating new hypotheses for prostate cancer carcinogenesis. Both were discovered by genome-wide searches and both genes unexpectedly are normally involved in host inflammatory responses to infections. The RNASEL gene encodes a single-stranded specific endoribonuclease involved in the antiviral actions of interferons. RNASEL is activated enzymatically after binding to unusual 5′-phosphorylated, 2-5As in viral infections. Virally mediated induction of cell apoptosis is defective in mouse cells lacking RNASEL. RNASEL mutations and some variants may allow genetically RNASEL –/– prostate epithelial cells to escape a potent apoptotic pathway created by a viral prostatitis. If they have become genetically altered, and are RNASEL defective in a normal apoptotic pathway, this might allow premalignant clones to survive in the context of prostatitis.

The finding of MSR1 germline mutations in HPC risk also suggests an impairment in macrophage function could be involved in pathogenesis of prostate cancer. In addition, normal macrophage functions have some protective effect. MSR1 is also involved in macrophage growth and maintenance, adhesion to the substratum, cell–cell interactions, phagocytosis, and pathogen clearance. Taken together, RNASEL and MSR1 have generated the hypothesis that inflammation from prostatitis could contribute to the DNA damage and survival of genetically altered prostate epithelial cells. In this hypothesis, the early loss of GST-π would confer susceptibility to DNA damage from reactive oxygen created by inflammatory intermediates in prostatitis. The testable implications are: (1) RNASEL –/– genotype carriers would have prostate cells that had lost an apoptotic signal in the milieu of interferon caused by

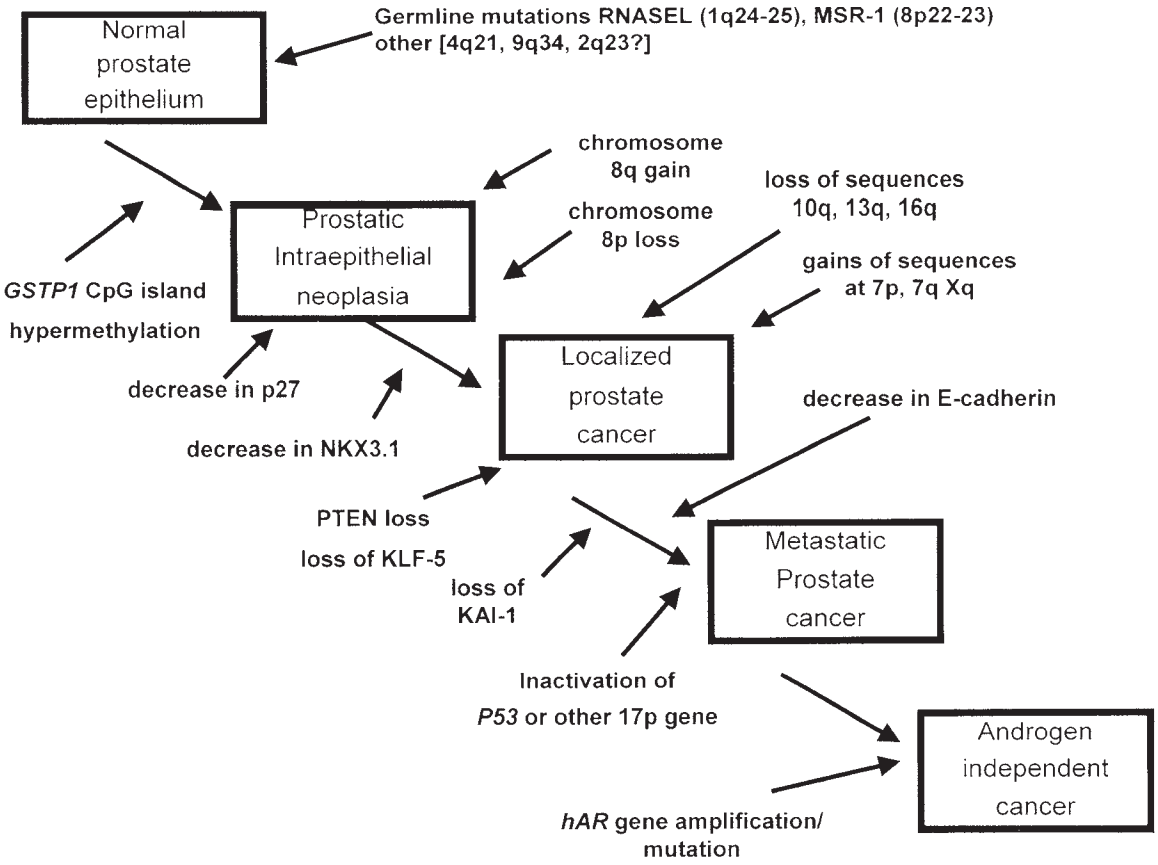

Figure 76-2 Multiple genetic alterations occur in prostate cancer progression. Many of these genomic alterations are not identified. GST, glutathione *S*-transferase.

prostatitis, and could survive with RNASE –/– mutations following prostatitis; and (2) MSR1 –/– genotype carriers might have persistent prostatitis from defects in macrophage clearance of infection in the prostate allowing far longer exposure to inflammatory oxygen free radicals. Although these predictions must be tested by genetic epidemiologists, the concept of genetic risk from prostatitis as a carcinogen for prostate cancer did not exist in the field in 2000. Of note, 9% of men 40–79 yr of age report suffering with symptomatic prostatitis. The key pathogens involved in the prostatitis—geographic differences in prostatic infection rates, population frequencies of the key alleles, and natural history of asymptomatic prostatitis and increased lifetime risk of prostate cancer—are not known. Also, though many cases of symptomatic prostatitis may be triggered by infections, pathogens are not always identified. Intensive molecular epidemiological studies have been launched on prostatitis as causative process in prostate cancer carcinogenesis, with a superimposed risk conferred by inheritance of RNASEL and MSR1 mutations or polymorphisms. *Helicobacter pylori* is a class I carcinogen for gastric cancer risk as a result of reactive oxygen damage from the bacterial infection on the gastric mucosal cells' DNA, not from insertion of oncogenes from the bacterium. The same concept of carcinogenesis from infection may apply to reactive oxygen intermediates' damage to the prostate epithelium from prostatitis. The epidemiological hunt for *H. pylori*—like bacterial and viral pathogens that could infect the prostate epithelium has begun.

In other genome-wide scans, genes on chromosomes 4q21, 9q34, and 2q23 also show evidence for some prostate cancer linkage in some families. Given the prevalence and extensive heterogeneity in the genetic aspects of prostate cancer disease, global data sets from large numbers of prostate cancer families will be needed to effectively dissect inheritance of genes conferring increased risk. Many more genes in the human genome may modify prostate cancer lifetime risk than originally anticipated.

THERAPEUTIC TARGETS

PROGRESSION: NKX3.1, PTEN, KLF5: MOLECULAR RECLASSIFICATION AND THERAPEUTIC TARGETS Despite the clinical use of Gleason Grade in prostate cancer pathology, its prognostic powers are limited. The majority of prostate biopsies are Gleason Grade 7, which cannot distinguish those tumors with metastatic potential from those without it. A molecular and mechanism-informing picture of prostate cancer is emerging that is likely to create a "Molecular Profiling with Gleason Grade" for prostate cancer. Figure 76-2 depicts this emerging molecular profile in prostate cancer progression. Tumor suppressor genes have been identified for prostate cancer progression including NKX3.1 from 8p21, PTEN from 10q23, p27/Kip1 from 12p13, and KLF5 from 13q21. In addition to their location in regions with frequent allelic losses, all have functional and/or genetic evidence supporting their contribution to prostate cancer progression. For example, Nkx3.1 homeobox gene plays an important role in normal differentiation of the prostatic epithelium; loss of function in differentiation may be an initiating event in prostate carcinogenesis. Nkx3.1 homeobox gene undergoes epigenetic inactivation through loss of protein expression. In transgeneic systems, loss of function of Nkx3.1 co-operates with loss of function of the Pten tumor suppressor gene in cancer progression in the activation of Akt (protein kinase).

Inactivation of the tumor suppressor gene PTEN is particularly of consequence in prostate cancer. Gene dose may have prognostic significance and create opportunities for the use of PTEN specific signal transduction inhibitors in prostate cancer. PTEN appears to be the most frequently mutated gene in advanced prostate cancer. Many clinical prostate cancers are –/+ for PTEN status. Experimentally, the gene dosage of PTEN mutations affects key downstream targets such as Akt, p27(Kip1), mTOR, FOXO3, and hypoxia-inducible factor (HIF)-1 involved in cell division, metabolic survival, angiogenesis and motility. The loss of the PTEN tumor suppressor phosphatase activity for phosphatidylinositol-3,4,5-trisphosphate allows AKT-1 signaling downstream and has become a major pathway for signal transduction inhibitor drug discovery for prostate cancer. Although the loss of a single allele of PTEN is haploinsufficient to suppress tumors experimentally, PTEN –/– prostate cancer tumors may have even more aggressive behavior than PTEN –/+ tumors. PTEN loss has dual consequences for the lethal phenotype of prostate cancer. PTEN also negatively controls the G1/S cell cycle transition as it regulates the levels of p27(KIP1), a cyclin-dependent kinase inhibitor. A ubiquitin ligase, the SKP-2 complex that mediates p27 ubiquitin-dependent proteolysis, is negatively regulated by PTEN phosphatase. Loss of PTEN affects SKP2 function and permits p27(KIP1) degradation and cell proliferation as well as increases AKT-1 downstream signaling. PTEN mutant, SKP-2 expressing, mTOR activated prostate cancer has become a major focus for development of signal transduction inhibitors. Researchers have discovered that mTOR inhibitors like CCI 779 are in vitro particularly effective against PTEN mutant prostate cancer cell lines in which mTOR is being activated by AKT-1. mTOR inhibitors like rapamycin and CCI 779 have entered phase I/II studies in advanced prostate cancer.

RNA ALTERATIONS IN PROSTATE CANCER: DIAGNOSTIC MARKERS AND THERAPEUTIC TARGETS With transcriptome profiling using arrayed cDNA biotechnologies, multiple candidate biomarkers, and regulatory genes have been identified by comparing prostate cancer and normal prostate epithelium. The expression and clinical utility of one of the most highly overexpressed—α-methylacyl coenzyme A racemase (AMACR)—has already entered prospective testing. Overexpressed in prostate cancer by global profiling strategies, AMACR upregulation in prostate cancer was confirmed by both reverse transcriptase PCR and immunoblot analysis. These studies were enabled by large tumor banks created by the National Cancer Institutes' SPORES program in the 1990s. Immunohistochemical analysis demonstrated an increased expression of AMACR in malignant prostate epithelia relative to benign cells. Tissue microarrays to assess AMACR expression in specimens consisting of benign prostate, atrophic prostate, PIN, localized prostate cancer, and metastatic prostate cancer demonstrated differences in staining intensity between clinically localized prostate cancer compared with benign prostate tissue. AMACR protein expression in prostate needle biopsy specimens demonstrated 97% sensitivity and 100% specificity for detecting prostate cancer. In less than 4 yr from original discovery to reduction to clinical research in pathology, AMACR is appearing useful in the interpretation of prostate needle biopsy specimens that are diagnostically challenging.

AMACR also may be a new therapeutic target given its differential overexpression in prostate cancer. α-methylacyl-CoA racemase is an enzyme involved in β-oxidation of branched-chain fatty acids. Overexpressed AMACR from both clinical tissues and prostate cancer cell lines is wild type by DNA sequence analysis and enzymatically active. Small-interfering RNA (siRNA) against AMACR, but not control siRNAs, reduces the expression of AMACR and significantly impaired proliferation in androgen-responsive prostate cancer cell lines. Simultaneous inhibition of both the AMACR pathway by siRNA and androgen signaling by means of androgen withdrawal or antiandrogen suppressed the growth of prostate cancer cells in vitro to a greater extent than either treatment alone. AMACR and β-oxidation of fatty acids is important in the optimal growth of prostate cancer cells, and inhibition of this enzyme has the potential to be a complementary target with androgen ablation in prostate cancer treatment.

ANDROGEN RECEPTOR AND ANTIANDROGENS: DISSECTION OF RESISTANCE TO THERAPY AND NEW THERPEUTIC TARGETS The mainstay of therapy for advanced prostate cancer is medical or surgical castration. Prostate cancer are hormone-dependent malignancies that respond to drugs that reduce circulating testosterone levels or prevent binding of this ligand to the androgen receptor (AR). Whereas effective, these approaches are not curative and, in almost all cases, clinical progression to an androgen refractory prostate cancer is eventually observed. Antiandrogens or androgen withdrawal causes apoptotic death of untreated prostate cancer cells. Growth of normal and neoplastic prostate is mediated by the AR, a ligand-dependent transcription factor activated by high affinity androgen binding. The AR is highly expressed in recurrent prostate cancer cells that proliferate despite reduced circulating androgen. Unlike breast cancer in which a significant percentage of tumors present with loss of estrogen receptors and progesterone receptors, AR expression is selected for in prostate cancer and retained in clinical progression.

Mechanisms of bypass of antiandrogen resistance whereas prostate cancer cells retain the nuclear expression of AR in patients treated with antiandrogens are being identified. The AR can drive prostate cancer progression through three mechanisms: AR overexpression via amplifications, point mutations in the AR gene, and ligand-independent activation of AR. AR gene amplification and mutations creating amino acid substitutions in the AR have been detected at some frequency in metastatic prostate cancers. These changes confer growth advantage to the tumor cells because of either hypersensitivity of AR to low, castrate-level androgens, or a realignment of the receptor conformation, leading to altered ligand specificity that enables adrenal androgens, nonandrogen steroids, or even nonsteroidal antiandrogens to act agonistically to increase AR activity. Persistence of signaling by the wild-type AR in therapy-resistant tumors may also be caused by receptor activity caused by cross talk of AR with multiple intracellular signaling cascades including the IL-6–IL-6 receptor intracellular signaling, phosphoinositide 3 kinase/Akt activation, and the receptor tyrosine kinase growth factors—activated mitogen-activated protein kinase (MAPK) pathways. These complex cross talk circuits in the absence of androgens may be essential pathways for prostate cancer progression in the absence of androgen. For example, epidermal growth factor (EGF) increases androgen dependent AR transactivation in the recurrent prostate cancer cell line CWR-R1 through a mechanism that involves a posttranscriptional increase in the p160 coactivator transcriptional intermediary factor (TIF) 2 /glucocorticoid receptor interacting protein (GRP) 1. Site-specific mutagenesis and selective MAPK inhibitors confirm EGF-induced increase in AR transactivation to phosphorylation of TIF2/GRIP1. EGF signaling increases the coimmunoprecipitation of TIF2 and AR, and AR stimulation by EGF can be

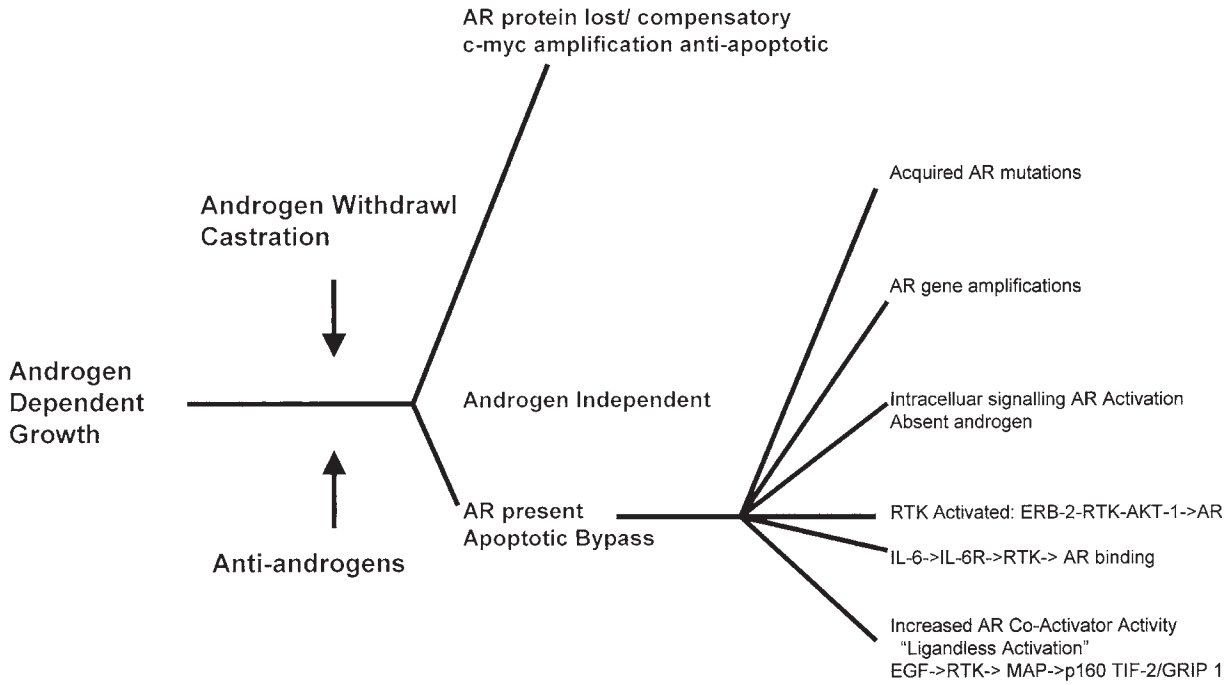

Figure 76-3 Androgen receptor expression is not, but antiandrogen resistance is a hallmark of the lethal phenotype of hormone refractory prostate cancer. In malignant progression, antiapoptotic effects of the androgen receptor are disconnected from the absence of circulating testosterone. Multiple mechanisms now permit a molecular profiling of the different phenotypes of hormone refractory prostate cancer for therapeutic development. IL, interleukin; MAPK, mitogen-activated protein kinase.

blocked by siRNA inhibition of TIF2/GRIP1 expression. EGF signaling through MAPK increases TIF2/GRIP1 coactivation of AR transactivation in recurrent prostate cancer. A molecular profile of different pathways of antiandrogen resistance has begun to emerge (Fig. 76-3).

Because a common element of these resistance mechanisms is restoration of antiapoptotic AR signaling, agents that target AR expression represent one of the most rational options for "final common pathway" targeting in disease progression following castration. Prior to ligand binding, AR exists in a complex with heat shock protein (Hsp) 90 and other cochaperones. The AR–Hsp90 interaction maintains AR in a high-affinity ligand-binding conformation that permits efficient response to dihydrotestosterone. Geldanamycin and 17-Allyamino-17-demethoxygeldanamycin (17-AAG) are inhibitors of the Hsp90 chaperone protein, a new class of antineoplastics. Pharmacological blockade of Hsp90 function causes the proteasomal degradation of proteins that require this chaperone for maturation or stability. Hsp90 chaperone "clients" include key proteins involved in tumor progression, including wild-type and mutated AR, Akt, and HIF-1. In murine models of prostate cancer, 17-AAG causes the degradation of these client proteins at nontoxic doses and inhibits the growth of hormone-naive and castration-resistant prostate cancer. In cancer cells Hsp90 exists in multi-chaperone complexes, but in normal, "unstressed" cells Hsp90 is in a latent, uncomplexed state. In vitro reconstitution of chaperone complexes with Hsp90 resulted in increased binding affinity to 17-AAG. These results suggest that prostate cancer cells contain Hsp90 complexes in an activated, high-affinity conformation that facilitates malignant progression, and that may represent a differentially expressed target that is essential for AR processing on which prostate cancer cell survival depends. 17-AAG has entered early clinical trials in hormone-refractory prostate cancer with molecular surrogate end points including the degradation of AR. Other approaches to the blockade of AR signaling effects on antiapoptosis pathways are also under investigation.

NEW TARGETS IN HORMONE-REFRACTORY PROSTATE CANCER: INHIBITORS OF ANTIMICROTUBULIN DYNAMICS

Of prostate cancer patients with metastatic disease, more than 90% develop osseous bone metastases in the absence of significant visceral organ metastases. Historically, the median survival of patients with hormone-refractory osseous prostate cancer is 12–18 mo. Two major developments have changed the picture of slow progress in medical oncology drug development in hormone-refractory prostate cancer.

With more than 30 yr of National Cancer Institute-sponsored combination cytotoxic chemotherapy clinical trials failing to demonstrate phase III trial increase in overall survival, one class of agents shows reproducible clinical benefits. Antimicrotubule targeting drugs appear to favorably affect clinical course in osseous, hormone-refractory prostate cancer. Four independent phase II studies seem to confirm this observation. Docetaxel, which acts primarily by inhibiting microtubular depolymerization, alone or in combination with other antimicrotubule inhibitors like estramustine, consistently demonstrated a palliative response, a decrease in serum prostate-specific antigen (PSA) levels by 50% or greater in more than 60% of patients, a decrease in measurable disease and single institution observations of improved survival. Two large randomized phase III clinical trials are evaluating phase II data that overall survival is improved with the use of docetaxel. Regarding toxicity, few World Health Organization grade 3 or 4 hematological and gastrointestinal side effects and few thromboembolic events have been observed in a population that includes a high percentage of men over 70-yr old receiving treatment.

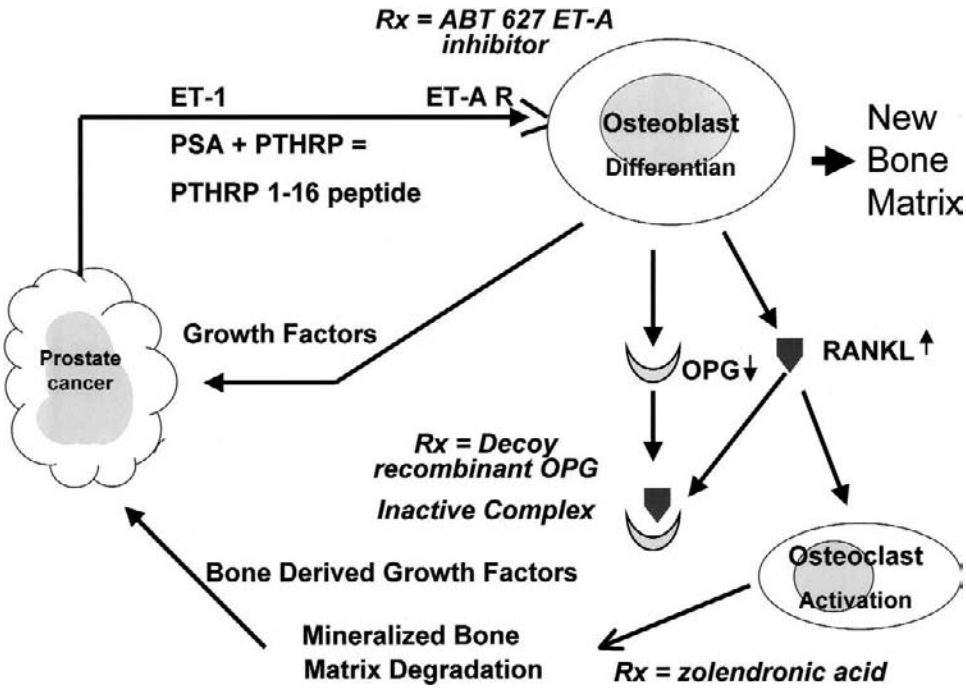

Figure 76-4 Osseous prostate cancer is the dominant form of metastatic disease. Disruption of activation of osteoclast and osteoblast interactions with the prostate cancer cells is a new strategy in cotargeting stroma and tumor interactions. PSA, prostate-specific antigen; Rx, treatment.

As hormone-refractory prostate cancer contains defects in apoptotic pathways—but does not have a high proliferative index (S fraction)—the question developed as to why microtubule-dynamics inhibitors would have activity in a tumor type that has a low fraction of cells in G2/M and moreover, why the clinical "signature" of activity would be reduction in PSA and pain in patients? A major emphasis is being placed on the mechanistic answer to this clinical question. For example, a novel class of microtubule inhibitors, 2 methoxyestradiol—which is a nonestrogenic metabolite—inhibits tumor growth and angiogenesis at concentrations that efficiently disrupt tumor microtubules in vivo. 2ME2, like paclitaxel and docetaxel, downregulates the transcription factor HIF in prostate cancer at the post-transcriptional level and inhibits HIF-1-induced transcriptional activation of vascular endothelial growth factor expression. Inhibition of HIF-1 protein levels occurs downstream of the 2ME2/tubulin interaction, as disruption of interphase microtubule s is required for HIF-α downregulation. 2ME2 is a small molecule inhibitor of a critical transcription factor in angiogenesis, and provides a new mechanistic link between the disruption of the microtubule cytoskeleton and inhibition of prostate cancer angiogenesis. 2ME2 has entered phase I trials for hormone-refractory prostate cancer. Effects of microtubule inhibitors in prostate cancer like docetaxel and 2ME2 may be at the level of disrupting interphase microtubules involved in HIF protein expression and the secretion of angiogenesis and HIF-1 regulated extracelluar growth factors—that cause prostate cancer pain and progression—as opposed to acting principally as cytotoxic drugs at mitosis. This has emerged as a new focus for drug discovery in prostate cancer. Chronic and lower dose treatment targeting microtubule disruption in hormone-refractory prostate cancer is a new avenue for clinical pharmacological investigation.

TARGETING BONE METASTASIS: COTARGETING STROMA AND TUMOR Despite 100 yr of description of the unique features of prostate cancer bone metastases with its predominant osteoblastic response around metastatic deposits of tumor and hallmark radio-opaque osteoblastic and sclerotic lesions on X-rays of bone, only recently molecular biology has been applied to understanding and revealing disruption of key pathways that may be unique to hormone-refractory prostate cancer survival in bone. The pathophysiological circuitry of the prostate cancer bone metastasis is beginning to be dissected (*see* Fig. 76-3). Studies show prostate cancer survival in the bone requires bidirectional signaling from stromal–epithelial interactions. These interactions appear to be critical for prostate cancer cells to survive and proliferate in the prostate and bone. Attacking both epithelial and stromal elements simultaneously is a unique approach to metastatic prostate cancer therapy, and proof of concept has been developed. Cotargeting both tumor cells and stroma requires identifying new tumor and stromal targets.

Castrate levels of testosterone increase the activity of bone-destroying cells, osteoclasts, and subsequent bone loss. The hypothesis is being tested that androgen deprivation therapy, by derepressing osteoclastic bone resorption and the release of growth factors, may increase the metastatic progression of prostate cancer to bone. In addition, osteoclastogenesis creates bone resorption and as the bone matrix is a storehouse of prostate cancer candidate and confirmed growth factors, bone metastatic progression may be promoted (Fig. 76-4). Targeting the inhibition of activated osteoclasts in prostate cancer bone metastases has shown clinical benefit. Zoledronic acid as a bisphosphonate decreases the risk of skeletal-related events, including spinal cord compressions and pathological fractures in men with bone metastases and disease progression after first-line hormonal therapy. These studies have been conducted in advanced hormone-refractory prostate cancer; whether osteoclast inhibition can improve survival with early treatment is under phase III testing.

Efforts are underway to further block the osteoclastic activation using recombinant proteins as new therapeutics for cotargeting.

For example, osteoprotegerin (OPG) is a decoy receptor that is a member of the tumor necrosis factor receptor family. OPG, an osteoblast-secreted decoy receptor, specifically binds to osteoclast differentiation factor and inhibits osteoclast maturation that is required for bone resorption around a metastasis. OPG prevents the binding of the receptor activator of nuclear factor-κB ligand (RANKL) to the RANK receptor on osteoclasts. Recombinant OPG decoy receptors given intravenously may disrupt the RANKL activation pathway created by prostate cancer and this approach is entering clinical trials in hormone-refractory prostate cancer.

Within the bone metastasis, prostate cancer cells secrete PSA and parathyroid hormone-related protein (PTHrP). PTHrP is a critical peptide factor for osteoclastic activation and osteolytic bone destruction. PSA however is a serine protease, which cleaves PTHrP into peptide fragments. One of these peptides, amino acids 1–16, has amino acid homology to endothelin, and binds to the endothelin receptor on osteoblasts and acts as an osteoblast mitogen. A unique difference between osseous breast metastases and prostate cancer is that PSA and the prostate-specific related exocrine serine protease hK2 converts PTHrP from an osteolytic to an osteoblastic signal in prostate cancer bone metastases.

A new picture for therapeutics is emerging for the treatment of prostate cancer bone metastases by cotargeting prostate cancer secreted agonists acting on the osteoblast. Transforming growth factor β, released from the metastasis degraded bone matrix, induces prostate cancer production of factors that promote the unique histological features of prostate cancer bone metastases, including osteoblastic responses and dysregulated new bone matrix formation. Three factors involved in prostate cancer bone metastases secreted by the tumor include endothelin-1, adrenomedullin, and insulin-like growth factor binding protein 3. The osteoblast receptors for all three ligands are being evaluated as potential targets for cotargeting blockade of prostate cancer bone metastases.

Of these three, disrupting the endothelin (ET)-1 axis using selective ET-1 A receptor antagonist ABT 627 (atrasentan) has entered phase III studies in hormone-refractory prostate cancer.

CONCLUSIONS

In some respects, prostate cancer offers unique challenges in oncology. The interactions of Western cooking, genes involved in infection and inflammation in the prostate, and human longevity are all new frontiers for understanding epigenetic influences on inherited risk and earlier detection. The discovery of the virtually universal inactivation of the GST-π gene at prostate cancer initiation has created the opportunity for new and mechanistic prostate epithelium-specific strategies of chemoprevention drug discovery. Intracellular signaling pathways in hormone-refractory prostate cancer are being dissected. Cotargeting stromal–tumor interactions in prostate cancer osseous metastases have emerged as a new paradigm in the medical oncology of prostate cancer. With the application of molecular biology and biotechnologies to human prostate cancer research, new targets in the lethal phenotypes of prostate cancer have been rapidly ascertained. How many are pharmacologically amenable and can be blocked with clinical relevance remains to be discovered. For all the emergent genetic and protein target insights, perhaps the greatest challenges will be the participation of more men with prostate cancer in translational research clinical trials that evaluate the new science of therapeutics designed specifically for prostate cancer.

77 Cutaneous Melanoma

Moira R. Jackson and Stephen P. Sugrue

SUMMARY

The incidence of cutaneous melanoma is increasing significantly and responds poorly to current therapies. At the root of this problem is the transformation of melanocytes, which normally synthesize melanin to protect the skin against ultra violet (UV) damage, into highly invasive cells which can colonize many different regions of the body, reminiscent of their neural crest origin. Paradoxically, UV radiation increases the incidence of melanoma and the penetrance of melanoma susceptibility genes such as CDKN2A. Abnormal expression of cadherins, integrins, and other cell adhesion and matrix proteins are key in melanoma cell transformation and in transendothelial migration, a key step in metastasis.

Key Words: Melanocyte; epidermis; radial growth phase; E-cadherin; CDKN2A; melanoma; UV radiation; vertical growth phase; N-cadherin; vasculogenic mimicry.

INTRODUCTION

The alarming increase in the incidence of melanoma presents a significant healthcare and research challenge. Over the last five decades melanoma rates have steadily risen in the United States and Western countries. Melanomas represent the fifth most common cancer in men and the sixth most common in women, with lifetime risks of 1.72 and 1.22, respectively. The incidence rates have risen more rapidly than mortality rates most likely owing to surgical resection in the earliest stages. Melanoma affects a relatively young population, it demonstrates a propensity to metastasize, and it exhibits a poor response to therapies. Once melanoma has successfully metastasized the survival rate is small. Research has revealed numerous genetic and molecular details defining the precise mechanisms of melanoma progression and importantly has revealed potential targets for specific new therapies. These include genetic deletions initially detected after studying familial melanoma, epigenetic alterations, and differences in levels of a variety of proteins involved in signaling pathways, oncogenes, cytokines, adhesion complex proteins, matrix molecules, and factors determining the formation of vascular supply to the tumors.

Cutaneous melanomas arise from the malignant transformation of the pigment producing melanocytes, which are located and evenly distributed in the basal epidermal layer of human skin, accounting for 1–2% of the epidermis. Melanocytes express adhesion proteins, which enable them to form connections with neighboring keratinocytes. The result of these melanocyte-keratinocyte connections is to control the rate of melanocyte division and migration and to maintain epidermal homeostasis. Cutaneous melanoma occurs when melanocyte division escapes normal control mechanisms, melanocytes proliferate unchecked, invade the underlying connective tissue compartment, and metastasize to numerous distant locations throughout the body.

All melanocytes are derived from the neural crest of the embryo. The neural crests are a multipotent population of cells that through extensive cell expansion and migration seed many distinct locations throughout organism. Progressive restrictions in the developmental potencies of neural crest cells are regulated by the action of external cytokines on the target progenitor cells. The selection and expansion of migratory melanogenic precursors to the skin depends on the local action of the cytokine endothelin-3 and the restriction to melanogenic lineage is reversible. Much like their ancestral neural crest cells, metastatic melanoma can colonize numerous visceral (lung, liver, small intestine) and nonvisceral sites (skin, lymph nodes, bones, and brain).

The study of melanoma initiation and progression has been defined to five steps in melanoma development. First, melanoma begins at a common, acquired or congenital, nevus with structurally normal melanocytes. Second, there is the change to a dysplastic nevus with structural and architectural atypia. Interestingly, a strong correlation exists of density (number/area) of dysplastic nevi and risk of melanoma development. The third step is referred to as the radial growth phase (RGP). By histological criteria, the RGP melanoma is considered to be at the early stage of primary melanoma development. RGP melanoma cells are primarily confined to the epidermis and are metastatically incompetent. The fourth step is called the vertical growth phase (VGP). By histological criteria, VGP melanoma is the advanced stage of primary melanoma. VGP melanoma is an important transition from RGP to a more aggressive condition, which is characterized by tumor cell invasion into the underlying dermis and subcutaneous tissue (Fig. 77-1). The fifth and final step in melanoma development is formation of metastatic melanoma, when the melanoma cells successfully migrate to additional distant locations.

There are significant molecular and biological differences between RGP and VGP melanoma cells and these differences have profound prognostic and therapeutic implications. In RGP neoplastic cells spread in the epidermis or demonstrate limited invasion of the dermis as single cells or small clusters of cells. In VGP, cancer cells expand in the dermis and generate significant tumor nodules.

Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

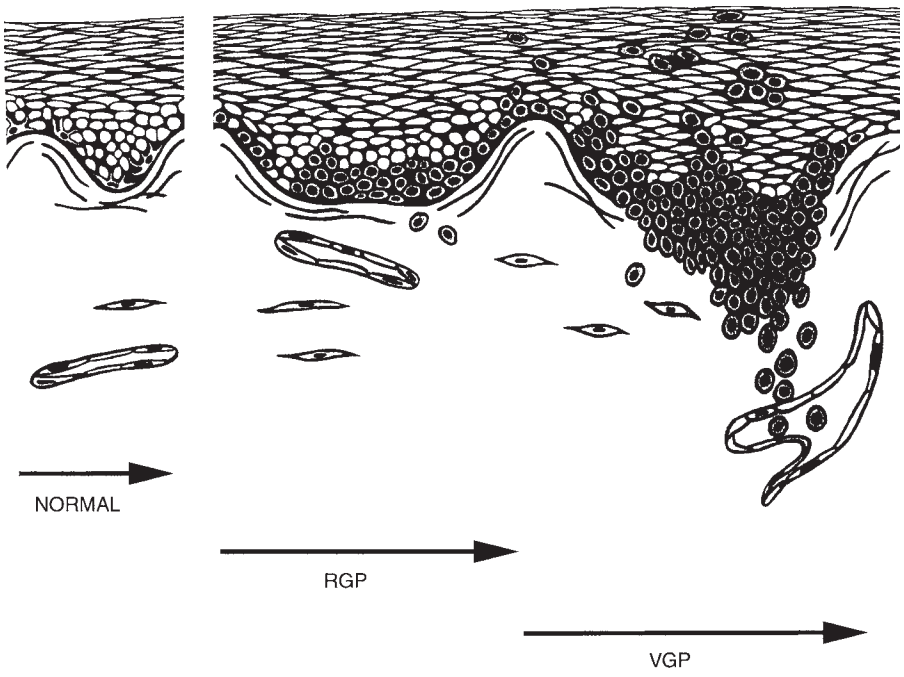

Figure 77-1 Progression of cutaneous melanoma. In normal skin, melanocytes are interspersed between keratinocytes along the dermal–epidermal border. Their dendritic processes transport melanosomes to more apical keratinocytes. During the RGP melanocytes lose their dendritic processes and proliferate in a horizontal direction predominantly within the epidermis. They have not yet acquired metastatic potential. As tumors progress to the more aggressive VGP, melanoma cells invade the underlying dermis and become metastatically competent.

Unlike the aggressive VGP melanoma cells, the RGP melanoma cells are difficult to maintain in tissue culture, have low colony forming ability, are nontumorigenic in nude mice, and do not have competence to metastasize. In the case of RGP tumors the disease can be cured by proper surgical excision. VGP cells acquire metastatic capability and may be resistant to common methods of therapy. Not surprisingly, the molecular details that may account for the transition from RGP to VGP have received much attention.

ETIOLOGY OF MELANOMA

The total risk of melanoma is determined through the interplay between genetic factors and exposure to sunlight. Ultra violet (UV) irradiation can cause DNA damage and the specific genetic background can predispose to susceptibility to UV irradiation. Differences in the relative exposure to UV radiation by latitude may contribute to the wide geographic variation in melanoma incidence rates. For example, the incidence of melanoma in Queensland Australia is notably high (lifetime incidence 1/15 or 1/20). The latitude of the residence and fair skin of the majority of the population have therefore combined to significantly increase the lifetime risk of developing melanoma for a person living in Queensland.

UV RADIATION One of the most crucial factors predisposing to melanoma development is the degree and timing of exposure to UV radiation, with childhood and/or intermittent exposures being key factors. Both UVA and UVB wavelengths can be harmful and cause DNA damage and/or immunosuppression. UVA, although having the ability to penetrate deeper into the tissue and cause immediate and persistent pigment darkening, does not seem to cause direct damage. UVA may, however, cause damage through the creation of reactive oxygen species. UVB (280–320 nm) is considered to represent the most carcinogenic waveband, inducing erythema, or sunburn, historically associated with skin cancer risk. UVB exposure is commonly associated with direct DNA damage. Nucleic acids and proteins absorb light within the UVB range, peaking at 260 and 280 nm, respectively (figures familiar to the molecular biologist). UVB causes two types of DNA lesions via creation of photoproducts between adjacent pyrimidine residues and pyrimidine dimers. Both lesions can lead to genetic mutations such as C > T or CC > TT transitions, the latter representing the hallmark of UV-induced mutagenesis.

Melanin affords protection from UV radiation. In dark-colored skin, melanocytes accomplish a highly organized presentation of melanosomes throughout the epidermis producing an effective protective screen from damaging UV. Melanin, because it effectively absorbs both UV photons and free radicals induced by UV irradiation, protects the skin from sun damage. There are two types of melanin, eumelanin found in dark skin and hair and pheomelanin found in red hair and freckled individuals. Eumelanin synthesis is upregulated by α-melanocyte-stimulating hormone (MSH) binding to the G protein-coupled melacortin-1 receptor (MC1-R). Loss-of-function mutations of MC1-R prevent eumelanin production and are associated with most red-hair phenotypes. Nonfunctional MC1-R has been linked to enhanced cytotoxic effects of UV, as well as an increased incidence of melanoma.

So why are melanocytes themselves sensitive to UV? Melanocytes may in fact respond to UV light differently than other cell types. Melanocytes produce the antiapoptotic protein B-cell leukemia/lymphoma gene (BCL-2) at high levels, which might explain the melanocytes' relatively high resistance to apoptosis subsequent to extensive UV-induced DNA damage. Both BCL-2 and its regulator microphthalmia-associated transcription factor (MITF) have been demonstrated to be critical to melanocyte survival; deficiency of either gene in mice leads to a depletion of melanocytes. The cellular decision to undergo apoptosis or cell

cycle arrest and DNA repair in melanocytes may also differ from other cell types. In fibroblasts the decision seems to be via dose dependent p53-dependent induction of p21 at low UVB doses, but Bax, not p21, is induced at higher UVB doses leading to apoptosis. The elevated levels of BCL-2 in melanocytes may allow mutant melanocytes the opportunity to survive a high dose of UVB. The survival of melanocytes may serve to maintain the integrity of the skin's sole source of melanin, ensuring uninterrupted protection from subsequent UV irradiation, but risking propagating severely damaged melanocytes and melanoma development.

MELANOMA SUSCEPTIBILITY GENES It is estimated that 10% of melanoma cases report a first or second degree relative with melanoma. Two genes that confer susceptibility to melanoma have been identified within the high-risk families, CDKN2A and CDK4. Of these melanoma families the CDKN2A locus, one of the earliest and most frequently encountered defects at chromosome 9p21, accounts for susceptibility in 25–40%, whereas mutations in the CDK4 gene have been documented in far fewer kindreds. Transgenic animals deficient in the CDKN2A (NK4a/ARF locus) develop cutaneous melanoma within a quarter of the time taken for wild-type mice to develop similar tumors. The CDKN2A gene is unique in that alternative splicing of exon 1B can result in two different proteins being transcribed in two different reading frames. The protein encoded by mRNA lacking exon 1B is the cyclin-dependent kinase inhibitor 2A, called p16/INK4a, which is involved in the retinoblastoma pathway. The protein encoded by inclusion of exon 1B of CDNK2A is called p14/ARF (**a**lternative **r**eading **f**rame) and is involved in the p53 pathway.

The p16/INK4a protein functions as a negative regulator of CDK4 activation by competing with cyclin D1 for CDK4 binding. Inhibition of CDK4 activity prevents phosphorylation of the retinoblastoma gene product (pRB). Phosphorylation of pRB results in the dissociation of pRB and E2F transcription factors and thus enables transcription of E2F target genes and progression of cells from G1 to S phase. Thus, p16/INK4a is considered as a tumor suppressor because it controls cell-cycle progression via this critical pathway. Loss of p16/INK4a results in hyperphosphorylation of pRB and, in turn, the uncontrolled activation of E2F-mediated transcription, resulting in excessive cellular growth. p16/INK4a may also play a role at the G2/M transition point in the cell cycle and loss of this protein may result in a lack of DNA repair following UV exposure as cells continue through successive divisions.

The p14/ARF protein appears to sequester Mdm2 in the nucleus so that it is not available to bind p53, an essential step in the nuclear export and proteosomal degradation of p53. Thus, a loss of p14/ARF would accelerate p53 degradation and reduce p53-mediated apoptosis. There is evidence that p14/ARF may be an independent melanoma predisposition gene. There is one report of a germline mutation that exhibited melanoma without other tumors. In addition, there is an unequivocal report of a germline deletion of p16/INK4a in the absence of concomitant loss of either CDKN2A or CDKN2B in a case of melanoma with neurilemmoma in the thoracic wall. p14/ARF may also influence the penetrance of CDKN2A mutation in mice. p14/ARF haploinsufficiency in a p16/INK4a null background suggests cooperation between p16/INK4a and p14/ARF.

Mutation in the gene encoding CDK4 itself, mapping to 12q14, has also been detected in three families predisposed toward melanoma development. Interestingly, the CDK4 mutations documented in the three families all occur at codon 24, which change arginine to either cysteine or histidine. Arginine at that position seems critical for interaction with p16/INK4a. Thus these mutations abrogate the capacity of p16/INK4a to associate with CDK4, reinforcing that loss of this inhibitory interaction as integral to melanoma susceptibility.

As mentioned, UV radiation increases the incidence of melanoma. It also increases the penetrance of known melanoma susceptibility genes such as CDKN2A. These increases may simply reflect an increase in mutational burden that would lead to a higher probability of accumulating sufficient additional mutations required for cancer to develop or a more direct mechanism may exist. For example, UV radiation induces p16/INK4A expression in human skin where it is involved in UV-induced G2 phase cell-cycle arrest. Mutations in the MSH receptor may also predispose toward melanoma development. Interaction of α-MSH with MSH receptor results in signaling responses that potentiate the UV-induced increase in p16 expression. In vitro experiments also indicate increased binding of p21 with cyclin E/cdk2 and cyclin A/cdk2 as well as p27 with cyclin E/cdk2 in transformed melanoma cells following exposure to UVB. Thus, the activities of cyclin-dependent kinases and transition through the cell cycle are key processes influenced by UV radiation in melanoma.

TUMOR INITIATION AND PROGRESSION Advances in genomic technologies have afforded the identification of many melanoma associated gene expression changes. The ability of transcription factors to control gene expression through gene activation or repression can enhance tumor formation and progression, and act to promote proliferation, migration, or to inhibit apoptosis.

Oncogenes are derived from genes with a role in cellular homeostasis that have undergone point mutations, amplifications, or promoter translocations that result in constitutive activation or inactivation of key regulatory pathways. The most commonly activated oncogenes in melanoma are those related to the RAS/mitogen-activated protein kinase (MAPK) signaling pathway, which conducts cellular signaling from growth factor receptors. Oncogenic events in melanoma typically include activating mutations in N-RAS. These mutations maintain the proteins in the GTP-bound state, thus constitutively active. In the mouse model, melanocyte-specific expression of mutated Ha-RAS was carried out in an INK4a null environment resulting in mice that develop high frequency of spontaneous cutaneous melanoma. The accumulating data derived from both human and murine models suggest that RAS activation contributes not only to growth advantage but also to tumor maintenance.

B-RAF is mutationally activated by point mutations in up to 60% of examined primary melanoma cell lines. B-RAF acts downstream of Ras in the MAPK pathway transducing signals from Ras through MAPK/ERK kinase to MAPK. Constitutive active B-RAF results in activation of downstream effectors that contribute to cell proliferation and inhibition of apoptosis. However, high frequency B-RAF mutation has been demonstrated in nevi, which are benign melanocytic proliferations. These data suggest that active B-RAF alone may not be sufficient to drive the transformation, but mutation in B-RAF may represent an early, perhaps prerequisite, step in the initiation of melanoma. In contrast however, B-RAF mutations were reported in only 10% of the earliest RGP melanomas, suggesting that B-RAF mutations may correlate with tumor progression and not initiation.

Downstream of the RAS/MAPK is Cyclin D1, an important regulator of the G1/S transition. Acral melanomas (those occurring

in the hands and feet), unlike cutaneous melanomas, are characterized by gene amplifications, frequently exhibiting amplifications of Cyclin D1. As mentioned, Cyclin D1 complexes with CDK4 to mediate the phosphorylation of pRB. Intriguingly, interfering with Cyclin D1 expression in a murine xenograft model of melanoma led to apoptosis and tumor regression, highlighting the role of this pathway in tumor maintenance.

Gain or loss of transcription factor gene function plays a major role in melanoma progression. Abnormal expression of transcription factors can in turn modulate several genes involved in tumor growth and metastasis. Alterations in activity/expression of transcription-related genes including activator protein (AP)-2, calcium/cAMP response element binding (CREB) protein, ATF-1, ATF-2 SNAI, MITF, and nuclear factor (NF)-κB have all been implicated to be involved in melanoma progression.

The role of AP-2 in progression of melanoma has received much attention and it is now accepted that AP-2 is a major transcriptional regulator of genes involved in melanoma progression. Highly metastatic melanoma cells do not express AP-2 and transfection of AP-2 into highly metastatic melanoma cells inhibits their growth and metastatic potential in nude mice. The transition of melanomas from radial to VGP is associated with the loss of c-KIT and the overexpression of melanoma cell adhesion molecule MCAM/MUC18. Interestingly, there appears to be a direct association between cKIT and AP-2 and an inverse correlation between AP-2 and MCAM/MUC18 and both these genes have AP-2 binding sites. AP-2 also regulates other genes involved in the progression of human melanoma such as E-cadherin, p21WAF, IGFR-1, matrix metalloproteinase (MMP)-2, and vascular endothelial growth factor (VEGF).

CREB expression correlates directly with metastatic potential of murine melanoma cells, and ATF is not detected in normal melanocytes but is easily found in metastatic melanoma cells. CREB/ATF-1 can act either as positive or negative regulators of transcription. CREB factors are thought to contribute to the acquisition of the metastatic phenotype in human melanoma by upregulating MMP-2 and MCAM/MUC18 expression, both of which have CRE regions in their promoters. CREB/ATF-1 may also act as survival factors for human melanoma cells.

A variety of additional transcription factors may also affect melanoma progression. Overexpression of SNAIL suppresses expression of E-cadherin, thus, significantly increasing the metastatic potential of melanoma cells. MITF plays an important role in the differentiation of melanocytes and other neural crest-derived cells by regulating tyrosinase, tyrosinase-related proteins, and dopachrome tautomerase, all involved in melanin synthesis. NF-κB regulates IL-8 and VEGF in melanoma cells and so plays a significant role in the progression of human melanoma.

Hence, loss of AP-2 and overexpression or hyperactivity of CREB/ATF-1, AFT-2, SNAIL, MITF, and NF-κB in metastatic melanoma cells may work in concert to regulate several genes contributing to the development of the malignant phenotype.

AUTOCRINE AND PARACRINE REGULATION BY CYTOKINES AND GROWTH FACTORS IN MELANOMA

Malignant melanoma cells express different growth factors and cytokines and their receptors at different stages of tumor progression, which by autocrine and paracrine effects enable them to grow autonomously and confer competence to metastasis. Autocrine growth factors (fibroblast growth factor [bFGF], melanocyte growth stimulatory activity/growth regulated protein [MGSA/GRO], IL8 and sometimes IL-6, platelet-derived growth factor [PDGF]-A, IL-10) produced by melanoma cells stimulate proliferation of the producing cell itself whereas paracrine growth factors (e.g., PDGF, EGF, transforming growth factor [TGF]-β, IL-1, granulocyte-macrophage colony-stimulating factor [GM-CSF], IGF-1, NGF, VEGF) modulate the microenvironment to benefit tumor growth and invasion. Paracrine effects include angiogenesis, stroma formation, activation of proteolytic enzymes, adhesion or motility and metastasis formation. Some growth factors have inhibitory effects on melanocytes and early lesions (IL-1, IL-6, TGF-β, oncostatin-M [OSM] tumor necrosis factor, and interferon) but not on advanced stage melanomas and in some cases they switch to an autocrine stimulator (IL-6, TGF-β). Understanding the involvement of different growth factors and cytokines in the molecular mechanism of melanoma progression may provide insight into new therapeutic approaches.

Autonomous overexpression of growth factors and their receptors are key events in melanocytic transformation. FGF-2 is a prime example of this process, whereby a normally repressed gene is activated and signals via its receptor in an autocrine manner, stimulating tumor growth. Overexpression of TGF-α, TGF-β, IGF-1, IGF-2, EGF, PDGF, and MGSA/GRO and their receptors have also been found in melanoma analyses.

A survey of expression patterns from melanoma tumors revealed that increased expression of WNT5A levels correlated with increased motility and invasiveness of the melanoma cells. In a series follow-up experiments, the levels of WNT5A were demonstrated to affect the motility characteristics of cells. The WNT5A effect may also be mediated through protein kinase C (PKC), which is thought to be associated with the cell's cytoskeletal organization, and that the PKC pathway also appeared to be downstream of the Frizzled5 (WNT5A receptor). These data may have uncovered an unexplored pathway in melanoma progression.

MELANOMA CELL ADHESION AND CELL MIGRATION

Progression of cutaneous melanoma is associated with alterations in the expression profiles of many types of cell adhesion molecules. Cadherins traverse the cell membrane and form calcium-dependent homotypic or heterotypic connections with identical proteins on neighboring cells and are connected to the actin cytoskeleton via α- and β- or γ-catenins. E-cadherin is the predominant cadherin expressed on keratinocytes and nontransformed melanocytes. During the transformation of a melanocyte to a melanoma cell, expression of E-cadherin falls and is replaced by N-cadherin. The switch from E-cadherin expression to mostly N-cadherin seems to be an important step in melanoma cell transformation. Indeed, the level of N-cadherin expression seems to correlate with stage of transformation of melanoma cells and with their migratory capability. Aggressive melanoma cell lines revert back to more quiescent cells following transfection with wild-type E-cadherin. Studies using melanoma cell lines have demonstrated an upregulation of the E-cadherin transcriptional repressor SNAIL is associated with reduced E-cadherin protein levels. Melanoma cells also express hepatocyte growth factor and its receptor c-Met, which act in an autocrine manner via PI3K and MAPK signaling to downregulate both E-cadherin and desmoglein, thus, dissociating keratinocytes from melanoma cells. Furthermore, the E2A gene product can also repress E-cadherin expression during the transition from an epithelioid to a mesenchymal phenotype observed in melanoma.

Not only are cadherin protein levels and localization important but their degree and nature of glycosylation may also be salient to melanoma progression. N-cadherin is heavily glycosylated and different types of glycosylation have been observed in melanoma cell lines from different stages of melanoma or different sites of metastasis. In vitro experiments have also shown that altering E-cadherin glycosylation can contribute to the suppression of metastasis in a murine melanoma cell line.

Normally vascular endothelial (VE)-cadherin is expressed only on endothelial cells and on placental trophoblast, both of which are exposed to circulating blood. VE-cadherin is expressed on the surfaces of melanoma cells, and cells expressing it appear to line channels within the tumor resembling blood. VE-cadherin expression and the ability to form channels has been correlated with aggressive melanoma metastasis. Clearly, strategies targeting restoration of E-cadherin expression or abrogation of N-cadherin or VE-cadherin function could have great therapeutic value.

Cadherins are linked to the actin cytoskeleton via catenins. β- and γ-catenins also act as modulators of transcription via the TCF/LEF-1 transcription complex. Thus, β-catenin is an essential component of the Wnt signaling pathway and its levels within the cytoplasm are tightly controlled. Phosphorylation of β-catenin by glycogen synthase kinase an essential step in its interaction with adenomatous polyposis coli and axin and subsequent degradation by ubiquitination and the 26s proteosome pathway. Mutations in β-catenin or adenomatous polyposis coli may result in increased cytoplasmic levels of β-catenin, which can then interact with TCF/LEF-1 in the nucleus and influence target genes that facilitate tumor survival and progression. Although mutations in the CTNNB1 gene that encodes β-catenin are rare in melanoma, increase in nuclear β-catenin is frequently observed during melanoma progression. It is thought that the increases in nuclear β-catenin are likely attributable to post-translational modifications. Interestingly, the presence of serine phosphorylation of β-catenin in malignant melanoma is an indication of a poor prognosis. LEF-1 transcripts are also increased in actively migrating melanoma cells perhaps because of increased levels of nuclear β-catenin. β-catenin-LEF-1-mediated regulation of MITF may also be pertinent to melanoma cell growth. Furthermore, transcripts of ICAT, a specific inhibitor of β-catenin-TCF signaling, in malignant melanoma are low or even absent. Interestingly, the ICAT gene is located at 1p36.2, one of the loci initially identified in loss of heterozygosity studies of familial melanoma.

One of the hallmarks of the progression of melanoma tumors from the nonmetastatic RGP to the potentially metastatic VGP is the downregulation of $\alpha_6\beta_1$ and $\alpha_v\beta_1$ integrins and increased expression of β_3-integrins. Several groups have observed a correlation between β_3-integrin levels and melanoma progression. Expression of the $\alpha_{IIb}\beta 3$-integrin appears to enhance melanoma tumor cell survival, promoting increased adherence and migration. In addition, levels of the vitronectin receptor $\alpha_v\beta_3$ correlate directly with both tumor thickness and progression in melanoma and are indicative of a poor prognosis. $\alpha_v\beta_3$-integrin is detected in all metastatic lesions and may prove an effective target for therapeutic intervention. Activation of $\alpha_v\beta_3$-initiates signals that promote metastasis through the phosphorylation of focal adhesion kinase and activation of SRC. Integrin-linked kinase is associated with β_1- and β_3-integrins and its activation results in increased expression of LEF-1 and its downstream transcriptional targets, which include the E-cadherin repressor SNAIL.

Melanoma cells also express several other adhesion molecules including MUC18/MCAM, ALCAM, and L1. Upregulation of MUC18/MCAM expression correlates with E-cadherin loss and metastasis from melanoma cell tumors in nude mice. Signaling via MUC18/MCAM can lead to focal adhesion kinase activation and downstream signaling. ALCAM has been shown to be expressed in metastasizing but not in nonmetastasizing melanoma cell tumors in nude mice by differential display.

Migration of melanoma cells involves, and may require, the degradation and remodeling of the extracellular matrix. MMPs and their inhibitors and components of the plasminogen activation system play leading roles in this process. Melanoma cells increase their ability to bind active MMPs that can degrade matrices in their path. Increased levels of active MMP-2 correlate with melanoma progression. Moreover, expression of MT1-MMP associated with MMP-2 activation increases tumor growth and vascularization in melanoma cells. Poorly aggressive melanoma cells do not appear to synthesize MMP-9 but do produce its inhibitor, tissue inhibitor of metalloproteinases-1. As melanoma progresses, this balance is reversed and cells derived from primary tumors increase MMP-9 synthesis whereas their production of tissue inhibitor of metalloproteinases decreases. Alendronate, a bisphosphonate, inhibits several MMPs and can reduce invasion of a melanoma cell line in vitro.

Components of the plasminogen activation system can also regulate cellular migration. Immunocytochemical studies indicate that both activators and inhibitors and urokinase-type plasminogen activator receptor are upregulated in primary cutaneous melanoma. Increased uPA and urokinase-type plasminogen activator receptor immunostaining may correlate with increased invasive potential, whereas the inhibitor PAI1 tends to be enriched at the periphery of the lesion in which keratinocytes may still have some level of communication and control over neighboring melanocytes. Levels of PAI1 in particular correlate with different stages of melanoma progression and may be used prognostically. Elevated levels of protease-activated receptor (PAR)-1, the thrombin receptor, are also detected in metastatic human melanoma cells lines. Cleavage of PAR-1 by thrombin activates signaling cascades that affect levels of growth factors, integrins and MMPs and promote invasion. AP-2, a repressor acting on the PAR-1 promoter in nonmetastatic melanoma cells, is downregulated in highly metastatic melanoma cells. Malignant melanoma cells also express tissue factor, which can activate thrombin, which may act as a growth factor in human melanoma cells.

METASTASIS Transendothelial migration is an essential step in the metastasis of melanoma. It involves adhesion to and then migration (diapedesis) across the endothelial monolayer. Many factors that are upregulated in melanoma tumors play a role in melanocyte chemotaxis and adhesion to endothelium or communication between melanomal and endothelial cells in vitro. Endothelial cells secrete chemokines that induce melanoma cell chemotaxis. One of the most crucial of these is IL-8, which acts through the CXCR1 receptor on melanoma cells. There is also evidence that interactions between melanoma cells and polymorphonuclear cells play a role in the adhesion of both cell types to the endothelium before transendothelial migration. As melanoma cells adhere to the endothelium, levels of VE-cadherin and PECAM between adjacent endothelial cells are diminished allowing melanoma cells to send membrane protrusions between endothelial cells. Melanoma cells appear to adhere to endothelium

via N-cadherin, $\alpha_v\beta_3$-integrin, cell adhesion molecule L1, and MCAM/ MUC18. Furthermore, several members of the tetraspanin superfamily (CD9, CD81, and CD151) localize to these heterotypic points of contact in two- and three-dimensional cocultures of melanoma cells and endothelial cells, and antibodies against CD9 inhibit melanoma cell transmigration.

TUMOR PERFUSION

Tumor growth requires adequate perfusion of blood and an ever-increasing network of vessels to convey that blood. Microvascular density within tumors is prognostically significant in the staging and diagnosis of melanoma. In general, histological examinations of highly aggressive melanoma samples show a greater density of microvessels than nonaggressive tumors. Doppler studies also indicate that greater blood flow is associated with poorer outcome. Thus, angiogenesis is considered one of the key targets for therapeutic intervention.

ANGIOGENESIS Melanoma cells synthesize a multitude of proteins, which are themselves angiogenic or cleave other proteins to produce factors that can influence angiogenesis. Levels of two well-characterized angiogenic cytokines, VEGF and FGF-2, are constitutively higher in transformed melanocytes than in normal melanocytes, and elevated serum levels of VEGF and FGF-2 are strongly correlated with poor overall prognosis of melanoma. Invasive melanomas also display higher levels of immunostaining for VEGF when compared with noninvasive tumors. Although VEGF is primarily angiogenic, FGF-2 also has an autocrine role in melanoma cell survival and proliferation; both factors are, therefore, required to maintain tumor growth. The three isoforms of MGSA/GRO are also known to stimulate angiogenesis, whereas experiments in mouse models have demonstrated significant roles for endothelial cell-selective adhesion molecule and IL-1β, IL-1α and the IL-1 receptor in the angiogenic response in melanoma cell-derived tumors. Neovascularization in melanoma is also achieved by reducing key antiangiogenic molecules. Indeed, invasion of both melanoma cells and endothelial cells is abrogated by angiostatin treatment.

VASCULOGENIC MIMICRY "Vasculogenic mimicry" is the phrase coined to describe the apparent formation of a network of channels within metastatic cutaneous lesions, which resemble the vasculogenic networks formed by differentiating endothelial cells in the embryo. This is a fascinating example of the plasticity of aggressive melanoma cells and constitutes an angiogenesis-independent pathway of facilitating tumor perfusion and preventing necrosis. Evidence of vasculogenic mimicry in tumors has a most unfavorable prognosis.

These channels are not lined by endothelial cells, yet erythrocytes and plasma can be detected within them raising the possibility that some anastomoses may occur between both endothelia-lined and nonendothelia-lined "vessels." They are formed by aggressive melanoma cells expressing VE-cadherin. Downregulation of VE-cadherin abrogates the ability of melanoma cells to form them. Introduction of aggressive melanoma cells into an ischemic environment (the hindlimb of a nude mouse) results in the expression of VE-cadherin and other endothelial associated genes and cell fate determination molecules reminiscent of embryonic vasculogenesis. Melanoma cells capable of engaging in vasculogenic mimicry express several endothelial-associated growth factors and their receptors including EphA2 and CD34. Notch 4 is also highly expressed by malignant melanoma cells undergoing neovascularization, and inhibiting tumor vasculogenic mimicry is relatively unaffected by endostatin and, thus, any therapy targeting tumor perfusion must also consider the characteristics of these nonendothelial lined channels. MMP-2 and MT1-MMP-dependent cleavage of the laminin-5γ2 chain produced fragments that could induce vasculogenic mimicry in poorly aggressive tumor cells in vitro if grown on an aggressive tumor cell conditioned matrix. Interestingly, the application of chemically modified tetracyclins, which inhibit MMP activity, also inhibits generation of fragments of laminin-5γ2 chain and the induction of vasculogenic mimicry-associated genes in less aggressive cell lines. Clearly, the microenvironment plays a significant role in neovascularization and targeting factors in the environment of aggressive melanomas may be a useful therapeutic adjunct.

78 Applications of Gene Expression Profiling to the Study of Malignant Gliomas

ANTHONY T. YACHNIS AND HENRY V. BAKER

SUMMARY

Malignant central nervous system tumors that originate from brain tissue or from the brain's coverings cause significant morbidity and mortality. Tumors of the glioma group are the most common primary brain tumors in adults and the most important group of diffusely infiltrating gliomas are the astrocytomas and oligodendrogliomas. Most gliomas are incurable because they infiltrate brain tissue, making it difficult to completely remove the tumor without damaging normal structures. Because of this, recurrences of such tumors are common, despite standard therapeutic efforts.

Key Words: Anaplastic astrocytoma; anaplastic oligodendroglioma; astrocytomas; brain tumor; diffuse astrocytoma; epidermal growth factor receptor; glioblastoma multiforme; glioma; mixed anaplastic oligoastrocytoma; mixed oligoastrocytoma; oligodendrogliomas.

INTRODUCTION

Malignant central nervous system tumors that originate from brain tissue or from the brain's coverings (i.e., primary tumors) cause significant morbidity and mortality. Each year 7–10 new cases of primary intracranial tumors are diagnosed per 100,000 population. Tumors of the glioma group are the most common primary brain tumors in adults and the most important group of diffusely infiltrating gliomas are the astrocytomas and oligodendrogliomas. The biological behavior of such tumors varies from slowly growing indolent lesions that may produce symptoms over many years to aggressive, rapidly growing neoplasms that can cause death within a year of diagnosis. Most gliomas are incurable because they infiltrate brain tissue, making it difficult to completely remove the tumor without damaging normal structures. Because of this, recurrences of such tumors are common, despite standard therapeutic efforts (usually radiation and/or chemotherapy).

Histology is the gold standard by which gliomas are classified. The following subtypes are recognized by the World Health Organization (WHO): diffuse astrocytoma, WHO grade II; oligodendroglioma, WHO grade II; mixed oligoastrocytoma, WHO grade II; anaplastic oligodendroglioma, WHO grade III (AO); anaplastic astrocytoma, WHO grade III (AA); mixed anaplastic oligoastrocytoma, WHO grade III (MAOA); and glioblastoma multiforme, WHO grade IV (GBM). Histopathological grading has provided clinically useful information regarding prognosis for *groups* of patients with diagnoses of glioma. Figure 78-1 shows the mean life expectancy after diagnosis of patients with the above subtypes of glioma.

However, variability in outcome for individual patients with the same pathological diagnosis is often observed clinically and this is a significant problem in managing patients with diffuse gliomas. The biological behavior of gliomas (and patient prognosis) correlates with certain microscopic characteristics (i.e., tumor grade) such as pleomorphism, mitoses, vascular endothelial proliferation, and tumor necrosis. However, histopathological diagnosis is highly subjective with significant interobserver variability depending on the pathologist's interpretation of or weight given to each histological characteristic. Although assessment of cell proliferation indices (e.g., Ki67 labeling index by immunohistochemistry) for gliomas has enhanced the ability to predict tumor behavior (rapid growth vs slow growth), such analysis is most helpful in distinguishing low (grade II) from intermediate grade (III) tumors and does not distinguish prognoses for patients with high-grade gliomas (grade IV). Most importantly, outcomes for individual patients cannot be accurately predicted by any brain tumor grading system. Also, few diagnostic markers are available for use in distinguishing neoplastic from normal cells and there are no reliable markers that distinguish glioma subtypes or grades of malignancy.

MOLECULAR CHARACTERIZATION OF BRAIN TUMORS

Molecular characterization of brain tumors has already proven useful in predicting response to therapy for a particular type of glioma, the AO (WHO grade III). In particular, subtypes of this tumor that have mutations (i.e., loss of heterozygosity) of chromosomes 1p and 19q have a better overall prognosis and a better response to chemotherapy with procarbazine, 1-(2-choloroethyl)-3-cyclohexyl-1-nitrosurea, and vincristine. However, not all AOs have 1p/19q deletions and not all tumors with 1p/19q losses respond to chemotherapy. Also, the success of chemotherapy with

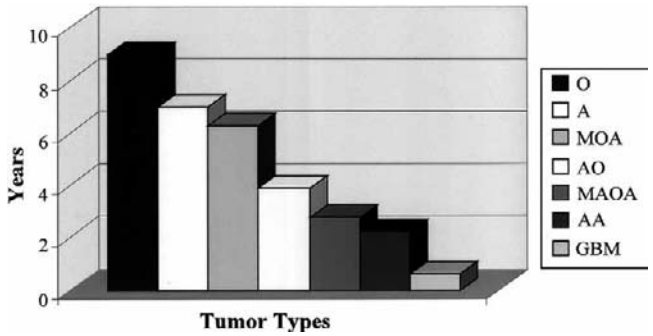

Figure 78-1 Life expectancy means after diagnosis of malignant glioma according to subtype. Oligodendroglioma, WHO grade II (O); diffuse astrocytoma, WHO grade II (A); mixed oligoastrocytoma, WHO grade II (MOA); anaplastic oligodendroglioma, WHO grade III (AO); mixed anaplastic oligoastrocytoma, WHO grade III (MAOA); anaplastic astrocytoma, WHO grade III (AA); and glioblastoma multiforme, WHO grade IV (GBM).

some AOs has created increased pressure among pathologists to make this diagnosis in any malignant glioma with histology even remotely suggestive of an oligodendroglial phenotype.

Functional genomics using DNA microarray technology is a major research tool in biology, particularly in the study of cancer biology. DNA microarray technology allows simultaneous analysis of the expression patterns of thousands of genes at one time. Therefore, instead of analyzing the expression state of a few genes using immunohistochemical markers, microarray technology allows for the analysis of literally tens of thousands of genes. Identifying genes whose altered expression is highly correlated with the malignant state will allow for better diagnostics simply by increasing the number of markers that signify the disease state. Furthermore, identification of genes that are aberrantly expressed in cancer cells will bring these genes into sharp focus for future studies aimed at understanding their role in the disease process. Gene expression profiles obtained from DNA microarray experiments and analyzed by various forms of statistics have already provided proof of principle of the utility of gene expression profiling in the analysis of various forms of cancer including gliomas.

Early investigations utilizing microarray technology demonstrated the promise and potential of this new technology as a major research tool for cancer biology and as a clinical tool for the diagnosis and prognosis of individual tumors. Unfortunately some early studies also served to illustrate potential pitfalls associated with improper experimental methodologies and inadequate or faulty computational analysis. Key to the analysis and interpretation of microarray data is the understanding that the parameter being measured, signal intensity of indirectly labeled probes, is many steps removed from the parameter being inferred, gene expression. A typical microarray experiment represents a large-scale physiological study in which cells are isolated, RNA is harvested, and labeled representations of the harvested RNA are prepared, and then used in hybridization experiments to indirectly label the nucleic acid probes constituting the array. Figure 78-2 shows the hybridization signal intensities of two Affymetrix GeneChips, one hybridized with material derived from an AO and the other from a GBM. The signal intensity of the label at each probe on the array is taken as a measure of gene expression for the genes specified by the probes. It is also important to realize that the inferred gene expression is not that of a single cell but rather that of a population of cells. In some cases the population of cells under investigation is made up of many different cell types, each of which may have varied expression profiles unique to themselves.

Microarray assays are sensitive, albeit indirect, assays capable of measuring the genomic response to both intracellular and extracellular changes in the environment that occur on and after neoplastic transformation. However, they are also capable of measuring gene expression changes resulting from uncontrolled variables that may occur at any step in the wet laboratory workup of specimens. Gene expression differences in response to uncontrolled experimental variables encountered during microarray experiments may add noise to resulting dataset and in some cases may be greater than differences associated with the pathophysiological state of the specimens. The extreme sensitivity of the microarray assay to uncontrolled experimental variables necessitates that replicate observations are performed before general inferences can be drawn regarding the global reprogramming that occur on transformation, or gene expression differences that distinguish one type and stage of cancer from another. Despite the limitations of the assay, with care it is possible to use microarrays as a tool to begin to discern the dynamic changes within cells undergoing neoplastic transformation and to probe different grades and classes of tumors for differences in gene expression patterns that may have relevance to the pathobiology of the disease.

Microarray studies have been used for the purposes of class discovery and class prediction. Class discovery studies aim to identify new subclasses of tumor based on differences in gene expression patterns. In class prediction studies the initial goal is to identify a classifier made up of a collection of genes whose expression pattern can be used to predict a class of tumor, in which class may refer to any of a number of phenotypes such as tumor diagnosis or predicting which tumors will respond to therapy. The classifier may be made up of a few to more than a thousand genes. Many studies start as class discovery exercises and mature into ones with class prediction goals. Class discovery studies typically utilize unsupervised methods of analysis; whereas class prediction studies require supervised methods of analysis.

Unsupervised methods of analysis, including principal component analysis, hierarchical clustering, k-means clustering, and self-organizing maps, can be used as tools for class discovery. Multidimensional scaling, a form of principal component analysis, has been used to separate high-grade GBMs from lower-grade astrocytomas (grades II and III) and oligodendrogliomas. Similarly hierarchical clustering can be used to distinguish high- and low-grade gliomas. Figure 78-3 shows an example of unsupervised hierarchical cluster analysis of 31 tumors and 3 non-neoplastic brain (NNB) tissue specimens; tumors of like diagnosis tend to cluster together based on the gene expression patterns observed. It is important to note that the clustering pattern was derived from the inherent gene expression profiles of the tissues and not based on prior knowledge of their diagnosis. In situations where standard methods of assigning class labels are incomplete or inadequate, unsupervised class discovery methods are especially powerful. One goal of unsupervised analyses is to identify similarities between specimens heretofore unrecognized.

Unsupervised approaches to determine differences in gene expression profiles among disease states have limitations that can be circumvented by the use of supervised learning methods.

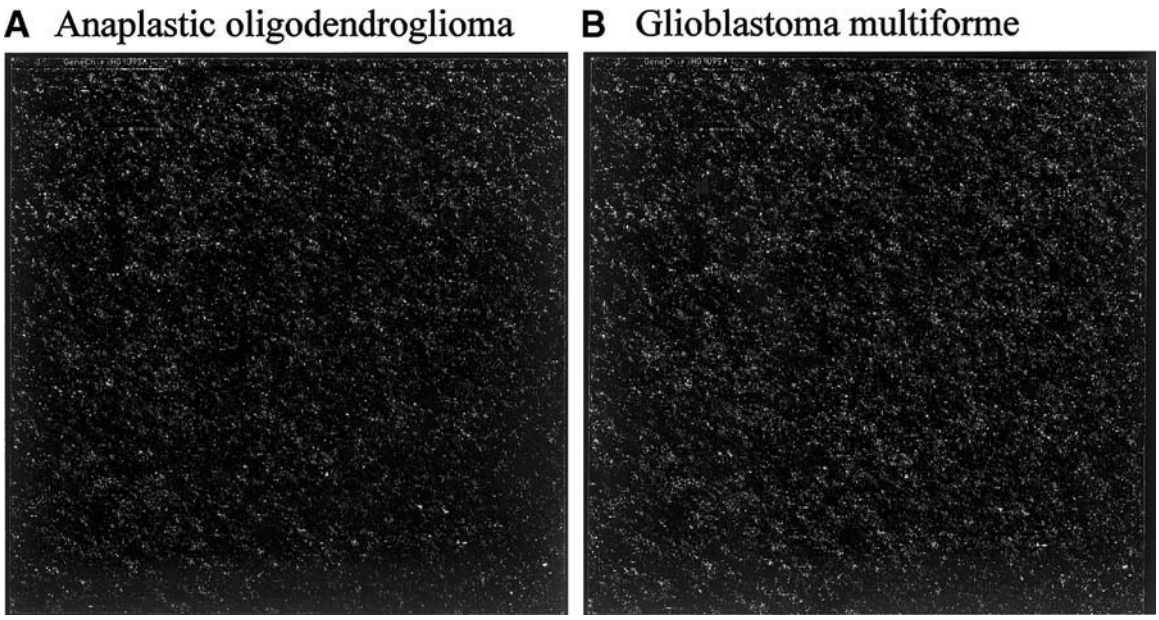

Figure 78-2 Apparent gene expression patterns of malignant gliomas detected by Affymetrix Hu95A GeneChips. **(A)** Scanned image of an Affymetrix Hu95A GeneChip hybridized with material derived from an anaplastic oligodendroglioma; **(B)** scanned image of an Affymetrix Hu95A GeneChip hybridized with material derived from a glioblastoma multiforme.

Supervised approaches include class information such as diagnosis, divergence in clinical course, and responsiveness to therapy in identifying gene expression differences between the specimens. Because supervised analyses employ statistical tests involving analysis of variance to identify genes differentially expressed between classes, it is necessary to have multiple specimens of each class under investigation.

In many cases, supervised analyses are used for purposes of identifying a classifier of probes or genes that can be used for class prediction; for example, to diagnose and differentiate diseased from normal tissue. In this case the investigators' goal is to identify genes whose collective expression patterns are predictive of the class labels. Once identified these gene expression patterns can be used to identify the nature of the specimen as normal or diseased using one or more of several prediction models. However, microarray experiments exemplify the "small *n* large *p*" trap. The number of probes on a typical microarray, tens of thousands, vastly exceeds the number of categories into which the arrays (tumors) can be classified. Thus, by chance alone therefore, it is likely that a few too many probes can be identified out of a typical dataset that seemingly can distinguish between the small numbers of class labels (tumor types) in a typical study. Cross-validation studies and Monte Carlo simulations may be employed to gauge the significance of the probes identified as predictors. As studies mature the best method of validating a classifier is not through cross-validation studies, but prospectively in which the classifier is trained on one set of tumors, used to predict the class of a new set of tumors that was not used during the training phase of the study. Many reports must be regarded as preliminary because of the small number of specimens from which the datasets were derived and the lack of cross-validation or prospective validation of the findings.

Methods for the diagnosis of infiltrating gliomas utilize a variety of modalities including clinical history and radiographic findings, in addition to histology and immunohistochemistry of biopsy specimens. Even among highly trained neuropathologists, the diagnosis of specific stages of glioma can be difficult and somewhat subjective. Care should be taken when supervised learning approaches are applied to diagnostically difficult gliomas because the supervised analysis can only be as good as the supervision applied. In an effort to increase precision and to reduce error resulting from misdiagnosis, at least two neuropathologists should review diagnostically difficult gliomas independently before they are included as specimens for supervised learning approaches.

One of the overarching goals in the application of microarray technology to the study of malignant tumors is to derive a list of sentinel genes whose expression levels may be used to predict the disease's clinical course and the tumors' responsiveness to therapy. Several studies have demonstrated the ability of gene expression patterns to predict differences in clinical course. The first study to do so was reported for lymphomas. For brain malignancies, the first used gene expression profiles to predict the clinical course of embryonal tumors. In the case of gliomas, gene expression profiling has been applied to create a classifier for distinguishing GBMs from AOs. A 19 gene classifier was derived using 14 classic GBM specimens and 7 classic AO specimens. Using the classifier with a five nearest neighbor prediction model (5 k-NN) and leave-one-out-cross-validation, the classifier had an accuracy rate of 86%. When the classifier was applied prospectively to nonclassic GBMs and nonclassic AOs, which are diagnostically difficult based on traditional pathology methods, the classifier gave significantly better separation of the tumors based on survival curves than did classification based on traditional pathology. Accurate predictions of a tumor's aggressiveness and responsiveness to therapy will aid physicians and patients in choosing the most appropriate treatment options.

Supervised analyses are also being used to identify gene expression differences among individuals within a given diagnosis

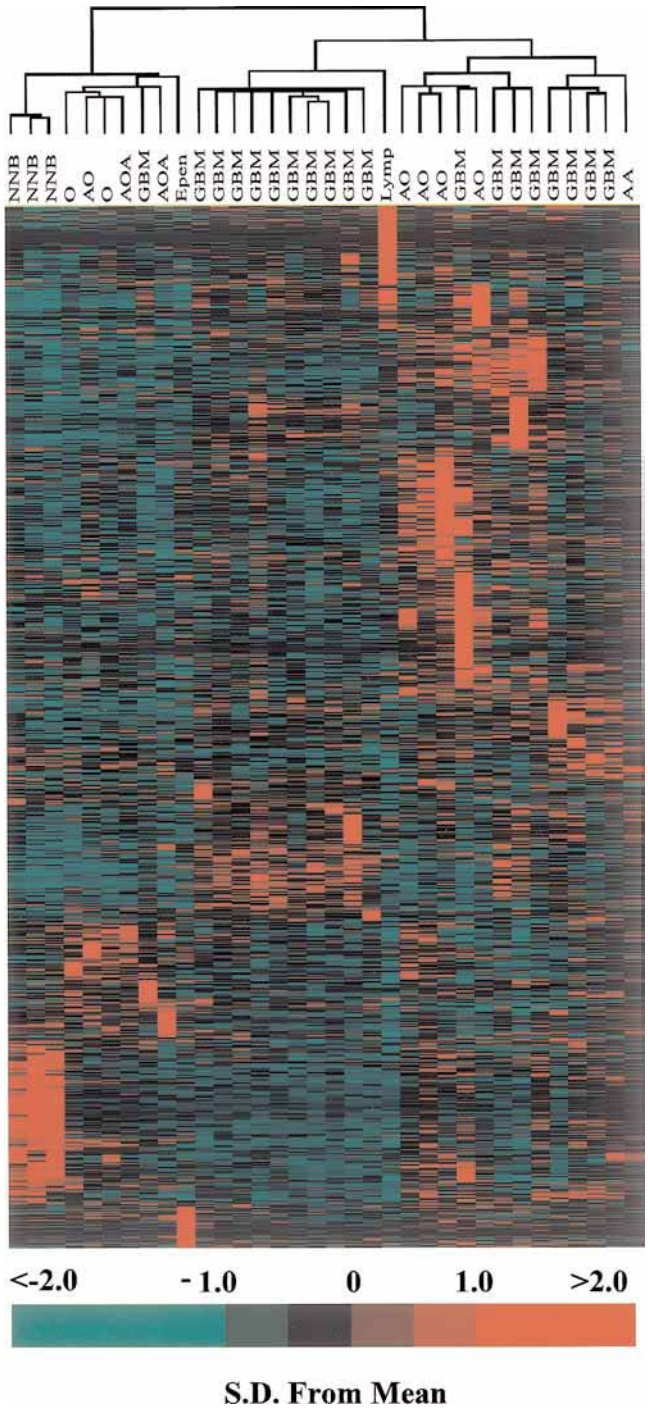

Figure 78-3 Unsupervised hierarchical cluster analysis of infiltrating gliomas and several other selected specimens. The image shows the gene expression patterns of 4658 genes whose expression varied most across the dataset. The hierarchical clustering dendrogram on top of the figure is derived from the Pearson's correlations and represents the similarity of the gene expression among the tissue samples. O, oligodendroglioma, WHO grade II; AO, anaplastic oligodendroglioma, WHO grade III; MAOA, mixed anaplastic oligoastrocytoma, WHO grade III; AA, anaplastic astrocytoma, WHO grade III; GBM, glioblastoma multiforme, WHO grade IV; Lymp, lymphoma; Epen, ependymoma; and NNB, non-neoplastic brain tissue.

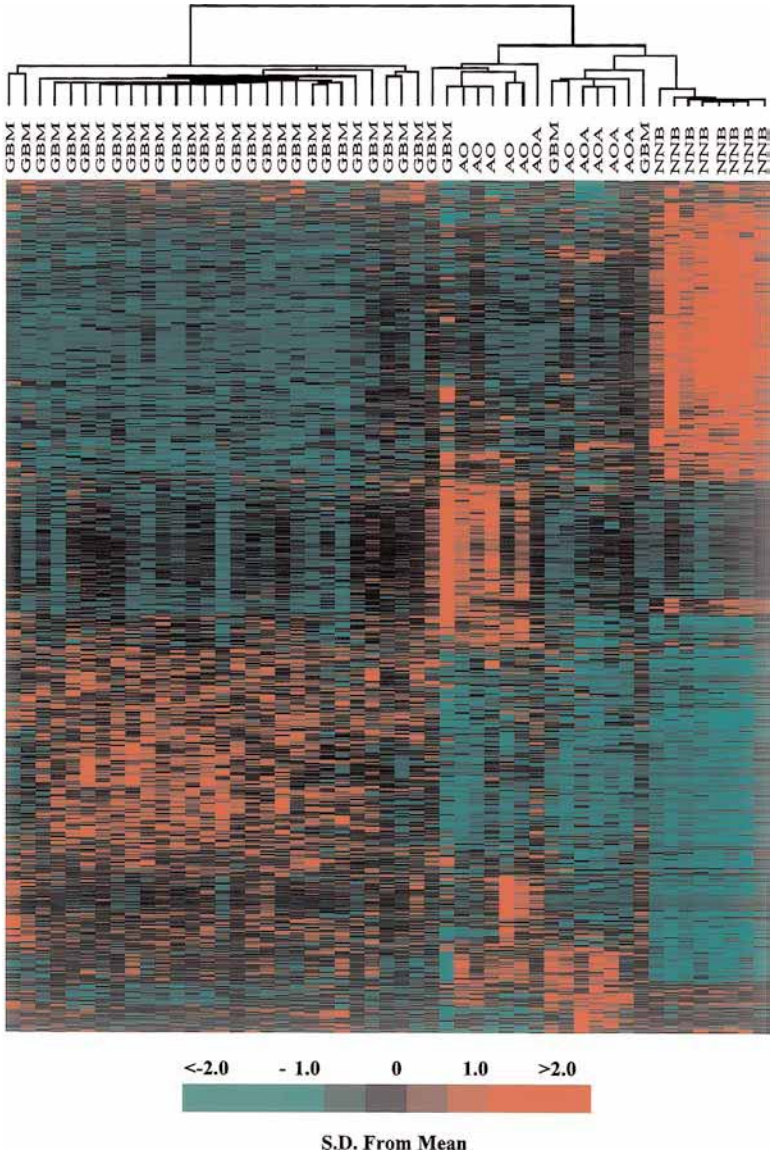
that have differing clinical courses. The precise strategy and the training sets used in supervised analyses of this nature depend on the specific characteristics of the dataset. For analyses of these types it is necessary to take into account obvious covariates such as sex and age. Once genes are identified whose expression levels correlate with clinical course within a given diagnosis of glioma, it will be necessary to validate the ability of those genes to act as a classifier capable of predicting clinical course and outcome.



Supervised learning approaches have been used to identify differences between GBMs that differ in their epidermal growth factor receptor (EGFR) status. Overexpression of EGFR has been associated with primary GBMs, but is rarely observed in secondary GBMs that arise from lower grade gliomas. Ninety genes were identified that could be used as classifiers of EGFR status of the GBMs in the study. Stratifications of GBMs based on EGFR status did not correlate with significant differences in survival; however, the study was small and may not have been adequately powered to detect such differences.

Multiclass classifiers can also be derived capable of differentiation among several grades of glioma and NNB tissue. Figure 78-4 shows the hierarchal cluster pattern of a 1071 feature classifier derived from 26 specimens capable of differentiating between AO, mixed anaplastic oligoastrocytoma, GBM, and NNB with an accuracy rate ranging between 80 and 88% when tested prospectively on 25 new tumor specimens using four prediction models including 1 k-NN, 3 k-NN, nearest centroid, and linear discriminant analysis.

At the basic science level, gene expression analysis can provide insights into the pathobiology of the disease process. In comparisons between GBM and NNB tissue, there is increased expression of genes encoding members of several signal transduction pathways, cell cycle genes, genes encoding components of the basement membrane, collagen binding proteins in addition to inflammatory response genes among other families of genes; whereas in NNB tissue there is elevated expression, compared to GBM tumor tissue, of genes involved in conducting normal brain functions such as genes encoding neurofilaments, and components of synaptic vesicles among others. Although these results are not unexpected, finding genes with elevated expression in GBMs known to play a role in cell migration and tumor genesis serves to validate the approach.

The information content of the datasets generated is tremendous and has yet to be exhausted. Future challenges include that many of the genes identified whose expression correlates with a disease state have unknown functions. What role, if any, do these genes play in the disease process? It is important to consider that finding a gene whose expression is correlated with disease state does not imply that the gene is involved with the pathophysiology of the disease state, rather the gene could be responding to the altered physiology of the cell and its environment in response to the disease state.

Supervised analyses allow for the identification of genes whose expression are consistently and reproducibly altered between different tumor types, between patients with different survival times who receive the same diagnosis, between patients who respond to radiation therapy and those who do not, and between patients who respond to chemotherapy and those who do not. In addition to stratifying patients regarding clinical outcome, these studies will identify genes whose expression is altered in neoplastic cells. This information will allow greater insights into the malignant process and may suggest targets for chemotherapeutic interventions leading to cures.

Hematological Malignancies

79 Acute Myeloid Leukemias

IRIS T. CHAN AND D. GARY GILLILAND

SUMMARY

The acute myeloid leukemias (AML) are a heterogeneous group of malignant diseases of hematopoietic progenitor cells with a spectrum of molecular genetic abnormalities, clinical characteristics, and variable outcomes with available treatments. A virtual explosion has been seen in the identification and characterization of disease alleles in AML in cell culture and murine models of leukemia. These insights have provided a platform for development of molecularly targeted therapies of AML that may improve clinical outcome.

Key Words: Acute myeloid leukemias; acute promyelocytic leukemia; core binding factor; hematopoietic stem cell; internal tandem duplications; RAS mutations.

INTRODUCTION

The acute myeloid leukemias (AML) are a heterogeneous group of malignant diseases of hematopoietic progenitor cells with a spectrum of molecular genetic abnormalities, clinical characteristics, and variable outcomes with available treatments. For several decades, the cornerstone for treatment of AML has been empirically derived cytotoxic chemotherapy. Although this remains the foundation of treatment, advances have been made in the development of molecularly targeted therapies of AML based on an improved understanding of the genetic basis of the disease. Furthermore, emerging data indicate that AML can be viewed as a hierarchy, similar to that observed in the normal hematopoietic development, in which there is a critical population of leukemic stem cells that are necessary for continued growth and propagation of AML. These leukemic stem cells are likely to be the basis for relapsed disease after remission induction, and may perhaps be the best target for developing novel therapeutic approaches to disease.

EPIDEMIOLOGY

AML is a rare disease, occurring at a frequency of about 1/100,000/yr in the general population. However, the age-specific incidence of AML rises linearly after age 40 yr with a median age of approx 65 yr. AML is rarely a heritable disease, but several congenital disorders predispose to the development of AML. These include Fanconi's anemia, and Bloom, Down, Kostmann, and Diamond-Blackfan syndromes, respectively. Antecedent hematological disease, including the myeloproliferative syndromes, myelodysplastic syndrome (MDS), and paroxysmal nocturnal hemoglobinuria, also increases the risk of AML development. Therapy-related AML may develop as a consequence of exposure to chemotherapy, including alkylating agents and epipodophyllotoxins, and ionizing radiation. Finally, there are rare, inherited predispositions to AML, such as the familial platelet defect with propensity to develop AML (FPD/AML) syndrome.

CLASSIFICATION OF AML AND RELATIONSHIP TO PROGNOSIS

Morphological criteria for the classification of AML were developed more than 25 yr ago, and are known as the French–American–British (FAB) classification. The classification has been modified by the World Health Organization to incorporate cytogenetics, molecular genetics, as well as morphological and immunophenotypic findings not previously described. In addition, a diagnosis previously required at least 30% bone marrow blasts, whereas AML is now diagnosed by World Health Organization criteria with a minimal blast percentage of 20% in blood or bone marrow. It is likely that the classification of AML will undergo further iterations as additional molecular abnormalities are identified and correlated with prognosis.

The diagnosis of AML requires morphological evaluation of the peripheral blood smear, bone marrow aspirate and core biopsy, cytogenetics, molecular genetics, and immunophenotyping. Cytogenetics are now recognized to convey important prognostic information that is interrelated with the type of therapy. For example, patients whose leukemic cells have translocations t(8;21), t(16;16), or inv(16) that involve the heterodimeric hematopoietic transcription factor core binding factor (CBF) have a favorable outcome with induction chemotherapy and intensive postremission consolidation chemotherapy with high-dose cytosine arabinoside. Similarly, patients with acute promyelocytic leukemia (APL) associated with t(15;17) have an excellent prognosis when treated with a combination of all-*trans*-retinoic acid (ATRA) and intensive induction chemotherapy that includes an anthracycline. In contrast, abnormalities of chromosomes 5, 7, 11q23 or complex karyotypes, have a very poor outcome with available induction and postremission chemotherapy. Patients with a normal karyotype or with trisomy 8 have an intermediate prognosis.

DISEASE ALLELES IN AML

Identification of mutant genes causally implicated in the pathogenesis of leukemia has been challenging, in part because leukemia

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

is a rare disease and most cases are sporadic. Thus, strategies that are informative in heritable diseases, such as generalized linkage analysis, are not applicable for elucidation of disease alleles in leukemia. There are several lines of evidence that AML is a clonal disorder that is the consequence of acquired somatic mutation that occurs in a hematopoietic progenitor. Among these are recurring cytogenetic abnormalities in leukemia cells, which have been valuable clues to the genomic localization of leukemia-associated alleles, as detailed later. However, there has also been a marked expansion of the number of disease alleles in AML that are not evident by conventional cytogenetic analysis. In all, more than 100 disease alleles have been identified, far exceeding the number of subtypes of AML recognized by other diagnostic criteria. Thus, one would expect that many of these mutations would target similar transcriptional or signal transduction targets. Mutations and gene rearrangements will be presented in a functional context that emphasizes the targeting of shared pathways of transformation.

MUTATIONS THAT TARGET SIGNAL TRANSDUCTION INTERMEDIATES Several clues revealed that mutations that activate signal transduction pathways and confer proliferative and/or survival advantages to hematopoietic progenitors would be important in AML. First, rare cases of *de novo* AML are associated with t(9;22), resulting in expression of the BCR-ABL fusion, a constitutively activated tyrosine kinase. Similarly, cases of AML arising from chronic myelogenous leukemia (myeloid blast crisis) also harbor activating mutations in *BCR-ABL*. In addition, it had been demonstrated that activating mutations in *RAS* family members, primarily *N-RAS* and *K-RAS*, are present in AML, as well as in solid tumors. Also, *FLT3*-activating mutations have been identified in AML at a frequency of approx 30%, making *FLT3* the most commonly mutated gene in AML. Collectively, mutations that constitutively activate signal transduction pathways have been identified in approx 50% of AML, and it is plausible that appropriate screens will identify similar mutations in the remainder. These mutations appear to form a complementation group, in that they do not occur together in the same AML patient. For example, *FLT3* and *RAS* mutations, though frequent in leukemia as individual mutations, rarely occur together in the same patient. This observation suggests that these mutations subserve similar functions in AML in providing proliferation and survival signals to leukemia blasts. Because these mutations may occur with disease progression, it is possible that on those very rare occasions when both mutations are observed in a patient with AML, they have arisen independently in separate clones.

MUTATIONS THAT CONSTITUTIVELY ACTIVATE RECEPTOR TYROSINE KINASES Activating mutations have been identified in *FLT3* (approx 30%) and *c-KIT* (<5%) in AML. In the context of FLT3, about 20–25% of AML cases harbor internal tandem duplications (ITD) of the juxtamembrane domain. These in-frame ITDs are highly variable between AML patients, and range in size from several to more than 50 amino acids. Structural data indicate that the FLT3 juxtamembrane domain is an autoinhibitory domain whose function is disrupted by the ITD mutations, resulting in constitutive kinase activation. In an additional 5–10% of cases, so-called activating loop mutations occur near position D835 in the tyrosine kinase, and also result in constitutive kinase activation. Analogous activating loop mutations at position D816 of c-*KIT* have also been reported in a fraction (≤5%) of AML cases.

Expression of FLT3-ITD by retroviral transduction into bone marrow cells in a murine bone marrow transplant model results in a myeloproliferative disease (MPD) rather than AML. The MPD is similar to that observed with myeloid leukemia associated tyrosine kinase fusion genes, such as *BCR-ABL* or *TEL-PDGFRB* in retroviral transduction models, and is characterized by neutrophilia, myeloid hyperplasia in the bone marrow, extramedullary hematopoiesis in liver and spleen comprised of maturing myeloid elements, and lack of transplantability into secondary recipient mice. As discussed in more detail later, *FLT3* mutations in humans may occur in conjunction with known gene rearrangements such as *RUNX1/ETO*, *PML/RARα*, *CBFβ/MYH11* or *MLL*; and *KIT* mutations occur at a higher frequency in association with the *CBFβ/MYH11* fusion. These data suggest that cooperation between these alleles may be important for the AML phenotype.

Several large studies indicate that *FLT3* mutations confer a poor prognosis, at least in patients under the age of 65, and occur at high frequency in both adult and pediatric populations. For these reasons, mutant FLT3 is an attractive candidate for molecularly targeted therapy with small molecule tyrosine kinase inhibitors. There are four small molecule inhibitors of FLT3 in clinical trials, including PKC412, MLN518, SU11248, and CEP-701. Although these are still in the early phases of clinical development, several generalizations can be made among the various inhibitors. Each appears to be well tolerated, with modest toxicity, and has activity in relapsed AML. Although complete remissions have been infrequent, the peripheral blood blast response has been striking in a number of cases, although in most cases the bone marrow blast response has been less impressive. Responses are short lived, and suggest that resistance to FLT3 inhibition develops rapidly, although the basis for resistance is not known. If resistance is attributable to acquired point mutations in the context of FLT3, analogous to imatinib-resistant mutations in BCR-ABL, then the availability of several active FLT3 inhibitors with differing chemical structures may be of value in preventing or overcoming resistance. Clinical approaches are focused on using FLT3 inhibitors upfront in combination with intensive induction chemotherapy.

KIT mutations are also attractive targets for therapy, in that the native KIT kinase can be inhibited by imatinib (Gleevec). In addition, deletion mutations in the juxtamembrane domain of *KIT* occur at a high frequency in gastrointestinal stromal cell tumors, and confer sensitivity to imatinib in that clinical context. Unfortunately, *KIT* D816X mutations confer resistance to imatinib, and thus it is unlikely that imatinib will be of value in treating this subset of patients. However, selected FLT3 inhibitors, such as PKC412, have activity against the KIT D816X mutants, and thus may be of therapeutic value.

Oncogenic *RAS* Mutations in *AML* Activating *RAS* mutations have been reported in both AML and MDS, typically at codons 12, 13, or 61 of *N*- or *K-RAS*. The incidence varies widely between studies ranging from 25 to 44%. Mutant *RAS* alleles were assessed by direct sequencing in one study that reported an 18% incidence of *N*- or *K-RAS* mutations, which conferred a poor prognosis. Because of the high frequency of oncogenic *RAS* mutations in AML and many other human tumors, considerable effort has focused on developing *RAS* inhibitors. RAS activity in mediating signals from upstream effectors is dependent on RAS localization to the plasma membrane. Farnesylation of RAS is required for membrane localization, and thus one attractive strategy for inhibiting RAS activity has been to develop farnesyl transferase inhibitors (FTIs). Convincing evidence reflects that FTIs have activity in

AML, though responses have not correlated with the presence of activating mutations in *RAS*. The basis for the response is not understood, but may be due to inhibition of other prenylated proteins in AML, "off-target" effects of FTIs, or inhibition of native RAS that is activated by upstream effectors such as FLT3 or KIT.

Murine models of oncogenic *K-Ras* expression from its endogenous promoter under conditional control demonstrate a myeloproliferative phenotype similar to that observed with constitutively activated tyrosine kinases such as FLT3. Animals develop neutrophilia with myeloid hyperplasia of the bone marrow and extramedullary hematopoiesis comprised of maturing myeloid elements. These cells do not serially replate, and are not efficiently transplanted into secondary recipients. These data indicate that, like activated FLT3, oncogenic *RAS* alleles are not sufficient to cause AML, and suggest that constitutively activated RAS is a functional equivalent of constitutively activated kinases. These findings correlate with the clinical observation that these two mutations do not occur together in the same patient with AML, and that they comprise a functional complementation group that confers proliferative and survival advantage to myeloid lineage progenitors, but does not affect differentiation and does not appear to confer properties of self-renewal as assessed by serial replating and transplantation assays.

Activating Mutations in PTPN11 (SHP2) Acquired mutations in the protein tyrosine phosphatase *PTPN11* (*SHP2*) have been identified in several hematological malignancies, including both sporadic cases of juvenile myelomonocytic leukemia and juvenile myelomonocytic leukemia arising in individuals with Noonan syndrome, as well as rare cases of AML and MDS. The molecular mechanisms of leukemogenesis associated with activating mutations in *SHP2* are not well understood, but provide another example of signal transduction mutations associated with myeloid leukemias. Murine models of activated *PTPN11* alleles knocked-in to the endogenous promoter also demonstrate that these mutant alleles when expressed alone result in a myeloproliferative phenotype.

MUTATIONS THAT TARGET TRANSCRIPTION FACTORS

Transcription factors were first identified as target genes in AML through the cloning of balanced reciprocal chromosomal translocations. However, it is increasingly evident that point mutations also target transcription factors, in particular those essential for normal hematopoietic development. In most cases, the available data indicate that these mutations result in partial or complete loss of function of the respective transcription factor, with an associated phenotype of impaired hematopoietic differentiation.

MUTATIONS AND GENE REARRANGEMENTS INVOLVING CBF

Chromosomal Translocations CBF is targeted by more than a dozen different chromosomal translocations, as well as loss of function point mutations. CBF in hematopoietic cells is a heterodimeric transcription factor comprised of a DNA binding subunit, RUNX1 (AML1), and a CBFβ partner that does not contact DNA but facilitates transcriptional activation of target genes by RUNX1. CBF is a critical regulator of normal hematopoietic development, and transactivates a spectrum of genes essential for both myeloid and lymphoid development. Homozygous loss of function of *Runx1* or *Cbfb* in knockout mice results in a lack of definitive hematopoiesis.

The two most common chromosomal translocations that target CBF in AML are the t(8;21)(q22;q22) and inv(16)(p13q22), respectively. The t(8;21) accounts for approx 12% of cases of AML, and occurs in association with a morphological subtype of AML M2 characterized clinically by a high incidence of granulocytic sarcomas, and morphologically by prominent Auer rods, salmon-colored granules, and large cytoplasmic granules and vacuoles. These patients have among the best prognoses in AML when treated with regimens that include high-dose cytosine arabinoside, and in many cases will not be considered for allogeneic bone marrow transplantation in first remission because of the high likelihood of long-term disease free survival with intensive chemotherapy alone. The consequence of t(8;21) is expression of a *RUNX1-ETO* fusion gene that acts as a dominant negative inhibitor of CBF through aberrant recruitment of the nuclear corepressor complex, including histone deacetylase (HDAC) to CBF binding sites. In vivo data that supports dominant negative activity include the observation that the phenotype of a RUNX1-ETO knockin to the *Runx1* locus is identical to the *Runx1*$^{-/-}$ phenotype, namely embryonic lethality with a lack of definitive hematopoiesis.

Conditional models that circumvent the embryonic lethality of the RUNX1-ETO knockin have allowed for expression of this AML associated oncogene in the adult hematopoietic compartment. Expression of RUNX1-ETO supports enhanced serial replating of hematopoietic progenitors in vitro, but animals do not develop AML unless treated with chemical mutagens to induce additional mutations. These findings indicate that *Runx1-Eto* expression may contribute to properties of self-renewal observed in populations of AML cells (*see* Section on Leukemia Stem Cells), but is not sufficient to cause AML when expressed alone. These observations, and the epidemiological observation that activating mutations in FLT3 may occur in patients with the *RUNX1-ETO* fusion suggest that these two mutations cooperate in pathogenesis of AML (*see* Section on Cooperating Mutations in AML).

The inv(16)(p13q22) is observed exclusively in the M4Eo subtype of AML, and accounts for approx 8% of cases. These patients, similar to those with the t(8;21), have a relatively good prognosis compared with non-CBF leukemias when treated with regimens that include high-dose cytosine arabinoside, although data indicate that their prognosis is somewhat less favorable than the t(8;21) patients. A *CBF*β*/MYH11* fusion gene is generated by chromosomal inversion or may also be expressed as a consequence of t(16;16)(p13:q22). The CBFβ-MYH11 chimeric protein contains nearly all of *CBF*β, including the heterodimerization domain for *RUNX1*, fused to the C-terminal sequences of *MYH11*, including its coiled-coil dimerization motif. The chimeric CBFβ-MYH11 protein thus retains its ability to bind to *RUNX1* and is also capable of forming high-molecular-weight multimers through the coiled-coil domain of *MYH11*. Like AML1-ETO, the CBFβ-MYH11 fusion is a dominant negative inhibitor of transactivation mediated by CBF. For example, mice that express the CBFB-MYH11 allele from the endogenous promoter have a similar phenotype to that observed with the RUNX1-ETO fusion, *Runx1*$^{-/-}$ or *Cbf*β$^{-/-}$mice, with midgestation embryonic lethality, absence of fetal liver hematopoiesis, and central nervous system hemorrhage. *Cbfb-Myh11* knockin mice also do not develop leukemia unless chemical mutagens are used to generate additional mutations. These data suggest that cooperating mutations are also required for leukemogenesis associated with the CBFβ/MYH11 fusion.

Loss of Function Point Mutations in RUNX1 in AML Loss of function point mutations have been described in heritable AML syndromes, as well as in sporadic AML. FPD/AML is an autosomal-dominant trait with characteristics of MDS, including

thrombocytopenia with platelet dysfunction, progressive pancytopenia that can affect all hematopoietic lineages with age, and progression to AML. FPD-AML is caused by loss of function mutations in *RUNX1*. In addition, approx 3–5% of sporadic cases of AML harbor loss of function mutations in *AML1*, with a higher frequency in M0 AML (approx 25%), in AML or MDS with trisomy 21, and in AML or MDS with deletion or loss of chromosome 7.

Targeted therapeutic approaches to CBF leukemias have included the development of HDAC inhibitors in an attempt to reverse the co-repression mediated by the leukemogenic fusion genes. These strategies are in early stages of implementation in clinical trials.

TRANSLOCATIONS INVOLVING THE RETINOIC ACID RECEPTOR-α LOCUS ON 17q22 ATRA induces complete remission in the majority of patients with APL. This empiric observation provided important insights in the cloning of the t(15;17)(q22;q22) breakpoint involving the retinoic acid receptor (*RAR*)-α locus on 17q22. The consequence of the translocation is fusion of the *RAR*-α gene on chromosome 17 to the *PML* (promyelocytic leukemia) gene on 15q22. Two reciprocal fusion RNA species are produced as a consequence of the translocation, *RARα-PML* and *PML-RARα*. The PML-RARα fusion protein contains the zinc finger of PML fused to the DNA- and protein-binding domains of RARα. Several other chromosomal translocations associated with an APL phenotype have been cloned and characterized. Each of these targets the *RARα* locus, with fusion to various partners that include *PLZF* and *NPM*. The best studied of these is the PLZF-RARα fusion that also aberrantly recruits the nuclear corepressor complex. However, in contrast with the PML-RARα fusion, ATRA is not able to relieve co-repression mediated by the PLZF-RARα fusion, and thus is not effective in patients that harbor the t(11;17) associated with this fusion gene.

The PML-RARα and PLZF-RARα fusion proteins are dominant negative inhibitors of retinoid induced transactivation. In addition to interfering with normal RARα interacting proteins, such as RXRα, the PML-RARα fusion also interferes with the function of the native PML protein, which is thought to function as a tumor suppressor gene based on analysis of mice that are deficient in *Pml*. The PML protein is a component of nuclear structures known as promyelocytic leukemia oncogenic domains or nuclear bodies. In APL cells, the integrity of the nuclear body is disrupted and a microspeckled distribution of PML-RARα is observed. Treatment of APL cells with ATRA causes the nuclear bodies to regenerate, with proper relocalization of PML. Arsenic trioxide also targets PML and PML-RARα to nuclear bodies and induces degradation of these proteins. Thus, the restoration of nuclear body structures by either ATRA or arsenic trioxide correlates with the ability of either of these agents to induce remission of APL.

The dominant interfering activities of the PML-RARα fusion protein result in a block in differentiation at the promyelocyte stage of development. The clinical response of APL patients is due to ATRA binding to the PML-RARα fusion protein and subsequent reversal of repression of target genes required for normal differentiation. Like the leukemogenic CBF fusion genes, the ability of the PML-RARα fusion protein to repress transcription is due in part to the aberrant recruitment of the nuclear corepressor complex, including HDAC, suggesting that pharmacological agents that inhibit HDAC may also be useful in therapy of APL.

Like CBF-associated leukemias, murine models indicate that development of APL requires mutations in addition to the t(15;17). Expression of PML-RARα in transgenic mice from promoters that direct expression to the promyelocyte compartment, such as Cathepsin G or MRP8, results in an APL-like phenotype. However, there is an approx 6-mo lag before the development of leukemia, incomplete penetrance of about 15–30%, and acquired clonal karyotypic abnormalities, all suggesting that second mutations are required for induction of leukemia. Coexpression of both the PML-RARα and RARα-PML under the Cathepsin G promoter results in increased penetrance, but retains a prolonged latency and acquisition of cytogenetic abnormalities, still supporting the need for additional mutations. Furthermore, data indicate a further increase in penetrance and decrease in latency when PML-RARα is expressed from the endogenous Cathepsin G locus in a knockin model. Surprisingly, the fusion gene is expressed at much lower levels in this model than in conventional transgenic models, indicating that level of oncogene expression is a critical determinant of leukemogenic potential. Activating mutations in *FLT3* have been reported in a high percentage of APL cases (approx 40%) and these individuals appear to have a worse prognosis than APL patients with wild-type FLT3. Mutant FLT3 cooperates with expression of PML-RARα in induction of APL in murine models. Retroviral transduction of FLT3-ITD into the Cathepsin G-PML-RARα transgenic mice results in an APL-like disease characterized by complete penetrance and markedly shortened latency when compared with the development of sporadic PML-RARα leukemias. ATRA is efficacious in these animals, and the model has allowed for preclinical testing of novel agents currently in clinical trials, such as arsenic trioxide and FLT3 inhibitors.

HOX Family Members in AML *HOX* genes are targeted by several chromosomal translocations that include the t(7;11) and t(2;11) that result in the expression of the *NUP98-HOXA9* and *NUP98-HOXD13* fusions, respectively. As with expression of the large family of HOX paralogs during development, there is tightly controlled coordinate regulation of *HOX* gene expression during hematopoietic development. HOXA9, for example, is expressed in early hematopoietic progenitor cells, but is downregulated during hematopoietic differentiation and is undetectable in terminally differentiated cells. Thus, enforced constitutive overexpression of *HOXA9* as a consequence of fusion to *NUP98* gene may result in aberrant differentiation. In addition, in cell culture and murine models of transformation, the NUP98 moiety aberrantly recruits transcriptional coactivators, such as CBP, and may thus potentiate dysregulation of HOX target gene expression. Although *HOX* genes are important targets of translocations involving the nuclear pore, components of the nuclear pore including *NUP98* and *NUP214* may be fused to a broad spectrum of partners in AML as a consequence of chromosomal translocation, including *DDX10*, *PMX1*, and *DEK*. These findings suggest the intriguing possibility that nuclear pore function may also contribute to the development of AML in some cases.

Dysregulated *HOX* gene expression may be important as a downstream effector of leukemogenesis because of mutations in other pathways. As discussed below, transformation mediated by *MLL* fusion genes is in part attributable to *HOX* gene dysregulation. As another example, t(12;13) associated with AML results in expression of high levels of CDX2 from the *TEL* promoter. CDX2 is a homeotic protein that regulates expression of HOX family members in the colonic epithelium, but is not normally expressed in hematopoietic progenitors. As in hematopoietic development, *HOX* gene expression is highest in colonic stem cells at the base of the colonic crypt, and is downregulated with maturation to

mature epithelial cells. It is thus plausible that high levels of expression of CDX2 as a consequence of the t(12;13) chromosomal translocation dysregulates *HOX* expression in hematopoietic progenitors and results in leukemia. Evidence to support this includes the ability CDX2 to induce leukemia in murine retroviral transduction models. Although CDX2 is not normally expressed in hematopoietic cells, its family member CDX4 has been cloned, and appears to play a similar role in hematopoietic development as CDX2 does in the gut. Of note, CDX4 appears to either be downstream or epistatic with MLL in regulation of *HOX* gene expression in hematopoietic cells.

C/(EBP)α Mutations in AML C/EBPα is a hematopoietic transcription factor required for normal myeloid lineage development. Loss of function results in severe neutropenia owing to lack of maturation of the myeloid lineage. Point mutations in *C/EBPα* have been identified in a fraction of M2 AML cases that confer dominant negative properties, and would be predicted to impair differentiation of myeloid lineage cells. Data indicate that *C/EBPα* mutations confer a favorable prognosis.

GATA-1 Mutations in AML *GATA-1* mutations are associated with a subset of acute megakaryoblastic leukemias (FAB M7), in particular leukemias arising in patients with Down syndrome (constitutional trisomy 21). These mutations appear to result in loss of function or dysregulation of GATA-1, and are thought to contribute to leukemogenesis. The mechanism through which hypomorphic alleles of *GATA-1* contribute to leukemogenesis in the context of +21 is not known. *GATA-1* mutations have only been associated with Down syndrome, and have not been observed in other infant acute megakaryoblastic leukemias.

TRANSCRIPTIONAL REGULATORY PROTEINS IN CHROMOSOMAL TRANSLOCATIONS The observation of mutations and gene rearrangements affecting the function of transcription factors important for normal hematopoietic development suggests that the target genes for these transcription factors, and their mutated counterparts, are important in disease pathogenesis. However, an interesting class of mutations has been observed in AML involving components of the transcriptional apparatus with no apparent DNA binding specificity. These include fusion genes involving transcriptional coactivators such as CMP, p300, MOZ, and TIF2, and transcriptional modulators such as MLL.

MLL Gene Rearrangements 11q23 translocations involving the *MLL* locus have been observed in several AML FAB subtypes, but occur most commonly in the M4 myelomonocytic and M5 monoblastic leukemias. In addition, t(4;11)(q21;q23) is the single most common cytogenetic abnormality in infants with acute leukemia, occurring in approx 70–80% of these cases. 11q23 translocations are also observed frequently in therapy-related leukemias in patients who have previously been treated with chemotherapy drugs that inhibit topoisomerase II, especially the epipodophyllotoxins.

MLL is a large protein (molecular weight approx 430 kDa), and contains several functional motifs that suggest that MLL has properties of a transcriptional regulatory protein. These include N-terminal adenine–thymine (AT)-hook motifs that bind to AT-rich sequences in the minor groove of DNA; a region of homology with DNA methyltransferases; two regions of homology to the *Drosophila trithorax* gene referred to as PHD or LAP domains; and a C-terminal SET domain. There are also transcriptional activation and repression domains. Targeted disruption of *Mll* in mice results in embryonic lethality at day E10.5, and *Mll* heterozygous mice have growth retardation, bidirectional homeotic transformations of the axial skeleton, and sternal malformations. In the *Mll* homozygous deficient mice, expression of *Hoxa7* and *Hoxc9* is abolished, whereas in *Mll* heterozygous mice, there is posterior shift of the anterior boundaries of expression of these genes. These findings indicate that MLL is a positive regulator of *HOX* gene expression during development, and provide evidence that MLL-related fusions might aberrantly regulate *HOX* genes in leukemogenesis.

MLL is involved in more than 40 different chromosomal translocations, with a diverse spectrum of partners. In addition, there is partial tandem duplication of *MLL* sequences in a subset of AML patients with trisomy 11 or a normal karyotype that duplicates the amino terminal AT hooks, the methyltransferase and repression domains of MLL. These findings suggest that the critical transforming event may be related to rearrangement of MLL itself, as opposed to contributions from the diverse fusion partners.

In support of this hypothesis, the MLL gene product is a propeptide that is cleaved by a novel protease, taspase 1. There appears to be aberrant regulation of *HOX* gene expression by noncleaved MLL, and it has been suggested that the *MLL* fusion genes and the *MLL* partial tandem duplications are surrogates for the noncleaved MLL protein. This hypothesis would explain in part the similarity in phenotype of most of the MLL fusions in AML, and also indicates that a critical transforming event in leukemia is dysregulation of *HOX* gene expression. The fusion partners might then contribute to lineage specificity or other phenotypic aspects of transformation related to *MLL* gene rearrangements.

As noted, most infant leukemias harbor the t(4;11)(q21;q23) that results in expression of the *MLL-AF4* fusion gene. Analysis of global patterns of gene expression indicates that these leukemias represent a distinct subclass of leukemia that can be readily delineated from AML or acute lymphoblastic leukemia by gene expression profiles. These data, and information on the target genes that are overexpressed in infant leukemia with the MLL-AF4 fusion such as FLT3, suggest novel approaches to therapy of this subtype of leukemia.

Important data on mechanisms of transformation by *MLL* fusion genes have been generated in retroviral transduction models of leukemia. Transduction of *MLL-ENL* fusion into primary murine bone marrow cells results in immortalization as assessed by serial replating assays, whereas constructs containing either N-terminal *MLL*, *ENL* alone, or vector controls could not maintain proliferative capacity beyond three passages. Furthermore, transplantation of *MLL-ENL*-transduced bone marrow into syngeneic recipient mice resulted in AML. These experiments were extended to analyze the importance of *HOX* family members in leukemogenesis by transduction of murine backgrounds genetically deficient in *HoxA9* or *HoxA7*. Transduction of *MLL* fusion genes into these backgrounds results in a marked attenuation of the leukemia phenotype, and demonstrates a critical requirement for certain *Hox* family members for leukemia transformation mediated by at least a subset of *MLL* fusion genes. These studies have been further extended to characterize the target cell for transformation. Retroviral transduction with *MLL-ENL* of purified committed progenitors that have no inherent capacity for self-renewal, such as common myeloid progenitors (CMP) or granulocyte-monocyte progenitors (GMP) confers properties of self-renewal. These data indicate that certain leukemia oncogenes can reprogram committed hematopoietic progenitors to acquire properties of leukemic stem cells.

The leukemogenic potential of *MLL* fusions has also been demonstrated in *Mll-AF9* knockin mouse model, in which chimeric animals developed AML within 6–9 mo.

GENE REARRANGEMENTS INVOLVING TRANSCRIPTIONAL COACTIVATORS IN AML The recruitment of transcriptional coactivators and corepressors by transcription factors involved in leukemia suggests a critical role for these proteins in leukemogenesis. In keeping with the recurring theme that the diverse and numerous chromosomal translocations in leukemia may share targets and functional activity, there are chromosomal translocations involving proteins that directly modulate and facilitate regulated gene expression.

Fusion genes associated with AML that directly involve coactivators include *MLL-CBP, MLL-p300, MOZ-CBP,* and *MOZ-TIF2*. Each of these involves a transcriptional coactivator with intrinsic histone acetyl transferase activity, and in the case of MOZ-TIF2, CBP or p300 can be recruited through interaction with the LXXLL motif in TIF2. The transforming properties of these fusion proteins are not well understood. Loss of function of CBP is responsible for the Rubenstein-Taybi syndrome that predisposes to the development of colon cancer, suggesting that CBP has properties of a tumor suppressor. This observation might suggest that the fusion genes involving coactivators act as dominant negative proteins. However, data also supports the hypothesis that MOZ-TIF2 may represent a gain of function for CBP based on mutational analysis in cell culture and murine models of leukemia. It has been demonstrated that MOZ nucleosome binding activity and TIF2 interactions with CBP are required for leukemogenesis, whereas MOZ histone acetyl transferase activity is not. These data suggest that the leukemogenicity of the fusion is based on recruitment of CBP to MOZ nucleosome binding sites. In addition, transduction of MOZ-TIF2 into committed hematopoietic progenitors, but not nonleukemogenic point mutants of MOZ-TIF2, confers properties of leukemic stem cells to this population that lacks the capacity for self-renewal. This observation extends the paradigm first reported for MLL-ENL, and may provide a platform for further characterization of self-renewal programs in normal and leukemic stem cells.

GAIN OR LOSS OF GENETIC MATERIAL IN AML The molecular basis of leukemogenesis in patients with numerical chromosomal abnormalities, such as monosomy 7, trisomy 8, or trisomy 21 is poorly understood, but may be related to changes in gene dosage of one or more genes, or duplication or loss of mutant genes. Identification of the gene(s) responsible for AML or MDS associated with recurrent chromosomal deletions, including 5q-, 7q-, and 20q-, is extraordinarily difficult. Efforts have focused on identification of classical tumor suppressor genes at these loci, in which there is loss of function of one allele owing to deletion, and of the other owing to mutation. The lack of success in identifying a *bona fide* tumor suppressor thus far, and observations that haploid gene dosage can contribute to hematopoietic phenotypes such as the FPD/AML syndrome, suggests that haploinsufficiency of one or more genes in the deleted regions may contribute to the leukemic phenotype.

COOPERATING MUTATIONS IN AML

Mutations in signal transduction intermediates associated with AML are not sufficient to cause AML. Rather, expression of these alleles alone, such as the FLT3-ITD, oncogenic Ras, or mutant PTPN11 results in a myeloproliferative phenotype. The phenotypes are similar, and include neutrophilia with normal maturation and differentiation, extramedullary hematopoiesis, and lack of self-renewal capacity as assessed by serial replating or serial transplantation assays. These mutations form a functional and epidemiological complementation group, in that only rarely do two of these mutations occur in the same patient.

In contrast, a second complementation group of mutant genes associated with AML has been identified that primarily involves hematopoietic transcription factors or transcriptional coactivators. These proteins, exemplified by RUNX1-ETO, PML-RARα, MLL-ENL, or MOZ-TIF2, are not sufficient to cause AML in cell culture or murine models of disease, but do appear to contribute to impaired hematopoietic differentiation and self-renewal potential of AML cells.

However, mutations from each of these complementation groups are often identified in the same AML patient, suggesting that mutant genes from each of these classes cooperates to engender the AML phenotype. From murine models of AML based on human genotypes, there is evidence for cooperation between these complementation groups. BCR-ABL cooperates with NUP98-HOXA9 to cause AML in a murine model of chronic myelogenous leukemia in myeloid blast crisis, as does TEL-PDGFβR and RUNX1-ETO. FLT3 mutations associated with t(15;17) and PML-RARα expression are common in human APL, and retroviral transduction of FLT3-ITD into a Cathepsin G PML-RARα transgenic mouse background results in APL with shortened latency and complete penetrance, consistent with cooperative effects. These data suggest cooperation between these two complementation groups in AML, and that molecular therapies targeted against each of the classes of mutation may be additive or synergistic in treatment of AML. For example, it may be feasible to treat APL patients with FLT3 mutations with a combination of small molecule inhibitors of FLT3 and ATRA.

THE LEUKEMIA STEM CELL Normal hematopoiesis is a hierarchy that has at its root the self-renewing hematopoietic stem cell (HSC) from which all other hematopoietic elements are derived. These cells are rare and often quiescent in normal adult bone marrow. Emerging evidence indicates that in AML, as in normal hematopoietic development, a hierarchy is governed by the so-called leukemic stem cell. Furthermore, the existence of cancer stem cells has also been demonstrated in several other contexts, including breast cancer and central nervous system tumors. There are important clinical implications of these observations. First, these data suggest that the bulk of any given tumor is made up of clonogenic progenitors that do not have the capacity to self-renew. Although cancer therapy is usually assessed by the efficiency of reduction of disease burden, the reduction and elimination of the cancer stem cell population will likely be the most important goal toward preventing disease relapse. Thus, it is important to understand the relationship of the normal stem cell and the respective cancer stem cell, to understand mechanisms of self-renewal in these populations, and to develop therapeutic strategies that specifically target this critical population of cells.

Leukemic stem cells exist among a primitive population of hematopoietic progenitors in human AML. Using murine models in which human AML cells are transplanted into immunodeficient recipient (NOD-SCID) mice, SCID leukemia-initiating cells (SL-IC) can be identified that occur at a frequency of about 1 in 10^5 AML cells. These cells are phenotypically identical to those of the AML patient from which they were derived, and can reconstitute

the AML phenotype in recipient animals. SL-ICs reside in a primitive compartment of hematopoietic progenitors identifiable by flow cytometric analysis as $CD34^+/CD38^-$ cells. Several lines of evidence have suggested that the target cell for transformation is the HSC itself. For example, the SL-IC is immunophenotypically similar to a normal HSC, and $CD34^+$ progenitors derived from AML patients often contain the diagnostic cytogenetic abnormality. In addition, there is theoretical support for the stem cell as a target for transformation, in that this population already has properties of self-renewal, and is long lived, which would allow for acquisition of the multiple mutations that are required for leukemic transformation.

However, other data provide a counterpoint to the HSC as a target for transforming events in AML. Expression of certain leukemia oncogenes in committed hematopoietic progenitors that are destined to apoptotic cell death can confer properties of self-renewal to these cells. As discussed previously, the *MLL-ENL* fusion gene can confer properties of leukemic stem cells in CMP or GMP that are irrevocably committed to terminal differentiation and apoptotic cell death, as demonstrated by the ability to serially replate in methylcellulose cultures, and to cause AML that can be serially transplanted into secondary recipient mice. The leukemias are immunophenotypically identical, regardless of the starting cell population (purified HSC, CMP, or GMP populations isolated by high speed multiparameter flow cytometry) that is transduced. These data suggest that the certain leukemia oncogenes like the *MLL-ENL* fusion can commandeer programs of self-renewal in committed progenitors, and enforce phenotypic expression of markers associated with the HSC. These findings provide a platform for identification of the transcriptional programs that control self-renewal. These in turn may allow for development of therapies that selectively target the leukemic stem cell, and may also provide insight into strategies to confer properties of self-renewal to adult somatic cells for therapeutic benefit, such as tissue regeneration.

SUMMARY AND FUTURE DIRECTIONS

A virtual explosion has been seen in the identification and characterization of disease alleles in AML in cell culture and murine models of leukemia. These insights have provided a platform for development of molecularly targeted therapies of AML that may improve clinical outcome. ATRA in the treatment of APL is one proof-of-principle example for this approach, and will hopefully be a harbinger for the development of additional efficacious treatments, such as FLT3 inhibitors and others. The data indicating that at least two mutations cooperate to cause the AML phenotype suggest strategies for independently targeting multiple pathways that contribute to AML, using animal models as a platform for testing combination therapies. Finally, the seminal observation that AML contains a small, but well-defined, population of cells with stem cell-like properties may allow for development of therapies that target this critical population.

80 Acute Lymphoblastic Leukemia

ALEXANDER E. PERL AND DONALD SMALL

SUMMARY

Advances in the understanding of childhood acute lymphoblastic leukemia (ALL) have transformed the disease from a rapidly progressive and usually lethal disorder to a disease with an 80% cure rate. These improved outcomes are owing to the development of multiagent, dose-intensive chemotherapy regimens, central nervous system prophylaxis, and improved supportive care. In parallel to the improved understanding of therapeutic approaches to ALL, knowledge of the pathogenesis of ALL has increased dramatically. But uncovering the molecular mechanisms behind this disease has not yet produced targeted therapies that specifically act on these elements, as has been the case, for example, with tyrosine kinase inhibition for chronic myelogenous leukemia. Such novel treatment approaches are needed in particular in adult ALL, which although morphologically indistinguishable from pediatric disease, has a considerably poorer response to chemotherapy and remains incurable in >50% of the cases. These differences are in part resulting from differing molecular pathogenesis, which results in a higher proportion of tumors with de novo pan-drug resistance

Key Words: Acute lymphoblastic leukemia; chemotherapy; chronic myelogenous leukemia; *E2A-PBX1*; *Tel-AML1*; tumor suppressor.

INTRODUCTION

Acute lymphoblastic leukemia (ALL) is the most common malignancy among children and represents 80 and 10–20%, respectively, of childhood and adult acute leukemias. Advances in the understanding of childhood ALL have transformed the disease from a rapidly progressive and usually lethal disorder to a disease with an 80% cure rate. These improved outcomes are resulting from the development of multiagent, dose-intensive chemotherapy regimens, central nervous system (CNS) prophylaxis and improved supportive care. In parallel to the improved understanding of therapeutic approaches to ALL, knowledge of the pathogenesis of ALL has increased dramatically. But uncovering the molecular mechanisms behind this disease has not yet produced targeted therapies that specifically act on these elements, as has been the case, for example, with tyrosine kinase inhibition for chronic myelogenous leukemia (CML). Such novel treatment approaches are needed in particular in adult ALL, which although morphologically indistinguishable from pediatric disease, has a considerably poorer response to chemotherapy and remains incurable in >50% of the cases. These differences in part result from differing molecular pathogenesis, which results in a higher proportion of tumors with *de novo* pan-drug resistance.

Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

ALL is characterized by the accumulation of malignant precursors of either B or T lymphocytes in bone marrow and/or peripheral blood. Although some maturation might occur in the periphery, the proliferating cells generally are arrested in early developmental stages within the marrow. The primitive cells crowd out the normal marrow elements, causing pancytopenia. Tumor infiltration frequently causes splenomegaly, hepatomegaly, and diffuse lymphadenopathy. Patients usually present with a few weeks of nonspecific symptoms such as fatigue, often resulting from anemia, or may have a flu-like syndrome. Fever, petechial rash, bleeding, or easy bruising owing to cytopenias may also prompt medical evaluation. Bone pain might also be present, especially in children. Leukostasis or leptomeningeal spread causing focal neurological deficits can occur at diagnosis, but is uncommon.

Complete blood counts usually point to the diagnosis, showing pancytopenia of mature cells and often circulating blasts. However, the WBC is variable, and might be decreased, normal, or elevated. Marked elevation of leukocyte count with >100,000 cells/mm^3 is not unusual. Lactate dehydrogenase is typically elevated and there may be evidence of disseminated intravascular coagulation or spontaneous tumor lysis with hyperuricemia, hyperkalemia, and hyperphosphatemia. A bone marrow aspirate and biopsy with immunophenotyping and cytogenetic analysis is used to confirm diagnosis. Lumbar puncture is mandatory to assess the presence of leukemic cells in the CNS, which, with the testes, can serve as a sanctuary site.

Untreated ALL is rapidly fatal, with death usually occurring in weeks to a few months. Therapy consists of several dose-intense cycles of multiagent, noncross-resistant chemotherapy. Many classes of chemotherapeutic agents share activity in ALL including anthracyclines, steroids, alkylating agents, vinca alkaloids, topoisomerase II inhibitors, asparaginase, antimetabolites, and purine analogs. With current treatment strategies, approx 80% of children with ALL are cured. In adults, the rate is closer to 30%, virtually all of them who are younger than 60 yr. The goal of therapy is to induce complete remission as defined by the elimination of leukemic blasts by diagnostic surveillance techniques and restoration of normal peripheral blood counts. Because of advances in laboratory detection of minimal populations of leukemic cells, it is somewhat difficult to compare the success rates of remission induction therapies to those in the past, when morphological data was primarily used. This is because

the flow cytometric and molecular probing techniques in use are considerably more sensitive to minimal populations of tumor cells. Indeed, current assays are capable of detecting as few as one leukemic cell among 1 million normal cells. Regardless, historic data show excellent responses to induction chemotherapy, with approx 98% of children and 80% of adults entering a complete remission, as defined by <5% blasts in the marrow and recovery of normal peripheral blood counts.

Induction chemotherapy is followed by several cycles of consolidation therapy, as well as prophylaxis of the CNS with intrathecal chemotherapy, high-dose systemic agents with CNS penetration, or radiation therapy. Treatment is typically given with minimal breaks between cycles for approx 6 mo, and is followed by maintenance therapy with low-dose oral chemotherapy for as long as 3 yr.

Once in remission, selected patients with high-risk profiles benefit from myeloablative chemotherapy and allogeneic stem cell transplantation. Relapsed disease may be treated again with dose-intense combination chemotherapy. However, except in unusual circumstances such as relapses following durable remissions, isolated CNS relapses, or relapses greater than 1 yr from the end of therapy, patients with relapsed disease generally cannot be cured unless an allogeneic stem cell transplant successfully follows the patient's second remission.

EPIDEMIOLOGY

According to the National Cancer Institute's Surveillance Epidemiology and End Results program, approx 3600 cases of ALL are diagnosed annually, with approx two-thirds of cases occurring in children. The annual disease incidence in children is measured at 28 cases per million, making it the most common pediatric malignancy. For unclear reasons, this incidence has increased by approx 50% over the last three decades. The disease is slightly more common in males (ratio of 1.3/1), and whites (regardless of Hispanic origin) are affected about twice as often as blacks. The peak incidence is in children ages 2–3. In adults, the disease is rare, and accounts for about 10–20% of the 11,000 cases of acute leukemia diagnosed yearly. Of adult ALL diagnoses, more than two-thirds occur before age 45. The incidence reaches a nadir by middle age and increases slightly thereafter.

There are no clearly implicated risk factors for ALL other than ionizing radiation, chemotherapy (especially topoisomerase II inhibitors), and benzene exposure. These identified risk factors, however, make up a small fraction of all cases. Certain karyotypic abnormalities, such as trisomy 21 (Down syndrome) carry an increased risk of acute leukemia, which may be myeloid or lymphoid. Patients with congenital DNA repair abnormalities (e.g., Bloom syndrome or ataxia telangiectasia) are also at increased risk for ALL, among other malignancies.

DIAGNOSIS AND MOLECULAR MARKERS OF DISEASE

A diagnosis of ALL requires the presence of more than 20% lymphoid blasts in a bone marrow aspirate. In most cases of ALL, the diagnosis is not difficult because of the predominance of these blasts. The French–American–British (FAB) morphological criteria (L1-3) were developed to categorize the disease based on morphological appearance. With the exception of the L3 morphology (mature B cell, or Burkitt leukemia), these descriptions are unfortunately neither predictive of clinical behavior nor useful to guide therapy. The FAB classifications largely have been supplanted by immunophenotypic diagnosis and cytogenetic analysis to risk stratify patients. Indeed, the World Health Organization classification of ALL focuses primarily on immunophenotype and karyotype (Fig. 80-1).

Unlike the myeloblasts of acute myeloid leukemia (AML), which may have Auer rods and cytoplasmic granulation, there are no morphological features that unmistakably identify malignant lymphoid blasts from their normal counterparts. The absence of staining for either myeloperoxidase or monocyte-associated esterases as well as the presence of terminal deoxynucleotidyl-transferase staining is useful in identifying ALL cells. The major morphological differential diagnosis is undifferentiated AML (M0), which may not stain for any myeloid markers but should be terminal deoxynucleotidyl-transferase negative. Immunophenotyping is critical for accurate diagnosis and has decreased the number of patients mistakenly assigned an inappropriate treatment regimen. The presence of lymphoid surface markers and immunoglobulin or T-cell receptor gene rearrangements are the most sensitive and specific findings used to confirm diagnosis of ALL.

No surface markers are truly lineage specific, however, and therefore the overall pattern of surface expression of multiple cluster designation (CD) antigens is used to determine the leukemia phenotype. It is not uncommon for both lymphoid and myeloid antigens to be aberrantly coexpressed, but the predominant lineage markers are used to identify the pedigree of the leukemic cells. Such distinctions are important, as therapeutic approaches to AML and the different subtypes of ALL differ radically, with significant differences in treatment outcome. In general, the strong expression of one of the common lymphoid markers (CD10, also known as the common ALL antigen, or CALLA) can be used as a sensitive screen for ALL, although patients with progenitor-B cell, precursor-T, or mature B-ALL may lack this marker. The presence of early B or T-cell antigens (e.g., CD19 or CD7, respectively) helps assign a lineage, although more specific antigen expression (surface immunoglobulin, cytoplasmic CD79a, Cμ, or CD5) helps to define the stage of maturational arrest. ALL that shows mixed lineage expression of both myeloid and lymphoid antigens is being increasingly noted and may represent a distinct diagnostic entity. When such expression is associated with mixed lineage leukemia (MLL) gene rearrangements at chromosome 11q23 (e.g., t[4;11]), a particularly poor risk group is defined, as is covered in greater detail later in this chapter.

RISK STRATIFICATION OF PEDIATRIC DISEASE

The therapeutic approach to treat children with ALL depends on a detailed relapse risk assessment. Because pediatric ALL therapies are frequently curative, yet have narrow therapeutic toxic ratios, selection of appropriate therapeutic intensity is especially important in these patients. A low-risk subset, when identified, can hopefully receive less intensive therapy without an unacceptable increase in relapse rate. The consequence of overtreating ALL in low-risk patients includes cognitive impairment, growth retardation, infection, as well as the gamut of transplant-related complications for those who may inappropriately receive this therapy. The greatest risk of undertreating high risk patients is, of course, relapse and the development of drug resistance, which lowers cure rates.

Cytogenetic and molecular profiling has generated a more accurate predictive model for risk stratification for ALL than FAB morphology or immunophenotyping. The most common

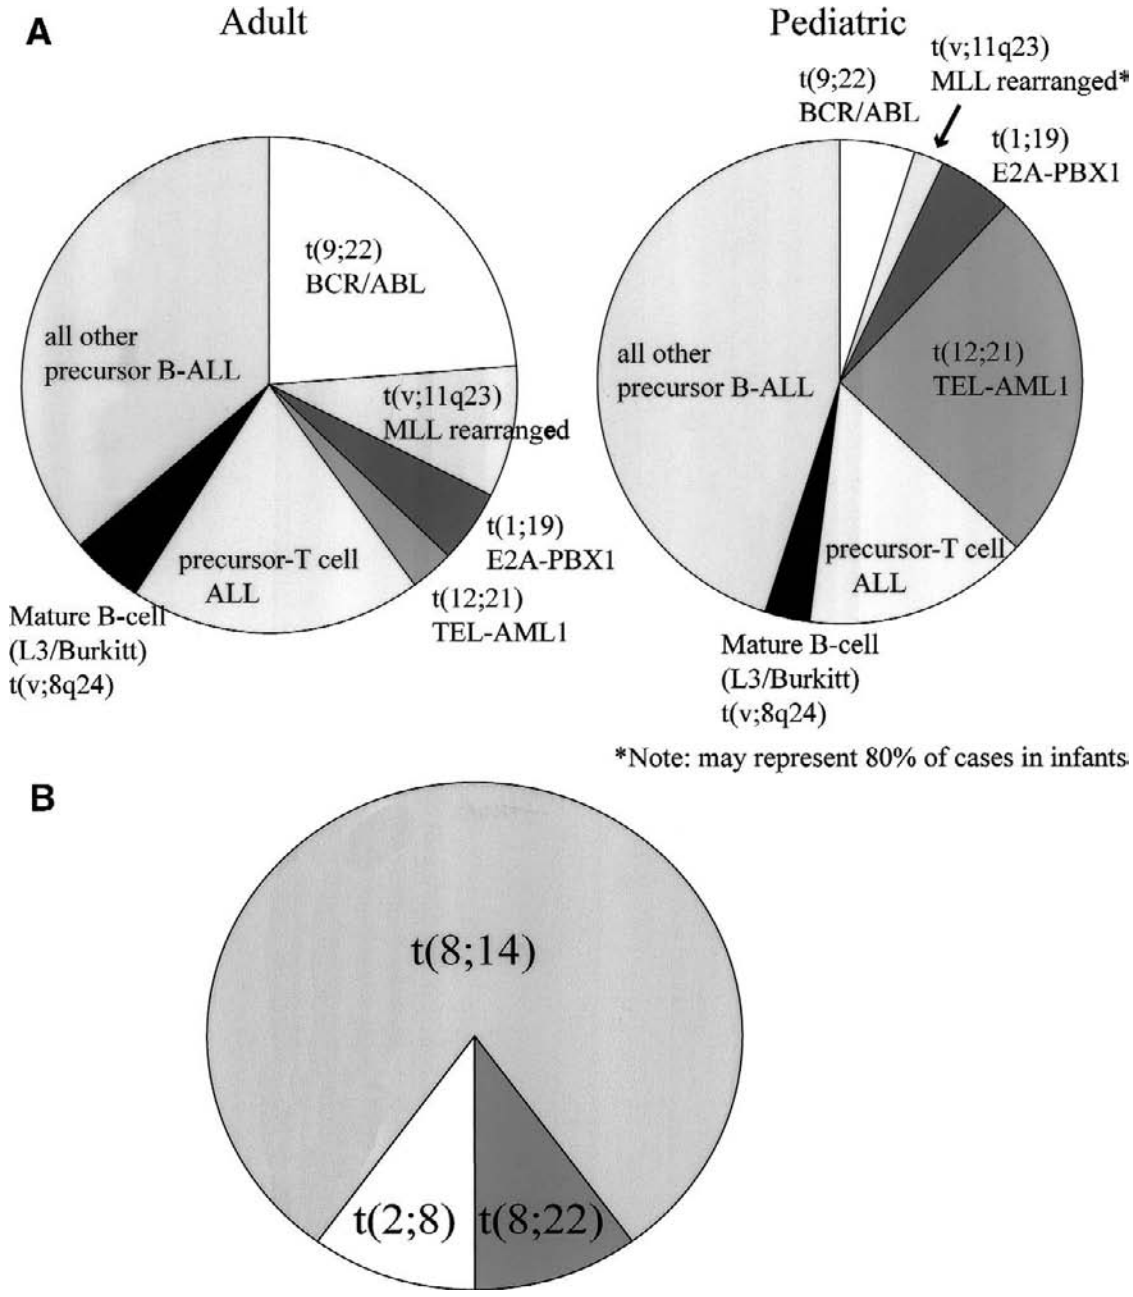

Figure 80-1 **(A)** Realtive incidence of adult and pediatric ALL subtypes. **(B)** Realtive incidence of c-*myc* translocations (chromosome band 8q24) in mature B-cell (Burkitt) ALL.

identifying molecular markers are specific, recurring translocations. Certain translocations confer favorable risk, such as t(12;21) (TEL-AML1). Others, such as t(9;22) (BCR-ABL) and t(v;11q23) (MLL rearranged), identify poor risk biology that necessitates more aggressive treatment approaches. The role of these particular translocations in leukemogenesis is expanded later.

Another prognostic marker is the overall number of chromosomes or ploidy. Hyperdiploid leukemia (i.e., those containing at least 50 chromosomes) has a particularly good prognosis, hypodiploid (<45 chromosomes) indicates poor prognosis, those between these extremes being intermediate. The presence of specific trisomies (e.g., chromosome 4,10) might account for the good prognostic significance of the hyperdiploid patients.

Previously, mature-B (L3 or Burkitt) and T lineage ALL were considered poor risk groups. Lineage-directed therapy has improved the cure rates for these diseases substantially. Both have an excellent cure rate and are considered standard risk leukemia at most centers. This finding validates the in-house directed therapeutic approach.

As in AML, WBC count at diagnosis is prognostically important in ALL. Elevated WBC indicates high tumor burden and is likely a continuous variable, with higher cell counts indicating higher risk. In adult disease, WBC counts above 30,000/mm^3 have been identified as a negative risk factor. Pediatric studies have indicated WBC elevation more than 20–25,000/mm^3 likely confers increased risk. The independence of leukocytosis as a risk factor is not entirely certain, as it usually correlates with particular

genetic abnormalities that portend unfavorable prognosis. Examples of these include translocations or partial tandem duplications of the MLL gene and the BCR/ABL fusion.

Age also appears to be an important prognostic factor. Adults and children younger than 1 yr typically develop high-risk disease. The cure rates for infant ALL (<20%) stand in stark contrast to that of older children (>80%). A probable explanation is the frequency of unfavorable cytogenetics. In the case of infant leukemias, this is generally results from MLL rearrangements. Similarly, children younger than 2 or older than 9 yr, adolescents, and adults are also less likely to have favorable karyotypes or ploidy, though the particular abnormalities are more heterogeneous than is the case for infants. Unfavorable disease biology and the inability to tolerate dose intensive therapy may largely explain the poorer prognosis associated with adult patients.

As mentioned, cytogenetics are invaluable in risk-stratifying ALL. It should be noted; however, that cytogenetic analysis is challenging in this disease owing to the relative difficulty of growing cells before analysis and the overall poor quality of metaphases in cells that are informative. For this reason, fluorescence *in situ* hybridization (FISH) has become a particularly powerful tool. The major translocations are easily identified by FISH probes and this allows rapid and accurate assignment of a risk profile to an individual case.

Last, perhaps the most important risk assessment tool is the response to chemotherapy. The speed of marrow response is a potent prognostic marker and can be informative as early as 1 wk following initiation of therapy. Minimal residual disease (MRD), assessed through flow cytometry or quantitative molecular studies, has proven highly prognostic in a number of studies. Slow marrow response to chemotherapy generally indicates the presence of drug resistance and is a poor prognostic marker, regardless of other prognostic indices. Overall, a period of more than 4 wk to achieve remission indicates a very high risk for relapse.

LEUKEMOGENESIS

Although the topic of stem cell origin of solid tumors is a relatively new concept, leukemia provides the most solid evidence of the existence of malignant stem cells. Among this evidence is the morphological and immunophenotypic similarity of blasts to normal hematopoietic stem cells as well as the capacity of malignant cells to differentiate in vitro to multiple hematopoietic lineages with the addition of growth factors. Such differentiation capacity may be seen in vivo and serves as the therapeutic rationale in some forms of AML (e.g., all-trans retinoic acid for acute promyelocytic leukemia). However, there has been no established therapeutic differentiating agent for ALL.

What remains controversial is the cell of origin of more mature leukemias. A long-held belief is that the malignant cell in acute leukemia is a normally differentiating cell that encounters genetic damage during its development and is arrested in its progression to terminal differentiation at the stage in which the critical genetic "hit" occurs. Underlying this logic, the stage at which differentiation block occurs determines the maturity of the proliferating cells.

In contrast, an emerging theory holds that even acute leukemias involving more mature cells arise from primitive stem cells whose progeny, owing to the genetic aberrations in the stem cell, possess limited differentiation ability. Although the accumulating cells may show some capacity for differentiation, a small number of genetically disordered parental cells remain at a very primitive stage of development. It is these leukemic stem cells that have unlimited self renewal capacity and supply the tumor with an unending supply of daughter cells. These progeny make up the majority of the cells seen clinically. Evidence to support this latter position includes demonstration of identical clonal karyotypic abnormalities in both patients' leukemic cells and their leukemic progenitors in the $CD34^+/CD38^-$ compartment. Indeed, it is only these immature $CD34^+/38^-$ cells that are able to propagate leukemia in NOD/SCID murine transplantation models.

Another concept with increasing acceptance in leukemia is that of multistep transformation. CML in lymphoid blast crisis provides one example of leukemogenesis that occurs at the stem-cell level, yet ultimately acquires genetic abnormalities that produce a disease molecularly similar to, if not indistinguishable from, a subtype of ALL.

Regardless of which theory of leukemogenesis is correct, one generally accepted concept is that leukemia, like all other cancers, arises from multiple genetic abnormalities. The work of Vogelstein in the 1980s suggested that the progression from normal colonic epithelial cell to adenoma, carcinoma *in situ*, and finally to invasive and metastatic tumor occurs through predictable, stepwise mutational events. This hypothesis can be generalized to acute leukemia, although the particular combinations of mutations appear to be more heterogeneous than in colon cancer. This finding reflects the diversity of tumor biologies encompassed within leukemia. The ability to perform karyotypic analysis on blood cells has added significantly to the understanding of these mutational "hits" in leukemogenesis. Such analyses show recurring karyotypic signatures that, although not entirely specific to a particular tumor type, predict within a particular diagnosis the phenotype and therapeutic response.

The most common karyotypic abnormalities in leukemia are translocations and deletions. When deletions cause tumor suppressor loss, inappropriate progression through the cell cycle and dysregulated growth occur. This is a common finding in both solid tumors and leukemia. By contrast, translocations are unusual in solid tumors, but relatively common in leukemia. Translocations produce chromosomal fusions that generally fall into two categories. The first type occurs when genes are removed from their normal transcriptional control and rearranged to loci in which new promoters inappropriately activate their transcription. This causes abnormal gene expression levels. The inappropriate activation of *myc* by its fusion with the immunoglobulin heavy chain gene through the t(8;14) translocation commonly found in Burkitt lymphoma/leukemia is one such example. The second type of translocation involves fusion of one part of each gene to encode a novel protein product that alters normal cellular survival, proliferation, and differentiation. The *PML-RARα* fusion in M3 AML that blocks differentiation is an example of the latter mechanism.

Studies involving cell lines consistently show malignant transformation following transfection with many fusion proteins commonly seen in ALL. It can be argued, however, that cell lines are already immortalized and represent partially transformed cells. Therefore it is difficult to determine if any of the transfected gene products truly transformed the cells. When fusion genes are used alone to transform primary murine bone marrow cells, few, if any, accurately generates a model of human leukemia. This is true for the most common translocation-generated fusion genes seen in ALL, including *BCR-ABL*, *TEL-AML1*, and *E2A-PBX1*. Often leukemia develops, but only after a long latency. This emphasizes

the need for multiple cooperative mutations to produce a full-fledged leukemia.

In leukemia, the types of cooperative mutations primarily fall into two categories, those affecting growth and/or survival pathways and those impairing differentiation. It is hypothesized that both types of mutations must be present to induce leukemia, although several mutations of each type may occur in a particular tumor cell.

TRANSLOCATIONS AND ASSOCIATED FUSION PROTEINS

A common finding in leukemias is the presence of distinct, recurrent chromosomal translocations. A consequence of these translocations is the formation of either novel oncoproteins or a change in the expression level of normal proteins by inappropriate transcriptional regulation. As might be expected, the genes most often involved in these alterations are those associated with cellular growth, differentiation, apoptosis, or cell-cycle regulation. In the next section, the most common and well-understood translocations and gene rearrangements are discussed.

***TEL-AML1* (Also Known As ETV6/CBFA2)** *Tel-AML1* is a gene fusion product that occurs from an often cryptic t(12;21)(p13;q22) translocation. Although difficult to detect by classic cytogenetics, molecular probes demonstrate the gene product in approx 25% of pediatric pre-B-cell ALL and less than 5% of adult disease. Tel-AML1 is a member of the core binding factor (CBF) leukemias. This group of diseases is characterized by translocations that encode chimeric proteins that serve as repressors of CBF activity. Inactivation of CBF both impairs differentiation and inhibits p53 function, which in turn inhibits apoptosis and may contribute to cell-cycle checkpoint dysregulation. Other CBF leukemias include AML with inv(16) (FAB M4Eo/*CBF*β-*SMMHC*), t(8;21) (*AML1-ETO*), and t(3;21) (*AML1-EVI1*). When seen in isolation, these all represent favorable karyotypes with above average responses and disease free survivals in response to standard chemotherapy, with the lone exception of t(3;21). The *TEL* gene is a member of the *ETS* family of transcription factors. *TEL* is widely expressed in both hematological and nonhematological tissues and serves a critical step in yolk sac angiogenesis during fetal development. Its function is dependent on an N-terminal helix-loop-helix domain known as the pointed domain. In the postembryonic period, *TEL* serves a critical role in establishing bone marrow hematopoiesis. *AML1* is a transcription factor with significant structural homology in its DNA binding domain to the *Drosophila* runt domain. *AML1* heterodimerizes with *CBF*β to increase its affinity and binds the enhancer core sequence *TGT/CGGT*. Through DNA binding, AML1/CBFβ helps activate and coordinate lineage-specific transcription, including such genes as IL-3, neutrophil elastase, myeloperoxidase, CSF-1 receptor, and the subunits of the T-cell antigen receptor.

In the t(12;21) translocation, *TEL* fuses in-frame with nearly the entire *AML1* gene. By unclear mechanisms, fusion with *TEL* reverses *AML1's* activity, and the chimeric protein acts as a transcriptional repressor of AML1 targets. The TEL pointed domain is critical for this change in activity. The pointed domain can also cause heterodimerization between nontranslocated *TEL* and *TEL-AML1*. Although it seems that this would lead to loss of function of the nontranslocated *TEL*, *TEL* deletions are commonly seen in the nontranslocated allele, suggesting a possible role for TEL as a tumor suppressor. On closer examination, however, this does not seem to hold true by Knudson's classic definition of the term. In this model, mutational inactivation of the remaining allele would be predicted in cases of ALL that featured *TEL* loss of heterozygosity but did not contain *TEL-AML1*. A loss of heterozygosity analysis; however, did not find such mutations among 33 cases examined.

E2A-PBX1 Of both adult and pediatric ALL, approx 5% contain the translocation t(1;19)(q23;p13.3), which encodes the fusion protein E2A-PBX1. This was previously thought to represent a poor prognostic marker, but intensification of therapy in pediatric patients has overcome its effects on outcome. The results of high dose chemotherapy with stem cell rescue in adults may also have this effect, but because the incidence of this cytogenetic marker is relatively low, it is difficult to draw a firm conclusion. The mechanism by which this translocation contributes to leukemogenesis involves both gain of function via upregulating transcription of a *HOX* gene cofactor as well as the loss of one copy of intact *E2A*, a candidate tumor suppressor gene.

E2A encodes two transcription factors, E12 and E47, through alternative splicing. Each protein is a member of the class I basic helix-loop-helix family and has two activation domains. Targeted disruption of this gene in mice causes early B-lineage maturational arrest with an inability to develop either immunoglobulin DJ rearrangements or CD19 expression, demonstrating its importance in early B-cell differentiation. E2A also has important functions in later B cells, including immunoglobulin class switching and plays a role in early T-cell development and maturation. Finally, *E2A* null mice almost invariably develop thymomas and aggressive T-cell lymphomas by 3 mo. Restoration of E2A functionality in cell lines derived from *E2A* null mice leads to rapid induction of apoptosis, confirming the tumor suppressor function of this gene. E2A's ability to activate expression of inhibitors of cyclin-dependant kinases (CDKs) such as Kip family genes (e.g., p27, p21) may provide a mechanism for how it serves as a tumor suppressor.

PBX1 is not normally expressed in lymphoid cells, though its function can be inferred from the role played by similar proteins in these cells (PBX2 and 3) and through its *Drosophila* homolog, *EXD*. *EXD* serves as a required cofactor for activation of several *HOX* homeodomain genes. Its sequence is highly conserved in the human gene *PBX1*. Numerous *HOX* genes, such as *HOXA9* and A10, are oncogenic when overexpressed.

In the formation of *E2A-PBX1* by translocation, a novel fusion protein is generated in which the expression of a putative oncogene cofactor falls under control of a heavily transcriptionally active gene. This activity seems to be increased further by an inability of cells to regulate the shuttling of *E2A-PBX1* between the nucleus and cytosol. Normally, *PBX1's* location is tightly regulated. However, the fusion product loses such controls and remains permanently located in the nucleus. There, opportunities for interactions with *HOX* genes would be favored and the activity of the chimeric gene is further augmented. In addition to these gain-of-function changes in the fusion protein, the loss of one allele of *E2A* might have a significant effect on cell-cycle regulation owing to its status as a tumor suppressor. The *E2A-PBX1* fusion may sequester *E2A* cofactors, such as *P300*, and, thus, further impair the ability of the remaining *E2A* to regulate transcription (Fig. 80-2).

Interestingly, murine transgenic and retroviral transduction models of *E2A-PBX1* fail to reliably generate B-cell neoplasms. As in the *E2A* null mice, T-cell lymphomas are most commonly generated. Further, there is a long latency period before the onset of malignancy, favoring the idea that the fusion protein requires

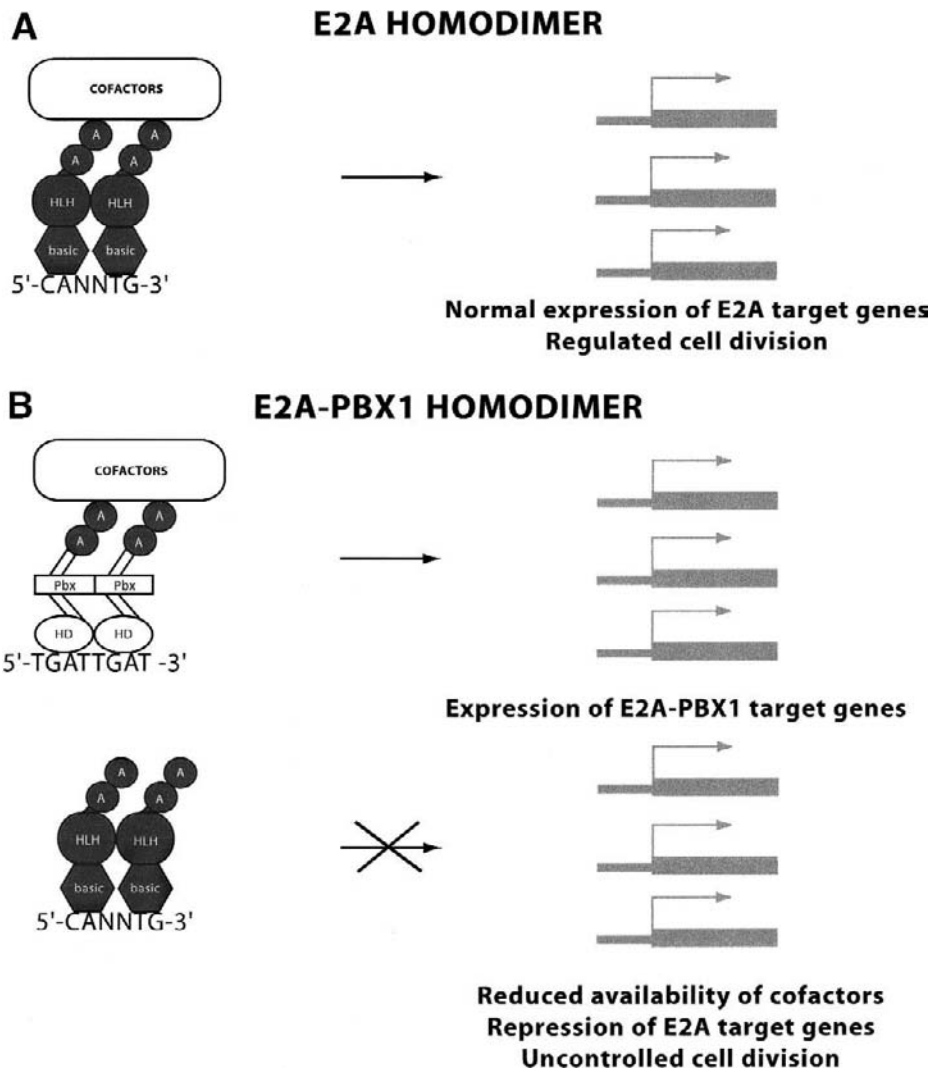

Figure 80-2 t(1;19) E2A/PBX1 and leukemogenesis. In normal hematopoiesis (upper figure), E2A binds DNA avidly, activating target genes that include cyclin-dependent kinase inhibitors to slow progress through the cell cycle. The t(1;19) fusion of E2A/PBX1 (lower figure) may contribute to leukemogenesis by several mechanisms. These include transactivation of Hox target genes via association with PBX1 as well as impaired wild-type E2A DNA binding, causing transcriptional repression of E2A targets (e.g., p21) and inappropriate progression through cell cycle. Sequestration of E2A cofactors by the fusion protein may contribute to the latter effect. (Reproduced with permission from Aspland SE, Bendall HH, Murre C. The role of E2A-PBX1 in leukemogenesis. Oncogene 2001;20:5708–5717. Copyright 2001 Macmillan Publishers.)

further mutational events to complete malignant transformation in vivo. The inability to demonstrate leukemogenesis of this fusion protein casts some doubt regarding gain-of-function activity of the fusion protein and may instead favor the hypothesis that loss of *E2A* underlies the malignant phenotype. Further support of this mechanism is seen in T-cell acute lymphoblastic leukemia (T-ALL) that contains rearrangements of the stem cell leukemic protein (*SCL*) gene, a transcription factor that also dimerizes with, and likely inactivates, E2A. This topic is covered in more detail in later sections.

MLL Translocations and partial tandem duplications of the *MLL* gene at chromosome 11q23 are seen in both AML and ALL and immunophenotypically often results in aberrant coexpression of both myeloid and lymphoid antigens. For this reason the malignancy may be called an mixed lineage leukemia (MLL). Sequencing of the *MLL* gene shows marked structural homology to the drosophila gene trithorax, which positively regulates several *HOX* genes. In murine models, overexpression of a number of *HOX* genes has been implicated in leukemogenesis. Although *MLL* is purported to serve as an analog of trithorax in humans, its function and mechanism of action have not been completely defined. A *MLL* (–/–) knockout mouse embryo has been developed that is characterized by defective yolk sac hematopoiesis with a differentiation block at the stage of early hematopoietic progenitor cells. This suggests an important role for *MLL* in the establishment of normal hematopoiesis. In leukemia, translocations of *MLL* generally fuse an intact promoter and amino terminus up to the breakpoint cluster region (BCR) between exons 5 and 11 with a partner gene's carboxy terminus. A variety of genes combine with *MLL*, and greater than 30 different translocation partners have been described. Although the multiple fusion partners may suggest that the contribution of specific translocations to leukemogenesis is to disrupt or destabilize *MLL* function, it should be noted that heterozygous *MLL* knockout mice do not develop leukemia or other cancers.

MLL rearrangement leukemias in some cases arise following DNA topoisomerase II inhibitor therapy, usually with a short

latency from exposure (in comparison to alkylating agent, benzene, or radiation-induced leukemia) that would suggest that few if any additional mutations are necessary for transformation. This and other lines of evidence favor a gain-of-function from translocation partners as the contribution of *MLL* toward leukemic transformation.

The most common *MLL* fusion partner in ALL is *AF4* on chromosome 4q21, which is a member of a transcriptional transactivating gene family. The presence of t(4;11)(q21;q23) is an ominous prognostic marker in ALL, as it is associated with hyperleukocytosis, extramedullary disease, early relapse following induction chemotherapy, and poor overall survival. This risk seems to be age-dependent, because infants and children over age 10 who harbor t(4;11) have a particularly poor prognosis, but patients with this karyotype between the ages of 1 and 10 fare no worse than standard risk ALL.

Gene expression profiling of infant leukemias harboring MLL gene rearrangements identified a distinct expression pattern that discriminates the disease from either AML or ALL. Interestingly, one of the most differentially expressed genes is *FLT3*, a receptor tyrosine kinase that is commonly mutated in AML, causing constitutive kinase activation, cellular proliferation, apoptotic inhibition, and impaired differentiation. Internal tandem duplications mutations of FLT3 strongly predict elevated WBC count in AML and are a negative prognostic marker in all FAB categories, with the possible exception of M3. In the case of infant MLL, *FLT3*-internal tandem duplications were not seen but other kinase activating mutations do occur. Highly overexpressed wild-type FLT3 may also be, in part, responsible for this phenotype. Data suggests that coexpression of *FLT3* ligand by leukemic cells may create an autocrine loop that creates constitutive kinase activation in the absence of receptor mutation. *FLT3*-selective tyrosine kinase inhibitors are cytotoxic to infant MLL cells both in vitro and in a murine model, and these inhibitors will undergo human clinical trials in infant leukemia.

The t(4:11)(q21;q23) is also the most common translocation that occurs in therapy-related ALL following topoisomerase II treatment. Indeed, 80% of leukemias that follow topo II exposure demonstrate *MLL* gene rearrangements. Within the BCR of the *MLL* gene lie 11 sequences that resemble topoisomerase II consensus binding sites and one complete consensus site. Treating leukemia cell lines with topo II inhibitors causes double-stranded breaks most commonly at these sites. Sequencing of the MLL gene in treatment-related leukemias shows this to be the region most often rearranged. As with infant leukemias, topo II-induced leukemias commonly relapse following standard chemotherapy and are usually treated with allogeneic bone marrow transplantation once a patient achieves a complete remission.

BCR-ABL and the Philadelphia Chromosome Nowell and Hungerford first noted the truncation of chromosome 22 in patients with CML in 1960, and this was the first recurrent cytogenetic abnormality described in cancer. This morphological change is known as the Philadelphia chromosome and was later found to be due to a recurrent translocation. The Philadelphia chromosome is seen in 95% of CML cases. t(9;22)(q34;q11) is also the most common and prognostically important translocation in adult ALL. Though uncommon in pediatric ALL, it is present in approx 35% of adults with B-lineage ALL. The translocation portends a poor prognosis because of pan-drug resistance that leads to early relapse. When feasible, allogeneic stem cell transplantation is recommended as therapy for ALL patients with this karyotype, regardless of the age at presentation.

The two genes involved in this fusion are the *BCR*, which is a gene of unknown function, and *ABL*, a cytoplasmic tyrosine kinase with structural homology to *src* kinases. Several different translocations of these genes are seen, with some predilection for particular malignancies. In CML, the most common gene product is p210BCR-ABL, a 210-kDa protein. The most common ALL fusion protein is known as p190*BCR-ABL*, which is a 190-kDa protein. The difference in molecular weights of the fusions results from differences in the portion of the *BCR* gene incorporated into the gene product. Sequencing of the various fusion products has enabled the development of FISH and reverse transcriptase PCR probes for these fusions. This allows for greater diagnostic accuracy, because there can be false negative results from cytogenetic analysis, allowing increased sensitivity for detection of MRD and early relapse. Because the presence or absence of BCR-ABL affects therapeutic recommendations, such probes have allowed for more effective risk-stratification of ALL patients, and consequently better cure rates with more appropriate therapy.

Both p210 and p190 fusion oncoproteins, and indeed all *BCR-ABL* fusion proteins that have been studied, constitutively activate the *ABL* tyrosine kinase, leading to several pathways of downstream signaling. These downstream targets include *PI3K/AKT*, *Ras/Raf/MAPK*, *myc*, *BCL2*, and *STAT5*, among others. As differentiation blockade is not a feature of CML, BCR-ABL signaling is not thought to significantly impair differentiation. Instead, antiapoptotic and proliferative signals are primarily induced by the constitutively activated kinase.

In vitro transformation by BCR-ABL has been well described. Structural analysis of the ABL kinase demonstrates SH2 and SH3 domains, an SH1 tyrosine kinase domain, and an F-actin binding region. The SH2 and SH3 domains are responsible for protein–protein interactions, and likely regulate the activity of the kinase as well as the specificity of binding with several effector molecules. As noted, the tyrosine kinase bears structural similarity to *src* kinases and is involved in activation of signaling of several growth and apoptosis regulatory pathways. BCR-ABL kinase activity is upregulated as much as sevenfold above that of the wild type kinase. The F-actin binding domain likely serves as a nuclear export signal region and is responsible for *ABL* kinase normally shuttling between cytosol and nucleus. With nuclear localization, the protein interacts with cell-cycle regulatory proteins. In contrast, the fusion oncoprotein does not localize to the nucleus. This restricted cytoplasmic localization may either prevent it from inhibiting cell-cycle progression or may prevent access to negative kinase regulators within the nucleus.

Although the normal function of *BCR* is unknown, its structure contains elements that are likely critical for malignant transformation. Among these features are a coiled-coil oligomerization motif that is responsible for dimerization of BCR, a phosphoserine, and phosphothreonine-rich SH2 domain, and a tyrosine residue at position 177. This tyrosine residue is a potential phosphorylation site that interacts strongly with the adaptor protein GRB2 to link BCR-ABL with the RAS-MAP kinase pathway.

The development of imatinib (Gleevec, or STI-571) has been a major breakthrough in the understanding as well as the therapy for CML. The drug will ultimately play a role in the treatment of Ph (+) ALL. Imatinib is a small molecule that competitively inhibits adenosine triphosphate binding to the active site of BCR-ABL,

thus abrogating the constitutive activation of the kinase. Imatinib induces apoptosis in vitro in *BCR-ABL*-containing cell lines and patient samples, and reverses the myeloproliferative state induced by forced *BCR-ABL* expression in a murine model. Human trials of the drug demonstrate normalization of hematological parameters in patients in 95% of patients with chronic phase and 50–80% of patients in accelerated phase CML.

In blast crisis CML, imatinib may induce short-lived hematological responses in patients. Following such disease stabilization, some patients may safely undergo allogeneic transplantation. These responses in blast phase occur with greater frequency than with other agents, including chemotherapy, interferon-α or the combination of these agents, and many hematological remissions are associated with major or complete cytogenetic responses. As a new drug, long-term follow-up is needed to see if these changes are associated with improved survival and/or cure. It should be noted that although the cytogenetic responses are better than any therapy agent short of allogeneic transplantation, the percentage of patients treated with imatinib in chronic phase who revert to undetectable levels of *BCR-ABL* transcripts by reverse transcriptase PCR is low.

As imatinib is active against both p210 and p190, trials of the drug in ALL are ongoing. Phase II data show activity of the agent in Ph (+) ALL, although resistance to the drug is acquired rapidly. Analysis of CML patients treated with imatinib demonstrates at least five mechanisms for resistance to the drug, with mutations in the adenosine triphosphate binding site of *BCR-ABL* that render the kinase inaccessible to the inhibitor being the most common. Other mechanisms include *BCR-ABL* amplification, mutations of additional genes causing *BCR-ABL*-independent growth, increased expression of α-1 acid glycoprotein, which binds imatinib, and increased expression of MDR-1/p-glycoprotein, which pumps the drug out of cells.

SCL Rearrangement in T-ALL In contrast to the frequent chromosomal rearrangements in B-lineage ALL, less than one-thirds of T-ALL cases show evidence of recurrent translocations. In addition, no association between karyotype and prognosis has been seen and therefore no treatment strategy exists that discriminates the various T-ALL patients into high, standard, and low risk. Although gene expression profiling analysis of T-ALL has shown distinct expression patterns within this group, suggesting that different mechanisms of leukemogenesis occur, the significance of these differences is clinically unknown. The most common translocations in T-ALL involve the T-cell receptor gene on chromosome 14q11. A number of transcription factors, including *LMO2*, *LYL-1*, and *SCL* (also known as *Tal-1*) each translocate to this locus, resulting in inappropriate expression and/or creation of a fusion product with altered characteristics.

SCL rearrangements are perhaps the best characterized among the putative oncogenes in T-ALL. The *SCL* gene encodes a class B, basic helix-loop-helix transcription factor that is normally lineage-restricted to fetal hematopoietic and vascular progenitor cells as well as the CNS. It serves a crucial role in establishing fetal hematopoiesis and is expressed in adult erythroid, mast cell, and megakaryocytic lines. Of note, it is not normally expressed in thymocytes. Forced expression and antisense in vitro experiments show that *SCL* plays a role in hematopoietic proliferation, differentiation, and apoptosis. SCL forms heterodimers with class B basic helix-loop-helix proteins, such as the products of the *E2A* gene, E47, and E12. The heterodimers bind DNA at E box motifs to transactivate target genes. In addition to binding DNA, the heterodimers of SCL-E2A bind several other proteins, including the lim domain proteins LDB-1 and LMO-2. This binding forms a large protein complex that bridges between the SCL/E2A heterodimer and the zinc finger transcription factor GATA-1. *SCL*, *LMO-2*, and *GATA-1* are expressed in nearly identical tissues and deficiency of each is embryonically lethal owing to failed hematopoiesis. This suggests a common role in early hematopoietic regulation.

Aberrant expression of SCL is a common occurrence in T-ALL and may occur owing to translocation within the T-cell receptor delta locus [t(1;14)(p33;q11)]. Another common mechanism involves a cryptic 90 kB deletion. This removes both the 5′ regulatory elements of *SCL* and the entire coding region of the ubiquitously expressed *SIL* gene, which lies immediately upstream. The karyotypically silent fusion product, *SIL-SCL*, falls under transcriptional control of the *SIL* promoter, leading to aberrant *SCL* expression. As is the case with B-precursor ALL featuring the fusion gene *E2A-PBX1*, there is controversy concerning whether the oncogenicity of aberrantly expressed SCL owes inappropriate activation of *E2A* target genes by the DNA-binding protein complex formation. As noted, *E2A* also serves a role similar to a tumor suppressor gene. Therefore, the formation of heterodimers with SCL may cause sequestration of E2A proteins and impair their ability to regulate the cell cycle.

Interestingly, transgenic models with forced *SCL* expression do not generate tumors. In addition, tumors are not seen when the *SIL* promoter is used to express *SCL* in murine T cells. Coexpression of SCL and similar basic helix-loop-helix transcription factors such as *LDB-1* and *LMO-2* do however greatly facilitate tumor formation. These other genes normally are silent in T cells but their coexpression can sometimes be seen in T-ALL. This finding further supports cooperative, multistep oncogenesis in T-ALL. The finding of T-ALL in two patients with severe combined immunodeficiency syndrome (SCIDS) treated by gene therapy further supports the cooperative role of LMO-2. In both patients the retrovirus used to replace their adenosine deaminase (ADA) deficiency resulted in insertional mutagenises in the *LMO-2* locus with resulting upregulation through the retroviral promoter.

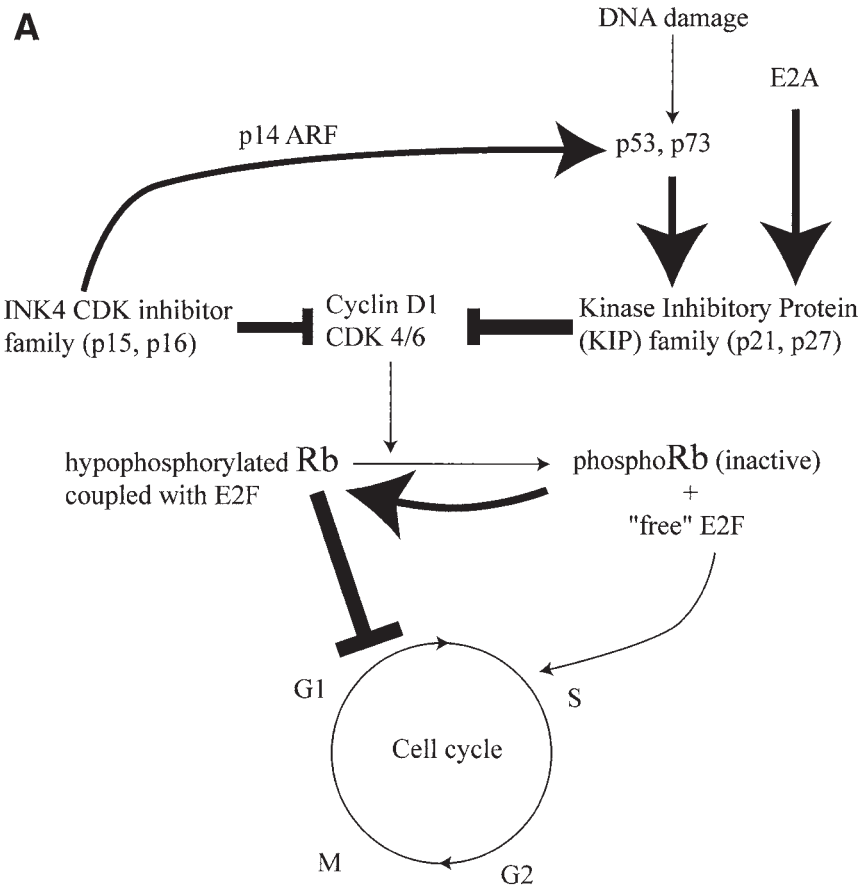
c-*myc*/Immunoglobulin Translocations in L3 ALL Burkitt's lymphoma and FAB L3 (Burkitt-type) ALL share molecular mechanisms to the extent that they can be considered phenotypic variants of a single disease, Burkitt's lymphoma/leukemia. The characteristic cytogenetic finding in BL is a balanced translocation between c-*myc* and one of the immunoglobulin loci, leading to markedly increased c-*myc* expression. The c-*myc* gene codes for a 64-kDa basic helix-loop-helix transcription factor that normally resides at chromosome 8q24. Of patients with BL, 80% show the classic translocation between c-*myc* and *IGH* [t(8;14)(q24,q32)] and approx 20% of patients show evidence of a variant translocation (Fig. 80-1B). These variants are divided evenly among translocations that pair *myc* with either the *IGK* [t(2;8)(p12;q24)] or *IGL* [t(8;22)(q24;q11)] loci. Through translocation, c-*myc* falls downstream of immunoglobulin enhancer sequences that are particularly active in mature B cells. This places c-*myc* under new transcriptional regulation, ultimately causing its overexpression, increased activation of *myc* targets, and cellular proliferation.

Enhanced c-*myc* function in BL occurs not only by translocation, but also by mutational stabilization that impairs *myc* turnover. Normally, *myc* turnover is regulated by phosphorylation

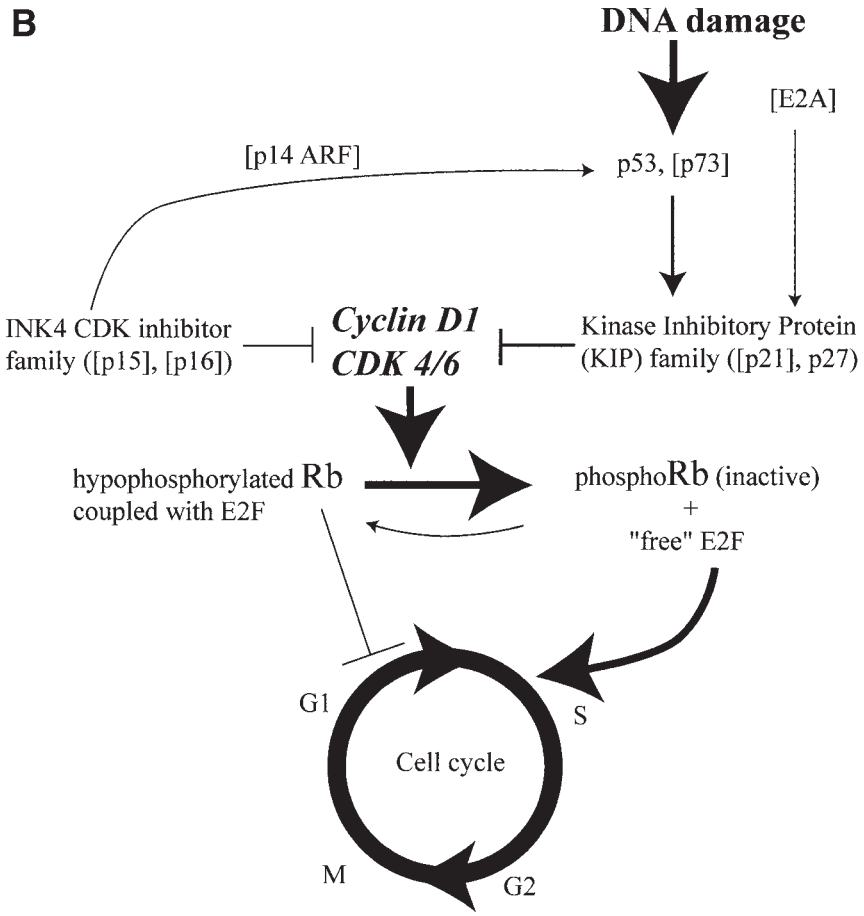
at threonine-58. This event targets *myc* for ubiquitination and proteosomal degradation. Thr-58 is a mutational hot spot in BL. Such point mutations are thought to impair phosphorylation, leading to escape from proteolysis and prolonged *myc* half-life. An additional method for increased *myc* activity is deletion of its negative regulatory elements. This is most clearly seen in BL that features t(8;14). The c-*myc* breakpoint in this translocation frequently lies downstream of a negative regulatory exon 1 and intron 1 sequence. Because the truncated gene that translocates lacks the negative regulatory element, it escapes this control. In other cases, the negative regulatory elements may be present but are mutated and thus inactivated.

Once overexpressed, c-*myc* not only interacts with components of the RNA polymerase transcriptional complex, but perhaps more importantly dimerizes with a small, basic helix-loop-helix leucine zipper known as MAX. Through this interaction, c-*myc* acquires DNA binding capacity. *myc*/MAX heterodimers bind the E-box DNA motif CACGTG to activate transcription. Additionally, the N-terminal domain of c-*myc* interacts with transactivating/transformation domain-associated protein, which plays a crucial role in *myc* oncogenesis. Transactivating/transformation domain-associated protein, in turn, recruits the GCN5 histone acetyltransferase to cause chromatin remodeling by increased histone acetylation in promoter regions, and transactivation of c-*myc* targets.

Upregulated *myc* activity is associated with enhanced cell proliferation and survival, increased metabolism, and arrested differentiation. In contrast to aberrant expression in cancer cells, c-*myc* expression is tightly regulated in normal cells in cell cycle and repressed in those undergoing terminal differentiation. Microarray analysis of cells engineered to conditionally express *myc* has identified multiple targets involved in cell-cycle control. Among these is cyclin D2, which is induced, and the cyclin-dependent kinase inhibitor p21, which is repressed. Using targeted homologous recombination, a c-*myc* (–/–) cell line was created that shows a threefold reduction in growth rate that was associated with significant lengthening of G_1 and G_2 and profound reductions in the activity of cyclin-dependent kinases during the G_0-S transition. By contrast, cell lines that overexpress c-*myc* show hyperphosphorylation of the retinoblastoma susceptibility gene, a shortened G_1 phase, and rapid progression through the cell cycle.



It should be noted that cell lines engineered with conditional *myc* knockouts do not experience cell-cycle arrest on loss of c-*myc*. Instead the speed of progression through the cell cycle is slowed. The speed of cell-cycle progression (and in particular G_1 phase) in tumors that overexpress c-*myc* may have profound implications for genomic instability. Studies using forced, transient c-*myc* overexpression in embryonic fibroblasts showed that the cells were readily transformed. Surprisingly, this effect persisted in the fibroblasts for over 30 d after removal of c-*myc* expression. This finding was associated with acquired karyotypic abnormalities such as polycentric chromosomes and hypersensitivity to DNA damaging agents. These data suggest that abbreviation of G_1 owing to *myc* overexpression may directly cause mutations. Alternatively, c-*myc* overexpression may contribute to oncogenesis by allowing tumor cells to speed past cell-cycle checkpoints, thereby predisposing to the propagation of "second-hit" mutations to daughter cells. Such mutations may be lesions responsible for the transformation seen in vitro long after the effect of overexpressed c-*myc* was removed. The extent to which this finding is true in human BL is unclear as most of these malignancies are not aneuploid.



TUMOR SUPPRESSOR LOSS AND CELL-CYCLE REGULATION Central to oncogenesis in many tumor types is the loss of tumor suppressor gene function. These genes regulate appropriate entry into and progression through the cell cycle, thus, keeping growth in check and ensuring that cells with damaged DNA do not replicate until repaired. Loss of proper cell-cycle checks and balances is a common finding in cancer, including ALL. As could be predicted, cell-cycle control is extensively regulated, so there are many genes whose function is crucial for inhibiting inappropriate progression. Mutational inactivation, deletion, or transcriptional silencing by promoter hypermethylation all contribute to tumor suppressor loss and leukemogenesis in ALL. The particular perturbations of cell-cycle regulation, however, appear to be tumor type-specific, as some of the most common aberrations in solid tumors are only rarely seen in hematological malignancies and vice versa.

The retinoblastoma susceptibility gene, plays a crucial role in cell-cycle regulation. RB functions to prevent $G_1 \rightarrow S$ progression in the cell cycle. This action depends on the RB protein remaining in an unphosphorylated state. Several kinases phosphorylate and inactivate RB, thus promoting entry to the cell cycle. Principal among these are CDK 4 and 6, whose action, in turn, is facilitated by cyclin D1 (also known as BCL-1). CDK 4/6 inhibitors provide a check to this activity and maintain RB in its active, unphosphorylated state. Among the inhibitors of CDK 4/6 are a group of genes known as the *INK4* family and the *KIP* family genes, which are downstream targets of *p53*. *p53*, in concert with genes such as *MDM-2*, *ATM*, *Chk1*, *Chk2*, and *p14ARF* acts to halt cell-cycle progression in response to DNA damage. *P14ARF* arises from alternative splicing of the *INK4* gene *p16*, showing a connection between these two regulatory pathways and demonstrating the potential for significant dysregulation of growth control owing to homozygous deletion of this locus.

About half of ALL cases feature decreased levels of *Rb* expression and many show abnormalities of cell-cycle regulatory genes that affect Rb phosporylation. The mechanism for decreased *Rb* expression in ALL is unclear as mutations and deletions of the gene are rare in this disease. Loss of Rb function, however, is well documented and the mechanisms have been elucidated in many cases. These include overexpression of CDKs, loss-of-function of CDK inhibitors such as INK4 or KIP family genes or those upstream of these targets (*see* Fig. 80-2). Among the *INK4* family, *p15* and *p16* appear to be the genes most frequently altered in ALL. In particular, p15 promoter hypermethylation and homozygous deletion of either *p15* or *p16* appear to be the principal ways through which loss of *INK4* family-controlled CDK inhibition occurs. *P15* hypermethylation occurs in approx 40% of B-cell precursor ALL and T-cell ALL, and deletion of either *p15* or *p16* occurs in up to 50% of T-ALL. In contrast, homozygous deletion of *p15* or *p16* occurs less frequently in mature B-cell neoplasms (<25%) and is generally not seen in AML, myelodysplastic syndrome, or CML outside of lymphoid blast crisis. Hypermethylation of *p16* is generally rare in hematological malignancies, regardless of histology.

p53 is known as the "guardian of the genome." Its role serves to halt the cell cycle in the face of DNA damage until repair is completed. This function is crucial to protect against the propagation of mutations to daughter cells. Mutational inactivation of *p53* is the most common genetic abnormality in cancer. It is somewhat surprising, therefore, that *p53* mutations are rarely seen in hematological malignancies and indeed are found in less than 5% of

ALL samples. Although *p53* mutations are rarely seen in ALL, loss of p53 effect through mutation, deletion, or methylation of regulators of its pathway, is commonly encountered.

p73 is a tumor suppressor gene that shares much structural homology with p53, including its DNA-binding, oligomerization, and transactivating domains. It also shares several downstream targets, including *KIP* family genes such as *p21*. Hypermethylation of CPG islands in the *p73* promoter region causes transcriptional silencing and is found in as many as 62% of T-cell ALL. Independent of *p73*, loss of *p21* function might also occur through methylation in up to 41% of patients with ALL. Methylation-induced p21 silencing was found to be an independent risk factor for ALL relapse, regardless of therapy type. Finally, *p14ARF* deletion occurs concomitant to *p16* deletion as noted. This gene serves as an upstream regulator whose inactivation results in *p53* inhibition (Fig. 80-3).

GENE EXPRESSION PROFILING AND OTHER NEW DIRECTIONS IN ALL An exciting new area in the understanding of leukemia biology is gene expression profiling. ALL, and indeed all cancers, represents a heterogeneous collection of biological mechanisms that are grouped together because of a common histological appearance. However, the similar morphological appearance and clinical presentation masks the diversity of biological mechanisms responsible for this presentation. This diversity is true even among tumor types that share common immunophenotypes or translocations. Although two leukemias may share a particular gene rearrangement, the additional mutational events required to fully transform the cells to leukemia are frequently divergent.

RNA expression profiling has allowed for precise determination of an expression "fingerprint" for a particular tumor and the ability to see similarities between, and differences among, multiple patient samples. This approach has been useful not only in terms of confirming and validating other diagnostic modalities, but also in terms of risk-stratifying patients within subgroups. The traditional karyotypic classifications can be recapitulated through gene expression profiling. Interestingly, some data appears to define additional subcategories among patients, in particular karyotypic groups that predicted later relapse or transformation to therapy-related AML. In addition, novel groupings outside of the known chromosomal rearrangements are seen. Although the underlying mechanisms of these tumors is not yet known, several putative oncogenes have been identified by this approach that otherwise would have escaped detection. Although the ramifications of these findings herald a new era in leukemia diagnostics, the predictive ability of this technology needs to be validated prospectively. Furthermore, the reproducibility of these techniques can be operator dependent. Therefore their applicability to clinical practice remains to be established.

Expression profiling is likely to be eventually integrated into diagnostics and may eventually play a role in prognostication. Real-time quantitative PCR allows the ongoing surveillance of pediatric and adult ALL patients with defined translocations who are in morphological remission. MRD sensitivities with this technique can be as low as detecting one cancer cell among 10^5–10^6 normal cells. This is a 10- to 100-fold improvement in sensitivity over flow cytometric analysis. Using PCR, MRD positivity following induction chemotherapy correlates strongly with future relapse. Low or negative MRD in the same patient population is associated with extended disease free survival. A similar increased risk for relapse after allogeneic transplant is seen in patients who have demonstrable MRD at the time of transplantation. These results might argue for additional pretransplant therapy or alternative treatment. Gene expression profiling from samples taken at diagnosis may also ultimately lead to the ability to prognosticate among patients who are MRD positive. With this approach, those who have residual disease but are still likely to be cured are spared excessive treatment and those who are likely to relapse despite therapy may be given more appropriate treatment.

CONCLUSION

Advances in the understanding of leukemia biology have steadily advanced the care of childhood ALL, transforming the disease from a universally fatal condition into among the most curable of cancers in a period of two decades. Improvements in the therapy for poor risk ALL patients, particularly infants and adults, is still desperately needed. ALL remains a collection of many disease processes with a deceptively common histopathological appearance. Through improved understanding of the molecular mechanisms through which leukemogenesis occurs, novel therapeutic approaches will be developed and cure rates will likely continue to rise. Ultimately, the field may strive for a goal of matching targeted therapies to molecular subcategories. By this approach, it is hoped the treatment of even good risk leukemic patients will become less toxic although sustaining a high level of efficacy.

Figure 80-3 **(A)** Simplified model of cell cycle regulation in normal cells. In normal hematopoiesis, DNA damage induces cell cycle arrest at the G1 → S checkpoint. Rb and p53 play a central role in the mechanism that halts cell cycle to allow time for DNA repair. Bars indicate inhibition and arrows stimulation. **(B)** Simplified model of disrupted cell cycle regulation in ALL. In contrast to the normal regulatory signals outlined in Fig. 80-3A, G1 → S checkpoint control is disordered in ALL owing to Rb phosphorylation. Mechanisms that promote this phosphorylation include overexpression (shown in italics) of cyclin-dependent kinases (CDK). In addition, reduced expression levels (shown in brackets) of CDK inhibitors and other tumor suppressors through either promoter hypermethylation or deletion contribute to Rb phosphorylation and loss of its negative regulatory function. Hyperphosphorylated Rb promotes inappropriate progression through cell cycle and dysregulated cellular proliferation. Bars indicate inhibition and arrows stimulation.

81 Chronic Myelogenous Leukemia

Brian J. Druker

SUMMARY

Chronic myelogenous leukemia is a clonal hematopoietic stem disorder characterized by excess numbers of myeloid cells that over time, lose the capacity for terminal differentiation. A series of discoveries led to the identification of the BCR-ABL tyrosine kinase as the cause of the disease and this provided the impetus for the development of specific agents that target this abnormality. This has also led to improved methods for diagnosis and molecular monitoring of patients with the disease.

Key Words: Allogeneic stem cell transplant; BCR-ABL; chronic myelogenous leukemia; imatinib; molecular monitoring; Philadelphia chromosome; RT-PCR; tyrosine kinase; tyrosine kinase inhibitors.

INTRODUCTION

Chronic myelogenous leukemia (CML) was the first malignancy to be associated with a specific chromosome abnormality. This abnormality, known as the Philadelphia (Ph) chromosome, results from a reciprocal translocation between chromosomes 9 and 22. This finding led to the identification of *BCR–ABL* as the causative molecular event of this disease and ultimately to the development of a therapy that targets this pathogenetic event. These developments are reviewed along with the understanding of the signal transduction pathways impacted by the BCR–ABL fusion protein.

CLINICAL FEATURES OF CML

CML is a malignant, clonal hematopoietic stem cell disorder. It accounts for 15–20% of all cases of leukemia, with an annual incidence of 1–1.5 cases/100,000. Although CML affects all age groups, the median age at diagnosis for patients not selected by referral is close to 60 yr of age. Clinically, the course of CML is divided into three phases. Most patients present in the chronic or stable phase of the disease, which after a variable length of time progresses through an accelerated phase to an invariably fatal acute leukemia, also known as blast crisis.

During the chronic phase, leukemic cells retain the capacity to differentiate normally with the peripheral blood smear showing a full spectrum of myeloid cells from blasts to neutrophils with blasts comprising less than 5% of the white blood cell differential. Basophilia is invariably present and eosinophilia is common. After a median of 4–5 yr in untreated patients, there is a transition from chronic phase CML to an accelerated or blastic phase. The accelerated phase is a transitional period that is poorly defined. The transition of CML to blastic phase is accompanied by the loss of the capacity of the malignant clone for terminal differentiation. Approximately 65% of patients evolve to blastic crisis with myeloid blasts, 30% have lymphoid blast crisis, and 5% of cases have biphenotypic, undifferentiated or T-cell blasts. Blastic phase CML responds poorly to cytotoxic chemotherapy. Median survival of patients in blastic phase is 3–6 mo, although patients with lymphoid blast crisis have a somewhat better outcome.

MOLECULAR PATHOGENESIS OF CML

MOLECULAR ANATOMY OF BCR–ABL TRANSLOCATIONS In 1960, Nowell and Hungerford described a consistent chromosomal abnormality in CML patients, an acrocentric chromosome that was thought to be a chromosomal deletion. This was the first example of a chromosomal abnormality linked to a specific malignancy. As chromosomal banding techniques improved, it became apparent that the abnormality was a shortened chromosome 22. Rowley later clarified that the shortened chromosome, the so-called Ph chromosome, was the product of a reciprocal translocation between the long arms of chromosomes 9 and 22, t(9:22) (q34;q11) (Fig. 81-1). The molecular consequence of this translocation is the fusion of the *abl* gene from chromosome 9 to sequences on chromosome 22, *bcr*, giving rise to a chimeric *bcr–abl* gene.

The breakpoints within the *ABL* gene at 9q34 can occur anywhere over a large (>300 kb) area at its 5′ end, either upstream of the first alternative exon Ib, downstream of the second alternative exon Ia, or, more frequently, between the two (Fig. 81-2). Regardless of the exact location of the breakpoint, splicing of the primary hybrid transcript yields an mRNA molecule in which *BCR* sequences are fused to the second exon of *ABL*, exon a2. In the majority of patients with CML and in approximately one-third of patients with Ph chromosome positive acute lymphoblastic leukemia (ALL), the break occurs within a 5.8-kb area spanning *BCR* exons 13 and 14, originally referred to as exons b2 and b3, and also known as the major BCR (M-*BCR*). Depending on the site of the translocation, fusion transcripts with either *BCR* exon b2 or b3 fused to *ABL* exon a2 can be formed. Each of these fusion mRNAs are transcribed into a 210-kd chimeric protein ($p210^{BCR–ABL}$). In the remaining patients with ALL and rarely in patients with CML, characterized clinically by prominent monocytosis, the breakpoints are further upstream in the 54.4-kb region

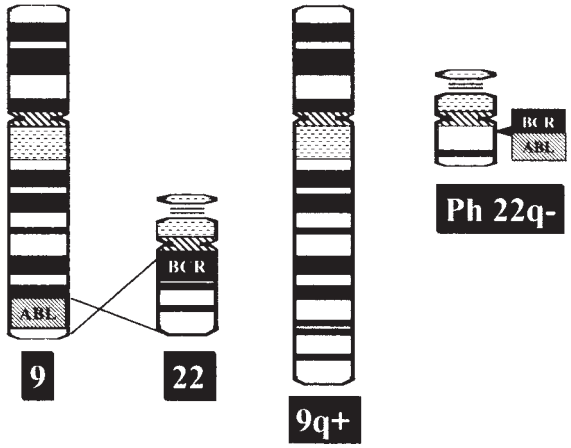

Figure 81-1 Schematic diagram of the translocation that creates the Ph chromosome. BCR, breakpoint cluster region. (Reproduced with permission from Deininger MW, Druker BJ. Specific targeted therapy of chronic myelogenous leukemia with imatinib. Pharmacol Rev 2003; 55:401–423.)

The molecular biology of chronic myeloid leukemia. Blood 2000;96:3343–3356. Copyright American Society of Hematology.)

between *BCR* exons 1 and 2, also known as the minor BCR (m-*BCR*). The resultant e1a2 mRNA is translated into a 190-kd protein ($p190^{BCR–ABL}$). A third BCR (μ-*BCR*) has been identified downstream of exon 19, giving rise to a 230-kd fusion protein ($p230^{BCR–ABL}$) associated with some, but not all cases of the rare Ph chromosome-positive chronic neutrophilic leukemia.

ANIMAL MODELS OF CML Several experimental approaches have demonstrated the ability of *BCR–ABL* to cause leukemia. In one set of experiments, transgenic mice that express *BCR–ABL* developed a rapidly fatal acute leukemia. Using a different approach, a *BCR–ABL*-expressing retrovirus was used to infect murine bone marrow. These *BCR–ABL*-expressing marrow cells were used to repopulate irradiated mice. The transplanted mice developed a variety of myeloproliferative disorders, including a CML-like syndrome. Although these approaches demonstrate the leukemogenic potential of *BCR–ABL*, it is possible that secondary changes are required for leukemia to develop. Researchers have placed *BCR–ABL* under the control of a tetracycline repressible promoter. Mice expressing this transgene develop a reversible leukemia dependent on the presence or absence of tetracycline, thus demonstrating the leukemic potential of *BCR–ABL* as a sole oncogenic abnormality.

BCR–ABL SIGNALING AND CML PATHOGENESIS BCR–ABL functions as a constitutively activated tyrosine kinase and significant advances have been made in determining the signaling pathways that are activated by BCR–ABL kinase activity (Fig. 81-3). Numerous substrates and binding partners have been identified and efforts are being directed at linking these pathways to the specific pathological defects that characterize CML. The pathological defects identified in CML cells include increased proliferation or decreased apoptosis of a hematopoietic stem or progenitor cell leading to a massive increase in myeloid cell numbers. Because patients have circulating immature myeloid progenitors, it has been postulated that there is a defect in adherence of myeloid progenitors to marrow stroma. An example of a cellular pathway that links to an increased proliferative rate is activation of the RAS pathway. STAT-5 (signal transducer and activator of transcription) mediated upregulation of the antiapoptotic molecule BCL_{XL} and phosphorylation of and inactivation of the proapoptotic molecule BAD promoter by AKT are postulated to lead to a protection from programmed cell death. CML cells also exhibit reduced adhesion to fibronectin, possibly as a downstream effect of CRKL phosphorylation. Despite the seemingly endless expansion of the list of pathways activated by BCR–ABL and the increasing complexity that is being revealed in these pathways, all of the transforming functions of BCR–ABL are dependent on its tyrosine kinase actvity.

MOLECULAR BIOLOGY OF DISEASE PROGRESSION Clonal cytogenetic abnormalities besides a single Ph chromosome may be acquired in patients with CML as their disease progresses; up to 80% of patients with overt blastic transformation have additional cytogenetic abnormalities. The molecular basis of disease progression is poorly defined in the majority of patients. Up to 25% of patients with myeloid blastic transformation of CML have point mutations or deletions in the *p53* tumor suppressor gene. As many as 50% of patients with lymphoid transformation show homozygous deletion in the *p16* tumor suppressor gene. Alteration of the retinoblastoma, *Rb*, tumor suppressor gene is associated with the rare megakaryoblastic transformation. Amplification of the *MYC* proto-oncogene appears to be rare. However, none of these lesions explains the loss of differentiation that is the most striking feature of transformation to blast crisis.

TREATMENT OPTIONS FOR CML

The treatment of CML has rapidly evolved. Standard treatment options for patients in the chronic phase are allogeneic stem cell transplantation, imatinib, chemotherapy such as hydroxyurea and busulfan, or interferon-α-based regimens. Allogeneic stem cell transplantation remains the only proven, curative therapy for CML. The overall survival for patients transplanted using a matched donor, whether sibling or unrelated is about 60–70% at 5 yr. The major risk factors for early mortality are increasing age and a higher degree of mismatch between the donor and recipient. Patients transplanted in the blast phase of disease have a 5-yr survival of less than 10% owing to a high percentage of relapses. Thus, transplant is most commonly recommended for younger patients with suitably matched donors in the chronic phase of the disease and ideally, within 1 yr of diagnosis. As the average age of onset of CML is greater than 50 yr of age, this factor, plus the inability to identify a suitably matched donor limits this option to a minority of patients. Thus, approximately one-third of patients with CML are transplanted and less than 20% of CML patients are cured with current treatment options.

Hydroxyurea is an efficacious, well-tolerated cytoreductive agent that can control blood counts in the majority of patients but does

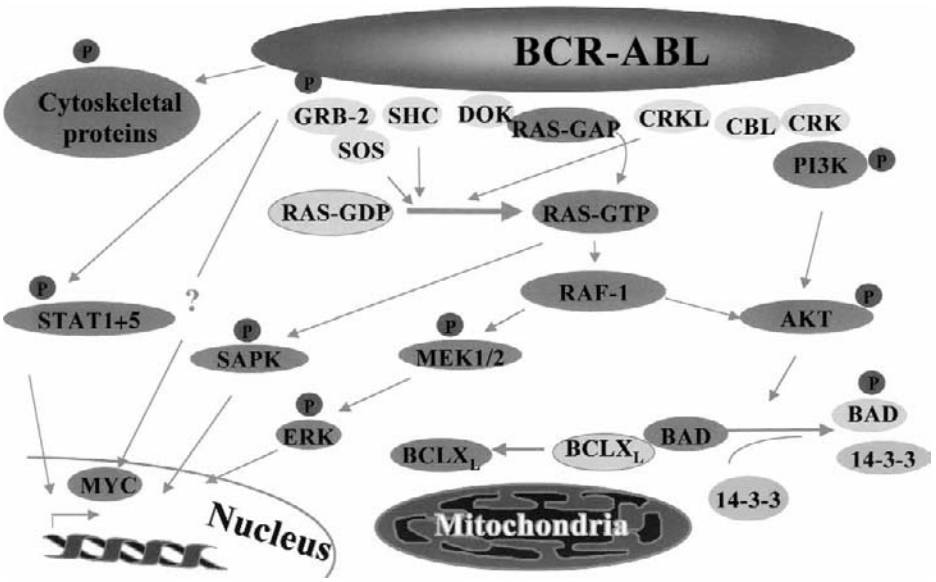

Figure 81-3 Signaling pathways affected by BCR–ABL expression. (Reproduced with permission from Deininger MW, Goldman JM, Melo JV. The molecular biology of chronic myeloid leukemia. Blood 2000;96:3343–3356. Copyright American Society of Hematology.)

little to alter the natural history of the disease. Interferon-α-based regimens induce complete hematological responses in 70–80% of patients and prolong survival by up to 20 mo as compared with hydroxyurea therapy. Patients achieving a major cytogenetic response (a reduction in the percentage of Ph chromosome positive bone marrow metaphases to <35%) may obtain the greatest survival benefit; however, major cytogenetic responses occur in only 20–30% of interferon-treated patients. Interferon therapy is associated with a well-described set of side effects, which are intolerable in up to 20% of interferon-treated patients.

IMATINIB: MOLECULAR BIOLOGY TO THERAPY From the above discussion, it should be clear the BCR–ABL possesses many characteristics of an ideal therapeutic target. It is expressed in the majority of patients with CML and it has been shown to cause CML. BCR–ABL functions as a constitutively activated tyrosine kinase and mutagenic analysis has shown that this activity is essential for the transforming function of the protein. Thus, an inhibitor of the BCR–ABL kinase would be predicted to be an effective and selective therapeutic agent for CML (Fig. 81-4).

Imatinib mesylate (Gleevec, Glivec, formerly STI571) is a relatively specific inhibitor of the BCR–ABL tyrosine kinase. Other tyrosine kinases inhibited by imatinib include the platelet-derived growth factor receptor, KIT, and ARG (*ABL*-related gene). Preclinical data showed significant specific activity against *BCR–ABL*-expressing cells lines in vitro and in vivo. In addition, imatinib could select for the growth of *BCR–ABL*-negative hematopoietic cells from CML patient samples in colony forming assays and long-term marrow cultures.

Based on the favorable preclinical data, imatinib was tested in phase-I and -II clinical trials in CML patients. These studies showed that imatinib has significant activity in all phases of CML. The results of the phase-II trials are summarized in Table 81-1. These data demonstrate that virtually all patients in the chronic phase of the disease achieve a complete hematological response with the majority obtaining a major or complete cytogenetic response, and these responses have been durable. In patients with more advanced disease, the majority of patients respond to imatinib, but

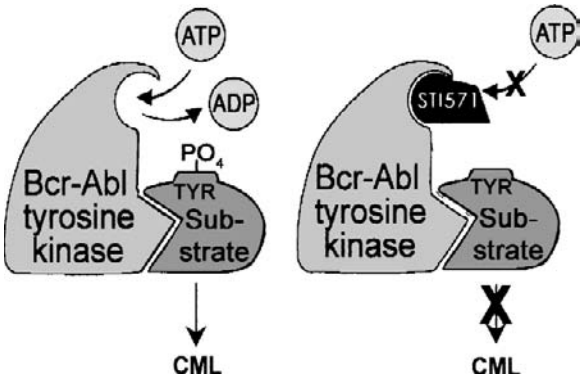

Figure 81-4 Schematic representation of the mechanism of action of the BCR–ABL tyrosine kinase and its inhibition by imatinib. TYR, tyrosine.

Table 81-1
Phase-II Results With Imatinib

	Chronic phase (IFN failure) (%)	*Accelerated phase (%)*	*Blast crisis (%)*

Results reported are with a median follow-up of 36 mo.

in patients with blast phase disease, the majority relapse while on therapy with imatinib.

A phase-III randomized study, comparing imatinib at 400 mg/d with interferon-α plus cytarabine (Ara-C) in newly diagnosed patients with chronic phase CML, enrolled 1106 patients from June 2000 to January 2001. Five hundred and fifty-three patients were randomized to each treatment. With a median follow-up of

Table 81-2
Phase III Results of Imatinib Vs Interferon-α Plus Cytarabine (Ara-C) for Newly Diagnosed Chronic Phase CML Patients

	Imatinib 400 mg (%)	*Interferon + Ara-C (%)*
CHR	97	69
MCR	87	35
CCR	76	14
Intolerance	3	31
Progressive disease	3	8.5

CHR, complete hematological response; MCR, major cytogenetic response (Philadelphia chromosome positive metaphases <35%); CCR, complete cytogenetic response. Intolerance leading to discontinuation of first-line therapy. Progressive disease to accelerated phase or blast crisis. (All of these differences are highly statistically significant with $p < 0.001$). Results reported are with a median follow-up of 19 mo.

19 mo, patients randomized to imatinib had statistically significant better results than patients treated with interferon-α plus Ara-C in all parameters measured (Table 81-2) including rates of complete hematological response, major and complete cytogenetic responses, tolerance of therapy, and freedom from disease progression. Despite the fact that 76% of patients randomized to imatinib achieved a complete cytogenetic response, the majority of these patients had detectable leukemia as analyzed by reverse transcriptase (RT)-PCR for *BCR–ABL* transcripts. When analyzed by log reduction in *BCR–ABL* transcript levels, 55% of patients achieved at least a three-log reduction in *BCR–ABL* levels, but only 5% have undetectable *BCR–ABL* transcript levels.

RESISTANCE TO IMATINIB THERAPY In evaluating relapse mechanisms, patients can be separated into two categories, those with persistent inhibition of the BCR–ABL kinase (BCR–ABL independent) and those with reactivation of the BCR–ABL kinase (BCR–ABL dependent) at relapse. In the largest studies of resistance or relapse, several consistent themes emerge. In patients with primary resistance, that is, patients who do not respond to imatinib therapy, BCR–ABL-independent mechanisms are most common. In contrast, the majority of patients who relapse on therapy with imatinib reactivate the BCR–ABL kinase. In these studies, greater than 50% and perhaps as many as 90% of patients with hematological relapse have *BCR–ABL* point mutations in at least 25 different amino acids scattered throughout the *ABL* kinase domain. Other patients have amplification of *BCR–ABL* at the genomic or transcript level.

In patients who relapse as a consequence of reactivation of the BCR–ABL kinase, the BCR–ABL kinase remains a good target. Alternate ABL kinase inhibitors have already been synthesized and two have advanced to clinical trials. One of these compounds, AMN107, was synthesized based on the knowledge of the crystal structure of the ABL kinase in complex with imatinib. This information was used to synthesize an ABL inhibitor that is approx 30-fold more potent than imatinib. An alternate approach was to profile existing compounds for activity against the ABL kinase. This led to the recognition that many SRC inhibitors are also inhibitors of the ABL kinase. One of these dual SRC/ABL inhibitors, dasatanib (BMS-354825), is over 100-fold more potent against ABL than imatinib. Both AMN107 and dasatanib inhibit most of the common imatinib-resistant BCR–ABL kinase domain mutations except T315I and have shown significant activity in imatinib-resistant patients in early clinical trials. Additional clinical trials are examining the combination of imatinib with agents that target downstream signaling pathways activated by BCR–ABL.

It should be noted that the studies described above represent a minority of CML patients. Most of the patients described in the studies of resistance had advanced phase disease. In contrast, the majority of patients diagnosed with CML will be in the chronic phase, most will obtain a complete cytogenetic response with imatinib, and very few have relapsed. However, only a minority attain a molecular remission. Hypotheses for the mechanism of molecular persistence can also be divided into BCR–ABL-dependent and -independent mechanisms. For example, stem cell quiescence has been postulated as a potential BCR–ABL-independent mechanism of resistance to imatinib. BCR–ABL-dependent mechanisms of molecular persistence include the possibility that low levels of BCR–ABL kinase activity prevent cells from proliferating, but are sufficient to protect cells from apoptosis. This could be because of imatinib's inability to completely inhibit the BCR–ABL kinase or to the fact that stem cells express high levels of P-glycoprotein that result in efflux of imatinib. Each of these scenarios suggests specific therapeutic interventions to overcome molecular persistence.

MOLECULAR DIAGNOSIS AND MONITORING OF CML

The traditional method of diagnosing CML and monitoring disease status is the cytogenetic analysis of bone marrow-derived metaphases for the presence of the Ph chromosome. However, cytogenetics are negative in approx 10% of patients at diagnosis and at least half of these patients will have a *BCR–ABL* fusion detectable by either fluorescence *in situ* hybridization (FISH) or RT-PCR.

FISH analyses relies on the colocalization of large genomic probes specific to the *BCR* and *ABL* genes. FISH has several advantages over conventional cytogenetics. It can be performed on peripheral blood and on metaphase or interphase cells. Comparison of marrow and blood samples by FISH analysis shows high concordance. One potential problem with FISH is the random colocalization of the signals from the *BCR* and *ABL* probes such that 8–10% of normal cells appear positive. This has been circumvented, in part, with D-FISH, which uses probes that span the breakpoint region. However, at diagnosis, in which the majority of cells are *BCR–ABL* positive, FISH is a highly accurate diagnostic test, as false negative results are rare and false positives are not a concern when greater than 90% of cells are positive.

RT-PCR can be used to amplify the region around the splice junction between *BCR* and *ABL*. The high sensitivity of this technique makes it the ideal for the detection of minimal residual disease. RT-PCR and quantitative RT-PCR have been used to detect residual CML cells following allogeneic stem cell transplantation. Whether persistence of *BCR–ABL* transcripts beyond 6 mo is predictive of relapse has not been resolved, but a rising level of *BCR–ABL* transcripts by quantitative RT-PCR after transplant is highly predictive of relapse. Similar to FISH, peripheral blood and marrow RT-PCR values show a high level of concordance. As the majority of patients treated with imatinib will be cytogenetically and FISH negative, PCR is frequently the only means to monitor patients on imatinib therapy. Further, *BCR–ABL* transcript levels correlate with progression-free survival; thus, quantitative PCR monitoring is currently recommended for the majority of patients with CML on imatinib therapy. Current efforts are being directed at increasing the availability of standardized PCR testing.

CONCLUSIONS

From the discovery of the Ph chromosome to molecularly targeted therapy of CML with imatinib, there is perhaps no other disease that has been so well characterized at the molecular level and in which the knowledge of the molecular biology has been exploited in the diagnosis, monitoring, and therapy of the disease. The current task for patients and their treating physicians is to make increasingly difficult decisions between treatment options. For the future, the goals will be to continue to improve and apply the knowledge of the molecular and immunological features of this disease to further improve treatment outcomes.

82 Non-Hodgkin's Lymphoma and Chronic Lymphocytic Leukemia

AYAD M. AL-KATIB AND ANWAR N. MOHAMED

SUMMARY

This chapter describes non-Hodgkin's lymphoma (NHL) and chronic lymphocytic leukemia (CLL). NHL is a complex and heterogeneous group of disorders characterized by clonal proliferation of lymphocytes at different stages of maturation. There are approx 30 types of NHL with varying clinical, pathological, and genetic features. Understanding some of its biological features has provided insights into the clinical behavior of NHL. CLL is a neoplasm of monomorphic small, round lymphocytes of B cell origin in 98% of the cases. It is the most frequent type of leukemia in the United States and Europe where the majority of patients are older than 50; it has a male:female ratio of 2:1. CLL remains an incurable, chronic disease with a variable survival depending on clinical stage at presentation.

Key Words: Anaplastic large-cell lymphoma; B-cell; Burkitt; chronic lymphocytic leukemia; diffuse large-cell lymphoma; mantle-cell lymphoma; non-Hodgkin's lymphoma; T-cell.

NON-HODGKIN'S LYMPHOMA

Non-Hodgkin's lymphoma (NHL) is a complex and heterogeneous group of disorders characterized by clonal proliferation of lymphocytes at different stages of maturation. There are approx 30 types of NHL with varying clinical, pathological, and genetic features. Understanding some of its biological features has provided insights into the clinical behavior of NHL. For example, lymphomas with high proliferative indices (like Burkitt's and lymphoblastic lymphomas) present with rapidly growing tumor masses, referred to clinically as high-grade lymphomas, and are rapidly fatal if not successfully treated. Histologically, these lymphomas have diffuse architecture, intermediate or large-cell morphology with large numbers of visible mitotic figures. In contrast, lymphomas with low proliferative indices (follicular and small lymphocytic lymphomas [SLLs]) have indolent clinical courses measured in years, affect older patients, and have small, mature-looking cell morphology. Ironically, the "aggressive," rapidly growing lymphomas are curable whereas the indolent ones remain incurable with available therapeutic strategies.

Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

Classification of NHL has been constantly changing. Each classification system becomes quickly outdated as new insights into the biological and genetic features of these disorders change the understanding of them and lead to recognition of new entities. The most recent classification is that of the World Health Organization (WHO) incorporating the latest advances in the understanding of the pathogenesis of NHL. Lymphomas are now viewed as distinct clinico-pathological genetic entities, each with distinct morphological, immunophenotypic and genetic features. Unique biological and genetic features of each lymphoma are aides to a more precise diagnosis and subtyping of NHL. It has also helped explain key biological behaviors of certain lymphomas. For example, rearrangement of *C-MYC* oncogene resulting from t(8;14) translocation may explain the high proliferative index and the high-grade nature of Burkitt's lymphoma. Understanding the molecular and genetic pathways of NHL may be more useful than improving diagnostic precision and delineation of new entities. Exploiting genetic abnormalities, which are at the root of lymphomagenesis, for therapy is already a reality. Clinicians, therefore, may not be able to dismiss knowledge of specific chromosomal translocations and oncogene rearrangements as important only for the experimentalists. It is possible that physicians will eventually treat NHL based on its genetic and immunophenotypic profile with a combination of antigene and monoclonal antibody reagents instead of a combination of cytotoxic agents. Anti-CD20 monoclonal antibody is now a standard therapy for certain B-cell lymphomas and bcl_2 antisense oligonucleotides are in clinical trials, ushering in a new era for NHL treatment.

This chapter addresses established molecular and genetic pathways of NHL. It should be noted, however, that genetic aberrations are final common pathways leading to the expansion of malignant clones. There are a variety of upstream events that are important etiological factors. Environmental factors, like exposure to pesticides, immune suppression, and the role of immune surveillance and bacterial infections like *Helicobacter pylori* are but few examples. The role of such factors, however, is not the focus of this chapter.

MOLECULAR PATHOGENESIS OF B-CELL NHL Acquired chromosomal translocation in lymphoma is a well-recognized mechanism that leads to activation of protooncogene. Similar to

acute myeloid leukemia, the translocations in NHL are usually balanced, reciprocal recombination between two chromosomal sites; in rare cases the translocations are complex affecting more than two chromosomes. The chromosomal translocations in lymphoma are usually nonrandom and associated with a specific clinicopathological category of NHL. The most commonly affected chromosome is 14, found in more than 50% of NHLs. In most instances, the translocations relocate transcriptional control genes to the vicinity of highly active promoter/enhancer elements of the immunoglobulin genes. The common consequence of the translocation is the dysregulated expression of the protooncogene sequences by two mechanisms: by changing the level of protooncogene expressed in normal cells or by activation of protooncogene that is physiologically not expressed in normal cells. A wide variety of translocation partner chromosomes recombined with 14q32 have been described in NHL; common to the majority of these cases is a B-lineage immunophenotype reflecting the rearrangement of the immunoglobulin H (IGH) locus at 14q32. Several protooncogenes were cloned and identified from the partner sites of the translocations. As already established, t(8;14) (q24;q32), commonly associated with Burkitt lymphoma/ leukemia, juxtaposes the *C-MYC* oncogene on 8q24 to the IGH locus in 14q32 resulting in the overexpression of the transcription factor c-myc protein. Subsequently, the chromosomal translocation t(11;14)(q13;q32), causing rearrangement of the *BCL1* gene locus and overexpression of cyclin D-1 (CCND1)/ PRAD1 protein, was shown to be highly characteristic of mantle-cell lymphoma (MCL). The most frequent chromosomal translocation in NHL is the t(14;18)(q32;q21), detected in up to 85% of follicular lymphoma and in 30% of diffuse large-cell lymphoma (DLCL). Molecular analysis of the t(14;18) breakpoints identified *BCL2* gene on chromosome 18q21 that is overexpressed because of its relocation next to the transcriptionally active IGH locus on chromosome 14q32. Later, functional studies revealed that increased production of bcl2 protein in B cells carrying this translocation prolongs their survival by blocking the programmed cell death.

Other significant translocations in lymphoma are t(3;14) and its variant, which are mainly seen in DLCL. The translocations involve rearrangement of *BCL6* protooncogene with various immunoglobulin loci. Several less common translocations have been also identified in lymphoma, for example, t(14;19), t(12;14), t(9;14) (Table 82-1). In all these recombination, the oncogene activation operates through a similar mechanism by bringing the oncogene under the control of constitutive regulatory sequences of immunoglobulin loci. The exception to the deregulation model of B-NHL translocations is the t(11;18) of mucosa-associated lymphoid tissue (MALT) lymphoma, which causes gene fusion resulting in a chimeric protein with oncogenic properties. Some of the well-characterized chromosomal translocations in B-NHL are described below.

t(8;14), C-MYC and Burkitt's Lymphoma The t(8;14)(q24;q32) is a highly consistent and specific translocation in Burkitt's lymphoma which plays a key role in the genesis of both the endemic (African) and the nonendemic (sporadic) forms, and obviously is not Epstein-Barr virus-dependent. The t(8;14) repositions the *C-MYC* protooncogene from its normal site on chromosome 8q24 to the vicinity of a highly active immunoglobulin enhancer on chromosome 14q32. In 75–85% of Burkitt's cases, the t(8;14) is responsible for *C-MYC* activation; however, two variant translocations t(2;8) and t(8;22) can produce the same effect in the remaining 15–25% of cases. However, t(2;8) and t(8;22) variant translocations move the *immunoglobulin-κ and immunoglobulin-λ* light chain genes respectively to the *C-MYC* locus on chromosome 8q24. *C-MYC* oncogene belongs to a small gene family with closely related members. The human *C-MYC* oncogene has three exons and two promoters, P1 and P2, controlling the transcription of the gene. The choice of the promoter depends on the myc protein level. P2 promoter is the most active and generates a 2.25-kb transcript, whereas P1 promoter produces a 2.4-kb transcript. The position of the molecular breakpoints in relation to the *C-MYC* gene on chromosome 8 and the *IGH* gene on 14q differ with the geographic origin of the disease. In endemic

Burkitt's lymphoma, the breakpoints occur some distance 5′ to *C-MYC* exon 1, whereas the breakpoints on chromosome 14 usually occur in the IGH joining regions (J_H). In sporadic and AIDS-related Burkitt's lymphoma, the t(8;14) breakpoints occur between exon 1 and 2 of *C-MYC* gene on chromosome 8 and within the IGH switch μ switch region on chromosome 14. In the two variant translocations, the breakpoints on 8q are located at variable distance 3′ of the *C-MYC* locus. The breakpoints on chromosomes 2 and 22 occur at 5′ of the immunoglobulin-κ and immunoglobulin-λ gene constant region segments, respectively. Therefore, *C-MYC* gene is translocated to der(14) in t(8;14), whereas in variant translocation, *C-MYC* remains on der(8). Because the immunoglobulin enhancers are constitutively active in mature B cells, their relocation close to *C-MYC* oncogene in Burkitt's lymphoma results in high levels of c-myc RNA and protein expression. In addition, *C-MYC* may be dysregulated by point mutations in the sequences of the gene by other mechanisms, further contributing to increased *C-MYC* activity.

The c-myc protein is a transcription factor of the helix-loop-helix/leucine zipper family that activates transcription through its heterodimerization with a partner protein, MAX. *C-MYC* dysregulation influences multiple cellular processes, including cell proliferation, apoptosis, and cellular metabolism. Furthermore, data have revealed that *C-MYC* regulates genes involved in cell growth, division, death, and adhesion, all of which contribute to cellular transformations. The role of c-myc protein in cell cycle regulation is complex but its expression is strongly associated with increased cellular proliferation. *C-MYC* overactivity promotes cell cycle progression, and therefore, it inhibits cellular differentiation. Another indirect mechanism that inhibits differentiation may be the repression of genes that have direct control on cellular differentiation such as *C/EBPα*. *C-MYC* also regulates a variety of metabolic pathways. The most relevant one in Burkitt's lymphoma is lactate dehydrogenase A, an enzyme highly expressed in Burkitt's lymphoma. The high level of lactate dehydrogenase A seems to help the cells to survive hypoxic conditions. *C-MYC* may also regulate genes that are involved in nucleotide and protein synthesis and iron metabolism, some of which are required for cellular transformation. Another hallmark of *C-MYC* overexpression is the induction of a high-level cellular apoptosis. This may be reflected by the starry-sky appearance characteristic of Burkitt's lymphoma which results from a high rate of apoptotic cell death. In addition, increased expression *C-MYC* leads to maintenance of telomerase expression, an enzyme that contributes to the immortalization of cells by protecting the end of the chromosomes.

As in the case of other specific neoplasia-associated translocations, additional chromosomal alterations superimposing the t(8;14) translocation are seen in most cases and become more numerous during disease progression. The most frequent secondary aberrations seen in >30% of cases are structural rearrangements of chromosome 1, often leading to partial gain in the long arm (q) of chromosome 1. Other recurrent abnormalities seen in association with t(8;14) are trisomy 7, 8, 12, and 18. Chromosome 6q abnormalities, particularly deletions, are frequent in Burkitt's lymphoma, suggesting the presence of suppressor genes in this lesion. Another area of secondary involvement seen in approx 30% Burkitt's lymphoma cases is alterations of the short arm (p) of chromosome 17, the site of the *p53* gene, which correlate with the frequency of p53 mutations in Burkitt's tumors. *BCL-6* gene on chromosome 3q27 is mutated in 30–50% of Burkitt's tumors causing dysregulation of *BCL-6* expression. These secondary genetic changes seem not to be specific for Burkitt's lymphoma, however, they are nonrandom and their appearance predicts clonal evolution associated with disease progression and clinical deterioration.

t(11;14) Translocation and the *BCL1* Gene The t(11;14)(q13;q34) involves a breakpoint on chromosome 14 within the *IgH* gene and the Bcl_1 region on chromosome 11. The breakpoints of the t(11;14) were initially shown to juxtapose the joining region of *IgH* to a region of 11q13 designated as *BCL1* (B-cell lymphoma/leukemia). Most of the rearrangements occur in the major translocation cluster region on 11q13. To identify a putative oncogene associated with the translocation, studies on a chromosome 11 inversion, inv(11) (p15;q13) in parathyroid adenomatosis, led to the characterization of PRAD-1. Analysis of the PRAD-1 sequence showed high homology with D-type cyclins and therefore the gene was renamed *CCND1* but is sometimes still referred to as *CCND1/ PRAD-1*. The coding region of *CCND1* is not altered by the t(11;14) translocation but CCND1 expression is abnormally induced by the translocation presumably reflecting the influence of the B-cell specific *IgH* gene enhancer from chromosome 14. The gene encodes a 295 amino acid, 36-kDa protein. CCND1 is not normally expressed in lymphocytes or myeloid cells but is expressed in high levels in MCL with t(11;14) (q13;q34) translocation attesting to the critical role of this translocation in the pathogenesis of MCL. Although some MCL cases express aberrant transcripts, most express two major CCND1 mRNA transcripts of 4.5 and 1.5 kb. Both transcripts contain the whole coding region of the gene but differ in the 3′ length of untranslated region.

CCND1 is involved in cell-cycle control. Specifically, it participates in accelerating G1 progression and G1-S transition by forming complexes with cyclin-dependent kinases 4 and 6 (CDK 4/6). These complexes (a regulatory subunit, the cyclin, and a catalytic subunit, CDK) promote phosphorylation of the retinoblastoma protein (Rb). Phosphorylation of the tumor suppressor Rb leads to its deactivation and release of its inhibitory effect on E2F. Uninhibited by Rb, the transcription factor E2F activates DNA synthesis, thus permitting the cell cycle to progress into S phase (Fig. 82-1). There are two families of negative cell-cycle regulatory proteins that inhibit the CCND1/CDK4/6 activity (cyclin-dependent kinase inhibitors, CKIs). One of these families is the INK 4 (inhibitor of CDK4), which consists of four proteins: p15INK4b, p16INK4a, p18INK4c, and p19INK4d. Generally, these proteins compete with D-type cyclins for binding to the CDK subunit; p8INK4c and p19INK4d are clearly related and preferentially bind CDK6. The other family is Cip/Kip (for CDK interacting protein/kinase inhibitory protein) consisting of three proteins: p21Cip1, p27Kip1, and p57Kip2; p21Cip1 was the first CKI identified. It is also known as Waf1 (wild-type p53-activated fragment) to indicate its involvement in p53-dependent DNA damage-induced G1 arrest. The amount of p21Cip1 increases following exposure to DNA damaging agents in wild-type but not in mutant p53-containing cells. As such, p21Cip1 is an effector molecule of p53 at the G1 checkpoint. Regulation of the p27Kip1, however, is complex, including transcriptional, translational, proteolytic, and localization mechanisms. The targeted disruption of p57Kip2 in mice showed a role for this CKI in the control of the commitment/withdrawal decision as well as differentiation and apoptosis in particular tissues.

The t(11;14)(q13;q34) translocation and the resultant overexpression of CCND1 is characteristically seen in MCL. This is a

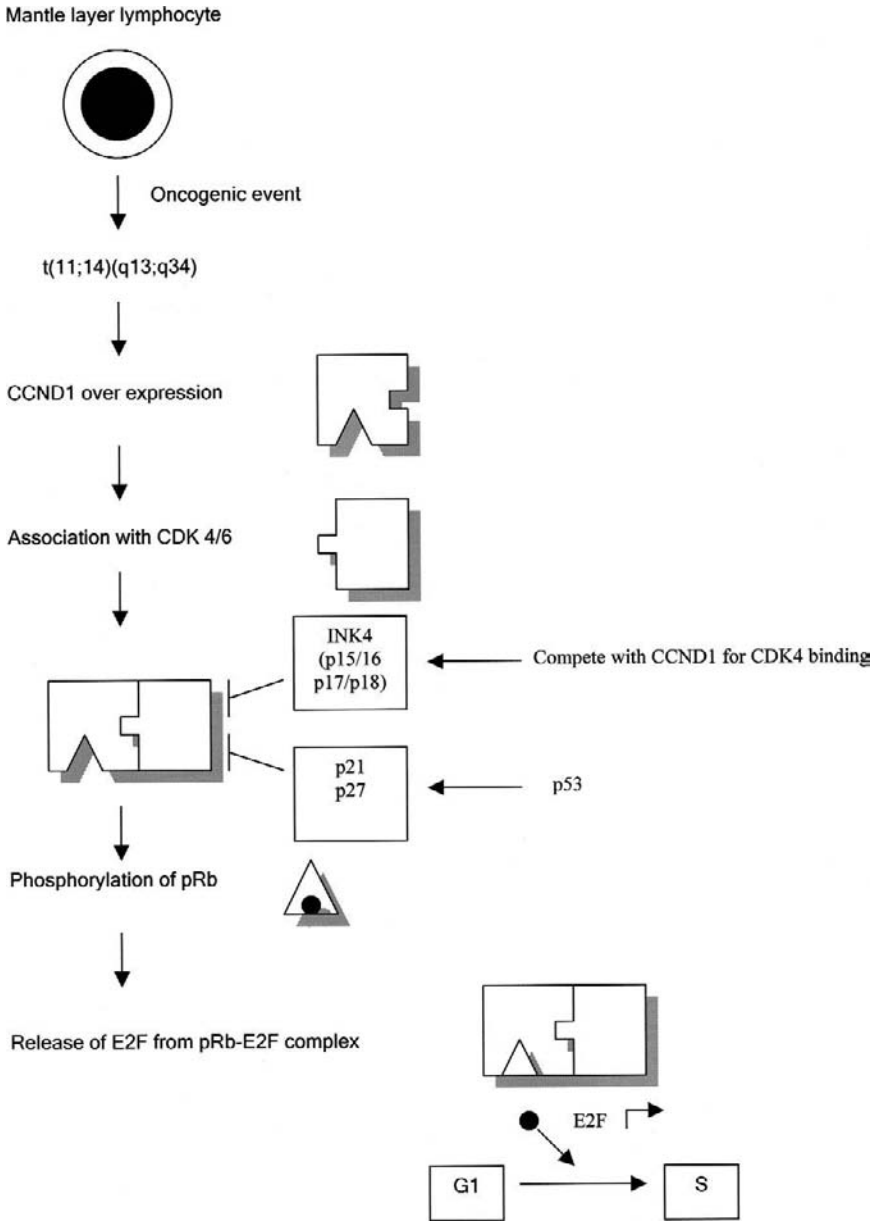

Figure 82-1 Genetic and molecular pathogenesis of MCL. The normal counterpart of MCL is thought to be the mantle layer of lymphocytes that surrounds the germinal center of lymphoid follicles. An "oncogenic" event yet unidentified leads to t(11;14) translocation and overexpression of cyclin D1 gene (CCND1). CCND1 associates with cyclin-dependent kinases 4 and 6 (CDK 4/6) resulting in binding and phosphorylation of the retinoblastoma tumor suppressor gene (pRb). Phosphorylation (inactivation) of pRb releases its inhibitory effect on the transcription factor E2F, which then permits the progression of cells from G1 to S phase. The CCND1/CDK4/6 complex is inhibited by two families of proteins, the inhibitors of CDK4 (INK4), which compete with CCND1 for CDK4/6 binding; and p21/p27. p21 is under the control of p53. INK4, inhibitor of CDK4.

B-cell neoplasm that arises from the mantle cell layer surrounding the germinal center of secondary lymphoid follicles. MCL includes 3–10% of NHL and occurs in middle-aged to older individuals. The most common sites of involvement are lymph nodes, spleen, bone marrow (with or without blood involvement), and gastrointestinal tract. The neoplastic cells are monoclonal B cells with rearranged Ig heavy and light chain genes and unmutated variable region genes indicating a pregerminal center B cell in the majority of cases. MCL is usually CD5+, FMC7+, CD10–, CD23–, Bcl2+, bcl6–. The coexpression of bcl_1 and bcl_2 makes this lymphoma one of the most difficult to treat. It has the worst features of both low-grade (incurability) and high-grade (aggressive growth) lymphomas. These biological characteristics can be explained by the coexpression of both bcl1 (which enhances proliferation) and bcl2 (which prevents programmed cell death and imparts resistance to chemotherapy). MCL has a median survival of 3–5 yr. The most consistently reported adverse histopathological prognostic parameter is a high mitotic rate (>10–37.5/15 hpf), blastoid variant and peripheral blood involvement (leukemic phase) at diagnosis. Secondary chromosomal abnormalities are identified including 13q 14 deletion, 17p deletion and total or partial plus 12; the latter being associated with shorter survival. At the molecular level, there is some evidence that deregulation of some regulatory elements involved in CCND1-driven G1-S transition are of prognostic importance in MCL. Examples include p53 mutations, loss of p21 waf1 and p16INK4a expression and deletion of p16INK4a gene.

Although t(11;14) (q13;q34) is characteristic for MCL, it is not exclusive. This translocation has been reported, albeit with much less frequency, in other lymphoproliferative disorders including splenic marginal zone lymphoma, occasional cases of chronic lymphocytic leukemia (CLL), prolymphocytic leukemia, DLCL, and multiple myeloma. However, CCND1 overexpression in these disorders is rare. Detection of CCND1, therefore, is a useful marker in the differential diagnosis of MCL from other B-cell leukemias and lymphomas. This test can be performed on small biopsy samples with limited material using immunohistochemical staining techniques.

t(14;18)(q32;q21) and the *BCL2* Gene in Lymphoma The *BCL2* protooncogene was identified through the molecular analysis of breakpoints involved in the t(14;18) chromosomal translocation, which is found in the majority of follicular lymphomas. Two other translocations, t(2;18) and t(18;22), are rare variants and all share the same clinical significance. This genomic aberration juxtaposes the *BCL2*, normally located on chromosome 18q21, under the control of the *IGH* gene enhancer on 14q32, leading to upregulation of the *BCL2* gene in lymphoid cells. The breakpoints on chromosome 14 are all 5′ of one of the J segments in *IGH* gene. As a result, the *IGH* constant region with an intact enhancer remains on the der(14)t(14;18). The *BCL2* gene consists of three exons and most of the breakpoints are clustered in the 3′ untranslated region of the gene (70% of cases) or more distal in 3′ of exon 3 (in 30% of cases). The t(14;18) does not affect the coding sequences of the *BCL2* gene but relocates *BCL2* to the der(14) next to immunoglobulin enhancer, which stimulates the expression of *BCL2*. The role of bcl2 protein in lymphomagenesis remained unclear for several years after the discovery of the gene. Several studies have since demonstrated that overexpression of bcl2 protein does not alter the proliferation activity of the bearing cells but acts to prolong their survival. Subsequently, *BCL-2* was confirmed to be an apoptosis inhibitor causing cell accumulation rather than transformation. The bcl-2 protein is the founding member of a large family of highly conserved proteins, several members of which appear to play important positive and negative roles in the control of cell death. The striking discovery of *BCL2* function has defined a new class of oncogenes, antiapoptotic genes, that protects against cell death. The dysregulation of the antiapoptotic genes has expanded the research field of genetic alterations that contribute to cancer development.

The *BCL2* gene encodes a membrane-associated protein found in the endoplasmic reticulum and mitochondrial membranes. The effects of *BCL2* overexpression on mitochondrial control of cell death are multifunctional and may act directly on mitochondrial membrane permeability, a process often associated with the release of cytochrome-*c* and subsequent cell death. Furthermore, *BCL2* may have some role in the regulation of basal mitochondrial energy metabolism as previous studies suggested that bcl2 protein might regulate proton transport across the inner mitochondrial membrane. *BCL2* is also capable of inhibiting cytochrome-*c* release pathways independent of mitochondrial permeability transition, such as Bid- and Bax-mediated cytochrome-*c* release. In addition, bcl2 protein cooperates with other oncoproteins such as c-myc to immortalize pre-B cell. Bcl2 protects cultured cells from c-myc-induced apoptosis, an activity that may explain that concomitant overexpression of both c-myc and bcl2 in lymphocytes of transgenic mice results in synergistic tumorigenesis, generating lymphoid tumors much more aggressively than either transgene alone.

Experimental studies have revealed that transgenic mice carrying *BCL2/IGH* gene fusion develop a polyclonal follicular lymphoproliferation, however, over time the hyperplasia transformed into monoclonal B-cell lymphoma. This suggests that *BCL2* activation is not sufficient for follicular lymphoma development but an initiating factor leading to cell immortalization through prolonged cell survival. This may be supported by observations that the majority of follicular lymphoma displayed additional genetic changes at initial diagnosis. The number and the type of secondary chromosomal alterations seen in association with t(14;18) are variable among cases but have nonrandom patterns, and are seen in different combinations. The most frequent secondary abnormalities are gains of chromosomes 7, X, followed by chromosomes 18/der(18)t(14;18), 5, 12, and 21. The majority of structural aberrations seen in t(14;18) lymphoma are unbalanced rearrangements mostly affecting 1p and/or 1q, deletions of 6q, 9p, 10q, and 13q.

Moreover, the type and frequency of the secondary abnormalities as well as the complexity and the ploidy of the karyotype are correlated with the morphological evolution of the t(14;18) follicular lymphoma. For example, gain of chromosome 7 in t(14;18) lymphoma is the most frequent abnormality seen in later disease and strongly associates with transformation to diffuse pattern. Gains of chromosomes 5 and 12, 13q- and 17p- are markers associated with expression of a higher-grade histology. Obviously most of the secondary abnormalities associated with t(14;18) are unbalanced, leading to gain or loss of genetic material. The molecular mechanisms associated with gains may include simple gene dose effects or duplication of active mutated oncogenes causing proliferation of selective cell populations leading to histological transformation. However, loss of active suppressor genes seems the likely underlying mechanism associated with deletions. The 17p abnormalities may reflect alterations of the p53 gene, which has been associated with follicular center cell lymphoma transformation. Rearrangements of 9p21 region harboring the p15 and p16 tumor-suppressor gene loci, leading to deletions, mutations, and hypermethylation of these genes with loss of the protein expression are important secondary genetic events in the progression of t(14;18) follicular lymphoma. Deletions of 6q are frequent in t(14;18) lymphoma as well as in other lymphoid neoplasms. Three distinct regions of minimal common deletions are identified, suggesting three separate tumor suppressor genes of importance in follicular lymphoma progression. Another less frequent but valuable genetic marker seen in t(14;18) lymphoma is the Burkitt's-type translocation t(8;14) or its variants. The later translocation is considered as clonal genetic evolution causing activation of *C-MYC* oncogene that is implicated in histological progression to blastic/blastoid transformation of follicular lymphoma.

t(11;18), *API2-Malt* Genes and MALT Lymphoma The t(11;18)(q21;q21) is the most common translocation found in marginal zone lymphoma of MALT. The t(11;18) occurs in 30–40% of gastric lymphomas, and is also found in MALT lymphoma of other mucosal sites but rarely in nodal B-cell lymphoma. The t(11;18) is one of the determinant factors in the treatment and outcome of gastric MALT because the lymphomas carrying t(11;18) are resistant to *H. pylori* eradication therapy. A remarkable finding is that the t(11;18) is the sole chromosomal alteration in most cases suggesting the importance of the translocation in the pathogenesis of MALT lymphoma. The breakpoints of t(11;18) translocation were found to involve *API2* gene at 11q21, and a previously unknown gene, *MALT*, at 18q21. Unlike other lymphoma-associated translocations, the t(11;18)

produces a chimeric fusion *API2/MALT1* gene located on der(11). *API2* belongs to a family of inhibitors of apoptosis (IAP), containing three N-terminal baculovirus IAP repeats, a middle caspase recruitment domain, and a C-terminal zing binding RING finger domain. Several of the IAP family proteins are potent IAP. The function of MALT protein remains unknown, but it was hypothesized that the API2/MALT fusion product of t(11;18) inhibited apoptosis, and therefore conferred a survival advantage to MALT lymphoma and allowed for antigen-independent proliferation. A second nonrandom translocation seen in association of MALT lymphoma is t(1;14)(p22;q32), which is significantly less frequent than t(11;18). This translocation has only been described in gastric and pulmonary MALT lymphoma. The t(1;14) juxtaposes the entire coding sequences of *BCL10* gene at 1p22 to chromosome 14 under the control of immunoglobulin enhancer and thus, upregulates *BCL10* expression. When *BCL10* expression is increased, it binds to its normal partner *MALT*, and together they act as a positive regulator of antigen receptor-mediated nuclear factor-κB activation. Alternatively, the same pathway can be activated by the novel fusion *API2/MALT*, which does not require bcl10. The nuclear factor-κB is a transcription factor for several survival-related genes including those involved in inflammation, cell viability, and immune response.

***BCL6, BCL3,* and Others** The t(3;14)(q27;q32) translocation and the two variants t(2;3)(p12;q27) and t(3;22)(q27;q11) share the same breakpoint on 3q27. The translocations are mainly seen in diffuse large B-cell lymphoma and rarely in follicular lymphoma. Cloning of the breakpoint 3q27 led to the discovery of the *BCL6* protooncogene, also identified as LAZ3. Bcl6 protein is a transcription factor containing six zing-finger DNA-binding motifs near the C terminus and a pox virus and zinc finger regulatory domain near the N terminus. Most of the *BCL6* rearrangements occur within the 5′ noncoding first exon (containing two promoters) or the first intron of the gene that results in dysregulated expression of structurally intact bcl6 protein. The partner genes involved in *BCL6* rearrangements are the *IGH* (mainly Sμ region) in 14q32, *IG*κ in 2p12, and *IG*λ in 22q11. Other rare partner genes located at variant breakpoints are listed in Table 82-1. Therefore, the partner gene fuses with the second exon of *BCL6*, resulting in a 5′ partner-3′ BCL-6 fusion transcript. The substitution of the *BCL6* promoter may be responsible for *BCL6* regulation, or a break in the breakpoint cluster region of *BCL6* may inhibit a sequence involved in *BCL6* regulation. In addition to gene rearrangements resulting from chromosomal translocations, point mutations of the 5′ regulatory regions of *BCL6* have been reported in high frequency in the DLCL as well as in follicular lymphoma of B-cell lineage. *BCL6* mutations are regarded as a genetic marker of B-cell transition through the germinal center. The t(3;14), its variants and 3q27 abnormalities are often associated with well known primary chromosomal translocations such as t(8;14), t(11;14), and t(14;18). As in other NHLs, secondary chromosomal anomalies are frequent in t(3;14)-lymphoma involving chromosomes 1, 6q, 10q, 12q, 13q, and 17p.

The t(14;19) translocation is a rare but recurrent translocation in B-cell malignancies, mainly CLL, described with atypical lymphocyte morphology and immunophenotype. A high proportion of patients with t(14;19)–CLL are less than 40 yr of age. Three-way variant translocations are relatively frequent such as t(14;17;19) and t(7;14;19); all share the rearrangements of *BCL3* gene. *BCL3* protooncogene, located on 19q13, consists of 9 exons, and the breakpoint is mostly located in the 5′ untranslated region of the *BCL3* gene. The *BCL3* is juxtaposed to the *IGH* locus on 14q32 in a head-to-head configuration. *BCL3* is expressed in a variety of tissues particularly spleen, liver, and lung. The *BCL3* gene encodes a protein containing seven ankyrin repeats which is a member of the inhibitor-κB family. BCL3 protein is a transcription factor and plays a role in B-cell development. The t(14;19) translocation does not interrupt the transcriptional activity of the *BCL3* gene, but is associated with increased production of normal size BCL3 RNA. Another rare recurrent translocation exclusively detected in B-cell lymphoproliferative disorders of mature phenotype, such as lymphoplasmacytic lymphoma, is t(9;14)(p13;q32). The translocation relocates the entire *PAX5* gene to chromosome 14q32 close to *IGH* locus. The breakpoints at 9p13 and 14q32 are variable, precluding PCR approach for detection of *IGH/PAX5* juxtaposition. The PAX5 protein belongs to the paired box family transcription factor. *PAX5* expression is continuously required in B-cell lineage commitment during early B-cell development. The role of *PAX5* in malignant B-cell transformation has remained uncertain, however, studies suggest that *PAX5* may acts as a dominant oncogene.

MOLECULAR PATHOGENESIS OF T-CELL LYMPHOMAS

Malignant T-cell lymphoid disorders are relatively uncommon, constituting approx 20% of all lymphoid neoplasms. They show significant differences in incidence in different parts of the world, which reveals some etiological associations. For example, the human T-cell leukemia virus is etiologically linked to adult T-cell leukemia/lymphoma and the incidence of this disease correlates closely with geographic distribution of the virus, particularly in Japan and the Caribbean basin. However, for most T-cell neoplasms, the cause is unknown. T-cell neoplasms include a variety of disorders that can be divided into two broad categories according to the World Health Organization classification: those derived from uncommitted (thymic) lymphocytes, i.e., precursor T-lymphoblastic leukemia/lymphoma, and those derived from mature (post thymic) T cells. Some of these disorders have distinct morphological, immunophenotypic and genetic features that allow precise diagnosis. In general, however, T-cell lymphomas show great morphological diversity and a spectrum of histological appearances within individual disease entities. Moreover, there is morphological overlap between disease entities. In contrast to B-cell lymphomas, specific immunophenotypic profiles are not associated with most T-cell lymphoma subtypes. The presence of an aberrant immunophenotype may point toward a diagnosis of malignancy. However, there are not convenient immunophenotypic markers of monoclonality. Because natural killer (NK) cells are closely related, and share some phenotypic and functional properties with T cells, NK neoplasms are often considered together with T cells. Moreover, given the biological similarity between precursor T-lymphoblastic leukemia and T-lymphoblastic lymphoma, the use of one or the other term is sometimes arbitrary. When the process is confined to a mass lesion with minimal or no evidence of blood or bone marrow involvement, the diagnosis is T-lymphoblastic lymphoma. With extensive marrow and blood involvement as the primary presentation, acute lymphoblastic leukemia is an appropriate term. The designation of leukemia or lymphoma in patients presenting with both features (i.e., soft tissue tumor masses and blood and marrow disease) depends on the degree of bone marrow involvement. If more than 25% of marrow cells are lymphoblastic, the term leukemia is preferred. Finally, specific genetic abnormalities have not been identified for many of the T-cell/NK neoplasms. One of the few exceptions is anaplastic

large-cell lymphoma (ALCL), which is strongly associated with the t(2;5) translocation. The molecular pathogenesis of most T-cell/NK neoplasms remains to be defined. For all these reasons, clinical features should be taken into consideration when defining any of these disorders. The two major molecular pathways that are best understood in T-cell/NK neoplasms are those involving the T-cell receptor (TCR) gene rearrangements and the t(2;5) translocation, which are addressed later.

TCR Gene Rearrangements There are two major classes of T cells: αβ and γδ. This distinction is based on the structure of TCRs. Chromosomal breaks in many T-cell lymphomas consistently appear near enhancers included in the TCR-β locus on chromosome 7, band q34 (7q34) or the α/δ locus on 14q11. These enhancers, being highly active in committed T-cell progenitors, stimulate the expression of translocated transcription factors, which play important roles in the molecular pathogenesis of malignant T-cell disorders (Table 82-2). The *TAL1* gene (T-cell acute leukemia 1, also known as stem cell leukemic protein, T-cell leukemia 5) located on 1p32 is activated by the t(1;14) or by an intragenic deletion of the 5′ side of the gene that places it under the regulation of the promoter of SIL (stem cell leukemic interrupting sequence), which is active during T-cell development. TAL1 protein can dimerize with E2A protein through its basic helix-loop-helix protein domain to form DNA-binding complexes and activate specific sets of target genes not normally active in T cells. It is of interest that the *Tal1* gene also plays an essential role in early hematopoietic development. Other types of regulatory genes can be rearranged near TCR loci including those encoding LMO1 and LMO2 (for cysteine-rich *LIM*-domain only) proteins (also known as RBTN1/TTG1 and RBTN2/TTG2 for thrombotin-like/T-cell translocation gene). These genes are located on chromosome 11p15 and 11p13, respectively. LMO2 interacts with TAL1 to form a transcriptional complex both in erythroid cells and in T-cell leukemia/lymphoma induced by these gene products. Both LMO1 and LMO2 induce thymic lymphomas in transgenic mice whose thymocytes express these genes under the control of T-cell promoters. *TAL1* was found to shorten the time to development of T-cell lymphomas induced by LMO2 in a double transgenic system that recapitulates the cooperation existing between these two regulatory proteins in human T-cell tumors.

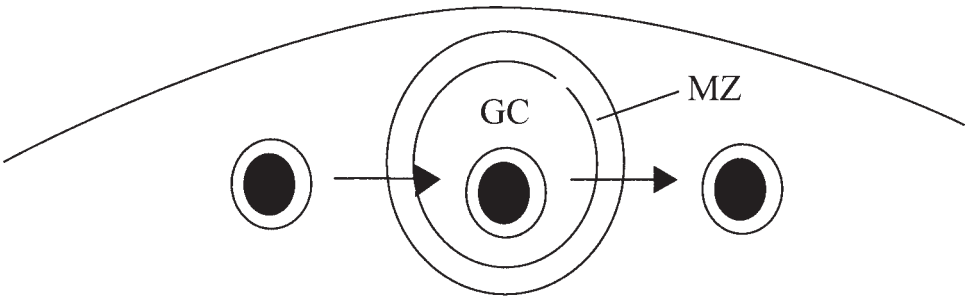
Hox11 represents a different type of developmental gene involved in T-cell leukemia/lymphoma when inappropriately placed under the control of TCR loci. This homeobox gene is located on chromosome 10q24 and encodes a homeodomain transcription factor that can bind DNA and transactivate specific target genes. Activation of *HOX11* by chromosomal translocations, either t(10;14)(q24;q11) or t(7;10)(q35;q24), in developing T cells is thought to interfere with normal regulatory cascades thereby promoting malignant transformation. Transgenic mice expressing *HOX11* in the developing thymus developed T-cell leukemia/lymphoma at high frequencies, demonstrating the oncogenic importance of *HOX11*. The transcriptional activity of *HOX11* depends on the N-terminal 50 amino acids of the protein. *HOX11* interacts directly with phosphates that normally regulate G2-phase cell cycle check points, suggesting that *HOX11* expression in T-cell progenitors may accelerate G2-M transition.

The *TCL1* (T-cell leukemia-1) locus is located on chromosome 14q32.1, distant only by approx 10,000 kb from the immunoglobulin heavy chain locus located on 14q32.3. *TCL1* is activated in T-cell prolymphocytic leukemia and other T-cell malignancies by translocations and inversions that juxtapose it to regulatory elements of TCR genes. Activation of *TCL1* in mature T cells causes T-cell leukemia/lymphoma in humans. The oncogenic nature of *TCL1* is confirmed in a transgenic mouse model. Functional analysis of *TCL1* revealed its involvement in PI3-kinase dependent Akt, PKB, prosurvival pathway through its interaction with Akt kinase, which increases Akt's enzymatic activity and promotes translocation of Akt to the nucleus.

ALK and t(2;5)(p23;q35) in ALCL ALCL is a subset of DLCL with characteristic immunophenotypic and genetic features. ALCL is a predominantly T-cell lymphoma accounting for approx 3% of adult NHL and 10–30% of childhood lymphomas. The majority of patients (70%) present with advanced stage disease (III or IV). This systemic form of ALCL frequently involves both lymph nodes and extranodal sites. Commonly involved extranodal sites include skin (21%), bone (17%), soft tissue (17%),

lung (11%), and liver (8%). Another form of this disease with fundamental genetic differences is the primary cutaneous ALCL in which the disease is limited to the skin. Both forms express CD30 antigen (also known as Ki-1 for Kiel-1) and the great majority express the epithelial membrane antigen and one or more T-cell antigens.

Approximately 90% of ALCLs show clonal rearrangement of TCR genes irrespective of whether they express T-cell antigens. The remainder shows no rearrangement of TCR or Ig genes (null ALCL). A pivotal step in the molecular pathogenesis of ALCL is the alteration of *ALK* on chromosome 2p23, which is a previously unidentified tyrosine kinase gene, hence named after this disease (anaplastic lymphoma kinase). The *ALK* gene encodes a tyrosine kinase receptor belonging to the insulin receptor super family, normally silent in lymphoid cells. The most frequent chromosomal translocation (seen in 70–80% of ALCLs) leading to *ALK* alteration is the t(2;5)(p23;q35) (*see* Table 82-2). This translocation links N-terminal sequences encoded by the ubiquitously expressed nucleophosmin (*NPM*) gene on chromosome 5q35 to the catalytic domain of *ALK*. The chimeric NPM-ALK fusion protein is responsible for activation of the *ALK* catalytic domain, i.e., autophosphorylation of the tyrosine kinase domain of *ALK* responsible for its oncogenic properties. The *NPM* phosphoprotein, which shuttles between the nucleolus and the cytoplasm, is highly phosphorylated during mitosis, binds to DNA and RNA and is thought to play a role in ribosomal assembly. The transforming potential of *NPM-ALK* has been demonstrated in NIH-3T3 cells and in mice reconstituted with bone marrow cells bearing the chimeric gene that developed large-cell lymphoma.



In addition to its role in understanding the molecular pathogenesis of the majority of ALCLs, the discovery of the *NPM-ALK* fusion gene has yielded definite clinical implications regarding accurate diagnosis and prognosis of this disease. With the availability of *ALK*-specific antibodies for immunodiagnostics, the broad morphological spectrum of ALCL is now apparent. The particular cytoplasmic, nuclear and nucleolar staining seen in t(2;5)-associated ALCLs can be explained by the formation of dimers between wild-type NPM and *NPM-ALK* fusion protein. Studies to examine the clinical outcome of ALCL have demonstrated a favorable prognosis of *ALK*-positive ALCL (approaching 80% 5-yr survival) compared with the *ALK*-negative subtype.

A number of variant translocations involving 2p23 are seen less frequently in ALCL (*see* Table 82-2), all of which lead to *ALK* activation. The t(1;2)(q25;p23) seen in 10–20% of cases involves the *TPM3* (tropomyosin protein) gene on chromosome 1q25. The chimeric TPM3/ALK protein leads to activation of *ALK* catalytic domain by inducing autophosphorylation of the *ALK* protein. Interestingly, *ALK* staining in this subset is restricted to the cytoplasm and cytoplasmic membrane of malignant cells. Other variant translocations seen commonly (2–5% of cases) include t(2;3)(p23;q35) leading to *ALK-TFG* (TRK-fused gene) fusion and the inv(2)(p23;q35), which involves the *ATIC* gene. The *ATIC* gene encodes the 5-amino-midazole-r-carboxamide-ribonucleotide transformylase-IMP cyclohydrolase, which plays a key role in the *de novo* purine biosynthesis pathways. Rare cases have t(2;17) involving breakpoints at 17q11-qter and 2p23, which juxtaposes the *ALK* to *CLTC* (clarithein heavy polypeptide). The *CLTC/ALK* mimics ligand binding, therefore allowing the autophosphorylation of the carboxy-terminal domain of the *ALK* protein. The molecular pathogenesis of *ALK*-negative ALCLs remains unknown. In contrast to the systemic ALCL in which the majority of cases are *ALK* positive, cutaneous ALCL are *ALK* negative. The *NPM-ALK* fusion transcripts have been reported in a few cases. However, such cases most likely represent systemic ALCL with cutaneous disease.

CLL/SMALL LYMPHOCYTIC LYMPHOMA

CLINICAL ASPECTS CLL is a neoplasm of monomorphic small, round lymphocytes of B-cell origin in 98% of the cases. It is the most frequent type of leukemia in the United States and Europe where the majority of patients are older than 50 yr; it has a male/female ratio of 2:1. CLL remains an incurable, chronic disease with a variable survival depending on clinical stage at presentation. Most patients are asymptomatic at diagnosis when the disease is discovered because of elevation of white blood cell and lymphocyte counts. Patients eventually develop symptoms of fatigue, lymphadenopathy, hepatosplenomegaly, autoimmune hemolytic anemia, and repeated infections. By definition, all cases of CLL have involvement of blood and bone marrow at time of diagnosis with lymphocyte count of more than 30% in bone marrow and more than 5000/μL in blood. SLL is the tissue counterpart of CLL in which the disease presents with enlargement of lymph nodes, liver, and spleen without significant involvement of blood and bone marrow. Biologically, however, CLL and SLL are one disease with the same cell morphology, phenotype, and natural history. CLL/SLL cells are monoclonal B cells that are positive for surface immunoglobulins (sIg) M or IgM and D, and have a characteristic phenotype that distinguishes this entity from other B-cell tumors by expressing CD5, CD19, CD 20(weak), and CD23 but not CCND1 and FMC7.

POSTULATED CELL OF ORIGIN CLL is thought to correspond to recirculating CD5+, CD23+, sIgM+, sIgD+ naïve B cells found in peripheral blood. However, important aspects of CLL biology have been elucidated in relation to its stage of differentiation and transforming events. It is now recognized that there are two variants of CLL arising at different stages of B-cell differentiation. The process of B-cell differentiation can be divided into three distinct stages: pregerminal, germinal, and postgerminal center phases. Selection and recombination of variable (V), diversity (D), and joining (J) genes are early events in the pregerminal phase. In the germinal center phase, cells undergo somatic hypermutation of the V(D)J-rearrangement, which can occur with or without antigen stimulation. Somatic mutations in the Ig variable genes (IgV) are present in approx 50% of CLL cases. Hence, it is now believed that two variants of CLL exist: a pregerminal variant originating from naïve B lymphocytes showing no IgV gene mutation and a postgerminal variant that originates from memory B cells exhibiting IgV gene somatic hypermutation. This discovery has led to recognition of clinical, phenotypic, and molecular genetic features that are predominantly associated with one or the other subset of this disease (Fig. 82-2). Correlation of the IgV gene mutational status with clinical data revealed that the presence of unmutated IgV is predictive for inferior prognosis. Expression of CD38 and ZAP 70 usually correlates with the presence of unmutated IgV genes and an unfavorable clinical outcome. These antigens can therefore be used as surrogate markers for mutational status of IgV and prognosis in CLL. Genetically, 13q14 deletion is seen less frequently in the IgV-unmutated variant than the mutated postgerminal variant. The reverse is true for deletions in 17p and 11q, which are detected almost exclusively in the IgV unmutated variant.

	Pre-germinal	Post-germinal
IgV gene mutation	-	+
Prognosis	worse	better
Prevelance among CLL	~50%	~50%
ZAP 70 expression	higher	lower
CD38 expression	+	-
13q14 deletion	less frequent	more frequent
17p,11q deletion	present	absent

Figure 82-2 Postulated cell of origin and comparative features of the two variants of CLL. Three stages of B-cell differentiation are recognized, pregerminal center, germinal center (surrounded by mantle zone) and postgerminal center. According to mutation status of Ig variable genes (IgV), CLL is subdivided into two variants: pregerminal without IgV mutations and postgerminal that has IgV mutations. This subtyping has immunophenotypic, genetic, and clinical-prognostic implications.

MOLECULAR GENETICS OF CLL Based on conventional chromosome banding analysis, genetic abnormalities are detected in 40–50% of CLL cases. This technique has been hampered in CLL by the low mitotic activity of the clonal B cells. In many cases only normal metaphase spreads are obtained resulting from mitotic activity originating from normal hematopoietic cells contained in the specimen. With conventional cytogenetic techniques, trisomy 12 was found to be the most common abnormality and is associated with poor prognosis. Other abnormalities associated with inferior survival were 11q and 17p deletions. In contrast, patients with structural aberrations of chromosome 13 (mostly 13q deletion) and those with normal karyotype seem to have a favorable outcome.

The development of fluorescence *in situ* hybridization (FISH) using DNA genomic probes has greatly enhanced the ability to detect chromosomal aberrations in CLL cells. The major advantage of this approach is its ability to detect abnormalities in both metaphase (dividing) and interphase (resting) cells. Using this approach, genomic abnormalities can now be detected in up to 80% of CLL cases. The most frequent aberration is 13q deletion followed by 11q deletion, 12q trisomy and 17p deletion. Research data using this technique indicate that genomic aberrations are important independent predictors of disease progression and survival. For example, patients with 17p or 11q deletion have more advanced disease stages and are more likely to have extensive lymphadenopathy, splenomegaly, and constitutional "B" symptoms.

Although genomic probing of CLL has led to a better understanding of the clinical heterogeneity of the disease, it has not yet led to understanding its molecular pathogenesis, although progress is being made. For example, observation that most frequent genetic aberration in this disease is loss of genetic material (chromosome deletions) points to involvement of a tumor suppressor mechanism. The most frequent area involved in genomic aberration (13q14.3) was investigated and 3 candidate genes have been isolated, *RFP2*, *BCMS*, and *BCMSUN*. The *RFP2* gene product is the homolog of the RET finger protein, RFP, which has a tripartite motif: a RING-zinc-finger domain (which mediates ubiquitination), a B-box domain, and a coiled-coil domain, which were found to repress gene expression through interaction with the enhancer of Polycomb E(Pc). The B-cell neoplasia-associated genes with multiple splicing (BCMS and BCMSUN) have multiple RNA splicing variants and belong to the group of noncoding RNAs. DNA sequence analysis has failed to detect mutations in any of these genes suggesting a different pathogenetic mechanism like haploinsufficiency.

CLINICAL APPLICATION OF MOLECULAR ALTERATIONS IN LYMPHOMA AND CLL

Most lymphoid malignancies have genetic alterations. The detection of recurrent nonrandom chromosomal translocations has permitted the identification and cloning of genes involved in the pathogenesis of lymphoma. These genetic alterations have provided important information for lymphoma diagnosis, classification, and treatment. Finding the clonal abnormality is useful in distinguishing malignant lymphoma from a benign lymphoid reaction. In addition, specific chromosomal abnormalities have defined distinct disease entities to add to the conventional classifications of lymphoma. For example, the discovery of t(2;5) translocation in

a subset of what was initially called malignant histiocytosis led to the recognition of a clinically distinctive category of T-cell lymphoma, known as ALCL.

The chromosomal alterations can be detected by conventional cytogenetics, Southern blot, PCR, and/or by FISH. FISH has revolutionized the field of genetics. Conventional cytogenetics requires fresh tumor tissues, and is limited in some cases by the inability of malignant cells to divide in culture, like in CLL and/or poor chromosome morphology. The diagnostic ability of FISH is increasingly used in clinical cytogenetics for the detection of chromosomal aberrations on metaphase and interphase cells and also can be performed on fresh or aged specimens, frozen or paraffin-embedded tissues. FISH is target-specific and has the ability to detect a cryptic rearrangement that would not be possible by classic banded chromosomes. For example, MCL has an aggressive clinical course and is refractory to standard chemotherapy; therefore, it is important to distinguish this disease from other B-cell neoplasms. Several studies have shown the superiority of FISH over PCR and conventional cytogenetic techniques in detecting t(11;14) /*IGH-CCND1* fusion, a genetic marker associated with MCL.

The genetic abnormalities can also be used as markers in staging and in detection of minimal residual disease. PCR to detect t(14;18)/*BCL2* rearrangement is being used to monitor patients undergoing bone marrow transplants for follicular lymphoma. In addition, the genetic abnormalities may affect the clinical outcome of disease and can identify high-risk patients. The presence of 13q- in CLL and multiple myeloma is an independent adverse prognostic factor. The t(11;18) in gastric lymphoma is associated with a low frequency of transformation to large-cell lymphoma but at the same time this translocation predicts failure of antibiotic therapy in eradicating this type of *H. pylori* infection-associated lymphoma. The t(2;5) in ALCL is associated with good prognosis. The use of microarray gene chip technology has also entered the clinical arena where biopsy of lymphoma tissue from patients can be screened for thousands of genes utilizing automated technology. Although still available only on a research basis, this technology allows for gene profiling of lymphoid malignancies and grouping of gene families according to function. By analyzing hundreds of cases and comparing results with normal lymphocytes, important data is emerging to enable grouping of lymphomas according to genetic profiles. The advantage of such technology lies in its large-scale screening ability and its automation. Finally, the future goal is to exploit knowledge of genetic defects clinically by designing new therapies targeting genetic mechanisms unique to each lymphoid disorder. Research efforts in this direction include the introduction of antisense oligonucleotides to bcl2 as therapeutic agents in clinical trials. Such strategy is aimed at downregulating bcl2, which can also be used to inhibit other oncogenes. There are also efforts to neutralize key gene products pharmacologically with small synthetic molecules that bind to key gene products and neutralize their function.

83 Multiple Myeloma

A Story of Genes and the Environment

KENNETH H. SHAIN AND WILLIAM S. DALTON

SUMMARY

Multiple myeloma (MM) is characterized by the clonal expansion of mature B cells within bone marrow. This malignancy is believed to arise from mutations involving nonrandom translocations between specific oncogenes and immunoglobulin coding regions of B cells. Further mutations parallel a relatively well-described progression from benign MGUS to MM and secondary plasma cell leukemia. Current literature suggests that in addition to genetic adaptations, specific effectors of the bone marrow microenvironment might contribute significantly to both MM pathogenesis as well as to treatment failure. Within this chapter we discuss the molecular and biochemical factors that contribute to malignant potential of MM.

Key Words: Adhesion; apoptosis; cell cycle; cyclin D; c-maf; FGFR; IL (interleukin)-6; MGUS (monoclonalgammopathy of unknown significance); myeloma; multidrug resistance; MMSET; microenvironment; oncogenes; Ras; STAT.

INTRODUCTION

Multiple myeloma (MM) is a hematopoietic malignancy characterized by the clonal expansion of mature B cells, a low proliferative index, clonal secretion of Ig, osteolytic bone destruction, and ultimate development of drug resistance. MM cells are thought to arise from postgerminal center (GC) plasma cells that have undergone immunoglobulin class switching and somatic hypermutation. Importantly, it is through these normal DNA recombinatorial processes of B-cell differentiation (Ig class switching and somatic hypermutation) that the initial transforming events in MM have been proposed to originate. Evidence for this hypothesis has been demonstrated through the identification of numerous immunoglobulin heavy chain (IgH) and light chain (IgL) translocations in MM and the premalignant monoclonal gammopathy of unknown significance (MGUS). Like their normal plasma cell counter parts, MM cells home to the bone marrow (BM) remaining closely associated with their physical extracellular environment. MM cells become BM independent only in the most terminal phases and only after the acquisition of secondary or tertiary transforming mutations. These later DNA alterations are frequently somatic mutations and secondary Ig-translocations leading to the constitutive activity of oncogenes. Further, the unique BM dissemination has been proposed to be integral in MM disease progression. The BM is rich in cytokines, growth factors, and other soluble factors, as well as in adhesive matrices including fibronectin (FN), hyaluronan and bone marrow stromal cells (BMSCs) that can support MM expansion. Therefore, the roles of both genetic and environmental effectors in MM pathogenesis are the focus of intense research. Research continues on the potential interplay between the genetically altered MM cell and its environment, leading to the identification of specific molecular and biochemical determinants that might serve as potential therapeutic targets. This chapter reviews some of the best-understood individual genetic and environmental aspects of MM. A working model is proposed of how these individual aspects form a potential network of pro-cancer effects promoting progression of this complex and terminal malignancy.

MM is a BM resident malignancy of plasma cells, diagnosed at a rate of approx 14,000 new cases per year, making it the second most prevalent hematopoietic malignancy, accounting for 15% of all hematopoietic cancers. This plasma cell dyscrasis occurs at higher rates in blacks than whites and is unbiased by gender. It is a disease primarily of older individuals with a median age of diagnosis of 68 yr for men and 70 yr for women, and is characterized by a number of clinical factors: focused skeletal destruction, hypercalcemia, clonal immunoglobulin production (M-component), urinary Bence-Jones protein, renal insufficiency, anemia, hypoγ-globulinemia, and recurrent infections. These clinical findings result from the unfettered expansion of a mutant Ig-secreting (99% of MM) plasma cell population within the BM. MM cells overgrow the BM compartment and in turn alter production of hematopoietic cells (anemia and hypoγ-globulinemia) leading to weakness and recurrent infection. Further, the primary presenting symptom of MM patients is bone pain as a result of localized osteolytic destruction in load-bearing structures such as the femur, pelvis, or vertebrae. Osteolytic lesions result from alterations in cytokine/chemokine signaling in the BM; as a result the osteoblast/osteoclast ratio is reduced favoring bone destruction. The subsequent osteoporosis manifests in bone weakness and pain, and clinically in hypercalcemia, a major factor in renal insufficiency. A number of the clinical signs can be successfully treated. Unfortunately, the most unavoidable characteristic of MM is its finality. Despite tremendous effort by clinicians and researchers, MM patient therapy is plagued by the ultimate development of

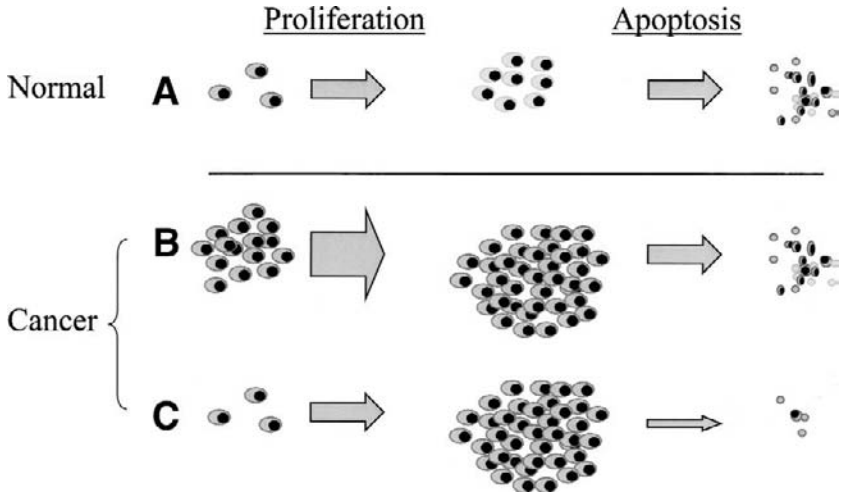

Figure 83-1 Cancer results from the imbalance in cellular fate. Tissue homeostasis is maintained through a balance between the number of cells produced and the number of cells eliminated. Under normal conditions the number of proliferating cells is equal to the number of cells undergoing apoptosis **(A)**. To this end, the total population of cells does not increase. In contrast, in cancer tissue, homeostasis is subverted resulting in the uncontrolled expansion of a population of cells. This expansion occurs as a result of a dysregulation of the processes governing progression through the cell cycle **(B)** or of the processes promoting cell death **(C)**. In scenarios **B** and **C**, the net effect of increasing the number of dividing cells or decreasing the number of dying cells is an increase in the overall population.

progressive disease, making MM one of the most challenging cancers to treat. The resiliency of MM to therapy has fostered a great deal of research into delineating the mechanisms by which MM cells evade and eventually become resistant to multiple regimens of chemotherapy. Improvements in the treatment of myeloma largely have been based on data collected from research investigating of the molecular and cellular determinants of MM, with new novel therapies under clinical investigation. MM disease progression and the phenomenon of multidrug resistance (MDR) have both genetic and environmental components.

As a cancer, MM adheres to a basic principle: MM cells have escaped the normal restraints governing proliferation and death. In the typical "life" of a normal cell, it proliferates, differentiates for a given task, and then is eliminated through a process termed apoptosis or programmed cell death (PCD). Under normal conditions the number of cells dividing equals the number of cells dying thereby maintaining tissue homeostasis. To this end, the expansion of a malignant population of cells results from the deregulation in progression through the cell cycle (uncontrolled proliferation) or in the mechanisms that promote cell death (decreased number of cells being eliminated) (Fig. 83-1). Cancers require alterations in both of these homeostatic controls. MM is no exception; its progression requires (1) the acquisition/utilization of mechanisms that drive MM cells through the cell cycle arrest afforded terminally differentiated B cells during normal maturation and (2) the acquisition/utilization of mechanisms that protect MM cells from both physiological and therapeutic effectors of PCD. In MM it has been proposed that these initial requirements are fulfilled by the translocation of a gene(s) that normally functions as determinants of cell proliferation or cell survival to regions juxtaposed to active Ig-enhancer elements, thereby facilitating the superfluous expression and subsequent function of that gene product (*an oncogene*). These translocations most frequently involve IgH (14q32) and to a lesser extent IgL (22q11 [λ], 2p11 [λ]) enhancer elements and a limited number of oncogenes including cyclin D_1 (11q13), cyclin D_3 (6q21), FGFR3/MMSET (4p16.3), c-maf (16q23), and others. IgH translocations connected with these oncogenes account for approx 75% of MM disease. Additional mutations are acquired throughout the course of the disease including chromosome 13 deletion, activating somatic mutations, and secondary Ig-translocations demonstrating a step-wise model for MM pathogenesis (Fig. 83-2). Importantly, although MM is a genetic disease by definition, it is apparent that both DNA mutations and the BM microenvironment contribute to the deregulation of life and death of MM cells. The MM BM microenvironment provides a myriad of soluble and physical growth and survival factors. Soluble factors such as interleukin (IL)-6, IL-10, granulocyte-macrophage colony stimulating factor, insulin-like growth factor (IGF)-1, vascular endothelial growth factor, fibroblast growth factor (FGF), and macrophage inflammatory protein-1α, are associated with MM expansion. Interactions between MM cells and specific extracellular matrix components and BMSCs have been demonstrated to protect cells from both physiological and chemotherapeutic mediators of apoptosis. Taken together, these data suggest that the MM microenvironment plays a significant role in the disease pathogenesis by providing a "sanctuary" for BM resident MM cells. Therefore, delineation of the specific molecular pathways utilized by the environmental effectors might provide an avenue to better attack the advance of MM. This chapter discusses the understanding of how genetic and environmental determinants influence MM progression through their influence on rates of cell proliferation and cell turnover.

CELL CYCLE PROGRESSION AND APOPTOSIS

Cancer is a disease that requires the inappropriate cell replication and sensitivity to apoptosis. Each process has specific constituents governing the transmission of signals within the cell. To better understand the mechanisms utilized by MM cells to overcome replication and PCD, a brief introduction to some of the molecular determinants of theses processes is presented. These determinants can be divided into two general categories: those that drive cell cycle progression or apoptosis-"the gas pedals" so to speak and those that stop cell cycle progression or apoptosis-"the

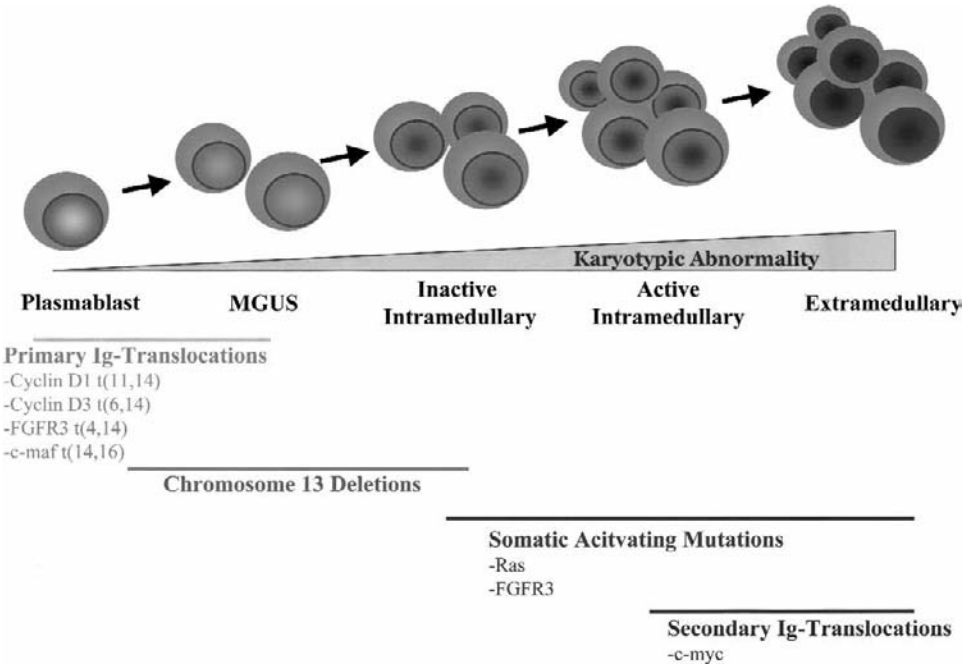

Figure 83-2 A multi-step progression of multiple myeloma (MM). MM can be staged from the pre-malignant MGUS, to smoldering/indolent MM, to an inactive intramedullary then active intramedullary stage, and finally to extramedullary disease (secondary plasma cell leukemia). Importantly, progression through this model parallels an accumulation of karyotypic abnormalities. Identification of a number of these karyotypic alterations has revealed a multi-step pathogenesis of MM. Examination of patient DNA has demonstrated a progression from primary Ig-translocations (cyclin D1 t[11q13], cyclin D3 [6p21], FGFR3 [4p16.3], and c-maf [16q23]), chromosome 13 deletions, activating somatic mutations (Ras and FGFR mutations), and secondary Ig-translocations or insertions (c-myc). Importantly, these are the most prevalent mutations observed. It is not proposed that these are the only causative DNA alterations associated with MM progression. FGFR, fibroblast growth factor receptor; MGUS, monoclonal gammopathy of unknown significance.

brakes." In the context of cell regulatory factors the "gas pedals" are termed oncogenes because they promote oncogenesis. In contrast, the "brakes" are denoted tumor suppressors as they oppose the actions cellular proliferation and survival thereby suppressing oncogenesis. To this end, overexpression (increased activity) of oncogenes and deletion (decreased activity) of tumor suppressors are requirements of cancer progression. For regulators of PCD the nomenclature would be reversed.

CELL CYCLE (G_1) Cellular replication entails succession through the four phases of the cell cycle, G_1, synthesis (S), Gap2 (G_2), and mitosis (M) and in some cases progression from a quiescent or nonproliferative state (termed G_0). Entry into and exit from the phases of the cell cycle involves a network of transient and sequential biochemical events modulating progression through two-phase transitions ($G_{1/0}$-S and G_2-M). Under normal conditions this process is stimulated by extracellular stimuli, frequently extracellular mitogens (cytokines and growth factors) that bind and activate transmembrane receptors. Ligand binding facilitates activation of signaling cascades that promote the expression of transiently expressed proteins termed cyclins. Interactions between cyclins and their constitutively expressed cyclin-dependent kinase (CDK) partners mediate progression through the cell cycle. Progression from G_1 to S requires expression of one or more of the D-type cyclins (cyclin D1, D2, D3), cyclin binding to the appropriate CDK (CDK4 or CDK6), and subsequent kinase activity mediated by the formation of cyclin D/CDK4/6 heterodimers (Fig. 83-3). Cyclin D/CDK heterodimers phosphorylate the tumor suppressor retinoblastoma protein (Rb). Rb is a molecular guardian blocking progression through the cell cycle. In its hypophosphorylated state, Rb inhibits

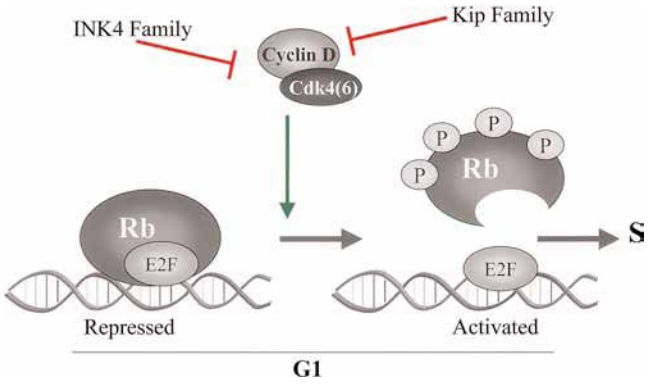

Figure 83-3 Cyclin D/cyclin-dependent kinase-4(6) regulation of G1-S progression. Progression from G_1 to S requires expression of the D-type cyclins (cyclin D1, D2, or D3). The transiently expressed cyclins bind to specific cyclin-dependent kinase inhibitors (CDKs [CDK4 or CDK6]), and subsequent kinase activity is mediated by the formation of cyclin D/CDK4/6 heterodimers. Cyclin D/CDK phosphorylates the retinoblastoma protein (Rb). Hypophosphorylated Rb inhibits cell cycle progression by repressing transcription of genes necessary for subsequent phases by sequestering E2F transcription factors. Phosphorylated Rb releases E2F facilitating transcription of genes required for DNA synthesis and succession through G_2 and mitosis.

cell cycle progression by repressing transcription of genes necessary for subsequent phases by sequestering E2F transcription factors. On phosphorylation by cyclin D/CDK4(6), Rb releases E2F facilitating transcription of genes required for DNA synthesis and succession through G_2 and mitosis, including thymidine kinase,

dihydrofolate reductase, c-Myc, c-Myb, c-Fos, cyclin A, and the G_2/M transition gate keepers, cyclin B and $p34^{cdc2}$ (cdc2). Therefore, expression of D-type cyclins is an initiating event in cell division, as such overexpression of one of the D-type cyclins would increase the proliferative potential of a cell.

CYCLIN-DEPENDENT KINASE INHIBITORS Just as cyclins and CDKs drive cell cycle progression, the cell governs transit through the cycle. As mentioned, Rb attenuates cell cycle progression as a transcriptional repressor. Cell cycle progression is also regulated by CDK-inhibitors (CKIs), a super family of proteins including the INK family ($p15^{INK4B}$ [CDKN2B], $p16^{INK4A}$ [CDKN2A], $p18^{INK4C}$ [CDKN2C], and $p19^{INK}$ [CDKN2D]), the Kip family ($p27^{Kip1}$ and $p57^{Kip2}$), and $p21^{waf}$. CKIs attenuate cell cycle progression by inhibiting the interactions between cyclins and CDKs. Hence CKIs block cell cycle progression, acting as brakes to allow for "checks" on energy supplies, metabolites, and DNA integrity before copying DNA. Because of their function in arresting cellular proliferation, CKIs are tumor suppressor genes. Oncogenesis often correlates with decreased expression of CKIs promoting uncontrolled progression through the cell cycle. Tumor suppressor dysfunction frequently involves homozygous deletion or loss of heterozygocity of the gene. Interestingly, $p15^{INK4B}$, $p16^{INK4A}$, and 18^{INK4C} deletions are rarely observed in MM. However, the expression of the INK-family is silenced in up to 75% of MM and MM cell lines. The decreased expression of these factors results from hypermethylation of their promoters. Promoter methylation alters the chromatin structure surrounding the promoter selectively inhibiting access to the DNA. A study examining MGUS patient samples demonstrated $p16^{INK4A}$ methylation in 19%, $p15^{INK4B}$ methylation in 36%, and both promoters were methylated in 6.5% of patients examined, suggesting that loss of this family of tumor suppressors might be important in early progression of MM.

APOPTOTIC SIGNALING Uncontrolled proliferation is only one regulatory system dysregulated in cancer (MM). MM expansion also depends on alterations in the mechanisms executing PCD. Dysregulation of apoptotic signaling affords MM cells' resistance to antitumor immune responses mediated by cytotoxic lymphocytes and to chemotherapeutic drugs. Physiological and chemotherapeutic mediators of apoptosis share a well-characterized sequence of biochemical events culminating in cell destruction. Under physiological conditions the antitumor immune response mediated by cytotoxic T cells and natural killer cells can implement apoptosis through the crosslinking of death receptors with transmembrane death ligands or soluble versions of death ligands. Death receptors constitute the tumor necrosis factor receptor/nerve growth factor receptor family including tumor necrosis factor receptor 1, tumor necrosis factor receptor 2, CD95/Fas/Apo-1, death receptor (DR) 4 (TRAIL-R1), and DR5 (TRAIL-R2). Crosslinking of death receptors by their cognate ligands (TNF-α, CD95L/FasL/Apo1L, or TRAIL/Apo2L, respectively) induces aggregation of specific molecular determinates and initiation of a proteolytic cascade of events involving a family of cysteine-aspartate specific proteases or caspases (Fig. 83-4). Ligation of death receptors induces receptor multimerization and recruitment of the adapter protein Fas-associated death domain containing protein (FADD) and procaspase-8, the initial proteolytic enzyme in the apoptotic cascade. DR localization of procaspase-8 mediates a proximity-induced cleavage of procaspase-8 and initiation of a zymogen cascade. Activation of procaspase-8 propagates cell death through proteolytic cleavage of downstream effector caspases, most notably procaspase-3. Activation of procaspase-3 by caspase-8 can occur directly (type I) or indirectly (type II) through a mitochondrial-dependent mechanism depending on the cell type and the DR stimulated. Mitochondria are important components of the apoptotic cascade as they are targeted by cytotoxic agents used in the clinic. Indeed, mitochondria are the major point of convergence between DR and chemotherapeutic drug-mediated apoptosis. Additionally, studies have demonstrated that therapeutic agents can also stimulate DR and death ligand expression facilitating DR crosslinking. Targeting of the mitochondria by either DRs or therapeutic drugs primarily entails cleavage and/or activation of proapoptotic members of the Bcl-2 family. Caspase-8 targets Bim; drugs have been demonstrated to activate Bax, Bak, Bim, and other small death-inducing Bcl-2 family proteins. Doxorubicin stimulates conformational changes of Bak and Bax facilitating mitochondrial targeting. These proteins induce mitochondrial permeability transition, mediating release of cytochrome-*c* and other proapoptotic effectors from mitochondria. Cytosolic cytochrome-*c* precipitates the formation of a large (approx 700 kDa) complex containing multiple apoptotic protease activating factor-1 and caspase-9 molecules, termed the apoptosome. Apoptosome aggregation results in a dATP-dependent cleavage and activation of caspase-9, which in turn targets effector caspases, procaspases-7 and -3. Active caspase-3 (-7) targets cytosolic, cytoskeletal, and nuclear factors facilitating cell death.

ANTI-APOPTOTIC EFFECTORS Uncontrolled activation of the earlier-mentioned apoptotic cascade would rapidly destroy a cell. Therefore, this cell death pathway must be tightly regulated to protect from spontaneous activation. To this end, the apoptotic effectors ("gas pedals") that drive this cascade are modulated by numerous proteins ("brakes") acting at specific stages of the cell death cascade to regulate the inappropriate activation of PCD. Regulation apoptosis can be divided into two categories; those that are specific to DR-mediated apoptosis (death-induced signaling complex formation and caspase-8 activation) and those that are common to both DR and chemotherapeutic drug-mediated PCD (mitochondrial and postmitochondrial events) phases of the cell death cascade.

Regulation of CD95-Mediated Apoptotic Signaling DR-induced PCD can be regulated at several levels (Fig. 83-5). Ligand crosslinking is inhibited by soluble CD95, soluble CD95L, as well as CD95-specific decoy receptor-3s (DcR-3). Regulation of DR expression also correlates with cellular sensitivity to ligand crosslinking. In MM, heterologous CD95 expression within a given MM cell population affords low CD95 expressing cells a survival advantage to DR ligation as compared to higher expressing cells. Further, specific mutations in the death domain of CD95 have been identified in MM patient samples that might negatively affect receptor signaling. Other potential mechanisms to CD95 resistance have also been identified in other model systems. Posttranslational modification of CD95 by the ubiquitin-like protein Sentrin/SUMO has been suggested to repress apoptotic signaling from CD95 by blocking recruitment and activation of apoptotic effectors. c-FLIP (c-FLICE-like inhibitory protein), an anti-apoptotic protein that shares significant similarity with procaspases -8 and -10, is proposed to inhibit CD95-mediated apoptosis by competing with procaspase-8 for FADD, thereby preventing or reducing the participation of procaspase-8 in the death-induced signaling complex and blocking activation of the proteolytic cascade. Expression of c-FLIP also directly contributes to expansion of hematopoietic tumors in vivo by protecting cells from CD95-mediated antitumor

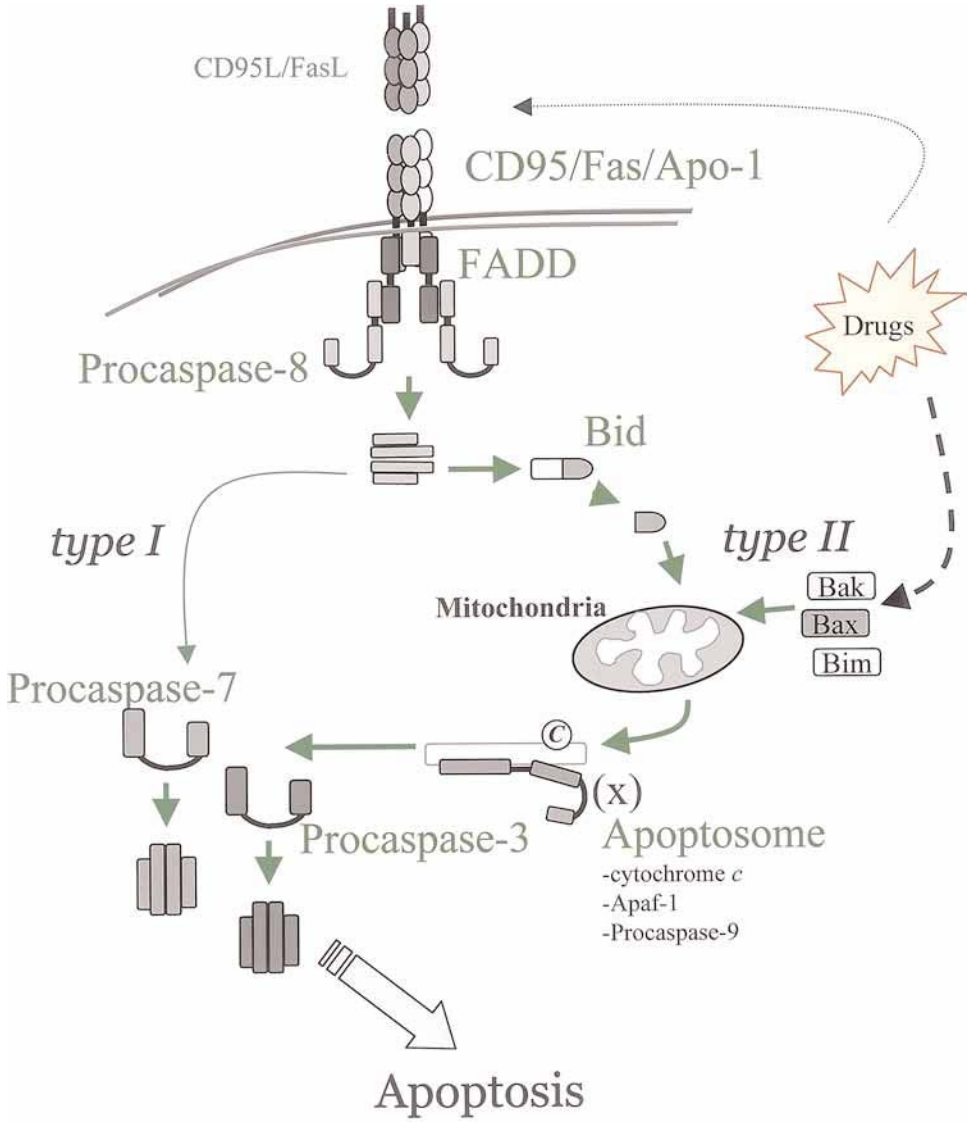

Figure 83-4 Apoptosis (extrinsic and intrinsic pathways). Cell death mediated by death ligands (extrinsic pathway of apoptosis) proceeds following ligand binding to specific death receptors. Receptor binding facilitates death-induced signaling complex formation initiating caspase-8 cleavage. Active caspase-8 propagates the cell death cascade by activating the downstream effector caspase-3, either directly or indirectly through mitochondria. Mitochondrial induced apoptosis (intrinsic pathway) represents a shared portion apoptotic pathway between death receptors and chemotherapeutic agents. Prevailing dogma indicates that most drugs activate the intrinsic pathway of programmed cell death by "directly" targeting the mitochondria facilitating the release of cytochrome-*c*, apoptosome formation, catalytic activation of procaspases-3 and -7, and subsequent cellular destruction. Other apoptotic-signaling components might also play a role in drug-mediated apoptosis. Apoptotic signaling from the CD95/Fas/Apo-1 death receptor has been demonstrated to mediate the cytotoxicity of certain drugs.

immune responses, demonstrating a direct correlation between cellular sensitivity to DR-mediated apoptosis and tumorigenesis.

Mitochondrial and Postmitochondrial Regulation Regulatory factors that act downstream of the death-induced signaling complex might also contribute to resistance to CD95- and chemotherapeutic-mediated apoptosis (*see* Fig. 83-5). As discussed, mitochondria are one of the pivotal components of the apoptotic cascade. A growing number of reports suggest that regulation of mitochondrial events might be of the utmost importance in dictating cellular fate in response to both DR and drug-induced apoptosis. The Bcl-2 family of proteins regulates mitochondrial membrane integrity. This family of proteins contains proteins that both promote (Bax, Bak, Bik, Bid, and Bad-apoptotic family members) and inhibit (Bcl-2, Bcl-X_L, Mcl-1, and A1/bfl-1-anti-apoptotic family members) mitochondrial membrane permeability transition and apoptosis. Mitochondrial function and mitochondrial cytochrome-*c* are maintained by a balance between or equilibrium between proapoptotic and antiapoptotic Bcl-2 family members. In response to apoptotic stimuli such as DR ligation or chemotherapeutic agents, cytosolic proapoptotic Bcl-2 family members target the mitochondria pushing the balance in favor of cell death thereby mediating mitochondrial membrane permeability transition and the release of apoptotic effectors including cytochrome-*c*. As such, an imbalance in this equilibrium would either stimulate cell death (increased proapoptotic activity) or conversely inappropriate cell survival through increased expression of antiapoptotic family members. Therefore, cellular fate is dependent on the expression and/or activity of the Bcl-2 family.

Postmitochondrially, the inhibitors of apoptosis (IAP) family of proteins has been demonstrated to block the activity of the caspases-9, -3, and -7. The IAP are considered a subset of antiapoptotic members within the BIR-containing protein family, a

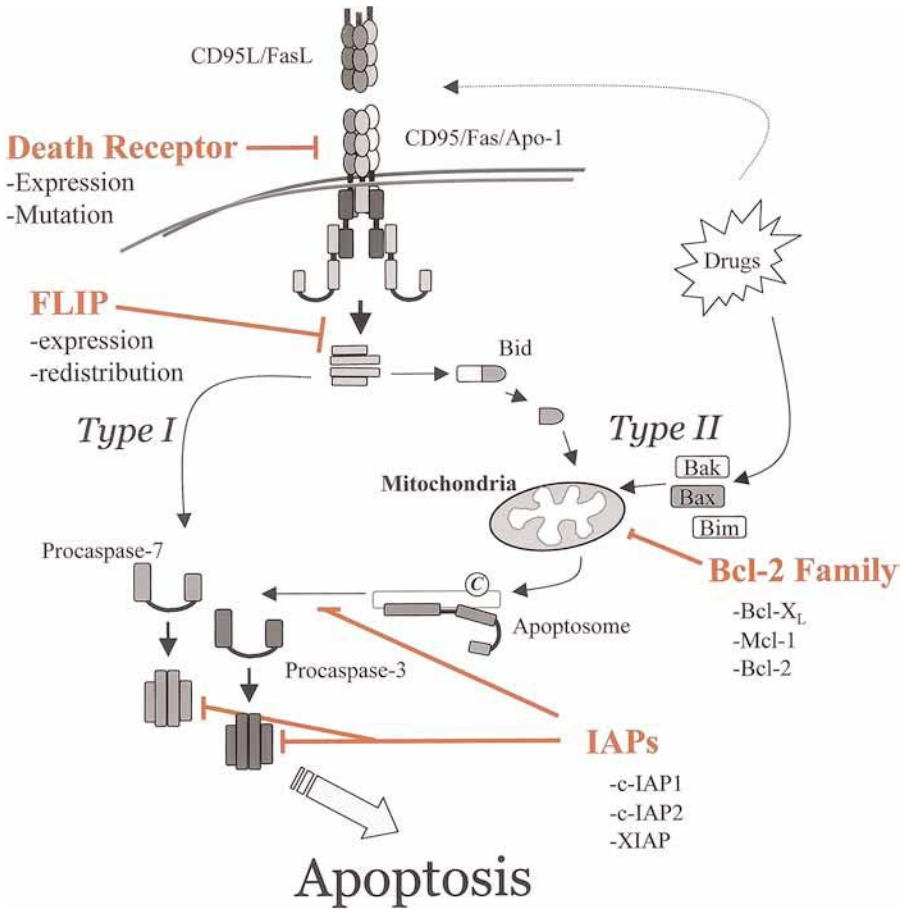

Figure 83-5 Regulators of the apoptotic cascade. Cellular control of CD95 and chemotherapeutic drug-mediated apoptosis has been demonstrated at both the initiation of the extrinsic cascade (DISC formation and caspase-8 activation), initiation of the intrinsic cascade (mitochondrial events), and in the execution phases (postmitochondrial) of the apoptotic cascade.

group of polypeptides characterized by the existence of one or more baculovirus inhibitor of apoptosis repeat domains. Baculovirus inhibitor of apoptosis repeat domains are protein–protein interaction domains important for at least some of the anti-apoptotic properties of IAP. A second important molecular structure of IAP is the carboxy-terminal RING domain. The RING domain promotes polyubiquitination of associated substrates; a covalent marker for 26S proteosome targeting and proteolytic degradation. IAP (XIAP, c-IAP1, and c-IAP2) are a unique group of antiapoptotic effectors in that they have multiple mechanisms through which they attenuate apoptosis dependent on the target molecule. The baculovirus inhibitor of apoptosis repeat 3 domain of XIAP associates with the small subunit of caspase-9 (exposed after proteolytic processing of caspase-9 in the apoptosome) and inhibits caspase-9 activity. Further, a sequence adjacent to the baculovirus inhibitor of apoptosis repeat 2 domain of XIAP (and c-IAP1 and c-IAP2) interacts with the substrate binding site of caspases-3 and -7 thereby inhibiting their apoptotic activity. Additionally, the RING domain of these antiapoptotic determinants also mediates poly-ubiquitinization of caspases-3 and -7 facilitating their degradation (inactivation). From this body of information it is apparent that IAP influence cellular sensitivity to apoptosis through multiple avenues (note: IAP have other antiapopototic, proapoptotic, and apoptosis-independent functions not discussed here). Apoptotic regulatory factors, including those affecting initiating events of both the extrinsic (FLIP) and intrinsic apoptotic cascades (Bcl-2, Bcl-X_L, and Mcl-1), as well as the execution phase of apoptosis (IAP), provide important checkpoints for cellular commitment to death. Whether through genetic alterations in genes or through communication with the tumor microenvironment, tumor progression (immune evasion and drug resistance) frequently involves the deregulation of these endogenous checks on PCD.

GENETIC CONTRIBUTION

MM is a cancer of plasma cells initiated by genetic "mistakes." These mistakes, in turn, disconnect the homeostatic controls governing cell growth and death. MM, as well as other B-cell neoplasms, has been proposed to occur as a result of mutations incurred during the normal processes of B-cell differentiation. Maturation of a B cell from a naive B cell to a long-lived memory B cell involves three independent DNA recombination events: VDJ recombination, GC-associated somatic hypermutation, and GC-associated isotype switch recombination resulting in the expression of an immunoglobulin with unique antigen-binding specificity (i.e., VDJ recombination and somatic hypermutation, and antibody activity [isotype class switching]). Analysis of MM chromosomal structure demonstrates that the primary mutations occur through reciprocal nonrandom IgH-translocations (and to a lesser extent IgL) with oncogenes at DNA breakpoints that correspond to sequences of DNA specific for somatic hypermutation (JH-regions) and switch recombination (switch regions). These data suggest that MM originates from B cells that have entered GCs having

undergone VDJ recombination and that the transforming mutations result from mistakes incurred primarily during somatic hypermutation and somewhat less frequently during switch recombination. Interestingly, the oncogenes involved in these Ig-translocations predominantly involve proteins that drive proliferation (cyclin D1, cyclin D3, c-maf, and FGFR3/MMSET), suggesting that escape from the quiescence of normal long lived memory B cells is an important early event in MM pathogenesis.

MM staging has been based on a number classification systems: Durie and Salmon, Kyle and Greipp, and British Columbia Cancer Agency, and on criteria set by the International Myeloma Group based primarily on degree of plasmacytosis, concentration of Ig (M-protein), the presence or absence of bone lesions, and end organ tissue impairment. From these criteria MM can be staged from the premalignant MGUS, to smoldering/indolent MM, to an inactive intramedullary then active intramedullary stage, and finally to extramedullary disease (secondary plasma cell leukemia). Importantly, progression through this model parallels an accumulation of karyotypic abnormalities (*see* Fig. 83-2). Furthermore, acquisition of specific genetic alterations is associated with the multi-step pathogenesis of MM involving primary Ig-translocations, chromosome 13 deletions, activating somatic mutations, and secondary Ig-translocations or insertions. Therefore, clinical staging of MM correlates with biochemical and molecular changes within the MM cell population that afford cells a more malignant phenotype (progression to the next stage of disease).

MONOCLONAL GAMMOPATHY OF UNKNOWN SIGNIFICANCE

MGUS represents the putative premalignant precursor to MM. MGUS progresses to frank MM at a rate of approx 1%/yr and nearly one-third of patients with MGUS progress to MM, although not all MM has a premalignant history. Therefore, MGUS might not be a prerequisite for MM. However, examination of MGUS provides novel insight into the genetic requirements of plasma cell transformation and the early requirements for MM. Karyotyping of MGUS patient specimens demonstrated the existence of primary Ig-translocations involving specific oncogenes. These reciprocal Ig-translocations put the expression of oncogenes under constitutively active IgH or IgL enhancer elements, thereby ensuring the overexpression of the participating oncogene. Karyotypic analysis demonstrated IgH translocations with cyclin D1 t(11q13) in 20% of MM tumors, cyclin D3 (6p21) in 5%, FGFR3 (4p16.3) in 15%, and c-maf (16q23) in 13% of MM tumors. Ig-translocations are absent in 25% of tumors indicating that unidentified genetic alterations can participate in transformation of plasma cells (or limitations in genetic analysis of MM cells). The remaining MM tumor translocation associated gene loci are with MUM1/IRF-4 (6p25), IRTA1 and IRTA2 (1q21-24), mafB (20q12), and others; however, the significance of these translocations is not well understood. The major oncogenes (cyclin D1, cyclin D3, FGFR3, and c-maf) accounting for 75% of observed Ig-translocations are all molecules with roles in controlling cell proliferation. As discussed, expression of D-type cyclins is an initial event marking entry into and progression through the cell cycle. To this end, overexpression of cyclins D1 or D3 would overcome endogenous regulatory mechanisms and drive inappropriate cell division. FGFR3, one of four bFGF (basic FGF) binding cell surface tyrosine kinase receptors, is not usually expressed of MM cells. FGFR3 signaling through signal transducer and activators of transcription (Stat) and the Ras/Raf/ERK1/2 pathways support growth of both human fibroblasts and hematopoietic cells. Constitutive FGFR3 signaling substitutes for IL-6, a major MM growth and apoptotic factor, in MM cell lines. Importantly, in MM cells with translocations involving FGFR3 (4p16), levels of cyclin D2 are elevated, demonstrating a link between initial Ig-translocations and cell cycle progression. The role of MMSET has not been clearly defined, however, evidence has demonstrated MMSET gene translocations independent of FGFR3, suggesting MMSET translocation is important in the transforming potential of t(4,14) translocations. c-Maf is a transcription factor that associates with jun and fos, components of AP-1, an important mitogenic transcription factor. c-Maf is the cellular homolog to the transforming avian maf retrovirus product, v-maf. Similarly to FGFR3/MMSET/Ig-translocations, elevated levels of cyclin D2 are observed in MM cells with c-maf/Ig-translocations. Examination of t(11,14), t(6,14), t(4,14), and t(14,16) Ig-translocations demonstrates that these primary transforming events directly or indirectly regulate progression through the cell cycle through the inappropriate regulation of D-type cyclin expression. Of note, this does not exclude FGF3R/MMSET and c-maf translocations from other potential transforming actions.

INTRAMEDULLARY MM

Intramedullary MM represents the next step in MM pathogenesis with identifiable genetic alterations (increase in karyotypic abnormality). Intramedullary MM is divided into two stages, an inactive and active phase defined by their proliferating cell-labeling index. Genetic analysis of metaphase MM cells of inactive intramedullary MM initially demonstrated increased rates of chromosome 13 deletions as compared to MGUS. However, a report examining 72 MGUS and smoldering MM patients with metaphase fluorescent *in situ* hybridization analysis showed that approx 50% had chromsome 13 deletion numbers equivalent to those observed in MM. These data suggest that although chromosome deletions might be subsequent to Ig-translocations, they might occur earlier than previously proposed. Although the specific requirements of chromosome 13 deletion are not completely elucidated, the tumor suppressor Rb locus is located on chromosome 13. Further, examination of MM patients demonstrated that Rb (13q14) deletion correlated with a more severe prognosis when coupled with cyclin D1 amplification.

Progression from inactive to active intramedullary MM is associated with the accumulation of somatic mutations (often point mutations) most frequently resulting in the constitutive activation of the GTPase Ras (N-Ras, K-Ras) and less frequently FGFR3. Interestingly, examination of human MM cell lines demonstrated that mutations in either Ras or FGFR3, but not both, are present, suggesting that they serve overlapping functions. In one study, Ras mutations (N12-Ras and K61-Ras) were observed in 54.5% of MM at diagnosis. This was compared to only 12.5% of MGUS and smoldering MM examined. Further, examination following relapse demonstrated 81% of MM with Ras mutations. FGFR3 Ig-translocations represent one of the primary genetic events in MM pathogenesis (plasma cell to MGUS); somatic mutations later in MM might lead to ligand independence and constitutive signaling from this oncogenic receptor. Two of three identified FGFR3 mutations were demonstrated to confer constitutive kinase activation in MM cell lines when overexpressed and all three mutations were capable of supporting fibroblast growth in colony-forming assays. Because of the proliferative activity of Ras and FGFR3 mutations, acquisition of these genetic changes

has been proposed to afford the increased proliferation of active intramedullary MM cells.

EXTRAMEDULLARY MM

Extramedullary growth has primarily been associated with secondary Ig-translocations. Unlike primary translocation these DNA malformations are infrequently reciprocal and are often complex involving multiple chromosomes. Therefore, these translocations are unlikely to manifest from the DNA recombinatorial events that mediate primary Ig-translocations. Secondary translocation of the oncogene *c-myc* (8q24.1) is most commonly observed and therefore has served as a paradigm for progression from intramedullary disease to extramedullary disease (secondary plasma cell leukemia), and on to human myeloma cell lines. c-Myc is not expressed in normal memory B cells, however, genetic alterations in *c-myc* are found in as many as 45% of advanced MM and in 86% of human myeloma cell lines. Importantly, the observation of *c-myc* translocation late in MM pathogenesis and the coordinate BM independent growth suggest that the constitutive expression of *c-myc* might provide the necessary growth and survival stimuli previously supplied by the BM microenvironment.

BONE MARROW MICROENVIRONMENT

Cancer requires alterations in the homeostatic mechanism controlling cell growth and cell death. The previous section discussed elegant work elucidating the genetic aspects of MM pathogenesis. The oncogenes associated with the proposed initiating events of MM are primarily involved in regulation of cellular proliferation (cyclin D1, cyclin D3, FGFR3, and c-maf). However, MM is a disease associated with a decreased propensity for cell death. Taken together these observations indicate that nongenetic (environmental) factors within the BM might influence the response of MM cells to apoptotic stimuli. Additionally, MM cells only escape the confines of the BM in terminal stages associated with highly proliferative c-myc mutations. This pattern of growth suggests that factors within the BM might also contribute significantly to MM disease pathogenesis through progrowth effects. This section reviews some of the major soluble factors and adhesive matrices that promote proliferation and prevent PCD.

SOLUBLE FACTORS IN MM The BM microenvironment of MM supplies a myriad of soluble factors that contribute to MM proliferation and survival. IL-6, a B-cell differentiation factor, is the primary growth and survival factor in MM. Other soluble factors including IGF-1, bFGF, granulocyte-macrophage colony stimulating factor and hepatocyte growth factor fulfill a similar role in MM growth and survival. The prominent role of IL-6 in MM disease has increased interest in the delineation of the signal cascades elicited following IL-6 receptor crosslinking. Signaling by IL-6 signaling requires the formation of a protein complex consisting of two IL-6, two IL-6R alpha (IL-6Rα/gp80) and two gp130 molecules (IL-6β) (Fig. 83-6). Intracellular signaling by IL-6 is mediated entirely through the gp130-subunit. Gp130 is a transmembrane signaling subunit required for signaling by IL-6R family members (leukemia inhibitory factor, ciliary neurotrophic factor, Oncostatin M, IL-11, and cardiotrophin-1). Gp80 and gp130 interactions stimulate phosphorylation of specific gp130 tyrosine residues by members of the Janus tyrosine kinase (Jak) family of nonreceptor tyrosine kinases (Jak1, Jak2, and Tyk2) that are constitutively associated with gp130. Phosphorylated tyrosine residues of gp130 function as docking sites for a number of cytosolic proteins, including Stat proteins, SHC (adaptor protein), phosphoinositide 3-kinase (PI3K), and src-homology domain 2-containing protein tyrosine phosphatase 2. Biochemical signaling events initiated by these gp130-associated proteins can independently regulate cell survival and proliferation. Recruitment of SHP2 to gp130 has also been implicated in the activation of both the Ras/MAPK and PI3K/Akt (protein kinase B) signaling cascades. However, both might also occur independently of SHP2. Therefore, IL-6 mediated gp130 signaling primarily activates three cascades, each established growth and survival signaling pathways (Jak/Stat3, PI3K/Akt, and Ras/MAPK [ERK1/2]).

Signal Transducer and Activators of Transcription Stats are family of src-homology domain 2-containing cytoplasmic proteins activated through phosphorylation of specific tyrosine residues by receptor associated tyrosine kinases (Jaks), growth factor tyrosine kinases (epidermal growth factor receptor, platelet-derived growth factor receptor), or nonreceptor tyrosine kinases (Src and Abl). The Stat family consists of seven members characterized by four highly homologous domains, a cooperative domain, a central DNA-binding domain, a dimerization domain (src-homology domain 2 domain containing region), and a transactivation domain. Stat phosphorylation induces homo- or heterodimerization (IL-6 signaling primarily involves Stat3 and to a lesser extent Stat1), nuclear translocation, DNA binding, and expression of genes involved in cell proliferation, survival, differentiation, development, and specific components of the immune response. The ability of Stats to promote neoplastic growth involves the expression of factors that control both cell survival and proliferation. Stat activity correlates with resistance to apoptosis mediated by CD95 ligation, interferon-γ, ultraviolet irradiation, as well as chemotherapeutic drugs. The primary prosurvival targets of IL-6 induced Stat3 activity in MM are Mcl-1 and Bcl-X_L, two antiapoptotic members of the Bcl-2 family. The role of Bcl-X_L in MM survival was demonstrated in studies examining Jak/Stat3 signaling in U266 IL-6 dependent MM cell line. Inhibition of Jak kinase activity or Stat3 DNA binding with Jak2 kinase inhibitor AG490 or Stat3 dominant negative (Stat3β), respectively, resulted in specific down-regulation of Bcl-X_L expression and increased sensitivity to CD95-mediated apoptosis, demonstrating a novel role for IL-6/Jak2/Stat3-signaling in CD95 resistance in MM. Further, as Bcl-X_L has been demonstrated to block apoptosis mediated by certain cytotoxic agents, it is likely that Stat3-mediated Bcl-X_L expression similarly correlates with endogenous resistance to chemotherapy. Mcl-1 is also an important downstream target of IL-6/Jak/Stat3 signaling in MM.

Jak/Stat-signaling also plays an important role in proliferation mediated by IL-6 in MM. Stimulation of Stat3 activity by nonreceptor protein tyrosine kinases mediates the expression of two key cell cycle regulatory proteins, cyclin D1 and c-myc. Stat3-dependent regulation of the D-type cyclins has been demonstrated in several cell models. In MM, IL-6 regulated Jak/Stat3 signaling specifically regulates cyclin D1 expression that, in turn, promotes cell proliferation. Treatment of IL-6-dependent MM cells with the Jak2 inhibitor AG490 inhibited Jak kinase activity and Stat3 signaling. The reduction in Stat3 signaling correlated with the downregulation of cyclin D1 and accumulation of cells in G1-phase of the cell cycle. To this end, Stat3-induced cyclin D1 expression might be an important effector of IL-6-mediated cellular proliferation in MM. c-myc is another potent oncogene involved in the regulation of the cell cycle targeted by Stat3 transactivation. c-myc controls a number of

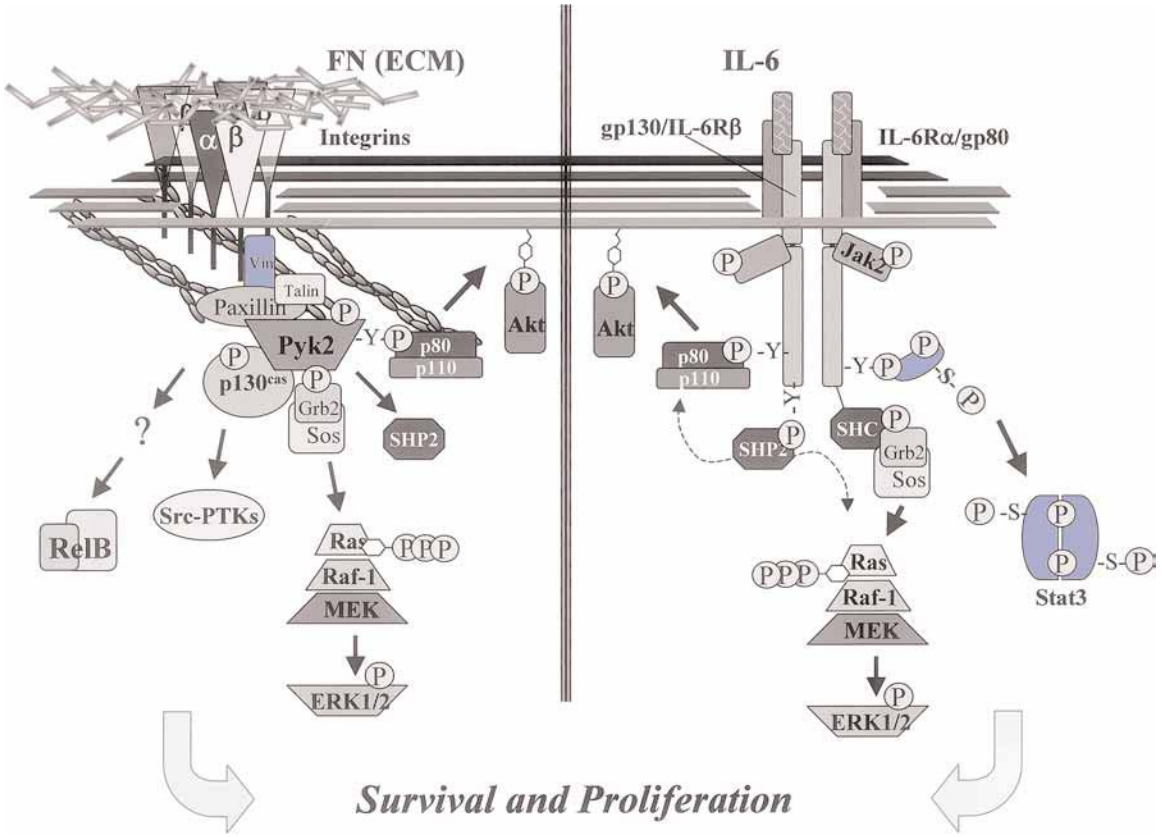

Figure 83-6 IL-6 and integrin-mediated signaling cascades. IL-6, a B-cell differentiation factor, has long been established as the primary growth and survival factor in MM. IL-6 signaling requires the formation of a protein complex consisting of two IL-6, two IL-6Rα (IL-6Rα/gp80) and two gp130 molecules (IL-6β). IL-6 signaling is mediated entirely through the gp130-subunit. IL-6Rα and gp130 interactions stimulates phosphorylation of specific gp130 tyrosine residues by members of the Janus tyrosine kinase (Jak) family of nonreceptor tyrosine kinases (Jak1, Jak2, and Tyk2) constitutively associated with gp130. Phosphorylated tyrosine residues of gp130 function as docking sites for a number of cytosolic proteins, including Stat3, SHC, PI3K, and SHP2. These three signaling cascades independently regulate cell survival and proliferation. Importantly these cascades are utilized by a number of other proMM survival factors. Ligand bound FNα and β-integrin heteromultimers facilitate the aggregation of a host of signaling and cytoskeletal proteins. Integrins lack intrinsic kinase activity, therefore, focal adhesions utilize associated nonreceptor protein tyrosine kinases (PTK) and receptor tyrosine kinases for intracellular signaling. Integrin signaling in MM involves Pyk2/RAFTK. Pyk2/RAFTK and associated with $p130^{Cas}$ are recruited to focal adhesions with the docking/cytoskeletal protein paxillin following integrin ligand crosslinking in MM cells. β_1-integrin occupancy stimulates Pyk2/RAFTK tyrosine phosphorylation and the recruitment of the Src PTKs $p53/56^{Lyn}$ and $p59^{Fyn}$ to Pyk2/$p130^{Cas}$ complexes. SHP2 also aggregates at focal adhesions in MM. Further, in other cell models, integrin stimulation has been shown to mediate a Pyk2/RAFTK-dependent activation of PI3K and ERK1/2 phosphorylation through the recruitment of Grb2/SOS and activation of Ras. Stat, signal transducer and activators of transcription.

aspects of G1 (cell cycle) progression, including increased activity of cyclin D/CDK4 complexes. As c-myc secondary Ig-translocations are observed in a large percentage of extramedullary MM and HMCLs, it is speculated that IL-6 and other BM effectors might modulate the expression of c-myc or c-myc-like activities thereby supporting MM expansion.

Phosphotidylinositol-3 Kinase PI3K is an inositol phospholipid phosphotransferase demonstrated to participate in MM survival and proliferation following IL-6 crosslinking primarily through the activation of Akt/protein kinase B and its downstream effectors. PI3K is a heterodimeric protein consisting of an adapter subunit (p85) and a kinase domain containing subunit (p110). On IL-6R stimulation the p85-subunit of PI3kinase associates with gp130 recruiting the p110-subunit. The PI3K heterodimer phosphorylates the 3′ OH ring of inositol phospholipids forming phosphotidylinositol (3,4,5) 3-phosphate and phosphotidyinositol (3,4) 2-phosphate on the inner leaflet of the plasma membrane. The cytosolic serine/threonine kinase Akt is recruited to the plasma membrane through interactions between the pleckstrin homology, PH, domain of Akt and the 3′-phosphorylated inositol phospholipids. Plasma membrane localized Akt is a substrate for phosphoinsitol-dependent protein kinase (PDK) 1 or PDK2. Phosphorylated (active) Akt subsequently phosphorylates a number of key determinants involved in MM proliferation and survival. Several Akt substrates have been associated with survival. Direct phosphorylation of the proapoptotic Bcl-2 family member Bad attenuates its apoptotic activity through cellular redistribution. Phosphorylation of procaspase-9 suppresses its apoptotic properties. Akt phosphorylation of FKHRL-1, a member of the Forkhead family of transcription factors, inhibits its transcriptional activity by targeting it for nuclear export. DNA associated unphosphorylated FKHRL-1 (nuclear) promotes expression of the DR ligand FasL, the proapoptotic Bcl-2 family member Bim, and the CKI $p27^{KIP1}$. So, Akt phosphorylation and nuclear export of FKHRL-1 would negatively regulate the expression of FasL, Bim, and $p27^{KIP1}$ potentially promoting survival and growth of IL-6 stimulated cells. Interruption of this cascade by molecular or pharmacological

inhibitors of PI3K/Akt signaling induces cell cycle arrest and apoptosis demonstrating a prominent role of this IL-6 induced pathway in MM expansion. Interestingly, the expression of the tumor suppressor PTEN, a dual specificity phosphatase (phosphotyrosine and phospholipids) shown to negatively regulate Akt signaling through the dephosphorylation of phosphoinositol phospholipids, was decreased in a number of MM cell lines. Further, the decreased levels of PTEN correlated with increased Akt signaling, suggesting that MM cells with decreased PTEN expression/activity might be more sensitive to PI3K/Akt activating stimuli.

Ras/ERK1/2 Activating Ras mutations are observed in greater than 50% of MM patients. These mutations maintain Ras in an active GTP-bound state. In this constitutively active state Ras promotes succession to a more pathogenic stage of intramedullary disease. Proliferative and anti-apoptotic signaling from IL-6 has also been shown to involve activation of one of the Ras isoforms (N-Ras, K-Ras, and H-Ras). Ras is a GTPase that is active when GTP is bound and inactive on GTP hydrolysis (GDP-bound). The ability of Ras to modulate signaling is dependent on plasma membrane localization facilitated by lipid modification. The lipid modification involves recognition of four conserved carboxy-terminal amino acids, proteolytic removal of the three terminal amino acids, and the linkage of farnesyl or geranylgeranyl lipid moieties to the terminal cysteine of Ras by farnesyl transferases or genranylgeranyl transferases, respectively. IL-6-mediated Ras activation requires the gp130 association and phosphorylation of SHC. SHC and the constitutively associated Grb2 protein recruit the guanine nucleotide exchange factor Sos to IL-6R complexes. Sos facilitates the exchange of GDP for GTP for membrane bound Ras. GTP-bound Ras (active) initiates a serine/threonine kinase cascade resulting in activation of ERK1/2 (MAPK). Interruption of this kinase cascade blocks IL-6 mediated MM cell proliferation. Further, constitutive activation of ERK1/2 signaling by the overexpression of activated Ras in IL-6 MM cell lines can compensate for the proliferative and antiapoptotic functions of IL-6. IL-6 and the signaling cascades elicited following receptor binding serve as a paradigm for cytokine and growth factor signaling in MM. Other soluble factors have been implicated in MM disease progression, all of which primarily elicit cellular response through the activation of these signaling effectors or similar signaling cascades.

ADHESION AND MM SURVIVAL Cell adhesion molecules (CAMs) consisting of the immunoglobulin family, cadherins, selectins, hyaluronate receptors, receptor tyrosine phosphatases, and integrins mediate interactions between cells and their physical environment. CAMs coordinate homing, lodging, differentiation, and survival of MM in the BM through specific homotypic and heterotypic interactions with environmental ligands. Integrins are the most well characterized members of this superfamily of surface glycoproteins. Integrins are heterodimeric (α and β) membrane receptors communicating the physical extracellular environment to intracellular events, including cytoskeletal rearrangements and signal cascades that control cell migration, cell growth, and survival. Twenty-two potential integrin receptors have been identified, comprised of specific dimers derived from 18 α-subunits and 8 β-subunits. Integrin binding requires transition from a low to high affinity ligand-binding state, allowing cell adhesion to extracellular matrix components such as FN, vitronectin, laminin, and collagens, or other CAMs. Stimulation of high affinity ligand binding involves a process termed "inside-out signaling." The cytoplasmic tails of integrins are indirectly targeted by the small prenylated GTPases Ha-ras, R-ras, and Rap, mediating conformational changes in the extracellular ligand-binding domain and thereby modulating adhesion (negatively or positively). Ligand-associated α and β integrin heteromultimers facilitate the aggregation of a host of signaling and cytoskeletal proteins. As integrins lack intrinsic kinase activity these unique molecular aggregates, termed focal adhesions, utilize associated nonreceptor protein tyrosine kinases and receptor tyrosine kinases for intracellular signaling. Signals originating from focal adhesions in anchorage-dependent cells primarily involve focal adhesion kinase, a nonreceptor PTK recruited to focal adhesions in association with cytoskeletal proteins talin, paxillin, and vinculin. Focal adhesion kinase is a docking protein involved in recruitment of integrin-signaling associated factors such as $p130^{cas}$ (Crk-associated substrate), Ras through Grb2/Sos, Src, and PI3K. However, in MM as opposed to focal adhesion kinase, the related nonreceptor PTK Pyk2/RAFTK (proline rich tyrosine kinase 2/RAFTK/CAKβ) modulates integrin multimerization. Pyk2/RAFTK is constitutively associated with $p130^{Cas}$ and recruited to focal adhesions with paxillin following integrin ligand crosslinking in MM cells. β_1 integrin occupancy stimulates Pyk2/RAFTK tyrosine phosphorylation and the recruitment of the Src protein tyrosine kinases $p53/56^{Lyn}$ and $p59^{Fyn}$ to $Pyk2/p130^{Cas}$ complexes. It has also been shown that integrin stimulation of MM cells facilitates the recruitment of the tyrosine phosphatase SHP2. In other cell models, integrin stimulation mediates a Pyk2/RAFTK-dependent activation of PI3kinase and ERK1/2 phosphorylation through the recruitment of Grb2/SOS and activation of Ras. However, the downstream effectors of integrin-mediated Pyk2RAFTK activation and the consequences of this activation on the cytoprotective effects of integrin adhesion have yet to be directly linked. β_1-integrin-mediated adhesion to FN of MM cells was demonstrated to stimulate nuclear localization and transcriptional activity of RelB, a member of the NF-κB family of transcription factors. The FN-mediated increases in RelB transcriptional activity correlated with elevated expression of the NF-κB regulated anti-apoptotic effector c-IAP, the CAMs syndecan-4 and CD83, as well as the cytokines IL-8 and IL-6. NF-κB activation has also been associated with adhesion of MM cells to BMSC, facilitating secretion of IL-6 by the BMSCs. From these studies it is apparent that integrin-mediated (or BMSCs') interactions with the physical environment can elicit a number of signaling cascades that might directly or indirectly confer a growth or survival advantage to adherent MM cells.

Most data indicates that MM integrin adhesion is associated with cell survival in response to both physiological and chemotherapeutic mediators of apoptosis. One important characteristic of a tumor is the ability to evade tumor-specific immune responses. MM cell adhesion to the extracellular matrix component FN confers resistance to CD95-mediated apoptosis. CD95-mediated caspase activation and apoptosis was reduced following β_1-integrin-mediated adhesion of hematopoietic cancer cell lines to FN. This resistance was associated with the intracellular trafficking of $c\text{-}FLIP_L$ from a membrane-associated subcellular location to a cytosolic location where $c\text{-}FLIP_L$ could be recruited to the death-induced signaling complex and inhibits apoptosis. FLIP expression is also regulated by adhesion and IGF-1 stimulation at the levels of RNA synthesis, suggesting that c-FLIP expression might be regulated at multiple levels by multiple BM effectors.

MULTIDRUG RESISTANCE

The failure of MM chemotherapy is defined by the phenomenon of MDR. Treatment of MM is characterized by initial response to chemotherapy, eventual relapse, and expansion of a therapy-resistant population of cells. MM cells become refractory to therapy through the acquisition of genetic changes that alter cellular susceptibility to cytotoxic therapy in the face of cytotoxic insult. This selective process results in acquisition of mechanisms that mediate resistance to multiple classes of therapeutic agents, or acquired MDR. The mechanisms of acquired MDR have been primarily elucidated using in vitro systems that have identified molecular changes within individual cells selected under prolonged exposure to cytotoxic insult. The mechanisms of acquired MDR in MM can be divided into three subcategories: reduced drug accumulation at target, alterations in drug target, and inhibition of apoptotic signaling pathways (Table 83-1). It is important to understand that although these mechanisms of acquired MDR have been categorized, within a given cell drug resistance frequently (if not always) results from multiple mechanisms.

In contrast to selected mechanisms of MDR or perhaps more appropriately in concert with acquired MDR, the environment has been demonstrated to modulate MM cell sensitivity to therapeutic drugs. As discussed, the BM environment produces cytokines, growth factors, chemokines, and adhesive matrices with the potential to confer a selective advantage to BM resident MM cells. An increasing number of these extrinsic effectors have been demonstrated to mediate drug resistance in MM (*see* Table 83-1). IL-6 and its associated signaling cascades modulate MM cell sensitivity to a number of drugs including dexamethasone (Dex). IGF-1, FGF, and hepatocyte growth factor also confer resistance to Dex through the activation of specific signaling cascades. Adhesion to specific BM extracellular matrixs attenuates the cytotoxic effects of the multitude of therapeutic agents, a phenomenon termed CAM drug resistance. These data indicated that the BM microenvironment might be a powerful mediator of a *de novo* MDR. Importantly, this de novo drug resistance might provide an initial resistance to MM cell in the face of therapeutic insult. In so doing the BM microenvironment might confer a selective advantage to resident MM cells allowing acquisition of more stable and durable mechanisms of MDR (acquired mechanisms). By targeting these effectors or the subsequent signaling cascades disruption of the survival network afforded MM cells by the BM might result, and in turn provide more successful treatment.

Table 83-1
Multidrug Resistance (MDR) in MM

Mechanisms of acquired MDR[a]
Reduced drug accumulation at target
P-glycoprotein
Multidrug resistance protein 1 (MRP1)
Breast cancer resistance protein (BCRP)
Lung resistance protein (LRP)/major vault protein (MVP)
Drug detoxification
CD98 expression
Alterations in drug target
Reduced topoisomerase II expression
Decreased glucocorticoid receptor (GR) expression
Deleted GR ligand binding domain
Anti-apoptotic proteins
Increased Bcl-2 family members
Decreased CD95 expression[b]
Mechanisms of de novo MDR[a]
Soluble factors
Interleukin-6
PI3K/Akt
Ras/ERK1/2
Jak/Stat3: Bcl-X_L and Mcl-1
SHP2: RAFTK
Insulin-like growth factor (IGF)[b]
Insulin receptor substrate
Ras/ERK1/2
Interferon α (IFN α)
Jak/Stat3: Mcl-1
Granulocyte-macrophage colony-stimulating factor[b]
Hepatocyte growth factor[b]
PI3K/Akt
Fibroblast growth factor
Macrophage inflammatory protein 1-α[b]
PI3K/Akt
Ras/ERK1/2
Direct cell contact
Integrin-mediated adhesion
Increased $p27^{Kip1}$
Intracellular redistribution of topo IIβ
Intracellular redistribution of c-$FLIP_L$[b]
Hyaleronon (a glucosaminoglycan)
Increased IL-6 stability/concentration at receptor
Bone marrow stromal cells (BMSC)
Production of IL-6

[a]Represents only mechanisms identified in MM.
[b]Antiapoptotic, however, no direct link to drug resistance has been established.

CONCLUSION

MM is a complex disease as demonstrated by the number of tumorigenic mechanisms presented in this chapter. Physicians and researchers using the reductionist theory have been examining MM, breaking down the disease and its manifestations to their most basic parts. Using this ideology MM research has revealed many molecular and biochemical factors involved. A handful of these molecular determinants and the mechanism by which they might individually contribute to MM pathogenesis have been presented. Importantly, synthesis of this enormous volume of data has given insight into the disease complexity. Progression from a maturing GC localized B cell to extrameduallry MM does not occur through a single event; a step-wise succession of genetic alterations occurs. Primary Ig-translocations involving a nonrandom set of oncogenes facilitates the earliest transforming steps in MM. These events are frequently paired with deletion or silencing of tumor suppressor genes. The acquisition of activating somatic mutations that might promote mitogen-independent growth are observed in more advanced stages of cancer. Finally, complex secondary Ig-translocations promoting the expression of c-myc (frequently) are observed in the most advanced stages of MM correlating with BM-independent growth. Importantly, these B cells (and MM cells) do not undergo genetic changes without other processes also occurring. Until the most terminal phases of MM, cells remain primarily in the BM. MM is not simply a mutated cell, it is a genetically altered cell residing in an environment rich in cytokines, growth factors, other soluble factors, as well as physical matrices. Therefore, it is likely that these environmental factors support MM growth and survival throughout the

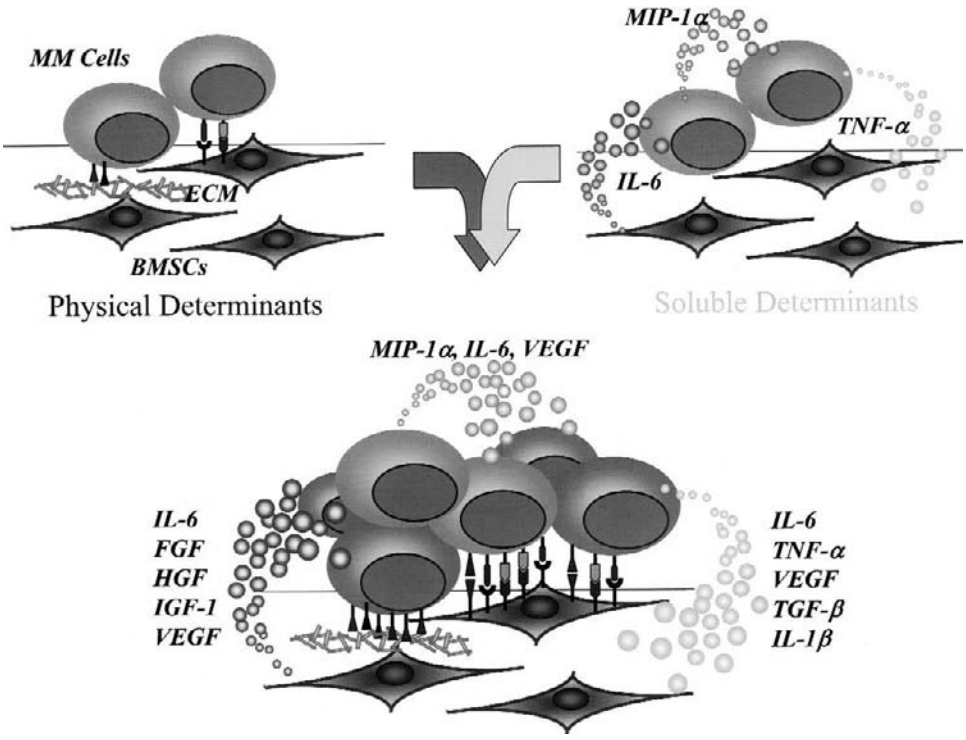

Figure 83-7 Myeloma bone marrow (BM) microenvironment: a network of promultiple myeloma (MM) survival determinants. The MM microenvironment plays a significant role in the disease pathogenesis by providing a "sanctuary" for BM resident MM cells. The environmental effectors have been proposed to constitute a network of paracrine and autocrine signaling, as well as regulatory events mediated by adhesion of MM cells to bone marrow stromal cells (BMSCs) or to adjacent MM cells that control MM cell growth and survival. FGF, fibroblast growth factor; ECM, extracellular matrix; HGF, hepatocyte growth factor; IGF-1, insulin-like growth factor-1; IL, Interleukin; MIP-1α, macrophage inhibitory protein-1α; TNF-α, tumor necrosis factor-α; VEGF, vascular endothelial growth factor.

course of intramedullary disease facilitating the acquisition of subsequent transforming genetic alterations.

Adding to the complexity, MM is not a single cell reacting to a single environmental cue. MM cells are constantly in contact with their physical environment and bathed with a multitude of soluble determinants. These environmental effectors have been proposed to constitute a network controlling MM proliferation and survival (Fig. 83-7). This network involves paracrine and autocrine signaling, as well as regulatory events mediated by adhesion of MM cells to BMSC (or to adjacent MM cells). Interestingly, cell adhesion is an important catalyst in the proposed survival network. Interactions between MM cells and BMSC induce production of the pro-expansion factor IL-6 by BMSCs. IL-6 signaling increases the adherent potential of MM cell lines to FN through an increase in macrophage inflammatory protein-1α secretion. Importantly, IL-6 mediated macrophage inflammatory protein-1α production was dependent on adhesion to FN, suggesting that FN-adhesion altered the manner in which the cell "interpreted" IL-6 stimulation. A number of soluble/adhesive networks have been elucidated. As with IL-6, MM cell adhesion to BMSCs modulates vascular endothelial growth factor secretion. Further, MM cell proliferation paralleled increased vascular endothelial growth factor levels. Vascular endothelial growth factor produced by MM cells also participates in paracrine signaling to adjacent BMSC, stimulating production of IL-6 by BMSCs. The cytokines IL-1β, TGF-β, and TNF-α produced by MM also facilitate BMSC secretion of IL-6. Moreover, TNF-α regulates increased adhesion of MM cells to BMSC through the expression of specific CAMs on both MM cells and BMSCs. The glucosaminoglycan hyaluronan was shown to contribute to MM cell resistance to Dex through the stabilization of IL-6 demonstrating a coordinated antiapoptotic effect involving both soluble and physical BM determinants in drug resistance. Together these studies suggest that MM progression might be mediated through a complex network. Further evidence for this hypothesis was demonstrated in experiments examining the antiapoptotic nature of specific coculturing conditions between MM cell lines and BMSCs. In these studies the degree of MM cell resistance to mitoxantrone was dependent on the coculture condition examined. MM cells were cultured alone, cocultured with BMSCs in transwells chambers (inhibiting adhesion), and directly cocultured with BMSCs (facilitating adhesion). MM cells cocultured in the absence or in the presence of intercellular contact with BMSCs were protected from mitoxantrone. MM cells cultured alone were unprotected. However, MM cells adhered to BMSCs were significantly more resistant to chemotherapeutic drugs than cells maintained in transwell chambers (not adhered). These data suggest that soluble factors and physical determinants might function in concert, potentiating the proliferative and/or protective effects of the individual constituents. MM must not be considered simply a genetic disease or a disease with one effector. MM is a complex disorder that requires an understanding of how genetic and environmental determinants contribute to tumorigenesis. Moreover, the significant role of the BM microenvironment in MM suggests that therapies designed to disrupt specific signaling cascades, ligand-receptor binding, or interactions between cells and the physical environment might be important targets in MM therapy.

84 HIV-1, AIDS, and Related Malignancies

MAUREEN M. GOODENOW AND JAMES J. KOHLER

SUMMARY

HIV type 1 (HIV-1) is a lentivirus that causes the global acquired immunodeficiency disease pandemic. HIV-1 infection of $CD4^+$ lymphocytes and macrophages modulates signal transduction pathways and immune response. Although rarely oncogenic itself, HIV-1 exacerbates clinical disease course in individuals dually infected by HIV-1 and hepatitis C virus, human papilloma virus, Epstein-Barr virus, or human herpesvirus-8. No vaccines or treatments to prevent or cure HIV-1 infection are available. Combinations of antiretroviral drugs reduce perinatal infection and HIV-1 associated morbidity and mortality. Increased survival among HIV-1 infected adults and children could lead to an increase in malignancies owing to chronic immune suppression, coinfection by oncogenic viruses, and/or persistent HIV-1 infection.

Key Words: Antiviral therapy; HIV-1; macrophages; signal transduction; virus–host cell interactions; quasispecies.

HIV-1 EPIDEMIOLOGY

HIV type 1 (HIV-1) is the etiological agent that causes AIDS. HIV-1 infection is a global pandemic afflicting more than 50 million adults, adolescents, and children. HIV-1 is spread primarily by sexual transmission, although maternal-to-child (MTC) transmission, needle sharing, and contaminated blood products also contribute to significant levels of infection. After 20 yr of the epidemic, there is no vaccine to prevent new infections and no cure for individuals once infected by the virus. Effective antiretroviral drugs that reduce significantly perinatal MTC transmission (but not pediatric infection by breast feeding) and control disease progression have been developed. Nonetheless, even prolonged suppression of HIV-1 replication fails to eliminate long-lived infected cells that can persist for years and serve as reservoirs for virus in children and adults. Continued viral replication results in evolution of genetic variants or quasispecies of HIV-1 that can evade drug therapies and immune response.

Although the HIV-1 epidemic extends worldwide, prevalence of infection is highest among populations in subSaharan Africa and other developing countries in Asia, South America, and the Indian subcontinent (Fig. 84-1). Seroprevalence varies dramatically but can reach levels as high as 9% in some countries in subSaharan Africa. A variety of subtypes of HIV-1, designated by letters A through K, are defined by molecular characteristics of the virus in contrast to traditional classification of viruses based on serotypes. Subtypes of HIV-1 tended initially to be localized in specific countries or regions, but mobility of individuals and recombination between viral subtypes that produces circulating recombinant forms of HIV-1 are contributing to global drifts in virus populations. HIV-2 is genetically related to HIV-1, has a more limited geographic distribution that colocalizes with HIV-1 infection in Western Africa, and causes less aggressive immune suppression.

MOLECULAR VIROLOGY OF HIV-1

HIV-1 is a lentivirus that is similar to, but genetically more complex than, the family of animal and human oncogenic retroviruses. HIV-1 virions contain two copies of a single-stranded RNA genome, which encodes a number of functions that are vital for the virus life cycle (Fig. 84-2A). The *gag*, *pol*, and *env* regions encode a variety of proteins including matrix, capsid, and nucleocapsid required for virion structure; protease, reverse transcriptase (RT), and integrase enzymes that function in virion maturation, synthesis of the DNA form of the virus, and integration of viral DNA into the host cell genome, respectively; and glycoproteins gp120 and gp41, the surface and transmembrane components of the viral envelope (Env) proteins, which mediate infection of target cells that express CD4 and an appropriate coreceptor (Fig. 84-2B). The HIV-1 genome encodes no less than six additional proteins that provide regulatory (Tat and Rev) or accessory (Nef, Vpr, Vif, Vpu) functions. Long terminal repeat (LTR) elements flanking the viral genome regulate reverse transcription and integration. In addition, *cis*-acting transcriptional elements localized in the LTRs regulate expression of the viral genome by host cell mechanisms. Antiretroviral drugs approved for treatment of HIV-1 infection target multiple key steps in the virus life cycle (Fig. 84-3). Entry can be blocked by inhibitors of Env interactions with coreceptors or fusion between virus and host cell. Early steps in virus replication are targeted by a variety of RT inhibitors, whereas late steps in virion maturation that are essential for infectious virus are blocked by PR inhibitors.

HIV-1 IMMUNE DEFICIENCY AND AIDS

HIV-1 affects multiple lineages of hematopoietic cells by direct infection of T lymphocytes, thymocytes, and monocyte/macrophages that coexpress CD4 and CCR5 or CXCR4, chemokine receptors that function as coreceptors for HIV-1. Over time, HIV-1 infection produces significant declines in CD4 T lymphocytes that, in combination

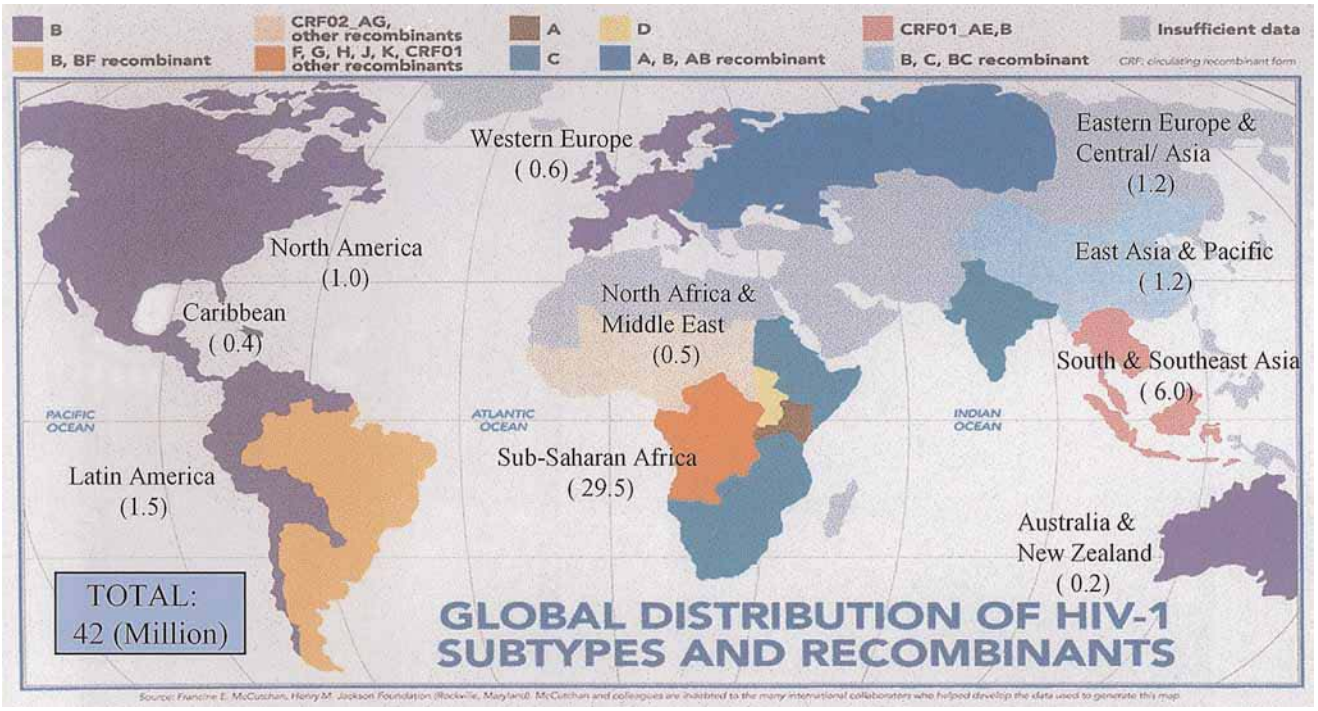

Figure 84-1 Global epidemiology of HIV type 1 subtypes and estimated number of infected individuals (in millions) at the end of 2002 according to the International AIDS Vaccine Initiative and the Joint United Nations Programme on HIV/AIDS. (Please s*ee* color insert.)

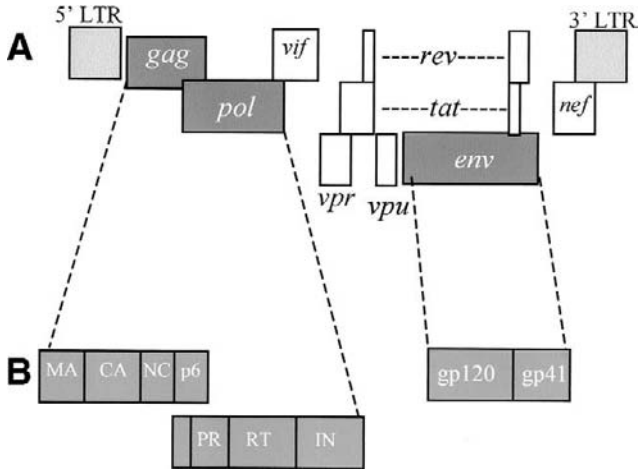

Figure 84-2 **(A)** HIV type-1 genome encodes three structural genes (*gag, pol, env*), in addition to accessory genes (*vif, rev, tat, nef, vpr, vpu*). Long terminal repeat elements flank the genome. **(B)** Gag proteins include matrix, capsid, and nuclear capsid. Pol proteins are protease, RT, and integrase. Envelope glycoproteins include surface gp120 and transmembrane gp41.

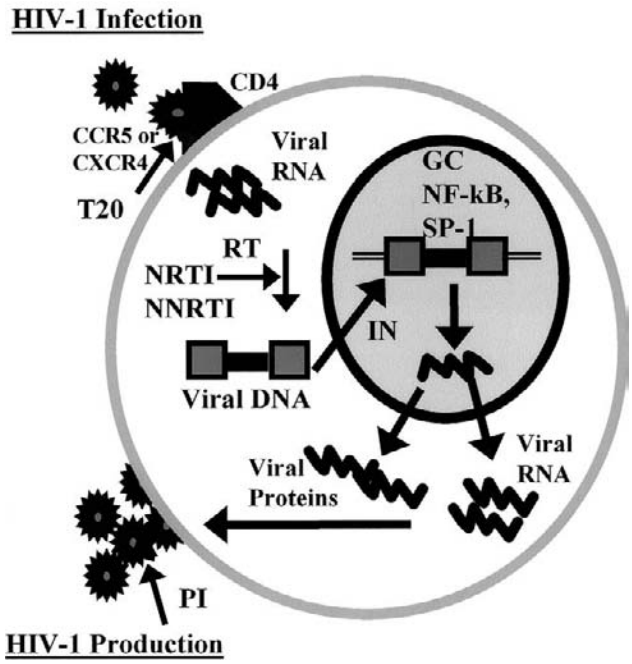

Figure 84-3 HIV type-1 viral life cycle. Virus infection is mediated at the cell surface by interactions between gp120 and receptor complex (CD4 plus CCR5 or CXCR4) on the surface of the host cell. DNA form of virus is a product of RT; integration into host genome is mediated by integrase. Regulation of HIV-1 gene expression involves host cell transcription factors such as glucocorticoid receptor (GC), or NF-κB and SP-1. Immature virions bud from the cell membrane. Processing by protease leads to mature, infectious virions. Inhibitors approved for clinical use include T20 (entry inhibitor, nucleotide and non-nucleoside RT inhibitors (NRTI or NNRTI), and protease inhibitors.

with indirect effects independent of infection of CD8 T cells, B lymphocytes, natural killer cells, and dendritic cells, contribute to global immune disregulation, profound immune dysfunction, and AIDS.

The Centers for Disease Control define AIDS in adults and adolescents by a spectrum of opportunistic infections and a heterogeneous group of malignancies, in particular Kaposi's sarcoma (KS), non-Hodgkin's lymphoma (NHL) including Burkitt's, immunoblastic, and primary brain lymphomas, and invasive

cervical carcinoma (ICC). HIV-1 infection increases significantly the risk of developing KS, NHL, or ICC, and can exacerbate hepatocarcinoma and leukemia. Estimates place the occurrence of some type of malignancy in as many as 40% of persons with HIV/AIDS.

Pediatric HIV-1 disease is also accompanied by a significant increase in malignancies. Between 1981 and 1996, approx 2% of children with AIDS in the United States developed cancer. In contrast to adults, HIV-1 infected children present a somewhat different spectrum of malignancies. For example, NHL was the predominant malignancy among children with HIV-1 infection in a large multicenter case-control study. KS is the AIDS defining tumor in only a small number of children in the United States, but is highly associated with pediatric HIV infection among African children.

Non-AIDS-defining malignancies, including lung, skin, head and neck, conjunctival, testicular, hepatic, and breast cancers, as well as multiple myeloma, leukemia, and leiomyosarcomas, also increase morbidity and mortality among HIV-1 infected individuals with AIDS. Leiomyosarcomas (smooth muscle tumors) and lymphoproliferative disorders, which could progress to malignancy, appear more frequently in children than adults.

Epidemiology of AIDS and non-AIDS related malignancies differs significantly between developed and developing countries. A variety of environmental and economic factors could contribute to geographical differences. In addition, any association that might occur between different HIV-1 subtypes or circulating recombinant forms of HIV-1 and malignancies is unknown.

ETIOLOGY OF MALIGNANCIES ASSOCIATED WITH AIDS

HIV-1 can with low frequency contribute directly by insertional mutagenesis into a region of c-*fes* proto-oncogene to development of malignancy in some T-cell lymphomas and in macrophages in non-T-cell lymphomas. For the most part, herpesviruses are major etiological agents of human AIDS-defining malignancies (Table 84-1). Human herpesvirus-8 (HHV-8) infection contributes to increased risk for KS; Epstein-Barr virus (EBV) infection increases risk for NHL, including primary brain lymphomas and leiomyosarcomas in children; and cervical infection by high-risk human papilloma viruses (HPVs) increases risk for ICC among HIV-1 or HIV-2 infected women worldwide. A subset of human malignancies associated with HIV-1 infection involves coinfection by other viruses. For example, hepatitis C virus (HCV) infection increases the risk for hepatic carcinoma, whereas two types of human T-cell leukemia viruses (HTLV-1 and HTLV-2) contribute to leukemia/lymphomas. Coinfection by oncogenic viruses and HIV-1 is facilitated by the high prevalence of the viruses in similar geographic locations, by similar modes of transmission of the viruses, and the impact of HIV-1 related immune dysfunction on susceptibility to infection and disease progression by at least some of the oncogenic viruses.

Table 84-1
Viral-Induced Malignancies Associated With HIV

Virus	*AIDS-defining malignancies*
EBV	NHL
	Hodgkin's disease
	Leiomyosarcoma
	CNS/Brain lymphomas
HHV-8	KS
HPV	Squamous cell neoplasia
	AIDS-associated malignancies
HCV	Hepatocellular carcinoma
Human T-cell leukemia virus	HTLV-1 associated myelopathy
	Tropical spastic paraparesis

ANTIRETROVIRAL THERAPY AND HIV-ASSOCIATED MALIGNANCY

Immune deficiency caused by chronic HIV-1 infection is a significant variable for risk of malignancy. Effective antiretroviral therapy (ART) for control of HIV-1 infection involves inhibitors that target RT, either alone or in combination with PR. No evidence implicates RT or PR inhibitors directly with increased risk for malignancy, as many of the studies of HIV-associated cancer risk were performed prior to widespread use of ART. Exposure *in utero* to zidovudine, one of the RT inhibitors that reduce significantly MTC transmission, provides no discernible risk factor for development of malignancies in children. Indeed, reduction and sustained control of HIV-1 viral burden by ART can result in reversal of immune suppression and a concomitant decline in risk for HIV/AIDS-related malignancies. For example, incidence of KS is exquisitely sensitive to immune deficiency and decreased significantly by ART. Incidence of NHL, including CNS or primary brain lymphoma, also decreases but requires longer periods of ART, implicating immune suppression as a risk factor. NHL is actually a heterogeneous group of malignancies, which could account for some reports that NHL is not markedly decreased by ART or that some HIV-1 infected individuals develop NHL despite suppressed viral replication and high CD4 T-cell counts. ART has no impact on high-risk HPV infection or development of cervical cancer, implying that factors unrelated to immune suppression or associated with processes independent of ART may contribute to some AIDS-related malignancies.

HIV INFECTION AND IMPACT ON SIGNALING CASCADES

HIV has direct and indirect impact on $CD4^+$ cells of the lymphocytic and monocyte/macrophage lineages (Table 84-2). Infection of macrophages by HIV-1 is correlated with progressive functional impairments, which include defects in chemotaxis, cytokine production, expression of surface proteins, and antigen processing and presentation. HIV-1 blocks the transcription of major histocompatibility class II determinants, which has a significant immunosuppressive effect on macrophages. HIV-1 Tat protein can compete with class II transactivator binding and subsequently block the expression of major histocompatibility class II genes. Specifically, cyclin T1 together with CDK9 forms the positive transcription elongation factor b complex, which binds to class II transactivator and can also bind to the activation domain of Tat.

HIV alters a variety of signal transduction pathways at multiple stages in infection. Beginning with entry, binding of gp120 to CD4 plus the chemokine receptors CCR5 or CXCR4 results in activation of intracellular protein tyrosine kinases. Presumably, binding of Env glycoproteins to the receptor complex can mimic binding of ligands, and result in activation of heterotrimeric G proteins, calcium fluxes, and tyrsosine phosphorylation of Pyk2, phosphatidylinositol-3-kinase, and the Ras-independent Lck/Raf-1 signaling pathway that leads to the MEK/ERK pathway. Microarray studies demonstrate global activation with overexpression of c-jun, JNK, MEK,

Table 84-2
Viral Proteins and Their Cellular Targets

Virus	*Viral protein*	*Target cell*	*Cellular targets*
HIV-1	Env gp120	$CD4^+$ lymphocytes	Protein tyrosine kinases, calcium fluxes
		Macrophages	Pyk2 phosphorylation; PI3; MEK/ERK pathway; STAT1, STAT3, STAT5; caspase-3 activation
	Nef	$CD4^+$ lymphocytes	Calcium signaling; activate NFAT, c-*fos*, Jun-D
		Macrophages	TGF-β, IL-4, MIP-1α, MIP-1β
	Vpr	$CD4^+$ lymphocytes	cAMP response element, G_2 arrest
	Tat	Monocytes	TNF-α, bFGF signaling pathways, type-IV collagenase
HHV-8	Homologs of IL-8 (vGPCR), bcl-2, IL-1, NCAMs	Endothelial-type cells	Cell proliferation, activation cascades, antiapoptosis signals, NF-AT
EBV	LMP1	B-lymphoid epithelial	Adhesion molecules, transferring receptor, TGF-β sensitivity, bcl-2 oncogene, CD40-CD40L signaling, NF-κB activation
	LMP2α/B	B cells	Inhibit lyn and syk kinases
	Unknown	Monocytes	Proapoptotic signaling
	Unknown	Dendritic cells	Inhibit DC development
HPV	E6	Keratinocytes, epithelial cells	P53 tumor suppressor activates TERT gene, IL-8 repression
	E7	Epithelial cells	p-RB, pCAF acetyltransferase, IL-8 repression
HCV	HCV core	Hepatocytes	Suppress immune response
		Macrophages	Reduce IFN-γ, IL-2
		Lymphocytes	Fas-mediated apoptosis
	NS5A	Lymphocytes	Inhibit PKR; phosphorylation of eIF-2α; CDK inhibitor p21/waf1; STAT2 activation; NF-κB, IFN-γ responsive genes
HTLV	Tax	T lymphocytes	Cytokine independent growth; transactivates NF-κB,CREB, cyclin D2, CDK2, p21; blocks G_1/S and G_2/M checkpoints; Jak1, Jak3, STAT3, STAT5, MIP-1α, C-C chemokine 3, IFN-γ, GM-CSF

DC, dendritic cell; FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; MIP, macrophage inflammatory protein; NCAM, neural cell adhesion molecules; NF, nuclear factor; TGF, transforming growth factor; TNF, tumor necrosis factor.

p38 MAPK, STAT, and JAK induced in HIV infected cells. Thus, HIV-1 entry into target cells modulates cellular signaling that may be necessary for replication or occur as a consequence of infection.

Gp120 induces not one, but at least three different STATs (STAT1, STAT3, and STAT5), with significant implications. First, each activated STAT represents a highly specific pathway that results in regulation of expression of a set of genes. Secondly, constitutive activation of STAT1, STAT3, and STAT5 is associated with malignant transformation induced by various oncoproteins. Cellular activation that is induced by HIV-1 precludes apoptosis. For example, envelope-mediated induction of infectious virus from purified resting $CD4^+$ T cells occurs without the induction of classic markers of T-cell activation or progression through the cell cycle. Impairment of cell-cycle progression may occur in part through HIV-induced activation of caspase-3 and cleavage of focal adhesion kinase. Intracellular signals resulting from HIV-1 envelope may have immunopathogenic consequences including anergy, syncytium formation, apoptosis, and inappropriate cell trafficking. Activation of STAT regulated genes provides a model for interactions by HIV-1 and oncogenic viruses coinfection in development of malignancies.

In addition to the influences of Env, Nef, Vpr, and Tat proteins can also affect host cell signaling pathways. Specifically, Nef stimulates calcium signaling to activate transcription factors such as nuclear factor of activated T (NFAT) cells, nuclear factor-κB (NF-κB), IRF-1, IRF-2, c-Fos, and Jun-D, which positively regulate the viral LTR regulatory domain. In addition, several cytokines, including transforming growth factor (TGF)-β and IL-4, together with the chemokines macrophage inflammatory protein (MIP)-1α and MIP-1β are upregulated by Nef in macrophages. Vpr can cooperate with Nef in NFAT-directed gene expression and upregulation of cAMP response element-directed transcription that may act by stabilizing interactions with CREB. Vpr also induces G2 arrest of lymphocytes through specific changes in gene expression patterns that differ from simple activation of stress response or cytokine response pathways. HIV Tat protein is secreted by infected cells, can act on other cells, independent of infection, and induces tumor necrosis factor (TNF)-α in human monocytes through protein kinase C and calcium pathways. HIV-1 Tat can enhance the endothelial cell growth and type-IV collagenase expression in response to basic fibroblast growth factor to induce KS-like lesions in transgenic mice.

Although HIV-1 infection alone is rarely oncogenic, the profound effects on host immunity, signal cascades, and gene expression could contribute to increased prevalence of malignancies because of coinfection with oncogenic viruses.

VIRUSES INVOLVED IN AIDS-DEFINING MALIGNANCIES

HUMAN HERPESVIRUS-8 The etiological agent of KS is HHV-8, also known as KS herpesvirus. HHV-8 is a double-stranded DNA virus that is a member of the γ-herpesvirus family, which also includes EBV. HHV-8 seroprevalence exceeds 40% among some populations in the regions surrounding the Mediterranean and in

sub-Saharan Africa where KS is endemic. In North America, northern Europe, Southeast Asia, and the Caribbean, where incidence of KS is low, seroprevalence ranges from less than 1% to approx 20%. HHV-8 infection can be detected in neonates and seroprevalence among children tends to be somewhat lower than in adults, but increases with age prior to puberty. Pediatric infection would indicate that HHV-8 can be transmitted not only by sexual activity and blood, but also by maternal transmission and close family contacts among siblings.

Seroprevalence among individuals with HHV-8 associated disease, including KS, primary effusion lymphoma (a rare B-cell lymphoma), and multicentric Castleman's disease, can be as high as 100%. HHV-8 malignancies are highly sensitive to host immune suppression, particularly related to HIV-1 infection or transplantation, but not to HIV-2 infection. Seroprevalence of HHV-8 increases in HIV-1 infected individuals with KS, whereas HHV-8 viremia and HIV-1 infection are significant risk factors for developing KS.

HHV-8 has a genome of approx 165 kb and encodes a remarkable number of proteins with functional homology to host cell genes that regulate cell proliferation, activation, and survival (*see* Table 84-2). For example, the HHV-8 genome includes homologies to human cyclin D, an IL-8-like G protein coupled receptor (vGPCR), bcl-2, no less than three chemokines, a variety of cytokines related to IL-1 and interferon (IFN) regulatory factors, as well as complement-binding proteins and neural cell adhesion molecule-like adhesion molecules. KS is a complex malignancy included spindle-formed cells expressing endothelial cell markers, newly formed blood vessels, and infiltrates of cells with characteristics of smooth muscle cells, macrophages, or dendritic cells. Only a minor subset of cells in a KS lesion express viral genes leading to a paracrine model of tumorigenesis in which expression of viral gene products by some cells affects regulation of surrounding cells. A paracrine mechanism could also provide a model for synergy between HIV-1 and HHV-8 infection in view of the different host cells targeted by each virus. Consistent with this model, HIV-1 Tat protein is secreted by infected cells, activates KS cell growth, and can collaborate with HHV-8 vGPCR protein to activate NFAT, a transcription factor expressed by a variety of cell types that is involved in regulation of expression of cytokine and adhesion molecule genes.

EPSTEIN-BARR VIRUS EBV is an ubiquitous human γ-herpesvirus that infects more than 90% of the world's population. Although infection is generally subclinical, EBV causes infectious mononucleosis and lymphoproliferative disorders in immunologically compromised individuals. EBV is etiologically linked to human malignancies involving lymphoid and epithelial cell origin, including Burkitt's lymphoma, T-cell lymphoma, nasopharyngeal carcinoma, post-transplant lymphoma, AIDS-associated lymphomas, parotid gland carcinoma, and gastric carcinoma. EBV strains are classified as type 1 or type 2, based on major sequence differences in the EBV nuclear antigen 2 (EBNA-2) and EBNA-3C genes. Type-1 EBV shows more potent transforming efficiency in vitro than type 2 and appears to predominate in the general Caucasian and Asian populations. Type-2 infection is more prevalent in immunocompromised patients; and both types are relatively common in equatorial Africa and New Guinea.

Several lines of evidence implicate a close association between HIV-induced immune suppression and EBV-associated lymphomas. Compared to healthy individuals, HIV-1 infected subjects usually have a higher EBV viral load and/or number of EBV-infected cells both in the peripheral blood compartment and lymphoid tissues. Expansion of EBV-positive B cells is probably because of chronic B-cell stimulation driven by HIV-1 antigens (especially in ART-treated individuals that results in increased $CD4^+$ immune cells but the continuance of a high viral load) and an impaired immunosurveillance against EBV. Individuals newly diagnosed with Hodgkin's lymphoma demonstrate stronger EBV association together with poorer survival and more aggressive clinical characteristics. EBV is responsible for lymphoproliferative disorders including cases of Burkitt's lymphoma in Africa, and is associated with higher frequencies of T-cell activation and IL-4-producing cells in the periphery, and higher susceptibility to activation-induced apoptosis. High viral burden with EBV is associated with the development of malignancy in HIV-infected children. In addition, EBV has a causal role in the oncogenesis of smooth muscle tumors (leiomyosarcomas), which represent the second most prevalent malignancy of children with AIDS. An association between some EBV tumors and immune suppression stresses the importance of immune responses in keeping a balance between the oncogenic virus and the infected host.

EBV binding to monocytes influences the differentiation stage of monocytes and inhibits development of dendritic cells from monocyte precursors by a unique interference that is independent of *de novo* synthesis of viral proteins or mRNAs. More specifically, exposure to EBV induces proapoptotic signaling in monocytes, which correlates with an aberrant response to both granulocyte-macrophage colony-stimulating factor and IL-4.

Genetic analyses define the genes of EBV that are essential for B-lymphocyte transformation and their potential functions and biochemical properties (*see* Table 84-2). The EBV genome encodes a unique set of latent genes designated as latent membrane proteins (LMP)-1, 2A and 2B that confer oncogenic potential and the ability to induce immortalization of B-lymphocytes in vitro. Globally, LMP1 has oncogenic properties that alter the phenotype of B-cell activation antigens, adhesion molecules, transferrin receptor and sensitivity to TGF-β, whereas inhibiting apoptosis through the induction of expression of *bcl*-2 oncogene. In addition, LMP1 mimics the signaling pathways that are activated by CD40-CD40L interaction, resulting in the activation of NF-κB. In fact, an increased ability of LMP1 variants to activate NF-κB is correlated with advanced nasopharyngeal carcinoma cases. Host cell factors, such as STAT genes, could influence the switch to latent, transforming gene expression of LMP1 and cellular proliferation.

LMP2 proteins exist in two forms, LMP2A and 2B, as a result of alternatively spliced mRNAs that contain exons located at both ends of the linear EBV genome. LMP2A has a 119 amino acid N-terminal cytoplasmic domain that contains an immunoreceptor-tyrosine-based activation motif. In B and T cells, cellular immunoreceptor-tyrosine-based activation motif s functionally bind Lyn and Syk kinases leading to activation of multiple signal transduction cascades. However, LMP2A can competitively sequester and degrade Lyn and Syk kinases, thereby inhibiting lymphoctye activation.

HUMAN PAPILLOMA VIRUSES HPV is a group of DNA tumor virus related to simian virus 40 and other polyomaviruses. HPVs are sexually transmitted and certain types of HCV are the etiological agent of cervical intraepithelial neoplasia (CIN), the precursor of cervical cancer, as well as ICC. Greater than 90% of CIN and ICC in women worldwide contain HPV DNA. Infection

by HIV-1 leads to a higher prevalence and prolonged persistence of cervical HPV infection, increased levels of HPV, and increased incidence of high grade CIN. Although HIV-1 infection and immune suppression are associated with overall prevalence of HPV, effective ART for HIV-1 fails to diminish the prevalence or pathogenesis of HPV.

HPV is classified into more than 90 different types, which present low- or high-risk for development of neoplasia. High-risk types are predominantly HPV 16, 18, 31, and 45, although HPV 16 is by far the most prevalent in premalignant CIN and occurs in about half of ICC. In addition, risk analysis indicates that HPV 26, 53, and 66, previously typed as low risk, should be classified as high-risk types. Prevalent and incident detection of HPV 16, unlike other types of HPV, displays only a weak association with immune status among HIV-1 seropositive women, raising the possibility that HPV 16 avoids host immunity, which would contribute to the significant relationship between this HPV 16 and malignancy.

High-risk HPV genomes encode two early proteins, E6 and E7 that are expressed concurrently, effect growth control of infected cells, and contribute to immortalization and transformation of a variety of cells, including keratinocytes and epithelial cells, by a variety of mechanisms (*see* Table 84-2). The HPV 16 E6 oncoprotein is 151 amino acids, contains two zinc-finger motifs, and binds to p53 tumor suppressor protein that activates p53 degradation by a ubiquitin-dependent pathway. E6 also activates expression of the TERT gene that encodes the catalytic subunit of the telomerase enzyme, which maintains chromosomal telomere length and inhibits senescence. HPV E7 is a multifunctional, 98-amino acid phosphoprotein. E7 binding to pRB, a tumor suppressor protein, releases transcription factors that promote progression of cells through the G1/S boundary into S-phase of the cell cycle. E7 also interacts with p300/CBP-associated factor acetyltransferase, a coactivator for a variety of transcription factors, including p53. In addition to functions as oncoproteins, HPV 16 E6 and E7 cooperatively repress IL-8 transcription. IL-8 is an inflammatory chemokine involved in initiation of local immune responses. Repression of IL-8 gene expression could contribute to HPV escape from immune surveillance.

The host cell range for HIV-1 and HPV differ, making direct effects by HIV-1 an unlikely explanation for increased HPV pathogenesis. More likely, the overall impact by HIV-1 on cytokines and factors modulates the cellular milieu to favor HPV replication and/or progression of HPV-mediated initiation of premalignant lesions.

VIRUSES INVOLVED IN AIDS-ASSOCIATED MALIGNANCIES

HEPATITIS C VIRUS HCV is a significant public health concern, affecting more than 170 million people worldwide and approx 4 million Americans. HCV causes chronic hepatitis, which can progress to cirrhosis and hepatocellular carcinoma, the fifth most common cancer in the world. Coinfection with HCV in HIV-infected persons occurs frequently as these viruses share routes of transmission and target cells. In the United States alone, 20–25% of HIV-1 infected people are estimated to be coinfected with HCV, whereas worldwide, 6.5–13 million individuals are estimated to be coinfected with HCV and HIV. The prevalence of chronic HCV infection is more than 50% among HIV-infected intravenous drug users. Effective ART and prolonged chronic HIV disease state increases HCV-related morbidity and mortality. Although HIV and HCV can be transmitted by percutaneous exposure to blood, through sexual intercourse, and from mother to child, relative efficiency of transmission by these routes varies. HCV, for example, is reportedly 10 times more infectious than HIV through percutaneous blood exposures.

HCV has little known effect on HIV disease, but infection with HIV adversely affects the outcome of hepatitis C infection, resulting in higher HCV RNA viral load and accelerated hepatopathology. HIV-associated decline in $CD4^+$ T helper lymphocytes and defective $CD4^+$ proliferation and apoptosis constitute critical factors of immunosuppression that correlate with ineffective host immune response to HCV and progression to end-stage liver disease. Interestingly, HCV/HIV coinfection results in decreased response to IFN therapy, although IFN therapy has protective effects against HCV-related cirrhosis independent of the patient's HIV status.

ART-associated hepatotoxicity can diminish effectiveness of HIV therapy and cause significant morbidity and mortality. Drug-induced hepatotoxicity may be more common among persons with HIV–HCV coinfection who are receiving PR inhibitors. Enhanced drug-induced hepatotoxicity among individuals coinfected with HIV and HCV may result from decreased drug metabolism, or increased susceptibility to mitochondrial dysfunction.

In addition to hepatocytes, various immune cells including macrophages, B cells, and T cells support HCV replication. HCV core protein is the first protein expressed during the early phase of infection (*see* Table 84-2). Through Fas-binding, HCV augments signaling mediated through caspase-3 activity, which increases susceptibility to Fas-mediated apoptosis. Therefore, HCV core protein has a demonstrated effect on immune responsiveness.

A late stage, nonstructural protein 5A (NS5A) is a serine phosphoprotein that binds and inhibits the homodimerization and kinase activity of the double-stranded RNA-dependent protein kinase, a major intracellular enzyme that mediates the antiviral action of IFN, phosphorylation of eIF-2α, and the attenuation of cellular protein synthesis. Furthermore, NS5A protein downregulates transcription of cell-cycle regulatory genes (i.e., the cyclin-dependent kinase inhibitor p21/waf1 gene) and mediates activation of transcription factors including STAT-3 and NF-κB. Arguably, NF-κB and/or STAT-3 may regulate gene expression of survival factors to further promote an antiapoptotic environment in the cells and favor oncogenesis.

HUMAN T-CELL LEUKEMIA VIRUS HTLV type 1 (HTLV-1) is a retrovirus that serves as the etiological agent for adult T-cell leukemia and the neurological disorder HTLV-1 associated myelopathy/tropical spastic paraparesis. HTLV-1 mediates transformation or transition from a cytokine-dependent to an independent phase of growth through its virally encoded 40 kDa regulatory phosphoprotein, Tax (*see* Table 84-2). Tax transactivates cellular genes driven by transcription factors such as CREB, NF-κB, and serum response factor. In addition, Tax alters expression of cell-cycle regulatory proteins, upregulating cyclin D2, cyclin E, CDK2, CDK4, CDK6, and $p21^{Waf1/Cip1/Sdi1}$, and downregulating cyclin D3 and p18. Thus, Tax blocks the G_1/S and G_2/M cell-cycle check points, linking Tax expression to chromosomal abnormalities and abnormal cell division. Upregulation of p21 results in at least two independent mechanisms of regulation: the enhancement of NF-κB activation and/or CREB signaling, and the excitation of antiapoptotic machinery. Further evidence suggests that HTLV-1-transformed T cells become functionally redundant for proliferation through the Jak3-STAT5 pathway, as AG-490 treatment has no effect on Jak3/STAT5 activation. In fact, Jak1, Jak3, and STATs

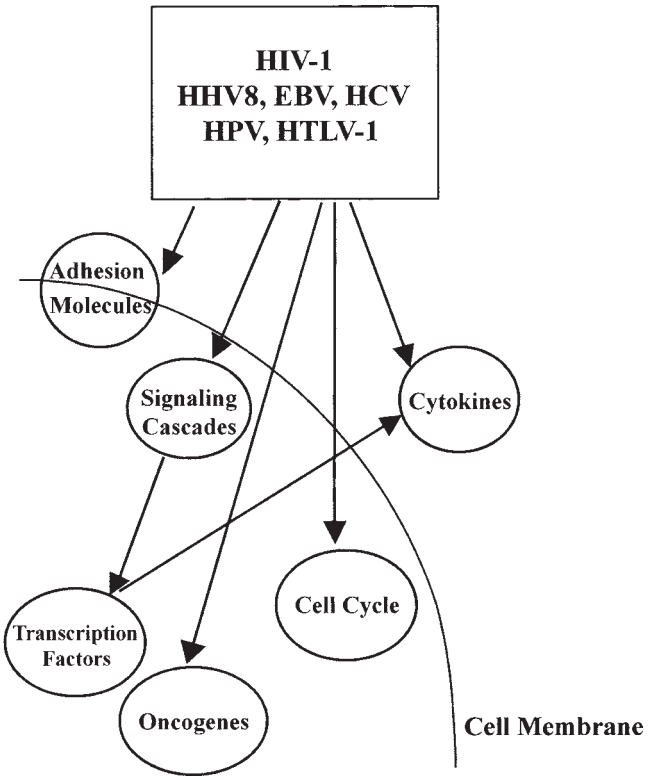

Figure 84-4 Cellular pathways induced by HIV type 1 and associated oncogenic viruses. HHV-8, human herpesvirus-8; EBV, Epstein-Barr virus; HCV, hepatitis C virus; HPV, human papilloma virus; HTLV-1, human T-cell leukemia viruses.

3 and 5 are constitutively activated in HTLV-1-transformed cells, rendering infected peripheral blood T cells IL-2 independent.

HTLV type 2 (HTLV-2) is endemic in some native American Indian and African tribes and has a high prevalence among HIV-1 infected individuals. HTLV-2 infection can potentially interfere with the replicative capacity of HIV-1 by upregulating the secretion of HIV-1 suppressive chemokines, in particular, C-C chemokine ligand 3/macrophage-inflammatory protein-1α (MIÎ-1α). HTLV-2 induces the secretion of IFN-g and granulocyte-macrophage colony stimulating factor, which in turn results in the activation of STAT1 or STAT5, respectively.

CONCLUSIONS

HIV-1 infection leads to immune dysfunction by multiple mechanisms that extend beyond attrition of CD4 T lymphocytes. Interactions by viral proteins with signal transducing and gene expression pathways may be necessary for HIV-1 replication or a consequence of infection. Nevertheless, the outcomes of HIV infection can modulate the cellular environment to promote malignancy by coinfecting oncogenic viruses (Fig. 84-4).

Increased survival by HIV-1 infected adults and children could lead to an increase in malignancies, because of chronic immune suppression, coinfection with oncogenic viruses, and/or persistent HIV-1 infection. Chemotherapy treatments of malignancies in HIV-1 infected children and adults are complicated by potential interactions with antiretroviral drugs, novel toxicities, metabolic abnormalities associated with ART, and immune suppression caused by HIV-1, as well as limited direct data for many drugs about dose and indications for use in pediatric patients. Even mild immunosuppression is associated with decreased ability to control HPV, which could have implications for treatment of women by ART that prolongs life, but increases by years mild immunosuppression and risk of HPV-associated neoplasia and ICC. Certainly management of individuals with HIV infection and malignancies needs to be examined. Continued surveillance of HIV-1 infected individuals throughout the world is imperative to identify any changes in prevalence of malignancies.

85 Disorders of the Red Cell Membrane

JEAN DELAUNAY AND GORDON W. STEWART

SUMMARY

Many genetic disorders may affect the red cell membrane and its skeleton, and usually result in hemolytic anemias. We will survey conditions that alter the mechanical properties of the red cells: hereditary spherocytosis, hereditary elliptocytosis and poikilocytosis, and conditions associated with an increase of the passive leak of the membrane to monovalent cations, the hereditary stomatocytoses. We will also consider some congenital dyserythropoietic anemias in which a reduction of the red cell production predominates, but which are associated with noticeable, secondary abnormalities of the membrane. The main clinical features and the molecular bases of these conditions will be presented.

Key Words: Membrane skeleton; red cell membrane; genetic disorders; hereditary elliptocytosis and poikilocytosis; hereditary spherocytosis; hereditary stomatocytoses; congenital dyserythropoietic anemias.

INTRODUCTION

The red cell membrane is made up of a lipid bilayer, studded with transmembrane proteins, and the membrane skeleton, or the erythrocyte skeleton, which laminates the inner surface of the bilayer and is connected with transmembrane proteins (Fig. 85-1). The main features of the major proteins and their genes are presented in Table 85-1. A set of hereditary conditions, called genetic disorders of red cell mechanical properties in this chapter, have been the subject of studies that have become classic. They include hereditary spherocytosis (HS), hereditary elliptocytosis (HE), and its aggravated form, hereditary poikilocytosis (HPP). Innumerable mutations have been found using the protein to gene approach. Interest has shifted to diseases in which the involved proteins are unknown. This applies to genetic disorders of the membrane permeabilility: overhydrated hereditary stomatocytosis (OHS), dehydrated hereditary stomatocytosis (DHS) and familial pseudohyperkalemias (FP). Some genes have been mapped but none have been individualized. Congenital dyserythropoietic anemias, types I and II (CDA I and CDA II, respectively), are considered within this chapter because the red cell membrane displays important secondary abnormalities. The gene whose mutations are responsible for CDA I has been identified.

CLINICAL FEATURES

The previously mentioned conditions share clinical signs common to hemolytic anemias: anemia, icterus, and splenomegaly, though widely varying in intensity. Some cases may produce fatal hydrops fetalis whereas others are discovered by chance. The main complications are gallstones and iron overload. Specific symptoms and complications are discussed along with the corresponding conditions. The incidence of the diseases also varies. HS is the most frequent condition, occurring in 1 in 2000 families among Caucasians. HE/HPP is less frequent in Caucasians (approx 1 in 5000), but is common in ethnic groups living in regions with malaria. The genetic conditions of membrane permeability to monovalent cations and CDAS are rare genetic disorders.

LABORATORY FINDINGS

Laboratory investigations include the determination of the following: red cell indices, serum bilirubin, haptoglobin, allo- and/or autoantibodies. Blood smears show a variety of abnormal shapes (Fig. 85-2). A bone marrow aspiration is indicated in specific cases (pronounced severity, CDAs). More specialized tests are discriminately conducted: osmotic gradient ektacytometry, which studies the osmotic and mechanical properties of the red cells in an increasing gradient of osmolarity, and polyacrylamide gel electrophoresis of red cell membrane proteins in the presence of sodium dodecylsulfate. The intraerythrocytic concentrations of monovalent cations and their fluxes across the membrane, in particular as a function of the temperature, should be performed in the genetic disorders of red cell membrane permeability. Light and electron microscopy of the bone marrow are appropriate in the investigation of the CDAs. The search for a Gilbert disease mutation and of the mutations responsible for genetic hemochromatosis will complete the checkup assessment, because their presence might aggravate the risks of gallstones or iron overload, respectively. In HS, HE/HPP, the responsible mutations are no longer elucidated on a routine basis. Most hospitals cannot afford the search, especially because the genes involved are often large (*SPTA1* gene), and some transcripts show complex splicing patterns (protein 4.1, among others). Additionally, knowledge of the mutations is not strictly necessary for management and may not bring about significant scientific information. This is the reason the last compendia of HS mutations were published some time ago. It remains that seeking mutations will be fruitful in cases with exceptional features. Elucidation of the mutations in freshly discovered genes

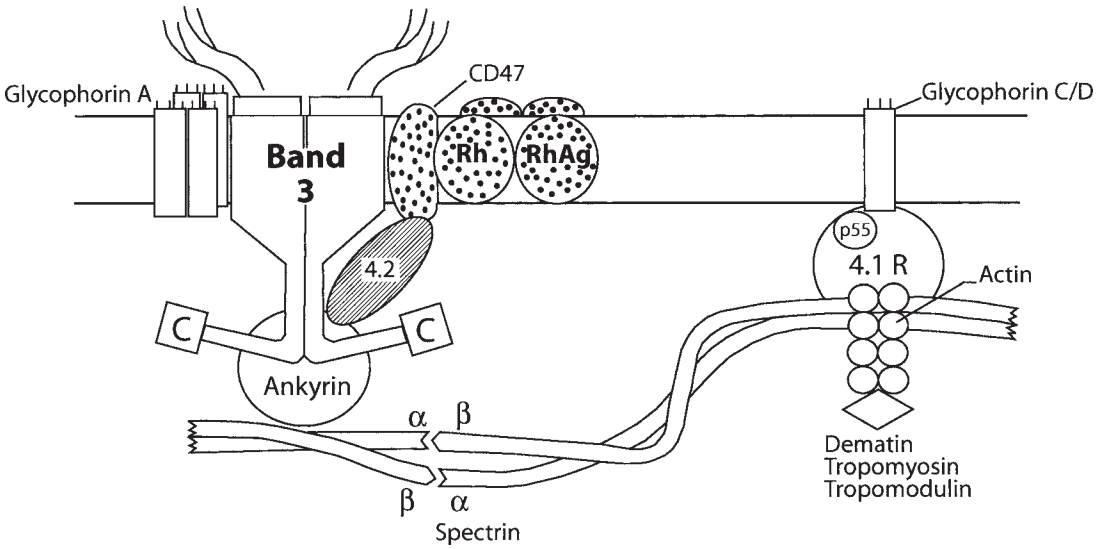

Figure 85-1 A simplified cross-section of the red cell membrane and skeleton. The band 3 complex, centered by a band 3 tetramer. The bulky part of each monomer represents the transmembrane segment, towered by a long polylactosaminoglycan chain that stems from asparagine residue 642. The stalky, hinged part of band 3 monomer accounts for its cytoplasmic domain and is the anchoring part of the protein. Among the anchored proteins are (i) ankyrin, which also binds to spectrin β-chain (*C*-terminal region); (ii) protein 4.2 (4.2); and (iii) a number of cytoplamic proteins (C: deoxyhemoglobin, glyceraldehyde-3-phosphate dehydrogenase, aldolase and others). Glycophorin A, which also exists as a tetramer, is decorated by numerous short, sialic acid-containing glycans. The Rh complex contains the Rh polypeptides (Rh) and the Rh-associated glycoprotein (RhAG), arranged as a heterotetramer, CD47, glycophorin B (not shown) and Landsteiner-Wiener antigen (not shown). A major finding is that CD47 interacts with protein 4.2, thus connecting the Rh complex and the band 3 complex into a macrocomplex. The protein 4.1 (4.1R) complex. Protein 4.1R interacts in a triangular fashion with glycophorin C, also decorated by numerous short, sialic acid–containing glycans, and p55. Additionally, protein 4.1R also interacts with one extremity of the spectrin tetramer (β-chain *N*-terminal region), in a region in which actin short filaments and actin-binding proteins are found as well. Spectrin: the $\alpha_2\beta_2$ tetramer of spectrin forms a dense network on the inner surface of the lipid bilayer. The α- and β-chains are antiparallel. Two dimers associate side by side, a process initiated at the nucleation sites on both chains, not far from the *C*-terminal and *N*-terminal regions of the α- and β-chains, respectively. Dimers associate head-to-head, *N*-terminal region of α-chains vs *C*-terminal region of β-chains, at the tetramerization (oligomerization) site in order to generate tetramers and high-order oligomers.

Table 85-1
Characteristics of the Main Membrane Skeleton Proteins and Their Genes Involved in Hereditary Disorders of the Cell Skeleton

Proteins	*Number of amino acids; molecular weights (kDa)*	*Number of monomers per red cell*	*Genes and their chromosomal locations*	*Gene sizes (kb) and exon numbers*	*Sizes of the messenger RNAs (kb)*
Spectrin α-chain	2429 281	242 000	*SPTA1* 1q22-q23	80 52	8.0
Spectrin β-chain	2137 246	242 000	*SPTB* 14q23-q24.1	>100 36	7.0
Ankyrin	1880 206	124 000	*ANK1* 8p11.2	>120 42	6.8; 7.2
Band 3	911 102	1 200 000	*SLC4A1* 17q12-q21	17 20	4.7
Protein 4.1	588 66	200 000	*EPB41* 1p33-p34.2	>250 >23	5.6
Protein 4.2	691 77	200 000	*EPB42* 15q15-q21	20 13	2.4

(CDA I) is the prime target, in view of further understanding of genotype/phenotype relationship.

PRIMARY GENETIC DISORDERS IN THE RED CELL MECHANICAL PROPERTIES

HEREDITARY SPHEROCYTOSIS The red cells in HS become mechanically fragile because the normal excess of membrane surface area (140 μm^2) relative to volume (85 μm^3) is diminished. This is owing either to the reduction in, or the lack of (in the most severe instances), a protein. The defect may be secondary. For example, spectrin reduction may stem from a primary deficiency in ankyrin. The red cell tends to acquire a spherical shape making it prone to premature sequestration by the spleen (*see* Fig. 85-2). Osmotic gradient ektacytometry shows that spherocytes are

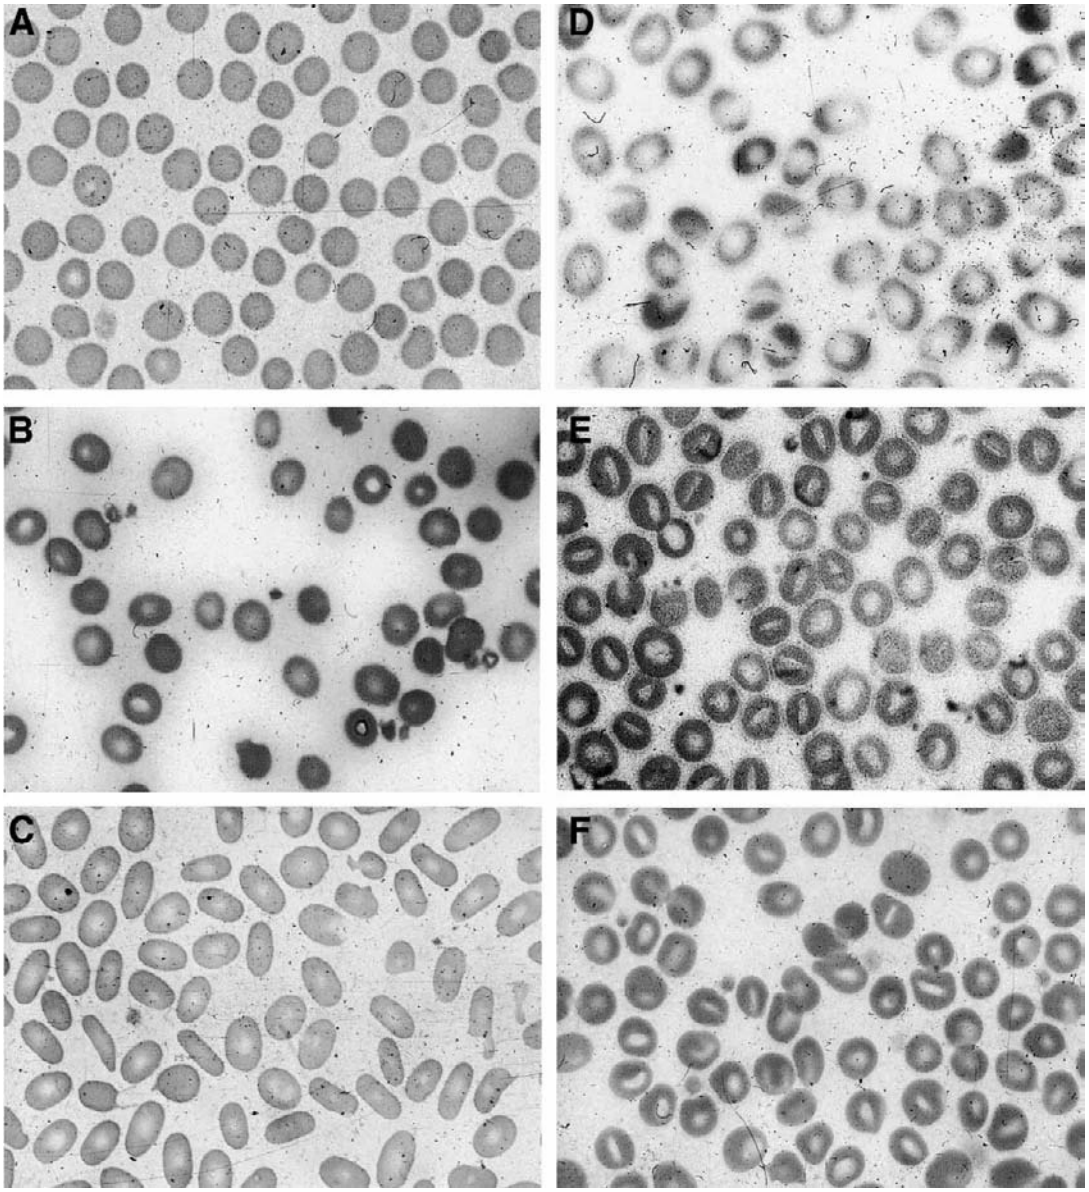

Figure 85-2 Gallery of normal and abnormally shaped red cells. **(A)** Normal red cells. **(B)** Spherocytes. **(C)** Elliptocytes with some poikilocytes. **(D)** Ovalostomatocytes in southeast Asian ovalocytosis. **(E)** Stomatocytes (OHS). **(F)** Stomatocytes (DHS).

osmotically fragile, in keeping with the increase in the percentage of hyperdense cells. Evidence is accumulating that the spheroid shape is, at least in part, acquired during erythropoiesis and not exclusively through the loss of microparticles once the mature erythrocyte has been launched into the circulation. Noteworthy, reticulocytes are small in genetically determined HS, whereas they are of normal size in spherocytosis of immune origin. In HS, parvovirus infections produce a dramatic, yet reversible, drop of the red cell count, acute erythroid aplasia combining with chronic hemolysis. HS in newborn and infants is the subject of ongoing studies; the symptoms are distorted by the "sluggish" phase exhibited by erythropoiesis during the first months of life.

Five genes can be basically responsible for HS (in the order of decreasing frequency): *ANK1*, *SLC4A1*, *SPTB*, *EPB42*, and *SPTA1* (*see* Table 85-1). The inheritance pattern is dominant for mutations in the three first genes and recessive for those in the two last. *De novo* mutations are common in the *ANK1* and the *SPTB* genes. Salient features have surfaced about these genes.

Mutations within the *SLC4A1* gene may produce a nonhematological disease, that is, distal renal tubular acidosis. As a general rule, mutations yielding the dominantly inherited variety of distal renal tubular acidosis fail to produce HS and *vice versa*.

Some remarkable mutations have been recorded, such as a mutation cancelling the initiation codon of spectrin β-chain (AUG→GUG; β-spectrin Promissão). These are natural mutations that pinpointed the protein (or one of the proteins) that links band 3 complex (including band 3, ankyrin, spectrin, glycophorin A, and protein 4.2, among others) and the Rh complex (including, in particular, of the Rh polypeptides, Rh-associated glycoprotein [RhAG], CD47, glycophorin B, and Landsteiner–Wiener antigen [LW]) (*see* Fig. 85-1). Briefly, in patients devoid of protein 4.2 or of band 3, CD47 was secondarily missing. In addition, it appeared that the glycosylation of some proteins (RhAG, in particular) was increased when protein 4.2 was missing. It was surmised that protein 4.2 or, in a secondary manner, CD47, could chaperone some glycoproteins. Their absence would disturb their trafficking toward

the membrane and alter their glycosylation. Mutations in some genes of the Rh complex lead to severe hemolytic anemia.

Natural HS mutations in the mouse have been found in the *Spna1* gene (chromosome 1), encoding spectrin α-chain (*sph*/*sph*, sph^{2BC}/sph^{2BC}, sph^{J}/sph^{J} mice), in the *Sptb1* gene (chromosome 12), encoding spectrin β-chain (*ja/ja* mouse), and in the *Ank1* gene (chromosome 8) encoding ankyrin (*nb/nb* mouse).

Mouse *Slc4a1* (chromosome 11) and *Epb4.2* (chromosome 2) genes have been knocked out. One of the mice with inactivated *Slc4a1* gene showed a hypercoagulable state. Orthologues of human genes have been found. In a remote biological context, these orthologues are likely to play different roles, and natural mutations will produce phenotypes distinct from the phenotypes in humans, most presumably. In the Zebra fish, mutation *retsina* alters the orthologue of human *SLC4A1* gene and produces a dyserythropoiesis. Nevertheless, it is questionable whether this dyserythropoiesis is similar or even close to human CDA II. In humans, the mature red cell membrane shows specific biochemical stigmata, which have not been investigated in the Zebra fish (nucleated) erythrocytes, and involve the glycan moiety of band 3. Also, the human CDA II candidate gene, at least one of them, has been mapped, which excluded the *SLC4A1* gene that is the polypeptide moiety of band 3. Still in the Zebra fish, mutation *merlot*/*chablis* involves the orthologue of human *EPB41* gene and generates a severe congenital anemia. Mutation *riesling* modifies the orthologue of human *SPTB* gene, that encodes β-spectrin, and yields HS.

There is a recurrent, weak *SPTA1* allele, allele α^{LEPRA}, which dramatically aggravates the expression of (rare) weak or null *SPTA1* alleles that would happen to occur *in trans*. In allele α^{LEPRA}, the c→t transition at position-99 of intron 30 results in the enhancement of an acceptor splice site at position-70, causing aberrant splicing, frameshift and premature termination of translation. In spite of this, 16% of the transcripts escape the abnormal splicing. Such a combination, the allele *in trans* of allele α^{LEPRA} being a virtually null allele of the *SPTA1* gene carrying a mutation in exon 51, has been encountered. The output of both abnormal *SPTA1* genes collapsed to 8% of normal. These observations underscore the fact that HS, unlike HE as next discussed, is in general the result of some reduced or missing red cell skeletal protein, analogous to the situation found in the thalassemias among hemoglobinopathies.

THE RH_{NULL} CONDITION As an extension of spherocytosis, it is pertinent to consider the recessive Rh_{null} condition, in which there is a failure of expression of all Rhesus antigen proteins on the red cell membrane. Hemolysis is associated with abnormally shaped red cells ranging from spherocytes to stomatocytes. There is a mild cation leak. A total of six proteins (CE and D Rh polypeptides, RhAG, CD47, LW, GP8), achieving the Rh complex, are absent from the membrane. If any core protein of the assembly, such as RhAG, is mutated, then the entire complex is unstable and/or cannot be trafficked to the membrane.

HEREDITARY ELLIPTOCYTOSIS AND ITS AGGRAVATED FORM, HEREDITARY POIKILOCYTOSIS Three genes may carry mutations causing HE and its aggravated form, HPP (*see* Fig. 85-2): the *SPTA1*, *SPTB*, and the *EPB41* genes (*see* Table 85-1). Except for the latter case in which protein 4.1 is reduced and exceptionally missing, spectrin mutations are basically "qualitative mutations" that alter specific functions within spectrin α- or β-chains. (The absence of either chain of spectrin would be past HS and would be lethal.)

Mutations in *SPTA1* and in *SPTB* genes are clustered in the 5′- and the 3′-regions of these genes, respectively. The spectrin α and β chains are organized in an antiparallel fashion, such that the mutations tend to affect the N-terminal region of the former and the C-terminal region of the latter. In spectrin α-chain, however, the cluster of mutations is somewhat stretched, covering approximately one-third of the entire polypeptide. The most upstream mutation (mutation Lograno; T→G, exon 2; I24S) lies in the first repeating segment (spectrin chains are made up of 106 amino acid repeating segments over most of their length). The mutation furthest downstream (mutation Saint-Claude; T→G, in the 3′-acceptor splice site of intras 19 ninth repeating segment, immediately upstream of the SH3 domain. By contrast, mutations in the *C*-terminal region of the β-chain are concentrated in the last (17th) repeating segment.

The previously mentioned mutations impede the head-to-head self-association process of spectrin dimers into tetramers or higher order oligomers. Mutations in the α-chain of spectrin that are situated more "inland" must act on oligomerization through ill-defined long distance interactions. The whole structure of the membrane skeleton is "loosened" and HE/HPP ensues.

Concerning *SPTA1*-related HE, a remarkable finding is that in virtually all kindreds, elliptocytosis may assume a mild to moderate presentation, depending on the intrinsic severity of the mutation, or a much more severe form (poikilocytosis in many instances). The aggravation takes place when a weak allele, coined allele α^{LELY}, lies *in trans* to the allele responsible for elliptocytosis, or the α^{HE} allele. Allele α^{LELY} is so common, with a 0.15–0.30 frequency in all ethnic groups investigated, that any kindred with a α^{HE} allele is likely to harbor allele α^{LELY} as well, making α^{HE}/allele α^{LELY} compound heterozygosity a most predictable combination among family members.

Allele α^{LELY} is made up of three mutations that have always been found in complete linkage disequilibrium: (1) A→G in exon 40; L1857V, (2) –12 g→t in intron 45, and (3) –12 g→a in intron 46. The first change is a functionally neutral polymorphism. The third one may appear alone in otherwise normal *SPTA1* alleles. The second mutation is the potentially deleterious alteration. It yields partial skipping of exon 45 (18 bp), corresponding to six amino acid residues, in exactly 50% of the transcripts. These six amino acid residues are essential for the onset of the side by side dimerization of an α-chain with its partner β-chain. It must be pointed out that the dimerization process takes place not far from the *C*- and the *N*-termini of spectrin α- and the β-chains, respectively, that is, at the end opposite to the self-association process. The absence of the exon 46-encoded six amino acids thus removes 50% of the α-chains issued from allele α^{LELY}, the remaining α-chains being expected to participate normally in the tetramerization process subsequently. This would appear to cause little harm, for α-chains are produced in large excess though the precise extent of this excess is not known with accuracy. Nonetheless, consider an α^{HE} allele lying *in trans* to allele α^{LELY}. In all likelihood, this dysfunctional α^{HE} allele will have a normal output and a normal ability to bind β chains, the HE mutation standing in the 5′ region. As a result, it will fill the room left by the reduced set of α-chains issued from allele α^{LELY}. More dysfunctional $\alpha^{HE}\beta$ dimers will thus be formed (rising from 50% to 66%) and the deficient self-association process will become more prominent. Eventually, the phenotype will be surprisingly aggravated (mimicking homozygosity). It often turns to poikilocytosis with torn red cells of every size and shape.

Some *SPTA1* HE mutations are frequent in malaria-infested regions, suggesting a potential protective effect against the disease. This is the case, among others, of the 648ins3 insertion in exon 4 (additional Leu in repeating segment 2), in sub-Saharan countries. Interestingly, this mutation followed migrations so that it is sporadically found in North Africa and Southern Italy as well, but not apparently in Spain. One explanation is that the mutation was absent when the Straits of Gibraltar was crossed but was present when the Straits of Sicily was passed by the North Africans.

Some odd situations may be encountered. For example, a case of HE was attributed to a double change in spectrin, both occurring close to the oligomerization site, but one (well known before) in the α-chain, and the other in the β-chain (β-chain ^{Kuwaitino}: C→A in exon 30; A2018D in repeat β17).

The sph^{Dem}/sph^{Dem} mouse carries a mutation in the *Spna1* gene (insertion of an intracisternal a particle element in intron 10 causing exon skipping and an in-frame deletion of 46 amino acids from repeat 5). It shows HE and thrombophilia. A mouse in which the *EPB41* gene was knocked out has been obtained.

The 4.1 (–) trait results from the absence of one haploid set of protein 4.1. It is symptomless. Very rare cases of totally missing protein 4.1 produce a rather severe poikilocytosis. Missing protein 4.1 results in the absence of glycophorin C and protein p55, which has hinted at a protein complex, now characterized.

SOUTHEAST ASIAN OVALOCYTOSIS Southeast Asian ovalocytosis (SAO) is a dominantly inherited, asymptomatic trait that alters the red cell morphology and mechanical properties in the heterozygous state. Homozygosity for the SAO allele has never been encountered and is thought to be lethal. SAO is widespread among various ethnic groups in Papua New Guinea, the Philippines, and Indonesia, resulting from its protective effects against malaria, and has diffused round the Indian Ocean shore in the wake of migration trails. From there, a few carriers reached Europe. Smears display unmistakable ovalostomatocytes (*see* Fig. 85-2). The genetic alteration is a 27 nucleotide deletion in the *SLC4A1* gene. As a consequence, amino acids 400–408, which stand at the very junction of the cytoplasmic and membrane domains of band 3 (*see* Fig. 85-1), are missing. Such a molecular defect is thought to be responsible for the cellular rigidity associated with ovalocytosis. The deletion is in linkage disequilibrium with the so-called "Memphis I" polymorphism (AAG→GAG; K56E).

GENETIC DISORDERS OF RED CELL MEMBRANE PERMEABILITY

There are a series of further conditions in which the main pathology lies not in a defect in the mechanical strength of the membrane, but in its permeability, especially to the cations Na^+ and K^+, an abnormality that can compromise the osmotic integrity of the cell and cause premature lysis. These are collected under the title, "hereditary stomatocytoses and allied conditions", reflecting the name given to the first pedigree, but subsequent experience has shown that there are leaky cases without stomatocytes, and that there are very stomatocytic cases without a cation leak.

The morphological abnormality "stomatocytosis" (*see* Fig. 85-2) is almost certainly secondary to expansion of the inner leaflet of the lipid bilayer. It is not clear why these leaky cells should show this feature; it is not simply the result of the cation leak, for a leaky cell swells up into a sphere before bursting. Theoretically, stomatocytosis could occur either because of a gross abnormality in membrane lipid composition, or because there is an imbalance in the forces that push lipids between one leaflet and the other, the best characterized of which is the aminophospholipid flippase.

There are a series of forms of these diseases, which can be distinguished on a number of criteria, as follows: *severity*, both of the hemolysis and the magnitude of the cation leak; *cell hydration*, which can be increased or decreased, as can easily be shown by osmotic gradient ektacytometry; the *effect of temperature on the passive leak*; the presence of the 32 kDa membrane protein "*stomatin;*" and the *presence of perinatal ascites* in a pedigree. The way in which these criteria apply is clarified below in the discussion of these conditions' different forms.

OVERHYDRATED HEREDITARY STOMATOCYTOSIS AND THE STOMATIN PROTEIN OHS is the most severe of these conditions and the first to be described. The patients show obvious hemolytic anemia (hemoglobin 8–12 g/dL) with jaundice and gallstones with a catastrophic diffusional, Fick-type cation leak.

There is a major molecular abnormality in these cells. A 32-kDa protein, now known as stomatin after this disease, is missing from the membrane. The human gene sequence is known but there does not seem to be any mutation in the gene in these patients. Mice in which the *Epb72* gene (encoding stomatin) has been inactivated fail to show stomatocytosis. The protein is ubiquitously distributed, from Archaea to humans, and is found in many (but not all) human cells. In OHS, it seems that the protein is lost as the cell matures through the reticulocyte stage. Whether this happens because of a structural abnormality in another supporting protein (as in Rh_{null} syndrome seen above), or perhaps because of the cation leak, is unknown. The function of the stomatin protein is likewise unknown. It is associated with cholesterol + sphingomyelin-rich "rafts" in the membrane.

DEHYDRATED HEREDITARY STOMATOCYTOSIS Also known as "hereditary xerocytosis," DHS is a milder condition than OHS, and the cells show a much less marked cation leak. As the name implies, the cells show a high mean corpuscular hemoglobin concentration. It is by far the commonest of this group. It is identical to the condition first labeled, "hereditary hyperphosphatidylcholine anemia," and typically phosphatidylcholine levels in the membrane are high. This condition maps to a locus on chromosome 16, but the responsible gene is not yet known.

In a minority of pedigrees, DHS can be associated with a very unusual syndrome of perinatal ascites, in which the fetus shows major fluid accumulation, especially in the peritoneal cavity. This tendency gradually abates after delivery and is gone after 6 mo of life or less. Ascitic taps are commonly required, either *in utero* or after delivery.

Some of the pedigrees show abnormal temperature effects in the passive leak, manifesting as pseudohyperkalemia, discussed later. Like OHS, DHS does not respond well to splenectomy, and after this procedure the patients show a tendency to thrombosis, which can be difficult to treat with anticoagulants and can be life threatening.

CRYOHYDROCYTOSIS This condition shows a mild hemolytic state, only occasionally requiring transfusions, with some stomatocytes on the film. The red cells show a blatant temperature effect. If left in the refrigerator overnight, the cells lyse dramatically. Like the pseudohyperkalemia that is found in some of the other variants, this cold lysis is secondary to an abnormality in the temperature dependence of the passive leak to Na^+ and K^+, which is markedly enhanced at 0°C compared with normal (Fig. 85-3), although the Na^+-K^+ pump is effectively silenced at these temperatures. The cells also lose K^+ and gain Na^+, because of similar temperature effects at room temperature. There is a prelytic

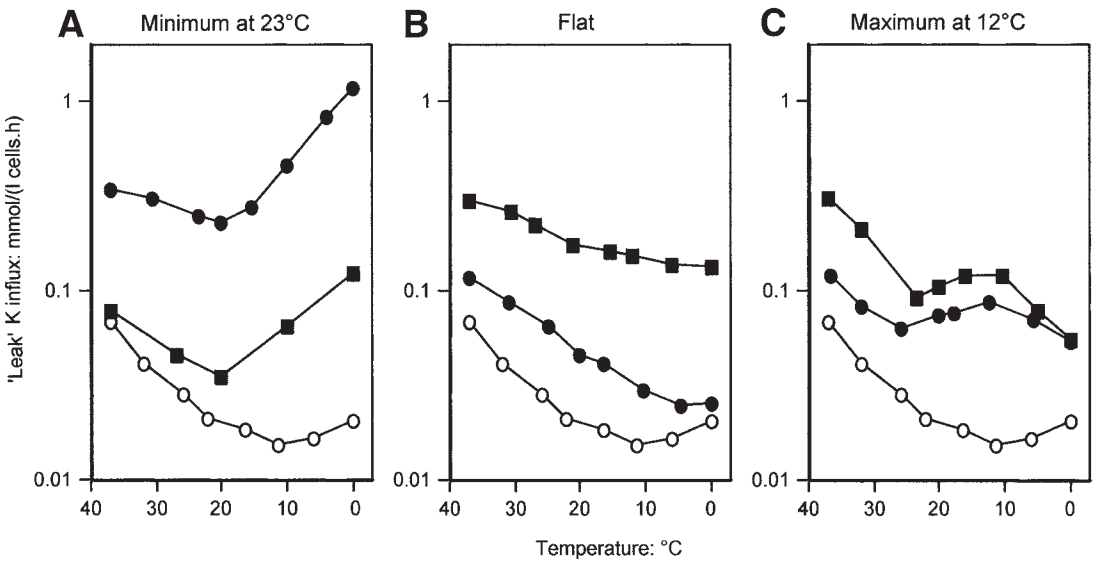

Figure 85-3 Different temperature variants among the hereditary stomatocytosis and familial pseudohyperkalaemia variants. K^+ influx, in the presence of ouabain and bumetanide, was measured using Rb as a tracer. In all panels, normals, which show a min. at about 8°C, are shown by open circles. **(A)** shows cryohydrocytosis "Hemel" (filled circles) and familial pseudohyperkalemias (FP) "Cardiff" (filled squares). **(B)** shows the "flat", "shallow slope" profiles: DHS "Blackburn" (filled squares) and FP "Edinburgh" (filled circles). **(C)** shows the "shoulder" profile: FP "Falkirk" (filled squares) and FP "Chiswick" (filled circles).

leak of Na^+ and K^+ (giving pseudohyperkalemia) before the cation abnormality becomes critical and the cell lyses, losing its entire K^+ content to the plasma.

FAMILIAL PSEUDOHYPERKALEMIA There are a series of hematologically trivial conditions that present via the chemical pathologists with unpredictably high plasma potassium concentrations, not associated with acidosis or renal failure or Addisonian stigmata. An artifact is suspected and the diagnosis of red cell pseudohyperkalemia can be revealed by a simple storage test on red cells at room temperature. It is a reflection of the major heterogeneity in all of these conditions that three variants can be distinguished from six unrelated pedigrees in the United Kingdom. The difference lies in the exact temperature dependence of the "leak" cation flux, most conveniently measured as the ouabain + bumetanide-resistant K^+ influx. The results are shown in Fig. 85-3. The normal curve shows a minimum at about 8°C; the "Edinburgh" pedigree (filled circles) shows a flat, shallow slope pattern; the "Chiswick" pattern shows a min. at 30°C, with a max. at 12°C, followed by a further fall. In the Cardiff variant, the temperature profile shows a min. at 23°C. In all of these cases, whereas the leak shows these abnormal patterns, the NaK pump to which the leak is opposed always shows the same monotonic fall with temperature. At room temperature, the leak and pump are not balanced and the red cell loses K^+ to the plasma, giving "pseudohyperkalemia." In all of these FP cases, the leak at 37°C is not markedly abnormal. The molecular basis of the leak in these conditions is not understood. One pedigree (Edinburgh) maps to the chromosome 16 locus as DHS.

CONGENITAL DYSERYTHROPOIETIC ANEMIAS

CONGENITAL DYSERYTHROPOIETIC ANEMIA, TYPE I CDA I is a rare genetic condition, and is the first CDA for which the responsible gene has been identified in humans. It includes dysplastic changes in the late erythroid precursors: internuclear chromatin bridges (Fig. 85-4), spongy heterochromatin, and invagination of the nuclear envelope carrying cytoplasmic organelles into the nucleus. The bone marrow is hyperactive, but the output of red cells is decreased. CDA I may be associated with a series of dysmorphologies of the skeleton. The severe ineffective erythropoiesis leads to iron loading.

Red cells that succeed in getting into the circulation show a number of altered shapes, such as elliptocytosis, dacryocytosis, and poikilocytosis. This indicates that the mature erythrocytes themselves are abnormal and account for the hyperhemolysis that aggravates the anemia of central origin. The red cell morphological changes are associated with a small but significant reduction of protein 4.1R, which is sufficient to alter the erythrocyte shape. It is part of the dyserythropoietic process, but must occur substantially downstream in the chain of events stemming from the primary genetic lesion. They provide an unknown yet simple and reliable aid to the diagnosis.

The *CDAN1* gene whose mutations are responsible for CDA I was mapped to chromosome 15 q15.1–15.3. Homozygosity mapping was used in a cluster of 45 highly inbred Israeli Bedouins living in the Negev Desert and constituting an isolate. The *CDAN1* gene has been identified. It is made up of 28 exons and encodes a ubiquitously expressed mRNA of 4738 bases. The encoded protein has been termed codanin-1 and contains 1226 amino acids. It is expected to be *O*-glycosylated. The first 150 residues of codanin-1 display sequence similarities with collagens and contain two short segments showing a weak resemblance with microtubule-associated proteins, MAP1B (neuraxin) and synapsin. Putative mouse and *Fugu* orthologs of codanin-1 were identified. The functions of codanin-1 are yet to be discovered.

In a different line, a treatment of CDA I has been found serendipitously. α-interferon, which was used to treat hepatitis C in a patient with CDA I, was also effective in controlling the CDA. Thereafter, a number of reports have confirmed the efficacy of α-interferon in CDA I, but the mechanism of action of interferon-α2b remains an enigma.

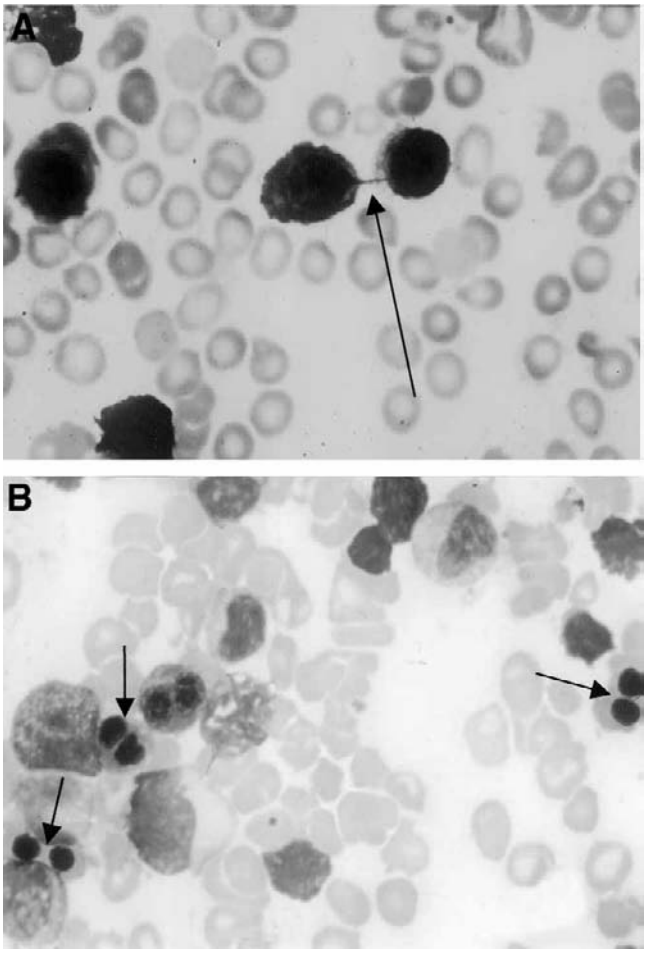

Figure 85-4 Eythroblasts in congenital dyserythropoietic anemia, types I and II (CDA I and CDA II). **(A)** CDA I. The most conspicuous aspect is the interchromatin bridge, which links two erythroblasts (arrow). **(B)** CDA II. The main feature is the numerous binucleated erythroblasts (arrows).

CONGENITAL DYSERYTHROPOIETIC ANEMIA, TYPE II

CDA II is a rare genetic condition. It is characterized by the presence of a number of binucleated erythroblasts (*see* Fig. 85-4). CDA II, which is a purely hematological condition, displays major changes in the *N*-glycosylation of band 3. Such a stigmata is easy to show and is pathognomonic of CDA II. The *CDAN2* gene has been mapped to 20q11.2, but not yet identified. Given the glycosylation abnormalities of band 3 and of membrane glycosphingolipids, too, it has been thought that some enzymes involved in the building-up of the glycan moiety were the primarily mutated proteins. Despite much effort and the exclusion of some genes, the culprit remains to be identified. As mentioned, it is likely that human CDA II is but loosely related to the CDA seen in the Zebrafish.

86 Paroxysmal Nocturnal Hemoglobinuria

Bruno Rotoli, Khedoudja Nafa, and Antonio M. Risitano

SUMMARY

Paroxysmal nocturnal hemoglobinuria (PNH) is a clonal hematopoietic disorder arising from a mutation in the X chromosome-linked *PIG-A* gene. The mutated cell is unable to build the GPI anchor, which is needed to bind a number of molecules on the outer cell surface. Some GPI-linked molecules are responsible for cell defense against activated complement; this is why PNH red cells are hypersensitive to complement attack and are continuously destroyed in the circulation, with paroxysmal exacerbations. However, many other defects are present on PNH cell membrane, involving red cells, granulocytes, monocytes, and platelets, leading to tendency to infection and thrombosis. This review highlights the molecular pathophysiology of the disease and analyses the mechanisms responsible for the expansion of a hematopoietic clone, which is paradoxically less vital as compared with normal cells.

Key Words: Aplastic anemia; bone marrow failure; CD55/DAF; CD59/MIRL; clonal hematopoiesis; complement-mediated lysis; escape theory; GPI anchor; GPI-linked molecules; intravascular hemolysis; pancytopenia; paroxysmal nocturnal hemoglobinuria; *PIG-A* gene; T-cell clonality; thrombophilia.

INTRODUCTION

Paroxysmal nocturnal hemoglobinuria (PNH) is a complex hematological disorder probably first described three centuries ago, and regarded as a mystery until the 1980s, when most of its pathophysiology was elucidated, followed by the 1990s, when the underlying molecular defect was finally unraveled. The original denomination, PNH, stresses only one component of the disease (i.e., a hyperhemolytic state). A more complete updated definition could read as follows: an acquired blood disorder characterized by the expansion of one or a few hematopoietic cell clones carrying a mutation in the X-linked phosphatidylinositol glycan class A *(PIG-A)* gene, which renders the cells unable to produce the glycosyl-phosphatidylinositol (GPI) anchor, against a background of a reduced bone marrow activity. Some landmarks in the history of understanding this disorder are listed in Table 86-1. Because of its complex pathophysiology, the disease has been variously classified among hemolytic anemias, myelodysplasia, myeloproliferative disorders or bone marrow failure syndromes; indeed, PNH has some features of each of these. This chapter reviews advances on genetic and pathophysiologic issues of PNH, including a summary of clinical, diagnostic, and therapeutic aspects.

GENETIC BASIS

Although this disease has a well-recognized genetic cause, it is neither inherited nor transmitted to the progeny. Indeed, it is a clonal disorder arising from a somatic mutation in the *PIG-A* gene of an early hematopoietic progenitor.

THE *PIG-A* GENE AND THE GPI ANCHOR *PIG-A* is a housekeeping gene located on the short arm of the X chromosome (Xp22.1), the cDNA of which was first isolated in 1993 through expression cloning and complementation of GPI-deficient cell lines. The organization of the genomic gene was established by Bessler in 1994 (Fig. 86-1). This gene encodes for a protein involved in the synthesis of the GPI anchor, a molecule used by cells to bind a number of proteins on their own outer surface without a transmembrane portion. The functional implications of the GPI anchoring of proteins are not completely understood; they include ease of assemblage and shedding, lateral mobility, capping, involvement in endo-, exo-, and potocytosis (a clathrin-independent form of endocytosis and recycling). There are examples of proteins existing in both transmembrane and GPI-linked configuration, as a result of various molecular mechanisms. The adhesion molecule leukocyte function associated (LFA)-3 (CD58) is encoded by a gene that may undergo alternative splicing producing two different polypeptides, one of which provides the site for GPI-anchor attachment. Instead, two alternative isoforms of the Fc-γ receptor III (CD16) result from two different genes expressed in a tissue-specific fashion (GPI-linked in neutrophils and transmembrane in natural killer [NK] cells). The strongest evidence that this type of membrane anchoring is important in cell biology is its high conservation among eukaryotic cells; indeed, it is found even in yeast and trypanosome. The protein encoded by *PIG-A*, in combination with at least two other proteins, is essential in the first step of the complex GPI-anchor biosynthesis pathway, i.e., in the transfer of *N*-acetyl glucosamine to phosphatidyl inositol (Fig. 86-2). By experimental mutagenesis, GPI-deficient cell lines showing defects in any of the various metabolic steps have been produced; however, the study of PNH has shown that the same early step is impaired in all patients, and all patients have a mutation in the *PIG-A* gene. The explanation for this finding is that among the various genes involved in the GPI-anchor synthesis, *PIG-A* may be the only one that is X-linked. As a consequence, a single mutation in that gene will produce an abnormal cell in either sex: males

AchE, acetylcholinesterase; DAF, decay accelerating factor (CD55); GPI, glycosyl-phosphatidylinositol; NAP, neutrophil alkaline phosphatase; PIG-A, phosphatidylinositol glycan class A; PNH, paroxysmal nocturnal hemoglobinuria.

have only one allele and females have only one functional allele (as result of X-chromosome inactivation). Although females have two *PIG-A* alleles, only half of the mutation will occur in the functional X; thus, the risk of having the disease is the same in both genders. Because a defect causing a metabolic block is generally recessive, it is unlikely (although not impossible) that a double mutation targeting both alleles of an autosomal gene in the same cell may occur in vivo.

***PIG-A* MUTATIONS IN PNH** Practically all types of mutations have been found in the *PIG-A* gene of PNH cells: small deletions or insertions producing frameshift, nucleotide substitutions resulting in stop codon, missense mutations causing amino acids substitutions or new sites for alternative splicing, large deletions. Most of the mutations occur in exon 2, probably because it is the largest; however, no particular clustering of mutations has emerged, and almost all mutations are unique to each patient (private mutations) (*see* Fig. 86-1).

Comparing the type of mutations found in PNH with those found in glucose-6-phosphate dehydrogenase deficiency, another (this time inherited) X-linked disorder of a housekeeping gene, shows a clear discrepancy. In PNH, a vast majority of mutations have extremely severe functional consequences, (i.e., production of truncated proteins), whereas missense mutations are rare; in glucose-6-phosphate dehydrogenase deficiency almost all mutations are missense, leading to single amino acid substitutions with conserved (although possibly altered) function. Two considerations may be relevant to this discrepancy: (1) In hereditary disorders, a complete absence of the product of a housekeeping gene is probably lethal; thus, only mutations with residual activity are seen. By contrast, if a mutation is somatically acquired, it will not affect organ development and, once occurred, it will affect the genetic make-up of only a small fraction of somatic cells, which may survive although with some functional abnormality. (2) If missense mutations in PNH are rare, this means that for a clonal expansion to take place, the gene must be seriously damaged. Indeed, the rare missense mutations found in PNH patients are associated with a marked reduction of GPI-linked proteins, indicating that they affected mRNA stability or protein function, or both.

MOLECULAR PATHOPHYSIOLOGY

The *PIG-A* mutation responsible for PNH arises in a multipotent hematopoietic stem cell, which is capable of differentiating along several lineages; maturation along erythroid, myeloid, and megakaryocytic lineages is almost always preserved, whereas lymphoid differentiation (along B- and/or T lineages) is observed in a minority of patients. As a consequence of the damage of the GPI-anchor synthesis pathway, all the affected cells in any state of maturation are deficient in all the GPI-linked molecules, and deficiency is often complete. More than 20 different proteins sharing the GPI-anchoring system have been described on the surface of human blood cells (Fig. 86-3). The understanding of their functional significance is limited; in many cases, the study of PNH patients or cells was an important source of information.

HEMOLYSIS IN PNH PATIENTS Intravascular hemolysis is the most characteristic clinical feature of PNH; it is because of increased susceptibility of PNH erythrocytes to complement-mediated lysis. This abnormality is caused by the absence on red cell membrane of two complement-regulatory proteins, CD59/MIRL (membrane inhibitor of reactive lysis) and CD55/DAF (decay accelerating factor), which are both GPI-linked. This membrane abnormality renders PNH erythrocytes extremely sensitive to complement activation, which translates in vivo into a hemolytic state and in vitro into red cell destruction in acified serum (Ham test). A low level of complement activation is probably a constant physiologic phenomenon, which is greatly amplified during inflammatory or infectious diseases; thus, PNH erythrocytes are chronically lysed with paroxystic exacerbations. It is unclear why exacerba-

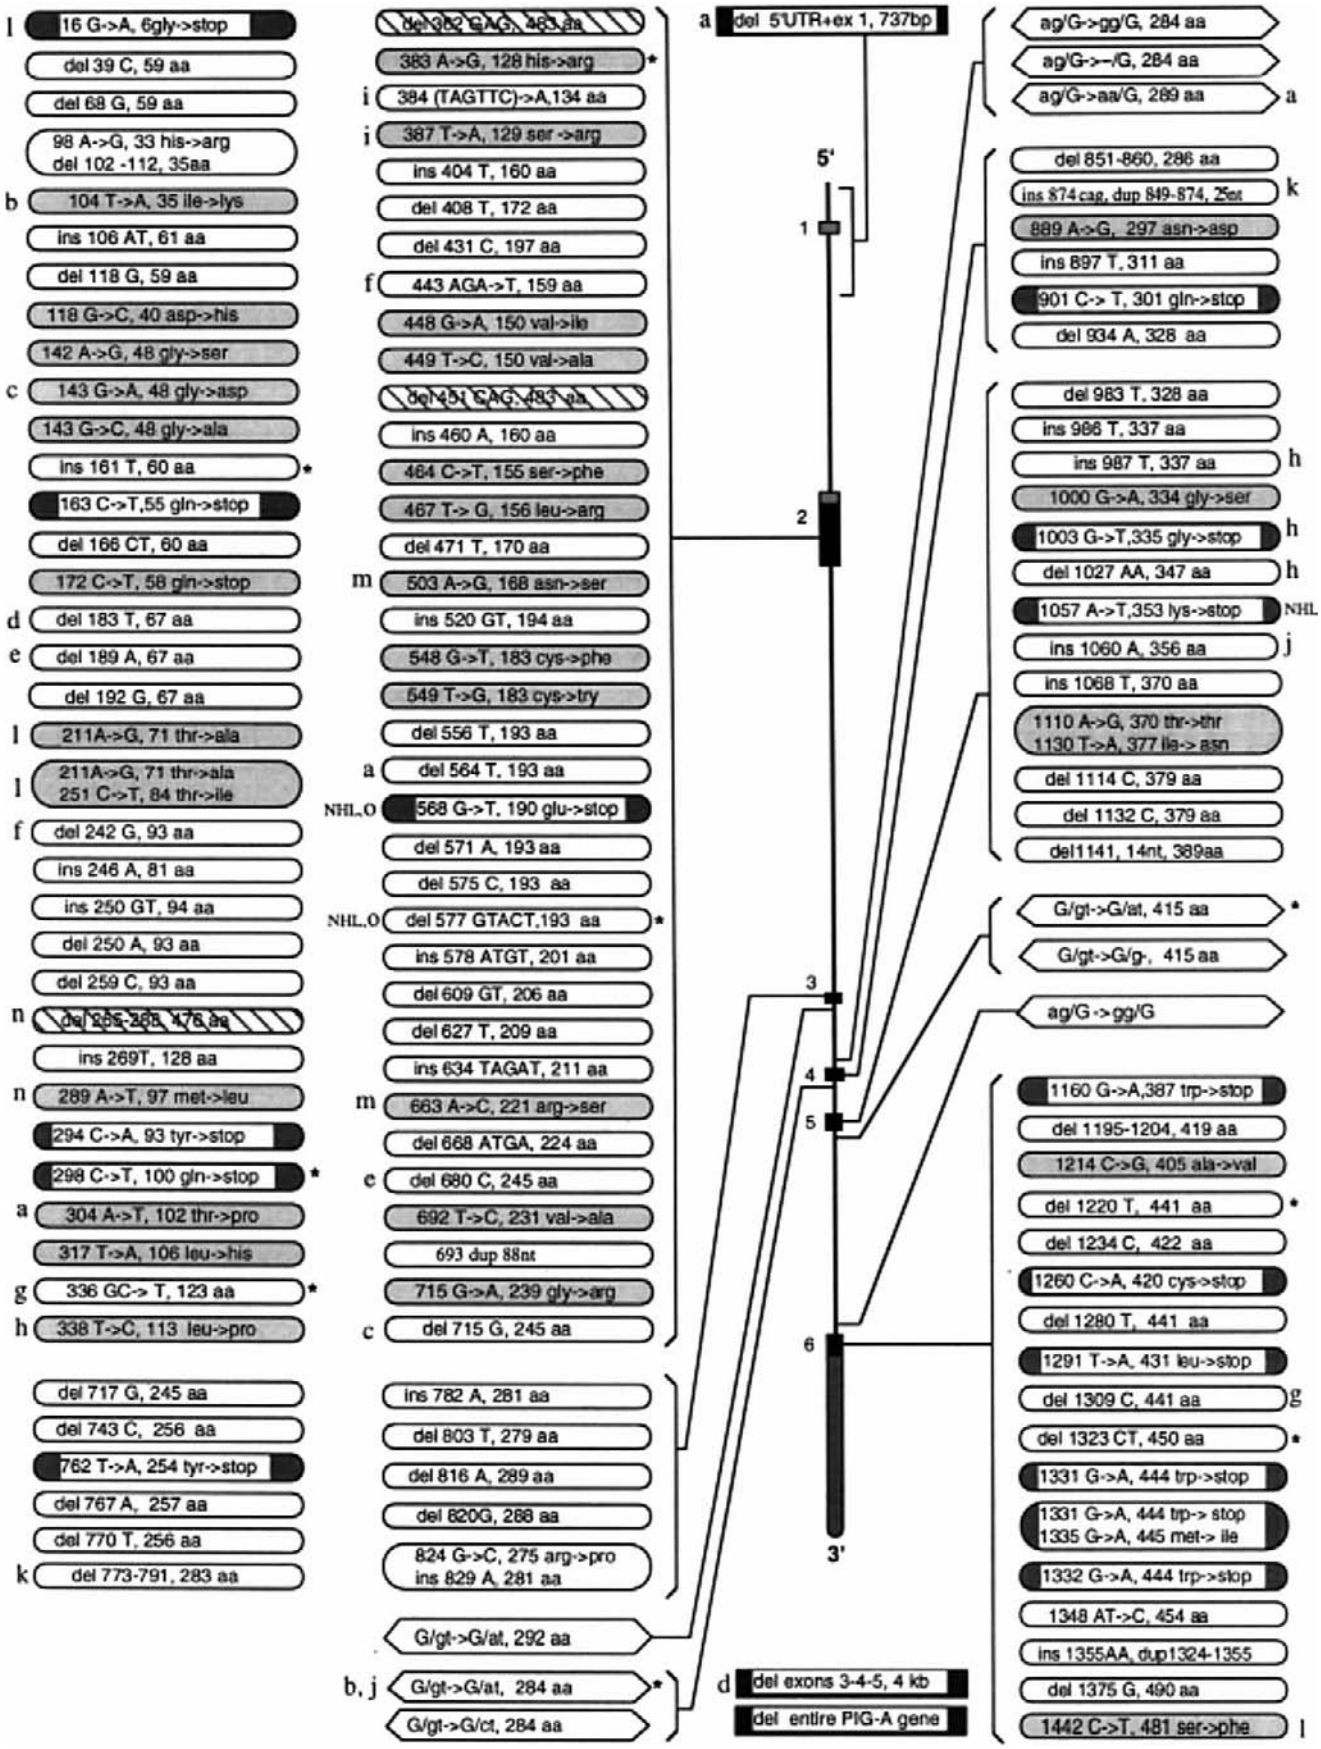

Figure 86-1 Phosphatidylinositol glycan class A gene structure and mutations. The genomic gene spans approx 17 kb. Exons (thick blocks, numbered) and introns (thin lines) are represented in the central bar; untranslated exon regions are in gray. Three mRNA transcripts arising from alternative splicing were found by Bessler et al., (1994) who also described an unproductive pseudogene mapped to 12q21. Mutations found to

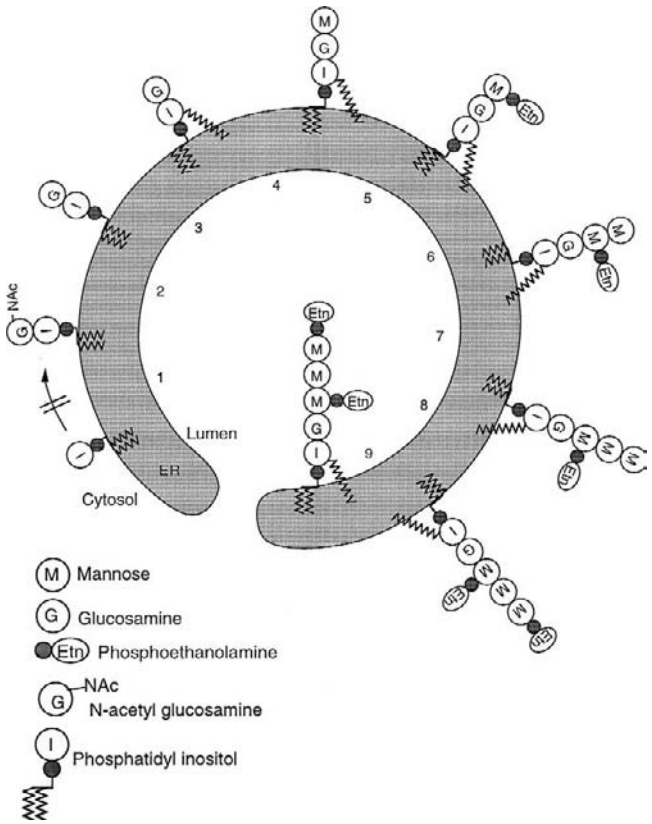

Figure 86-2 Glycosyl-phosphatidylinositol-anchor biosynthesis. The anchor synthesis is a multistep (1–9) process that occurs in the endoplasmic reticulum (ER), starting on the cytoplasmic side, then flipping into the luminal side. The anchor is transferred *en bloc* on the C-terminal of the protein, which is cleaved of a short sequence of 20–30 amino acids led by a signal sequence called ω. Although GPI-deficient cell lines obtained by experimental mutagenesis have shown defects in any step of the synthesis, all paroxysmal nocturnal hemoglobinuria patients studied so far are defective in the first step (⊣⊢).

tions occur mainly during the night. In a functional hierarchy, CD59 plays a major role, as discovered by studying rare inherited conditions in which a single molecule is lacking. A CD59-deficient patient had a PNH-like picture, whereas subjects deficient of CD55 on red cell membrane (those carrying the rare Inab blood group phenotype) show no hyperhemolysis. Although CD59 and CD55 are deficient also on leukocytes, there is no evidence of reduced leukocyte life-span in PNH patients, probably because nucleated cells have an additional transmembrane (i.e., non-GPI-linked) molecule (CD46) that protects them from complement activation. Sensitivity to complement is the best known, but not the only defect, of PNH cells. Table 86-2 lists other molecules that are deficient and their specific function, when known.

HEMATOPOIESIS IN PNH PATIENTS A wide spectrum of clinical picture emerges when several PNH patients are compared with each other, ranging from almost asymptomatic individuals to severely ill subjects. Several mechanisms are responsible for such phenotypic heterogeneity:

1. The coexistence of a variable percentage of normal cells, which are progeny of residual GPI+ stem cells.
2. A selective destruction of particles succumbing to the activated complement attack (this is particularly true for PNH red cells after a paroxysm of hemolysis).
3. The type of molecular lesion in the *PIG-A* gene, leading to PNH cells with a variable sensitivity to complement-mediated lysis (PNH II and PNH III populations).
4. The degree of commitment of the stem cell having the *PIG-A* mutation; if the mutation occurs in a totipotent stem cell, even lymphocytes will carry the PNH defect, whereas a mutation in a multipotent myeloid cell will not produce PNH lymphocytes.

In theory, a mutation in a more committed progenitor could generate a monolineage PNH; however, patients with a purely myeloid *PIG-A*-deficient clone, giving rise to only granulocytes and/or platelets may remain undetected, as the sparing of the erythroid lineage implies lack of the typical symptoms suggesting PNH.

PNH hematopoiesis is certainly clonal, but clonal does not necessarily mean monoclonal. Initial observations that more than one abnormal cell population may be present in a single PNH patient were first inferred by functional studies based on different sensitivity to complement-mediated lysis and then by flow cytometry in the early 1990s. The final confirmation of such an unusual pattern came from DNA analysis, which documented the simultaneous presence of two or even more different *PIG-A* mutations in several PNH patients, each originating a distinct multilineage PNH clone. A mechanism that may explain the expansion of more clones carrying the same functional defect but arising from different mutations is selection. A theory based on this mechanism was developed for PNH in 1989 and termed the "relative advantage," later the "escape" hypothesis; it is supported by several pieces of circumstantial evidence, but still requires a direct confirmation. According to this theory, a mutation in the *PIG-A* gene might be a fairly common phenomenon, which has no biological consequences, because the mutated cell has no chance of expanding in the presence of a vast majority of normal cells. However, if normal hematopoiesis is inhibited by a primary cause (as in idiopathic aplastic anemia [AA]), and if the killing mechanism is directly or indirectly mediated by one or more proteins that are GPI-linked on the surface of progenitor cells, *PIG-A* mutated cells survive, undergoing clonal expansion. Because only cells severely GPI-deficient are able to survive, in PNH serious molecular lesions (i.e., frameshift, stop codon, and deletion) prevail over single amino acid substitutions. Several observations indirectly support this theory; in patients with a B-cell lymphoproliferative disorder treated by Campath-1H (a monoclonal antibody that kills lymphocytes targeting the GPI-linked protein CD52), severely GPI-deficient T cells emerged; they were cloned and showed mutations in the *PIG-A* gene. When a banked blood specimen that had been drawn before monoclonal antibody treatment was searched for the *PIG-A* deficient clone, a few cells carrying the same molecular defect were detected. On Campath-1H discontinuation, the GPI-deficient T cells gradually disappeared. Thus, this model elucidates most features of the PNH pathogenesis: the preexistence of *PIG-A*

Figure 86-1 ***(Continued)*** date are displayed. ⬭: small deletion or insertion and resulting in frameshift and truncated protein; ⬭: nonsense mutation; ⬭: mutation causing altered splicing; ▭: vast deletion; ▨: deletion, in frame; ▬: missense mutation. *Mutations found in more than one patient. A small letter outside the box identifies multiple mutations found in a single patient. Only one polymorphism has been described (55C→T, 19 arg→trp).

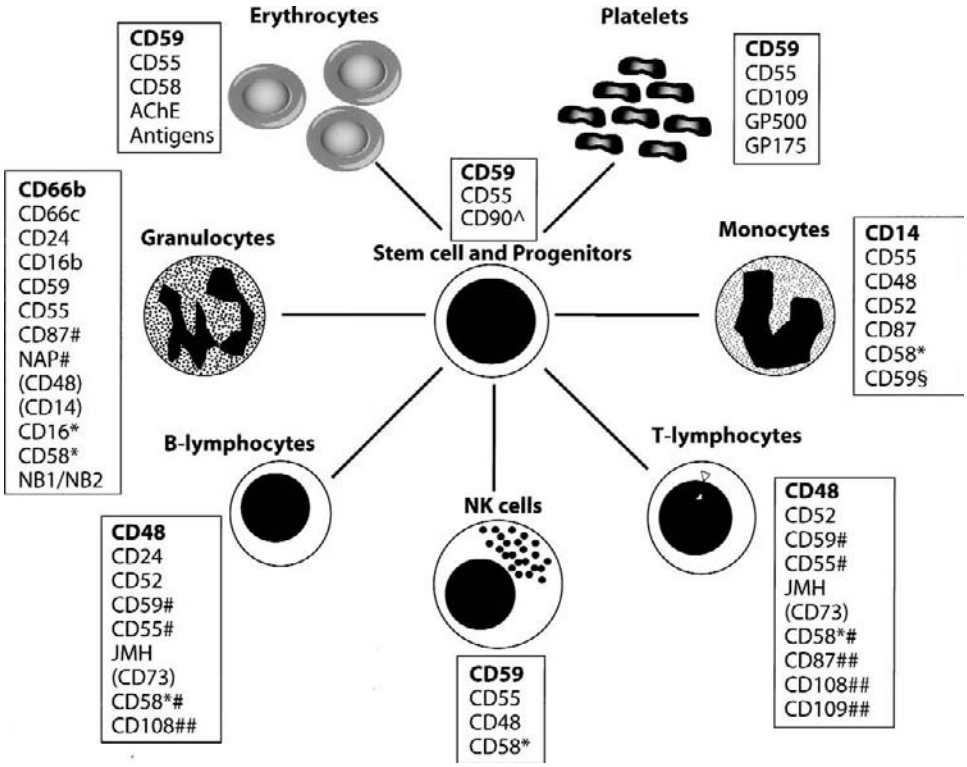

Figure 86-3 GPI-linked molecules on blood cell surface. For each cell type, the molecules are listed in order of sensitivity for detecting deficient cells (in bold, highest sensitivity; molecules in parenthesis, weak expression; *, also transmembrane; #, increased on cell activation; ##, expressed only on cell activation. ^, approx 25% of early hematopoietic progenitors express CD90, which is the analog of murine Thy-1. §, in our hands, CD59 was often present on PNH monocytes. A few molecules have been omitted that need better knowledge of their lineage-restricted expression (ULBPs, PRV-1, PrP^c, TRAIL-R3).

mutated cells, their expansion under a selective pressure negatively acting on normal cells by a mechanism to which the mutated cells are resistant (for the absence of CD52), and the gradual disappearance of the mutated clone once the selective mechanism has been removed. The existence of a few (10–50 cells per million) PNH cells in peripheral blood of healthy individuals has been documented by analyzing cytometrically a large number of granulocytes. A nested PCR technique confirmed the clonality of these cells by identifying the specific *PIG-A* mutation. The absence of an intrinsic genomic instability in PNH patients has been shown by comparison with another bone marrow failure disorder, Fanconi anemia (FA). The measurement of *PIG-A* spontaneous mutation rate in B-lymphoblastoid cell lines derived from PNH or FA patients showed a normal rate of mutation in PNH patients, contrasting with a markedly elevated rate in FA patients. Thus, the development of PNH cannot be attributed to increased risk of *PIG-A* mutations, but only to the expansion of pre-existing rare mutant clones. The finding that FA patients, although having both more *PIG-A* mutated stem cells and reduced marrow cellularity, do not develop PNH, strongly supports the escape theory: because bone marrow failure in FA is owing to a mechanism that does not involve GPI-linked molecules, there is no growth advantage for the mutated cells.

Murine Models of PNH To explore experimentally the growth of PNH hematopoietic stem cells, murine models have been generated. A complete knockout animal could not be produced, demonstrating that *pig-a* is necessary for embryogenesis. When the mouse *pig-a* gene was inactivated in embryonic stem (ES) cells with the conventional knockout gene targeting technique, in vitro studies demonstrated that *pig-a* deficient ES cells were able to differentiate into mature cells of various hematopoietic lineages, showing that *pig-a* is not necessary for differentiation and maturation of hematopoietic progenitors. When tested in vivo, with chimeras obtained by inserting *pig-a* knocked out ES cells during early embryonic development, in the few surviving chimeras the proportion of GPI-deficient blood cells was low at birth and decreased with aging, proving that there is no absolute growth advantage for PNH cells as compared with normal cells coexisting in the same organism. Mice showing in vivo expansion of *pig-a* mutated hematopoiesis, thus better mimicking the human PNH disease, have been obtained with a more sophisticated approach. A conditional inactivation of the murine *pig-a* gene was implemented using the Cre recombinase and its specific recombination sites, loxP. When the Cre/loxP system was targeted to the hematopoietic stem cells or the erythroid/megakaryocytic lineage using tissue-specific c-FES and GATA-1 regulatory sequences, respectively, the generation of mice having almost 100% of red cells with the PNH phenotype was obtained. Such mice are under investigation to answer open questions in PNH pathophysiology.

In Vitro Decreased Susceptibility of PNH Cells to Immune Effector Mechanisms Several contradictory data have been produced on a putative differential sensitivity of normal and PNH hematopoiesis to inhibitory stimuli. Susceptibility to apoptosis has been reported increased, normal, or decreased in different models; it has been shown that human cell lines carrying the PIG-A mutation are less susceptible to NK-mediated killing compared with their normal counterpart, a phenomenon that was reverted by transfection with a *PIG-A* cDNA. In a more sophisticated model, GPI-deficient

Table 86-2
GPI-Linked Proteins on Blood Cells and Their Function

Antigen	*Alternative denomination*	*Function*
CD14	LPS-LPB-r	Monocyte adhesion and activation
CD16	FcγR-IIIb	Low affinity receptor for IgG
CD24		Ca^{2+} flux, triggers H_2O_2 production by polymorphonuclear leukocytes
CD48	BLAST-1	Counter-receptor for CD2
CD52	Target of Campath-1	Unknown
CD55	DAF	Accelerates C3 and C5 convertase decay, Cromer antigen
CD58	LFA-3	Counter-receptor for CD2
CD59	MIRL	Binds C8/C9, thus inhibiting MAC assembly
CD66b	CGM6 (CEA family member)	Granulocyte adhesion/activation
CD66c	NCA	Granulocyte adhesion/activation
CD73	5′-NT	Purine/pyrimidine ribo/deoxyribonucleoside phosphorylation
CD87	uPAR	Urokinase receptor
CD90	Thy-1 analog	Adhesion
CD108		Unknown
CD109	Platelet Gove/b alloantigen	Unknown
CD157	BST-1	Enzyme; adhesion/signaling (CD38 family)
ACHE	Red cell acetylcholinesterase	Enzyme, unknown substrate on RBC
NAP	Neutrophil alkaline phosphatase	Enzyme, granulocyte function
PrP^c	Cellular prion protein	Unknown
TRAIL R-3	Trail receptor III; DcR-1	Decoy receptor for TRAIL
ULBPs	UL-16 binding proteins	Activating ligand for NKG2D/DAP10 receptor
PRV-1	Polycythemia rubra vera 1	Unknown
NB1/NB2		Neutrophil antigen
JMH	John Milton Hagen antigen	Red cell antigen
Holley Gregory		Red cell antigen
Dombrock		Red cell antigen
YT		Red cell antigen
Platelet GP500		Platelet antigen
Platelet GP175		Platelet antigen

LFA, leukocyte function associated; uPAR, urokinase plasminogen activator.

cells showed impairment in inducing primary and secondary stimulation of both antigen-specific and alloreactive T cells, providing experimental support for the hypothesis that the PNH clone could inefficiently interact with the immune system. Higher apoptotic rate of GPI+ progenitor cells compared to GPI-deficient progenitors from the same PNH patient has been also documented. A new family of molecules has been identified: UL16 binding proteins (ULBPs). They are GPI-linked proteins belonging to the major histocompatibility complex class I superfamily, expressed in several tissues including immature and mature blood cells. They bind the activating receptor NKG2D/DAP10, which is expressed on NK and CD8+ cells, thus generating a dominant and potent stimulus for innate and adaptive immunity; the lack of ULBPs on PNH cells may explain the differential susceptibility to apoptosis of GPI+ and GPI– cells, providing a rationale for escaping from immune attacks.

However, the exact mechanisms causing the escape are elusive. They may include the absence of one or more GPI-linked molecules directly targeted by T lymphocytes or NK cells and leading to apoptosis of GPI+ cells; nonspecific structural changes of the raft structure on the membrane outer surface; and impaired sensitivity to common effector mechanisms involving GPI-linked molecules.

Evidence of an Immune-Mediated Disorder in PNH Patients An immune attack against normal hematopoietic progenitors may explain marrow failure in PNH and the close boundary with idiopathic AA, an immune-mediated disorder. Antigen-driven immune responses are characterized by in vivo oligoclonal expansion of specific T-cell subsets, which become dominant over the residual normal repertoire. T-cell receptor analysis represents a powerful tool for detection of clonality. In PNH, oligoclonality of the T-cell receptor repertoire has been documented by some groups through molecular analysis of the β-chain complementary determining region 3, by both size-distribution analysis (spectratyping or immunoscope, Fig. 86-4) and direct sequencing of dominant clonotypes. In some instances, a PNH clone was associated with the presence of extremely expanded T-cell subsets, resembling large granular lymphocyte leukemia. These observations are consistent with a T-cell response involving immunodominant cytotoxic T-lymphocyte clones, a mechanism already advocated for idiopathic AA; it may explain marrow failure in PNH, even if the putative triggering antigens have not been identified.

If the escape theory is confirmed, several implications can be drawn:

1. PNH patients always have two concomitant defects: one (or a few) early hematopoietic progenitors carrying a *PIG-A* mutation and a bone marrow failure syndrome, the mechanism of which is permissive for the expansion of GPI-deficient cells. This explains the frequent association of

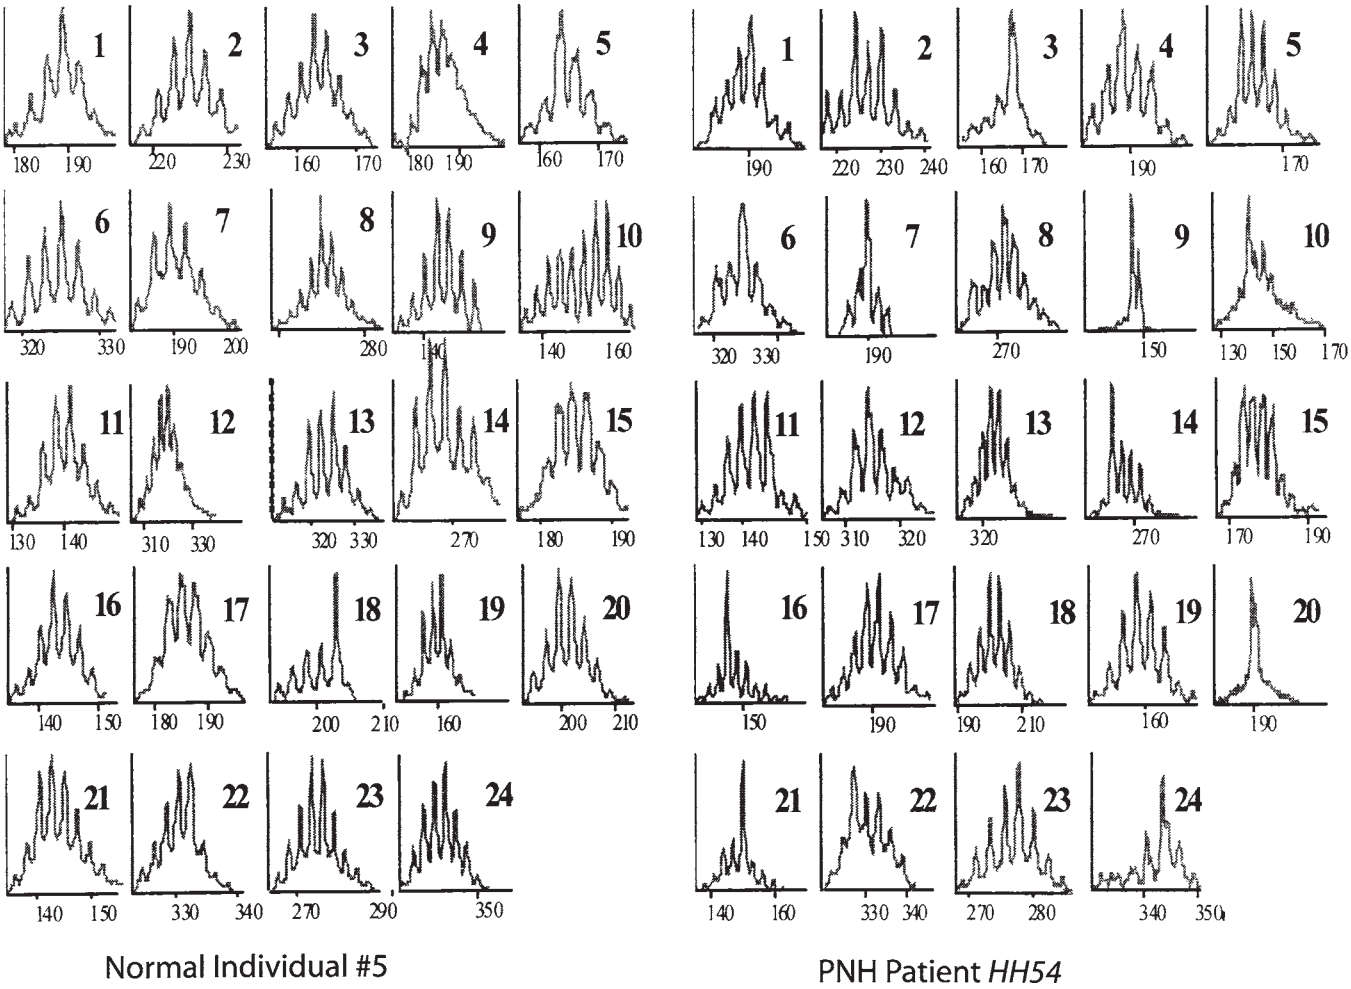

Figure 86-4 T-cell repertoire by TCR-VB CDR3 size-distribution analysis (immunoscope) in paroxysmal nocturnal hemoglobinuria (PNH) patients. The complementary determining region 3 (CDR3) mRNA pool is amplified by reverse transcriptase-PCR using a fluorescent constant-B primer and the specific variable-B (VB) primer. The complexity of the VB-CDR3 repertoire is resolved on acrylamide gel and displayed as relative fluorescence intensity (vertical axis): peaks represent mRNAs of identical length (horizontal axis). In healthy individuals, the normally diverse repertoire consists of 6–10 peaks, 3 nucleotides distanced from each other (representing in-frame functional rearrangements), with a bell-shaped (Gaussian like) distribution. In PNH, T-cell oligoclonality results in the appearance of prominent peaks out of the bell (skewing); in this paradigmatic PNH patient, VB3, VB7, VB9, VB14, VB16, VB20, VB21, and VB24 are skewed. (Reproduced with permission from Karadimitris A, Manavalan JS, Thaler HT, et al. Abnormal T-cell repertoire is consistent with immune process underlying the pathogenesis of paroxysmal nocturnal hemoglobinuria. Blood 2000;96:2613–2620. © American Society of Hematology.)

PNH with AA, the increased incidence of PNH in countries where AA is more frequent, as well as the frequent association of both diseases with human leukocyte antigens known to be related to autoimmune disorders.

2. The PNH clones, although responsible for a number of clinical consequences, are not invasive; rather, they should be considered "salvage" clones, which positively mitigate the consequence of bone marrow failure. Indeed, the gene expression profile of CD34+ PNH cells as studied by a microarray technique is similar to that of CD34+ cells from normal individuals, whereas phenotypically normal CD34+ cells sorted from PNH patients showed overexpression of genes possibly related to immune-mediated damage, such as TRAIL, interferon-γ, p53, and caspase 3, as seen in AA patients.
3. The long survival of patients with PNH demonstrates that a single stem cell may support most of hematopoiesis for several years. The same single *PIG-A* gene mutation detected at diagnosis (often on a banked specimen) was present after 6–10 yr of disease course. However, additional clones may develop, as seen in a patient relapsing after syngeneic bone marrow transplant who showed a *PIG-A* mutation different from that occurring at diagnosis.
4. The aim of treatment should be to recover normal hematopoiesis rather than to destroy or to repair the PNH clone.

CLINICAL FEATURES

The disease is rare (prevalence approx 1–2/million), but it occurs throughout the world, with increased prevalence in parts of Asia (e.g., Thailand, China), in which unexplained higher incidence of AA is also observed. PNH is characterized by chronic hemolytic anemia with erratic exacerbations, frequent leukopenia and thrombocytopenia, tendency to thrombosis, and, to a lesser extent, to infection. The clinical picture can range from mild to severe, severity being dictated by extreme pancytopenia (the PNH/AA syndrome), hyperhemolysis, or recurrent thrombosis.

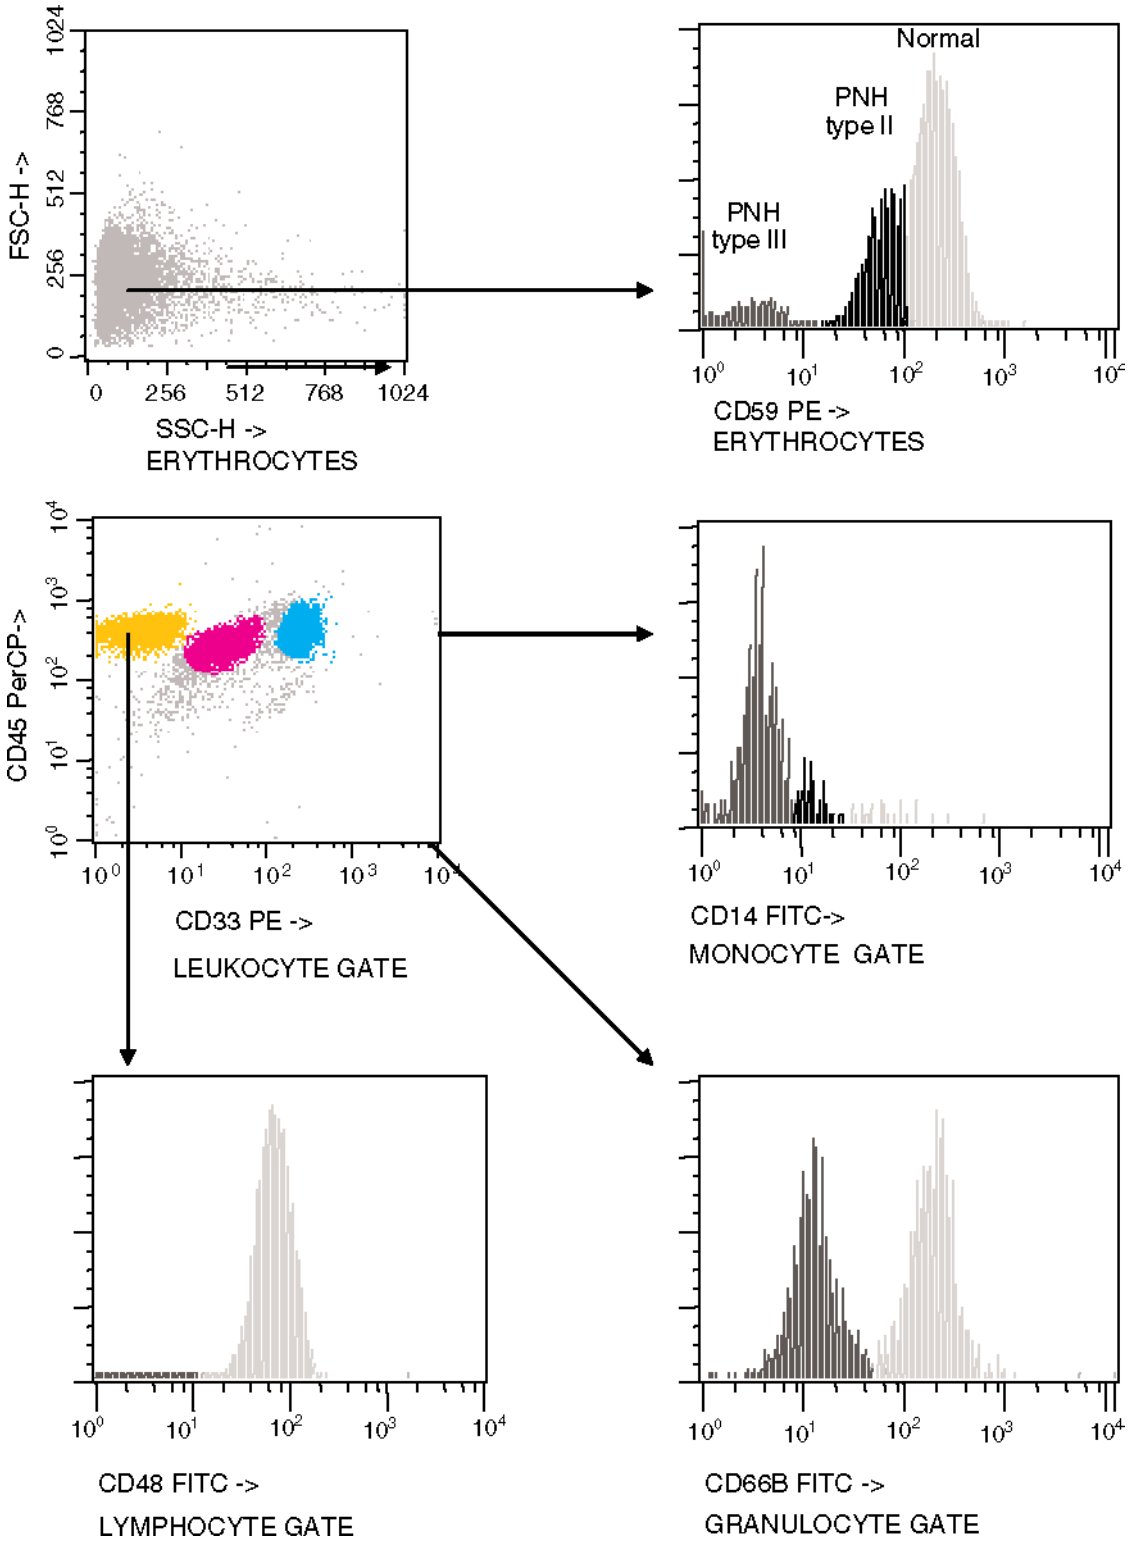

Figure 86-5 Blood cell flow cytometry profile in a representative paroxysmal nocturnal hemoglobinuria patient. **(Upper panels)**: ungated red cells stained with anti-CD59 monoclonal antibody (mAb), showing three RBC populations, one normal, a second partially CD59 deficient (PNH II) and a third, completely CD59 deficient (PNH III). (**Middle left panel**): WBC are gated into three discrete populations by the combination of anti-CD45 and anti-CD33 mAbs. Granulocytes, stained with an anti-CD66b mAb, show two well-cut populations, one normal, and the other CD66b deficient; monocytes, stained with an anti-CD14 mAb, show a major population completely CD14 deficient and two smaller populations (one partially deficient and few normal cells); lymphocytes stained with an anti-CD48 mAb show a single peak of positive cells.

Although the disease is not malignant (progression to acute leukemia is rare, and the frequency may have been overestimated), with a median survival of 10 yr in large series, the course may be stormy and the quality of life poor. The major cause of death is thrombosis, often occurring in sites unusual for patients with other types of thrombophilia (suprahepatic veins leading to Budd-Chiari

syndrome, mesenteric veins, cerebral veins). The mechanisms leading to the thrombophilic state in PNH are poorly understood. They include platelet activation resulting from membrane hypersensitivity to activated complement, thrombogenic properties of microvesicles released by red cells during hyperhemolysis and by the endothelium, and fibrinolytic system impairment owing to lack of membrane-bound and excess of soluble urokinase plasminogen activator. The risk of thrombosis correlates with the PNH clone size, thus being higher in patients with the hemolytic type of disease (as opposed to the aplastic type).

DIAGNOSIS

A mild jaundice without splenic enlargement, anemia with moderate reticulocytosis, elevated serum lactate dehydrogenase, episodes of dark urine, and constant hemosiderinuria are clues for diagnosis. Until the late 1980s, the only confirmatory test was the Ham test (lysis of a portion of red cells in acidified serum); simpler but less specific tests were the sucrose and sugar–water tests (red cells' lysis in serum with reduced ionic strength). Today, flow cytometry analysis of blood cells represents the most sensitive and specific diagnostic test and has rendered obsolete the Ham test. Several GPI-anchored proteins (GPI-APs) are expressed on different blood cells, and fluorochrome-conjugated monoclonal antibodies specific to each protein are available for routine diagnostic test. Simultaneous multiparameter cytometers allow accurate detection of GPI-AP deficient populations, measuring their extent within each cell lineage. By this technique, one or two populations with abnormal expression of GPI-AP may be shown: one completely lacking GPI-AP expression (type-III PNH cells), and another characterized by their faint (dim) expression (type-II PNH cells) (Fig. 86-5). The simultaneous absence of different GPI-linked proteins on the same cells validates the specificity of the test. Flow cytometry analysis allows detection of even small PNH clones (<1% of the tested cell population). Molecular studies on DNA or mRNA to identify the specific mutation within the *PIG-A* gene are fully confirmatory tests; however, they do not add clinically informative data and are usually limited to research purposes.

TREATMENT

The treatment of PNH is essentially supportive. Prevention and early treatment of concurrent infectious or inflammatory diseases may help in reducing the frequency and severity of paroxysmal exacerbations. Folate supplement and red cell transfusions are the basis for ameliorating anemia. Iron supplement (to balance the persistent urinary loss of iron in the form of hemosiderinuria) or iron chelation (if iron overload develops because of frequent transfusions) may be needed in selected patients. Anticoagulants are used to treat or prevent thrombosis.

Based on the escape theory and on the likelihood that the mechanism inhibiting the normal hematopoiesis is immune-mediated, as in most cases of AA, immunosuppressive regimens with antilymphocyte or antithymocyte globulin associated with high-dose prednisone and cyclosporin A have been used, with variable results. Stem cell transplant approaches have been tried. Autologous transplant is precluded by a marked deficiency of normal progenitor cells in PNH bone marrow, as already suggested by a poor growth of hematopoietic progenitors in vitro; also, attempts to mobilize a sufficient number of stem cells by growth factors have failed. Allogeneic stem cell transplant from a human leukocyte antigen-matched sibling is the best option for patients younger than 45 yr, with a cure rate of approx 50%. Allogeneic transplants in older patients or from matched unrelated donors in young patients carry a high transplant-related mortality, which can be tolerated only if the quality of life of the patient is poor. If the escape theory is correct, there is little room for futuristic approaches with cell therapy (insertion of molecules on the outer surface of blood cells) or with gene therapy (insertion of a functional *PIG-A* gene in early hematopoietic progenitors) in PNH, because a repair of the damaged cell may result in cell destruction. In most PNH patients, a residual population of normal hematopoietic progenitors already exists, but it is unable to repopulate bone marrow.

A supportive treatment has been envisaged by using a monoclonal antibody targeting the fraction C5 of the complement cascade eculizumab; by blocking the formation of the terminal membrane attack complex, both chronic and paroxysmal hemolysis can be reduced, with favorable clinical consequences at least concerning hyperhemolysis (decreased lactate dehydrogenase, reduced transfusion requirement), even if the PNH population remains unchanged or even increases.

FUTURE DIRECTIONS

Although many pathophysiological aspects of PNH have been unraveled, several important items require clarification, such as:

1. The functional properties of the GPI-anchoring system in human cells.
2. The structure and the function of the protein encoded by *PIG-A*.
3. The exact role of each GPI-linked molecule on blood cell development and function.
4. The amount of transfer of GPI-linked molecules that may take place in vivo from one cell to another.
5. The hierarchy by which the various molecules are preferred in the cell for anchor attachment, when a reduced amount of anchor is produced.
6. The reason for the nocturnal exacerbation of hemolysis.

Also, a formal proof of the escape theory is needed. If confirmed, PNH could be regarded as a special type of nonneoplastic clonal disease, in which the expansion of the mutated cell results from a survival advantage rather than a growth advantage.

ACKNOWLEDGMENTS

The experimental work on PNH by the authors was performed in Prof. Lucio Luzzatto's laboratories in several countries and in Dr. Neal Young's lab at NIH; we also thank Prof. Luzzatto for reviewing the manuscript. We thank Dr. Luigi Del Vecchio for useful discussion and updated information on surface antigens and flow cytometry data.

87 Iron Metabolism

NANCY C. ANDREWS

SUMMARY

Iron is an essential element that is toxic when it accumulates in excess. Intricate regulatory mechanisms have evolved to maintain iron homeostasis within cells and between different tissues of complex organisms. This chapter discusses the proteins involved in iron transport and storage, and their regulation in health and disease.

Key Words: Anemia; divalent metal transporter (DMT)1; erythropoiesis; ferritin; ferroportin; hemochromatosis; hepcidin; intestinal absorption; iron; transferrin.

INTRODUCTION

Iron is an essential element abundant in the environment that is toxic when accumulated in excess. Intricate regulatory mechanisms have evolved to maintain iron homeostasis within cells and between different tissues of complex organisms. Nearly all organisms exploit the redox flexibility of iron for enzymatic reactions requiring electron transfer and, in vertebrates, for oxygen transport. However, the same properties that make iron useful can make it toxic when it is present in excess or not bound by proteins. Free iron promotes the formation of dangerous oxygen radicals through the iron-catalyzed Fenton reaction:

$$O_2^- + Fe^{3+} \rightarrow O_2 + Fe^{2+}$$

$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + HO^\bullet + OH^-$$

$$O_2^- + H_2O_2 \rightarrow O_2 + HO^\bullet + OH^-$$

These reactive oxygen species attack cellular lipids, proteins, and nucleic acids. Consequently, protective mechanisms have evolved to limit the reactivity of iron and to maintain iron homeostasis. Human iron disorders result from disruption of iron balance or abnormalities of iron distribution. This chapter reviews the proteins involved in tissue iron transport and storage, describes regulatory mechanisms that modulate these processes, and briefly outlines how they are perturbed in common iron disorders.

INTESTINAL IRON ABSORPTION

In normal, nontransfused individuals, diet is the only source of iron. Individuals who consume a typical Western diet ingest approx 10 mg of ferric (Fe^{3+}) nonheme iron and 2 mg of heme iron (primarily from meat sources) on a daily basis. Heme iron is better absorbed than nonheme iron, though the details of heme iron uptake are not understood. However, animal experiments have provided a molecular model for nonheme iron absorption, discussed later. Other dietary constituents can affect the efficiency of iron absorption—animal proteins and ascorbic acid tend to promote absorption, whereas tannins, phytates, phosphates, and antacids inhibit it.

Food is solubilized by low gastric pH and the mechanical activity of the digestive system to release Fe^{3+} salts. This nonheme iron is reduced to Fe^{2+} by an enzymatic ferrireductase. This ferrireductase is most likely duodenal cytochrome-*b* (Dcytb), which is present on the apical brush border of the proximal small intestine. Dcytb is a heme protein expressed almost exclusively in the small intestine and induced in iron deficiency. It has a potential binding site for ascorbate, which may potentiate its activity. The resulting Fe^{2+} ion is a substrate for divalent metal transporter-1 (DMT1, formerly known as Nramp2, DCT1), a 12-transmembrane segment proton-dependent metal carrier. Like Dcytb, DMT1 is preferentially expressed on the apical brush border, in which it carries iron and several other divalent metal cations into the enterocyte. Aside from its general structure, it does not resemble any other class of transporters, and it uses a proton gradient, rather than ATP, to produce energy for its transporter function. Mice and rats with inactivating mutations in DMT1 develop profound iron and manganese deficiency, confirming that this molecule has a primary role in intestinal absorption of those metals. DMT1 is only functional in an acidic environment, with maximal metal transport activity at pH 5.5–5.8. For this reason, iron transport is most efficient just distal to the pylorus in which emptying gastric contents maintain a low pH. Like Dcytb and other proteins of iron absorption, expression of DMT1 is also induced by iron deficiency. DMT1 is also expressed in other tissues; in particular, it plays an important role in iron uptake by erythroid precursors.

Once it enters the enterocyte, iron may be shuttled into either of two pathways. Some is retained within the cell, and some is transported across the basolateral membrane by a distinct transporter, ferroportin (also known as IREG1, MTP1). Ferroportin function is not well characterized, but it also appears to recognize Fe^{2+}. It has approx 12 predicted transmembrane segments, and is not structurally related to DMT1 or other transporters. Ferroportin is also widely expressed, and has a particularly important role in macrophage iron export. Iron leaving the cell through ferroportin must be reoxidized to Fe^{3+} to bind to the plasma iron carrier, transferrin. A multicopper oxidase protein expressed in enterocytes, named hephaestin in honor of the mythological god who forged iron, may carry out this

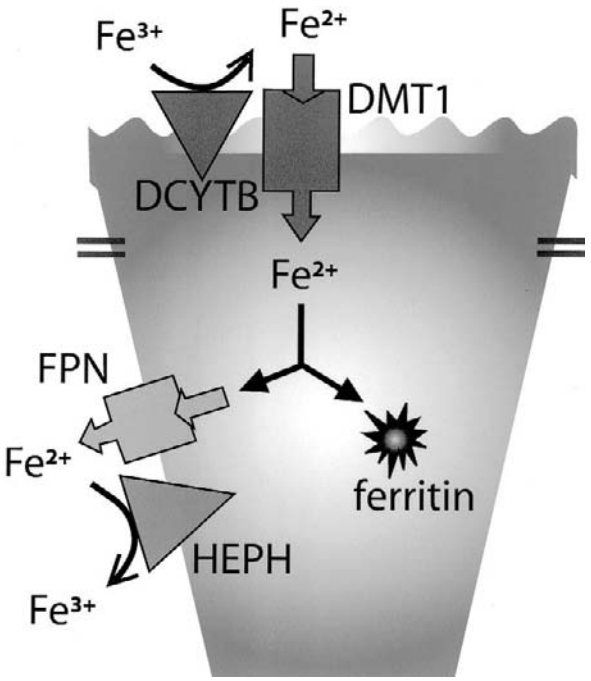

Figure 87-1 Nonheme iron transport through intestinal absorptive cells. A single absorptive enterocyte is shown in the diagram. According to the model, dietary nonheme iron (Fe^{3+}) is reduced by duodenal cytochrome-*b*-like protein (DCYTB) to its divalent form (Fe^{2+}). Fe^{2+} enters the cell through divalent metal transporter 1 (DMT1). It follows either of two routes—to storage in ferritin or to export across the basolateral membrane by ferroportin (FPN). Hephaestin (HEPH) probably oxidizes iron at some point in the export process. Iron that has transited the epithelial cell is rapidly taken up by circulating transferrin for delivery throughout the body.

function. Mice with a deletion mutation in the hephaestin gene retain more iron in enterocytes, consistent with its putative role in oxidizing the iron exported by ferroportin. Fig. 87-1 summarizes the postulated roles of DCYTB, DMT1, ferroportin, and hephaestin in nonheme iron absorption. These and other iron-related proteins are also described in Table 87-1.

Relatively little is known about heme iron absorption, though there is evidence for the existence of a heme receptor. Presumably, heme iron is taken up by the enterocyte and shuttled to a site where heme oxygenase catalyzes enzymatic release of iron from protoporphyrin. Ultimately, heme-derived iron must enter the same transport pathway as nonheme iron, but it is not clear when this occurs. It remains possible that DMT1 is necessary for heme iron transport, and likely that ferroportin and hephaestin mediate export of heme-derived iron from enterocytes.

UTILIZATION OF IRON BY THE ERYTHRON

After iron transits the absorptive enterocyte it is bound to transferrin, an abundant plasma protein that serves to solubilize ferric iron, shield its reactivity, and deliver it to cells. In normal individuals, essentially all plasma iron is bound to transferrin. Thus, the total iron-binding capacity is determined by the availability of transferrin iron-binding sites. However, in patients with hemochromatosis, plasma iron levels exceed the binding capacity of transferrin and free iron circulates loosely bound to albumin and low-molecular weight compounds. There are distinct cellular uptake pathways for transferrin-bound and nontransferrin-bound iron. The transferrin cycle is well defined, but little is known about the molecular mechanisms of nontransferrin iron uptake.

Transferrin has two high affinity binding sites for iron, each of which can bind one metal atom. Diferric transferrin is preferentially recognized by specific cell surface transferrin receptors (TFRs). TFRs are expressed at a low level on the surface of many types of cells, generally decreasing in number as the cells differentiate and proliferation ceases. This is logical, because most cells have minimal iron needs after they are fully mature. However, there are two important exceptions. Erythroid precursors transiently induce high-level TFR expression after the pronormoblast stage to promote the assimilation of iron for hemoglobin production. Additionally, circulating lymphocytes induce TFR expression on activation, though it is not known whether this is to facilitate iron uptake or for some other purpose. The importance of TFR for the development of erythroid precursors is underscored by the observation that mutant mice lacking murine TFR begin to develop normally *in utero*, but die during fetal development from severe anemia. Embryonic stem cells lacking TFR can reconstitute most tissues in chimeric mice, but fail to produce erythroid cells or lymphocytes.

After diferric transferrin interacts with its receptor, the complex is internalized by receptor-mediated endocytosis of clathrin-coated vesicles. Early endosomes are acidified through the action of a proton pump, lowering their internal pH to approx 5.5. In that environment transferrin and TFR undergo conformational changes that fortify the transferrin—TFR protein interaction but simultaneously lead to iron release. The liberated iron leaves the endosome through DMT1 located on the endosomal membrane. It moves within the cell to the mitochondrion for heme biosynthesis and to ferritin for storage (*see* below). Meanwhile, transferrin and TFR-containing endosomes recycle to the cell surface, to free both proteins for further cycles of iron delivery.

It is not known how erythroid iron is directed to the mitochondrion or how it gains access to the inside of the organelle, in which ferrochelatase inserts one iron atom into protoporphyrin to make heme. However, iron status must be sensed in some way, because heme biosynthesis and globin protein production appear to be coordinately regulated to ensure that iron, heme, and globin proteins accumulate in balanced amounts to assemble mature hemoglobin molecules.

Normal adult erythropoiesis requires approx 20 mg of iron per day to continuously replenish the circulating population of erythrocytes. Because daily intestinal iron absorption averages 0.5–2 mg, red blood cell production relies heavily on mobilization of iron stores and, in iron balance, on recycling of iron from effete erythrocytes. Iron recycling is conducted by specialized tissue macrophages, primarily in the liver and spleen, which recognize and phagocytose old and damaged erythrocytes, releasing 20–25 mg of iron per day. Heme oxygenase aids in enzymatic degradation of heme, and recovered iron is exported by ferroportin, which is highly expressed in tissue macrophages. Iron export is facilitated by ceruloplasmin, a multicopper oxidase homologous to hephaestin. Patients and animals lacking ceruloplasmin retain iron in macrophages (and hepatocytes) and have difficulty mobilizing iron from those cells.

Iron released from macrophages is picked up by plasma transferrin. The amount of plasma iron carried by transferrin (expressed as the transferrin saturation, the ratio of serum Fe to total iron-binding capacity) is determined primarily by the balance of macrophage iron release and erythroid iron consumption, with

Table 87-1
Proteins Important in Iron Metabolism

Protein (other names)	*Functions*
Ceruloplasmin (Cp)	Multicopper oxidase involved in oxidation of iron released from cells
Duodenal cytochrome-*b*-like protein (Dcytb)	Brush border ferrireductase; reduces dietary Fe^{3+} to Fe^{2+}
Divalent metal transporter 1 (DMT1, NRAMP2, DCT1)	Transmembrane iron transporter mediating cellular iron entry; functions at the apical brush border of small intestine enterocytes, in transferrin cycle endosomes, possibly other sites
Ferritin	Heteromultimer made up of L-ferritin and H-ferritin subunits; stores iron in solid state in cells
Ferroportin (IREG1, MTP1)	Transmembrane iron transporter mediating cellular iron egress; functions at the basolateral surface of small intestine enterocytes, in differentiated macrophages, possibly other sites
Hemojuvelin (HFE2)	Unknown; mutations in the hemojuvelin gene cause severe, early onset iron overload
Hepcidin (HAMP)	Regulatory hormone that controls intestinal iron absorption and macrophage iron release; mutations in the hepcidin gene cause severe, early onset iron overload
Hephaestin	Multicopper oxidase thought to be involved in oxidation of iron released from intestinal enterocytes
HFE	Atypical MHC class I protein involved in regulation of iron homeostasis; mutations in the HFE gene cause adult-onset hemochromatosis
Iron-regulatory protein 1 (IRP1)	Iron-containing RNA-binding protein involved in translational control of several proteins of iron metabolism
Iron-regulatory protein 2 (IRP2)	RNA-binding protein involved in translational control of several proteins of iron metabolism
Neutrophil gelatinase-associated lipocalin (NGAL)	Small plasma molecule that may serve as an iron carrier early in development
Transferrin	Major plasma iron-binding protein; binds two atoms of iron per molecule
Transferrin receptor 1 (TFR)	Cell surface receptor for iron-transferrin; brings iron into the cell through receptor-mediated endocytosis
Transferrin receptor 2 (TFR2)	Homolog of transferrin receptor 1; may be involved in iron delivery and/or sensing; mutations in the transferrin receptor 2 gene cause adult-onset hemochromatosis

small contributions from intestinal iron absorption and mobilization of iron from other storage sites. Thus, plasma iron levels fall when macrophage iron release is impaired or erythroid demand increases; conversely, when macrophage iron release is potentiated (as in hereditary hemochromatosis) or erythroid iron acquisition is impaired, plasma iron levels increase.

Erythropoiesis is exquisitely sensitive to iron availability. Normal red cell production continues until iron stores have been depleted, but rapidly becomes iron-restricted thereafter. Stores can be assumed to be depleted when serum ferritin drops below 10 μg/L. At that time, newly made erythrocytes are likely to be iron deficient, as signified by decreased reticulocyte hemoglobin content, elevated free and zinc protoporphyrins and elevated serum TFR fragment. The bulk population of erythrocytes begins to show abnormalities as new red blood cells are produced under iron deficient conditions. At that point increased red cell distribution width, microcytosis, and hypochromia become apparent. Frank anemia is a relatively late indicator of iron deficiency.

TISSUE IRON STORAGE

Tissue macrophages store iron in addition to recycling it. Hepatocytes also provide a major depot for iron reserves. The amount of iron in both cell types is reflected in serum ferritin levels, though the details of the biogenesis and secretion of the glycosylated, iron-poor ferritin found in the circulation are poorly understood. Much more is known about intracellular ferritin, which has the capability of concentrating inorganic iron in a solid, nonreactive, mobilizable form. Ferritin is a large, cage-like protein with eight iron transport pores and 12 mineral nucleation sites involved in sequestering iron oxides. It is a 24-subunit heteropolymer of light ("L," 19 kDa) and heavy ("H," 21 kDa) polypeptides encoded by different genes. H-ferritin has an intrinsic ferroxidase activity that aids in iron incorporation. The ratios of H- and L-subunits vary among tissues, according to cell-specific iron and oxygen homeostatic needs. In addition, there is a mitochondrion-specific form of ferritin, Mt-ferritin, which is homologous to H-ferritin. Mt-ferritin is found in perinuclear granules in sideroblasts from patients with X-linked sideroblastic anemia, but its function is not yet known.

The liver is the primary target organ in iron overload disorders. However, other tissues, primarily the heart and endocrine glands, also take up excess iron avidly. Their capacity for storing iron without toxicity appears to be much lower than that of the liver. Cardiac and endocrine sequelae of iron overload are particularly prominent when iron accumulation occurs rapidly, for example, in patients given frequent red blood cell transfusions.

REGULATION OF IRON BALANCE

CELLULAR IRON HOMEOSTASIS Cytoplasmic ferritin expression is regulated by iron at the level of translation to ensure that it is made only as needed for iron storage. The 5′ untranslated regions (UTRs) of both H- and L-ferritin mRNAs contain similar RNA stem-loop structures with a characteristic bulge in their stems. These structures are known as iron-regulatory elements (IREs) because they modulate translation through binding of iron regulatory proteins (IRPs). There are two known IRPs in mammals—IRP1, which is identical to cytoplasmic aconitase, and IRP2, which is related but has no aconitase activity. Depletion of intracellular iron results in increased IRP binding to IREs, with the consequence of inhibiting the initiation of ferritin translation. The molecular details of this regulation are well understood. IRP1 contains an iron–sulfur (4Fe4S) cluster, and acts as a non-RNA binding aconitase when the cluster is intact. When less iron is available, the cluster is not present in the protein and it converts to an RNA-binding protein with no aconitase activity. IRP2, though structurally similar, is regulated by iron-induced degradation.

IRP2 levels rise when cellular iron stores are depleted. Binding of either of these proteins to the ferritin IREs prevents assembly of the translational initiation complex on the ferritin mRNA.

Interestingly, these same IRPs are involved in a very different translational regulatory mechanism when they bind to IREs located in the 3′ UTR of TFR mRNA. Under conditions of cellular iron depletion, IRP binding stabilizes TFR mRNA by preventing endonucleolytic degradation. This results in increased TFR translation and placement of more TFR molecules on the cell surface to mediate iron uptake. Thus, the same protein regulators act to modulate ferritin and TFR gene expression coordinately as appropriate for iron status. There are also IREs in the 3′ UTR of some isoforms of DMT1 mRNA and in the 5′ UTR of ferroportin mRNA, which are thought to regulate translation in a manner similar to TFR and ferritins, respectively.

SYSTEMIC IRON HOMEOSTASIS Iron balance must also be regulated at the level of the entire organism. Systemic iron homeostasis requires complex signals between remote tissues including the intestine, bone marrow, and liver. Because humans have no mechanism for deliberate iron excretion, regulation of iron availability requires coordinate control of intestinal absorption, and mobilization of iron from stores (particularly macrophages, hepatocytes). Four conditions are known to modulate absorption and release: deviation of the levels of stores from normal, increased need for iron for erythropoiesis, inflammation, and hypoxia. Following on nomenclature of Finch, these will be referred to as *stores*, *erythroid*, *inflammatory*, and *hypoxia regulators*, respectively. These can coexist, e.g., in the setting of iron deficiency anemia, when both the *stores* and *erythroid regulators* should act to increase iron availability. There appears to be a hierarchy of activity; the *stores regulator* can modulate iron absorption and availability modestly, over a range of no more than threefold, whereas the *erythroid regulator* is much more potent, capable of increasing iron absorption as much as 10-fold or more. When increased iron stores and iron-restricted erythropoiesis occur simultaneously, as in the rare disorder atransferrinemia (severe deficiency of serum transferrin), the more powerful *erythroid regulator* predominates, and intestinal iron absorption is markedly increased in spite of tissue iron overload.

Previously, these regulators were observed as clinical phenomena, but not understood on a molecular level. In 2001, a new iron-regulatory hormone was discovered, designated hepcidin because it is produced in the liver and bears similarity to antimicrobial peptides. The primary activity of hepcidin appears to be to inhibit intestinal iron absorption and cellular iron release. Levels of hepcidin are modulated by each of the four known regulators. Expression of hepcidin is increased in iron overload (*stores regulator*) and inflammation (*inflammatory regulator*), presumably to compensate for excess iron and to keep iron away from invading pathogens, respectively. Activation of the *inflammatory regulator* and consequent elevation of hepcidin levels likely explains some, if not all, of the features of the anemia of inflammation (also called the anemia of chronic disease). Expression of hepcidin is decreased in response to iron-restricted erythropoiesis (*erythroid regulator*) and hypoxia (*hypoxia regulator*), likely as a measure to boost production of oxygen-carrying red blood cells. These activities are summarized in Fig. 87-2.

Although hepcidin is undoubtedly important, there are clearly other components of systemic iron-regulatory networks. These have been ascertained through study of genetic iron overload disorders, a heterogeneous collection of diseases triggered by single gene mutations (Table 87-2). Most of these disorders are characterized by

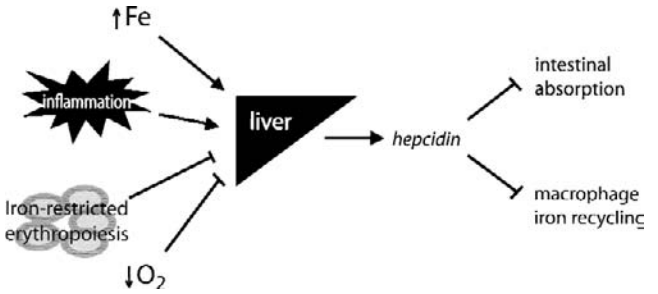

Figure 87-2 Regulation and activity of hepcidin. Hepcidin is produced in the liver. Its production is induced by iron overload (↑Fe) and inflammation and diminished in response to iron-restricted erythropoiesis and hypoxia ($\downarrow O_2$). Hepcidin acts to interrupt both intestinal iron absorption and macrophage recycling.

increased intestinal iron absorption leading to deposition of excess iron in parenchymal cells of the liver, heart, and endocrine glands. Iron toxicity, presumably associated with increased production of oxygen free radicals, causes hepatic fibrosis and cirrhosis, hepatocellular carcinoma, cardiomyopathy, diabetes mellitus, and, rarely, hypogonadotropic hypogonadism. Treatment is aimed at decreasing the body iron burden through serial phlebotomies, removing approx 200 mg of iron as hemoglobin in every 500 mL of blood drawn.

The prototype iron overload disorder is hereditary hemochromatosis resulting from mutations in the hemochromatosis disease gene (HFE). HFE encodes an atypical major histocompatibility class I-like molecule that complexes with β-2 microglobulin but has no known role in immunoregulation. Approximately one in eight individuals of Northern European descent carry a missense mutation that results in a cysteine to tyrosine substitution in amino acid 282 of the HFE protein (C282Y). Patients who are homozygous for the C282Y mutation are at significant risk for the development of clinical hemochromatosis, though estimates of disease penetrance vary markedly, from <1% to almost 50%. This wide range is owing, in part, to different definitions of clinical hemochromatosis. Severely affected individuals are unusual.

The normal role of HFE in iron homeostasis is not well understood, but there are several important clues. First, studies in mouse models have shown that the C282Y mutation results in a loss of HFE activity. Second, the HFE molecule forms a protein—protein complex with TFR. However, the function of the HFE/TFR complex is controversial. Data from several groups suggest that HFE precludes transferrin binding and, therefore, decreases iron uptake through the transferrin cycle, whereas data from another group suggest that HFE serves to make the transferrin cycle more efficient. This issue has not been resolved. Finally, studies indicate that patients and mice with HFE hemochromatosis have inappropriately low levels of hepcidin. Accordingly, forced expression of hepcidin in HFE mutant mice prevents hemochromatosis. Taken together, these observations suggest that HFE is normally involved in the regulation of hepcidin expression, and that loss of normal regulation leads to a failure to limit iron absorption and cellular iron release in HFE hemochromatosis. However, much remains to be learned about how this occurs.

A similar iron overload disorder is observed in patients who are homozygous for any of a number of different mutations in the gene encoding transferrin receptor 2 (TFR2). TFR2 is a close relative of TFR that shares some of its properties. TFR2 can mediate cellular

Table 87-2
Genes Mutated in Patients With Iron Overload

Gene (Online Mendelian inheritance in man database designation)	*Inheritance*	*Chromosomal location*	*Role in iron homeostasis*	*Clinical test*
HFE (*HFE1*)	Autosomal-recessive	6p21	Regulates levels of hepcidin	Genetic study for C282Y mutation and for H63D polymorphism
Hemojuvelin (*HFE2*)	Autosomal-recessive	1q21	Not known - regulates levels of hepcidin?	N/A
Hepcidin (*HFE2B*)	Autosomal-recessive	19q13	Hormone that controls iron absorption, release of iron from macrophage stores	N/A
Transferrin Receptor 2 (*HFE3*)	Autosomal-recessive	7q22	Resembles the transferrin receptor involved in cellular iron uptake; role not clear	N/A
Ferroportin (*HFE4*)	Autosomal-dominant (distinct pathology)	2q32	Iron transporter	N/A

N/A, test not yet available.

iron uptake from transferrin less efficiently than TFR, but its role in vivo is uncertain. It is primarily expressed in the liver and in hematopoietic precursor cells. Both TFR and TFR2 normally exist in cells as protein dimers, and heterodimers made up of one molecule of TFR and one molecule of TFR2 form at low levels. However, unlike TFR, TFR2 cannot form a protein–protein complex with HFE. The relationship between TFR2 and hepcidin, if any, has not been elucidated.

Aggressive, early-onset, "juvenile hemochromatosis" is rare in comparison to other iron overload disorders. Juvenile hemochromatosis is pathologically similar to HFE and TFR2 hemochromatosis, but iron loading is accelerated and severe complications typically present in the second decade of life. Patients are more likely to have cardiac and endocrine complications, and somewhat less likely to develop cirrhosis. Juvenile hemochromatosis is caused by homozygosity for loss-of-function mutations in either of two genes. Perhaps not surprisingly, one of these is hepcidin itself. As predicted from mice lacking hepcidin, absence of hepcidin in human patients leads to severe iron overload.

The gene mutated in other families with juvenile hemochromatosis encodes a novel protein, termed hemojuvelin. Curiously, the only known protein related to hemojuvelin is a chicken protein (called RGM, for repulsive guidance molecule) involved in axonal patterning in the developing nervous system. The expression pattern of hemojuvelin gives little additional information about its function in iron homeostasis; it is expressed at highest levels in skeletal muscle, heart, and liver. Patients homozygous for hemojuvelin mutations also have inappropriately low levels of hepcidin suggesting that hemojuvelin, like HFE, may participate in the regulation of hepcidin expression. However, hemojuvelin remains enigmatic.

A fifth genetic iron overload disorder differs from the first four in several regards. Inheritance follows an autosomal-dominant, rather than recessive pattern. Iron loading occurs first in tissue macrophages and only later affects parenchymal cells. This disorder is usually less aggressive, perhaps owing to the distinct pathology. It results from missense mutations in ferroportin. No truncation or nonsense mutations have been identified, suggesting that the disease results from alteration of protein function, rather than from a complete loss of one ferroportin allele. The most likely explanation is that the missense mutations preferentially inactivate ferroportin in macrophages, but have little if any effect on the activity of ferroportin in intestinal iron absorption. A unique ferroportin mutation, Q248H, has been detected in African and African-American patients with iron overload. This mutation may explain a previously described disorder, originally termed "Bantu siderosis," which is prevalent in individuals in sub-Saharan Africa and exacerbated by ingestion of an alcoholic beverage brewed in nongalvanized steel drums.

Although genetic iron overload disorders are relatively common as a group, genetic iron deficiency disorders are rare. There are several case reports of patients with inherited iron deficiency, but genetic analysis has failed to reveal mutations in any of the known genes of iron metabolism. It seems likely that elucidation of the molecular etiology of genetic iron deficiency will also contribute to the overall understanding of the intricate networks governing iron homeostasis.

88 Correction of Genetic Blood Defects by Gene Transfer

Marina Cavazzana-Calvo, Salima Hacein-Bey-Abina, Adrian J. Thrasher, Philippe Leboulch, and Alain Fischer

SUMMARY

Gene therapy has been proposed as an appealing tool for introducing a normal gene into affected hematopoietic stem cells to correct their inherited defect. Theoretically, in the absence of a related human leukocyte antigen identical donor, gene therapy could be an alternative given the accessibility and the information available on the hematopoietic stem cell biology. This chapter describes the progress and limits of the gene therapy approach applied to some genetic blood defects that appear to be good targets for this strategy.

Key Words: ADA; Fanconi anemia; gene therapy; hematopoietic stem cells; SCD; SCID.

RATIONALE FOR THE GENE THERAPY OF GENETIC BLOOD DISEASE

Gene therapy has been proposed as an appealing tool for introducing a normal gene into affected hematopoietic stem cells (HSC) to correct their inherited defect.

In addition to some particular forms of T-cell primary immunodeficiencies, the blood genetic defects potentially curable by this strategy include Fanconi anemia (FA), hemoglobinopathies, and phagocyte disorders. The treatment of choice for all these nonmalignant hematological disorders consists in allogeneic stem cell transplantation from a related or unrelated human leukocyte antigen (HLA)-matched donor. In the presence of a related HLA-genoidentical donor, this treatment leads to a high rate of disease cure with most patients being long-term survivors. Theoretically, in the absence of a related HLA-identical donor, gene therapy could be an alternative given the accessibility and the information available on the HSC biology. In practice, this option is only partially available taking the following issues into account: need to provide a selective growth advantage to transduced cells, uncertain identification of the human stem cells, poor knowledge on HSC self-renewal, limited transduction efficiency of HSC by the available oncoretrovirus type C derived vector, and need to carefully assess the risk/benefit balance in relationship with the severe adverse events (SAE) that occurred in the X-linked severe combined immunodeficiency (SCID)-X1 clinical trial. This chapter describes the progress and limits of the gene therapy approach applied to some genetic blood defects that appear to be good targets for this strategy.

SEVERE COMBINED IMMUNODEFICIENCY DISEASE

SCID is a heterogenous group consisting at least nine different forms united by one common characteristic: the complete block in T-cell development that is always associated with a direct or indirect impairment of B-cell immunity (Fig. 88-1 and Table 88-1). Consequently these patients are highly susceptible to infection with many micro-organisms, causing early mortality, usually within the first year of life, unless treated by HSC transplantation. HSC transplantation from related HLA-genoidentical donor, for instance, is highly successful as reported in the European survey. Otherwise, the transplantation-related mortality can vary from 5–70% depending on age at treatment, newborn patients having the best outcome; presence of active viral infections; lung impairment; disease type (B+ vs B– SCID forms); and degree of HLA disparity. Overall 5-yr survival from haploidentical hematopoeitic stem cell transplant is approx 70–75%. Moreover, SCID patients treated by a haploidentical transplant present a long-term decline of the immunological reconstitution and an infrequent correction of the B-cell immunity because of several contributing factors such as the likely absence of stem cells engraftment in the absence of fully myeloablative conditioning regimen, and the potential allogeneic damage to the thymic epithelium. Therefore, several groups have developed active preclinical research to try to establish alternative treatments based on the "ex vivo retrovirus transduction" of autologous HSC. SCID indeed appeared as good candidates for this approach for several reasons: they are monogeneic diseases, the involved genes have been mostly identified and these disease are lethal, HSC are accessible for manipulation, although an immune response against the transgene is not expected and more importantly, the presence of a growth selective advantage for transduced cells has been well demonstrated by clinical and preclinical studies.

ADENOSINE DEAMINASE DEFICIENCY Adenosine deaminase (ADA) deficiency was the first disease to be treated

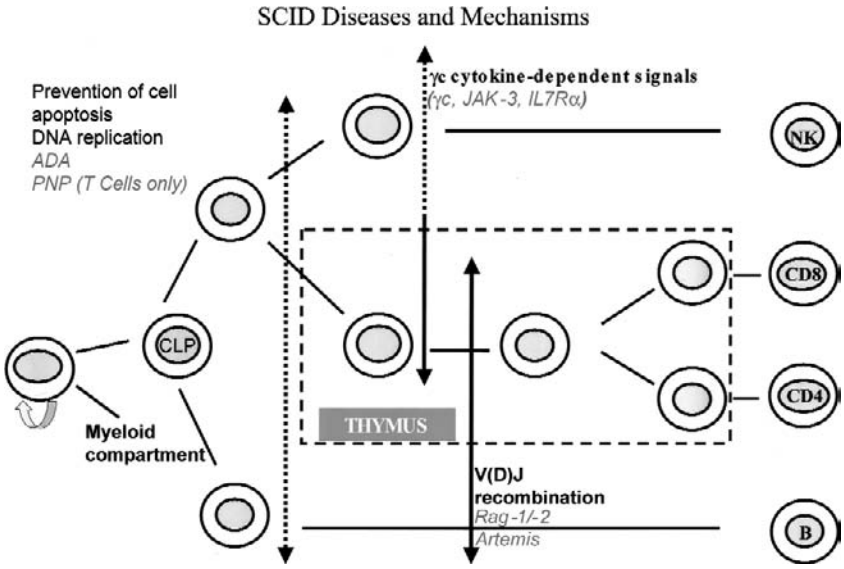

Figure 88-1 X-linked SCID and mechanisms.

Table 88-1
Characteristics of the Different SCID Conditions

	Disease	*Gene*	*Inheritance*
T(–),B(+)			
NK(–)	SCID-X1	γc	XL
NK(–)	SCID	Jak3	AR
NK(+)	SCID	IL7Rα	AR
NK(+)	SCID	?	AR
T(–),B(–)			
Myeloid(–), NK(–)	Reticular dysgenesis	?	AR
NK (variable)	ADA	Adenosine deaminase	AR
NK(+)	Alymphocytosis	RAG-1 or RAG-2	AR
NK(+)	Alymphocytosis	Artemis	AR
NK(+)	SCID	CD45	AR

using gene therapy, following identification of the disease gene. This enzyme is responsible for detoxification of metabolites in the murine salvage pathway and its deficiency is responsible for the selective accumulation of deoxy ATP, which inhibits cell division and induces cell death by apoptosis. In this disease, there is a premature death of early lymphoid precursor cells caused by the accumulation of toxic metabolites. Other tissues and organs can be damaged in ADA deficiency such as the thymic epithelium, the lung, and the liver. This widespread toxicity can explain in part the rather poor prognosis of allogeneic bone marrow transplantation and thus justify the search for other therapeutic strategies including enzymatic substitution with polyethylene glycol-conjugated bovine-ADA (PEG–ADA) and gene therapy. Five gene therapy clinical trials have been conducted since 1990. The first two consisted of repeated infusions of peripheral T cells transduced ex vivo with an ADA–cDNA retroviral vector.

Two patients have been enrolled in the M. Blaese's trial and each of them received a total of approx 10^{11} cells over a period of approx 2 yr. During and after treatment they continued to receive PEG–ADA, therefore, conclusions on the clinical benefit are difficult to establish. In one patient, levels of transduced positive cells ranged from 20 to 40% of his circulating lymphocytes whereas the second one had <1% of transduced cells. Nevertheless, important information, up to 12 yr postgene therapy for the gene therapy field, has been provided by this pioneer trial. No adverse event occurred despite the injection of huge numbers of autologous modified T cells transduced with a first generation retroviral vector. The life span of human T cells can be prolonged, up to 12 yr following in vitro induction of their division. The Moloney retroviral promoter can drive transgene expression for long periods of time without silencing the gene. Immunodeficient patients with oligoclonal repertoire can mount efficient immune responses both against the retroviral envelope and the fetal calf serum used in the transduction procedure, confounding the interpretation of the clinical results and requiring changes in retroviral vector design and culture conditions to try to circumvent these problems.

In the second protocol performed by Bordignon's group, six patients received multiple infusions of autologous transduced peripheral blood lymphocytes as well as HSC. Among them, in one patient, who received 3.3×10^9 transduced peripheral blood lymphocytes, PEG–ADA treatment could be discontinued. The discontinuation led to a selective growth advantage of gene-transduced T lymphocytes although absolute CD34+ T-cell counts comparable to age-matched control were not reached. Some improvements of the immunological tests were also noted. Both protocols showed the limits of this strategy and opened the way to the HSC gene therapy of ADA patients. Three protocols attempted to target autologous HSC; however, the PEG–ADA substitutive treatment administered simultaneously is likely to have exerted a deleterious effect by decreasing or abrogating the presumed advantage conferred to the transduced cells. Other factors that could have contributed to the loss of benefit are the nonoptimal ex vivo transduction protocol and the retroviral vector used that could have been silenced in vivo. Candotti et al. enrolled four ADA

patients in an optimized protocol. Higher levels of transduction have been achieved by using the vector called MND-ADA, which contains five mutations in the long terminal repeat. Frequency of circulating transduced cells is in the 1×10^{-5} order of magnitude. Despite these technical improvements, patients were maintained under PEG–ADA treatment and showed no clear changes in their immunological status after 1 yr of follow-up; it will be interesting to follow the consequences of PEG–ADA discontinuation.

All these limiting factors have been circumvented by Aiuti et al. who showed that gene therapy in the absence of concomitant PEG–ADA treatment, with a mild myeloablation can successfully treat ADA deficiency. Four patients have been treated and longer follow-up in two showed a significant correction of the immune deficiency. Whether this success is owing to PEG–ADA omission and/or to the addition of a mild myeloablation is unknown. Expression of ADA by T cells alone may not be sufficient to correct the overall metabolic ADA deficiency; therefore, myeloablation, by increasing the level of hematopoietic correction, is likely to be a contributing factor.

X-LINKED SEVERE COMBINED IMMUNODEFICIENCY SCID-X1 is the most frequent form of SCID accounting for 50% of cases. Absence of mature T and natural killer (NK) lymphocytes associated with a normal B-cell differentiation are the main characteristics of this disease, which results from mutations of the gene encoding the γ-common (γc-chain) subunit of the hematopoietic cytokine receptors family. The γc-chain is shared by several receptors of this family including the interleukin (IL)-2, IL-4, -7, -9, -15, and -21. The defective IL-7 and -15 induced growth and proliferation signaling are responsible for the early block observed in T and NK differentiation pathway, respectively.

The role of the γc-chain in the survival, proliferation, and differentiation of the lymphoid precursors led to the expectation that its expression could confer a major selective growth to the transduced cells over nontransduced counterparts. This expectation was fulfilled in a well-documented case of reversion of a point mutation that naturally occurred in a boy with an attenuated form of SCID-X1. In this case, the mutation reversion occurred in a single T-cell progenitor, after the branching point of the NK, as the patient presented low circulating numbers of oligoclonal T cells expressing the normal γc molecule, although NK cells were absent and γc expression on B lymphocytes and monocytes, which all carried the original mutation, was not detectable. This clonal reversion allowed limited but sustained immunological functions up to 6 yr of age after which the patient has been successfully transplanted.

In addition to this observation, a number of preclinical studies provided clear data in favor of this approach. All confirmed that the ex vivo transduction of γc-deficient HSC restored the differentiation of NK and T cells without any detectable adverse effect. The first clinical trial was initiated in March 1999. Ten children under the age of 1 yr were enrolled by May 2002. Detailed analysis of the gene therapy results of the first five treated patients has been reported. A second clinical trial was established in the United Kingdom and enrolled four patients affected by the classic form of SCID-X1. These two trials were proposed for SCID-X1 patients lacking an HLA-identical donor. The protocol consisted of marrow harvesting; CD34-cell positive selection; preactivation in the presence of early acting cytokines as stem cell factor, FLT3-L, megakaryocyte growth and developmental factor, IL-3 or IL-6; and three cycles of infection with the supernatant containing the defective amphotrophe or GALV retroviral vector in sterile bags coated with CH-296 fibronectin fragment. After ex vivo transduction, cells were infused to the patients who did not receive any myeloablative therapy.

In 13 out of the 14 treated patients, transduced T cells appeared 60–90 d after treatment and their counts reached the normal or close to normal range within 4–6 mo following gene transfer, remaining stable thereafter. The different T-cell subsets, including T-cell receptor (TCR) αβ and γδ+ cells were detected in normal proportions and were found functional as evidenced by proliferation in the presence of mitogens and of immunization antigens. Despite a very low (approx 1%) transduction rate of B lymphocytes, the treated children developed B-cell antibody responses, enabling a majority of patients to discontinue intravenous immunoglobulin therapy. Conversely, the NK-cell restoration appeared limited over time; following a rapid normalization of the NK-cell counts after gene therapy (i.e., approx d 45–60), the NK-cell compartment declined. Two explanations that are not mutually exclusive can account for this result, i.e., a limited expansion capacity of the NK-precursor cell and the potential lack of a γc-dependent hematopoietic cell able to sustain NK-cell development or survival.

As a consequence of the development of T- and B-cell immune responses, a favorable clinical outcome ensued allowing the patients to resume normal growth and to enjoy a normal life despite cessation of all treatment. Although these findings indicate that immunological correction of SCID-X1 condition by gene therapy is achievable, two SAE occurred 3 yr after gene therapy, which forced reassessment of the delicate balance between risk/benefit of this powerful therapeutic approach. Two children developed a clonal T-cell lymphoproliferation owing, at least in part, to the consequences of insertional mutagenesis. The two patients who developed this clonal lymphoproliferation have been treated by conventional chemotherapy and are in complete remission. The retrovirus vector integrated close to the LMO_2 (LIM domain only) transcription factor and induced its aberrant expression on immature T cells. This transcription factor is a master gene in embryonic and adult hematopoiesis and is involved in acute T-lymphoblastic leukemia both in mice and in humans. Additional factors must have contributed to these SAE justifying the transitional hold of this clinical trial and close monitoring of the other treated patients whereas the search continues for other contributive factors, such as age, disease, and genetic susceptibility μo_2. Altogether these studies should lead to a precise evaluation of the risk as well as a modification of the vectors to decrease or prevent the occurrence of these adverse events.

JAK 3 DEFICIENCY This form of SCID is characterized by an immunological phenotype identical to that of SCID-X1 described earlier. The Jak-3 protein tyrosine kinase is indeed associated to γc and mediates cytokine-induced signaling. The results obtained after transferring the JAK3 gene in vitro and in vivo argue in favor of using this therapeutic approach. In support of this, it was found that the retroviral transduction of the cDNA into Epstein-Barr Virus Jak-3(–) lineages restored the expression and phosphorylation of this protein and caused these cells to proliferate in response to IL-2 and IL-4. The transduction of bone marrow cells in Jak3 (–) mice induced T- and B-lymphocyte differentiation and restored their functions. This result clearly demonstrates the existence of a selective advantage for ex vivo corrected hematopoietic cells and represented the first animal model demonstration

of the concept. One study performed by the same groups in a larger number of animals has excluded the possibility of any toxic effect. One 3-yr-old child has been enrolled in a clinical trial. No correction has been observed possibly because of the relative old age of the patient.

SCID WITH T AND B ALYMPHOCYTOSIS Of patients suffering from SCID, approx 20% have complete absence of mature T- and B-lymphocytes, whereas NK cells are present in normal numbers and are functional. Inheritance is autosomal-recessive and the thymus in these patients is hypoplastic. The phenotype is reminiscent of that of natural mutant SCID mice, characterized by a lack of T and B differentiation. This form may be subdivided into two groups on the basis of cell sensitivity to ionizing radiation, distinguishing SCID with normal sensitivity to ionizing radiation and SCID with increased sensitivity. The ionizing radiation causes double-strand breaks in the DNA and their repair involves proteins that are also necessary for *rearranging the genes* involved in the formation of TCR and B-cell receptor encoding genes.

The molecular basis of the genetic defect presented by subjects who are suffering from SCID with increased sensitivity to ionizing radiation has been identified; radiosensitive SCID is caused by mutation of the Artemis gene. Patients suffering from T(–) B(–) SCID, but not showing any abnormal sensitivity to ionizing radiation, present mutations in the genes coding for the RAG1 and RAG2 proteins responsible for initiating the V(D)J recombination process. These SCID conditions are good candidates for gene therapy because a selective advantage should be also confered to transduced cells, and unregulated expression of this protein should not be toxic because the V(D)J recombination is obtained solely through the combined action of the RAG1 and RAG2 proteins and Artemis ubiquitously expressed. Mice transgenic for one of these two proteins do not show any lymphohematopoietic abnormalities. The preliminary data obtained after Rag2 gene transfer into the hematopoeitic cells of RAG2-deficient mice showed that normal cell and humoral immunity was restored and remained stable for more than 1 yr without any detectable toxicity.

WISKOTT–ALDRICH SYNDROME

Wiskott–Aldrich syndrome (WAS) is a rare inherited disease characterized by immune dysregulation and microthrombocytopenia. In its less severe form, known as X-linked thrombocytopenia, mutations in the same gene produce the characteristic platelet abnormality but minimal immunological disturbance. Clinical manifestations of the immune disorder in WAS include susceptibility to pyogenic, viral, and opportunistic infection, eczema, autoimmune phenomena, and increased incidence of B-cell lymphoproliferative disease. The most invariable abnormality is thrombocytopenia (platelet count usually $<70{,}000/mm^3$ in the absence of splenectomy) with small platelet volume (mean platelet volume usually <5 fL), that is present from birth. As a consequence, the majority of patients present with related complications, which vary from minor bruising to life-threatening gastrointestinal or intracranial hemorrhage. In general, a platelet count of $<10{,}000/mm^3$ is predictive of severe bleeding complications, although higher counts are not necessarily protective. A progressive decrease in T-cell number (in peripheral blood and lymphoid tissue) and function during childhood is associated with restricted defects in proliferative responses of WAS T cells (particularly CD3-mediated proliferation, but also depressed responses to mitogens), deficient antibody responses to polysaccharide and protein antigens, and low or absent levels of isohemagglutinins. Quantitative abnormalities of immunoglobulin levels evolve in many patients, manifesting typically as low levels of IgM and increased levels of IgA, IgD, and IgE. Immune dysregulation may also manifest as food allergy, or as autoimmune disease, including hemolytic anemia, vasculitis, inflammatory polyarthritis, and inflammatory bowel disease. The median survival for WAS patients is approx 15–25 yr, and the usual causes of death (unrelated to transplantation procedures) are infection, bleeding, and malignancy, with a considerable variability in disease severity.

The WAS gene encodes a proline-rich intracellular protein, WASp, which belongs to a defined family of more widely expressed proteins involved in transduction of signals from receptors on the cell surface to the actin cytoskeleton. WASp itself is expressed exclusively in hematopoietic cells, including stem and progenitor cells.

The molecular control of actin filament assembly and disassembly is of necessity highly regulated and coordinated, as reflected in the complex modular domain structure of WASp that supports its role as a platform for integration of signals from diverse input pathways. The activity of WASp is modulated by multiple signals, including binding of the Rho GTPase Cdc42 in the GTP-bound state, phosphatidylinositol-4,5-bisphosphate, SH-2 domain containing proteins, and tyrosine and serine phosphorylation. In the activated configuration, WASp triggers actin polymerization through binding to the actin related protein, Arp2/3 complex. This initiates actin nucleation, which is the rate-limiting step in polymerization of monomeric G-actin. The biological mechanisms responsible for the pathophysiology of WAS are therefore linked to deficient actin polymerization in hematopoietic cells. As a result, WASp-deficient cells exhibit profound cytoskeletal defects leading to abnormalities of chemotaxis, migration, phagocytosis, receptor-mediated (including TCR) signaling, and platelet function.

CONVENTIONAL TREATMENT Conventional therapy includes the use of prophylactic antibiotics and immunoglobulin for infections, and platelet transfusion in circumstances of life-threatening hemorrhage (e.g., intracranial) or prior to surgical procedures. Splenectomy is usually effective in increasing platelet numbers and reducing bleeding complications, but also increases the risk of infection. The only curative therapy for WAS is allogeneic stem cell transplantation. Survival rates following transplantation from HLA-identical sibling donors and matched HLA-unrelated donors in WAS approach 90%. However, transplantation with HLA-nonidentical grafts, and transplantation in older patients results in an exceptionally high incidence of graft rejection, graft-vs-host disease (GVHD) and Epstein-Barr virus-related lymphoproliferative disease (39% of HLA-nonidentical transplants, European Group for Bone Marrow Transplant Registry).

GENE THERAPY For those patients without an HLA-matched donor source, stem cell gene therapy is a highly attractive proposition. Emerging preclinical data suggest that this will be feasible. Interestingly, several reports suggest that "corrected" T cells from classic WASp-null patients have significant growth and survival advantages over mutant cells. For example, in one member of a classic WAS kindred, in vivo reversion of a 6-bp deletion led to the reconstitution of WASp expression in the majority of circulating T cells (presumably derived from a single precursor), but not in myeloid cells, B lymphocytes, or NK cells. In a second

example, a second site mutation in a precursor resulted in deletion of the disease causing primary mutation, and reconstitution of functional WASp. A small fraction of the total T-cell population expressed WASp, but this was enriched in the CD45RO fraction indicating an advantage for acquisition of immunological memory. Correction of cells by gene transfer (stem cells or lineage restricted T-cell populations) would, therefore, be expected to provide similar survival pressures. It has previously been suggested that selective pressures may also exist for homing of stem cell populations, which may, therefore, positively influence the engraftment potential for corrected cells. This is supported by serial murine transplantation and competitive reconstitution experiments demonstrating that WASp-null bone marrow cells, including HSCs, have decreased homing and engraftment capacities.

Reconstitution of cytoskeletal defects by gene transfer has been reported for lymphoblastoid cell lines, and reconstitution of anti-CD3 mediated proliferation in WAS T cells and T-cell lines derived from patients. Partial correction of a murine model in terms of antigen receptor-mediated proliferation of WAS T cells has been demonstrated following gene transfer to HSCs. All these studies have used conventional γ-retroviral vectors, and although adverse effects have not been reported, some concerns remain related to transgene toxicity. Certainly, in cell lines, overexpression of WASp leads to polymerization of actin in highly abnormal structures. A mutation in WASp that results in its constitutive activation has been shown to predispose to myelodysplasia and genetic instability. The identification of natural regulatory sequences or promoters that mimic physiological gene expression is, therefore, an important goal for optimization of safety, and will be facilitated by the development of sophisticated lentivirus-based vector systems. In preliminary studies, such systems have been used to demonstrate correction of cytoskeletal defects in WASp-null T-cell lines, macrophages, and osteoclasts, and are being tested in murine models in preparation for clinical studies.

HEMOGLOBINOPATHIES

Thalassemias and sickle cell disease (SCD) were the earliest monogenic disorders considered for gene therapy. These hemoglobinopathies are associated with high morbidity and mortality throughout the world. β-Thalassemia is caused by various mutations or deletions within the adult β-globin gene or its controling elements that result in decreased expression levels and the accumulation of toxic, unbound α-globin chains. This in turn causes ineffective erythropoiesis and hemolytic anemia requiring lifelong red cell transfusions. Premature death occurs from complications of iron loading in spite of iron chelation therapy. Although patients' survival has improved, β-thalassemia remains a serious public health problem.

SCD was the first genetic disorder to be understood at the protein and subsequently DNA levels: the substitution of valine for glutamic acid in human β-globin codon 6. In homozygotes, the abnormal hemoglobin (Hb) HbS ($\alpha_2\beta^s_2$) polymerizes in long fibers on deoxygenation within red blood cells, which become deformed (sickled), rigid, and adhesive, thereby triggering microcirculation occlusion, anemia, infarction, and organ damage. SCD is one of the most prevalent autosomal-recessive disorders worldwide. In certain regions of tropical Africa, the frequency of heterozygotes reaches 40%, as heterozygosity confers a protective advantage against malaria. In the United States, approx 1 out of 13 African Americans carries the mutated gene, which is also common among individuals of Mediterranean, Middle-Eastern, or Indian descent. SCD patients still suffer from high morbidity and increased mortality despite progress in symptomatic disease management and partial pharmacological inhibition of sickle cell formation with hydroxyurea and butyrate derivatives. For both β-thalassemia and SCD, the only hope of cure remains allogenic bone marrow transplantation from a related, HLA-matched donor. However, only a small subset of patients have a compatible donor and those who do still face the risk of severe and often lethal consequences of GVHD.

The idea of a gene therapy for the β-hemoglobinopathies was in principle straightforward: integrating in the HSC chromosomes a normal β-globin gene or an antisickling gene, for β-thalassemia and SCD, respectively, with sufficiently high expression in the red blood cell lineage. Retroviral vectors were the vector of choice, because they were the only effective means to integrate genes into the HSC genome. Regarding the choice of the antisickling gene, various globin chains are known to inhibit HbS polymerization. Human γ-globin is a much stronger inhibitor of HbS polymerization than human β-globin, because it is excluded from the polymer and it interferes with its formation through intermolecular contacts. Previously, β-globin gene transfer into HSC in mice has been too low to warrant instigation of a clinical trial. The most important technical challenge has been to design stable vectors containing the functional globin gene and the necessary regulatory elements, such as the β-locus control region (LCR), to achieve high-level and stable globin gene expression in developing erythroblasts. The first (β-globin/LCR) retroviral vectors tested were notoriously unstable with low titers and multiple rearrangements of the integrated proviral structure. Unwanted splicing of the retroviral RNA prior to packaging into virions was found to be the main mechanism of instability of (β-globin/LCR) retroviral vectors. Also, mutagenesis of the main cryptic splice sites can prevent this instability. A similar result was achieved by sequence permutation of LCR elements.

Even with these stable LCR retroviral vectors, initial reports have indicated that despite the inclusion of elements from the LCR into the retroviral vectors, the level of β-globin expression was suboptimal, decreased over time and was suffering from position effect variegation, which is a reflection of the effects of flanking chromatin in differentiated cells and of chromatin remodeling at the site of integration in the progeny of pluripotential cells. To avoid in vivo HSC β-globin gene silencing, ex vivo preselection of retrovirally-transduced stem cells using GFP expression (green fluorescent protein gene marker) juxtaposed to the β-globin/LCR segment was investigated. All mice engrafted with preselected cells showed sustained expression of human β-globin and GFP in red cells.

To allow larger LCR elements to be successfully transferred in an effort to surmount the limitations observed in long-term β-globin gene expression, the use of RNA export elements such as the Rev protein of HIV together with its Rev-responsive element has been proposed. Extending previous evidence on the utility of lentiviral vectors for gene transfer to HSCs, HIV-based lentiviral vectors carrying a Rev-responsive element allowed successful transfer of large LCR fragments with dramatic amelioration of β-thalassemia in transplanted mouse β-thalassemia models of various severity. When a high-titer (β-globin/LCR) lentiviral vector was used to achieve multiple provirus copy integration (approx 2–3/HSC), balanced expression opposing variegation was achieved with high,

pan-erythroid expression of the β-globin gene that was completely corrective.

In the case of SCD, because the γ-globin gene appeared difficult to be transferred by lentiviral vectors at high viral titers, an antisickling β-globin variant, $\beta^{A\text{-}T87Q}$, was made that incorporates one amino acid residue from the γ-globin gene suspected to be responsible for most of the antisickling properties of γ-globin. Mice were then transplanted with bone marrow cells transduced with the optimized antisickling [$\beta^{A\text{-}T87Q}$/LCR] lentivirus. Long-term expression was achieved, without preselection, in all transplanted mice with erythroid-specific accumulation of the antisickling protein in up to 52% of total Hb and 99% of circulating red blood cells. Because no transgenic mouse model perfectly recapitulates the exact disease characteristics of human SCD patients, the efficacy of the ($\beta^{A\text{-}T87Q}$/LCR) lentiviral vector was then evaluated in two different SCD transgenic mouse models: SAD and Berkeley (BERK). Inhibition of red blood cell dehydration and sickling was achieved with correction of hematological parameters, splenomegaly, and prevention of the characteristic urine concentration defect. Other groups have now derived lentiviral vectors based on the use of a γ-globin gene construct. Together, these studies clearly showed that recombinant lentiviruses bearing large fragments of the human β-globin gene and LCR can achieve therapeutic levels of circulating Hb.

Before these (β-globin/LCR) vectors can be evaluated in clinical trial, they are being further modified for added safety. Self-inactivating vectors comprising extended deletions of the enhancer/promoter regions of the viral long terminal repeats and chromatin insulators, such as cHS4, have been constructed in an effort to prevent untoward activation of adjacent oncogenes by the LCR enhancers present within the integrated proviral structure. In addition, a conditional suicide gene such as herpes simplex virus-thymidine kinase casset has also been incorporated in the vector for additional safety, with minimal decrease in viral titers. The use of a "super-split" packaging system is also being proposed to render the risk of contamination with a replication-competent lentivirus virtually impossible. Regarding bone marrow conditioning before bone marrow transplantation with transduced HSCs, single agent myeloablative regimen (e.g., Busulfan) as well as in vivo selection systems based on transfer of a *cis*-linked selectable cDNA is being investigated in animal models.

Beside the most common strategy of adding a normal copy of the gene to hematopoietic cells, other strategies including correction of globin chain imbalance through the induction of fetal Hb synthesis by sustained secretion of erythropoietin (Epo) in β-thalassemia mice (by adeno-associated viral vector-mediated gene transfer or by naked DNA electro transfer into mouse muscle) have been explored. The latter induced a stable correction of anemia and improved erythropoiesis. Intense Epo stimulation induced the expansion and differentiation of erythroid progenitors committed to fetal erythropoiesis. Clinical trials in human β-thalassemia with recombinant human Epo administration indicate that this growth factor provides clinical benefit to some patients. Epo gene therapy could, therefore, be envisaged for Epo responsive patients.

FANCONI ANEMIA

FA is a genetically and phenotypically heterogeneous autosomal-recessive disease whose common characteristic is the cellular hypersensitivity to DNA crosslinking agents. Clinically, FA is characterized by congenital abnormalities, progressive bone marrow failure, and predisposition to acute myeloid leukemia and other malignancies. The clinical features include skeletal abnormalities, abnormal skin pigmentation, abnormal development of cardiac, renal and gastrointestinal organ systems, and decreased fertility. Children with FA frequently develop pancytopenia during the first decade of life and death often results from complications of bone marrow failure.

Complementation studies have shown that there are at least eight separate FA complementation groups (A through G, including D1 and D2). The genes responsible for the defect in each of these FA complementation groups have been identified. Complementation groups A (65%), C (15%), and G (10%) account for most patients with this disorder reported to the International Fanconi Anemia Registry.

Although the most common malignancies in FA are hematologic, FA patients develop a wide array of different neoplasias because of the high degree of genomic instability. The relationship of genomic instability to cancer has received great input by the evidence of interactions of ataxia telangiectasia mutated protein, ATM, and breast cancer susceptibility proteins BRCA1 and BCRA2 (identified as FANCD1) with the other FA proteins strongly suggesting that FA proteins have a significant role in DNA repair/recombination and cell cycle control. Despite these advances, several aspects of FA genetics remain unclear hindering the establishment of new therapeutic strategies.

Because the death of these patients is often caused by clinical consequences of bone marrow failure, allogeneic bone marrow transplantation is still the treatment of choice, which can worsen the cancer susceptibility of these patients owing to the conditioning regimen toxicity and to the consequences of GVHD lesions. Thus, gene therapy of autologous HSC represents an appealing tool. In favor of this strategy are the reports of in vivo selection of wild-type HSCs in a murine model of FA and in one of two affected siblings demonstrating the growth selective advantage of reverted cells over nonreverted ones.

Nevertheless, despite these encouraging data several obstacles require consideration:

1. CD34 FA cells are not easily mobilized by hematopoietic cytokines. Of the four patients enrolled in a clinical trial at the National Institutes of Health, three successfully mobilized, despite the low number of HSC present in the bone marrow of these patients. PCR+ granulocyte-macrophage colony-forming units that were resistant to treatment with mitomicin-C were detected in two of the patients several months after the gene therapy. Of note, transduced positive cells were detected in one patient only after irradiation for a gynecologic malignancy.
2. A nonoptimized transduction protocol of HSC associated with late harvest of HSC and the absence of in vivo selection by a pharmacological agent of the transduced cells may explain the absence of clinical benefit.
3. Available clonogenic tests setup for normal committed precursors are not adapted for the growth of HSC from FA patients.
4. All human FA-associated genes have mouse homologues, but the phenotype of Fanca–Fancc, and Fancg-null mice is not as severe as that of humans. The life span of the animals is normal and no anemia or increased tumor incidence has been observed. Phenotypic abnormalities close to that described in humans develop only after treatment

with DNA crosslinking agents and with ionizing radiation. Altogether, these data represent limiting factors for the evaluation of pertinent strategies for the treatment of FA patients. Nevertheless, one published paper shows that using lentiviral vectors efficient genetic correction can be achieved in quiescent hematopoietic progenitors from Fanca$^{-/-}$ and Fancc$^{-/-}$.

89 Bone Marrow Failure Syndromes

J. Eric Turner and Thomas C. Shea

SUMMARY

Of the many causes of bone marrow failure, some are associated with syndromes that affect only hematopoiesis and peripheral blood counts, whereas others present with more systemic manifestations. The genetic and molecular basis of many of these disorders is being investigated with better understanding of the pathogenesis as the goal of research. Most of these syndromes can be treated with supportive care for variable periods of time, but stem cell transplant offers the only hope for cure in many cases.

Key Words: Aplastic anemia; dyskeratosis congenita; fanconi anemia; hematopoiesis; Myelodysplastic syndromes (MDSs).

INTRODUCTION

Bone marrow failure is an encompassing term that describes the pancytopenia arising from a variety of clinical disease entities and etiologies (Table 89-1). More specifically, the definition includes peripheral blood cytopenias that are caused by inadequate marrow production of either single or multiple cell lines. This can be because of either defective or insufficient marrow production. This chapter summarizes the pathogenesis, clinical features, diagnosis, and therapeutic features of several causes of bone marrow failure. Included are the acquired and congenital aplastic anemias, myelodysplastic syndromes (MDSs), myelofibrosis, nutritional marrow failure states, and isolated cytopenias.

ACQUIRED APLASTIC ANEMIA

Aplastic anemia was first described in 1888 by Paul Ehrlich in an autopsy report of a young, pregnant woman who died after a severe illness characterized by profound anemia and bleeding. The marrow of this patient was fatty in nature and lacked the compensatory changes usually found in severe anemia, representing a classic example of failed hematopoiesis. Aplastic anemia is a state of absent or diminished hematopoietic stem cell precursors in the bone marrow. It is estimated that the overall incidence in the United States is about two new cases per million population per year. The age distribution appears bimodal with the first peak at 15–25 yr of age and the second at 60 yr or older. Another epidemiological feature of aplastic anemia is the geographic variation in incidence rates. Rates of aplastic anemia in Asia are higher than in Western countries. For example, the incidence in various parts of Thailand ranges from 4.0 to 5.6/million compared with an estimated annual incidence of 7.4/million in China. No consistent sex or racial differences exist for aplastic anemia.

CLINICAL FEATURES Signs and symptoms of aplastic anemia arise as a result of low blood counts (Fig. 89-1). Frequently, patients complain of fatigue and lassitude, shortness of breath, ringing in the ears, or chest pain as sequelae of severe anemia. Bleeding manifested as gum oozing, irregular menses, nosebleeds, and easy bruising secondary to thrombocytopenia often prompts patients to seek medical care. Severe neutropenia manifests as recurrent infections, most often bacterial, in the form of urinary tract infections, pneumonia, or sepsis. Invasive fungal infections can be seen when patients have prolonged, severe neutropenia. Patients' physical appearance may range from a normal to someone who appears quite ill. Petechiae of the oropharynx, palate, and dependent body surfaces are common. Pallor of mucosal membranes and nail beds may be present with bruising at sites of minor trauma. Lymphadenopathy and splenomegaly are not present nor is fever unless the patient presents with a concurrent infection. Congenital causes of aplastic anemia may present in adulthood. For example, finding typical anomalies plus areas of hyper- or hypopigmentation may indicate a congenital Fanconi anemia (FA), whereas the finding of misshapen nails can be a sign of dyskeratosis congenita (DC, discussed later).

DIAGNOSIS Typically, all peripheral blood counts are depressed, although the degree for each cell line may vary. An absent or subnormal reticulocytosis is also found with the red cell size being normocytic or macrocytic. Platelets are not typically enlarged as seen in other disease states of thrombocytopenia. Generally, although the elements of the peripheral blood are reduced in number, the morphology remains normal. Examination of the bone marrow typically shows a hypocellular marrow with the marrow space made up of fat cells and stroma. Malignant cells and fibrosis are absent and the remaining hematopoietic cells have normal morphology.

HEMATOPOIESIS Hematopoiesis is greatly impaired in aplastic anemia. Patients with severe aplastic anemia have neutrophil counts <200/mm^3, platelet counts <20,000/mm^3, and low reticulocyte counts. Normally, the bone marrow would consist of mostly the precursors of these peripherally circulating cells. In aplastic anemia, the marrow has scant early erythroid, myeloid, and megakaryocytic cells at any stage of maturation. Early progenitor and stem cells that normally express the cell surface cytoadhesive protein CD34 on flow cytometric assays are greatly reduced in aplastic anemia, with severe cases having <10% of normal

Table 89-1

Folate deficiency
Myelodysplastic syndromes
Paroxysmal nocturnal hemoglobinuria

amounts. Survival and growth of progenitor cells within the marrow is dependent on the local stromal environment. Stromal cells from patients with aplastic anemia are not usually defective and will support hematopoiesis by normal CD34+ cells in vitro. Most studies have shown that stromal cells of aplastic patients produce normal to increased amounts of hematopoietic growth factors in vitro. Typically, serum concentrations of erythropoietin, thrombopoietin (TPO), and granulocyte colony-stimulating factor (GCSF) are elevated. Use of these agents has, therefore, had limited benefit in attempts at restoring normal hematopoiesis in patients with aplastic anemia. Chemotherapy and radiation therapy commonly cause transient marrow hypoplasia, but only occasionally are the cause of pure aplastic anemia. Additionally, idiosyncratic drug reactions from a variety of agents and direct toxic effects of certain chemicals can also cause marrow aplasia. Data suggest that 15–25% of aplastic anemia cases are drug related. Some agents have a direct toxic effect leading to DNA damage and apoptosis (programmed cell death). Drug toxicity is thought to be mediated through metabolites that interact with DNA and other proteins within cells. Benzene and its metabolites bind to marrow-related proteins and DNA allowing for production of toxic quinone metabolites. The marrow has limited detoxifying enzymes compared with other tissues and, thus, marrow failure can ensue. There is also an interaction between the immune system and hematopoietic cells. For example, patients who failed bone marrow transplant for aplastic anemia had improvement of their pancytopenia despite the immunosuppressive drugs intended to help with marrow engraftment. Studies of T cells in culture show they overproduce interferon (INF) and tumor necrosis factor (TNF), both of which are cytokines that have inhibitory properties for hematopoietic progenitor and stem cells in vitro. Effects of these cytokines include action on the mitotic cell cycle as well as cell killing. Both cytokines induce expression of the Fas receptor found on CD34+ progenitor cells. Activation of this Fas receptor by its ligand induces apoptosis. Cellular effects of INF are regulated, in part, through interferon regulatory factor 1, which inhibits gene transcription and entry into the cell cycle. INF also induces transcription of genes responsible for toxic effects on cells including NO synthase and NO itself. Other signal transduction pathways are affected by the Fas receptor binding to its ligand, TNF, and INF, which ultimately influences cell cycling and cell viability.

GENETICS Human leukocyte antigen (HLA)-DR2 is the histocompatibility type most often associated with aplastic anemia and is found up to twice as frequently as in the general population. Other HLA types including A2, B14, Cw7, DR4, and Dpw3 have been seen. Hepatitis-associated aplastic anemia has been linked to HLA-B8. In Japanese populations, HLA haplotypes have been associated with response to cyclosporine and rate of relapse; however, other studies have not supported this finding. An association with HLA class II molecules has also been found with clozapine-induced agranulocytosis and some idiosyncratic drug and chemical reactions causing aplastic anemia.

MANAGEMENT The main treatment options for aplastic anemia involve immunosuppression and/or stem cell transplant. Antithymocyte globulin (ATG) made from sera of horses or rabbits against human thymocytes produces hematological responses within a couple of months of therapy with some patients achieving transfusion-independence without additional treatment. The mechanism of action may involve stimulation of lymphocytes to produce growth factors and cytokines such as IL-3. There may also be direct enhancement of hematopoiesis by the binding of ATG to cell surface proteins, which in turn affects certain signal-transduction pathways. Additionally, data show that the inhibitory affects of CD8+ lymphocytes on hematopoiesis may be decreased with ATG treatment. Cyclosporine either alone or in combination with ATG and steroids can be used for the treatment of aplastic anemia. Combination regimens produce higher hematological responses than either drug alone. For appropriate candidates, consideration of a peripheral blood stem cell transplant (PBSCT) or bone marrow transplant is appropriate and may be in the form of a matched-sibling or matched-unrelated donor allogeneic transplant. Cure rates can be as high as 70–90% in both adults and children undergoing matched-sibling transplants. Matched-unrelated donor transplants are associated with cure rates of about 40%.

CONGENITAL APLASTIC ANEMIAS

As mentioned, the age of most acquired aplastic anemias at presentation is 15–25 yr or older than 60 yr. In contrast, congenital aplastic anemias peak at 2–5 yr of age. These syndromes may

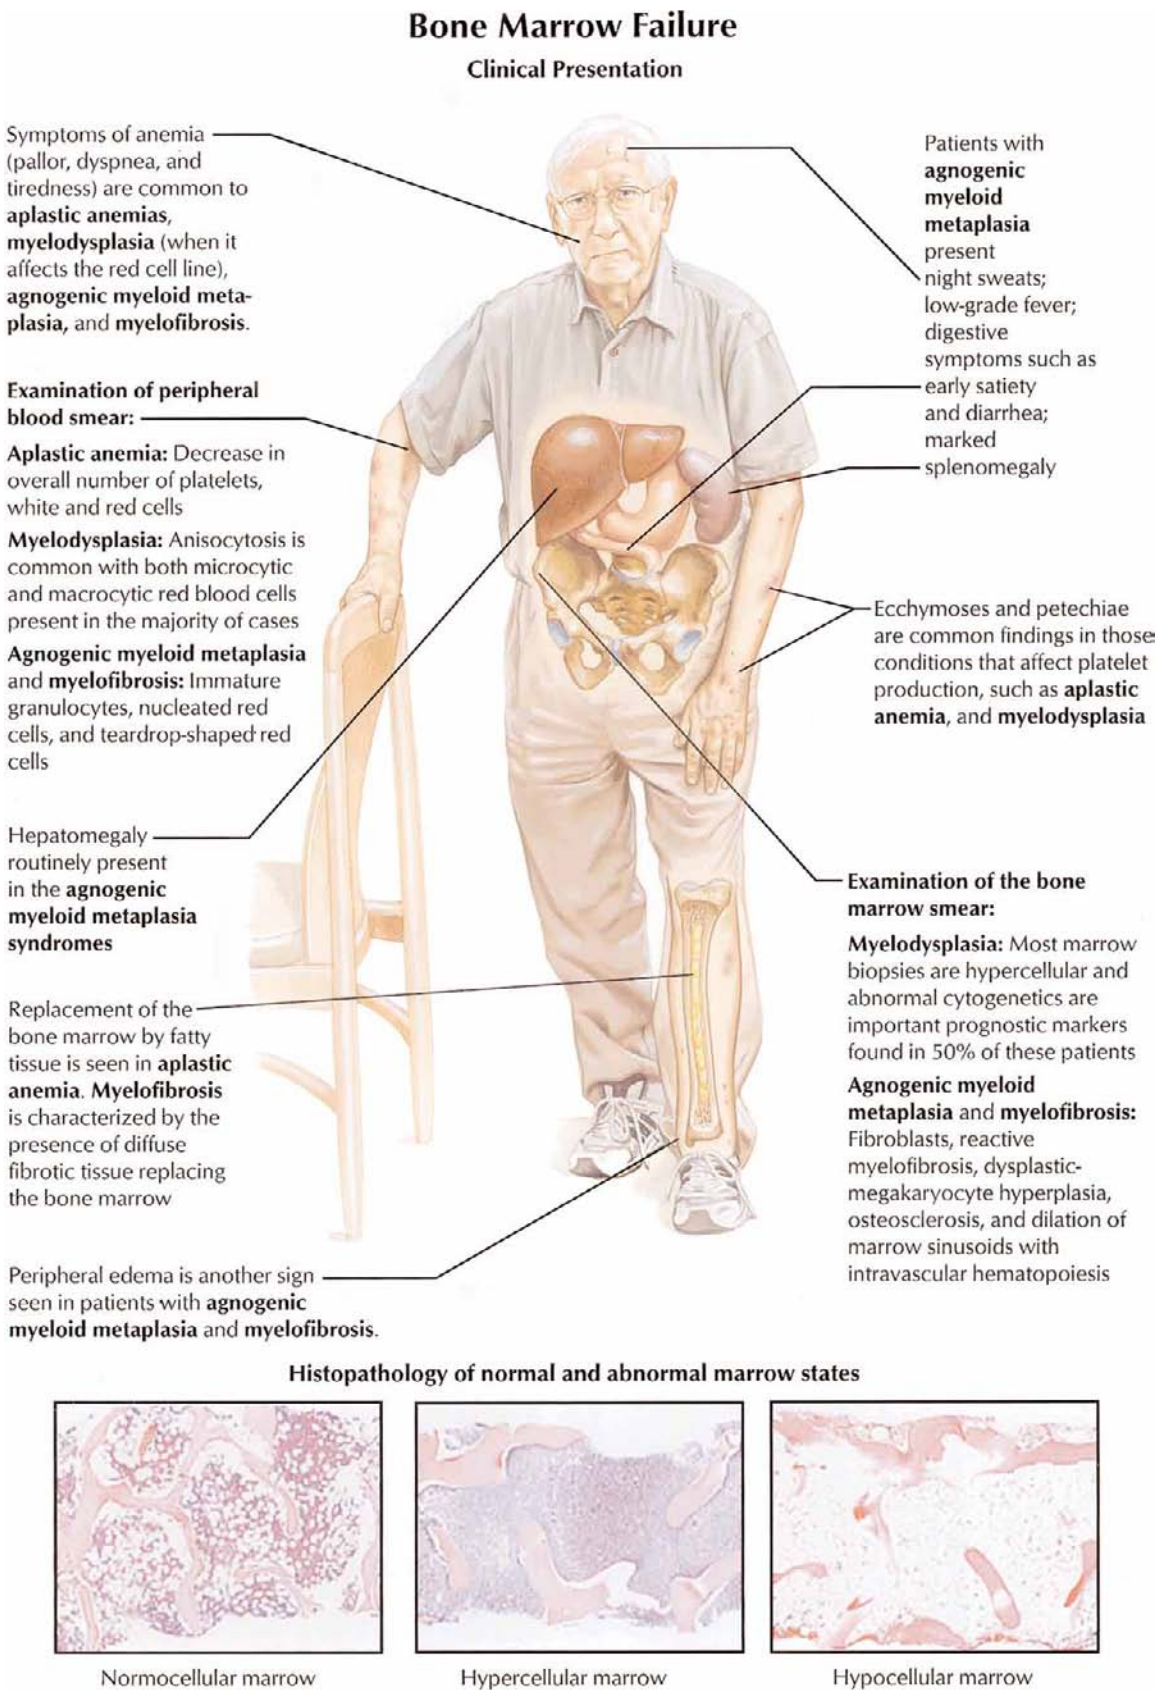

Figure 89-1 Clinical manifestations of bone marrow failure syndromes. (Used with permission from Icon Learning Systems, a division of MediMedia USA, Inc. All rights reserved.)

or may not present with characteristic physical exam findings and as with acquired causes of aplastic anemia, display varying degrees of pancytopenia in the initial phase of the disease. Clinical presentations of these disorders are again variable and depend on the degree and types of cytopenias exhibited. Discussed here are three major congenital causes of aplastic anemia: FA, DC, and Shwachman–Diamond syndrome (SDS).

FANCONI ANEMIA FA is the most common and well-defined form of congenital aplastic anemia. It follows an autosomal-recessive pattern of inheritance and occurs in all races and ethnic groups. The heterozygote frequency is about 1/300 in western countries.

Clinical Features The mean age at diagnosis in children is 6–9 yr, although many cases are diagnosed earlier. Up to 70% of cases have characteristic anomalies, including hyper- or hypopigmentation, abnormal thumbs, microcephaly, short stature, hypogonadism, and structural renal abnormalities. Also, facial features including broadened nasal base, epicanthal folds, and micrognathia can be seen. The remaining patients may have no inherited abnormalities. The hematological abnormalities usually develop by a median age of 7 yr and up to 70% of children with FA have evidence of marrow failure by age 10 yr. Similar to the acquired aplastic anemias, patients present with bleeding, pallor, fatigue, or recurrent infections as a result of their various cytopenias.

Diagnosis The peripheral blood smear shows varying degrees of pancytopenia. Often there is a macrocytosis that is almost "pernicious-like." The bone marrow is fatty and hypocellular as seen in acquired forms of aplastic anemia. The diagnosis should be suspected in patients with typical physical malformations and worsening cytopenias. Patients with FA have chromosomes that exhibit characteristic breaks when exposed to diepoxybutane or mitomycin-C. The gold standard for diagnosis is culturing patient lymphocytes in the presence of one of these agents. The diagnosis can be made prenatally and siblings of affected patients should be tested whether or not physical anomalies exist.

Genetics The ability to break chromosomes with diepoxybutane or mitomycin-C actually allowed for the discovery of the genes responsible for FA. There are at least 12 complementation groups that can be involved. Eight of these genes have been cloned (FANCA, FANCC, FANCD1, FANCD2, FANCE, FANCF, FANCG, and FANCL). FANCA and FANCC were the first genes to be mapped by complementation studies and up to 65% of patients with FA have FANCA. FANCA has been mapped to 16q24.3 whereas FANCC localizes to 9q22.3. It is speculated that the normal gene products of these complementation groups control genomic stability, apoptosis, and cell growth. At least six of the FANC proteins form a core protein complex with disruption of this complex leading to the FA phenotype. FANCA is a phosphoprotein whose phosphorylation is required for its binding to other FANC proteins, nuclear localization, and possibly DNA crosslink repair. FANCD1 is homologous to BRCA2 and also likely involved in DNA repair similar to the mechanism by which BRCA1 and BRCA2 are involved in DNA repair in breast cancer. There is evidence that FANC proteins are important in oxidative damage repair. FANCA and FANCG interact via disulfide linkages to form multimers in response to oxidative damage. This interaction stabilizes FANCG and is essential for their function within the nucleus. The linkage of these two proteins occurs concomitantly with the monoubiquitination of FANCD2. FANCA may play a critical role in the monoubiquitination of FANCD2 as mutant cells lacking FANCA show much lower levels of FANCL than wild-type cells. FANCL has E3 ubiquitin ligase activity and is a catalytic subunit for the monoubiquitination of FANCD2. It is speculated that once FANCA and FANCG undergo multimerization they act as a core to form a larger FANC protein complex (Fig. 89-2). This complex stabilizes FANCL allowing for the monoubiquitination of FANCD2 and its subsequent localization to the nucleus following DNA damage in which interactions with other DNA damage repair factors likely occur. As mentioned, cytokines such as IFN and TNF are thought to play a role in marrow failure via upregulation of the Fas receptor on hematopoietic progenitor cells. FANCC knockout mice have diminished hematopoietic colony-forming ability in the presence of INF-γ. Gain of function studies with transgenic mice that overexpress FANCC showed that marrow cells from these mice were several-fold less sensitive to the effects of cytokine exposure vs wild type when incubated in the presence of INF, TNF, or a Fas-triggering antibody. Additionally, there is upregulation of an INF-inducible gene, MxA, in these groups further supporting a role for increased apoptosis in signaling pathways that involve cytokines such as IFN and TNF. These data support a role for FANC genes in a pathway that regulates apoptosis as cells with absent or defective FANC genes are more susceptible to apoptotic stimuli.

Management Survival for patients with FA has increased over the past several decades with median survival at approx 30 yr of age. The first specific therapy for FA was androgenic steroids. Response was seen in up to 75% of patients, but most relapsed on withdrawal of therapy. Late complications, such as hepatocellular carcinoma, were also seen in some of the androgen-responsive patients. Hematopoietic growth factors have given mixed results. Leukocyte counts may rise, but other counts tend to not improve significantly. PBSCT offers a potential for cure. Data from the international bone marrow transplant registry show a 2-yr survival of 66% after a matched-sibling transplant. Unrelated donor or partially matched transplants, according to the international bone marrow transplant registry, perform poorly with a 2-yr survival of only 29% among these patients. Gene therapy is also attractive given that several of the complementation groups have been identified and cloned. Although retroviral vectors have been developed that allow expression of FANC proteins in human progenitor cells, in vivo data have been limited and corrected cells could only be demonstrated in the peripheral blood for brief periods following transduction.

DYSKERATOSIS CONGENITA DC is a rare disorder typically characterized by a triad of abnormalities including changes in skin pigmentation, nail dystrophy, and mucosal leukoplakia. Multiple other noncutaneous lesions have also been reported (gastrointestinal, neurological, pulmonary, dental, and musculoskeletal) and support the consideration of this disorder as an inherited multisystem syndrome. Bone marrow failure occurs as well and is the principle cause of early mortality. It is most commonly inherited in an X-linked fashion, thus >90% of affected patients are male. Autosomal-recessive and autosomal-dominant forms of the syndrome are also recognized.

Clinical Features Clinical manifestations have variable rates of presentation. For example, in X-linked cases, the median age of skin changes, nail dystrophy, and leukoplakia is 6–8 yr of age; however, the ranges vary from 1 to 25 yr. Almost 25% of patients develop pulmonary complications with reductions in diffusion capacity. Approximately 85% of patients develop peripheral cytopenias of one or more cell lines with approx 80% developing

pancytopenia. Median age of onset for hematological abnormalities is 8 yr with half developing pancytopenia before age 10. Bone marrow failure rates approach 94% by age 40. Patients with DC are predisposed to MDS and acute myelogenous leukemia (AML) in similar fashion to patients with FA.

Diagnosis Diagnosis is based on recognition of the components of the syndrome and the appropriate inheritance pattern among family members in a patient with progressive bone marrow failure. Peripheral blood again shows varying degrees of cytopenia among one or more cell lines. Bone marrow examination typically reveals a hypoplastic marrow with increased fat similar to other aplastic syndromes.

Genetics X-linked disease results from mutations in the *DKC1* gene in band 2, subband 8, of the long arm of chromosome X. The *DKC1* gene is made up of 15 exons across a region of 15 kb. The affected protein, dyskerin, has 514 amino acids with a molecular weight of 57 kDa. Dyskerin is a nucleolar protein associated with small nucleolar RNAs involved in ribosomal RNA biosynthesis. Based on functional studies of two homologs, the rat gene *NAP57* and the yeast gene *Cbf5p*, it appears that dyskerin is a member of the ribosomal RNA pseudouridine synthase group. These enzymes catalyze the isomerization of uridine to pseudouridine in noncoding RNA. The exact function of DKC1 and how genetic mutations within this gene lead to DC are unknown. Dyskerin is also associated with telomerase RNA as cells with genetic mutations of dyskerin have lower levels of telomerase activity. Patients with DC have shorter than normal telomeres, which may compromise the proliferative capacity of cells within the blood and epithelia. The gene responsible for an autosomal-dominant form of DC has been mapped to an 821-bp deletion on chromosome 3q, which removes the 3′ 74 bases of the telomerase RNA gene. Two additional point mutations within the telomerase gene have also been described. One is a novel heterozygous C→T mutation in the telomerase RNA gene at position 116 in affected family members with DC following an autosomal-dominant pattern. A second mutation in another family following autosomal-dominant inheritance involved a heterozygous C→G mutation at position 204 of the telomerase RNA gene. These findings suggest that DC develops as a result of defective telomerase activity. Defects in ribosomal RNA synthesis and/or inability to stabilize the telomerase enzyme may affect tissues dependent on constant renewal via stem cells such as gut, skin, and bone marrow leading to the multisystem syndrome of DC.

Management Treatment options for DC are limited. Use of steroids and growth factor support may be of benefit for short periods of time. The mainstay of treatment lies in allogeneic stem cell transplantation. Data on both related and unrelated allografts are limited secondary to the rare nature of this syndrome. Some evidence for long-term survival exists, although early and late fatalities from pulmonary complications after PBSCT have led to poorer overall results than with other conditions such as aplastic anemia or FA. Other systemic manifestations of DC are not corrected with PBSCT. Because DC is a single gene disorder, it is a good candidate for hematopoietic gene therapy. Creation of vectors with wild-type DKC1, for example, may be a therapeutic option for patients with X-linked DC.

SHWACHMAN–DIAMOND SYNDROME In 1964, SDS was first described in five patients with exocrine pancreatic deficiency and leukopenia. Further characterizations of the syndrome made up of exocrine pancreatic insufficiency, bone marrow failure, and skeletal changes with possible effects also seen in the

liver, kidneys, dental, and immune systems. SDS is the second most common cause of exocrine pancreatic insufficiency in children next to cystic fibrosis, occurring at an estimated incidence of 1/100,000–200,000. It is an autosomal-recessive disorder with the SDS locus mapped to chromosome 7.

Clinical Features Hematological abnormalities are varied regarding cytopenia and cell lines affected, many of which are detected in the neonatal period. Neutropenia is also a required diagnostic feature and approx 25% of patients develop marrow failure and aplastic anemia. There is also an increased risk of MDS and AML as with other congenital aplastic anemia syndromes.

Diagnosis Peripheral blood smears display varying degrees of cytopenias with neutropenia being the most common abnormality, occurring in 88–100% of cases. Anemia is usually normocytic, but macrocytosis is also found. Thrombocytopenia is seen in 25–90% of patients. Pancytopenia, seen in up to 65% of patients, is a poor prognostic sign and carries a higher chance of developing severe aplastic anemia if present. Hypoplasia and fatty infiltration are typically seen in varying degrees, and severity of cytopenia does not necessarily correlate with bone marrow findings. Many findings suggest that SDS is actually an MDS from its onset because it is a stem-cell disorder with peripheral cytopenia, ineffective hematopoiesis, scattered foci of dysplastic changes in the marrow, varying degrees of marrow cellularity, and a risk of transformation into acute leukemia. If dysplasia is a prominent feature, it signifies malignant myeloid transformation, which for SDS means more advanced stages of MDS.

Genetics Several different cytogenetic abnormalities have been reported in patients with SDS. Of these patients, 24% had isochromosome 7q[i(7q)], a finding uncommon in AML, acute lymphocytic leukemia, or MDS without SDS. It is likely a specific clonal marker for SDS given its high occurrence rate and is probably related to the SDS gene locus being at 7q11. Other chromosome 7 abnormalities have been described including monosomy 7, combined i(7q) and monosomy 7, and deletions or translocations involving the long arm of chromosome 7. This population of patients with chromosome 7 abnormalities has a high likelihood of developing subsequent MDS or AML. The exact mechanism of malignant myeloid transformation is not known, but it is possible the SDS gene product is required for the development and maintenance of stem cells or progenitor cells of other tissues. The SDS gene locus has been mapped to the centromeric region of chromosome 7 (7p10-7q11). Several mutations in the gene responsible for SDS, called *SBDS*, have been reported. The gene contains five exons and encodes a 250 amino acid protein of uncharacterized function. It is speculated that the *SBDS* gene product is involved in RNA metabolism. There is also a pseudogene, *SBDSP*, located in a duplicated genomic segment of 305 kb that shares 97% nucleotide identity with *SBDS*. Originally, SDS was thought to be a result of gene mutations involving a region within exon 2 of the *SBDS* gene. These mutations resulted from gene conversions owing to recombination with the *SBDSP* pseudogene. Although these data were from patients of European ancestry, other data from Japanese patients have identified two recurrent mutations (96-97insA, 258 + 2T→C) and three novel mutations (292-295delAAAG, 183-184TA→CT + 201A→G, and 141C→T + 183-184TA→CT + 201A→G). These mutations occurred in various locations between intron 1 and exon 3, not just within exon 2 as previously described. Additional studies are needed to help elucidate the exact mechanism by which these genetic mutations lead to the SDS phenotype.

Management Frequent monitoring of cytopenias and supportive care are mainstays of therapy for the hematological problems in patients with SDS. For severe neutropenia, growth factor support is often used and intravenous antibiotics are given if infection occurs. Occasional responses to immunosuppression have been reported but are rare. PBSCT is the only curative option for the hematological complications of SDS. PBSCT has been used more commonly during the MDS phase of the syndrome. Of seven patients transplanted during an MDS phase, one had a matched-related donor and was alive at 2 yr follow-up. Of the six receiving unrelated transplants, two were alive at 12 and 41 mo, whereas the other four died. Treatment for patients progressing to acute leukemia is standard induction therapy with an effort toward PBSCT as soon as possible.

MYELODYSPLASTIC SYNDROMES

MDSs are a group of hematological conditions characterized by one or more peripheral blood cytopenias with accompanying bone marrow dysfunction. They can occur *de novo* or secondary to treatment with chemotherapy or radiation therapy for other diseases. The secondary form of MDS usually has a poorer prognosis than *de novo* forms. Approximately one-third of cases of MDS progress to acute myeloid leukemia. The annual incidence is approx 4.1/100,000 with most series showing a male predominance. This compares to approx 2.1/100,000 for acute leukemia.

CLINICAL FEATURES MDS occurs predominantly in patients older than 60 yr. Common findings include anemia, fatigue, dizziness, exercise intolerance, and easy bruising (*see* Fig. 89-1). All are sequelae of peripheral cytopenias and not disease specific. Often patients are asymptomatic and diagnosed from routine blood work. Neutropenia is responsible for a high incidence of infections in patients with MDS. Autoimmune phenomena including arthritis, pericarditis, iritis, myositis, and peripheral neuropathy. Cutaneous vasculitis can occur although hepatosplenomegaly is an uncommon finding on physical exam.

DIAGNOSIS Normocytic or macrocytic anemia with a low reticulocyte count is almost uniformly present. About 50% of cases are present with neutropenia. Granulocytes often display decreased segmentation with reduced or absent granulation, a finding known as the pseudo-Pelger-Huet anomaly. Some degree of thrombocytopenia is present in approx 25% of cases. The bone marrow is usually hypercellular with single or multilineage dysplasia. The diagnosis of MDS should be considered in any patient with cytopenias of unclear etiology with a diagnostic work up including a peripheral blood smear and bone marrow biopsy with cytogenetics.

GENETICS Chromosomal abnormalities occur in up to 70% of MDS cases. The most common abnormalities are del(5q) and monosomy or del(7q). Trisomy 8, del(17p), and del(20q) are also frequently seen. Trisomy 8, del(5q), and del(7q) are seen in both MDS and AML; however, balanced translocations are distinct for AML and almost never seen in MDS. With the exception of the 5q-syndrome (deletion of the long arm of chromosome 5), cytogenetic changes do not typically correlate with any specific morphological subtype of MDS. In the 5q-syndrome, 80% of patients have refractory anemia and only approx 15% of these patients transform to acute leukemia. Although the majority of cases have an interstitial del(5)(q13q33), other deletions including del(5)(q15q33) and del(5)(q22q33) have been described. The mutations necessary for leukemic transformation in MDS are not known. Changes in the N-ras oncogene, p53 and *IRF-1* tumor suppressor genes, *Bcl-2*

Table 89-2
International Prognosis Scoring System in Myelodysplastic Syndrome

Variable	0	0.5	1.0	1.5	2.0
Marrow blasts (%)	<5	5–10	–	11–20	21–30
Karyotype	Good	Intermediate	Poor	–	–
Cytopenias	0–1	2–3	–	–	–
Risk group	*IPSS score*	*Median survival (yr)*			
Low	0	5.7			
Intermediate-1	0.5–1.0	3.5			
Intermediate-2	1.5–2.0	1.2			
High	>2.5	0.4			

Karyotypes: Good = normal, –Y, del(5q), del(20q); poor = complex (>3 abnormalities) or abnormal chromosome 7; intermediate = all others.
Cytopenias: neutrophils <1800/uL, platelets <100,000/uL, hemoglobin <10 g/dL.

apoptotic gene, and transcription factor genes such as *EVI1* and *MLL* have all been implicated.

PROGNOSIS Patients without cytogenetic abnormalities have a low likelihood of developing AML although complex cytogenetic abnormalities increase the chance of transformation to AML and are associated with refractory disease and subsequently shortened survival times. Overall, progression to AML occurs in 20–35% of patients. Prognosis is best for del(5q) and del(20q) abnormalities, intermediate for other single cytogenetic abnormalities, and poor if complex abnormalities are present. Single cytogenetic defects of chromosome 7, especially involving 7q32 also yield poor outcomes. There is an international prognostic scoring system (IPSS) for MDS based on percent marrow blasts, number of cytopenias, and types of cytogenetic abnormalities present (Table 89-2). Median survival times for good, intermediate, and poor outcome groups are 3.8, 2.4, and 0.8 yr, respectively, and correlate most strongly with the frequency of marrow blasts.

MANAGEMENT The four goals of treatment for MDS are to control symptoms resulting from cytopenias, improve quality of life with low toxicity, improve overall survival, and slow progression to AML. Treatment assessment should be based on age, performance status, and IPSS-defined risk category. Furthermore, treatments are categorized into high intensity (intensive chemotherapy regimens and stem cell transplant) vs low intensity (growth factor support and low intensity chemotherapy). In general, patients younger than 60 yr of age with a good performance status who have an IPSS intermediate to high-risk profile should be offered high intensity therapy. Those with low-risk IPSS profiles generally receive low intensity therapy. Those older than age 60 most often get low intensity therapy, although each patient must be evaluated individually. Supportive care with growth factors, antibiotics as needed for infections, and transfusional support are given to poor performance status patients. Treatments such as 5-azacytidine appear to delay the time to development of AML and reduce the frequency of transfusions by promoting cell differentiation through methylation of DNA.

AGNOGENIC MYELOID METAPLASIA/ MYELOFIBROSIS

There are both malignant and nonmalignant causes of collagen deposition within the bone marrow leading to myelofibrosis. The idiopathic form of myelofibrosis, also known as agnogenic myeloid metaplasia (AMM), is discussed here. This is a malignant disorder of the hematopoietic stem cell that leads to a nonclonal fibrosis of the marrow characterized by anemia, splenomegaly, and extramedullary hematopoiesis. First described in the late 1800s, it is classified with other myeloproliferative disorders including essential thrombocythemia, polycythemia vera, and chronic myelogenous leukemia. Essential thrombocythemia and polycythemia vera can develop into AMM. All of the myeloproliferative disorders are at risk for transformation into acute leukemia as well. The annual incidence of AMM is approx 0.5/100,000 with a median age at diagnosis of 60 yr. Noted risk factors include exposure to radiation, benzene, and thorium dioxide (used as a radioactive contrast agent). Viral origins for AMM and the other myeloproliferative disorders remain speculative.

CLINICAL FEATURES Symptoms of fatigue, weakness, palpitations, and dyspnea are not uncommon and may be disproportionate to the degree of anemia (*see* Fig. 89-1). Splenomegaly is typically present and may be massive in nature leading to early satiety and weight loss. Despite the multitude of symptoms that can be involved in AMM, at least 25% of patients are asymptomatic at presentation and the diagnosis is made by routine lab screening. Exam findings include pallor, jaundice, hepatosplenomegaly, petechiae, and easy bruising. Thrombosis of the portal or hepatic veins as well as increased portal blood flow from an enlarged spleen resulting from extramedullary hematopoiesis secondary to marrow fibrosis may occur and cause portal hypertension.

DIAGNOSIS The characteristic peripheral blood smear in AMM shows teardrop-shaped red blood cells with poikilocytosis. Immature myeloid cells and large platelets are also seen. The bone marrow often produces a “dry tap” secondary to fibrosis. The core biopsy shows patchy cellularity with clusters of dysplastic megakaryocytes. Reticulin stains are positive for varying degrees of fibrosis.

GENETICS No consistent cytogenetic abnormalities have been noted with AMM, although trisomy 8, 9, and 21 have been described. Other abnormalities including del(13q) and del(20q) have been reported. Although the hematopoiesis in AMM has a clonal nature, the fibrosis in AMM is thought to be a chronic reactive stromal process. Collagen deposition is increased within the marrow stroma with greater amounts of collagen types I, III, IV, and V present. This increased collagen deposition at sites of clustered megakaryocytes in AMM led to the search for possible cytokines that could explain the pathogenesis of fibrosis in this disorder. Platelet-derived growth factor, transforming growth factor (TGF)-β, and fibroblast growth factor-acidic are all cytokines contained within platelet granules. These cytokines can induce marrow fibroblast proliferation leading to AMM. Specifically, TGF decreases the synthesis of enzymes that degrade collagen and increases expression of certain genes responsible for creating various form of collagen. Other actions of TGF include stimulating increases in platelet-derived growth factor from endothelial cells within the marrow. This may allow for augmentation of fibroblast proliferation and increased collagen deposition as well. TGF-β may also cause a TPO-induced myelofibrosis as seen in mouse models. The bone marrow stem cells from wild-type and TGF-β null mice were infected with a retrovirus encoding TPO protein and engrafted into lethally irradiated hosts. Over time, myelofibrosis was seen in the spleen and marrow of all mice engrafted with wild-type cells vs no fibrosis in mice engrafted with TGF-β

null cells. AMM is associated with changes in megakaryocytopoiesis with accumulation of megakaryocytes within the marrow. This adds to the thought that activation of stromal cells by cytokines released by megakaryocytes may be the etiology of AMM. GATA-1 is a transcription factor with differentiating effects on erythroid and megakaryocytic cell lines. Mice with the GATA-1^{low} mutation develop a myelofibrosis-like disease suggesting that alterations in GATA-1 expression may also contribute to AMM pathogenesis. An exact gene locus responsible for AMM has not been elucidated, although candidate genes being studied include retinoblastoma, p53, p16, and RAS.

MANAGEMENT Treatment is instituted once a patient develops symptoms from severe anemia or thrombocytopenia, symptomatic splenomegaly, or from symptomatic extramedullary hematopoiesis, which can be in various tissues of the body. For suitable candidates, allogeneic stem cell transplant represents the only curative option. This is typically attempted in young patients with a matched sibling. Agents such as hydroxyurea and IFN have been used to reduce symptomatic splenomegaly and improve peripheral cell counts. Growth factor support has also been used with limited success in those who are not candidates for stem cell transplant. Certain subsets of patients with severe thrombocytopenia, refractory associated hemolytic anemia, portal hypertension with gastrointestinal bleeding, and symptomatic, massive splenomegaly should be considered for splenectomy. Symptoms of more than 50% of patients improve despite the transient decrease in blood counts frequently following such a procedure. If a patient is inoperable, splenic irradiation may be a reasonable alternative. Median survival for AMM is approx 5 yr. The presence of circulating early precursors cells, severe anemia, and cytogenetic abnormalities decreases survival by as much as 50%.

OTHER CAUSES OF BONE MARROW FAILURE/PERIPHERAL CYTOPENIAS

DIAMOND–BLACKFAN ANEMIA Diamond–Blackfan anemia (DBA), a rare congenital hypoplastic anemia, presents in infancy at an incidence of 4–5/million live births. Dominant and recessive inheritance is found in approximately one-fourth of cases. Patients have a moderate-to-severe macrocytic anemia, occasional neutropenia and thrombocytosis with erythroid hypoplasia in a normocellular bone marrow. Head and upper extremity anomalies are present in one-fourth of individuals. Linkage studies including families with dominant and recessive inheritance patterns have localized the DBA gene to chromosome 19q13. In 25% of dominantly inherited DBA, mutations in a critical 1 Mb region coding for ribosomal protein S19 are found with up to 60 mutations across the entire gene having been described. The protein is ubiquitously expressed in hematological and nonhematological tissues, but it remains unclear how defects in this gene cause problems with erythropoiesis.

KOSTMANN SYNDROME Kostmann syndrome (KS) is an autosomal-recessive disorder notable for severe neutropenia resulting in frequent bacterial infections and early death. Bone marrow shows normal erythroid and platelet precursors with absent or markedly reduced myeloid cells. Increased risks of MDS and/or AML exist for these patients. Some evidence of a defect in the GCSF receptor exists although the data are inconclusive and contradictory. Expression of Bcl-2 is decreased in myeloid progenitor cells of patients with KS although mitochondrial release of cytochrome *c* and apoptosis are increased compared with controls. Additionally, treatment with GCSF improved both Bcl-2 expression and progenitor cell survival although partially reversing cytochrome *c* release from mitochondria. This points to a possible role for mitochondria-dependent apoptosis in the pathogenesis of KS and lends support to the use of hematopoietic growth factors in treating the syndrome. Although the exact genetic mechanism of KS remains unclear, treatment with recombinant GCSF can have a positive impact on the lives of patients with this disorder, and stem cell transplant is used only in rare circumstances in which treatment with GCSF is unsuccessful.

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA Congenital amegakaryocytic thrombocytopenia (CAMT) is a rare disorder that presents in infancy with isolated thrombocytopenia and progresses into pancytopenia later in childhood. TPO is important for megakaryopoiesis as well as early hematopoiesis with high levels of TPO found in the sera of patients with CAMT. Assays for reactivity to TPO in platelets and early progenitor cells in patients with CAMT were negative. Further flow analysis found an absence of the TPO surface receptor c-mpl in patients with this disorder. Several point mutations in the c-mpl gene lead to complete loss of receptor function. It is postulated that this is the cause of the thrombocytopenia and progressive pancytopenia seen in CAMT. For example, one point mutation leads to an exchange of arginine 102 to proline, which may alter protein folding and subsequent binding of TPO to its receptor.

NUTRITIONAL CAUSES OF PANCYTOPENIA Severe nutritional deficiencies can result in single or multilineage cytopenias. Three prominent deficiencies include vitamin B12, folate, and iron. With B12 and folate deficiencies, patients typically present with a megaloblastic anemia that results from impaired DNA synthesis. Hereditary forms of B12 deficiency exist, such as Imerslund–Grasbeck's disease (megaloblastic anemia 1) that is inherited in an autosomal-recessive pattern and caused by malabsorption of intrinsic factor-B12 complex. A disease specific mutation called P1297L (FM1) in the IF-B12 receptor, cubilin, results in loss of affinity of the mutant receptor for the IF-B12 complex and thus decreased absorption of B12. Hematological findings of B12/folate deficiency include a macrocytic anemia, elevated lactate dehydrogenase and bilirubin from ineffective erythropoiesis, normal to low reticulocyte count, and normal to low leukocytes and platelets. Neutrophils are typically hypersegmented (>5% of neutrophils with five or more lobes or 1% with six or more lobes). Bone marrow biopsy shows a hypercellular marrow with megaloblastic erythroid hyperplasia. Iron deficiency results from many causes with blood loss being the most common etiology. Malabsorption of iron is uncommon but does occur with such disease entities as celiac sprue. The anemia is microcytic/hypochromic in nature. Symptoms such as fatigue, dyspnea, and poor exercise tolerance ensue as the anemia progresses. With severe anemia from any nutritional deficiency, pancytopenia may occur and disorders such as MDS, AML, and aplastic anemia must be excluded.

90 Coagulation Disorders

Stephan Moll and Gilbert C. White II

SUMMARY

Venous thrombosis is mostly caused by disturbances in the plasma coagulation system with platelet participation playing a minor role, whereas in arterial thrombosis platelets play the predominant role, with some participation of the plasma coagulation system. This paradigm helps explain why coagulation factor abnormalities, such as factor V Leiden, or deficiencies of protein C, protein S, and antithrombin predominantly lead to venous thromboembolism. An understanding of the role of abnormalities predisposing to arterial thromboembolism, such as platelet receptor polymorphisms, is just emerging. At present, inconsistent findings of studies regarding the association of these polymorphisms with arterial thromboembolism limits their clinical usefulness.

Key Words: Hypercoagulability; thrombophilia; thrombosis.

PHYSIOLOGY OF COAGULATION

When vascular integrity is interrupted, the coagulation process is initiated by the contact of plasma factor VIIa with tissue factor expressed on extravascular cells, mainly fibroblasts and monocytes. Thrombus formation is complex and involves four major systems:

1. Activation of coagulation factors in several steps (initiation, amplification, and propagation).
2. Participation of platelets.
3. Limitation of clot extension via the natural anticoagulant system.
4. Dissolution of thrombus through the fibrinolytic system.

INITIATION OF COAGULATION

Low concentrations of activated factor VII (VIIa) normally circulate in the bloodstream. Disruption of vascular integrity brings plasma factor VIIa in contact with tissue factor expressed on extravascular cells. Although free factor VIIa is a weak enzyme, the enzymatic activity of factor VIIa markedly increases on binding to tissue factor. The membrane-bound complex of tissue factor and factor VIIa (TF–VIIa complex) initiates coagulation (Fig. 90-1A). Factor X binds to this complex and becomes activated to factor Xa. When factor Xa leaves the protected environment of the cell surface, it is rapidly inactivated by antithrombin or tissue factor pathway inhibitor, but the factor Xa that remains on the tissue factor-bearing cell surface leads to limited proteolysis of inactive factor V, thus generating factor Va. The factor Xa–factor Va complex on the tissue factor-bearing cell leads to cleavage of prothrombin and the production of small amounts of thrombin. Amplification and propagation steps are needed to generate sufficient amounts of thrombin for thrombus formation. Another event that occurs in the initiation phase is the activation of factor IX to IXa by the TF–VIIa complex. However, factor IXa cannot activate factor X to factor Xa because factor VIIIa, a necessary cofactor, has not yet been formed. Factor VIIIa becomes available only after the initial small amount of thrombin has been generated and has enzymatically cleaved factor VIII to factor VIIIa.

AMPLIFICATION

The small amount of thrombin generated on the surface of the tissue factor-bearing subendothelial cells during the initiation phase activates platelets that have adhered to the subendothelial matrix via von Willebrand factor at the site of injury. In addition, this phase includes the activation of platelet-bound factor VIII to factor VIIIa, activation of factor V to factor Va, activation of inactive TF–VII complex to TF–VIIa complex, activation of factor XI to factor XIa, and further activation of factor IX to factor IXa (Fig. 90-1B).

PROPAGATION

During the propagation phase, the activated coagulation factors generated during the amplification phase combine with their cofactors on the activated platelet surface and form the “tenase” and “prothrombinase” complexes. This combination results in large-scale thrombin generation, or the so-called thrombin burst, which leads to fibrinogen cleavage and fibrin polymerization. The main pathway for the thrombin burst is via TF–VIIa complex-induced activation of factor IX to factor IXa. The direct activation of factor X to factor Xa by the TF–VIIa complex plays a minor role in this propagation step.

PLATELET PARTICIPATION

The initial response of platelets in the coagulation process is to adhere to the extravascular matrix at the site of vascular injury. The interaction of the platelet glycoprotein (GP) Ib/IX/V receptor complex with collagen through the binding of von Willebrand factor mediates platelet adherence to the matrix. The platelet surface provides the phospholipid-binding proteins for coagulation factors so that the platelet membrane-based coagulation reactions leading to the thrombin burst can occur. The thrombin burst during the propagation phase of coagulation further activates platelets, which

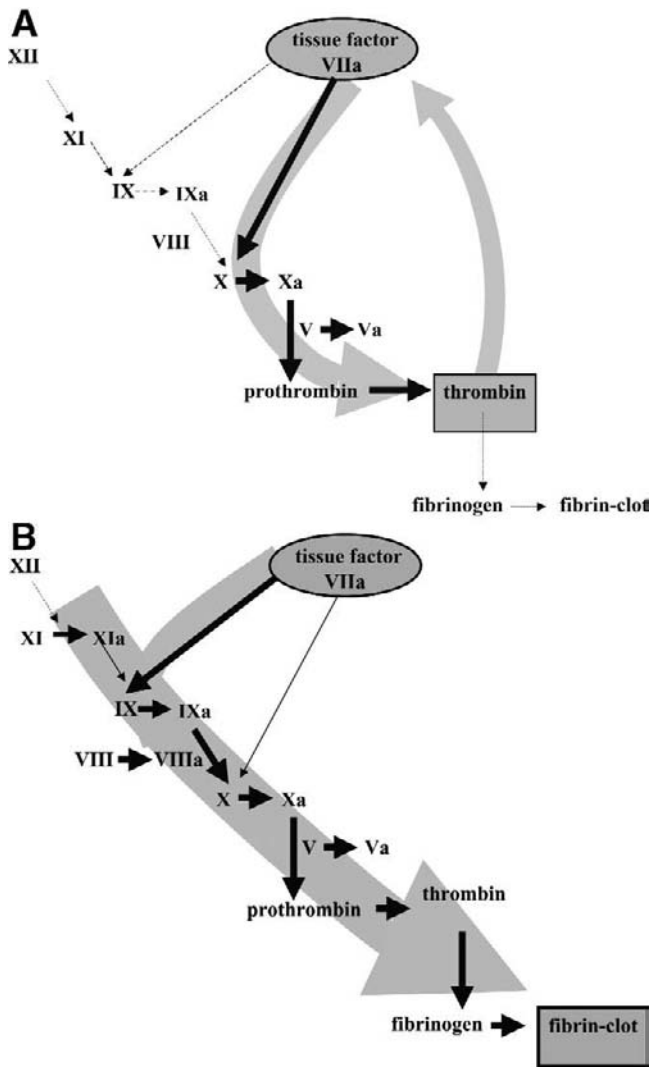

Figure 90-1 **(A)** Initiation step of coagulation. (**B)** Propagation and amplification steps of coagulation.

causes a conformational change of the GP IIb/IIIa receptors. Fibrinogen and other adhesive molecules can then bind to these altered receptors. The bivalent fibrinogen molecules bridge two GP IIb/IIIa receptors of adjacent platelets, thus, forming platelet aggregates and stabilizing the clot.

CLOT STABILIZATION

Once the platelet–fibrin clot has formed, fibrin is stabilized by factor XIII. In the presence of fibrin, thrombin converts factor XIII to the enzyme factor XIIIa. Factor XIIIa catalyzes the formation of intermolecular ε-(γ-glutamyl) lysine bonds between various protein substrates such as fibrinogen monomers, α_2 antiplasmin, fibronectin, and collagen. These intermolecular crosslinking reactions contribute to hemostasis and to wound healing.

NATURAL ANTICOAGULANT SYSTEM

When thrombin is generated and a thrombus forms at the site of vascular injury, a system of natural anticoagulants is activated that inhibits extension of the thrombus by several containment mechanisms.

TISSUE FACTOR PATHWAY INHIBITOR Tissue factor pathway inhibitor, a 276-amino acid GP produced by endothelial cells, is the main inhibitor of the tissue factor pathway. It inhibits the tissue factor–factor VIIa/factor Xa complex by binding to both tissue factor–factor VIIa and factor Xa.

ACTIVATED PROTEIN C Activated protein C (APC) inhibits thrombin generation by regulating levels of factor Va and VIIIa, which are cofactors in the reactions leading to generation of thrombin and factor Xa. In an autoregulatory mechanism, thrombin activates protein C in a reaction localized to the vessel wall. Thrombin binds to thrombomodulin, which is expressed on the endothelial cells adjacent to the site of vascular injury. Thrombomodulin is a cofactor for the conversion of protein C to APC by thrombin. Together with its cofactor protein S, APC inactivates factor Va and factor VIIIa. Factor Va is cleaved by proteolytic degradation at amino acid positions 506 and 306, and factor VIII is cleaved at positions 562 and 336.

ANTITHROMBIN Antithrombin, formerly antithrombin III, inhibits thrombin, factor Xa, and other serine proteinases, such as factors IXa, XIa, XIIa, and kallikrein. Because antithrombin inhibits free thrombin and free factor Xa more efficiently than thrombin and factor Xa bound to platelet surfaces or clots, its main role may be to control low-level basal activation of the coagulation system that occurs in the normal circulation. Alone, antithrombin is not a very effective anticoagulant, unless given in high doses. The inhibitory action of antithrombin is markedly potentiated by heparin.

HEPARIN COFACTOR II Heparin cofactor II (HcII) is a 480-amino acid GP produced in hepatocytes that circulates in plasma. Although it inhibits thrombin, HcII does not inhibit factor Xa or other coagulation factors. Unlike antithrombin, HcII has the advantage of inhibiting surface-bound thrombin. HcII probably participates in the in vivo inhibition of thrombin as indicated by the presence of low levels of thrombin–HcII complexes in normal plasma samples. Binding of heparin potentiates HcII thrombin inhibitory activity about 1000-fold.

FIBRINOLYTIC SYSTEM

Once formed, clots can be lysed by the action of plasmin on fibrin. Plasmin is the primary enzyme of the fibrinolytic system and is generated by the activation of the precursor protein plasminogen to plasmin. Plasminogen, which circulates as an inactive zymogen in plasma, is incorporated throughout the thrombus by binding to lysine-binding sites on the polymerizing fibrin molecule. In response to poorly understood stimuli, possibly via thrombin, tissue plasminogen activator (tPA) is released from endothelial cells. tPA converts plasminogen, especially plasminogen bound to fibrin, to the active serine protease plasmin. Under physiological conditions, α_2-antiplasmin rapidly and irreversibly inactivates plasmin. Because free plasmin is more rapidly and efficiently inhibited than fibrin-bound enzyme, fibrin-bound plasmin can actively degrade fibrin. The primary role of the plasminogen–plasmin system is not to dissolve large clots, but to prevent excessive fibrin and clot formation.

PATHOPHYSIOLOGY OF THROMBUS FORMATION

Venous thrombosis is usually caused by disturbances in the plasma coagulation system, with minimal platelet participation. In contrast, platelets play a major role in arterial thrombosis, with some participation of the plasma coagulation system. This paradigm

Table 90-1
Summary of Genetic and Molecular Properties of Blood Coagulation Proteins

	Chromosome location	*Gene symbol*	*DNA basepairs*	*Number of exons*	*Amino acid length*	*Molecular weight (kDa)*	*Plasma concentration*	*Function*

helps explain why coagulation protein abnormalities, such as factor V Leiden or deficiencies of protein C, protein S, and antithrombin, usually lead to venous thromboembolism. In addition, this scenario explains why antiplatelet drugs prevent arterial thrombosis, but are less effective on venous disease. Thrombus formation in the cardiac ventricles and atria is often attributed to stagnant blood flow in akinetic, dyskinetic, or aneurysmal parts of the heart chambers or in fibrillating atria. Arising in a slow-flow environment, these thrombi are more likely caused by mechanisms similar to the ones that lead to venous thrombosis.

Arterial clots usually form in areas of atherosclerotic vascular damage. The events leading to atherosclerosis, mainly lipid disturbances, oxidative stress, and inflammation, are discussed elsewhere. The composition and vulnerability of plaque, rather than its volume, and the severity of stenosis are the most important determinants for the development of arterial ischemic syndromes. Monocytes and macrophages in plaque express high levels of tissue factor. When the fibrous cap or endothelium overlying an atheromatous plaque is disrupted, collagen and tissue factor are exposed, which causes platelets to adhere and aggregate and thrombus to form. Understanding of the events leading to arterial thrombosis has led to the development of treatment strategies that are directed against the local vascular prothrombotic milieu. These strategies include the following: (1) topical application of anticoagulants; (2) placement of stents or grafts with virus-transduced confluent endothelial cells that secrete anticoagulants; and (3) locally applied gene therapy to express inhibitors of tissue factor or to manipulate function of vascular smooth muscle cells or local inflammatory processes.

Stasis of blood is a well-known trigger factor for venous thrombosis. However, the events that trigger an episode of spontaneous (often called "idiopathic") venous thromboembolism in a specific location and at a certain time are not well understood. The lack of understanding of the initiating events of spontaneous venous thrombosis makes it impossible to develop locally active antithrombotic strategies.

Although the events leading to arterial thromboembolism are better understood than those leading to venous thromboembolism, the thrombophilic abnormalities predisposing to arterial events are less understood. Multiple inherited abnormalities that increase a patient's risk for venous thromboembolism are known, but few are known that predispose to arterial events. The defects involving the protein C anticoagulant pathway, mainly protein C and S deficiency, factor V Leiden, and APC resistance, have been well studied and have been associated with venous thromboembolism. Scientists are beginning to understand how a specific genotype leads to a certain phenotype and to disease for several of the polymorphisms, such as the fibrinogen and platelet GP receptor molecules (Table 90-1). However, results have been conflicting regarding the association of many polymorphisms with arterial thrombotic disease.

FIBRINOGEN

Fibrinogen is a complex GP that consists of two disulfide-linked monomers. Each monomer is 1482 amino acids long and comprises three different polypeptide chains: an α-, β-, and γ-chains. The complete amino acid sequence for human fibrinogen has been determined. The complex assembly of the three polypeptide chains

that form the trinodular fibrinogen structure has been partially defined. Fibrinogen is synthesized, processed, and assembled primarily in hepatocytes. The synthesis of fibrinogen is markedly increased during an acute-phase state caused by inflammation, tissue damage, or stress. Production of interleukin-6 by inflammatory cells stimulates hepatocytes to increase the production of hepatocyte nuclear factor, which increases transcription of fibrinogen. Fibrinogen is transformed to fibrin after thrombin proteolytically removes fibrinopeptide A from the amino-terminus of the α-chain and fibrinopeptide B from the β-chain. Removal of these peptides exposes sites on the fibrinogen molecule that allow for polymerization or for intermolecular reactions between fibrinogen dimers, thereby forming a fibrin network.

High levels of plasma fibrinogen, an important risk factor for arterial disease, are associated with the development of ischemic heart disease, stroke, and peripheral vascular disease complications. The relative risk for most of these associations is up to twofold when comparing patients in the top 10% of the distribution of fibrinogen levels with the remainder. Several mechanisms for this increased risk have been postulated: (1) increased blood viscosity, (2) increased fibrin formation, and (3) increased availability of fibrinogen for platelet aggregation. However, an alternative explanation for this association is that fibrinogen levels increase as atherosclerotic disease progresses. The association may, therefore, reflect a reactive rather than a causative process.

Genetic variation in the fibrinogen genes may contribute to the rate of synthesis of fibrinogen, such as an increased basal rate of transcription of the β-fibrinogen gene. Several polymorphisms have been identified in the three genes coding for fibrinogen, including –455G/A, –854G/A, C148T, and *Bcl*I in the β-chain gene, and *Taq*I and Thr312Ala in the α-chain gene. However, results of studies of the association of these polymorphisms with increased fibrinogen levels and vascular disease have been conflicting.

The –455G/A polymorphism, which defines a recognition site for the restriction enzyme *Hae*III, has been of particular interest. The A allele of –455G/A has distinct nuclear protein-binding properties and is associated with a higher basal rate of transcription of the β-fibrinogen gene. This allele could increase the risk of vascular disease, and some studies have shown an association between the polymorphism and arterial occlusive disease (peripheral, coronary, or cerebrovascular); however, other studies have not. Studies of the –455G/A polymorphism and a critical review of the relations between genotype, phenotype, and disease within clinical studies have been published. Even though a small effect cannot be excluded, –455G/A does not appear to be an important genetic determinant of arterial vascular disease.

High fibrinogen levels are a risk factor for venous thromboembolism, and the increase in risk of thrombosis is four times higher in patients with plasma fibrinogen levels greater than 5 g/L than in those with low levels. Fibrinogen gene polymorphisms have been less extensively studied in venous thromboembolism. No association was found between the C148T, the –455G/A, or the *Bcl*I polymorphisms and venous thromboembolism. The Thr312Ala polymorphism was associated with pulmonary embolism, but not deep vein thrombosis.

Several fibrinogen gene mutations have been identified that lead to dysfibrinogenemias. The clinical presentation varies. About half of the patients are asymptomatic; the other half has either a bleeding or clotting tendency. Venous thrombosis predominates over arterial thrombosis.

FACTOR VII

Factor VII is a vitamin K-dependent, 416-amino acid single-chain GP that is produced in the liver and circulates in plasma as a zymogen. Factor VII is converted to the serine protease factor VIIa by limited proteolysis in the presence of thrombin, factor IXa, factor Xa, and factor XIIa. The TF–VIIa complex further activates factor X to factor Xa and factor IX to factor IXa and initiates subsequent thrombin formation.

High levels of factor VII activity were associated with an increased risk of ischemic heart disease in the Northwick Park study. However, in several follow-up studies, such as the Prospective Cardiovascular Munster study, the Edinburgh Artery study, and the Etude Cas Temoin sur l'Infarctus du Myocarde study, no association was found. Small amounts of activated factor VIIa circulate in plasma under physiological conditions. However, increased factor VIIa levels are not associated with an increased risk of coronary artery disease or previous myocardial infarction. Increased factor VII levels are not associated with venous thromboembolism.

Several polymorphic sites have been identified in the factor VII gene. These sites are associated with plasma factor VII levels and together may account for up to 40% of the fluctuations in factor VII plasma levels. However, the relation between these polymorphisms and ischemic vascular disease has not been consistently shown. The most extensively studied polymorphism is Arg353Gln. Homozygosity for the Gln allele appears to lower plasma factor VII levels. Although decreased factor VII levels were associated with a lower risk of myocardial infarction in individuals with the Gln allele of the Arg353Gln polymorphism in one study, these findings were not confirmed in several large studies. Moreover, the Gln allele was associated with an increased risk of myocardial infarction in the Survival of Myocardial Infarction Long-term Evaluation study. A recent study indicates that the Gln allele of the Arg353Gln polymorphism with its associated lower factor VII plasma levels protects against myocardial infarction only in patients with pre-existing coronary artery disease. No association has been found between factor VII polymorphisms and stroke or venous thromboembolism.

FACTOR VIII AND VON WILLEBRAND FACTOR

FACTOR VIII Factor VIII, a 2330-amino acid GP, is one of the largest coagulation proteins. Activated factor VIIIa is a cofactor in the tenase complex for the activation of factor X to factor Xa by factor IXa. Factor VIIIa increases by 200,000-fold the rate of activation of factor X to Xa. Primarily synthesized by hepatic sinusoidal endothelial cells and Kupffer cells and to a lesser degree by hepatocytes, factor VIII is an acute phase protein that is transcriptionally responsive to interleukin-6.

High factor VIII levels have been associated in several large studies with an increased risk of ischemic heart disease and stroke. However, high levels were not an independent risk factor for coronary heart disease in the Atherosclerosis Risk in Communities study.

When measured at a time separate from the acute thrombotic event, high factor VIII levels are the single most common abnormality detected in patients with unexplained venous thromboembolism, occurring in 25.4% of patients. High factor VIII levels are associated with a fivefold risk for venous thromboembolism and are a risk factor for recurrence. The mechanisms that cause high factor VIII levels are unclear.

VON WILLEBRAND FACTOR Von Willebrand factor is synthesized primarily in endothelial cells and has three functions: (1) binding to exposed subendothelial collagen at a site of vascular injury, (2) promoting platelet adhesion via the GP Ib/IX/V receptor, and (3) binding and stabilizing factor VIII, which prolongs its half-life in plasma. Factor VIII and von Willebrand factor circulate in plasma bound to one another. These factors, therefore, have similar associations with cardiovascular disease. Evidence suggests, albeit inconsistently, that von Willebrand factor is an independent risk factor for cardiovascular disease. Several studies reported an association between high levels of von Willebrand factor and cardiovascular disease; however, no independent association with coronary heart disease or stroke was found in two studies. von Willebrand factor is not an independent risk factor for venous thromboembolism.

FACTOR IX AND FACTOR XI

Factor IX is a vitamin K-dependent GP, which, when activated by factor VIIa–tissue factor or factor XIa, converts factor X to factor Xa. The formation of factor Xa leads to the formation of the fibrin clot. Increased factor IX levels are a risk factor for venous thromboembolism. The risk of venous thrombosis is two to three times higher in patients with factor IX levels above the 90th percentile of control subjects than in those below the 90th percentile.

Factor XI is activated to factor XIa by thrombin. Factor XIa participates in the coagulation process and thrombin formation. High levels of factor XI are a risk factor for deep vein thrombosis, and the risk is doubled at levels that are present in 10% of the population.

FACTOR V

Factor V, a 2196-amino acid protein with a molecular weight of 33 kDa, is activated to factor Va in the initiation step of coagulation by factor Xa and in the subsequent amplification and propagation steps by thrombin. Factor Va participates as a cofactor in the prothrombinase complex formation that leads to the generation of thrombin. APC inactivates factor Va at two primary cleavage sites, Arg 506 and Arg 306. Two mechanisms for this cleavage have been proposed. In one view, initial cleavage at Arg 506 promotes a more rapid cleavage at Arg 306, which is the main inactivation step. The second hypothesis is that cleavage at both sites is random but is much slower at Arg 306.

FACTOR V LEIDEN A common polymorphism, G1691A, leads to an Arg506Gln mutation (also called R506Q) and is referred to as factor V Leiden. The expressed mutant is resistant to APC because it lacks the APC cleavage site at Arg506. Factor V Leiden, discovered in 1994 by a group of researchers in Leiden outside of Amsterdam, is a mutation that arose in Europe and is predominately found in Caucasians and, to a lesser degree, in populations that have some Caucasian ancestry. The carrier frequency is 8.8% in Europeans, 5.3% in Caucasian Americans, 2.2% in Hispanic Americans, 1.25% in Native Americans, 1.2% in African Americans, and 0.45% in Asian Americans. Haplotype analysis of factor V gene polymorphisms indicates that the factor V Leiden mutation arose 21,000–34,000 yr ago and originated from a single Caucasoid ancestor. The mutation does not occur in native Africans and native Asians.

Factor V Leiden is the most common inherited risk factor for venous thrombosis. The risk of thrombosis is seven times higher for heterozygous patients and 80 times higher for homozygous patients than for those without this mutation. This risk is further amplified by other genetic and environmental thrombosis risk factors. The absolute annual incidence of spontaneous venous thromboembolism in asymptomatic carriers of the factor V Leiden mutation is low (0.26% per year). Although some studies indicated that the risk for recurrent venous thromboembolism might not be higher in carriers of factor V Leiden than in those without it, a meta-analysis of these studies indicated a slightly higher recurrence risk in carriers. However, current recommendations for length of oral anticoagulation after a first thrombotic event are the same for carriers and noncarriers.

The role of factor V Leiden in arterial disease has been studied with inconsistent findings. In most studies, factor V Leiden was not associated with arterial disease. However, an occasional study has shown a slightly increased risk for arterial thrombotic disease with factor V Leiden or reported a positive association in highly selected populations, such as women younger than 45-yr old who smoke. Most investigators conclude that factor V Leiden does not affect ischemic heart disease or stroke, except in highly selected subgroups of patients in the presence of other arterial risk factors.

The diagnosis of factor V Leiden is made either by genetic testing or by the functional coagulation test called the APC resistance assay. The sensitivity of the assay varies, depending on the test kit and the APC ratio cutoff used and can be as high as 97.1%. Depending on the APC resistance assay used and the population studied, up to 37% of patients with an abnormal APC resistance test do not have factor V Leiden. An abnormal APC resistance test should always be followed by genetic testing because other conditions, such as a lupus anticoagulant, can cause an abnormal result.

FACTOR V HR2 HAPLOTYPE An HR2 haplotype of factor V has been described, which includes a 4070 A > G polymorphism in exon 13 of the factor V gene, replacing His (R1 allele) by Arg (R2 allele) at position 1299 of the B domain. Because the HR2 haplotype was associated with decreased plasma factor V levels, this haplotype was suspected to increase the risk of thrombosis if factor V Leiden was also present (i.e., if a patient was double heterozygous). The findings of several case–control studies have been conflicting on whether the HR2 haplotype increases the risk of venous thrombosis, either by itself or in combination with factor V Leiden. A large prospective study found that homozygosity for the HR2 haplotype is rare but may be a risk factor for venous thrombosis. Although the heterozygous HR2 haplotype is not a risk factor for venous thrombosis, patients who are double heterozygous for HR2 and factor V Leiden have a higher risk of venous thrombosis than those with factor V Leiden alone. The HR2 haplotype is not associated with an increased risk of myocardial infarction.

FACTOR V CAMBRIDGE A G1091C factor V polymorphism leading to an Arg306Thr substitution is referred to as factor V Cambridge and has been associated with APC resistance in one report. In a study of 104 patients with venous thromboembolism and 208 controls without thrombosis, factor V Cambridge was found in only one control participant. These limited data suggest that factor V Cambridge may not be a risk factor for venous thromboembolism.

FACTOR V HONG-KONG A polymorphism in the factor V gene (A1090G) results in an Arg306Gly substitution and is referred to as factor V Hong-Kong. In one report, factor V Hong-Kong was not associated with APC resistance. In a small study of 43 Chinese patients with venous thromboembolism and 40 controls without thromboembolism, factor V Hong-Kong was found in 4.7% of thromboembolic patients and 2.5% of controls. The

data are too few to assess whether this polymorphism is a risk factor for venous thromboembolism in Chinese patients. However, because of its rarity in Caucasians, this polymorphism is not a risk factor in that group.

PROTHROMBIN (FACTOR II)

Prothrombin is a 579-amino acid GP that circulates in plasma as a zymogen. During the final stages of the blood coagulation process, prothrombin is converted to thrombin by the cleavage of an internal Arg-271-Thr peptide bond. This reaction is catalyzed by factor Xa in the presence of factor Va, calcium ions, and phospholipids. A complex of these components is called the prothrombinase complex.

A G to A substitution at nucleotide position 20210 in the 3′ untranslated end of the prothrombin gene is common. Individuals who are heterozygous for this polymorphism have slightly higher levels of circulating prothrombin and are at a 2.8-fold increased risk for venous thromboembolism over those who are homozygous for the wild type. The overall prevalence of heterozygous II20210 is 2% in Caucasians, 3% in southern Europeans, and 1.7% in northern Europeans. The prothrombin variant is rare in individuals of Asian and African descent and in African Americans, of whom 0.3% are heterozygous for the prothrombin 20201 mutation. The homozygous prothrombin 20210 mutation is uncommon, occurring in approx 1 in 10,000 individuals, and fewer than 50 cases have been reported. Several homozygous individuals had venous thromboses and several were asymptomatic; however, the small number of reported cases precludes a solid risk assessment.

The prothrombin 20210 mutation has not been associated with arterial thrombotic disease in most studies. However, some studies have shown an association in selected subgroups, such as patients with premature atherosclerotic disease who have had a myocardial infarction or who have major cardiovascular risk factors.

PROTEIN S

Protein S, first isolated and characterized from human plasma in 1977, is a vitamin K-dependent, 635-amino acid single-chain GP. “S” stands for Seattle, in which the discovery was made. Forty percent of protein S is found in a free form and the remaining 60% in a complex with C4b-binding protein. Only free protein S functions as a cofactor of APC in the inactivation of factor Va and VIIIa. Protein S can be cleaved by thrombin, which inactivates protein S cofactor activity.

Protein S deficiency, an autosomal-dominant disorder, was first described in 1984. A database of protein S gene mutations comprising 131 different mutations that cause protein S deficiency has been published. Severe protein S deficiency caused by homozygous or double heterozygous mutations leads to severe neonatal purpura fulminans and death.

Three types of protein S deficiency have been identified. Type I, a quantitative deficiency, is characterized by decreased levels of both free and total protein S antigens. In type II deficiency, which is a qualitative defect caused by a dysfunctional protein, protein S activity is low, but free and total antigen levels are normal. In type III deficiency, another quantitative defect, free protein S antigen levels are low, but the total antigen level is normal. Type III deficiency reflects either a high concentration of C4b-binding protein in plasma or an abnormal binding of protein S to this carrier protein. Most mutations (approx 93%) lead to a quantitative deficiency, either type I or type III.

The prevalence of inherited protein S deficiency in the general population varies between 0.03 and 0.13%; however, the true prevalence is unknown because of diagnostic difficulties. In addition, protein S deficiency occurs as an acquired condition in the setting of oral contraceptive use, pregnancy, liver disease, nephrotic syndrome, disseminated intravascular coagulation, and therapy with vitamin K antagonists. Inherited protein S deficiency cannot be diagnosed in these circumstances until the underlying condition is corrected.

Inherited protein S deficiency predisposes mainly to venous thromboembolism. Arterial thromboembolism has been reported, but a true association has not been shown. Inherited protein S deficiency increases the risk of venous thromboembolism 2.4- to 11.5-fold. Some investigators have not found an increased risk of thrombosis in individuals with inherited protein S deficiency. The clinical phenotype of patients with protein S deficiency is clearly heterogenous, a fact that should be considered when making decisions on anticoagulant treatment and family counseling.

The presence of free and bound protein S in plasma makes the diagnosis of protein S deficiency difficult. The most useful measurement or reference range for diagnosing this deficiency has not been identified. The diagnosis is further complicated by an overlap of protein S levels in normal and heterozygous protein S-deficient individuals and by fluctuations in protein S levels over time. Furthermore, age, sex, pregnancy, and hormonal status affect protein S levels. A reliable test for quantitative protein S deficiency is the determination of free protein S antigen levels. However, type II protein S deficiency may be missed when antigen levels alone are determined. If only activity is determined, some patients with quantitative and qualitative protein S deficiency may not be diagnosed because some activity assays give false–normal results. Therefore, both functional testing (protein S activity) and immunological testing (free and total protein S antigen) should be conducted in the evaluation of protein S deficiency.

PROTEIN C

Protein C is a 461-amino acid, vitamin K-dependent GP that circulates in the blood as a precursor to a serine protease. Protein C is converted to APC by the thrombin–thrombomodulin complex on endothelial cells. APC is a serine protease that acts as a natural anticoagulant. Together with protein S as a cofactor, APC inactivates factor Va and factor VIIIa by proteolytic cleavage, rendering them incapable of acting as cofactors in the activation of factor X and prothrombin. Thus, protein C regulates the tenase and prothrombinase complexes.

Protein C deficiency as a cause of thromboembolism was first described in 1981. Type I deficiency is a quantitative deficiency with low functional protein C (activity) and immunological (antigen) levels, whereas type II is a qualitative deficiency with low activity but normal antigen levels. Type II varieties include defects in activation of protein C by the thrombin–thrombomodulin complex; abnormal binding to thrombomodulin, calcium, or phospholipid; and defective protease activity against factor Va or factor VIIIa. Of the reported cases, approx 85% have type I deficiency and 15% type II.

The prevalence of inherited protein C deficiency in the general population is approx 1 in 500–600. Like deficiency of antithrombin and protein S, protein C deficiency is a risk factor mainly for venous thromboembolism. A few cases of arterial thromboembolism have been reported in patients with protein C deficiency,

and one study showed that congenital protein C deficiency contributes to earlier onset of arterial occlusive diseases, especially acute myocardial infarction. However, a causative relationship with arterial thrombosis was not found in other studies.

The degree of risk for venous thrombosis associated with protein C deficiency varies, as with protein S deficiency. The risk of venous thromboembolism increases 3.8-fold when protein C deficiency is diagnosed by repeatedly low protein C activity and 6.5-fold when a protein C gene mutation is identified. Homozygous protein C deficiency is associated with catastrophic thrombotic complications at birth, manifested by purpura fulminans. When testing a patient for protein C deficiency, a protein C functional (activity) test should always be performed because obtaining only antigen levels will miss type II deficiencies.

ANTITHROMBIN

Antithrombin, a 432-amino acid, single-chain GP, is a member of a superfamily of proteins known as serine proteinase inhibitors (serpins) and is the most important natural anticoagulant and inhibitor of thrombin. Inhibition of proteinases by antithrombin involves the active site of the proteinase binding to the reactive center of antithrombin, which inactivates the proteinase–inhibitor complex. In addition, antithrombin has a binding site for heparin and similar glycosaminoglycans. Binding of heparin to the latter site induces a conformational change of antithrombin that accelerates the inhibition of proteinases.

First described in 1965, antithrombin deficiency is inherited as an autosomal-dominant trait and has an incidence in the general population of 1/500 to 1/600. Antithrombin deficiency is classified as type I when both functional and immunological levels are low or as type II when a dysfunctional protein leads to low activity but normal antigen levels. Patients with heterozygous antithrombin deficiency usually have approximately half the normal level of antithrombin activity. Several cases of homozygous deficiency have been described.

Most of the many mutations that cause antithrombin deficiency have been identified in families with thrombophilia, and information on these mutations is available on the Internet. Type I deficiency can be caused by a variety of point mutations, small insertions, and partial and whole gene deletions. Type II deficiency is caused by reactive site defects, mutations in the heparin binding site, and mutations with pleiotropic effects. Some antithrombin mutations lead to increased binding of heparin to antithrombin and others to decreased binding, resulting in clinically relevant heparin sensitivity or heparin resistance.

Antithrombin deficiency is often considered a strong risk factor for venous thrombosis but is rarely associated with arterial thrombosis, although it has been reported. The occurrence of symptomatic venous thrombosis in individuals with inherited antithrombin deficiency varies significantly. Some studies report that venous thrombosis develops in approximately half of antithrombin-deficient individuals before the age of 30, whereas the risk is lower in other studies, with only 23.5% of antithrombin-deficient individuals developing a thrombosis during their lifetime. The decision to start anticoagulation in an individual with antithrombin deficiency who has never had a clot should be made on an individual basis, as do decisions on length of anticoagulant treatment in a patient with antithrombin deficiency who has had a thrombosis. Antithrombin deficiency, a less common thrombophilia, is found in approx 1.1% of patients with a first thrombotic event.

The following factors should be considered when diagnosing antithrombin deficiency: (1) antithrombin levels can be decreased at the time of an acute clot or during heparin therapy; (2) liver synthetic dysfunction and nephrotic syndrome can lead to low antithrombin levels; and (3) specific reference ranges that consider age, sex, and use of oral contraceptives should be used. Some patients were probably mistakenly diagnosed as antithrombin-deficient because antithrombin levels were tested at the time of the acute clot or during heparin therapy.

ANTIPHOSPHOLIPID ANTIBODIES

Antiphospholipid antibodies (APLA) are acquired antibodies against phospholipids or phospholipid-binding proteins, such as β-2-glycoprotein-I (β-2-GPI) and prothrombin. APLA have been associated with arterial or venous thrombosis and spontaneous pregnancy loss. The mechanisms of thrombosis are highly heterogeneous and multifactorial and include the following: interference with the protein C pathway by antibody-binding to protein C or inhibition of the activation of protein C; inhibition of tissue factor pathway inhibitor; interference with plasminogen activation and fibrinolysis; promotion of tissue factor synthesis and exposure; endothelial injury; induction of apoptosis on vascular cells; activation or agglutination of platelets; and disruption of the annexin-V anticoagulant shield in the placenta.

APLA syndrome is defined as the occurrence of thrombosis (arterial or venous) or recurrent pregnancy loss in patients with repeatedly positive APLA tests (lupus anticoagulant and/or at least moderately increased IgG or IgM anticardiolipin antibodies). APLA syndrome can be a primary syndrome not associated with any other diseases, or a secondary syndrome associated with autoimmune diseases, malignancy, or drugs. Patients who have developed a thrombosis are at high risk for recurrence, and indefinite anticoagulation is often indicated after one episode of venous or arterial thromboembolism. The optimal oral anticoagulation level has been debated, and the international normalized ratio is invalid in some patients on oral anticoagulants because of a lupus anticoagulant effect on the ratio. Alternative tests, such as chromogenic or clot-based factor II or X activity, to measure the oral anticoagulant effect are indicated in these patients. Individual treatment decisions should be made with the help of a thrombophilia specialist.

Familial clustering of increased APLA levels has been described, but the characterization of the APLA syndrome, coexisting autoimmune diseases, and clinical complications has been heterogenous. Genetic factors may be involved in the pathophysiology of the APLA syndrome. In studies of the genetic variants of β-2-GPI, the valine/leucine247 polymorphism has been identified as a genetic marker for having anti-β-2-GPI antibodies and APLA syndrome.

FACTOR XIII

Factor XIII stabilizes the fibrin clot. Thrombin activates the proenzyme factor XIII to the enzyme factor XIIIa, which catalyzes the formation of intermolecular ε-(γ-glutamyl) lysine bonds between various proteins, such as fibrin monomers, fibronectin, α_2-plasmin inhibitor, and collagen. These reactions increase the mechanical strength, elasticity, and resistance to degradation by plasmin and promote wound healing. Factor XIII deficiency leads to a bleeding disorder and wound healing problems.

Factor XIII, with a molecular weight of 320 kDa, is a heterotetramer that comprises two A-subunits and two B-subunits held together by noncovalent bonds. The A-subunit contains the catalytic site, whereas the B-subunit appears to protect or stabilize the A-subunit. Several factor XIII polymorphisms have been identified in the gene encoding the A-subunit. The Val34Leu polymorphism is of relevance for thrombophilia because several studies have shown that the Leu34 polymorphism is associated with a decreased risk of occlusive arterial disease such as myocardial infarction, thrombotic cerebral artery occlusion, and venous thromboembolism. However, findings have not been consistent, and some studies did not show an association with arterial or venous thrombotic disease.

Val34Leu resides just three amino acids upstream of the thrombin cleavage site of the factor XIII A-subunit at Arg37-Gly38. The 34Leu allele is cleaved more rapidly and by lower doses of thrombin than 34Val, which affects the structure of the crosslinked fibrin clot and produces a finer meshwork, thinner fibers, and altered permeation characteristics. This finding supports the protective role of 34Leu polymorphism against thrombosis. However, the biochemical consequences of the 34Leu polymorphism are not fully understood, and the finding that factor XIII 34Val and factor XIII 34Leu have the same mean specific factor XIII activity in plasma can be used to argue against an association of the polymorphism with thrombosis. Thus, the association of the Val34Leu polymorphism with arterial or venous thrombosis is not clearly defined.

PLATELET MEMBRANE GLYCOPROTEINS

Membrane GPs play a fundamental role in platelet adhesion and aggregation. Integrins are membrane GP heterodimers made up of noncovalently associated α- and β-transmembrane subunits. Several integrins have been defined on human platelets, including α_{IIb}/β_3 (also known as GP IIb/IIIa or fibrinogen receptor), α_2/β_1 (GP Ia/IIa or collagen receptor), α_5/β_1 (fibronectin receptor), and α_6/β_1 (laminin receptor). Several polymorphisms of platelet membrane GPs have been described and have been identified in some studies as risk factors for arterial thrombotic events. However, findings have not been consistent, and no polymorphism has been unequivocally found to predispose to arterial thrombosis. No studies suggest that the polymorphisms are associated with venous thromboembolism.

GLYCOPROTEIN IIb/IIIa COMPLEX GP IIb (integrin α_{IIb}) is a 150-kDa protein that associates with the 90-kDa protein GP IIIa (integrin β_3) to form the covalent heterodimer GP IIb/IIIa, also known as integrin αIIb/β3. GP IIb/IIIa is anchored in the platelet membrane, is the most abundant GP on the platelet surface, and is abundant in platelet α-granules. Platelet activation leads to translocation of GP IIb/IIIa from within the platelet to the surface, increasing the receptor surface density by 30–50%, from approx 40,000 to nearly 80,000 molecules per platelet and to a conformational change of GP IIb/IIIa that markedly increases ligand-binding affinity. The major ligand for GP IIb/IIIa is fibrinogen, which binds to the receptor via the C-terminal 12 residues of the γ-chain (H12). In addition, GP IIb/IIIa binds von Willebrand factor, fibronectin, vitronectin, and thrombospondin; all of these adhesive molecules contain the Arg–Gly–Asp (RGD) sequence, which is the minimal recognition sequence for the receptor.

A point mutation in GP IIIa results in a substitution of Leu to Pro at position 33. The Leu wild type is called the Pl^{A1}, and the Pro polymorphism is the Pl^{A2}. About 85% of individuals of northern European ancestry are homozygous for Pl^{A1}, 13% carry Pl^{A1} and Pl^{A2}, and 2% are homozygous for Pl^{A2}. The Pl^{A} polymorphism is located near the ligand-binding pocket of GP IIb/IIIa but does not appear to affect fibrinogen binding. Pl^{A2} platelets have a lower threshold for activation, although the reason is unknown. This finding may suggest that individuals with the Pl^{A2} polymorphism have a higher risk for thrombotic disease; however, clinical data supporting this assumption have been inconsistent.

Although initial studies indicated that Pl^{A2} is a risk factor for acute coronary thrombosis, several large studies did not confirm this association. Furthermore, a meta-analysis showed that the Pl^{A2} polymorphism was not associated with an increased risk of myocardial infarction, either overall or in selected subgroups, such as patients with premature disease onset (age ≤60 yr), patients with a first acute myocardial infarction, male patients, female patients, and Caucasian patients. The data on whether the Pl^{A2} polymorphism leads to higher risk of in-stent thrombosis or restenosis after coronary stent placement are inconsistent; some studies show an association, and others do not.

Studies indicate that the response to antiplatelet drugs varies, depending on which Pl^{A} allele is present. Heterozygous Pl^{A} platelets are more sensitive to inhibition of aggregation by pharmacologically relevant concentrations of aspirin. The findings on the response to the GP IIb/IIIa antagonist abciximab have been inconsistent: increased sensitivity of heterozygous Pl^{A} platelets in one study and decreased sensitivity in another.

GLYCOPROTEIN Ib/IX/V COMPLEX The GP Ib/IX/V complex is the platelet receptor for von Willebrand factor and mediates binding to collagen. The receptor comprises four gene products: GP Ibα, GP Ibβ, GP IX, and GP V. Three polymorphisms in the GP Ibα gene are possibly associated with thrombotic disease. One is a 39-bp variable nucleotide tandem repeat (VNTR) for a 13 amino acid repeat, with up to four polymorphic forms with one, two, three, or four repeats. These repeats affect the length of the extracellular domain of GP Ib, which affects the distance between the von Willebrand factor binding domain and the platelet surface. It is not known whether this influences platelet function. This hypervariable region is linked to a Thr145 Met substitution of uncertain consequences for platelet function. The third polymorphism, –5T/C, was reported as a determinant of the membrane levels of the GP Ib/IX/V complex in one study, but not in another. An association of these polymorphisms with cardiac or cerebral arterial thrombotic disease has not been established. In two studies, the 39-bp VNTR/Thr145Met polymorphisms were associated with coronary artery disease, but the association was not seen in three studies. The GP Ibα polymorphisms were associated with cerebrovascular disease in several studies but not in one.

GLYCOPROTEIN Ia/IIa COMPLEX The GP Ia/IIa complex (α_2/β_1 integrin) is a major collagen receptor on platelets. The ability of platelets to adhere to collagen varies among individuals because of the wide variation in expression of GP Ia/IIa on platelets. A silent polymorphism at position 807 (C to T) of the α_2-gene, which does not change the sequence of GP Ia, is associated with variation in GP Ia/IIa receptor density. Carriers of the 807 T allele express higher levels of GP Ia/IIa. The T allele has been associated with myocardial infarction and acute coronary syndrome in some studies but not in all.

TISSUE PLASMINOGEN ACTIVATOR

Synthesized mainly in endothelial cells but also in many different tissues, tPA is a 68-kDa serine protease. One of two physiological

plasminogen activators, tPA (the other is urokinase) is usually found in a complex with its primary inhibitor, plasminogen activator inhibitor-1 (PAI-1). Paradoxically, increased levels of tPA are a risk factor for future arterial occlusive events. This finding may be because of the fact that increased tPA levels reflect pre-existing disease or because of increased PAI-1 levels, which form an inactive complex with tPA. Several polymorphisms for the tPA gene have been described. An Alu insertion/deletion within the intron between the exons 8 and 9 has been associated with an increased risk of myocardial infarction in one study but not in another.

PLASMINOGEN

Plasminogen is a single-chain GP produced primarily in the liver. Cleavage of plasminogen by tPA, urokinase, and streptokinase forms the active serine protease, plasmin. Fibrin-bound plasmin degrades fibrin.

The first case of hereditary plasminogen deficiency was published in 1978, followed by several hundred reports of cases. Type I plasminogen deficiency is a quantitative deficiency of both activity and antigen, whereas type II is a qualitative defect (dysplasminogenemia) with low activity but normal antigen levels. At least 11 different mutations lead to plasminogen deficiency, but whether the heterozygous presence of a mutant gene is associated with an increased risk of thromboembolism is unknown. The prevalence of familial plasminogen deficiency in the general population may be as high as 2.9/1000. Several studies indicate that heterozygous plasminogen deficiency is not a risk factor for thrombosis, but others suggest it is a mild risk factor for venous thromboembolism. Plasminogen deficiency is not a risk factor for arterial thromboembolic disease.

PLASMINOGEN ACTIVATOR INHIBITOR-1

Produced mainly by endothelial cells and adipocytes, PAI-1, a 52-kDa GP, may also be produced by monocytes, hepatocytes, smooth muscle cells, and megakaryocytes. In human blood, platelets are the major pool of PAI-1, which is the main inhibitor of tPA. Diurnal variation is seen in PAI-1 plasma antigen levels. Because of significant intra- and interindividual variation, assays for PAI-1 in individual patients cannot be usefully interpreted. The concentration of PAI-1 in atheromatous plaque is high. Increased PAI-1 levels have been associated with coronary artery disease and myocardial infarction in many studies, but statistical significance is often lost after adjustment for other risk factors. This may be because of the fact that many metabolic changes, such as those seen in the insulin resistance syndrome and diabetes, affect PAI-1 levels. The increased risk of arterial disease associated with hyperinsulinemia may be partially mediated through increased PAI-1 levels.

Several PAI-1 polymorphisms have been described, including a 4G/5G insertion/deletion –675 bp from the start of the promoter and a *Hind*III site at the 3′ region of the gene. These polymorphisms may affect PAI-1 plasma levels, but this finding has not been consistent. Furthermore, the impact of polymorphisms on the heritability of PAI-1 levels is small. Although some studies have suggested an association between the 4G/5G polymorphism and cardiac and cerebrovascular ischemic disease, other well-designed studies have not. In a summary of all studies, PAI-1 genotype does not appear to play an important role in ischemic heart disease. An association between the 4G/5G polymorphism and venous thromboembolic disease has been found but not consistently.

Table 90-2
Laboratory Coagulation Workup for Thrombophilia

Arterial Thromboembolism
Protein C activity
Protein S activity, free and total protein S antigen
Antithrombin activity
Anticardiolipin IgG and IgM antibodies
Lupus anticoagulant[a]
Fibrinogen activity
Factor VIII activity
Fasting homocysteine levels
Venous Thromboembolism
Factor V Leiden
Factor V HR2 haplotype, in patients who have factor V Leiden
Prothrombin 20210 mutation
Protein C activity
Protein S activity (free and total protein S antigen)
Antithrombin activity
Anticardiolipin IgG and IgM antibodies
Lupus anticoagulant[a]
Fibrinogen activity
Factor VIII activity
Factor IX activity
Factor XI activity
Fasting homocysteine levels

[a]Two different tests should be used (i.e., dilute Russell viper venom time, lupus-sensitive activated partial thromboplastin time, kaolin clotting time) because of the heterogeneity of lupus anticoagulants.

CLINICAL IMPLICATIONS

Medical practitioners have not reached a consensus on the extent of laboratory work-up for thrombophilia in patients with thrombosis and on the criteria for selecting which patients and asymptomatic family members should be tested for thrombophilia. Both sides can be argued, and the importance of testing is weighed differently by individual health-care providers, by patients, and by health-care politicians.

Physicians may want a patient to undergo testing for thrombophilia because the results may influence the decision to initiate prophylactic anticoagulant treatment, the choice of drug, or the length of treatment after an episode of thrombosis, help explain why a patient developed a thrombosis, and help in counseling a patient about the future risk of thrombosis. Patients may want to get tested to understand why a clot developed, to be encouraged to make lifestyle changes that may decrease the risk of thrombosis, and to be able to inform health-care providers of the thrombophilia to receive better prophylaxis for thrombosis. Reasons to decide against thrombophilia testing include the lack of therapeutic consequences if the result is abnormal, the risk of misinterpretation of a test result by the health-care provider and of incorrect or debatable medical advice, the risk of increased costs for health or life insurance premiums or of being denied insurance, the possibility that paternity may have to be questioned if the inheritance pattern is inconsistent with test results of other family members, and the expense of testing.

Tests that might be considered in the work-up of patients suspected of having thrombophilia are listed in Table 90-2. However, the need and extent of testing for thrombophilia should be assessed on an individual basis. In conducting tests for thrombophilia, the physician is responsible for ensuring that patients

and their families are counseled about the implications of positive or negative test results and educated about the thrombophilia. Availability of a genetic counselor, a specialized thrombophilia clinic, and patient education materials are important. Although some patient education tools are available, better and more widely available education materials are needed.

PATIENT EDUCATION MATERIALS AND RESOURCES

The opportunity to perform thrombophilia testing brings a responsibility to counsel patients and their families about the implications of positive or negative test results and to educate them about their thrombophilia. Availability of patient education materials is important. Patient education materials are available in print and downloadable from the web through the nonprofit national patient advocacy group NATT (National Alliance for Thrombosis and Thrombophilia; http://www.nattinfo.org); these include articles on factor V Leiden, the prothrombin 20210 mutation, homocysteine and the MTHFR mutation, and antiphospholipid antibodies. Health-care providers operating in thrombosis clinics, anticoagulation clinics, or offices where patients with thrombosis and thrombophilia are seen, can print these articles as handout material for their clinics and patients from the NATT website (http://www.nattinfo.org/learn-resources.htm).

CONCLUSION

Significant progress has been made in the understanding of physiological hemostasis and in the identification of laboratory risk factors (inherited or acquired) predisposing to arterial or venous thrombosis. The identification of these risk factors will allow differentiated approaches in the management of patients with identified thrombophilia regarding (1) prediction of the likelihood of future thrombotic events, (2) modification of thrombosis risk factors, (3) use of anticoagulation prophylaxis in thrombosis risk situations, (4) length of anticoagulant treatment in patients with thrombosis, and (5) recommendations for family screening. This type of patient management is particularly applicable for venous thromboembolism because of the identification of the factor V Leiden and the prothrombin 20210 polymorphisms. Less impressive clinical consequences have been achieved in the identification of thrombophilic abnormalities predisposing to arterial thrombotic disease. Although some coagulation abnormalities help clinicians to stratify the risk in patients with arterial disease, the studies of the associations of various polymorphisms with arterial thrombosis have not been conclusive. A meaningful use of these polymorphisms in clinical decision-making is not possible.

91 Advances in Transfusion Safety

Lorna M. Williamson and Jean-Pierre Allain

SUMMARY

Although transfusion is now extremely safe, the tools of molecular biology are continually being harnessed to improve diagnosis and therapy. Viral genome testing has been introduced in the developed world for HIV and HCV, to detect donors in the infectious "window period" before sero-conversion. Pathogen inactivated fresh frozen plasma and platelets are already available, but alloimmunization has halted trials of pathogen-inactivated red cells. Development of synthetic oxygen carriers has included perfluorocarbons, and crosslinked, polymerized or mutated human or bovine hemoglobin, either free or encapsulated. No perfect replacement for the human red cell is yet on the horizon.

Key Words: Bacterial transmission; blood substitutes; perfluorocarbons; hemoglobin solutions; nucleic acid viral testing; pathogen inactivation; transfusion safety; transfusion-transmitted parasites; transfusion-transmitted viruses.

INTRODUCTION

For many years, there were few changes to the way blood for transfusion was processed and tested. Whole blood donations were separated into red cells, platelets, and plasma, while virus testing usually consisted of serological assays for either viral antigens or antibodies in the donor. The viral safety of blood, already high in the more affluent parts of the world, potentially took a quantum leap with the development of rapid, automatable genome amplification assays on the one hand, and pathogen inactivation techniques on the other. Meantime, there was a search to find a way of avoiding human blood transfusion altogether, by developing alternative ways of transporting oxygen from the lungs to the tissues. This chapter outlines the rapid change in these fields in the last two decades, and attempts to set these into the context of policy making for national blood supplies.

RED CELL SUBSTITUTES

WHAT IS NEEDED AND WHY "Artificial blood," meaning a synthetic oxygen carrier, has been the holy grail of transfusion research for decades. Innovation in this area was originally driven by military requirements for a long shelf life battlefield solution that would need neither refrigeration nor matching with the recipient. The publicity surrounding transfusion-transmitted infections since the 1980s (HIV, hepatitis B and C, West Nile virus [WNV], and now prions) provided a new impetus to these developments. Now many countries face chronic blood shortages. In developed countries, this is primarily because of an imbalance between the blood requirements of an aging population and a diminishing donor base, whereas in the developing world, lack of infrastructure to collect, test, and store blood safely is a major issue. So the need for alternatives to human blood remains.

However, the task facing developers of oxygen carriers is daunting. The human red cell is a miracle of evolution; its shape, the gas exchange properties of its membrane, and the complex interactions between oxygen, CO_2, 2,3 diphosphoglycerate (2,3 DPG), the vessel wall, and hemoglobin itself make the creation of a substitute a challenging task. Moreover, it has become increasingly clear that a "one size fits all" solution will not work, and that the specification of a product for transfusion dependent patients could differ from what is needed for acute hemorrhage. Virtually all development in this area has focused on acute replacement, and the term "bridge oxygenator" has appeared to describe solutions designed to maintain tissue oxygenation until the patient can receive conventional red cell transfusion.

Two classes of compounds have been extensively studied as potential oxygen carriers: perfluorocarbons and hemoglobin solutions. Each type has its merits and problems (Table 91-1). A number of promising first generation compounds of both types failed clinical trials, forcing a return to basic research on the events in the microvasculature that determine outcome in acute severe blood loss. Much more is now understood concerning the optimal characteristics of synthetic oxygen carriers, and although none is yet licensed in either Europe or North America, second generation products may perhaps fulfill early hopes.

PHYSIOLOGICAL RESPONSE TO HEMORRHAGE In acute hemorrhage, physiological responses designed to preserve the blood supply to vital organs at the expense of peripheral perfusion are automatic. Peripheral vasoconstriction is mediated by autonomic reflexes. At less than 50% blood loss, fluid shifts into circulation to maintain blood volume, so hematocrit and viscosity fall. This reduces the shear forces exerted on the endothelium, resulting in a reduction of production and release of natural vasodilators such as nitric oxide (NO) and prostacyclin. Peripheral resistance therefore rises further, and tissue blood flow slows even more, until a point is reached when oxygen supply is insufficient for tissue demands. Then anaerobic respiration takes over, leading to buildup of CO_2 and lactic acid. Once established, this state of metabolic acidosis is difficult to treat.

Table 91-1
Advantages and Disadvantages of Hemoglobin Solutions and Perfluorocarbons

Advantages	*Disadvantages*
Hemoglobin solutions	
High capacity for O_2 and CO_2	Short plasma half-life
Functions at physiological pH	Potential renal toxicity
Oncotic activity	Vasoactivity
Absent red blood cell antigens	Auto-oxidation
Prolonged shelf life	
Virus inactivation possible	
Perfluorocarbons	
Large-scale production	Need to be emulsified
Low production costs	Particles not uniform size
Prolonged shelf life	High FiO_2 required
Minimal infection risk	Low O_2 capacity at physiological O_2
Minimal antigenicity	Rapid plasma clearance

FIRST GENERATION HEMOGLOBIN SOLUTIONS Some hemoglobin solutions were initially developed by military or academic institutions, but all are now licensed to commercial companies for development (Table 91-2). They have most commonly used outdated human blood donations as the source of hemoglobin, although one company (Biopure) uses bovine blood, whereas another (Somatogen) used recombinant technology. The biological challenges to the development of a hemoglobin solution include the following.

1. Free hemoglobin dissociates into α/β dimers that oxidize rapidly and are cleared by the kidney, resulting in a short half-life and in renal toxicity if their concentration reaches critical levels. Various mechanisms have therefore been used to crosslink the α/β-subunits through either the α- or β-chains, using chemicals or recombinant technology.
2. In the absence of 2,3 DPG, the oxygen dissociation curve of free hemoglobin is left shifted when compared to hemoglobin in red cells. Early investigators considered this as a potentially useful characteristic, but this increase in oxygen affinity means that oxygen does not readily off-load from the carrier to the tissues. Strategies taken to reverse this shift include pyridoxylation, site-directed mutagenesis, polymerization, and internal crosslinking, all discussed later. A completely different approach is to use bovine hemoglobin, which, although having 90% sequence homology with human hemoglobin, responds allosterically to chloride ion rather than to 2,3 DPG. Therefore, at physiological chloride concentrations, its oxyhemoglobin dissociation curve resembles that of human hemoglobin within red cells.
3. Free hemoglobin exerts considerable oncotic pressure, drawing fluid from the tissues into the circulation.

A variety of modifications were therefore introduced into the molecule by different companies to counteract the problems previously outlined (Fig. 91-1).

Chemical Crosslinking of α- or β-Chains This not only prevents dimerization in vivo but in theory could stabilize the molecule sufficiently to permit viral inactivation. The HemAssist product developed by Baxter used 3,5 *bis* (dibromosalicyl) fumarate to crosslink the α-chains. The dimensions of the crosslinker meant that it reacted only with $Lys\alpha_1$ 99 and $Lys\alpha_2$ 99 in the internal cavity of the molecule, binding the two halves together. This also had the useful effect of raising the P_{50} (Fig. 91-2), but the product had significant vasoactivity in animal studies of shock. Phase III clinical trials in stroke and trauma gave disappointing results, and development of the product was discontinued in 1998.

The Hemolink product developed by Haemosol in Canada uses open ring (oxidized) raffinose to crosslink specific amino acids in the β-chains in the 2,3 DPG pocket, which also has the effect of raising the P_{50}. The *O*-raffinose is also used to polymerize the molecule.

Polymerization Polymerization can be achieved through the use of crosslinkers that target surface amino groups. Polymers of various lengths can be produced using gluteraldehyde, as the reaction can be quenched using lysine. This strategy has been employed by Northfield Laboratories to polymerize human hemoglobin (PolyHeme). This product is also pyridoxylated, which raises the P_{50}, resulting in a product similar to human blood in terms of oxygen affinity and colloid oncotic pressure. Gluteraldehyde polymerization is also used by Biopure for production of their bovine hemoglobin product (Hemopure). This product can transport oxygen to the tissues effectively, and even in low doses can raise arterial pressure and lower cardiac index. It was reported to be life saving in a case of severe autoimmune hemolytic anemia, and has been licensed in South Africa for orthopedic surgery. Currently, a trial is proposed in which Hemopure is used in cardiac surgery to improve tissue oxygenation by diffusion through an atheromatous obstruction in coronary arteries. Finally, as mentioned, the HemoLink product is polymerized using *O*-raffinose.

Recombinant Technology Building on ideas generated at the UK's Medical Research Council laboratories in Cambridge, Somatogen (and later Baxter Healthcare) developed a human hemoglobin solution produced in *Escherichia coli*, using synthetic genes encoding the human α- and β-globin polypeptides and expressed from a single operon. The purified recombinant hemoglobin had the correct stoichiometry of the α- and β-globin polypeptides, which associated into soluble tetramers, and incorporated heme. Each globin chain also contained an additional methionine as an extension to the amino terminus. The recombinant hemoglobin had an high-performance liquid chromatography profile essentially identical to that of human hemoglobin A and comigrated with hemoglobin A on polysaccharide gel electrophoresis. The visible spectrum and oxygen affinity were similar to that of native human hemoglobin A, but the recombinant protein showed a reduction in Bohr and phosphate effects, possibly because of the presence of the methionine at the amino termini of the α- and β-chains.

Because the oxygen affinity of this free hemoglobin in the absence of 2,3 DPG was too high to allow adequate oxygen offloading in the tissues, a variant was created using an expression vector containing one gene encoding the naturally occurring Asn-108β to Lys mutation (hemoglobin Presbyterian), which reduces the oxygen affinity and enhances the Bohr effect slightly. In addition, to prevent α β-dimerization and renal toxicity, and to increase the half-life, the product was made using one duplicated, tandemly fused α-globin gene, resulting in end-to-end fusion of the two α-globin-subunits. The short distance (2–6 Å) between the N-terminal residue of one α-chain and the C-terminal residue of the other allowed the insertion of a glycine residue as a bridge. Despite these elegant modifications, this product led to gastrointestinal side effects, and Baxter discontinued its development at the same time as studies on HemAssist were stopped.

Table 91-2
Red Cell Substitutes and Their Current Status

Company	*Product*	*Source*	*Modification*	*Development status*
Perfluorocarbons				
Alliance Pharmaceutical Corporation	Oxygent	–	Emulsified perflubron	Phase III cardiac surgery, hemodilution, hemorrhage
Hemogen	Oxyfluor	–	–	Discontinued
Hemoglobin solutions				
Apex Bioscience (now Curacyte)	PHP	Human	Pyridoxylated; conjugated to polyoxyethylene, binds NO	Phase IIc, shock
Baxter Healthcare	HemAssist	Human	α-α crosslinked with "diaspirin"	Discontinued 1998 at phase III stage
Biopure	Hemopure	Cow	Gluteraldehyde-polymerized; purified to remove tetramers	Phase III with hemodilution, +compassionate use Licensed for surgery in South Africa FDA license submitted Trial planned in cardiac surgery
Biopure	Oxyglobin	Cow	Gluteraldehyde-polymerized	Licensed for use in dogs
Enzon	PEG-hemoglobin	Cow	PEG; tetramer	Not in active development
Hemosol	Hemolink	Human	*O*-raffinose to crosslink β-chains and to polymerize; tetramers remain	Phase III cardiac surgery, studies with erythropoietin in renal failure and surgery
Northfield Laboratories	PolyHeme	Human	Pyridoxylated; gluteraldehyde polymerized; purified to remove tetramers	Phase III trauma
Sangart	Hemospan (MP4)	Human	PEG; polymer; virus treated with riboflavin	Phase II, orthopedics, Sweden, and now USA
	Hemospan PS	Human	Hemospan + pentastarch	
Somatogen/Baxter	Optro-r hemoglobin-1.1	Recombinant	Tetramer; α-chains fused end to end; β-chain mutation	Discontinued 1998
Synzyme	Hemozyme	Human	Polymerized	Preclinical

FDA, Food and Drug Administration; PEG, polyethylene glycol; PHP, pyridoxal hemoglobin polyoxyethylene.

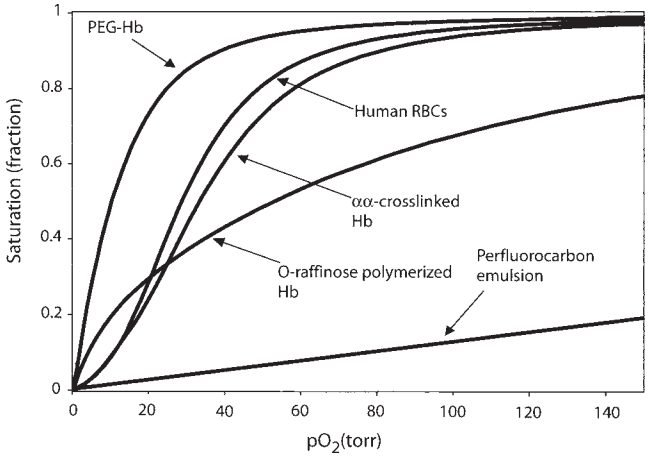

Figure 91-2 Oxygen dissociation curves of various hemoglobins and perfluorocarbon. Note that all hemoglobins give sigmoid curves, whereas perflurocarbon gives a linear relationship. (Reprinted with permission from Blackwell Publishing from Stowell CP, Levin J, Spiess BD, Winslow RM. Progress in the use of blood substitutes. Transfusion 2001;41[2]:287–299.)

Surface Modification The 42 lysine amino groups on the surface of hemoglobin are targets for attachment of small molecules such as polyethylene glycol (PEG) and polyoxyethylene (POE), which stabilize the tetramer and increase the molecular weight. The resulting increase in oncotic pressure and viscosity was considered therapeutically useful in expanding the plasma volume. It was also thought that this type of modification would render the molecule less visible to the reticulo-endothelial system, minimizing its antigenicity. Products in this category include

bovine hemoglobin modified by PEG, which was manufactured by Enzon, but this may no longer be in active development. However, a human hemoglobin solution designated pyridoxal hemoglobin polyoxyethylene developed by Apex Bioscience is in phase IIc trial in shock.

Encapsulation To prevent the renal toxicity and short half-life associated with free hemoglobin, attempts have been made to enclose hemoglobin in liposomes consisting of synthetic lipids in various combinations. Phosphotidylcholine has been used to produce bilamellar spheres loaded with a hemoglobin solution, whereas the addition of cholesterol increases elasticity and half-life. In theory, the oxygen affinity could be modulated by the inclusion of 2,3 DPG, whereas methemoglobin reductase could be added to prevent oxidation. However, there are technical difficulties in controlling the size of the liposomes, and it is not yet clear what effects the clearance of large amounts of phosphotidylcholine would have on the reticuloendothelial system. These products remain at the preclinical stage of development.

PROBLEMS WITH FIRST GENERATION OF SUBSTITUTES AND NEW APPROACH TO HEMOGLOBIN SUBSTITUTES Many first generation compounds failed clinical trial because of unacceptable hypertension, bradycardia, chest and abdominal pain and nausea/vomiting. At first these effects were thought to be owing to contaminants, but are now considered to be the result of reflex vasoconstriction. Discoveries regarding the functioning of the microvasculature, facilitated by new techniques for viewing small vessels, have changed the thinking behind the ideal properties of a hemoglobin substitute.

1. Identification of NO as the endothelium-derived relaxing factor. The heme group binds NO with high affinity, and this is especially true of free hemoglobin. This property of free hemoglobin contributes to the hypertensive properties of some solutions.
2. The realization that diffusion of cell-free oxygenated hemoglobin can be harmful, as it leads to constriction of precapillary arterioles and thus reduces tissue perfusion. Significant amounts of oxygen leave the circulation at the precapillary arteriolar stage. These vessels are rich in nerve endings, and appear to be extremely sensitive to oxygen. The so-called facilitated diffusion of oxygen that is bound to the free hemoglobin can be limited by increasing both the diameter of the hemoglobin molecule itself and the viscosity of the solution. Modified hemoglobin molecules of different radii have varying vasoactive properties, even though their interaction with NO is the same. Widespread prearteriolar vasoconstriction in the presence of a normal blood volume leads to hypertension; conversely vasoconstriction with an inadequate blood volume results in shock, volume depletion and ultimately collapse of the nonmuscular capillary walls, which rely on vascular pressure to keep them open. To overcome this undesirable side effect, oxygen availability from the hemoglobin substitute should be less than that from natural red cells. Oxygen availability to the precapillary arterioles can be limited by increasing the oxygen affinity of the molecule and decreasing its concentration in the solution.
3. Production of vasodilators stimulated by shear forces on the endothelium can be maintained by having a solution of fairly high viscosity. At rest, therefore (though not during exercise), the maintenance of microvascular blood flow, vascular volume and acid–base balance are more important than oxygen carrying capacity. These observations change the theoretical requirements of an oxygen carrier (Table 91-3). This logic has determined the design of the modified hemoglobin solution Hemospan (MP4, Sangart, *see* Table 91-2).

Table 91-3
Past and Current Concepts in the Design of a Blood Substitute

Parameter	*Considered optimal for first generation oxygen carriers*	*Considered optimal for second generation oxygen carriers*
Oxygen binding	Like blood: P50 28 mmHg	P50 5–10 mmHg
Viscosity	Like water: 1 cP	Like blood: 4 cP
Oncotic pressure	Like blood: 15 mmHg	Increased
Hemoglobin concentration	Like blood: 15 g/dL	As low as possible

Modified from Winslow RM. Current status of blood substitute research: toward a new paradigm. J Intern Med 2003;253(5):508–517.

Made from outdated red cells, this compound has the lysine residues thiolated then further surface modified by the addition of PEG. It is subjected to pathogen reduction using the riboflavin technique. This solution has a P_{50} of only 4 mmHg, which is predicted to limit early oxygen off-loading at the arteriolar stage. The large increase in radius as a result of the PEG also limits the undesirable oxygen diffusion, maintains plasma viscosity, and hence shear forces on the endothelium, and confers a half-life of 43 h. The compound resulted in 100% survival and absence of hypertension in a hemorrhagic rat model (Fig. 91-3), and in primate studies, no vasoconstriction or hypertension was seen. The compound is now in phase II clinical trial in orthopedic surgery in Sweden, and a trial in the United States is planned.

PERFLUOROCARBONS The perfluorocarbon class of compounds is characterized by a linear or cyclic carbon backbone that is highly fluorinated, with other halogens sometimes also present.

They can dissolve large amounts of oxygen and CO_2 whereas being chemically and biologically inert. Their properties were famously displayed in images of a mouse living and breathing "underwater" in a beakerful of oxygenated fluorocarbon. At a pO_2 of 100 torr, dissolved oxygen can reach 10 mL/dL, compared with 0.5 mL/dL for plasma and 20 mL/dL in blood with a hemoglobin concentration of 15 g/dL. Unlike hemoglobin, the oxygen dissociation curve is linear (*see* Fig. 91-2), so if the patient can breathe very high levels of inspired oxygen, greater amounts of oxygen can be carried. However, because fluorocarbons are immiscible with plasma, they have to be emulsified by mixing with a surfactant (usually a phospholipid) to produce particles of submicron size, although precise size is difficult to control. The surfactant can comprise a high percentage of the solution by weight, and may not be totally biologically inert.

The original compound, Fluosol-DA, was licensed by the US Food and Drug Administration in 1990 for use in percutaneous transluminal coronary angioplasty, but became obsolete and was withdrawn for this purpose in 1994. Clinical trials in acute hemorrhage demonstrated no improvement in clinical outcome. Later compounds have smaller particle size, which should reduce flu-like symptoms attributable to cytokine and complement activation, and greater solubility for oxygen. Oxygent (Alliance Pharmaceuticals) is an emulsion of perflubron (perfluoro-octyl bromide) and egg yolk phospoholipid. It is in a phase II/III clinical trial to assess

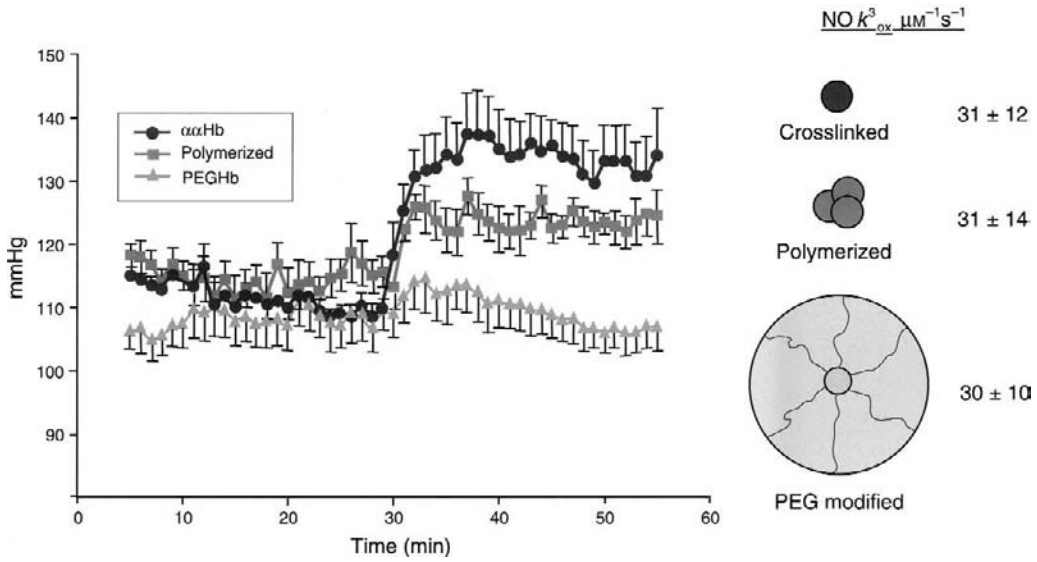

Figure 91-3 Mean arterial pressure response in the rat to infusion of three modified hemoglobins. The sizes of the molecules are drawn to scale relative to each other, and the association rate constants for NO are given at the right. (Reprinted with permission from Blackwell Publishing from Winslow RM. Current status of blood substitute research: toward a new paradigm. J Intern Med 2003;253[5]:508–517.)

whether its use can increase the permitted degree of acute normovolemic hemodilution, thus improving the extent of blood saving. A further trial is designed to examine its effect in acute hemorrhage. Another fluorocarbon (Oxyfluor) was designed to absorb the microbubbles that form on cardiopulmonary bypass circuits and are thought to be responsible for neurovascular complications. This is no longer in development.

ONGOING ISSUES IN THE DEVELOPMENT OF A BLOOD SUBSTITUTE

How to Evaluate the Product Regulatory authorities increasingly expect clinical end points from studies of new products. One of the difficulties is that the red cells used as controls have not themselves been subjected to studies of similar rigor, and there are no established criteria for assessing their efficacy. Mortality and transfusion avoidance have been used in some trials, but other end points may evolve as different clinical scenarios are studied.

Short Half-Life Short half-life is still a major problem. Even the best substitutes (encapsulated/surface modified) have circulatory half-lives of only 2–3 d, with most being only 12–24 h. This still restricts the usage to acute hemorrhage, with no sign of a product to treat chronic anemias.

A Safe and Reliable Source of Start Material Although not an issue for perfluorocarbons, of which there is limitless supply, sourcing adequate amounts of human hemoglobin is a challenge. With optimal stock management, outdates are low (<2% in England), and for safety reasons, the donor exclusion criteria cannot be relaxed to increase supply. Yields of free hemoglobin from outdated red cells are rarely more than 50%, so targeted blood collections would have to be organized to provide start material.

The use of bovine blood seems questionable at this point, as possible prion transmission is a key concern of blood suppliers. Accredited bovine spongiform encephalopathy-free herds could be developed, but the possibility of unknown bovine agents exists. Recombinant technology remains a possibility once the optimal formulation is established, but it is uncertain whether any process could be adequately scaled up to meet demand.

The Safety/Cost Balance In the two decades of development of blood substitutes, blood itself has become increasingly safe from the virus point of view. The residual risk of HIV, HBV, and HCV is now 1 in $10^{5–6}$/U in many parts of the world. Even when a new agent emerged (WNV in the United States and Canada in 2002), genome testing was in place within 12 mo. Developed countries are questioning the spiraling costs of blood components, and the high costs of steps providing only small incremental increases in safety. In the United States, virus inactivated pooled solvent detergent fresh frozen plasma (FFP) did not become an established product, and is now withdrawn. In Europe, in which one pathogen inactivation system is now licensed for platelets, uptake is limited, and cost-effectiveness is one factor in this. Ironically, the parts of the world that might gain most benefit from a blood substitute are unlikely to be able to afford it. Another related issue is the safety of the products themselves. As blood safety increases, the acceptance of possible serious side effects of a blood substitute will fall.

Further Advances in Knowledge of the Red Cell Intriguingly, a recent study suggested that red cells themselves may be able to respond to hypoxia by releasing NO generated from the reduction of nitrite by deoxyhemoglobin. It remains to be seen whether this newly discovered property of red blood cells will present another obstacle in the search for an artificial oxygen carrier.

SUMMARY Although it might be considered disappointing to not have a single licensed blood substitute, a great deal has been learned about the physiology of oxygen delivery to tissues and the sequence of events when it goes wrong. The next decade may see one or more products reach the clinic. Issues of cost-effectiveness, safety, and availability will ultimately determine whether these products become true blood substitutes or niche products for a limited number of patients.

GENOMIC DETECTION OF VIRAL AGENTS

METHODS Methods enabling the detection of the genome of infectious agents have been developed, initially in research, then for diagnostics, and finally for blood screening. Methods such as direct hybridization and its more sensitive version called “branched

Table 91-4
Impact of HCV and HIV NAT on Blood Safety

Country	Author	Number screened (millions)	Estimated risk/million transfusions			
			HCV		HIV	
			Pre NAT	Post NAT	Pre NAT	Post NAT
United States	Stramer	35.7	4.3	0.61	0.75	0.52
France	Pillonel	4.9	1.0	0.15	0.71	0.4

HCV, hepatitis C virus; NAT, nucleic acid testing.

DNA" are not adapted to the mass screening approach required for testing in the transfusion context. Methods including amplification such as PCR, ligase chain reaction, transcription mediated amplification, or nucleic acid sequence-based amplification have been developed and used in transfusion, in which requirements of high sensitivity, high specificity, and high throughput need to be met. Quantitative PCR based on the use of Taqman probes has been introduced and seems to be well adapted to the demand of the transfusion market.

Nucleic acid testing (NAT) was first introduced in 2000 for the detection of the hepatitis C virus (HCV) genome. Soon after other NAT targets such as HIV, hepatitis B virus (HBV), and WNV were added, creating a momentum for the development of multiplex NAT, enabling simultaneous detection of genomes of two (duplex) or three (triplex) different viruses in a single reaction tube.

Automation is critical in blood screening for transfusion. No system is available to integrate all three basic steps of NAT: nucleic acid extraction, amplification, and detection, in a unique automated instrument. A fair amount of manual operation remains that will be eliminated when the prototype automated instruments become commercially available.

SAMPLES The considerable cost of NAT on a large scale led to the development of the concept of plasma pool testing by which mixtures of individual plasma samples from blood or plasma donations are mixed and tested in a pool. The pool size ranges from 8 to 512 depending on the target genome and the method used. Pooling has a clear impact on test sensitivity. This inherent lack of sensitivity was overcome in different ways: one was extreme sensitivity of assays with the attached toll on specificity, the other was concentration of targets by various methods, the most popular being ultracentrifugation. When NAT targeted viruses such as HCV or HIV that replicate very rapidly to viral load above 10^5 copies/mL, pooling did not substantially affect screening efficacy, although most national blood transfusion organizations progressively reduced the number of samples per pool from 96 to 48, 24, and 16. The lower viral load observed with HBV and WNV during the infectious window period led blood services to reduce further pool size to 8 or 10 samples. Ultimately, individual donation NAT already implemented by some blood organizations will likely become the rule, particularly with the relative decrease in costs introduced by multiplexing.

IMPLEMENTATION OF NAT IN TRANSFUSION NAT was first introduced in the late 1990s by the plasma derivative industry following the transmission of HCV by intravenous IgG that was not virally inactivated. NAT of various sensitivities was applied to large pools of plasmas prepared for fractionation. Later, despite the initial reticence of both regulators and the blood bank community, NAT applied to HCV RNA was mandated by the EU and US regulatory bodies but the pool size was not specified, only a clinical sensitivity of 5000 IU/mL was to be achieved by the methods used. In 2004, all EU countries have implemented HCV NAT. HIV NAT was simultaneously implemented in France, Germany, and the United States, soon followed by other countries such as Australia, Japan, and more European countries.

The WNV epidemics in the United States that spread between 1999 and 2003 raised a new level of concern regarding transmissibility of emerging viruses by transfusion, and in a 6-mo period, commercial NATs under investigational new drug regulation were implemented in July 2003 in the United States and Canada. The epidemiology of WNV in other areas such as Western Europe does not warrant a similar approach.

Discussions are ongoing to determine the usefulness of NAT for other transfusion transmissible viruses with known residual risk such as HBV and human erythroviruses that include parvovirus B19. HBV DNA screening is already implemented in Japan, Germany, Austria, and Luxemburg. The successive implementation of several NATs in addition to the serological screening assays is adding not only to the financial burden, but also to the complication of operations, therefore increasing the risk of errors. Following implementation of HCV, HIV, and HBV NAT, the rate of errors has become a major factor in calculating residual risk of viral transmission by transfusion. Complete automation is expected to reduce that risk. However, as the number of NATs is likely to continuously increase, alternative strategies such as pathogen inactivation need to be considered, both from a safety and a financial point of view.

IMPACT OF NAT ON BLOOD SAFETY The impact of NAT on the safety of the blood supply has been estimated in several countries. Owing to the rarity of transmission cases, no direct assessment can be done and only calculated estimates can be provided. Table 91-4 indicates preliminary results from France and the United States.

In the present circumstances of a widespread epidemic, epidemiological review of the WNV NAT implemented in North America revealed that several hundred viremic donations had tested positive, and it is estimated that approx 1000 cases per year of transmission would be avoided. This result contrasts with the 5 and 55 cases avoided per year with the HIV and HCV NAT, respectively.

Emerging viral infections originating either from new viruses (mostly animal) breaking into humans or from previously unknown viruses recently discovered are candidate for additional NAT. However, before implementation, several criteria need to be met. The emerging virus should be pathogenic, transmissible by transfusion, in relatively low prevalence, and infectious/persistent for a long enough period of time. The recent severe acute respiratory system, SARS, infection epidemic falls into the first category; although no evidence of transfusion transmission has been provided. The second category includes GB virus-C, TT virus, and SEN virus. The first virus is of low prevalence but no evidence of pathogenicity has been found, whereas the other two, which are in the same family of human circoviridae, are ubiquitous and with no identified pathogenicity.

MOLECULAR DETECTION OF BACTERIALLY INFECTED BLOOD Bacterial infection of blood components is relatively frequent in platelet concentrates because this product is stored at 20°C under constant agitation, which is highly favorable to growth of aerobic bacteria. Among the many methods developed to detect bacterial contamination, the most effective practiced method is culture, with detection either by accumulation of CO_2 or consumption of O_2. These methods are very sensitive, but require a period of natural bacterial growth to amplify the number of bacteria to a detectable level. This procedure takes time (at least 24 h), a major handicap for a product whose shelf life is only 5 d. Molecular methods including an amplification step can overcome this drawback but the diversity of bacterial genome makes it difficult to cover a large spectrum of organisms. Methods targeting the 16S ribosomal (r)RNA have been proposed, whereas others use a universal bacterial rRNA probe. To date, despite a sensitivity of 6–500 organisms/100 μL, these methods do not cover a sufficiently large spectrum of bacteria and are considered expensive and labor intensive. Considerable development is needed before molecular methods can be considered as suitable replacement for methods involving culture.

MOLECULAR DETECTION OF PARASITES IN TRANSFUSION MEDICINE Parasites are transmissible by transfusion but are mostly limited to circumscribed geographic areas. However, immigration from endemic areas and intensive travel have resulted in a real risk of malarial transmission from African and Asian tropical areas in the Northern hemisphere and of *Trypanosoma cruzi* transmission from Central and South America to the Northern part of the American continent. Rules of donor exclusion according to place of origin or traveling have been implemented, but the yield is poor and the number of undeserved donor deferrals high. Various methods have been proposed to distinguish between donors presenting with and without a real risk of transmission. In the case of malaria, antibody detection identifies individuals who have been infected in the past but are not necessarily infectious, whereas antigen detection or thick blood smear are not sufficiently sensitive and, for the latter, discouragingly labor intensive. Genomic amplification methods have therefore been developed using nested PCR or quantitative PCR to detect one parasite per 100 μL of whole blood. The cost-effectiveness of such methods has been evaluated but their clinical efficacy remains to be assessed.

T. cruzi infection is highly immunogenic, with infection occurring mostly in young children. The presence of antibodies in a blood donation is considered synonymous with infectious risk, and high-performance assays are systematically used in endemic areas. Molecular methods have not been considered to help in the deferral of at risk blood donors.

A similar situation is found with tick-transmitted parasites such as Babesia that is endemic in the Northern hemisphere.

PATHOGEN REDUCTION OF BLOOD COMPONENTS Although they have resulted in extensive reductions in risk, donor selection and testing have not eliminated pathogen transmission by transfusion. With the continual discovery of new pathogens, it is clear that the addition of a new test for each adds complexity and loss of donations and donors with false positive reactions. Pathogen inactivation is an adjunct and in some cases a possible alternative to developing individual tests and donor exclusion criteria to address each pathogen individually.

Since the early 1990s, a long series of compounds have been evaluated for their ability to inactivate viruses or other infectious agents without unacceptable loss of cellular function. The last and most promising generation of such compounds targets nucleic acids directly, which are altered and made unable to replicate. In addition to having the potential to inactivate viral and bacterial nucleic acids, compounds such as Psoralens (S59), Inactine, and Riboflavin can inactivate parasites and leucocytes, particularly lymphocytes responsible for transfusion-associated graft-vs-host disease, a universally fatal complication. These follow other chemicals such as methylene blue or solvent detergent-based methods already in use. Because solvent/detergent is effective by disrupting viral (and possibly bacterial) membranes, the spectrum of activity is limited to enveloped viruses.

Table 91-5
Pathogen Inactivation Methods for Blood Components

Component	*Compound*	*Phase of development*
Platelet	Amotosalen (S59)	Clinical practice EU
RBC	FRALE (S303)	Interrupted
RBC	Inactive (PEN 110)	Interrupted
FFP	Amotosalen (S59)	Phase 3 completed; submitted for EU license
FFP	Solvent detergent	Clinical practice EU, discontinued in United States
FFP	Methylene blue	Clinical practice EU

EU, European Union; FFP, fresh frozen plasma; RBC, red blood cell.

Among the compounds listed in Table 91-5, Solvent detergent and methylene blue can only be used in fresh frozen plasma as it disrupts cell membranes. Clinical use of Amotosalen has been started in some European countries, following CE marking. Published randomized trial results indicate efficacy of the system, and although there is a systematic reduction of platelet yield compared to standard products, this difference did not seem to affect clinical efficacy in preventing bleeding. In vitro and in animals, no evidence of oncogenic or other toxicities have been found in short- and long-term studies. However, clinical trials of two different pathogen reduction systems for red cells (S303 and Inactine) have both been suspended following development of red cell alloantibodies. The long-term future of pathogen reduction of red cells and platelets remains to be seen.

92 Immunomodulation

JUAN C. GEA-BANACLOCHE

SUMMARY

Immunomodulation encompasses all therapeutic interventions aimed at modifying the immune response. Augmentation of the immune response is desirable to prevent infection in states of immunodeficiency, to fight established infections and to fight cancer. In immunodeficiencies, treatment of the cause is most important (e.g., malnutrition, HIV). Specific immune defects can seldom be corrected, and the establishment of a new immune system by allogeneic stem cell transplantation should be considered. To prevent infection, vaccination, is the most effective immunomodulatory technique. New tools to manipulate the response to vaccines involve the use of cytokines, viral vectors and even "naked DNA." For the treatment of established infections, attempts to shift the immune response toward a Th1-type phenotype are desirable. For the treatment of cancer, efforts have focused mainly in making the cancer the preferred target of the immune system of the patient. To this effect, a variety of approaches have been used, including cytokines, anti-CTL-4, tumor-specific antibodies and cellular therapies using tumor infiltrating lymphocytes and even stem cell transplantation. In allergy, autoimmunity and organ transplantation the goal is to weaken the immune response. Selected allergies may be treated by specific desensitization. In autoimmunity and transplantation, drugs that blunt all immune responses are often used. A variety of drugs with different targets are used alone and in combination to induce immunosuppression. These agents interfere with antigen presentation (anti-CD154, CTLA4-Ig), T-cell activation (calcineurin inhibitors, including cyclosporine A and tacrolimus), or T-cell proliferation (sirolimus, mycophenolate mofetil, leflunomide). Corticosteroids act at several levels of the immune response and also have significant anti-inflammatory properties. These drugs are necessary in solid organ transplantation to prevent rejection, or treat it if it ensues. When rejection proceeds despite the use of immunosuppressive agents, the graft is lost and a new organ is required. In stem cell transplantation, the equivalent of rejection is graft vs host disease, a pathological condition where the newly acquired immune system recognizes the recipient as foreign and mounts an immune response against it. When graft vs host disease does not respond to steroids, the treatment options are very limited and the prognosis is poor.

Key Words: Allergy; autoimmunity; calcineurin inhibitors; corticosteroids; extracorporeal photopheresis graft vs host disease; immunodeficiency; immunomodulation; lymphocytes; rejection; tumor infiltrating lymphocytes; transplantation; vaccination.

INTRODUCTION

The term immunomodulation is used in its broadest sense in this chapter, encompassing any intervention directed at modifying the immune response with therapeutic intent. The terms immunotherapy and immune-based therapies have also been used to describe the same array of interventions. The different clinical situations in which it may be desirable to manipulate the immune response are presented, and the therapeutic interventions used in each of them addressed.

Disease states characterized by an insufficient immune response are reviewed first, followed by others in which the problem is an excessive immune response. Naturally, the goals of immunomodulation are different (Table 92-1).

IMMUNOMODULATION DIRECTED AT INCREASING THE IMMUNE RESPONSE

In principle, a more active immune response may be desirable in two general types of situations: when the immune response is pathologically decreased (i.e., disease states characterized by insufficient immune function) and when the "normal" immune response proves inadequate to control a specific infection or pathological condition. The first situation is called immunodeficiency and includes several congenital and acquired conditions.

IMMUNODEFICIENCY

Acquired Immuodeficiencies The most common specific immunodeficiency in the world is AIDS. AIDS is caused by a retrovirus, HIV, which infects and destroys CD4 T cells, causing a progressive failure of host defenses *(see* Chapter 93). This results in the development of opportunistic infections and some specific types of cancer.

Immunodeficiency develops also as a consequence of malnutrition, cancer (and its treatment), and infection. Protein-calorie malnutrition may in fact be more prevalent than HIV infection, but the immune defects associated with it are much less well defined. Cancer, particularly when widespread, is associated with defects in cell immunity and increased risk of infections. Some lymphoreticular malignancies like Hodgkin's disease are accompanied by defects in cell-mediated immunity, even before they are widely disseminated. The treatment of cancer with intensive chemotherapy and radiation also makes patients vulnerable to infections. Some viral infections, most notably

Table 92-1
Examples of Immunomodulation in Clinical Practice

Immune augmentation	*Intervention*
Immunodeficiency states	
Primary immunodeficiencies	Replacement of IVIG in B-cell defects; IFN-γ in some diseases with phagocytic defect
Acquired immunodeficiency	Treatment of the causative process (e.g., in AIDS, suppress viral replication)
Infectious diseases	
Bacterial diseases	Granulocyte transfusions; hematopoietic growth factors
Fungal diseases	IFN-γ and other cytokines
Viral diseases	Specific immunoglobulin, IFN-γ cell transfer
Parasitic diseases	IFN-γ
Cancer	
Renal cell carcinoma	IL-2, activated lymphocytes
Melanoma	IL-2, tumor-infiltrating lymphocytes
Immunosuppression	
Allergy and autoimmunity	
Allergy	Corticosteroids, desensitization
Autoimmunity	Corticosteroids, anticytokine therapies, immunosuppressive agents (*see* text)
Transplantation	
Solid organ transplants	Immunosuppression to prevent graft rejection and treat rejection episodes
Bone marrow transplantation	Immunosuppression to prevent graft vs host disease

IVIG, intravenous immunoglobulin.

measles and human T-cell lymphotropic virus I, cause immunodeficiency. Both can infect T cells, and this may be the explanation for the immune defect.

For all the acquired immunodeficiencies, removal of the cause is the most important step. In the case of AIDS, dramatic clinical success has been achieved by stopping HIV replication using antiretroviral agents. A variety of immune-modifying interventions have been attempted in HIV disease, but none of them is effective. There is a persistent quest for an HIV vaccine that might be administered to HIV-infected individuals to induce a state of stable equilibrium between the virus and the recipient's T cells. In terms of interventions directed toward rebuilding the lost immune system, the administration of interleukin 2 (IL-2, the T-cell growth factor) is effective at increasing the number of CD4 positive T cells when given in the presence of reasonably suppressed HIV replication. It is not known if the IL-2-induced increase in CD4 cells is also accompanied by an improved immune function and decreased number of infections.

Primary Immunodeficiencies The primary immunodeficiencies provide unique insights on the different components of the immune response. Genetic defects at different steps in the development of lymphocytes or the mechanisms of immune responses give rise to a variety of disease states with characteristic phenotypes. Unfortunately, the ability to increase the activity of the immune system in many of these patients is limited. Many of these diseases are potentially curable by allogeneic hematopoietic stem cell transplantation (allo-HSCT). By this procedure, the immune system of the recipient is completely replaced by that of the donor. In diseases characterized by B-cell defects (e.g., Bruton's agammaglobulinemia, common variable immunodeficiency), the administration of intravenous Ig obtained from blood donors IVIG results in decreased incidence of infections. In diseases in which the defect lies on the T cells, there are no proven interventions of value, and gene therapy or allogeneic stem cell transplant may be considered. Patients suffering from chronic granulomatous disease, a group of genetic defects characterized by defective generation of the respiratory burst during phagocytosis, benefit from the administration of interferon (IFN)-γ. IFN-γ may also be useful in patients with the dominant form of IFN-γ receptor deficiency, a rare form of immunodeficiency in which deletions in the gene that codifies the intracellular domain of IFN-γ R1 result in a truncated form of the receptor that binds IFN-γ but does not generate a signal.

IMMUNOMODULATION TO FIGHT INFECTIONS

Vaccination The single most successful manipulation of the immune response is vaccination. In vaccination, protective adaptive immune responses are generated by exposing the host to a harmless form of the pathogen (e.g., inactivated or attenuated virus, as in influenza or measles, respectively) or parts of it (e.g., tetanus toxoid, a harmless preparation of the tetanus toxin, the agent of tetanus caused by the bacterium *Clostridium tetani*). Interestingly, most successful vaccines antedate by centuries (in the case of vaccinia for smallpox) or decades the current detailed molecular knowledge of the immune system. However, the current knowledge has already resulted in more effective vaccines against bacteria (*Hemophilus influenzae*) and viruses (hepatitis B), and has the promise of resulting in even safer and more effective vaccines in the future.

Vaccination started following the observation that people who had survived some infections would not develop them again. Inducing the infection on purpose, with small doses of the causative agent, was a logical first experiment to confirm and attempt to apply this knowledge. In the case of smallpox, the inoculation of dried material from a smallpox pustule was called variolation, and was reasonably effective, although it sometimes resulted in systemic severe smallpox in a few of those exposed.

The observation by Jenner that persons who had been infected with cowpox were protected from smallpox began the era of modern vaccination, and what is arguably immunology's greatest

triumph, the eradication of smallpox. It was also a useful proof of the principle that a live pathogen that can infect without causing disease may induce long-lasting immunity to a similar, much more virulent agent. *Vaccinia*, the virus that causes cowpox, typically causes only a local infection in humans (although it can occasionally disseminate in the recipient and even be transmitted) but it generates an immune response that will successfully protect the individual from becoming infected with the much more dangerous smallpox virus.

There are three general strategies for vaccination in clinical use: attenuated infectious agents, killed complete infectious agents, and selected parts of infectious agents, frequently synthesized in the laboratory. The newest strategy, experimental at this point, involves the use of DNA from the pathogen of interest.

Attenuated infectious agents are the most effective form of vaccination, because they mimic the infection and result in an immune response very similar to that induced by the virulent form of the pathogen, including CD4 cells, CD8 cells, B cells, and, frequently, mucosal immunity. Vaccines with attenuated virus are in use against polio, measles, mumps, rubella, and typhoid fever. Attenuated viruses are strains that have been grown in nonhuman cells for many generations. Evolution and natural selection result in viruses that are much less able than their wild type counterparts to cause disease in humans. However, as they do cause infection, they are presented to the immune system by the same pathways as the pathogenic variants (including the major histocompatibility complex [MHC] class I pathway that generates CD8 cytotoxic responses), resulting in the most complete immune response. The most complete immune response involves CD4 T cells, CD8 T cells, and antibodies. An inactivated virus cannot infect cells and synthesize proteins to be processed and presented as MHC-I associated peptides, and so it is incapable of generating a proper T-cell-mediated immune response. However, this may not be necessary, as often the most important mechanism of defense against viruses is neutralizing antibody.

If an attenuated version of the pathogen is not an option, selecting the right antigens to generate a protective immune response may be attempted. Understanding how the immune system works is important in this setting. For instance, although polysaccharide antigens are typically T-cell independent (i.e., they generate an antibody response even without T-cell "help"), in infants they do not generate an adequate immune response. The bacteria *H. influenzae* and *Streptococcus pneumoniae* have a polysaccharide capsule that can serve as a vaccine, but they are most important pathogens in infants. The capsule alone would not elicit an adequate immune response in the target group of subjects. This problem may be overcome by administering the polysaccharide antigens conjugated to a protein "carrier." The presence of the protein carrier engages the T-cell arm of the immune response, and a much more effective antibody response is achieved.

It is known that antigens are presented to B and T cells in the lymphoid organs by dendritic cells, the professional antigen-presenting cells (APCs). As the understanding of dendritic cells' recognition and processing of antigens has improved, the possibilities to intervene at this stage have expanded. It seems possible to create the conditions to favor the desired immune response by administering cytokines (e.g., IL-12 when a Th1 response is the goal) simultaneously with the administration of the antigen.

The lessons learned through the use of attenuated virus have been put to work by the use of viral vectors as carriers of the antigens of interest. There are some viruses, like fowlpox, which cannot result in productive infection in humans. If the virus is used as a carrier of genes of other virus, however, the abortive infection will result in a few cells that will synthesize (and process via the MHC class I pathway) the carried proteins from the virus of interest. This is most attractive when attempting to generate immune responses against pathogens for which CD8-mediated cytotoxicity is considered essential (HIV is the prime example, but similar strategies are being used in cancer immunotherapy).

DNA vaccination is a recent discovery. The intramuscular administration of DNA from a given virus results in the development of antibody and cytotoxic T cells that allow the animal to resist challenge with the whole, infectious virus. This implies the "naked" DNA is actually taken up and transcribed by cells, giving rise to viral proteins that are presented through human leukocyte antigen (HLA) class I and HLA class II pathways. The DNA of interest may be inserted in a plasmid carrying other genes, for instance cytokines like granulocyte/macrophage colony-stimulating factor (GM-CSF), which may boost the immune response to the viral gene. There are no vaccines in clinical use that have made use of this new technology, but this approach is being used experimentally for the development of tumor vaccines and vaccines against chronic infections.

Modulation of the Immune Response to Established Infections The goal of vaccines is to prevent infection. Once the infection has taken place, however, it may be desirable to augment or modify the immune response to allow the patient to fight it more effectively. At the center of the idea of using immunomodulation for the treatment of infections lies the concept of different types of immune response to the same pathogen, which has been well characterized in animal models but only partially successful when applied to human disease.

The Th1-Th2 Paradigm Mouse CD4 T cells incubated in vitro exposed to different cytokine environments develop differently. When they are incubated in the presence of IFN-γ, the cells mature into "Th1" lymphocytes, which secrete mainly IL-2 and IFN-γ. If the culture medium contains IL-4, the resulting T cells ("Th2") produce mainly IL-4, IL-5, and IL-10.

In the mouse model, the immune response as a whole may be manipulated toward a type in which Th1 cells and their cytokines predominate or a type in which Th2 cells and their cytokines are the dominant component. Experiments with infection with the parasite *Leishmania major* demonstrated that strains of mice resistant to the infection exhibited a "Th1 type" of immune response (high expression of IFN-γ), and strains of mice susceptible to the infection exhibited a "Th2 type" of response (high expression of IL-4). If expression of IL-4 was prevented, the previously susceptible mice were able to overcome the infection.

At its most basic, the Th1-Th2 model postulates that different antigens under different circumstances in different hosts tend to produce an immune response characterized by vigorous cell-mediated immunity and granuloma formation (Th1) or an immune response characterized by the production of antibody (Th2). Exactly what is the cause that shifts the balance toward one type or another in vivo is not clear. In the laboratory, in vitro, polarized Th1 and Th2 responses are reproducibly elicited by the presence in the medium of IFN-γ (Th1) or IL-4 (Th2). In vivo, many factors probably interact to determine what kind of response a given individual is going to mount against a specific antigen. As discussed next, abnormal Th2 responses give rise to atopic allergy. Conversely, abnormal Th1 responses may

be responsible for the immunopathogenesis of several autoimmune diseases.

Regarding infections, there are many situations in which a shift toward a Th1 response is desirable, and the shift toward a Th2 response inadequate. A successful response to some intracellular bacteria like *Mycobacterium tuberculosis* involves the production of IFN-γ by Th1 cells to activate the macrophages and enable them to effectively destroy the bacteria they have ingested by phagocytosis. Lack of a Th1 response in this situation results in disseminated, uncontrolled disease. In some animal models the administration of Th1 cytokines (i.e., cytokines that shift the response toward Th1, mainly IFN-γ, IL-12, and IL-18) results in clinical improvement. In several clinical situations in humans in which this pathway is defective (*see* Primary Immunodeficiencies) the administration of IFN-γ results in clinical improvement and control of the infection. However, IFN-γ does not seem to be helpful in apparently normal subjects with infections, although there are anecdotal reports of their use in invasive fungal infections.

The cytokine IFN-α is licensed in a variety of forms for the treatment of chronic hepatitis B (IFN-α 2B) and C (IFN-α 2A, 2B). Its mechanism of action is probably a combination of antiviral and immunomodulatory effects. IFN-α acts on hepatocytes to induce the synthesis of several enzymes that block viral replication; it also increases expression of class I MHC molecules and promotes the development of Th1-type responses.

IMMUNOMODUTATION IN THE THERAPY OF CANCER

Cancer is the result of the unregulated proliferation of a clone of transformed cells. These transformed cells may or may not be detected by the immune system, depending on how many new antigens they express, where the tumor is located and whether there is associated necrosis or inflammation. The concept of immune surveillance, formulated in the 1950s, and stating that one of the functions of the immune system is to recognize and eliminate transformed cells when they appear, before they can develop into a significant tumor, seems to be applicable only in a minority of cases. It is relatively easy to demonstrate immune activity against tumors in animal models, and particularly when the tumors are secondary to the action of a virus. The extreme effectiveness of the immune response against cancer in some of these models has driven the field of cancer immunotherapy for decades, with relatively few widely applicable results.

There are several ways of taking advantage of the immune system to fight cancer. For some tumors that elicit an immune response, the enhancement of such response may be helpful. Intravesical Bacillus Calmette-Guerin, the attenuated Mycobacterium used as a vaccine for tuberculosis and known to be a potent immune adjuvant has been used for decades for the treatment of superficial bladder cancer. Renal cell carcinoma is probably the best example of immunotherapy-responsive tumor. The administration of IL-2 results in significant long-term responses in a small fraction of patients with renal cell carcinoma. No other manipulation of the immune system is required, suggesting that a specific immune response was already present and only required potentiation by supraphysiological doses of the cytokine. IFN-α is used for the treatment of renal cell carcinoma, hairy cell leukemia and chronic myelogenous leukemia, and in some responding patients CD8 T-cell responses to the leukemia have been detected. The use of natural killer cells from patients, expanded and activated in vitro with IL-2 lymphokine-activated killer cells, is a variation of this same approach. However, the use of lymphokine-activated killer cells was associated with significant toxicity and only marginal effectiveness, and it served more as a proof of principle than as a viable therapeutic approach. Metastatic melanoma is often treated with IFN-α, but its efficacy in this setting is questionable. Kaposi sarcoma, the most common tumor arising in HIV-infected men, may be treated with IFN-α, although the mechanism of action is unclear. Interestingly, effective anti-HIV therapy, with subsequent immune reconstitution, has been associated with delayed progression and even regression of some Kaposi sarcoma lesions.

The systemic administration of cytokines that enhance the antitumor response is conceptually similar to the administration of anti-CTLA-4. This is a monoclonal antibody directed against CTLA-4 (CD152), a molecule expressed by activated lymphocytes that downregulates the immune response following its interaction with B7.2 on the surface of follicular dendritic cells or other APCs. The anti-CTLA-4 antibody prevents the interaction between B7.2 and CTLA-4. By blocking the inhibitory signal, an enhanced immune response is achieved. Interestingly, the clinical use of this molecule has resulted in partial responses in melanoma, but also in the development of autoimmune diseases, most notably colitis, hepatitis, and hypophysitis. This observation shows that autoreactive clones of T cells are present despite the processes of positive and negative selection in the thymus, and that peripheral tolerance plays a more important role in preventing autoimmunity than previously thought.

A different approach involves the administration of antibodies that specifically target the malignant cells. It is logical to consider this intervention some form of immunotherapy, but in fact the role of the patient's immune response is questionable. It is possible to develop monoclonal antibodies directed against antigens that are present on the cancerous cell. As long as the target molecule is present on the malignant cells only or predominantly, this treatment has the potential to have exquisite specificity and very few side effects.

The best scenario in terms of developing a treatment that is universally applicable is when the targeted antigen is present in a significant fraction of the patients with that type of cancer. For instance, many B-cell lymphomas express the surface molecule CD20. Adding a monoclonal antibody directed against CD20 (rituximab, an IgG1-κ antibody that has mouse variable and human constant regions) to conventional chemotherapy results in improved clinical outcomes. Another example is anti-Tac (a monoclonal directed against CD25, one of the chains of the IL-2 receptor) for adult T-cell lymphoma–leukemia, a form of cancer caused by the retrovirus HTLV-I in which the malignant cells are CD4 T cells that typically overexpress CD25.

There may be several different mechanisms of action of antibody-based therapy. Rituximab may have three distinct mechanisms of action: antibody-dependent cell-mediated cytotoxicity (ADCC), complement-mediated cell lysis, and direct stimulation of apoptosis in target cells. The effects of different monoclonal antibodies on different malignancies are diverse.

Another example of effective therapy with a monoclonal antibody against cancer is trastuzumab, a monoclonal antibody directed against HER-2/neu (also known as HER2 or c-erb-B2). This is a surface molecule with protein kinase activity, member of the epidermal growth factor receptor family. HER-2/neu is overexpressed in many ovarian and breast cancers, as well as in pancreatic and colorectal carcinomas. The addition of trastuzumab to chemotherapy for breast cancer resulted in improved survival.

A similar chimeric IgG1 monoclonal antibody, cetuximab, has shown effectiveness against colorectal carcinoma. It is unclear if there is any immune effect mediating the efficacy of these agents.

The effectiveness of monoclonal antibodies may be increased when they are used synergistically with other agents, as in the case of rituximab (previously mentioned). These other agents are typically chemotherapeutic, but it is possible to combine immune-modulating therapies. If the main action of an antibody is to stimulate ADCC, which is most typically mediated by natural killer cells, agents that increase the number or activity of these cells (like IL-2) may show increased effectiveness.

In a different variation of this approach, the antibody may carry toxic molecules and deliver them to the malignant cells (immunotoxins). A monoclonal antibody directed against CD22, a surface marker of B cells present in the malignant cells in hairy cell leukemia, produced lasting responses in two-thirds of patients with disease that had been refractory to chemotherapy. Antibodies may also be linked to radioactive isotopes, delivering local radiation therapy, or even to enzymes that can transform a prodrug into an active cytotoxic agent (antibody-directed enzyme prodrug therapy).

More elaborate attempts to manipulate the immune response involve the use of tumor vaccines. The first step is to find specific tumor antigens that elicit a strong immune response. This is frequently the limiting factor, as most tumors do not express these so-called tumor rejection antigens. Once the antigens are found, the second step is to find the best way in which to elicit an effective immune response against them by administering them to the patient with an adequate vector and appropriate costimulation. A variety of experimental approaches are being used to enhance the immunogenicity of tumor vaccines, including transfecting tumor cells with genes that encode costimulatory molecules (e.g., B7) or cytokines that attract APCs (e.g., GM-CSF).

Another strategy involves using tumor antigens to expand clones of cytotoxic T cells in vitro. These tumor-specific T cells may then be administered to the patient. IL-2 may be given at the same time to foster the growth of the antitumor clones in vivo.

The most radical form of immunotherapy for the treatment of cancer is allogeneic stem cell transplantation. The effectiveness of this procedure against leukemia goes beyond what could be expected from the effect of the chemotherapy or radiotherapy received by the patient. The clinical importance of the "graft-vs-leukemia" (GVL) effect shows clearly in the fact that transplants from fraternal twins are more effective to cure chronic myelogenous leukemia than transplants from homozygotic twins (so-called syngeneic transplants). In fact, the treatment of leukemia with allogeneic transplant is often followed by administrations of lymphocytes from the donor (donor lymphocyte infusions), and these achieve the "complete remission" of the disease. However, it is not clear if the "GVL effect" is truly tumor specific or if it is part of the more general phenomenon of graft-vs-host disease (GVHD). That is, the malignant cells are being destroyed not because there is a specific antitumor immune response, but because they express host antigens and there is an immune response against the host. The separation of GVHD from GVL is one of the most sought after and elusive goals of allo-HSCT.

There is evidence that allogeneic transplant may be clinically effective against solid tumors, particularly renal cell carcinoma. However, even if graft-vs-tumor effect can be demonstrated in some more common cancers, including breast adenocarcinoma, the clinical utility of this approach has not been demonstrated.

IMMUNOMODULATION TO DECREASE A HARMFUL IMMUNE RESPONSE

Allergy and autoimmunity are situations characterized by the presence of a harmful immune response. Sometimes they are considered together under the general term "hypersensitivity." The main difference between allergy and autoimmunity is the source of the antigen against which the immune response is directed. In allergy, it is extrinsic; in autoimmunity, it is intrinsic. This distinction, absolutely clear-cut in most cases, becomes blurred when what starts as a reaction to some external antigen becomes autonomous and lasts weeks after the offending agent has been (presumably) eliminated. In fact, many autoimmune diseases are clearly triggered by external stimuli (mainly infections).

ALLERGY (IMMEDIATE HYPERSENSITIVITY) Allergy is, in fact, the most common class of disordered immune responses; up to 20% of adults in industrialized countries suffer some form of allergy, like allergic rhinitis or asthma. The first step in the treatment of allergic diseases is to find the causative agent. When the causative agent ("allergen") is identified, avoidance is the first and most successful approach to therapy. When avoidance of the allergen is not possible, anti-inflammatory drugs are used. Changes in the immune response may be attempted, and in some cases are successful (e.g., allergy to some insect venom treated by desensitization), but for the majority of affected individuals the modification of the immune response is not practical or effective.

The prototypic allergic condition is immediate hypersensitivity or atopy. Clinical manifestations include anaphylaxis, allergic rhinitis, extrinsic asthma, food allergy, and eczema. This is the prime example of a pathogenic Th2 immune response. In atopy, genetically predisposed individuals respond to a variety of external antigens (common environmental proteins and chemicals) by producing IgE. IgE binds to Fc receptors on the surface of mast cells. With subsequent antigen encounter, crosslinking of the IgE molecules on the surface of mast cells results in mast cell degranulation, the release of vasoactive substances that cause the disease manifestations. The pathogenesis of atopic reactions involves varying combinations of vasodilation, increased vascular permeability, smooth muscle contraction, mucus production, and inflammation. In the most severe form, anaphylaxis, the systemic release of these substances (histamine, bradykinin) results in sudden cardiovascular collapse and severe bronchospasm, both of which may be lethal if not promptly treated. At the other end of the spectrum, someone may experience itchy, runny eyes, together with rhinorrhea and sneezing in the presence of cats: annoying symptoms, but hardly life threatening.

Atopic allergy is characterized by increased levels of IgE, but this in turn reflects T-cell dysregulation. Nonatopic individuals respond to the same antigens by producing IgG or IgM. The production of IgE is a consequence of isotype switching by the B cells, and is caused by Th2 cells, through a two-signal process. The first signal is IL-4 (IL-13 may have the same effect); the second signal is the interaction between CD40 ligand on the T-cell and CD40 on the B-cell surface. Other Th2 cytokines play a significant role in the allergic immune response: IL-5 activates eosinophils and IL-13 stimulates mucus production; however, mast cells orchestrate the allergic reaction.

It is not known why the same substances induce a Th2 response in some people and a Th1 response in others. Genetic factors undoubtedly play a role (candidate genes have been mapped

to chromosomes 11q and 5q), but there are some characteristics that many allergens have in common: they are small proteins presented to mucosal surfaces in very small quantity. It is thought that dendritic cells pick up the allergen, process it and present it to T lymphocytes in neighboring lymph nodes. The Th2 pathway is favored in the presence of IL-4, IL-5, IL-9, IL-10, and IL-13. In the presence of IL-12 of IFN-γ, Th1 development is favored. The role of dendritic cells in determining Th differentiation is not completely understood. It is possible that a Th2 response is the default differentiation pathway when the antigen is presented in the absence of other inflammatory signals. The fact that atopic allergy is increasing in industrialized countries has been linked by some theories to a decrease in the exposure to infections in early childhood.

Immunomodulation in allergic diseases is sometimes attempted in clinical practice. Desensitization is the term used to describe the gradual administration of increasing doses of the allergen to the patient, with the aim of shifting the response to a normal Th1 phenotype. In practice, desensitization works in diverse clinical settings by different mechanisms. When rapid desensitization (performed in the course of hours) is used to administer a life-saving drug (commonly, an antibiotic) to which the patient is allergic, there is no time to effect a change in the immune response. However, the procedure is typically successful, suggesting that the gradual addition of increasing amounts of allergen resulted in the saturation of all IgE receptors without eliciting crosslinking and subsequent degranulation. In this case, the patient is not "cured" of the allergy, and the procedure would have to be repeated if the drug were to be needed again. In the case of allergy to insect venom, the continued application of a desensitization schedule during years may eventually result in the generation of a normal immune response to that specific antigen, and in some cases it is possible to stop the administration of venom and still maintain the desensitized state. The vast majority of desensitization procedures applied for the treatment of allergic rhinitis or asthma have not shown to be more effective than placebo in controlled clinical trials, even if they are attempted frequently ("allergy shots").

AUTOIMMUNITY Autoimmune diseases are characterized by the presence of a harmful immune response against self-antigens. Each is relatively uncommon, but together they affect up to 5% of the population in industrialized countries.

Autoimmunity is a consequence of the limitations of self-tolerance. During development, lymphocytes are generated that are able to recognize virtually all possible antigens, including self-antigens. The lymphocytes that have receptors specific against self-antigens must not become activated and start an autoimmune reaction. This state, by which self-reactive lymphocytes are not activated by self-antigens, is called self-tolerance. Several mechanisms exist during lymphocyte development to prevent autoreactive clones from reaching the periphery (central tolerance); nonetheless many potentially autoreactive clones persist and they are kept from initiating an immune response against self-antigens by other mechanisms that together constitute what has been called "peripheral tolerance." Some of the mechanisms of peripheral tolerance follow. Peripheral lymphocytes that strongly recognize their target in the absence of the necessary costimulation become anergic or die by apoptosis. Lymphocytes that recognize antigen weakly, however, may not be eliminated or anergized, and instead they may persist in a state of "ignorance." They do not react under normal circumstances, but may become part of an autoimmune reaction in the right setting. For instance, an infection may cause inflammation and deliver costimulatory signals at the same time and place that "ignorant" lymphocytes are being presented with their potential target. Activation and development of a full immune response by the previously ignorant lymphocytes may follow. Other cases of autoimmunity may just be the result of cross-reactivity; some viral or bacterial antigens, presented on some specific HLA molecules, may be similar enough to self-peptides that an autoimmune reaction may ensue.

Once established, autoimmune reactions persist until the offending antigen is eliminated. For many self-antigens, this never happens, and the disease becomes chronic. For some other self-antigens, the autoimmunity results in the complete destruction of the target.

Multiple classifications of autoimmune diseases have been used. The most common divides them into organ-specific (only a specific tissue or organ system is involved) and systemic (affecting multiple organ systems). This classification provides little insight, because it is based on the phenotype instead of the cause. It is also misleading, because many diseases affect predominantly one organ but can involve many. However, this classification remains of practical interest. A classification based on the pathogenesis of the effector mechanism (i.e., diseases mediated mainly by antibodies, by immune complexes or by T cells) is similarly inadequate because multiple pathogenic mechanisms may be active simultaneously (for instance, in systemic lupus erythematosus, the classic example of systemic autoimmune disease, there are autoantibodies, immune complex-mediated disease, and T-cell-caused pathology). Table 92-2 shows some examples of autoimmune diseases and includes information on the identified self-antigens and the most important pathogenic mechanisms.

The treatment of autoimmune diseases is deeply unsatisfactory. As opposed to allergic diseases, avoidance of the antigen is not an option. For most autoimmune diseases involving the endocrine system, hormonal replacement if the glandular function has been lost or inhibition of the action of excess hormone is the treatment of choice, and the pathological immune response is not addressed at all. Immunomodulation in autoimmunity, as in transplantation, is based on the use of drugs that control inflammation and broadly diminish the immune function. An expected side effect of immunosuppressive drugs is that they make the recipient susceptible to infections, but many other toxicities accompany the use of these drugs.

IMMUNOMODULATING AGENTS The different immunomodulating agents available can be classified according to the part of the immune response in which they are more active. Immune responses occur through several steps that can be conceptually separated as follows:

1. Antigen processing and presentation to T cells.
2. T-cell activation.
3. T-cell proliferation and subsequent effects.

This classification can provide the framework on which to understand the possibility of combination therapy with several different immunosuppressive agents. Ideally, drugs that act on different steps of the immune response could achieve synergistic effect.

At the time of this writing, the most important immunomodulating/immunosuppressive agents in clinical practice belong to categories 2 and 3 (Table 92-3).

Corticosteroids Corticosteroids have a diverse array of effects, and are difficult to include in any of the categories outlined above.

Table 92-2
Examples of Autoimmune Diseases

	Antigen/autoimmune mechanism	*Immunomodulatory therapy*
Multisystem diseases		
Systemic lupus erythematosus	Auto-antibodies against DNA, histones, ribosomes result in arthritis, renal disease, and vasculitis.	Corticosteroids, azathioprine, cyclophosphamide, rituximab
Rheumatoid arthritis	Unknown antigen in joint synovium. The immune response results in destructive arthritis.	Corticosteroids, azathioprine, cyclosporine, methotrexate, etanercept, infliximab, leflunomide, anti-IL-1 (anakinra)
Polyarteritis nodosa	Hepatitis B virus surface antigen. Vasculitis of medium and small-sized vessels results in systemic disease.	Corticosteroids, cyclophosphamide
Organ-specific autoimmune diseases		
Diabetes mellitus type I	Antigen in β cells in the pancreas. Immune response by TH1 cells, CTL, and antibodies results in destruction of insulin-producing cells.	Vaccination with different peptides is being attempted to try to prevent total destruction of the β cells.
Multiple sclerosis	Myelin basic protein; T-cell-mediated immune response results in repeated episodes of CNS demyelination.	Corticosteroids, IFN, daclizumab, natalizumab
Guillain-Barre syndrome	Antibodies directed against components of peripheral or cranial nerve myelin.	Plasma exchange and administration of intravenous Ig are beneficial; corticosteroids are not.
Anti-GBM antibody disease (Goodpasture's syndrome)	Protein in the basement membrane collagen type IV. Antibody and complement-mediated inflammation of glomeruli and lung alveoli results in glomerulonephritis and pulmonary hemorrhage.	Plasmapheresis to eliminate the antibody present, combined with cyclophosphamide and corticosteroids
Idiopatic thrombocytopenic purpura	Platelet membrane proteins (gpIIb/IIIa integrin). Antibodies cause opsonization and phagocytosis of platelets.	Corticosteroids, intravenous Ig
Graves disease	TSH receptor. Antibodies bind to TSH receptors and cause thyroid hormone secretion.	None for the hyperthyroidism; corticosteroids for the ophthalmopathy

These derivatives of the glucocorticoid hormones are the mainstay of treatment of autoimmune diseases. They may be used at very small doses (e.g., prednisone 5–10 mg daily) as anti-inflammatory agents, at intermediate doses (e.g., prednisone 0.5–1 mg/kg daily) as immunosuppressive agents and at very high doses (e.g., methylprednisolone 500–1000 mg daily) as lymphocyte-depleting agents. Glucocorticoids enter the cell and bind with the steroid receptor, which resides in the cytoplasm, forming a complex with the heat-shock protein, Hsp90. After binding, the glucocorticoid-steroid receptor complex translocates to the nucleus, in which it binds to specific DNA sequences in the promoter regions of steroid-responsive genes, resulting in the activation of the transcription of multiple genes and the suppression of many more. The overall result is a decrease in the synthesis of proinflammatory cytokines, including IL-1, tumor necrosis factor (TNF)-α, IL3, GM-CSF, and chemokines. At very high doses, steroids may induce lymphocyte apoptosis, and this mechanism may play a role in the effect of the very high doses ("pulses") of methylprednisolone used for the treatment of acute attacks of multiple sclerosis or lupus glomerulonephritis.

Agents That Interfere With Antigen Processing and Presentation Most agents in this category are experimental. The interaction between APCs and lymphocytes can be targeted at several points, including preventing the interaction between CD40 on B cells and CD40 ligand (CD154) on activated T cells using an anti-CD154 antibody (ineffective in a randomized controlled trial in lupus); and preventing effective costimulation by blocking CD80 and CD86 (B7.1, B7.2) on APCs by the use of CTLA4-Ig (promising in rheumatoid arthritis and psoriasis).

Agents That Interfere With T-Cell Activation Probably the most important drugs in medical transplantation are the calcineurin inhibitors, cyclosporine A and tacrolimus. Cyclosporine A and tacrolimus (FK506) act by reducing the expression of cytokine genes that are normally expressed during T-cell activation, including IL-2, the most important T-cell growth factor. These drugs are most effective to prevent immune activation, and accordingly are much more important in transplantation (to prevent rejection) than in autoimmunity (in which the immune response is already in progress). Cyclosporine and tacrolimus bind to different target proteins called immunophilins (cyclosporine to cyclophilin, tacrolimus to the FK-binding protein), but both result in the binding and inhibition of calcineurin, a phosphatase that becomes activated in T cells after T-cell receptor binding. Calcineurin activates a number of transcription factors, and its inhibition prevents effective T-cell activation and clonal expansion. Tacrolimus and cyclosporine act on the same step of T-cell activation, and they have similar efficacy. The

Table 92-3
Selected Immunomodulators

	Description/mechanism of action	*Uses*
Interference with antigen processing and presentation		
CTLA4-Ig	Fusion molecule that binds CD80 and CD86 on the surface of APCs blocking the interaction with CD28 that would deliver a costimulatory signal to the T cell	Phase II studies in rheumatoid arthritis, psoriasis and transplantation
Anti-CD40 ligand	Blocks the interaction between CD40 on macrophages and B cells and CD40 ligand (CD154), which is expressed on activated T cells	Animal models, including xenotransplantation
Efalizumab (anti-LFA-1)	Binds to LFA-1, preventing LFA-1-ICAM interaction, resulting in blocking T-cell adhesion, trafficking and activation	Phase III trials in psoriasis, I/II in transplantation and rheumatoid arthritis
Natalizumab (anti α-4 integrin)	Humanized monoclonal antibody prevents the interaction between α-4 integrin on the surface of inflammatory cells and VCAM-1 on vascular endothelial cells, preventing leukocyte migration across the blood–brain barrier in multiple sclerosis.	Approved for use in remitting-relapsing multiple sclerosis; was withdrawn from the market owing to serious side effects
Interference with T-cell activation		
Cyclosporine A	Binds to cyclophilin. The complex cyclosporine-cyclophilin binds and inhibits calcineurin, preventing the activation of the transcription factor nuclear factor of activated T cells (NFAT). This blocks the activation of T cells and the production of IL-2.	Prevention of solid organ rejection and of GVHD. Approved for rheumatoid arthritis and psoriasis; often used in several other autoimmune diseases
Tacrolimus (FK506)	Tacrolimus binds the protein FKBP, and this complex binds and inhibits calcineurin. Same effect as cyclosporine	Prevention of solid organ rejection and of GVHD. Approved (topical) for atopic dermatitis. Often used in several other autoimmune diseases
Inhibition of T-cell proliferation		
Rapamycin (Sirolimus)	Rapamycin binds the intracellular protein FKBP. The complex rapamycin-FKBP binds MTOR, arresting cell cycle between G1 and S	Prevention of rejection in solid organ transplant; prophylaxis of GVHD, treatment of steroid-refractory GVHD
Leflunomide	Inhibits the *de novo* pathway of pyrimidine synthesis, suppressing T-cell proliferation	Effective in rheumatoid arthritis. Experimental use in solid organ transplant
Azathioprine	Antimetabolite through purine synthesis inhibition	Prevention of rejection in solid organ transplant
Mycophenolate mofetil (MMF)	Antimetabolite through purine synthesis inhibition, selective for lymphocytes	Prevention of rejection in solid organ transplant; prevention of GVHD
Methotrexate	Antifolate antimetabolite.	Induction and maintenance in solid organ transplantation; prevention of GVHD, treatment of rheumatoid arthritis and vasculitis
Dacluzimab	Humanized monoclonal antibody directed against CD25 (part of the IL-2 high-affinity receptor)	In solid organ transplant it has been used as part of the induction regimen; in allo-HSCT, it has been used as treatment of steroid-refractory GVHD.
Basiliximab	Monoclonal antibody directed against CD25 (part of the IL-2 high-affinity receptor)	In solid organ transplant it has been used as part of the induction regimen.
Lymphocyte depletion		
Antithymocyte immunoglobulin	Polyclonal immunoglobulin obtained from horse or rabbit	Treatment of aplastic anemia. Treatment of acute rejection in renal transplantation
Muronomab-CD3	Anti-CD3 monoclonal antibody	Treatment of acute rejection in solid organ transplantation. Treatment of GVHD in allo-HSCT

(Continued)

Table 92-3 ***(Continued)***

	Description/mechanism of action	*Uses*
Alemtuzumab (Campath-1H)	Humanized monoclonal antibody directed against CD52	FDA-approved only as antineoplastic in chronic lymphocytic leukemia; it has been used to treat some autoimmune diseases, including autoimmune cytopenias, refractory rheumatoid arthritis and vasculitis. In allo-HSCT it has been used to prevent GVHD.
Other agents		
Corticosteroids	Multiple mechanisms of action. Steroid complexes with cytosolic receptors and translocates to the nucleus, binding to glucocorticoid response elements in the promoter regions of cytokine genes. The result is prevention of T-cell recruitment and activation.	The basic drugs used to prevent and treat solid organ recjection, prevent GVHD and treat a wide variety of autoimmune diseases
Etanercept	Recombinant form of the extracellular domain of human p75 tumor necrosis factor receptor fused to the Fc fragment of human immunoglobulin G1. Blocks TNF-α action	Used in rheumatoid arthritis, psoriasis and ankylosing spondylitis. Experimental in other autoimmune diseases
Infliximab	Chimeric antibody against human TNF-α. Blocks TNF-α action	Used in Crohn's disease (an autoimmune colitis) and ankylosing spondylitis. In allo-HSCT it has been used to treat steroid-refractory GVHD.

FKBP, FK-binding protein.

combination of both drugs would not be expected to be more active that either of them at optimal dose, and is typically not used.

Agents That Interfere With T-Cell Proliferation One of the consequences of T-cell activation is proliferation. T-cell proliferation may be inhibited in different ways. IL-2, the T-cell growth factor, which is released in the course of T-cell activation, may be blocked by the monoclonal antibodies daclizumab or basiliximab, directed against CD25 (the α chain of the IL-2 receptor). Blockade of the interaction between IL-2 and its high-affinity receptor (which is expressed only on activated T cells) inhibits the proliferation of activated T cells. These antibodies are used to prevent rejection in solid organ transplant, and they may act in a synergistic way with the calcineurin inhibitors.

Sirolimus (rapamycin) binds (like tacrolimus) to FK-binding protein, but the rapamycin–FK-binding protein complex does not interfere with calcineurin. Instead, it binds another intracellular protein, MTOR, (the mammalian target of rapamycin), which regulates the cell cycle. The final effect is arrest of cells in the G1 phase of the cell cycle. As it acts at a different step than cyclosporine and tacrolimus, the combination of rapamycin with either of these agents would be expected to result in more potent T-cell inhibition.

Leflunomide interferes with the *de novo* pathway of pyrimidine synthesis, limiting T-cell clonal expansion on activation. As rapamycin, it results in G1 phase arrest. This drug has been used successfully in rheumatoid arthritis, but its use in transplantation has been more limited because of safety concerns.

Azathioprine and mycophenolate mofetil (MMF) are antimetabolites that act by inhibiting purine synthesis. Azathioprine effectively blocks the *de novo* synthesis of adenine and guanine nucleotides, and it has effects on all replicating cells (commonly resulting in the undesirable side effects of leucopenia and thrombocytopenia). MMF is metabolized to mycophenolic acid, which blocks a lymphocyte-specific isoform of inosine monophosphate dehydrogenase, inhibiting the synthesis of guanine nucleotides in lymphocytes only. Given its similar mechanism of action and efficacy with reduced toxicity, MMF has replaced azathioprine in transplantation.

Cyclophosphamide is a cytotoxic drug from the nitrogen mustard family of compounds. It kills lymphocytes and many other dividing cells. Its toxicity has contributed to decreasing use, but it is still the treatment of choice for some severe autoimmune diseases (lupus nephritis and Wegener's granulomatosis).

Other Immunomodulatory Agents TNF-α blockade has emerged as an extremely useful form of therapy in some autoimmune diseases, namely rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, and inflammatory bowel disease. Blockade of TNF may be attained pharmacologically by one of two agents, infliximab and etanercept. Infliximab is a humanized monoclonal antibody that binds to TNF-α and prevents it from acting. It showed efficacy in the treatment of enteric fistulas in Crohn's disease, a type of inflammatory bowel disease. Etanercept is a recombinant fusion protein that combines the extracellular domain of the TNF receptor (TNFR p75) with an immunoglobulin IgG1 Fc fragment. It also acts by binding free TNF. It has shown great benefit in rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis, but not in Crohn's disease.

Anakinra is a recombinant IL-1 receptor antagonist (IL-1Ra). It competes with IL-1 for binding to the IL-1 receptor, and in this way it can block the effects of IL-1. It is effective in rheumatoid arthritis.

Lymphocyte depletion may be attempted with antilymphocyte immunoglobulin (ATG), a polyclonal immunoglobulin obtained by immunizing horses or rabbits with human thymic extract, or with monoclonal antibodies directed against CD3, CD4, CD52, or CD20. Antilymphocyte globulin is profoundly immunosuppressive, and its indications are limited to organ transplantation and aplastic anemia.

Anti-CD3 monoclonal antibody has also been used in organ transplantation. Anti-CD4 monoclonal antibodies were used unsuccessfully in multiple sclerosis and rheumatoid arthritis, in which they resulted in long-term CD4 depletion without clinical benefit, but newer humanized versions of anti-CD4 are being tested in psoriasis. The anti-CD52 rat monoclonal alemtuzumab (Campath-1h) causes significant, long-lasting lymphocyte depletion and has been used in refractory rheumatoid arthritis and transplantation.

SOLID ORGAN AND STEM CELL TRANSPLANTATION In transplantation, as in autoimmunity, there is a harmful immune response that needs to be suppressed. However, there are two very important practical differences. First, in the case of solid organ rejection (and its equivalent in hematopoietic cell transplantation, GVHD) the timing and intensity of the immune response are predictable, so prevention is an option. In fact, prevention is the best alternative, as it has been proven that controlling immune responses is much more difficult than avoiding them. Second, animal models of transplantation are more similar to the human conditions than animal models of autoimmunity. This has allowed for a smooth transition between experiments and clinical practice in transplantation immunology that is not present in autoimmune diseases.

Solid Organ Transplantation Transplantation is the treatment of choice for end-organ damage in many clinical conditions. Kidney, liver, heart, and lung transplantation have become standard medical–surgical procedures. Pancreatic islet cell and intestine transplantation are experimental procedures that are becoming closer to standard of care. Other than donor availability, rejection is the main obstacle to successful transplantation. An immune response to the transplanted organ may take place by one of two mechanisms, called direct and indirect. The direct pathway involves the recognition of donor HLA antigens on donor APCs by the recipient's T cells. This direct recognition of nonself MHC molecules on the transplanted organ is thought to be the most important pathway for rejection, as a significant fraction of the T-cell repertoire is directed against allo-MHC molecules. The indirect pathway involves the activity of the recipient's professional APCs that process and present a variety of donor antigens from the graft.

Organ rejection after transplantation may take one of three forms: hyperacute, acute, and chronic. The immunopathogenesis of the three differs. Hyperacute rejection (typically occurring within hours after the procedure) is caused by pre-existing antibodies directed against donor endothelial antigens. The binding of the antibodies to the endothelium in the blood vessels of the transplanted organ causes complement activation, endothelial damage, inflammation, thrombosis, and vascular occlusion that result in irreversible ischemic damage. This form of rejection is not amenable to immunomodulation, and it must be prevented by screening transplant recipients for the presence of antibodies. Acute rejection begins after a few days, and is caused by T cells (both CD4 and CD8) that are activated mainly by the direct or recognition pathway of alloantigens as previously outlined. This is the predictable response that can be prevented by immunomodulation. Episodes of acute rejection may occur for years after transplant, and continued immunosuppression is required for prevention. When an episode of acute rejection ensues despite prophylaxis, more intensive immunosuppression is required. Chronic rejection represents an immunological phenomenon only partially, is not responsive to therapy and requires retransplant or removal of the damaged organ.

Prevention of Acute Rejection The standard regimen includes triple therapy with corticosteroids, calcineurin inhibitor (cyclosporine/tacrolimus) and an antilymphoproliferative agent (MMF, azathioprine, or rapamycin [Sirolimus]). Some groups add "induction with antibody," using ATG, anti-CD3 or anti-CD25 monoclonal antibodies to minimize the risk of acute rejection. It is not known if any one of these antibody therapies results in a better long-term outcome. The possibility of corticosteroid-free immunosupression for organ transplantation has been explored for islet cell transplantation for diabetes according to the so-called Edmonton protocol, which combines sirolimus, tacrolimus, and daclizumab. Steroid elimination is a desirable goal in all transplants, and more studies are being done using this approach for transplants other than islet cell.

Treatment of Acute Rejection Once acute rejection begins, the treatment has to be directed against already activated T cells, although keeping the possible blockages on proliferation and activation, to prevent the expansion of the immune response. High-dose intravenous glucocorticoids are the treatment of choice for acute rejection, although the exact regimen of choice is unclear (relatively few comparative studies have been done). The mechanism of action of such high dose of steroids is not known, although there is evidence that they cause lymphocyte apoptosis and elimination of dendritic cells from the peripheral blood.

Allogeneic Bone Marrow (Hematopoietic Stem Cell) Transplantation Allo-HSCT has become the treatment of choice for a variety of hematological malignancies. It can also cure several nonmalignant hematological conditions and immunodeficiencies. In this procedure, precursor hematopoietic cells are administered to the patient. If the transplant is successful, the stem cells engraft and develop into myeloid blood cells and lymphocytes. A new immune system, derived from the stem cells of the donor, develops over time. This immune system is able to contribute significantly to the effective control of the leukemia, lymphoma, or solid tumors present in the recipient (GVL effect). However the donor's immune system may also recognize the recipient as "foreign," and unleash a multi-organ attack called GVHD, which has emerged as the main obstacle for the wide use of this therapeutic modality.

The MHC proteins are the most important initiators of the GVHD response, and consequently stem cell transplants are performed ideally using donors that are HLA identical to the recipient. The presence of mismatched "minor histocompatibility antigens" explains why GVHD still occurs in up to one-third of transplants, even when the donor and the recipient are "HLA identical." Minor histocompatibility agents are also the explanation for the fact that GVHD is much more common when unrelated (i.e., not family) donors are used, even if they are a "perfect" HLA match. Siblings that share HLA antigens are likely to share also a significant fraction of minor antigens; the same is not true for unrelated individuals. GVHD is the mirror image of solid organ rejection. Strong evidence from animal models suggests that the host's APCs are the ones that activate the donor's T lymphocytes (note this is equivalent to the "indirect" pathway described in solid organ transplantation). Compared with solid organ rejection, however, GVHD has one critical complicating factor. Whereas a rejected organ can be removed or replaced, thus eliminating the rejection episode, when the new immune system engrafted with the stem cells is directed against the recipient, the only possible option is to control the untoward immune response.

Most individuals who need an HSCT do not have an HLA-identical sibling. This requires the use of some other source of stem cells: an unrelated donor, a family member with some common HLA, or stem cells obtained from newborns' cord blood. With unrelated donors, whether they are HLA-matched (matched-unrelated

donor transplant) or partially mismatched, the frequency of GVHD, as expected, increases significantly. Lastly, when used as treatment of cancer or leukemia, part of the beneficial effect of allo-HSCT is mediated by an immunologically mediated GVL effect. Lower incidence of GVHD has been associated with a higher incidence of leukemia relapse after transplantation. Hence, allo-HSCT presents a unique challenge in that the immune response cannot be completely abrogated without a significant loss in effectiveness. In a way, and at the population level (as opposed to individual cases), GVHD is the price one has to pay to develop a significant GVL.

Prevention of Acute GVHD The attempts to prevent GVHD start by selecting a donor that is as closely HLA matched to the recipient as possible, there are several possible ways of preventing GVHD. Acute GVHD is caused by T cells already present in the administered stem cell (or bone marrow) infusion. It follows that lymphocyte depletion of the graft is a possible approach to prevent GVHD. Indeed, when lymphocyte depletion results in a dose of CD3+ cells of 3×10^4 cells/kg, it is possible to completely prevent GVHD, even in the presence of one HLA mismatch. In fact, in stem cell transplant from an unrelated donor, T-lymphocyte depletion is a commonly used strategy, which unfortunately generates its own set of problems (graft dysfunction, usually caused by rejection, delayed immune reconstitution, with its attendant risks of infection, and post-transplant EBV-related lymphoproliferative disorder, and leukemia relapse).

In the case of transplant from an HLA-identical sibling, a pharmacological approach to the prevention of GVHD is most often used. The standard of care is dual therapy with either cyclosporine or tacrolimus combined with methotrexate. In the standard approach, cyclosporine is initiated before the infusion of stem cells with the aim of preventing T-cell activation, and methotrexate is then added. Methotrexate, by inhibiting purine biosynthesis, is supposed to prevent the proliferation of any T-cell that might have encountered antigen and undergone activation. The combination indeed is more effective than cyclosporine alone to prevent GVHD and the addition of methylprednisolone to cyclosporine and methotrexate may result in still lower rates of acute GVHD, confirming the potential for synergistic activity of immunosuppressive agents with different targets.

Treatment of Acute GVHD Despite the use of prophylaxis, GVHD still develops in 25–50% of HLA-matched sibling transplants. In 20–40%, it is severe enough to require systemic treatment. Corticosteroids are the treatment of choice, at a dose equivalent to 2 mg of methylprednisolone/kg/d. Patients who do not respond to steroids ("steroid-refractory" GVHD) have a particularly poor prognosis, and no treatment has established efficacy in this setting, even if many different immunosuppressive agents have been used. The agents used include many of the immunomodulator agents mentioned earlier (rapamycin, infliximab, daclizumab, alemtuzumab, ATG, and anti-CD3) as well as other experimental monoclonal antibodies including anti-CD3, anti-CD147, denileukin diftitox (human IL-2 fused to diphtheria toxin), and others.

Chronic Graft-vs-Host Disease Chronic GVHD may appear after acute GVHD or *de novo* a few months after transplantation. It typically involves the skin (with scleroderma-like features), the eyes, and mouth (with sicca syndrome similar to Sjoegren's) and the liver (with chronic cholestasis or hepatitis). The lungs may also be involved with a pattern of progressive obliteration of small airways. The cause of chronic GVHD is less well understood, and it has many features of autoimmune diseases. Treatment involves intense immunosuppression, usually using corticosteroids, combined with some other immunosuppressive agents in resistant cases. Photopheresis is another immunomodulatory technique often beneficial in chronic GVHD. In this procedure the patient's peripheral blood mononuclear cells are extracted by pheresis, exposed to the photoreactive agent methoxsalen and ultraviolet A (UVA) radiation, and then reinfused. It is unknown how photopheresis results in immunomodulation, but in chronic GVHD it seems to allow decreasing the dose of steroids. Methoxsalen, after being exposed to UVA radiation at the proper wavelength, irreversibly cross-links DNA thymine bases and arrests cell proliferation. Some findings suggest that the reinfusion of peripheral blood mononuclear cells after exposure to UVA-activated methoxsalen results in an immune response against proliferating T-cell clones. According to this theory, activated clones of T cells undergo apoptosis during the procedure, are phagocytized by monocytes and dendritic cells and presented to other T cells to induce an immune response against the activated T-cell clones. Extracorporeal photopheresis is licensed for the treatment of cutaneous T-cell lymphoma, in which it is supposed to act in a similar way, except in this case it would target a malignant, instead of activated, T-cell clone.

93 HIV Molecular Biology, Treatment, and Resistance

FRANK MALDARELLI

SUMMARY

HIV has infected more than 40 million individuals on six continents since emerging in 1981, with an estimated 15,000 new infections transmitted daily. The rapid spread and lethal nature of the HIV-1 pandemic has made the development of useful and widely available therapy a compelling imperative. As such, many of the molecular mechanisms of HIV replication have been investigated as potential therapeutic targets. This chapter summarizes key molecular events in HIV replication, their use as therapeutic targets, and the inevitable emergence of resistance to therapy.

Key Words: Drug resistance; HIV; integrase; non-nucleoside reverse transcriptase inhibitor (NNRTI); nucleoside reverse transcriptase inhibitors (NRTI); *vif*.

INTRODUCTION

HIV has infected more than 40 million individuals on six continents since emerging in 1981, with an estimated 15,000 new infections transmitted daily. Untreated, HIV infection results in a progressive, inexorable immunodeficiency culminating in death from opportunistic infections or neoplastic diseases. Over half of all infected individuals have already died and, without intervention, the remainder are expected to succumb in the next 10–15 yr. The rapid spread and lethal nature of the HIV-1 pandemic has made the development of useful and widely available therapy a compelling imperative. As such, many of the molecular mechanisms of HIV replication have been investigated as potential therapeutic targets. This chapter summarizes key molecular events in HIV replication, their use as therapeutic targets, and the inevitable emergence of resistance to therapy.

HIV is a lentivirus member of the retroviruses, a family of RNA viruses that replicate via a DNA intermediate using a viral encoded reverse transcriptase (RT). Infection with two distinct HIV variants, HIV-1 and HIV-2, have been described in humans; HIV-1 is a pandemic strain found worldwide, and accounts for the majority of infections. Sequence homology studies have subdivided HIV-1 into three principal groups: M (main), O (other), and N (non-M, non-O); Group M has been further subdivided into 10 distinct subtypes. HIV-2 represents a related, but clearly distinct virus of with two principal subtypes (A and B), which have a limited geographic circulation, principally in West Africa. The precise origin(s) of HIV remain uncertain; simian immunodeficiency viruses similar to HIV-1 and HIV-2 are present in many primate species, and convincing evidence supports the theory that independent zoonotic transmission events from primates to humans are responsible for HIV-1 and HIV-2 epidemics, and perhaps for HIV-1 M, N, and O groups as well. Interestingly, the simian immunodeficiency viruses presumed precursors of HIV infect and replicate to high titer in their natural primate hosts without inducing severe immunodeficiency. As such, there is no single viral component or replication event that is intrinsically or universally pathogenic. Instead, in the cross-species transmission, the combination of new host and viral factors resulted in a highly virulent outcome.

HIV-1 transmission occurs when virus or virus-infected cells directly contacts susceptible host cells, either as exposed mucosa during sexual transmission, or lymphoid elements during bloodborne transmission. Within days, HIV-1 replication expands from local sites of infection principally to lymphoid tissue (lymph nodes, gut associated lymphoid tissue, thymus, spleen) and to central nervous system elements. Wide dissemination of HIV-1 results in relatively high viral and humoral response, viremia declines to a surprisingly stable "set point" characteristic of the individual. Over time, the consequence of persistent HIV-1 infection is a progressive immune deficiency. HIV-induced immunodeficiency is difficult to quantitate, but CD4 cell concentrations represent a useful and reasonable measure of immunity. In general, morbidity and mortality from HIV infection are secondary to opportunistic infections and neoplastic diseases, although HIV replication alone may be responsible for central nervous system disorders including dementia. The relative risk of opportunistic infection or characteristic neoplasm increases with degree of CD4 lymphopenia; AIDS is a specific diagnosis requiring the presence of specific infections (e.g., *Pneumocystis* pneumonia), neoplasms (e.g., Kaposi sarcoma), or decline in CD4 cell counts to <200 cells/μL.

The precise mechanism of CD4 lymphopenia during HIV infection remains uncertain. Although viral cytopathic effects are likely to contribute to cell death in vivo, the fraction of CD4 cells that are HIV infected (typically 1:1000–1:10,000) is relatively small, suggesting direct cell killing does not account for the significant CD4 lymphopenia. Alternative possibilities for the progressive loss of CD4 cells include: (1) bystander effects, with killing of uninfected cells proximal to, or in contact with, infected cells and (2) induction

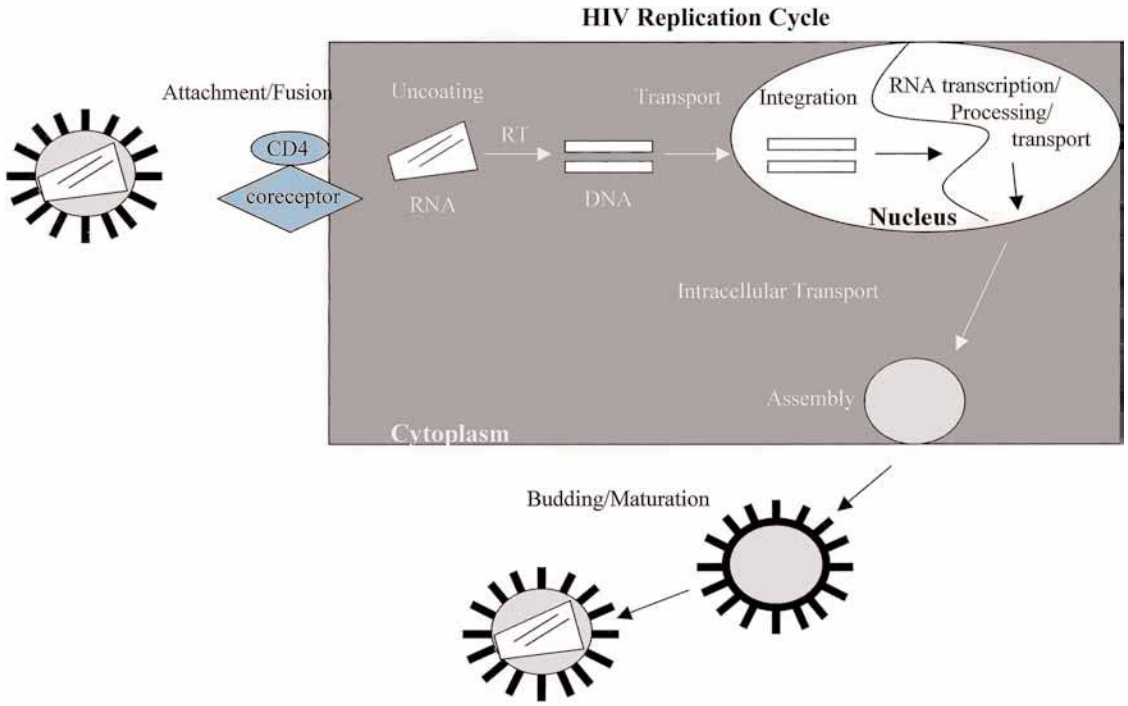

Figure 93-1 Replication cycle of HIV showing binding at cell surface membranes, entry via fusion, reverse transcription, transpost and integration, HIV expression, translation of HIV proteins, and assembly and maturation. The HIV replication cycle may be completed in as little as 1 d. RT, reverse transcriptase.

of apoptosis occurring in immune cells that have become nonspecifically activated but that have not encountered antigen.

As morbidity and mortality from HIV infection is closely related to CD4 cell numbers, strategies to counteract the CD4 lymphopenia directly through the use of growth factors, notably IL-2, have been explored as potential therapy to directly counteract HIV-induced immunodeficiency. IL-2 therapy results in sustained increases in peripheral CD4 cell numbers and expansion in the pool of CD4 naïve and central memory cells. Large multinational studies are underway to determine whether the numerical increases in CD4 cell concentrations induced by IL-2 correspond to improvement in morbidity and mortality from HIV infection.

MOLECULAR EVENTS OF HIV REPLICATION

HIV-1 replication may be divided into a series of molecular events, including attachment and fusion, uncoating, reverse transcription, integration, RNA expression and transport, virion assembly, virion budding, and virion release (Fig. 93-1). Many of these steps have been investigated as potential therapeutic targets for HIV infection.

HIV-1 replication is initiated by virions or infected cells interacting with specific host cell receptors. HIV-1 entry is mediated by multimeric complexes of gp120–gp41 glycoprotein on the virion surface and has been dissected into two stages: attachment and membrane fusion.

ENTRY OF HIV During the attachment phase of entry, gp120 engages two surface proteins expressed on host cells, a primary receptor, CD4, and a coreceptor. HIV-1 coreceptors are cytokine receptors and are principally divided into two broad types: X4, (CXCR4), and R5 (CCR5). Essentially all HIV bind to CD4 (rare CD4-independent variants have been identified), and coreceptor specificity defines the range of cell type infection (Fig. 93-2) and cytopathicity in vitro. HIV with R5 specificity infects both macrophage and lymphocytes, whereas R4 viruses infect lymphocytes. R5 viruses are critically involved at the time of infection; large genetic surveys have demonstrated that individuals homozygous for a mutation in CCR5 that prevents HIV binding have a very low risk of infection, suggesting R5 viruses act as the initial inoculum in an infection. During chronic HIV infection, both R5 and X4 viruses circulate in an infected individual. In general, R5 viruses have been associated with slower disease progression, and a switch from R5 to X4 has been associated with accelerated CD4 cell decline and disease progression. Dual tropic viruses capable of using either CCR5 or CXCR4 have been reported with marked cytopathicity. Additionally, several alternative molecules have been identified that may be used infrequently as coreceptors. The residues involved in coreceptor specificity have been identified, and can be assigned either phenotypically or predicted by bioinformatics techniques.

Inhibition of attachment and entry has been investigated as an important therapeutic target. Direct inhibition of gp120-CD4 binding in vitro has been achieved in vitro typically using specific antibody, but in vivo studies have not been widely successful. In contrast, small molecule inhibitors of gp120-coreceptor binding have been identified for both X4 and R5 coreceptors; competitive inhibitors of R5 binding are in phase I trials. Fortunately, some R5 inhibitors appear to be quite specific and do not have detectable R5 agonist activity, so they bind to CCR5 without interfering with normal host CCR5 signaling activity. One concern in the development of all coreceptor inhibitors, however, is that use of one coreceptor inhibitor may shift viral populations to use the alternative coreceptor; for example, use of a CCR5 inhibitor could result in a change in circulating HIV so that it exclusively uses CXCR4; the consequences of such a drug-induced coreceptor switch are unknown.

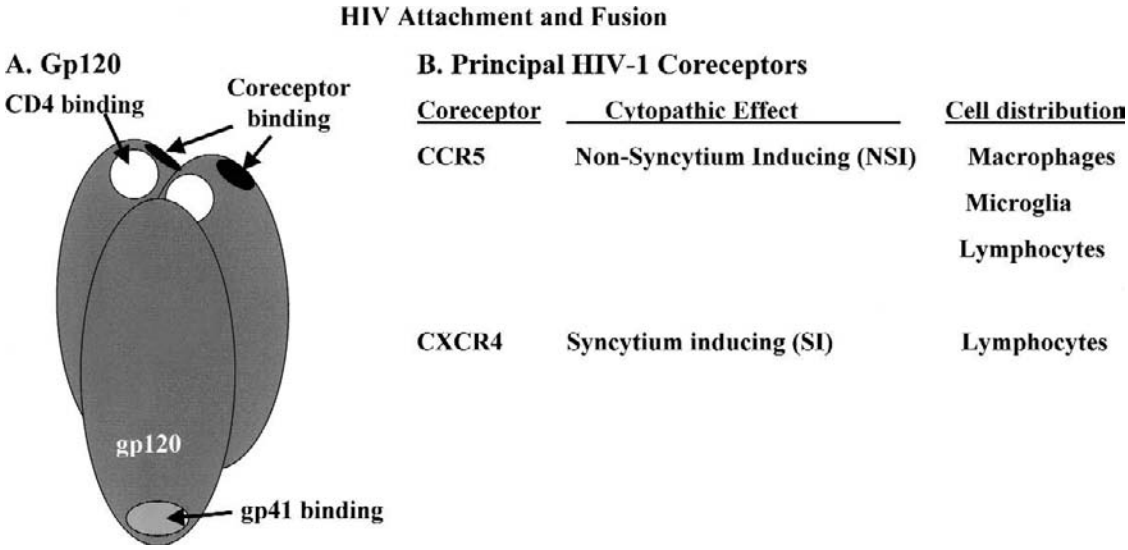

Figure 93-2 **(A)** Schematic of gp120 trimer, indicating positions for CD4, coreceptor, and gp41 binding. **(B)** HIV attachment is mediated by interactions between the HIV surface protein, gp120 and CD4 and a host coreceptor expressed on the host. CCR5 and CXCR4 represent the most common coreceptors generally with distinct cytopathic effects in vitro, and host cell expression in vivo.

Attachment and engagement of CD4 and coreceptor result in conformational changes in gp120 that trigger further rearrangements in gp41 structure, exposing a specific domain to activate the fusion reaction. The fusion domain of gp41 consists of a series of heptad repeats that, on gp120 attachment, become organized into a series of antiparallel α-helices; once assembled, these helices function as a spring-loaded mechanism forcing the fusion of viral and cellular membranes. Several inhibitors interfering with the formation of the fusion domain have been identified. Small amino acid peptides bind to the fusion domain and interfere with organization of the heptad repeats, thereby preventing the spring-loaded intermediate from forming. One inhibitor, T-20, has been approved by the Food and Drug Administration (FDA) for use in HIV infection. In general, therapy with T-20 results in a prompt and sustained decrease in HIV RNA levels; as with all antiretrovirals, resistance (*see* below) may emerge on therapy.

POSTENTRY EVENTS Uncoating of HIV-1 remains poorly understood, although observations have demonstrated that critical interactions with host proteins are essential. In experiments investigating the innate high level resistance to HIV-1 infection in certain monkey cell lines a host protein, trim5-α, was found to bind to Gag structural protein, and prevent nucleic acid replication. Such an observation suggests that further investigation of these early events may identify new potential therapeutic opportunities.

REVERSE TRANSCRIPTION Following uncoating, HIV nucleic acid replication takes place (*see* Fig. 93-1). HIV-1, like all retroviruses, contains RNA in virions, but encodes no RNA replicating machinery. Instead, HIV encodes two critical enzymes to resolve this molecular paradox, RT and integrase. RT converts the RNA in virion into double-stranded DNA, and integrase integrates the viral DNA into the host genome, thereby permitting access to the cellular RNA synthetic machinery and rendering it capable of directing new virion RNA.

RT is a DNA polymerase structurally similar to a variety of cellular DNA polymerases with characteristic palm, fingers, and thumb domains; unlike other DNA polymerases, RT uses RNA as template instead of DNA (Fig. 93-3). RT enzymatic activities include

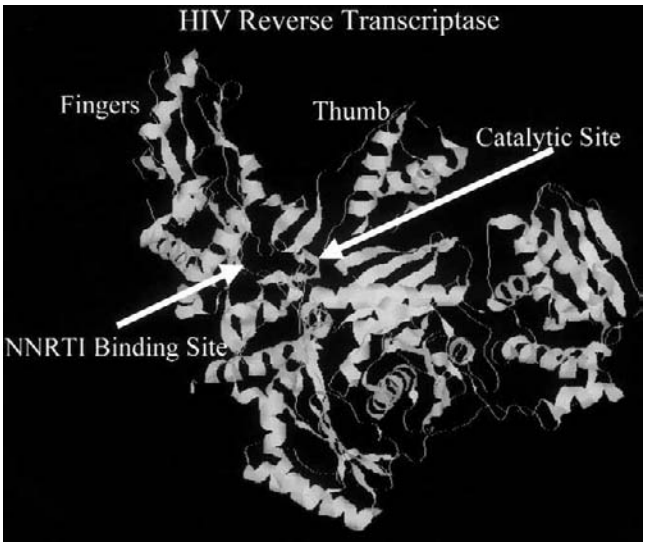

Figure 93-3 Structure of HIV RT noting active site and NNRTI binding domain beneath the catalytic surface. The RNA (or DNA template) and the primer bind within a groove between the thumb and fingers domains. Mutations in NNRTI binding domain result in strong cross-resistance. NRTI and NRT inhibitor mutations may result from mutations limiting drug access to the active site or from mutations enhancing excision of newly incorporated nucleotides. RT crystallographic coordinates were rendered using Rasmol (Data from Hsiou Y, Das K, Ding J, et al. Structures of Tyr188Leu mutant and wild-type HIV-1 reverse transcriptase complexed with the non-nucleoside inhibitor HBY 097: Inhibitor flexibility is a useful design feature for reducing drug resistance. J Mol Biol 1998;284[2]:313–323).

(1) RNA-dependent DNA polymerization to convert the virion plus stranded RNA into minus strand DNA, (2) DNA-dependent DNA synthesis, to copy minus strand DNA into plus strand DNA, (3) an RNase H activity, to remove the RNA in the RNA–DNA hybrid molecule created during initial RNA to DNA synthesis, and (4) a nonspecific excision reaction that can catalyze the removal of an

incorporated nucleotide at the end of the growing DNA chain, which may function as a rudimentary nonspecific proofreading capability, especially under conditions of drug resistance.

The central role of RT in HIV replication, and extensive pharmaceutical experience in development of nucleoside analogs have made RT an attractive therapeutic target. Several types of inhibitors of RT have been developed, including nucleoside RT inhibitors (NRTIs), nucleotide RT inhibitors, and non-nucleoside RT inhibitors (NNRTIs). NRTIs are structurally similar to dNTP DNA precursors, but do not contain 3′-OH moiety on the sugar base. NRTIs are recognized by RT and are incorporated into growing DNA strand; because of the lack of 3′-OH group, no additional nucleotides may be incorporated and strand synthesis ceases. NRTIs represent the oldest class of HIV inhibitors and FDA approved NRTIs include AZT, ddI, ddC, 3TC, FTC, D4T, and abacavir.

Like all DNA precursors, NRTIs require phosphorylation in order to be recognized by RT and incorporated into the growing DNA strand. Phosphorylation may be a limiting step in activation of certain NRTIs and drug development has attempted to bypass at least one of the phosphorylation events. One such successful attempt is the drug tenofovir disoproxil fumarate, a nucleotide RT inhibitor with a structure that simulates a monophosphorylated nucleotide. Tenofovir has no sugar moiety, and is an effective chain terminator.

NNRTIs are noncompeptitive inhibitors of HIV RT that bind outside the RT active site (*see* Fig. 93-3). A binding pocket forms around the NNRTI molecule that disrupts RT structure and prevents DNA synthesis. The NNRTI binding domain is similar for all available NNRTIs (nevirapine, delavirdine, efavirenz).

During early events in HIV replication, cellular defense mechanisms are activated to restrict HIV replication. A new innate cellular response was identified that may represent a potential therapeutic target. During productive HIV infection, a host cytidine deaminase, denoted APOBEC 3G, is incorporated into HIV virions; on infecting new host cells in the *next* round of infection the incorporated APOBEC 3G selectively deaminates cytidine residues (yielding uridine residues) on the first (negative strand) of newly synthesized cDNA. As plus strand DNA synthesis occurs, the uridine residues basepair with adenine residues, resulting in a series of G to A transition mutations (Fig. 93-4) throughout the genome. To counteract this host restriction mechanism, the product of the HIV-1 *vif* gene is incorporated in the virion in productively infected cells; Vif is believed to bind APOBEC 3G directly, targets its degradation through the proteosomal pathway, and prevents the host enzyme from corrupting the HIV genome. APOBEC 3G represents a profound restriction mechanism; *vif* defective mutants are >1000-fold less infectious than wild-type viruses. As such Vif–APOBEC 3G interactions are under investigation as a potential therapeutic target, as preventing Vif binding would unleash a potent innate antiviral mechanism.

INTEGRATION After reverse transcription, the newly synthesized DNA copy of HIV-1 is transported to the nucleus and integrated into the host genome (*see* Fig. 93-1). The process of integration is catalyzed by the virally encoded integrase, in three concerted reactions. Integrase homodimers binding to the termini of the linear HIV cDNA excise two nucleotides from the 3′ ends of each of the molecules, creating staggered DNA ends. Next integrase introduces single strand nicks in the host genome, and ligates one strand of the cDNA into the host genome; finally, the corresponding phosphodiester bond on the opposite host strand is hydrolyzed and ligated to the remaining HIV-1 DNA strand. The separate reactions have been detailed to some degree in vitro and used in the development of specific inhibitors.

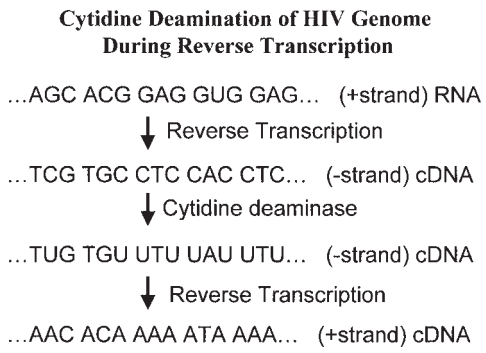

Figure 93-4 The initial viral sequence in (+ strand) RNA is reverse transcribed into first strand (– strand) cDNA. After the first RT-mediated DNA synthesis of (+ strand) RNA to (– strand) DNA, a cytidine deaminase APOBEC 3G deaminates the cytidine residues to uridine; on second strand synthesis of (– strand) DNA to (+ strand) DNA, these uridine residues basepair with adenine, ultimately resulting in a G to A transition. In this example, the initial amino acid sequence, Ser–Thr–Glu–Val–Glu is mutated to Asn–Thr–Lys–Ile–Thr.

Development of anti-integrase inhibitors will represent an especially important step in HIV-1 therapy. Integrase is the last essential HIV-1 enzyme without a corresponding inhibitor. Antiretroviral regimens targeting two HIV-1 enzymes have been relatively successful as first line agents, but such combinations have not been particularly effective in therapy of drug resistant virus. The possibility of having active inhibitors of all viral enzymes critical for HIV-1 replication may represent an important advance both as initial suppression and in salvage therapy.

No integrase inhibitors have been approved yet for therapy; development of integrase inhibitors has been delayed by structural, functional, and pharmacological limitations. Integrase has been more difficult to crystallize as an intact molecule, hindering identification modeling of candidate small molecule inhibitors; fortunately, portions of the molecule including the active site have been crystallized. As described, integrase enzymatic reactions are relatively complex, and adapting integration reactions for high throughput screening has taken significant development but has been achieved. Several classes of compounds have been identified, including the diketo acids and their derivatives. None of these agents has been FDA approved for use in therapy although clinical trials are ongoing.

POSTINTEGRATION EVENTS Following integration, HIV RNA transcription and processing events are executed by host enzymes as directed by combination of viral regulatory proteins bound to essential RNA secondary structures at key positions within HIV-1. RNA transcription is carried out by RNA Pol II machinery; recruitment of the complex and the efficiency of RNA elongation is mediated by the HIV gene product Tat that binds to a specific RNA stem loop target, denoted TAR, upstream of the HIV RNA start site. The use of RNA transcriptional activation represents a novel and effective mechanism that transactivates HIV expression >100-fold.

HIV-1 encodes 10 genes, but only a single promoter; the primary RNA product, a 9.2-kb RNA, is used for expression for all of the HIV-1 gene products. Alternative splicing from a major splice donor to numerous splice acceptors results in production of a series of RNA molecules to express HIV proteins. Balancing the relative

amounts of unspliced and spliced RNAs is coordinated through regulated transport from nucleus to cytoplasm and is mediated by the HIV protein Rev. HIV RNAs encoding early regulatory proteins (Tat, Nef, Rev) are encoded by a small RNA (approx 1.8 kb) and are transported to cytoplasm without the requirement for specialized transport. Singly spliced and unspliced RNAs encoding Vif, Vpu, structural, and envelope proteins encode specific RNA sequences, *cis* responsive sequences that retain the RNA in the nucleus. Transport of these RNAs requires binding of the HIV-1 Rev gene product to a structured target, the Rev responsive element (RRE) present in all of these RNAs. Once bound to the RRE, the Rev gene product engages the cellular transport machinery and results in transport of these RNA to the cytoplasm.

Both the Tat–TAR and Rev–RRE interactions are essential for HIV-1 replication, and have been targeted for therapy using gene therapy (to express antisense RNA) as a form of intracellular immunization and small molecule inhibitors, but these efforts remain in the early stages of development.

ASSEMBLY AND MATURATION Late steps in HIV-1 replication take place at cell membranes, especially the plasmalemma (*see* Fig. 93-1). Intense investigations have identified a series of distinct events, including core protein/RNA association, intracellular transport, particle assembly, membrane association, virus budding, and virion release. HIV-1 structural proteins are capable of self-assembly with nucleic acids, although proper assembly appears to be accelerated by small molecules, such as phosphorylated inositol species. Like other steps in HIV-1 replication, assembly and maturation occur as viral functions "co-opt" cellular factors. Viral structural components are enriched in cholesterol-laden lipid rafts, which are likely to provide transport to the cell membrane. In an elegant series of experiments, it was demonstrated that HIV-1 redirects components of the endocytotic and endosomal sorting pathways resulting in virus production. For example, interactions of HIV-1 proteins with cellular endosomal sorting pathway result in reversal in the direction of the endocytotic pathway that would normally generate endocytotic vesicles by pinching off portions of the cell membrane into the cell; instead the host machinery coopted by HIV participates in creating new HIV particles by budding outward at the cell surface. A number of specific protein–protein interactions have been identified that represent potential targets for small molecule interruption. Reducing the cholesterol content of lipid rafts has also been suggested as a possible therapy for reducing circulating virus; in vitro, exposure to statins has reduced the relative amounts of HIV-1.

Final maturation is completed at the cell membrane with specific proteolytic cleavage of structural polyprotein precursors mediated by the viral encoded protease. Immature virions containing nonprocessed proteins are completely noninfectious, thus blocking maturation represents an attractive therapeutic goal. The HIV-1 aspartyl protease required to process viral Gag and Gag/Pol polyprotein precursor is a homodimer of 99 amino acid subunits (Fig. 93-5). Nine HIV cleavage events are necessary for full maturation; the processing sites distributed throughout the precursor molecules are not identical, but have some common elements, often including prolyl residue on the N-terminal side of the cleavage followed by a large hydrophobic residue on the C-terminal side. The HIV protease dimer accommodates the various cleavage sites using a relatively flexible active site and adjacent "flap domains" that mediate access to the active site (*see* Fig. 93-5).

To inhibit HIV protease, peptidomimetic inhibitors have been developed using crystallographic knowledge of protease and amino acid sequence information of the cleavage sites. Protease inhibitors are capable of accessing the active site and act as competitive inhibitors of proteolysis. HIV protease inhibitors are highly specific; newer agents have been developed with high therapeutic indices against wild-type virus. As such, protease inhibitors represent a strong backbone yielding effective combination HIV therapy.

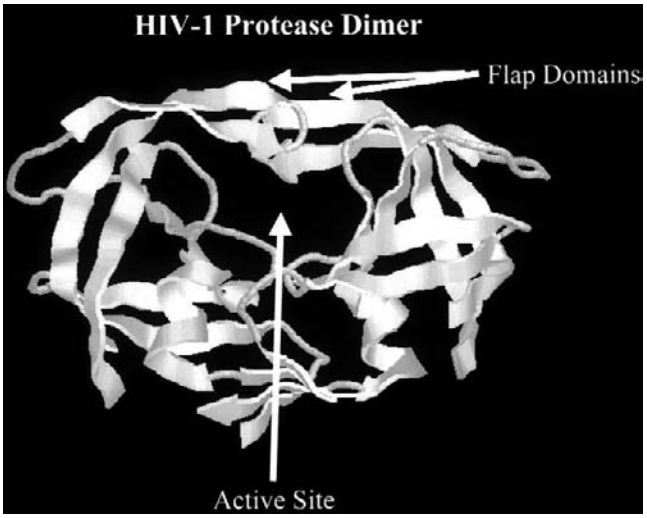

Figure 93-5 Structure of HIV protease dimer noting active site and flap domains involved in access to catalytic site. Mutations conferring resistance to protease are found in the amino acids near the active site and in flap domains. Crystallographic coordinates were rendered using Rasmol (Data from ref. Hodge CN, Aldrich PE, Bacheler LT, et al. Improved cyclic urea inhibitors of the HIV-1 protease: Synthesis, potency, resistance profile, human pharmacokinetics and X-ray crystal structure of DMP 450. Chem Biol 1996;3(4):301–314).

HIV DRUG RESISTANCE

A fundamental property of all inhibitors of HIV replication is the emergence of drug resistance. Drug resistance emerges as a consequence of the HIV replication program, which is rapid (generation time approx 1 d) and error prone (approx 3–5 mutations/10^5 nt synthesized, or one new mutant per one to two new genomes). As a single cycle of replication, the HIV-1 replication program may appear highly inefficient; most of the mutations formed are lethal and, therefore, not propagated, and only a small fraction of these new mutants are viable. However, over time, the combination of rapid and error-prone synthesis results in a large reservoir of genetically diverse viruses capable of responding quickly to new selective forces. A straightforward illustration of this phenomenon can be found in in vivo studies of the RT inhibitor 3TC. 3TC is a potent inhibitor of HIV RT, but resistance is conferred by the presence of a single amino acid change at amino acid position 184 of the RT. Single nt mutations in codon 184 of RT can naturally occur in the absence of therapy, resulting in different changes from the most common amino acid (methionine) to less fit alternatives (isoleucine or valine). In untreated individuals, the large majority of HIV encodes the methionine variant, and probably <0.01% of viruses encode either the valine or isoleucine variant. Under normal drug naive circumstances in vivo, HIV populations are substantial enough that the cost of maintaining the less fit variants at a low frequency can be well tolerated. In the presence of a strong selective drug pressure, however, the situation changes markedly. Treatment with the RT inhibitor 3TC results in inhibition of the wild-type virus containing methionine at position 184, whereas the mutants

encoding either isoleucine or valine continue to replicate in the presence of 3TC. As a consequence, the isoleucine or valine encoding mutants emerge within weeks after introduction of 3TC monotherapy, as the wild-type virus is rapidly replaced. The rate of replacement is much faster than what would be predicted if new drug resistant mutations had to be generated after drug therapy was introduced. Pre-existence of drug resistant mutants permits a dynamic response that effectively rescues virus infection. Rather than an inefficient replication mechanism, the HIV replication program represents a potent pathogenic determinant to evade immune or pharmacological suppression.

RESISTANCE TO SPECIFIC HIV DRUG CLASSES Monotherapy studies have consistently demonstrated that mutations quickly emerge that confer resistance. In attachment/entry step, resistance occurs through steric mechanisms that reduce drug binding. Exposure to CCR5 inhibitors results in emergence of mutations in gp120 that result in reduced binding of coreceptor inhibitor; these mutant HIV variants can still engage CCR5, but not the CCR5 inhibitor, thus attachment proceeds. Similarly, resistance to the T-20 fusion inhibitor occurs with the emergence of one or more mutations in the critical heptad repeat T-20 binding domain, reducing drug binding, but permitting fusion activity to continue.

Two general mechanisms confer drug resistance to NRTIs: excision and steric hindrance. HIV RT can catalyze the removal of an incorporated nucleotide in an excision mechanism. Mutations that enhance this function cause resistance by enabling the RT to remove the otherwise lethal chain terminating nucleotide analogs more efficiently. Mutations increasing RT excision confer resistance to AZT, D4T, abacavir, and perhaps ddI. Resistance to the nucleotide RT inhibitor tenofovir is less well understood but may involve an excision mechanism. Excision is an energy-requiring step, using either ATP or pyrophosphate as the energy source. An intriguing observation that the mutations conferring resistance to AZT and D4T are located near the ATP binding site suggests that a direct mechanism exists for increasing excision activity.

Steric mechanisms also confer resistance to some NRTIs (e.g., 3TC, ddC); elegant structure functions studies have demonstrated that mutations of one or more sites within the enzyme result in a protein that excludes access of the antiretroviral nucleoside RT to the enzyme active site although still permitting access to normal dNTP DNA precursors.

NNRTI inhibit RT activity by binding to a specific binding domain. Resistance occurs by steric mechanisms; mutations change the structure of the binding domain, rendering NNRTI binding unstable and reducing drug activity. The binding domain is common for all available NNRTIs and cross resistance in NNRTI drug class appears absolute.

In in vitro studies, resistance to all active integrase inhibitors has been detected, although the precise mechanism remains uncertain. Interestingly, significant differences in resistance mutation profiles have been identified among the different candidate integrase inhibitor compounds, suggesting the possibility that combinations of integrase inhibitors may be particularly effective.

Resistance to protease inhibitors occurs with mutations both in regions near the active site and in adjacent "flap" domains that permit drug access to the active site. Mutation patterns that confer resistance to the protease inhibitors are often complex, reflecting an extreme tolerance for mutations. Strikingly, 20–30% of all the sites within protease may be changed and still yield a functional enzyme. In general, individual protease inhibitors have associated characteristic primary mutations that confer strong resistance, as well as secondary mutations, which by themselves do not result in resistance, but in the presence of the primary mutations, result in significantly higher drug resistance. Although primary resistance mutations may be relatively specific to individual protease inhibitors, secondary mutations contribute to significant cross-resistance among protease inhibitors.

Protease mutants continue to carry out proteolysis, albeit at a lower rate; and replication rates of HIV encoding protease mutations may be reduced. In addition to mutations to protease itself, additional mutations may emerge at protease cleavage sites in the Gag-Pol precursor; these changes facilitate proteolysis by the mutant protease, potentially compensating for the less active mutant. Thus resistance to protease mutants may undergo refinements to maintain resistance and improve overall viral replication.

CLINICAL DRUG RESISTANCE Clinically, drug resistance emerges in a substantial proportion of treated individuals; with new potent regimens, resistance will likely represent a significant problem for 25–40% of treated patients. Resistance manifests as a persistent rise in HIV viremia and is associated with emergence of characteristic mutations that confer on the virus the ability to replicate in physiological concentrations of the drug. A variety of HIV drug resistance assays are available for clinical use, but are generally divided into assays that determine either genotypic or phenotypic resistance.

HIV Genotyping Genotyping assays determine the nucleic acid sequence of RT and protease portions of the HIV genome relevant to drug resistance. Assays are not widely available for detecting T-20 resistance. The HIV sequence is obtained from plasma virions using an RT-PCR strategy to amplify an exogenous DNA copy of the viral RNA. In the most common analysis, direct nucleotide sequencing yields the patient sequence that is compared with the sequence of standard laboratory strain HIV to identify changes corresponding to drug resistance. Genotyping is useful in clinical management, but does not represent an all-encompassing solution to HIV drug resistance. Genotyping can identify drugs to which the patient is resistant, but cannot dictate the next effective regimen. Sequencing can only provide information about viral species representing substantial portions (≥20%) of circulating viruses. This method does not detect minority species that may represent important reservoirs from which new mutations may emerge. Viral genotypes from extensively treated patients tend to be complex, and often require sophisticated algorithms to arrive at useful interpretation.

HIV Phenotyping HIV phenotyping assays are an alternative functional method to evaluate drug susceptibility. Recombinant plasmids are cloned using *gag/pol* sequences from patient isolates and laboratory-adapted HIV backbone. The chimeric products are tested in in vitro infections and compared to the laboratory-adapted strain. Infections are carried out in the presence of increasing concentrations of antiviral agents; growth in high drug concentrations indicates resistance and an IC50 measure of resistance, the amount of drug required to inhibit virus replication by 50%, can be obtained using dose response curves. High IC50 values are associated with drug resistance, but the degree of virological resistance associated with clinical drug failure is not clear in all circumstances. Establishment of effective cut offs has been a major aspect of phenotyping assay development. Similar to genotyping, phenotyping may be a useful adjunct in the treatment of drug resistance, but does not represent a solution to the fundamental problem of drug resistance.

SUMMARY AND FUTURE DIRECTIONS

HIV infection carries out a relatively complex replication program using unique viral-encoded functions and exploiting host machinery. Several steps in HIV replication have been targeted for therapy, and several more are under investigation. Antiretroviral therapy has matured over the last 15 yr from transiently effective monotherapy to sustained suppression with combinations of antiretroviral agents. Therapy remains, however, severely limited. Despite suppressive therapy, HIV infection remains incurable, and available therapies are at risk of failure from the emergence of resistance. New strategies to effectively deal with resistance are clearly necessary, and novel approaches to HIV infection will be essential to eradicate infection.

94 Cellular and Molecular Aspects of Pneumonia

Marcus J. Schultz and Tom van der Poll

SUMMARY

Immunotherapy aimed at modulation of immune responses may serve as an important adjuvant to antibiotic therapy in the treatment of pneumonia. Alveolar macrophages and polymorphonuclear cells play a prominent role in innate immunity in the lungs. These cells need to communicate in mounting an effective host defense against invading pathogens. Cytokines, chemokines, and colony-stimulating factors play a critical role in this process. Side-products of the coagulation cascade also enhance local inflammation. Activation of the complement system results in the formation of several proinflammatory mediators that can attract and activate polymorphonuclear cells, and formation of molecules with antimicrobial activity.

Key Words: Chemokines; coagulation; complement; cytokines; factor VII; fibrinolysis; granulocyte colony-stimulating factor; IL-10; plasminogen activator inhibitor-1; pneumonia; tissue factor; tumor necrosis factor-α.

INTRODUCTION

The airways are continuously exposed to respiratory pathogens, either by inhalation or by (micro)aspiration. Infectious agents that have passed structural defenses enter the terminal airways, in which they may cause pneumonia, one of the most common infectious diseases.

The growing number of immunocompromised patients susceptible to pneumonia, and a rise of antibiotic resistance among microorganisms have made the treatment of pneumonia more difficult. Hence, there is a need for novel therapeutic approaches for lower respiratory tract infections. Immunotherapy aimed at modulation of the immune response may serve as an important adjuvant to antibiotic therapy in the treatment of pneumonia. However, new therapeutics for patients with pneumonia must be approached with caution because underlying cellular and molecular mechanisms of pneumonia are not fully understood.

Pulmonary host defense includes both innate and specific immune responses. Innate immune responses are primarily responsible for the elimination of bacterial pathogens from the alveolar spaces; specific immune responses are involved in eradication of encapsulated pathogens, and pathogens that survive after phagocytosis. This chapter focuses on innate immune responses (Table 94-1). Innate defenses consist of structural defenses, antimicrobial molecules, and phagocytosis by resident alveolar macrophages (AMs) and recruited polymorphonuclear cells (PMNs). AMs and PMNs play a prominent role in innate immunity in the lungs. These cells can phagocytose and kill microorganisms, and PMNs can release the microbicidal contents of their granules. AMs and PMNs need to communicate in mounting an effective host defense against invading pathogens. Proinflammatory and anti-inflammatory cytokines, chemokines (cytokines with chemotactic activities), and colony-stimulating factors play a critical role in this process. Side-products of the coagulation cascade also enhance local inflammation. Finally, activation of the complement system results in the formation of several proinflammatory mediators that can attract and activate PMNs, and formation of molecules with antimicrobial activity (e.g., the membrane attack complex). Furthermore, several complement components can induce the production of cytokines, chemokines, and other proinflammatory cytokines by several cell types.

Potential immunomodulating strategies that may hold promise for patients with pneumonia are aimed at targeting AMs, the cytokine network, the coagulation cascade, and the complement system. This chapter discusses such strategies during experimental respiratory infections. Most of this knowledge has been obtained from animal studies; only a limited number of human studies have been performed in the last decade.

TARGETING AMs IN PNEUMONIA

Respiratory pathogens that have entered the terminal airways are first encountered by AMs. AMs play a central role in pulmonary host defense. The recruitment of large numbers of PMNs in the alveolar space from the marginated pool of leukocytes in the pulmonary circulation is initiated when the microbial challenge is too large or too virulent to be contained by the AMs alone. These recruited PMNs provide auxiliary phagocytic capacities, critical for the effective eradication of pathogens. AMs can bind, phagocytose, and kill pathogens, and, thus, can directly influence the bacterial load. Furthermore, AMs can also secrete a large range of inflammatory mediators. Some of these mediators act directly on respiratory pathogens, whereas others exert their effects indirectly by recruiting PMNs. Finally, AMs can phagocytose apoptotic PMNs. From this it can be concluded that AMs (or AM-derived

substances) play a regulating role in the pathogenesis of pneumonia, both in the initiation of the inflammatory response, and in its resolution.

AMs CONTRIBUTE TO THE RECRUITMENT OF PMNS DURING PNEUMONIA Compared with control rats, PMN numbers were decreased in bronchoalveolar lavage fluids (BALF) of AM-depleted rats after instillation of a sublethal dose of *Pseudomonas aeruginosa* into the airways, concordant with significantly decreased levels of tumor necrosis factor (TNF)-α and macrophage inflammatory protein (MIP)-2 mRNA expression in one study. In another study, in which AMs from lipopolysaccharide (LPS)-exposed mice were transferred to the lungs of naive recipient mice, nearly a threefold increase in the number of PMNs in BALF was found compared with instillation of AMs from unexposed mice.

AMs AND BACTERIAL CLEARANCE/SURVIVAL IN EXPERIMENTAL PNEUMONIA MODELS Evidence exists for the importance of AMs in host defense against different respiratory pathogens. In particular studies in which rodents were treated with a mixture of clodronate and liposomes via the airways, resulting in a selective depletion of AMs by induction of programmed cell death (apoptosis), have provided valuable information. Impaired survival was found in mice depleted of AMs in a murine *Streptococcus pneumoniae* pneumonia model. In this model, PMN-recruitment was largely increased in AM-depleted mice, but no difference in bacterial outgrowth could be observed. By contrast, in a murine *Mycoplasma* pneumonia model, AM-depletion resulted in elevated outgrowth of *Mycoplasma* from the lungs. AM-depletion exacerbated the *Mycoplasma* infection in *Mycoplasma*-resistant mice by reducing killing of the pathogen to a level comparable to that in *Mycoplasma*-susceptible mice without AM-depletion, suggesting that defective AM-function is the likely explanation for the difference between susceptible and resistant mice. Interestingly, higher numbers of PMNs in lavage fluids were recovered from the AM-depleted mice, indicating that the differences in killing of the invading pathogen could not be explained by an effect on the recruitment of PMNs. In a murine *Klebsiella pneumoniae* pneumonia model, AM depletion influenced mortality dramatically, with 100% lethality after 3 d in AM-depleted mice compared with 100% long-term survival in nondepleted mice. This was accompanied by an increased outgrowth of *K. pneumoniae* from lungs and blood in AM-depleted mice, and similar to the former study, an increase in PMN-influx into the pulmonary compartment. Similar data were reported on a murine pneumonia model with *P. aeruginosa*, in which AM depletion resulted in a delayed bacterial clearance compared with control mice. However, it was also demonstrated that early after the initiation of pneumonia, compared with control mice, AM-depleted mice had lower concentrations of chemokines and fewer PMNs in BALF, and a significant improvement in lung edema. Importantly, although AM depletion improved early-phase inflammation, (late) survival was not altered. These data illustrate both the beneficial and deleterious effects of AMs during the orchestration of inflammation during pneumonia. Depletion of AMs in the early phase of *Pseudomonas* pneumonia may initially improve lung injury, but may worsen the eventual outcome, as seen in the models of pneumonia with this pathogen, and other pathogens like *K. pneumoniae*, *S. pneumoniae*, and *M. pneumoniae*.

AMs AND RESOLUTION OF INFLAMMATION Whereas initially AMs readily phagocytose and (thereby) eliminate certain inhaled pathogens, they later represent important effector cells in the resolution process. The (previously mentioned) observation of overzealous and persistent PMN-infiltration in the absence of AMs may be related to the equally important function of AMs during resolution of inflammation. To reinstitute tissue homeostasis, all processes involved in the initiation of inflammation must be reversed and one important prerequisite for resolution to occur is the removal of extravasated PMNs. Several lines of evidence support the hypothesis that PMNs undergo apoptosis followed by rapid clearance by AMs. Apoptosis thereby provides an injury-limiting mechanism because the membrane of PMN remains intact, preventing potentially injurious granule contents from being released. The role of AMs as regulator of inflammation has further been illustrated by studies demonstrating that AMs engulf apoptotic PMNs and release anti-inflammatory mediators. These data indicate that the role of AMs in host defense is not limited to the generation of the initial inflammatory response, but extends to regulation of inflammation, including elimination of phagocytosed pathogens.

No human studies on targeting AMs or AM-functions during pneumonia have been performed.

TARGETING THE CYTOKINE NETWORK IN PNEUMONIA

Cytokines are small proteins produced by many different cell types (including AMs and PMNs), having effects on a large variety of (immune) cells. Cytokines are considered to be involved in the early response after the recognition of a pathogen (e.g., TNF and interleukin [IL]-1β), in the recruitment of immune cells to the site of infection (the so-called chemokines, such as IL-8), or in the activation of AMs and recruited PMNs (e.g., TNF, IL-1β, interferon [IFN]-γ, IL-12, IL-17, IL-18, IL-6, and IL-10). Cytokines are considered to have proinflammatory or anti-inflammatory properties, or both. Colony-stimulating factors are a cytokine family required for the proliferation and differentiation of hematopoietic progenitor cells. This family includes granulocyte macrophage colony-stimulating factor, granulocyte colony-stimulating factor (G-CSF), and IL-3. G-CSF plays an important role in maintaining the normal PMN-count in blood and enhancing the functional properties of PMNs.

ACTIVATION OF THE CYTOKINE NETWORK DURING PNEUMONIA The early response cytokines TNF and IL-1β, both typical proinflammatory cytokines, have been studied extensively in the context of pulmonary host defense. Increased expression of TNF and IL-1β has been observed in bacterial pneumonia, both in animals and in humans. TNF and IL-1β play important roles during host defense because these cytokines can activate AMs and PMNs, leading to augmented phagocytosis, oxidative burst, protein release, and bacterial killing; contribute to the recruitment of PMNs by stimulating the expression of adhesion molecules; and induce the production of chemokines.

Chemokines are low molecular weight cytokines involved in the recruitment of immune cells to the site of infection. Certain chemokines (e.g., IL-8, epithelial neutrophil activating protein-78 in humans; MIP-2 and KC in mice) exhibit chemotactic and activating effects on PMNs. Elevated chemokine levels have been detected in lungs of mice with experimental pneumonia; elevated levels of IL-8 have also been found in BALF of patients with pneumonia, and IL-8 levels correlated with PMN-counts in, as well as PMN-chemotactic activity of pleural fluid.

IFN-γ is a cytokine mainly produced by antigen-activated T and natural killer cells. The secretion of IFN-γ is induced by TNF and IL-12. IFN-γ exerts several immune regulatory activities, including activation of phagocytes, stimulation of antigen-presentation by increasing the expression of major histocompatibility complex molecules class I and II on antigen-presenting cells, orchestration of leukocyte–endothelium interactions and stimulation of the respiratory burst. Macrophages are stimulated by IFN-γ to secrete TNF and IL-12, setting up a paracrine positive-feedback cycle. Like the production of TNF, IL-1β, and chemokines, the production of the proinflammatory cytokine IFN-γ is enhanced during murine pneumonia. Similarly, the expression of another proinflammatory cytokine, IL-12, is enhanced in bacterial pneumonia. IL-17 is a cytokine that induces granulopoiesis via G-CSF production and stimulates the production of chemokines. The release of IL-17 in the lungs in pneumonia has been demonstrated before. IL-18 is another proinflammatory cytokine, with many similarities to IL-1. IL-18 is expressed constitutively in lungs and IL-18 concentrations increase marginally during experimental pneumonia. Nonetheless, findings suggest that either constitutively expressed IL-18 influences the innate immune response during respiratory tract infection or that the modest rise in IL-18 levels is biologically significant in the context of murine pneumonia. IL-6 is both a proinflammatory and an anti-inflammatory cytokine. The production of IL-6 is under the influence of TNF and IL-1β. Many cell types, including macrophages, T and B cells, and parenchymal cells produce IL-6. Like the other cytokines, IL-6 is produced in the lung during pneumonia.

IL-10 is a typical anti-inflammatory cytokine. IL-10 attenuates the production of TNF, IL-1β, chemokines, IFN-γ, and IL-12, and has potent inhibitory effects on PMNs resulting in reduced phagocytosis and bacterial killing. IL-10 is produced in the pulmonary compartment in mice with pneumonia.

AMs from patients with pneumonia produce G-CSF spontaneously, whereas AMs from healthy individuals only produce G-CSF on stimulation with LPS. It has been hypothesized that production of TNF and IL-1, which subsequently stimulates AMs to produce G-CSF, is one of the major roles of local macrophages: in this hypothesis, G-CSF acts locally during pneumonia to recruit PMNs to the infected lung and subsequently activate the recruited PMNs.

ROLE OF PROINFLAMMATORY CYTOKINES DURING PNEUMONIA Proinflammatory cytokines appear to play a protective role in pulmonary host defense. Indeed, systemic neutralization of TNF-attenuated host defense in pulmonary bacterial infections with *S. pneumoniae* and *K. pneumoniae* resulting in decreased survival, although administration of low doses of exogenous TNF, or augmentation of local expression of TNF in the lungs through gene therapy significantly diminished mortality and enhanced bacterial clearance from the pulmonary compartment during severe pneumonia with these pathogens. Similarly, IL-1 receptor type I deficient mice demonstrated an impaired clearance of *S. pneumoniae* and a reduced capacity to form inflammatory infiltrates. Treatment with a neutralizing anti-TNF antibody made IL-1 receptor-deficient mice extremely susceptible to pneumococcal pneumonia, more so than IL-1 receptor knockout mice treated with a control antibody and wild-type mice treated with anti-TNF, indicating that the concurrent action of TNF and IL-1 is required for an adequate host defense against pneumococcal pneumonia.

Comparable data are present for IL-12, IFN-γ, IL-17, IL-18, and IL-6. Neutralization of IL-12 attenuated bacterial clearance and increased mortality of mice with *K. pneumoniae* pneumonia, whereas overexpression of IL-12 reduced mortality. In accordance, IL-12 knockout mice had a normal host defense against *S. pneumonia*; bacterial outgrowth from lung tissue and survival was similar to wild-type mice in a pneumonia model with this pathogen. The role of IFN-γ in the setting of bacterial pneumonia is less clear. Although in one study IFN-γ knockout mice demonstrated higher mortality compared to wild-type mice, and in other studies local overexpression of IFN-γ in rats resulted in increased bacterial clearance from the pulmonary compartment, other data suggest that endogenous IFN-γ may impair an effective pulmonary defense in pneumonia. Indeed, pulmonary clearance of *S. pneumoniae* was attenuated in IFN-γ-R knockout mice, as well as in IFN-γ knockout mice compared to wild-type mice. IL-17 receptor-deficient mice were exquisitely sensitive to intranasally administered *K. pneumoniae* with 100% lethality after 48 h compared with 40% mortality in control mice. The IL-17 receptor-deficient mice displayed a significant delay in PMN recruitment into the lungs, associated with significant reduction in local G-CSF and MIP-2 levels. From these data it can be concluded that IL-17 receptor signaling is critical for host defense against *K. pneumoniae*. IL-18 deficient mice demonstrated a reduced clearance of *S. pneumoniae* and were more susceptible to progression to systemic infection at 24 and 48 h after an intranasal challenge with this pathogen. Although survival was not different between knockout mice and wild-type mice, these data suggest that IL-18 plays a protective role in the early host response during pneumococcal pneumonia. Evidence for the importance of IL-6 in host defense during pneumonia was obtained from a study on *S. pneumoniae* pneumonia in IL-6 knockout mice. IL-6 knockout mice had more bacteria in their lungs after an intranasal challenge with this pathogen, and died significantly earlier than normal mice.

ROLE OF CHEMOKINES DURING PNEUMONIA Several studies suggest a regulating role for chemokines in pneumonia: administration of chemokine neutralizing antibodies resulted in a reduction in PMN influx, which was associated with an attenuation of bacterial clearance from the lung, and an increased incidence of bacteremia in several murine pneumonia models. Local chemokine overexpression in the lung of transgenic

mice led to an increase in PMN influx after intratracheal administration of bacteria, which was associated with a striking improvement in survival, increased bacterial clearance from the lungs, and reduced incidence of bacteremia.

ROLE OF ANTI-INFLAMMATORY CYTOKINES IN PNEUMONIA Evidence exists that the anti-inflammatory cytokine IL-10 plays a detrimental role in the clearance of bacteria during pulmonary infections; administration of exogenous IL-10 reduced survival and increased outgrowth of bacteria in lungs of mice with *S. pneumoniae* pneumonia. Conversely, neutralization of endogenous IL-10 led to enhanced clearance of bacteria and improved survival in mice with pulmonary infection with *K. pneumoniae* or *S. pneumoniae*. Thus, although the proinflammatory cytokines and chemokines appear to play a protective role in pulmonary host defense by initiating a protective inflammatory reaction, the anti-inflammatory cytokines demonstrate a detrimental role in the innate immunity against respiratory pathogens by resolving the immune responses.

From the point of view that after the initiation and, if necessary, reinforcement of the inflammatory reaction, there is a need for innate immune responses to be stopped when the invading pathogens have been erased from the pulmonary compartment, it is logical that both proinflammatory and anti-inflammatory cytokines are produced locally in an inflammatory reaction. This fine-tuning of inflammation is necessary to protect the host from an overzealous reaction.

IS THE ROLE OF CYTOKINES COMPARABLE WITH ALL TYPES OF PNEUMONIA? The majority of the aforementioned models on the role of different cytokines involved infection with *S. pneumoniae* or *K. pneumoniae*. Importantly, the role of these cytokines may be different during pneumonia with other pathogens. Indeed, although endogenous TNF was important for clearance of *S. pneumoniae* and *K. pneumoniae* from mouse lungs, TNF impaired host defense mechanisms during pneumonia with *P. aeruginosa*. Similarly, although IL-1 receptor I-deficient mice demonstrated an impaired bacterial clearance and a reduced capacity to form inflammatory infiltrates during infection with *S. pneumoniae*, during infection with *P. aeruginosa* IL-1 receptor I-deficient mice demonstrated an enhanced bacterial clearance. Results from two studies demonstrate opposite roles for IL-18 during pneumococcal pneumonia and during pneumonia caused by *P. aeruginosa*, comparable to the results previously mentioned. Whereas in pneumococcal pneumonia the absence of endogenous IL-18 resulted in a reduced clearance of *S. pneumoniae*, in IL-18 deficient mice challenged with *P. aeruginosa* enhanced bacterial clearance was found. Furthermore, although endogenous IL-10 hampered bacterial clearance in mouse models of *S. pneumoniae* and *K. pneumoniae*, IL-10 improved host defense in a model of pneumonia caused by *P. aeruginosa*.

These data suggest that in more gradually developing pneumonias, such as that caused by *S. pneumoniae* and *K. pneumoniae*, a certain proinflammatory cytokine response within the pulmonary compartment is required to combat the invading microorganism, whereas in a more acute form of pneumonia, such as caused by *P. aeruginosa*, an excessive inflammatory response contributes to an adverse outcome. However, it must be emphasized that the murine *Pseudomonas* pneumonia model has some potential flaws, because a rather large amount of bacteria must be installed into the airways to induce pneumonia in mice, using lower inocula, bacteria are cleared from the airways and no pneumonia will develop; and because compared with the other experimental pneumonia models in which pneumonia develops in some days, in this model an acute pneumonia develops within 6–24 h; and *Pseudomonas* almost invariably causes pneumonia in the immunocompromised host, whereas the vast majority of mouse models used previously healthy immunocompetent animals. Hence, experimental models of *Pseudomonas* pneumonia described in the literature may not adequately mimic the clinical situation.

GCS-F: RESULTS FROM PRECLINICAL AND CLINICAL STUDIES In animal models of pneumonia, G-CSF is important for survival of pneumonia. Indeed, in a *S. pneumoniae* pneumonia model, administration of G-CSF before challenge improved survival in splenectomized mice. Furthermore, during infection with *K. pneumoniae*, IL-17 receptor-deficient mice were more likely to die compared with control mice, which was associated with significant reduction in local G-CSF levels.

Based on favorable effects of G-CSF in preclinical studies, several clinical studies with G-CSF in patients with pneumonia have been performed, unfortunately all with disappointing results. One was a randomized, placebo-controlled, multicenter trial of G-CSF up to 10 d as an adjunct to antibiotics in patients with pneumonia. Although G-CSF accelerated radiological improvement and appeared to reduce serious complications, such as empyema, adult respiratory distress syndrome (ARDS), and disseminated intravascular coagulation, mortality and length of hospitalization were not affected. In a second study G-CSF was compared with standard therapy in hospitalized adult patients with multilobar community-acquired pneumonia. In this study only a trend toward reduction of mortality in patients with pneumococcal bacteremia was seen in the study group. In another study, use of G-CSF did not reduce mortality and frequency of nosocomial infections in neutropenic patients requiring intensive care medicine. Finally, in two double-blind, randomized studies in patients with pneumonia and sepsis, there was no reduction of mortality or complications in the study group as compared with controls.

Thus only animal studies have shown beneficial effects of certain strategies aiming at modulation of the cytokine network. Unfortunately, results from these additive therapies are dependent on the causative pathogen, or may even be detrimental (Table 94-2). G-CSF has failed to improve mortality or any other important outcome measure in patients suffering from pneumonia.

TARGETING THE COAGULATION SYSTEM IN PNEUMONIA

Local changes in coagulation and fibrinolysis during pneumonia are remarkably similar to systemic changes in coagulation and fibrinolysis during sepsis and changes found in BALF of patients with ARDS. Interestingly, pathways responsible for local activation of coagulation and inhibition of fibrinolysis during pneumonia, both responsible for enhanced fibrin formation in the airways, are thought to be similar to those in the systemic compartment during sepsis (Fig. 94-1).

ACTIVATION OF COAGULATION AND INHIBITION OF FIBRINOLYSIS IN PNEUMONIA In humans with pneumonia, increased local thrombin generation has been observed. Next to activation of coagulation, inhibition of fibrinolysis has been demonstrated. Like in the systemic procoagulant state during sepsis, during pneumonia expression of tissue factor is suggested to play a key role in thrombin generation in the bronchoalveolar compartment. In one study of mechanically ventilated patients

Table 94-2
Cytokines Influence Host Defense During Respiratory Tract Infections, Although Their Role May Vary Depending on the Pathogen

Cytokine	*Streptococcus pneumoniae*	*Klebsiella pneumoniae*	*Pseudomonas aeruginosa*
TNF	+	+	+/–
IL-1β	+	?	–
Chemokines	?	+	+
IL-10	–	–	+/–
IL-6	+	?	?
IL-12	0	+	?
IL-17	?	+	?
IL-18	+	?	–
IFN-γ	+/–	?	+/–

+, indicates a beneficial role in case of respiratory infection with the specified pathogen; –, indicates a detrimental role in case of respiratory infection with the specified pathogen; +/–, indicates conflicting data; ?, indicates that there are no data on the effect of this cytokine; 0, indicates no effect.

IFN, interferon; IL, interleukin; TNF, tumor necrosis factor.

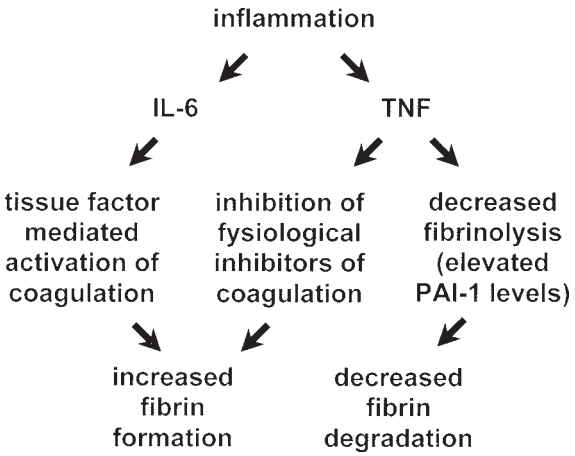

Figure 94-1 Schematic presentation of pathways involved in enhanced fibrin formation in sepsis and pneumonia. Coagulation activation is stimulated by IL-6, although inhibition of fibrinolysis is under control of TNF-α. It is uncertain if inhibition of natural inhibitors of coagulation is a feature of local inflammation in the lung. PAI, plasminogen activator inhibitor.

who developed pneumonia, tissue factor expression preceded the clinical manifestation of pneumonia, suggesting that this response indeed is important in the pathogenesis of pneumonia. Disturbed local fibrin turnover is also substantially resulting from depression of fibrinolysis. In the lung, the most important plasminogen activator appears to be urokinase-type plasminogen activator (u-PA). Although plasminogen activator inhibitor (PAI) type-1 is in almost all tissues the principal inhibitor of fibrinolysis, in the bronchoalveolar compartment PAI-2 seems to play an important role as well. Both PAI-1 and PAI-2 are increased in ARDS and pneumonia, and are probably derived from AMs and lung epithelial cells, fibroblasts, and endothelial cells, respectively. Markedly enhanced levels of PAI-1 and PAI-2 were noted in BALF from mechanically ventilated patients with pneumonia, compared with healthy controls. Also noted is that the depression of bronchoalveolar fibrinolysis precedes the clinical occurrence of pneumonia. In this study, PAI-1 levels decreased before the clinical diagnosis of pneumonia was made.

DOES DISTURBED FIBRIN TURNOVER IN PNEUMONIA INFLUENCE HOST DEFENSE? Although fibrin formation accompanies pneumonia, the importance of local coagulopathy in host defense during pneumonia is not known. Accumulation of fibrin may upregulate local inflammation during respiratory tract infections. In this way fibrin formation may play a positive role in pulmonary host defense.

As yet, studies on the role of activation of coagulation in the pathogenesis of pneumonia are lacking and studies on the role of inhibition of fibrinolysis in the pathogenesis of pneumonia are sparse. However, u-PA and the u-PA receptor play an essential role in experimental murine pneumococcal pneumonia. U-PA receptor deficiency was associated with reduced PMN-recruitment, enhanced bacterial outgrowth, extensive dissemination of infection, and reduced survival. In contrast, u-PA deficient mice showed enhanced host defense in this model, associated with more PMN-influx and less outgrowth of bacteria. These results suggest that the function of u-PA receptor in the response to infection is particularly pronounced when this receptor is unoccupied by u-PA. That these mechanisms are independent of fibrinolytic activity is illustrated by similar experiments in plasminogen or PAI-1 deficient mice that showed no effect on the immune response to infection.

The relationship between inflammation and coagulation is a two-way interaction: activation of coagulation (and inhibition of fibrinolysis) is, at least in part, under the control of TNF and IL-6. However, activation of coagulation can also importantly modulate inflammatory activation. In this context, therapy aimed at normalization of local abnormalities in coagulation and fibrinolysis may have a detrimental influence on pulmonary host defense.

Future studies are necessary to draw firm conclusions on whether modulation of the local fibrin formation during respiratory tract infections has beneficial effects on morbidity and mortality.

TARGETING THE COMPLEMENT CASCADE IN PNEUMONIA

The complement cascade is another important part of the immune system; it plays a significant role in the elimination of invading pathogens. Patients and animals deficient in complement system components are more susceptible to bacterial infections, and have increased morbidity and mortality on bacterial challenge. Three separate pathways can activate complement: (1) the "classic" pathway, in which activation occurs when antibody/antigen complexes interact with the first complement component (C1), (2) the "alternative" pathway, an antibody-independent, self-amplifying pathway that can be activated by a variety of mechanisms (e.g., biomaterials, yeast cell walls, tissue type-PA), and (3) the "lectin" pathway, also an antibody-independent pathway, which is activated by binding of mannose-binding lectin to carbohydrate structures on the surface of bacteria, yeast, protozoa, and viruses (Fig. 94-2). The three previously described pathways merge at C3, which is cleaved into C3a and C3b. C3b stimulates cleavage of C5 into C5a and C5b, and the addition of C6, C7, C8, and multiple C9 units results in the formation of C5b-9, also known as the "membrane-attack complex." Apart from the formation of this important membrane-attack complex, important for killing invasive pathogens, several side-products are produced on complement activation (e.g., C3a, C5a), all with proinflammatory properties.

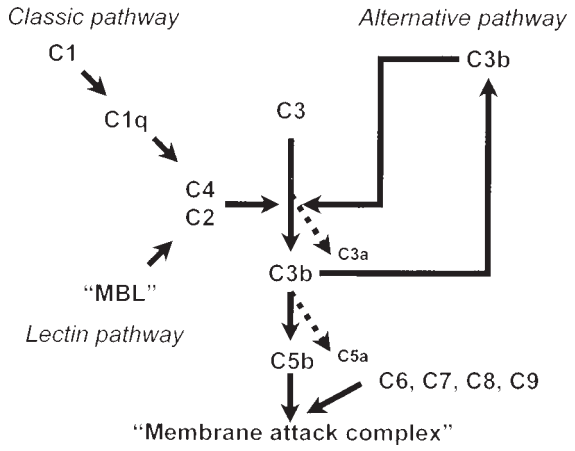

Figure 94-2 Schematic presentation of complement pathways. Three pathways of complement activation ("classic," "alternative," and "lectin") merge at complement component C3, eventually leading to the formation of the important "membrane-attack complex." Important side-products are C3a and C3b. Mannose-binding lectin, MBL. (Adapted and modified with permission from ref. Bhole D, Stahl GL. Therapeutic potential of targeting the complement cascade in critical care medicine. Crit Care Med 2003;31:S97–S104.)

C3a and C5a primarily act on white blood cells; although C3a mostly interacts with eosinophils, C5a interacts with PMNs. C5a attracts PMNs, increases PMN adherence to the endothelium, and stimulates the production/release of reactive oxygen species, granule content, and leukotrienes. Furthermore, C5a induces the production of cytokines and chemokines.

ACTIVATION OF THE COMPLEMENT SYSTEM DURING SEPSIS AND PNEUMONIA Activation of complement, mainly via the classic pathway, is clearly involved in the pathogenesis of sepsis. Indeed, increased plasma levels of activated complement components have been found after injection of LPS in animals and in septic patients. It is speculated that overzealous activation of the complement system is responsible for morbidity and mortality during sepsis, and several animal studies support this hypothesis. Activation of the complement system has also been described in patients with acute lung injury or pneumonia; in a study on trauma patients, in patients developing ARDS significantly higher C3 concentrations and a higher C3a/C3 ratio were found in the first few hours after multiple trauma. Follow-up BALF demonstrated strongly increased C3a levels during the first 24 h, mainly in ARDS patients and, to a lesser degree, in non-ARDS patients. In a study of neutropenic febrile patients, activated complement components were measured in BALF, revealing higher C3a and C5a levels in patients who developed pneumonia. Similar results have been shown in mechanically ventilated patients developing pneumonia. In this study, in patients with pneumonia, BALF levels of C3a were higher as compared with patients not developing pneumonia. Moreover, local levels of C3a rose toward the diagnosis of pneumonia.

TARGETING THE COMPLEMENT SYSTEM There is evidence that therapeutic targeting of the complement cascade may be of value in the treatment of patients with pulmonary diseases. In an aspiration model in rats, complement inhibition by recombinant human soluble complement receptor type 1 or complement depletion by *cobra venom* factor, significantly reduced lung edema, protein accumulation in BALF, and improved tissue oxygenation. Similar results were found in mice. In addition, in a study on septic primates, anti-C5a antibody treatment not only attenuated some of the systemic manifestations of sepsis but also ARDS.

C5a receptor deficient mice, in comparison to control mice, were unable to clear intrapulmonary-instilled *P. aeruginosa*, despite a marked increase in neutrophil influx, and died because of pneumonia. These C5a-receptor-deficient mice challenged with sublethal inocula of *Pseudomonas* become super-infected with secondary bacterial strains. Targeting the complement cascade is an interesting approach that needs attention in the near future.

CONCLUSION

Immunotherapy, aimed at modulating the immune response, may serve as an important adjuvant to antibiotic therapy in the treatment of infectious diseases. Immunomodulating therapy for patients with pneumonia must be approached with caution because underlying cellular and molecular mechanisms of pneumonia are not yet fully understood. This chapter discussed several components of pulmonary host defense. Thus far, only G-CSF has reached the status of immunomodulating agent in clinical studies, and results were negative. Future studies are needed to show whether immunomodulation can be safely and successfully used in patients with pneumonia.

95 Molecular Pathogenesis of Fungal Infections

Brahm H. Segal

SUMMARY

Opportunistic fungal infections are a major cause of morbidity and mortality in the immunocompromised. Fungi have evolved complex and coordinated mechanisms to survive in the environment and the mammalian host. These include the ability to adhere to and colonize a variety of sites (e.g., skin, gastrointestinal mucosa, and intravenous catheters), invade tissue, establish localized disease, and disseminate. Fungi must adapt to "stressors" in the host, including nutrient acquisition, pH, and reactive oxygen and nitrogen intermediates. Knowledge of the immunopathogenesis of fungal infections has paved the way to promising preclinical studies and clinical trials of immunotherapy. The availability of genomic databases for key fungal pathogens will shed light on fungal pathogenesis and response to stressors both from host defense pathways and antifungal drugs, and will identify promising targets for drug development.

Key Words: Antifungal agents; *Aspergillus*; *Candida*; *Cryptococcus*; dimorphic fungi; drug development; genomics; vaccine; virulence factors.

FUNGAL INFECTIONS

Opportunistic fungal infections are a major cause of morbidity and mortality in immunocompromised patients. McNeil et al. evaluated trends in mortality because of invasive mycosis in the United States between 1980 and 1997 based on an analysis of death certificates. During the study period the annual number of deaths associated with an invasive mycosis increased from 1557 to 6534. In patients with AIDS, *Pneumocystis jiroveci* (formerly *P. carinii*, more appropriately classified as a fungus than a protozoan based on genetic similarity) and *Cryptococcus neoformans* accounted for the majority of opportunistic mycoses associated with mortality. Even before the availability of protease inhibitors targeted against HIV, there was a decrease in mortality from opportunistic mycoses associated with HIV infection; this may be related to the availability of early antiretroviral regimens with modest efficacy and antimicrobial prophylaxis. Among those without HIV infection, there has been a dramatic increase in mortality due invasive aspergillosis and "other mycoses," presumably related to the increase in patients receiving potent immunosuppressive therapy for malignancy and transplantation.

Opportunistic yeasts produce a spectrum of clinical disease that ranges from superficial and mucosal infections to disseminated disease. Oral mucosal candidiasis usually reflects severe T-cell depression commonly associated with AIDS or high-dose systemic corticosteroids. *Candida* spp. are endogenous flora that may gain access to the bloodstream through breaches in anatomical barriers. The bowel is the principal portal of entry in patients with acute leukemia receiving mucotoxic regimens.

Host defense against *C. neoformans* is also principally dependent on T-cell immunity. Immunoglobulins directed against capsular epitopes and complement facilitate phagocytosis of the organism, and play a role in host defense. The principal portal of entry for *C. neoformans* is by inhalation, with subsequent spread to the blood and central nervous system.

Endemic dimorphic fungi are so named because of their characteristic geographic distribution. These organisms include *Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis, Paracoccidioides brasiliensis*, and *Penicillium marneffei*. Dimorphic refers to their existence in nature in the fruiting mycelial stage and conversion to the yeast stage at body temperature. Because some of these pathogens may be quiescent during the initial infection and only manifest clinically during depression of cell-mediated immunity, a detailed travel history is essential.

Filamentous fungi (molds) are ubiquitous soil inhabitants whose conidia (spores) we inhale on a regular basis. The sinopulmonary tract is the most common portal of entry. The respiratory mucosa and alveolar macrophages constitute the first line of host defense against conidia. At the hyphal stage, circulating neutrophils are most important in controlling infection. *Aspergillus* infection and other filamentous fungi are a major cause of morbidity and mortality in highly immunocompromised patients. Patients at risk include those with prolonged neutropenia, hematopoietic stem cell transplant (HSCT) recipients (mostly allogeneic), solid organ transplant recipients (particularly lung), advanced AIDS, and chronic granulomatous disease (CGD).

Most filamentous fungal infections are caused by *Aspergillus* spp. Prolonged and persistent neutropenia is a critical risk factor for aspergillosis. Invasive aspergillosis has become the leading cause of infection-related mortality in allogeneic HSCT recipients, with most cases occurring in the postengraftment rather than the neutropenic period, with immunosuppressive therapy for GVHD being a principal risk factor.

Zygomycosis is also being observed with increased frequency in patients with hematological malignancies and allogeneic HSCT

at some centers in association with use of voriconazole, an agent with a broad spectrum of antifungal activity but poor activity against zygomycetes. Infections by less common pathogenic fungi including dark-walled moulds, *Scedosporium* species, and *Fusarium* species have increased over the past 20 yr among patients with hematological malignancies and allogeneic HSCT recipients.

This chapter will focus on the major mechanisms of virulence in pathogenic fungi. Because of the key importance of host defense against opportunistic fungi, host–pathogen interactions will be discussed and related to novel strategies aimed at immune augmentation, including vaccine development. Recent developments in the antifungal armamentarium and new opportunities for drug discovery created by a greater understanding of the molecular pathogenesis of fungal infections and genomics will be discussed.

FUNGAL VIRULENCE FACTORS IN RELATION TO HOST DEFENSE

Both the pathogen and the host contribute to microbial pathogenesis. Nowhere else is this more true than in mycology. Thus, a "virulence factor" or a "virulence gene" occurs in the context of the specific host. All of the major opportunistic fungal pathogens are associated with a broad range of virulence factors, which enable the pathogen to adhere to the host cell or foreign body surfaces (such as *Candida* biofilms adhering to intravenous catheters), invade, damage tissue, and disseminate. Virulence factors enable the pathogen to survive within a hostile host environment and specific host conditions including body temperature (37°C), pH within the tissue, nutrient deficiency, reactive oxidants, and numerous nonoxidant-dependent host defense pathways (e.g., defensins, cathepsins, elastases, and other neutrophil granule constituent proteins). Fungal genes that mediate resistance to antifungal agents are also legitimately classified as "virulence factors" in the specific context of exposure to the relevant drug.

Falkow proposed the following criteria for Koch's molecular postulates:

1. The phenotype or property under investigation should be associated with pathogenic members of a genus or species.
2. Specific inactivation of the gene or genes associated with the suspected virulence trait should lead to a measurable loss in pathogenicity or virulence.
3. Reversion or allelic replacement of the mutated gene should lead to restoration of pathogenicity.

The second and third criteria are routinely evaluated by generating "knockout" and "knockin" strains in which the relevant gene is inactivated or restored, respectively.

Most opportunistic fungi grow in the environment independent of an animal host. Casadevall et al. used the term, "dual use" virulence factors to describe certain virulence factors that confer a survival advantage both in the environment and in animals. In *C. neoformans*, virulence in animals may have originated from factors that enabled persistence in amoeboid and nematode predators. For example, following ingestion by *Acanthamoeba castellani*, *C. neoformans* replicates and forms polysaccharide-containing vesicles in the cytoplasm, a process mirrored by the interaction between macrophages and ingested cryptococci.

Virulence genes require a context. For example, a wild-type strain of *Aspergillus fumigatus* and a strain with a deleted gene of interest will likely both be nonvirulent in normal mice challenged via the intratracheal route. However, if mice are first rendered neutropenic, we may discover that the deletant strain is less virulent than the wild-type strain. Genes that permit *Candida* spp. to adhere to epithelial surfaces are a prerequisite for infection. In an immunocompetent person, this virulence factor may permit asymptomatic colonization of mucosal surfaces without clinical relevance. In healthy women, this virulence factor may be a requisite for vaginitis. In advanced AIDS, this virulence factor may be a requisite for disabling oral mucosal and esophageal candidiasis. In a patient receiving cytotoxic chemotherapy, this virulence factor may facilitate candidemia and disseminated candidiasis arising from defects in the gastrointestinal mucosa.

Host damage can result from microbial factors, host response, or both. Casadevall and Pirofski elegantly illustrated the limitations of the "microorganism-centered" and "host-centered" paradigms. They proposed the "damage-response" framework of microbial pathogenesis in which the host relevant outcome of the host–microorganism interaction is determined by the amount of damage to the host.

ADHESION

Adhesion is a prerequisite to colonization and invasion. Inhaled pathogens (e.g., filamentous fungi, dimorphic fungi, *C. neoformans*) generally establish infection by adhering to respiratory epithelium. *Candida* spp. colonize the gastrointestinal and vaginal tracts, the skin, and foreign bodies (e.g., catheters). Understanding the molecular biology of adherence is of key importance in development of drugs and immunotherapy aimed at inhibiting adhesion.

There is strong evidence for the importance of adherence in *Candida* virulence. There is a correlation between the degree of endothelial cell adherence and virulence of different *Candida* spp. Several adhesins of *C. albicans* have been characterized. Mutants deficient in genes encoding these adhesins showed decreased adherence to host cell substrates in vitro and decreased virulence in animal models. *Hwp1p* mediates adherence to buccal epithelial cells by acting as a substrate for transglutaminase. *EAP1* mediates adherence to polystyrene and renal epithelial cells. *CaMnt1p* mediates O-linked mannosylation of proteins and plays a role in *C. albicans* cells adhering to each other and to host epithelial cells. *CaMnt1p* null mutants had reduced virulence in systemic infection in mouse and guinea pigs. Reduced virulence of null mutants in guinea pigs was associated with decreased ability to reach and/or adhere to internal organs. *Csf4* is a putative glycosidase that plays a role in adherence and filamentation; a null mutant had attenuated virulence in disseminated candidiasis in mice.

The *C. albicans ALS* gene family consists of at least eight members that encode cell surface proteins characterized by three domains. The N-terminus contains a putative signal peptide, the central region consists of a variable number of tandem repeats, and the C-terminus is serine-threonine rich and contains a glycosylphosphatidylinositol anchor. The Als proteins have diverse substrate specificities for adherence that is conferred by the N-terminal domain. Sheppard et al. suggested an analogy between Als proteins and antibodies. The Als proteins contain hypervariable regions (similar conceptually to the hypervariable region of antibodies) that mediate substrate specificity. The genetic variability in the Als family enables binding to multiple proteins, which may in turn enable adherence to a broader range of anatomic surfaces during infection.

Als proteins may therefore be attractive targets for drug development and vaccine development aimed at inducing antibody

responses that target key Als epitopes and inhibit adherence to host tissue. A vaccine made up of the recombinant N-terminus of *Als1p* reduced fungal burden and improved survival in experimental candidiasis in both immunocompetent and immunocompromised mice. The vaccine-mediated protection by enhancing cell mediated, but not humoral, immunity.

Candidemia is a major cause of nosocomial infection related morbidity and mortality. The two major portals of entry are breaches in the gastrointestinal tract (such as occurs following mucotoxic antineoplastic chemotherapy) and intravenous catheter-associated infections. *Candida* biofilms are *bona fide* virulence factors in the context of catheter-associated candidal infections. *Candida* biofilm production occurs through specific maturation phases and requires the generation of a polysaccharide extracellular matrix. Mature *Candida* biofilms have a heterogeneous architecture in terms of the relationship between fungal cells and matrix. Similar in concept to other biofilm-producing pathogens such as staphylococci, *Candida* biofilms facilitate pathogen adherence to foreign bodies such as catheters, leading to a persistent nidus of infection that may be refractory to antimicrobials. Biofilm formation is also important in the development of denture stomatitis.

Mukherjee et al. showed that *C. albicans* biofilms mediate resistance to fluconazole in vitro, and that resistance involves a complex interaction between azole efflux pumps and the maturity of the biofilm. At early time-points of biofilm production, wild-type *C. albicans* was resistant to fluconazole, but strains deficient in drug efflux pumps were resistant. At later time-points, all strains were resistant indicating that drug resistance was independent of the efflux pumps. Lipid formulations of amphotericin B and echinocandins retain antifungal activity even in the presence of mature biofilms; the clinical importance of this finding merits further study.

Blastomyces dermatiditis is an extracellular dimorphic fungus that can cause progressive pulmonary, soft tissue, and disseminated infection. BAD1 (formerly WI-1), a 120-kDa protein, is a major adhesin and immune modulator in *B. dermatiditis*. It contains tandem repeat sequences homologous to invasin, an adhesin of *Yesernia* species . BAD1 is released extracellularly before association with the yeast surface and mediates attachment to CD18 and CD14 receptors on human macrophages. Genetically engineered BAD1-deficient strains of *B. dermatitidis* bind poorly to the lung ex vivo and to macrophages in vitro, and have greatly diminished virulence following experimental infection in mice. BAD1 also modulates host immunity. Early in the course of infection, BAD1suppressed host tumor necrosis factor (TNF)-α production through transforming growth factor (TGF)-β-dependent and independent mechanisms. Deletion of the C-terminal epidermal growth factor (EGF)-like domain of BAD1 prevented localization of BAD1 to the yeast surface and impaired yeast adherence to macrophages. However, the deletant strain and the purified deletant protein suppressed TNF-α production in phagocytes and in the lung as effectively as BAD-1-reconstituted wild-type strains and retained virulence in experimental infection in mice. Thus, the requirements for adhesion and immune modulation by BAD1 occur in discreet domains.

MORPHOLOGICAL ADAPTATION

Morphogenesis and phenotypic switching allow opportunistic fungi to adapt to different environments and survive in the infected host. These changes in structure are under complex genetic control. The ability of *C. albicans* to transform from the yeast to the filamentous phenotype confers the ability to penetrate host tissue and escape phagocytosis by macrophages. Filamentation occurs in response to several stimuli, including elevated temperature, growth in serum, pH changes, and the presence of an extracellular matrix. Mutants in the hyphal-regulating transcriptional factors, *Efg1P* and *Cph1P*, are unable to grow in the filamentous form in serum and other media at 37°C, but can filament in matrix at lower temperatures. These mutants have attenuated virulence in systemic infection in mice.

Hyphal growth in *C. albicans* is influenced by the local topography, and may be important for mucosal invasion and growth along indwelling catheters. In artificial membranes, reorientation of the hyphal tip occurs in response to scratches and pores, referred to as "thigmotrophism." Thigmotrophism may require activation of stretch-sensitive calcium channels. *CZF1p*, a zinc finger protein, is important in mediating hyphal development when *C. albicans* is grown within matrix. During growth within matrix, *Efg1p* may inhibit filamentation, and *CZF1p* reverses this inhibition.

The dimorphic fungi exist in the yeast form at body temperature and in the filamentous form at lower temperatures. *C. immitis* is endemic in the Southwestern United States. The tissue form is the spherule. Arthroconidia are inhaled from the environment in which they convert into spherules. Spherules enlarge (20–100 μm) and segment internally into hundreds of endospores. Mature endospores rupture through the spherule in which they can extend the local infection or disseminate. The spherule prevents access of neutrophils to maturing endospores, and following rupture, endospores are themselves covered by a matrix from the inner spherule wall which may also aid in evading phagoctyosis. The potential for *C. immitis* to widely disseminate has prompted the search for extracellular fungal proteinases that may be targets for inhibitors or vaccines.

A randomized placebo-controlled study involving 2867 subjects from endemic regions showed no benefit of the formalin-killed spherule vaccine in preventing coccidioidomycosis. Additional candidate vaccines for coccidioidomycosis are being developed, with efforts focused on identifying immunodominant Coccidioides antigens to be used in subunit vaccines (Cox, Magee, 2004). Studies in multiple laboratories have shown that antigen 2/proline-rich antigen (Ag2/PRA) as both protein and DNA vaccines provide significant protection in experimental coccidioidomycosis. The completed and genomic sequence of *C. immitis* may facilitate identifying new candidate antigens for vaccine development.

C. neoformans is unique among the pathogenic fungi in having a polysaccharide capsule that is a major virulence factor that allows the pathogen to evade phagocytosis. Acapsular variants of *C. neoformans* have attenuated virulence. The *C. neoformans* capsule also interferes with dendritic cell (DC) activation and maturation, a mechanism by which the fungus may suppress an effective T-cell response. The capsule is made up of primarily of glucuronoxylomannan (GXM). GXM has an α-1,3 linked mannose backbone that is O-acetylated and substituted with single-side chains of xylose and glucouronic acid. The degree of acetylation and xylose substitution can vary, producing four serotypes. Serial isolates of *C. neoformans* from chronically infected patients show changes in virulence, karyotype, and capsular polysaccharide structure, suggesting that structural changes occur during chronic infection. "Phenotypic switching" (high frequency reversible changes in colony morphology) has been described in several strains of *C. neoformans*. For example, phenotypic switching in *C. neoformans* SB4 is associated with changes in colony morphology that

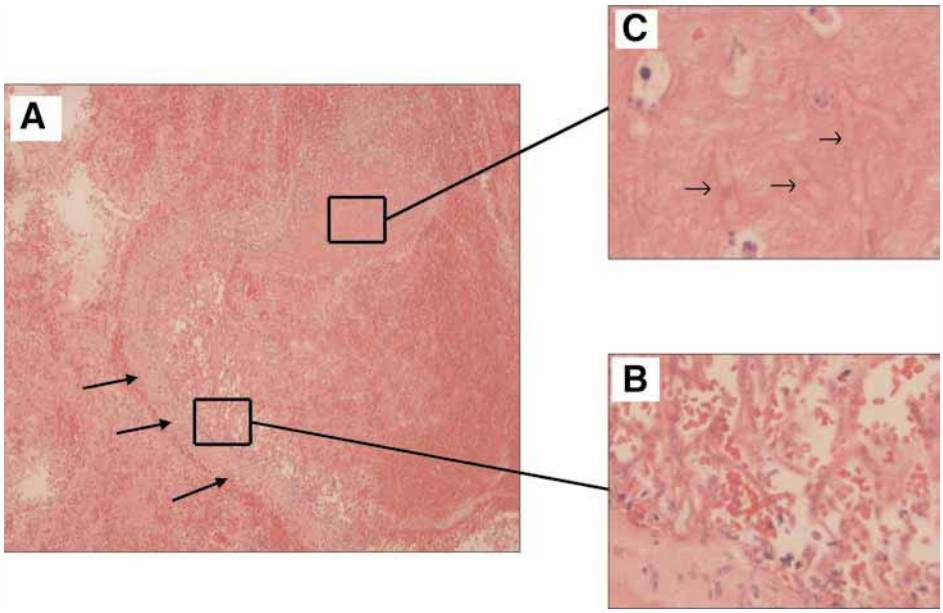

Figure 95-1 Invasive pulmonary aspergillosis in an allogeneic hematopoietic stem cell transplant recipient at autopsy. **(A)** Lower power view shows arterial thrombosis (Hematoxylin & Eosin, 40×). Arrows, vessel wall. **(B)** Higher power magnification shows hyphae invading the arterial wall (×200) and **(C)** invasive hyphae (arrows) within the thrombus (×400). included: (1) smooth, (2) wrinkled, and (3) serrated. The wrinkled phenotype was the most virulent in experimental infection. Infection of rats with serrated *C. neoformans* produced the most intense inflammatory responses characterized by granuloma formation and necrosis. Wrinkled *C. neoformans* produced a minimal inflammatory response. Thus, phenotypic switching affects *C. neoformans* virulence and the host inflammatory response, which may confer an advantage in establishing chronic infection and evading host defense. Antibodies directed against capsular epitopes confer protection in murine cryptococcal infection. Murine IgG1 (Mab 18B7) was well-tolerated in a Phase I dose-escalating trial in patients with cryptococcal meningitis.

ANGIOINVASION

Filamentous fungi have a propensity to angioinvasion in the highly immunocompromised host, leading to thrombosis, infarction, and coagulative necrosis (Fig. 95-1). Conidia are inhaled, germinate, and transform into the hyphal stage. In the susceptible host (e.g., severe neutropenia), hyphae (but not conidia) are capable of invading surrounding tissue and blood vessels. The molecular mechanisms underlying angioinvasion are poorly understood. Lopes Bezerra and Filler, showed that both *A. fumigatus* conidia and hyphae induced endothelial cell microfilament changes and subsequent endocytosis in vitro. Endocytosed conidia and hyphae caused endothelial cell injury, but only hyphae (either live or killed) activated endothelial cell tissue factor, a key mediator of thrombosis.

C. albicans stimulates multiple endothelial responses, including expression of leukocyte adhesion molecules and production of prostaglandins and proinflammatory cytokines. *C. albicans* hyphae are endocytosed by endothelial cells in vitro. Als1 mediates adherence to endothelial and epithelial cells. Sanchez et al. noted a relationship between *C. albicans* virulence in hematogenous infection in animals and endothelial damage in vitro. *C. albicans* did not stimulate endothelial cell tissue factor activity. The ability to induce endothelial cell tissue factor activity may be why vascular thrombosis is characteristic of invasive aspergillosis but not invasive candidiasis. Interestingly, tissue invasive aspergillosis in CGD is not angioinvasive in contradistinction to neutropenia and other immunocompromised conditions in which angioinvasion occurs. Further studies aimed at defining pathogen/endothelial cell interactions at the molecular level will be important in designing therapeutic modalities aimed at preventing angioinvasion.

DAMAGE

PHOSPHOLIPASES Most pathogenic fungi are saprophytes, living on decayed animal or plant material for nutrition. Extracellular degradative enzymes such as proteinases and phospholipases cause host cell damage. These enzymes break down epithelial mucosa and extracellular matrix, a requirement to establish infection, and likely increase the availability of host-derived nutrients. Because the vast majority of pathogenic fungi exist in the environment and are not dependent on an animal host for their life cycle, these degradative enzymes likely have a dual use purpose in the saprophytic setting.

Extracellular phospholipases are virulence factors in pathogenic fungi and have been implicated as virulence factors in pathogens including clostridia, *Pseudomonas aeruginosa*, *Rickettsia rickettsii* (agent of Rocky Mountain spotted fever), *Rickettsia prowazekii*, *Toxoplasma gondii*, *Entamoeba histolytica*, and *Listeria monocytogenes*. Fungal phospholipases enhance virulence through damage of host cell membranes. Other potential mechanisms of virulence include phospholipase-mediated signal transduction and augmentation of the host inflammatory response. There is precedent for these effects in bacteria and *E. histolytica*.

Birch et al. suggested that *A. fumigatus* produces extracellular phospholipases A, B, C, and D based on phospholipid degradation products. Phospholipase C (PLC) activity (assessed using p-nitrophenylphosphorylcholine as a substrate) was initially observed at

30 h after growth and increased during stationary phase. PLC activity was greater at 37°C than at lower temperatures. The authors noted the pathological similarities of necrotizing fasciitis and clostridial gangrene, ecthyma gangrenosum caused by *P. aeruginosa* and invasive aspergillosis regarding angioinvasion, infarction, and tissue necrosis. Because each of these pathogens produces extracellular PLC, the authors speculated that PLC may account for some of the pathological characteristics of invasive aspergillosis. Extracellular PLC activity was higher in clinical strains of *A. fumigatus* whereas phospholipid acyl hydrolase activity was higher in environmental strains, suggesting that specific phospholipases may influence host trophism.

Ibrahim et al. showed that *C. albicans* strains exhibiting increased phospholipase B (PLB) activity had greater virulence in experimental disseminated candidiasis in mice. Genetically engineered mutants of *PLB1* had diminished virulence in mice, and reintroduction of a functional *PLB1* gene into the null mutant restored virulence. PLB expression during *Candida* invasion of the gastrointestinal tract of infant mice was localized to the growing hyphal tips. PLB production is under complex regulatory control and is influenced by nutritional supplementation, pH, and growth phase.

PLB is also a pathogenic factor in *C. neoformans*, promoting survival and replication in macrophages in vitro. It likely contributes to cryptococcal virulence through lysis of host defense cells, and may help evade macrophage host defenses by increasing fungal eicosanoid production, leading to down-modulation of macrophage function. Using a *PLB1* null mutant and a *PLB1* reconstituted *C. neoformans* strain, Santangelo et al. showed that PLB was required for spread to draining lymph nodes and hematogenous dissemination following endotracheal challenge in mice. Secreted PLB in *C. neoformans* has three phospholipase activities in the one protein: PLB, lysophospholipase, and lysophospholipase transacylase. Only inhibitors of PLB had antifungal activity in vitro.

Phospholipases are promising therapeutic targets. Approaches include identification of inhibitors by chemical screening or by inhibitor design based on the tertiary structure of the protein. Hanel et al. identified phospholipase inhibitors with antifungal activity from the β-blocker category of drugs. These agents when combined with fluconazole were more effective than fluconazole alone in murine disseminated candidiasis. Vaccine development may exploit fungal antigens distinct from mammalian phospholipases. Because phospholipases are released during infection, their detection may facilitate early diagnosis of invasive fungal infection.

PROTEASES Many pathogenic fungi secrete proteases during infection, though the function of specific proteases in vivo is often difficult to determine. Secreted endoproteases (which cleave internal peptides within a polypeptide) consist of aspartic proteases of the pepsin family, serine proteases, and metalloproteases. Pathogenic fungi also secrete aminopeptidases, carboxypeptidases, and dipeptidylpeptidases. Secreted proteases play an important role in the pathogenicity of dermatophytes, which grow exclusively on keratinized tissue such as skin, nails, and hair. Proteases from dermato phytes are similar to those from other fungi such as *Aspergillus* species, but with different substrate specificities.

In *C. albicans*, secreted aspartyl proteinases (SAPs) are encoded by at least 10 genes and contribute to virulence. The *C. albicans* SAPs. Two distinct groups are clustered within the family. SAP1-SAP3 have 67% similarity and SAP4-SAP6 are 89% identical. Different SAP proteins mediate adherence and tissue damage and are differentially regulated under a variety of in vitro growth conditions. SAP4-SAP6 are upregulated after phagocytosis by murine macrophages and their respective null mutants are killed more efficiently following ingestion. Ripeau et al. showed that *C. albicans* SAPs were differentially expressed during oral infection in wild type and transgenic mice expressing HIV-1. Schofield et al. also detected differences in *SAP* and *PLB* gene expression in experimental oroesophageal vs gastric *C. albicans* infection.

Naglik et al. evaluated the in vivo expression of genes encoding the SAPs and PLB in 137 human subjects with oral or vaginal candidiasis or carriage. They demonstrated differential expression of these genes in active disease and by anatomic location. Because *Candida* spp. can infect multiple tissues (skin, endothelial cells, and visceral organs in hematogenous infection), a spectrum of proteolytic enzymes under differential regulation may facilitate entry into a greater repertoire of niches. The genome of *C. albicans* is sequenced and DNA microarrays have been generated. These will further increase our understanding of gene regulation in host cell interactions.

Protease inhibitors used to treat HIV infection also inhibit *Candida* SAPs. In addition to their salutary role in controlling HIV replication and enabling reconstitution of cellular immunity, protease inhibitors may also reduce the frequency of oral mucosal candidiasis through inhibition of SAPs. De Bernardis et al. longitudinally evaluated *Candida* isolates from the oral cavity of HIV-infected patients receiving antiretroviral therapy with and without protease inhibitors. Protease inhibitors reduced SAP expression in vivo, but did not eliminate *Candida* carriage or affect susceptibility to antifungal agents. More potent inhibitors of the *Candida* SAP enzymes may be more effective antifungals. SAPs may also be promising targets for vaccine development. Vilanova et al. showed that immunization of mice with SAP2 elicited immunoglobulin responses that correlated with protection following experimental systemic *C. albicans* infection.

A. fumigatus conidia are internalized in vitro by lung epithelial cells. Uptake into those nonprofessional phagocytes may facilitate evasion of host defense in the lung. *A. fumigatus* secretes a variety of proteases, including an alkaline serine protease, a metalloproteinase, an aspartic protease, and elastases. Their likely roles in mammalian infection are to degrade the extracellular matrix layer in the respiratory mucosa. Kogan et al. showed that *A. fumigatus* secretes proteases that perturb the organization of the actin cytoskeleton in A549 pneumocytes, leading to formation of actin aggregates, cell blebbing, and disruption of focal adhesion sites. These changes were blocked by antipain, a serine and cysteine protease inhibitor. Antipain also reduced *Aspergillus*-induced A549 cell death and detachment from matrix, suggesting an important role for *A. fumigatus* proteases in causing lung epithelial cell damage and breaching the epithelia barrier.

SURVIVAL UNDER STRESS

IRON ACQUISITION The ability of microbes to compete with their hosts to acquire iron is a major requirement for pathogenicity. Siderophores (low molecular weight ferric iron chelating agents) involved in iron acquisition under iron-limited conditions are virulence factors in a wide variety of plant and animal pathogens.

Ramanan and Wang identified two genes, *CaFTR1* and *CAFTR2*, that encode high affinity iron permeases in *C. albicans*. *CaFTR1* is induced under iron-limited conditions and repressed when iron supplies are adequate, whereas *CaFTR2* is regulated in the reverse.

CaFTR1, but not *CaFTR2*, is required for growth in iron-deficient medium. *CaFTR1* null mutants are unable to establish systemic infection in mice. Like many bacteria, *C. albicans* is able to use hemin and hemoglobin as iron sources. *RBT5* encodes a mannosylated protein induced under iron starvation that is necessary in using hemin and hemoglobin as iron stores. Iron-starvation inducible heme-binding proteins are conserved in other *Candida* spp. and in *S. cerevisiae*.

Addition of hemoglobin to *C. albicans* cultures increases adhesion to several host proteins. This activity is mediated by a cell surface hemoglobin receptor and is independent of iron acquisition. Hemoglobin induces the expression of several genes, including a heme oxygenase that facilitates acquisition of iron from heme and hemoglobin. Iron is also required for endothelial injury by *C. albicans* in vitro. The siderophore iron transporter of *C. albicans* (SIT1) mediates uptake of ferrichrome-type siderophores and is required for epithelial cell invasion in vitro, but was not required for systemic infection in mice. This suggests that different iron acquisition mechanisms exist during mucosal infection compared with hematogenous infection in which other sources of iron, such as heme, are available.

Iron acquisition pathways in filamentous fungi are less well defined at the molecular level than those in *Candida*. *A. fumigatus* survival in human serum requires siderophores that extract iron from transferrin. Five siderophores were purified from *A. fumigatus* culture medium, the two major ones were triacetylfusarinine and ferricrocin. Of the filamentous fungi, zygomycosis (also termed, "mucormycosis") is most frequently associated with iron overload states and deferoxamine (an iron chelator) therapy. Boelaert et al. showed that *Rhizopus* (a member of the zygomycetes) uses deferoxamine as a siderophore. The iron-deferoxamine complex abolishes the fungistatic effect of serum on *Rhizopus* and accelerates in vitro growth. The effect of the iron chelate complex on iron uptake and growth in vitro were far more impressive for *Rhizopus* than *A. fumigatus*, and close to nil in *C. albicans*. Deferoxamine also aggravated experimental *Rhizopus* infection in guinea pigs. Renal failure reduces clearance of the iron chelate, which may account for the increased frequency of zygomycosis in dialysis patients receiving deferoxamine.

MELANIN Melanins have attracted considerable interest as virulence factors in pathogenic fungi. They are widely produced by several pathogenic fungi, including *C. neoformans*, *Aspergillus* species, *Sporothrix schenckii*, and the dark-walled moulds. The majority of melanins produced by fungi are derived from the 1,8-dihydroxynaphthalene pathway. In *C. neoformans*, melanin is produced when laccase (laccases are copper containing proteins that require oxygen to oxidize phenols and other substrates) catalyzes the oxidation of certain aromatic compounds, including L-DOPA (a brain catecholamine), to quinones that then polymerize to melanin.

C. neoformans has provided an excellent model to understand the role of melanin in pathogenicity. Melanization has been associated with protection of *C. neoformans* against environmental stressors, including ultraviolet radiation, temperature extremes, oxygen and nitrogen free radicals, silver nitrate (a toxic heavy metal in the environment), and enzymatic degradation by predator microbes in the environment. The diverse protective effects of melanin likely have dual roles in facilitating survival of *C. neoformans* in the environment and in animals. Laccase, an essential enzyme for melanin synthesis in *C. neoformans*, is tightly associated with the cell wall and accessible for interaction with host cells. Salas et al. showed that the laccase gene *CNLAC1* was an essential virulence factor in cryptococcal infection in mice.

Melanin may also have an anti-inflammatory role facilitating evasion of host defense. Synthetic melanin reduced the production of several proinflammatory cytokines (TNF-α, IL-1B, and IL-6) following stimulation of monocytes with endotoxin. By conferring protection against reactive oxidant and nitrogen species, it may enhance the ability of *C. neoformans* to survive within host phagocytes. Melanins may also reduce susceptibility of fungi to antifungal agents. Van Duin et al. showed that nonmelanized *C. neoformans* and *H. capsulatum* had increased susceptibility to amphotericin B and caspofungin. Fungal melanins bind to amphotericin B and caspofungin in vitro, which may attenuate their antifungal activity.

REACTIVE OXYGEN AND NITROGEN INTERMEDIATES Host phagocytes produce reactive oxygen and nitrogen intermediates in response to infection. To survive in this milieu, mechanisms that scavenge or detoxify reactive intermediates are essential. Superoxide dismutases (enzymes that catalyze the conversion of superoxide to hydrogen peroxide) and catalases (enzymes that detoxify hydrogen peroxide) are produced by most bacteria and fungi. *C. albicans* possesses an inducible nitric oxide defense mechanism involving flavohemoglobin genes. Melanin may also scavenge reactive oxygen and nitrogen intermediates in *C. neoformans*.

Narasipura et al. showed that a strain of *C. neoformans* deficient in the Cu, Zn superoxide dismutase gene *(SOD1)* was more susceptible to neutrophil killing in vitro and had attenuated virulence in a mouse model. The *SOD1* null mutant was also deficient in laccase, urease, and phospholipase, raising the possibility that *SOD1* has a signaling role related to the expression of other virulence genes.

The essential role of reactive oxygen intermediates in host defense is illustrated in CGD, an inherited disorder of the NADPH oxidase characterized by recurrent life-threatening bacterial and fungal infections, almost all of which produce catalase. The importance of catalase in the CGD pathogens was posited to relate to the ability of catalase to scavenge the pathogen-produced hydrogen peroxide within the CGD phagolyosome. Activation of the NADPH oxidase in neutrophils leads to the release of cationic granule proteins into the phagolysozome, among which are elastase and cathepsin G that are bound to the anionic proteoglycan matrix in the inactivated state. Mice deficient in the cationic granule proteins (but with an intact NADPH oxidase) recapitulate the CGD phenotype in terms of susceptibility to bacterial and fungal infections. Activation of preformed granule proteases is likely to be one of the principal mechanisms of NADPH oxidase-mediated host defense. Catalase-deficient *Aspergillus nidulans* were just as virulent as the wild-type strain in experimental pulmonary infection in the $p47^{phox-/-}$ mouse model of CGD. This finding raises the possibility of redundant pathogen-derived reactive oxygen scavengers that may compensate for the lack of catalase.

Gliotoxin, a toxin produced by *A. fumigatus* and other fungi, has immunosuppressive properties that may facilitate evasion of host defense, including inhibition of the NADPH oxidase. It inhibits $p47^{phox}$ phosphorylation and its subsequent translocation to the membrane-bound flavocytochrome, a key step in NADPH oxidase assembly and activation. Gliotoxin also inhibits ingestion of *A. fumigatus* by macrophages, inhibits cytotoxic T-lymphocyte

cytotoxicity, induces apoptosis of thymocytes, splenocytes, and mesenteric lymph node cells, and can selectively deplete bone marrow of mature lymphocytes in mice. Gliotoxin inhibits activation of NF-κB (a transcriptional factor that is a key mediator of cytokine and inflammatory responses) in T and B cells. Stanzani et al. showed that *A. fumigatus* extract suppressed human cellular immune responses via gliotoxin-mediated apoptosis of antigen presenting cells; they suggest that in addition to evading host defense during infection, gliotoxin may cause a more global immunosuppression predisposing to other opportunistic infections.

ADAPTATION TO pH For organisms that grow over a wide range of pH, mechanisms are required to sense and respond appropriately. Pathogenic fungi usually encounter a wide range of pH in the environment and in animal hosts. *C. albicans* causes infection in diverse anatomic sites with different pH, including the oral cavity, gastrointestinal tract, and vaginal tract. Pathogenic fungi with a host intracellular stage may be exposed to the acidic environment within the phagolysozome. For example, *A. fumigatus* conidia can survive and germinate in the acidic phagosomes of respiratory epithelial cells in vitro.

The ability to respond to alkaline environments is governed by signal transduction pathways. The pacC pathway has been extensively studied as a model of pH regulation in *A. nidulans*. The *pal* gene family consists of six members encoding proteins that signal under alkaline conditions to activate by proteolytic cleavage the zinc finger transcriptional factor PacC. This in turn upregulates "alkali-expressed genes" and prevents the expression of "acid-expressed genes." Mutations inactivating *pacC* or the pal signaling pathway lead to absence of expression of alkaline genes and derepression of acid genes, resulting in "acidity mimicry." Constituitively expressed *pacC* mutations, which bypass control of the pal pathway, lead to constant activation of alkaline genes, "alkaline mimicry." *pacC* has homology to other transcription factors, including the inflammatory regulator NF-κB and the sterol regulatory element binding protein that mediates lipid metabolism.

Homologues of the pal/pacC system are present in a variety of filamentous fungi, *S. cerevesia*, and *Candida* spp. Ramon et al. showed that *CaRIM101*, the *pacC* homologue in *C. albicans*, is activated under alkaline conditions. Null mutants were unable to regulate gene expression in response to pH and were defective in filamentous growth, a key virulence factor. CaRIM101 null mutants had attenuated virulence in mice and were less damaging to endothelial cells than wild-type strains. The CaRIM101 pathway also mediates pH-independent responses, including resistance to high concentrations of lithium and to the drug, hygromycin B.

CALMODULIN AND CALCINEURIN Calcium signaling via calmodulin and calcineurin is critical for regulation of stress responses in fungi. Calmodulin is a 17-kDa Ca^{2+} binding protein that is highly conserved throughout evolution that regulates transcription factors, protein kinases, phosphatases, and cytoskeletal components. Calcineurin is a serine–threonine phosphatase that is also highly conserved, is activated following binding with Ca^{2+}/calmodulin, and has important cell signaling functions.

Studies in *C. albicans* and *C. neoformans* show that calcineurin is important for virulence, but acts through distinct mechanisms in each fungus. In *C. albicans*, Ca^{2+}/calmodulin signaling is important for transition from the yeast to the filamentous form. *C. albicans* calcineurin mutants had significantly reduced virulence in systemic infection in mice. Calcineurin was not required for survival at 37°C, filamentation, host-cell adhesion and invasion, or germ tube formation, but was required to colonize and grow in kidneys of infected animals and to grow in serum in vitro. In contrast, in *C. neoformans* calcineurin is required for growth at 37°C and for maintenance of cell-wall integrity. Strains lacking calcineurin are avirulent in animal models.

Calcineurin inhibitors (cyclosporin A and tacrolimus) are used widely as immunosuppressive agents to prevent rejection of transplanted organs and GVHD. These agents have antifungal activity in vitro against *C. albicans, C. neoformans, S. cerevesiae,* and *A. fumigatus*, and can act synergistically with existing antifungal agents. Development of fungal-specific calcineurin inhibitors merits further study, but may be limited by the significant homology of eukaryotic calcineurins.

Heat shock proteins (HSP) are molecular chaperones that are often upregulated during physiologic stress and regulate folding, transport, and degradation of a diverse set of client proteins, many of which function in cell signaling. Cowen and Lindquist showed that fungal Hsp90, in combination with its client protein, calcineurin, exerts distinct effects on drug resistance in evolutionarily distant fungal pathogens. It potentiated the emergence of resistance to fluconazole (a cell membrane acting agent) in *S. cerevisiae* and *C. albicans* by enabling mutations in the ergosterol biosynthetic pathway to have immediate phenotypic effects. Hsp90 was also required for resistance to an echinocandin (a cell wall acting agent) in *Aspergillus terreus*. Hsp90 likely confers resistance by enabling adaptive changes in protein structure in response to drugs that alter the fungal cell membrane and cell wall. That Hsp90-mediated drug resistance is exerted through calcineurin raises the prospect of novel drug combinations that pair inhibitors of these "stress" pathways with "conventional" antifungal agents that target fungal biosynthetic pathways.

PATHOGEN RECOGNITION AND POTENTIAL FOR IMMUNE AUGMENTATION

Toll-like receptors (TLR) are a conserved family of receptors that recognize common protein and DNA pattern motifs present in microbes, and initiate signaling for cytokine production and T-cell and DC maturation. During phagocytosis, TLRs recognize pathogen specific motifs within the vacuole, distinguish between pathogens, and trigger an appropriate inflammatory response. TLRs have homology to IL-1R1 and share a similar signaling cascade leading to activation of NF-κB and mitogen activated protein kinases, a process that mediates gene expression and regulation of inflammatory responses.

TLR-dependent antifungal pathways are highly conserved in nature as demonstrated by their presence in Drosophila. TLRs recognize motifs on *Candida* and *Cryptococcus* species and regulate inflammatory responses. TLR4-defective mice are more susceptible to *C. albicans* infection, and this is associated with impaired chemokine expression and neutrophil recruitment.

Aspergillus conidia, but not hyphae, stimulate macrophages to produce proinflammatory cytokines TNF-α and IL-1 in a TLR4-dependent fashion. In contrast, *Aspergillus* hyphae, but not conidia, stimulated production of the anti-inflammatory cytokine IL-10 through TLR2-dependent mechanisms. The authors consider that this switch from a proinflammatory to an anti-inflammatory state during germination may help *Aspergillus* evade host defense. Wang et al. reported that both CD14 and TLR4, but not TLR2, mediate activation of human monocytes by *A. fumigatus* hyphae. Other investigators found that both TLR2 and TLR4 recognize *Aspergillus* hyphae, stimulate proinflammatory cytokines in effector cells, and stimulate neutrophil recruitment.

Bozza et al. showed that DCs pulsed with *Aspergillus* antigens activated CD4+ Th1 cells capable of conferring resistance to infection. Local delivery of unmethylated CpG oligodeoxynucleotides (which signal through TLR9) and the Asp f 16 *Aspergillus* allergen resulted in activation of airway DCs capable of inducing Th1 priming and resistance to the fungus. Romani et al. showed that thymosin α-1, a naturally occurring thymic peptide, induced maturation and IL-12 production in DCs pulsed with *Aspergillus*, an effect mediated by distinct TLRs. In mice, thymosin α-1 augmented Th1 immunity against *Aspergillus*, accelerated myeloid recovery in neutropenic mice, and was protective against *Aspergillus* challenge in bone marrow transplant recipients. These studies provide a rationale to stimulate or inhibit specific classes of TLRs as a means of enhancing immune effector functions to fungi.

Pentraxins (PTX) are a superfamily of conserved proteins characterized by a cyclic multimeric structure. PTX3 is produced as a 10- to 20-subunit multimer by macrophages and other cells after stimulation by lipopolysaccharide, IL-1, or TNF-α. Similar to TLRs, PTX3 is a pathogen recognition protein, binding to specific pathogens including *P. aeruginosa*, *Salmonella typhimurium*, and *A. fumigatus*. Genetically engineered PTX3-deficient mice were highly susceptible to *Aspergillus* infection. These mice demonstrated defective recognition of conidia by alveolar macrophages and DCs, as well as inappropriate induction of type 2 cytokine responses. Administration of PTX3 protected against *Aspergillus* challenge in mice that had undergone T-cell depleted allogeneic bone marrow transplantation, and potentiated the effect of subtherapeutic dosing of amphotericin B.

Vaccine development is a priority for several fungal pathogens, including *Candida* spp., *C. neoformans*, *Aspergillus* spp., and the dimorphic fungi, *H. capsulatum*, *C. immitis*, and *B. dermatiditis*. This requires knowledge about host–pathogen interactions and mechanisms that the pathogen has evolved to evade host defense and survive in a hostile environment. Knowledge about specific mechanisms (virulence factors) that the pathogen uses to colonize, invade, and proliferate in the host sheds light on potential targets for drug development and immunotherapy.

ANTIFUNGAL DRUGS AND DRUG DISCOVERY

The need for new antifungal agents stems from the increased frequency of invasive fungal infections in the highly immunocompromised and the inadequacy of current antifungal regimens. This is particularly acute in invasive aspergillosis and other filamentous fungal infections. Despite the long-standing availability of amphotericin B, a potent fungicidal agent acting principally at the level of the fungal cell membrane, the prognosis of invasive aspergillosis has been poor. In a review of 595 patients with invasive aspergillosis, a complete response occurred in only 25% and death resulting from or with aspergillosis in 65% of patients treated with amphotericin B. Lipid formulations of amphotericin B, which allow for greater amounts of drug delivery with less toxicity, may provide a more favorable prognosis. Amphotericin B colloidal dispersion had similar efficacy, decreased nephrotoxicity, and increased infusional toxicity compared with conventional amphotericin B in a randomized study of primary therapy for invasive aspergillosis.

There have been important new developments in antifungal agents. Voriconazole, posaconazole, and ravuconazole are second generation triazoles, but currently only voriconazole is licensed (October, 2005). These agents are active against *Candida* spp. (including most isolates resistant to fluconazole), *Aspergillus* spp., *Scedosporium* spp., dark-walled moulds, *Fusarium* spp., and dimorphic fungi. Voriconazole was more effective at controlling invasive aspergillosis and had increased survival compared with conventional amphotericin B. However, the poorest prognosis occurred in allogeneic HSCT recipients in whom only 32% of patients receiving voriconazole and 13% receiving amphotericin B had successful outcomes.

Echinocandins target glucan synthase, resulting in depletion of glucan, a major fungal cell-wall constituent. Caspofungin and micafungin are licensed echinocandins, and anidulafungin is being evaluated in a phase III trial in invasive candidiasis. The echinocandins have an excellent safety profile. They are potently cidal against virtually all *Candida* spp., including azole-resistant strains. Caspofungin was at least as effective and significantly safer than amphotericin B as therapy for candidemia and invasive candidiasis. Caspofungin as salvage therapy for invasive aspergillosis led to a favorable response in 37 (45%) of 83 patients.

There has been significant interest in combination antifungal therapy pairing an echinocandin with either an amphotericin B preparation or an azole with activity against *Aspergillus* spp. The rationale is that echinocandins target a unique site (the B-glucan constituent of the fungal cell wall) distinct from the polyenes and azoles that target the fungal cell membrane. Marr et al. recently reported a survival advantage of voriconazole plus caspofungin compared with voriconazole alone in a retrospective analysis of salvage therapy for invasive aspergillosis. This database, though encouraging, involved small numbers of patients and the two groups of patients evaluated were noncontemporaneous; therefore, other host and infection-related factors may have influenced the outcome. A randomized, prospective study is required to definitively assess the benefit of combination antifungal therapy in invasive aspergillosis. Table 95-1 summarizes common clinical uses of antifungal agents and recently completed trials.

There are numerous classes of antifungal agents with different mechanisms of action in preclinical development (Fig. 95-2). These include a wide variety of naturally produced and synthetic antifungal peptides with antifungal activity. For example, nikkomycin Z inhibits chitin synthase leading to depletion of chitin, a major fungal cell-wall constituent. Nikkomycin is potently active against *C. immitis*. It has weak activity when used alone against *Aspergillus* species, but is potently synergistic when combined with an echinocandin.

Fungal genomics offer an outstanding opportunity to develop novel antifungal agents that are complementary to traditional drug screening methods focused on existing targets. The diploid genomic sequence of *C. albicans* and the genomic sequence of *C. neoformans* and *A. fumigatus* are at advanced stages of completion and annotation (www.tigr.org), and sequencing of *C. immitis* is underway. DNA microarray chips for *A. fumigatus* are now being made available to investigators through The Institute for Genomic Research through a contract from the National Institutes of Allergy and Infectious Diseases. Emerging experimental analysis tools, such as chemogenomics, fitness profiling, transcript profiling, and proteomics will further enhance the analysis of genome-wide functional studies.

It would be ideal to characterize fungal genomics in vivo after experimental infection in animals. However, purifying adequate levels of fungal RNA and separating it from mammalian contami-

Table 95-1
Systemic Antifungal Agents

Antifungal agents	*Comments*
Azoles	
Fluconazole	Acceptable alternative to amphotericin B for candidemia at dose of 400 to 800 mg/d; broad range of MICs to *C. glabrata*; *C. krusei* is resistant; prophylaxis in high-risk patients (e.g., acute leukemia during neutropenia, hematopoietic transplantation); maintenance therapy for cryptococcal meningitis; inactive against filamentous fungi.
Itraconazole	Active against *Candida* sp., *Aspergillus* sp., dimorphic fungi, dark-walled moulds. Cyclodextrin formulation has ↑bioavailability compared with capsules and can be administered parenterally. Itraconazole solution approved for empirical therapy for neutropenic fever.
Second generation azoles	Second generation antifungal triazoles (voriconazole, posaconazole, and ravuconazole) have broad spectrum of activity, including *Candida* spp. (including most, but not all, fluconazole-resistant isolates), *Aspergillus* spp., dimorphic fungi, *C. neoformans*, *Trichosporon* spp., *Fusarium* spp., *P. boydii*, and dark-walled moulds.
Voriconazole	New standard of care as initial therapy for invasive aspergillosis; treatment of other filamentous fungi resistant to amphotericin B (*Fusarium* sp, *P. boydii*, and dark-walled moulds); poor activity against zygomycetes; acceptable alternative to amphotericin B formulations as empirical therapy for neutropenic fever; similar efficacy compared with amphotericin + fluconazole in non-neutropenic patients with candidemia.
Posaconazole[a]	Similar spectrum of activity to voriconazole, but active against zygomycetes; growing clinical database from compassionate use protocols for treatment of *Aspergillus* spp. and other refractory filamentous fungi (*Fusarium* spp., *P. boydii*, and dark-walled moulds). Phase III studies evaluating posaconazole as prophylaxis in high-risk neutropenic patients and in allogeneic HSCT recipients with GVHD have completed enrollment.
Ravuconazole[a]	Phase I–II study as prophylaxis in HSCT recipients has completed enrollment.
Polyenes	
Nystatin	Topical agent useful for mucosal candidiasis; parenteral liposomal nystatin is experimental
Amphotericin B desoxycholate (AMB-D)	Broad spectrum of antifungal activity, but with significant infusion-related and nephrotoxicity
Lipid formulations of amphotericin B	Equal to or superior efficacy and ↓ toxicity compared with AMB-D; ↑↑pharmacy acquisition cost
Liposomal amphotericin B (LAMB)	↓ proven breakthrough fungal infections and ↓infusion- and nephrotoxicity vs AMB-D as empirical therapy for persistent neutropenic fever; ↓ infusion- nephrotoxicity vs amphotericin B lipid complex as empirical therapy
Amphotericin B lipid complex (ABLC)	Extensive compassionate use database for patients with refractory invasive fungal infections or intolerance to AMB-D; successfully used in hepatosplenic candidiasis in pediatric patients; ↑↑ levels in reticuloendothelial system
Amphotericin B colloidal dispersion	Similar efficacy, ↓ nephrotoxicity, but ↑ infusion toxicity vs AMB-D in a randomized study of primary therapy for invasive aspergillosis and in a randomized study of empirical therapy for persistent neutropenic fever
5-flucytosine (5-FC)	Randomized studies support combination AMB-D and 5-flucytosine for cryptococcal meningitis; pyrimidine analog with dose- and duration-dependent myelotoxicity and gastrointestinal toxicity; monitoring of serum levels and adjustment of dosing for azotemia required
Echinocandins	Class of antifungal peptides that inhibit synthesis of glucan, a fungal cell wall constituent; potently cidal against *Candida* spp, including fluconazole-resistant; fungistatic against *Aspergillus* spp, principally acting at growing hyphal tips; infrequent infusion-related events and not nephrotoxic
Caspofungin	Compassionate use study of patients with refractory invasive aspergillosis or intolerance to licensed antifungal agents showed 41% successful responses (superior to carefully-matched historical controls) led to approval for this indication; favorable rate of successful outcomes and ↓ toxicity vs AMB-D for invasive candidiasis; comparable efficacy and ↓ toxicity vs LAMB as empirical therapy for neutropenic fever
Micafungin	Reduced frequency of empirical antifungal therapy and trend toward ↓ invasive aspergillosis compared with fluconazole in HSCT recipients
Anidulafungin[a]	Similar efficacy to fluconazole in AIDS-associated *Candida* esophagitis; effective in phase II study of candidemia; data from phase III candidemia trial being analyzed
Terbinafine	Inhibits ergosterol synthesis; mostly used to treat dermatophyte infections

[a]Nonlicensed compounds as of October, 2005.

This table is modified from: Segal BH, Walsh TJ, Gea-Banacloche JC, and Holland SM. Infections in the cancer patient. (Chapter 53, Table 53-5) in Cancer: Principles and Practice of Oncology, 7th edition. Editors: DeVita VT Jr., Hellman S, Rosenberg SA Lippincott Williams & Wilkins, Philadelphia, PA, 2005.

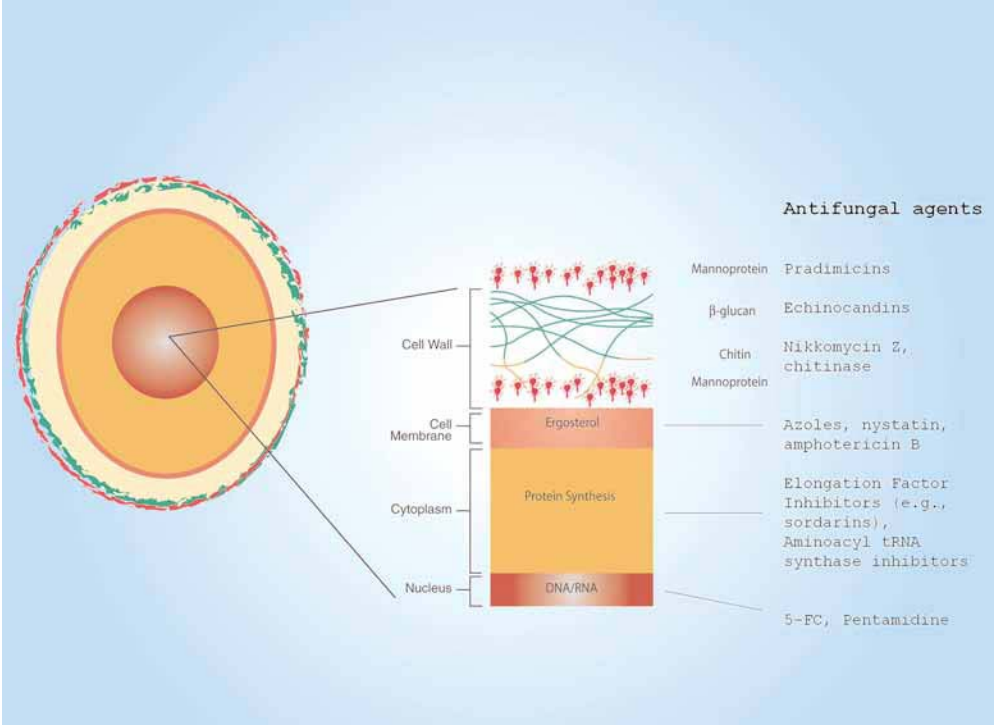

Figure 95-2 Targets of antifungal agents. The drawing includes both licensed (azoles, amphotericin B, echinocandins, 5-FC) and experimental antifungal agents (e.g., nikkomycin Z and sordarins). There is significant interest in combination antifungal regimens using agents with different targets that may interact synergistically.

nation is very difficult. An alternative method is to study gene profiles under conditions that may (imperfectly) simulate mammalian infection. This may involve studying changes in gene profiles that occur in response to temperature, pH, fungal morphogenesis, and adhesion to endothelial cells in vitro. Promising genes that may mediate these phenotypes and their importance to virulence can further be characterized by examining the pathogenicity in genetically engineered null mutants.

Antifungal agents cause broad changes in gene expression profiles in *S. cerevisiae* and *C. albicans*. Characterizing specific gene profiles that result from single and combination antifungal regimens will enable us to identify pathways that the pathogen uses to remain viable under the stress of a given antifungal regimen, and thus help to prioritize the development of specific inhibitors of these pathways. For example, increased production of cell-wall chitin compensates for the defects in assembly of cell-wall glucans in the ggp1δ mutant of *S. cerevisiae*. This strain shows increased susceptibility to nikkomycin Z, a chitin synthase inhibitor. The combination of an echinocandin (a glucan synthase inhibitor) and nikkomycin Z would simultaneously target both glucan and chitin synthesis, and would be expected to cause greater loss of cell-wall integrity than either agent alone. The combination may also elicit unique pathogen gene profiles whose products may be promising targets for drug discovery.

Indeed, as new classes of antifungal agents are developed, there will be a need for effective in vitro modeling of multiple antifungal agents against a target pathogen (demonstrating synergy, neutrality, or antagonism) that will predict efficacy in vivo. The inconsistent correlation between in vitro and in vivo results is a key limitation, and emphasizes the need for novel and improved methods for modeling antifungal agents.

DERMATOLOGY XII

SECTION EDITORS:
LUIS A. DIAZ AND LOWELL A. GOLDSMITH

Abbreviations

XII. DERMATOLOGY

ABCDE	asymmetry, irregular borders, color variegation, diameter
ACE	angiotensin converting enzyme
ACR	american College of Rheumatology
AD	autosomal-dominant
AF	anchoring filament
AI	amelogenesis imperfecta
ANA	antinuclear antibodies
AP-3	adaptor protein-3
APC	antigen-presenting cell
APCs	antigen-presenting cells
APL	atrichia with papular lesions
AR	autosomal-recessive
ARF	alternate reading frame protein
ASA	argininosuccinic aciduria
AT	ataxia telangiectasia
Atp7a	mouse mottled gene
AVM	arteriovenous malformation
BASC	BRCA1-associated genome surveillance complex
BCC	basal cell carcinoma
BCIE	bullous congenital ichthysiform erythroderma
BCNS	basal cell nevus syndrome
BLOC	biogenesis of lysosome-related organelles complex
BMPs	bone morphogenetic proteins
BMZ	basement membrane zone
BP	bullous pemphigoid
BPAG1	230-kDa bullous pemphigoid antigen
BPAG2	180-kDa bullous pemphigoid antigen
cAMP-PDE	cyclic adenosine monophosphate-phosphodiesterase
CBF	CCAAT-binding factor
CDSN	corneodesmosin
CDSN	corneodesmosin gene
CGH	comparative genomic hybridization
CGRP	calcitonin gene-related peptide
CHRPE	congenital hypertrophy of the retinal pigment epithelium
CHS	Chédiak-Higashi syndrome
CMN	congenital melanocytic nevus
CNS	central nervous system
COL17A1	Type XVII collagen
COX-2	cyclo-oxygenase-2
CP	cicatricial pemphigoid
CsA	cyclosporine A

Immune Mediated

96 Psoriasis

JAMES T. ELDER

SUMMARY

Psoriasis is a chronic, inflammatory and hyperproliferative disease of the skin, scalp, nails, and joints. There is wide agreement that psoriasis is driven by interactions between the innate and acquired immune systems. However, the root cause of psoriasis remains unclear. This chapter reviews psoriasis' protean clinical manifestations, diagnosis, differential diagnosis, and management, and what has been accomplished to solve its long-standing riddle, particularly in the areas of immunology and genetics.

Key Words: Corticosteroids; emollients; joints; methotrexate; nails; psoriasis; skin.

INTRODUCTION

Psoriasis is a chronic, inflammatory and hyperproliferative disease of the skin, scalp, nails, and joints, affecting 1–2% of the US population. It is found worldwide; its frequency varies from 0 to 3% among different ethnic groups. Most of its variable clinical presentations eventuate into erythematous, scaly plaques with or without nail disease and arthritis. Susceptibility to psoriasis is unmistakably heritable, but the phenotype is controlled by multiple genes as well as environmental factors. Trauma, stress, and infections are important determinants of disease onset and severity. At the cellular level, psoriasis is characterized by markedly increased epidermal proliferation and incomplete differentiation; elongation, dilatation, and "leakiness" of the superficial plexus of dermal capillaries; and a mixed inflammatory and immune cell infiltrate of the epidermis and papillary dermis. A multitude of plausible pathomechanisms have been envisaged for psoriasis, with early concepts focusing on the now epidermal hyperplasia characteristic of this disease. There is wide agreement that psoriasis is driven by interactions between the innate and acquired immune systems in the skin and joints. However, the root cause of psoriasis remains unclear. This chapter reviews psoriasis' protean clinical manifestations, diagnosis, differential diagnosis, and management, and what has been accomplished to solve its long-standing riddle, particularly in the areas of immunology and genetics.

CLINICAL FEATURES

HISTORY Psoriasis was first clearly described by Celsus (25BC–45AD), and conditions resembling psoriasis are present in the works of Hippocrates. In 1809 Robert Willan was the first to accurately describe the various forms of psoriasis; in 1818 Alibert noted its association with a distinctive form of arthritis.

SKIN Several types of psoriatic skin lesions are recognized, including chronic plaque, guttate, pustular, inverse, palmoplantar, and generalized (Fig. 96-1). Of these, chronic plaque lesions are by far the most common, and over time, most other forms eventuate into chronic plaque disease. The typical chronic plaque is a well-demarcated, erythematous lesion with loose, silvery scale that can vary from a few millimeters to many centimeters in diameter. Lesions are typically located over the extensor surfaces of the extremities and scalp and often display striking symmetry. The next most common form is *eruptive*, or *guttate psoriasis* (Latin *gutta*, "drop"), which appears rapidly as tens to hundreds of 5- to 10-mm papules on the trunk and proximal extremities. Usually seen in young patients following a streptococcal or other upper respiratory tract infection, guttate psoriasis has been strongly associated with human leukocyte antigen (HLA)-Cw6.

NAILS Psoriasis produces distinctive nail changes in approx 50% of psoriasis patients, including *pitting*, *onychodystrophy* (destruction of the nail plate), and *"oil drop" spotting* (Fig. 96-2A). *Pits* are 1- to 2-mm depressions in the surface of the nail plate produced by defective terminal differentiation of keratinocytes in the nail matrix. Onychodystrophy arises from disease of the nail bed and ranges from separation of the nail plate (onycholysis) to thick, yellowish, crumbly nails, to complete loss of the nail. *Oil-drop spots* are orangish to brown discolorations underneath the nail, resulting from the leakage of serum proteins through the nail bed capillaries.

JOINTS Essentially the only systemic manifestation of psoriasis, psoriatic arthritis typically presents between the ages of 35 and 45, usually but not always after onset of skin disease. Estimates of the prevalence of arthritis in psoriatic patients range from 5 to 40%, which is at least three times that of the general population. Disease is often oligoarticular and asymmetric, and tends to be most severe in the small joints of the hands and feet and the large joints of the legs (Fig. 96-2B,C). The rheumatoid factor is almost always negative. *Enthesopathy* is the result of inflammatory cell accumulation at tendon or ligament insertions, and can progress to involve the entire digit, producing "sausage digit." Fortunately, only approx 5% of psoriatic arthritis patients develop highly severe, deforming joint disease (*arthritis mutilans*).

COURSE The natural history of psoriasis is unpredictable. Onset is usually in childhood to the early twenties, with a median age of 15–20 yr; great than 90% of cases present by the age of 40.

Note thick, adherent scale and sharp cutoff at the hairline. (Photos courtesy of Harrold Carter and James Rasmussen.)

Typically, lesions wax and wane, and might reappear in the same or different locations. At some point in their lives, approx 25% of patients experience a complete remission, which might last from 1 to 50 yr. The *Köebner phenomenon* (*isomorphic response)* refers to the tendency of psoriasis to arise at sites of cutaneous injury. The phenomenon is reported by 25% of patients, requires epidermal and possibly high dermal injury, and is usually seen in the setting of flaring rather than stable or regressing disease.

DIAGNOSIS

CLINICAL EVALUATION Based on the clinical features described earlier, the diagnosis of psoriasis is generally straightforward. The Auspitz sign (pinpoint bleeding on removal of scale) is well known but neither sensitive nor specific for psoriasis. Fungal infection, seborrheic dermatitis, chronic eczema, candidiasis, cutaneous T-cell lymphoma, drug eruptions, syphilis, pityriasis rosea, lichen planus, and lupus erythematosus can present an occasional diagnostic challenge. Skin biopsy can be useful in these cases.

HISTOPATHOLOGY The histopathological features of psoriasis are variable yet distinctive (Fig. 96-3). They include epidermal hyperplasia, loss of the granular layer with retention of keratinocyte nuclei (parakeratosis) with or without collections of neutrophils in the stratum corneum, dilatation and tortuosity of the superficial dermal capillaries, and a moderate mononuclear cell infiltrate of the epidermis and dermis.

LABORATORY Anti-streptolysin O titers suggestive of recent infection are found in 30–40% of psoriasis patients. Specific strains of *Streptococci* can often be recovered from intertriginous sites, and *Staphylococcus aureus* colonization is increased in frequency. Serum uric acid levels are also increased in approx one-third of patients, although frank gout is rare. None of these tests is specific enough to be of diagnostic value.

GENETIC BASIS OF DISEASE

GENETIC EPIDEMIOLOGY Twin studies and family studies provide strong evidence that susceptibility to psoriasis is controlled by genes. Inheritance patterns found in certain large psoriasis kindreds suggest autosomal-dominant inheritance with reduced penetrance. However, there are many other families that do not fit any mode of single-gene inheritance. The weight of evidence indicates that susceptibility to psoriasis is determined by multiple genes as well as environmental stimuli, known as *multifactorial* inheritance. The onset of psoriasis peaks between 15 and 25 yr, with onset before the age of 40 in 75–90% of patients. A smaller second peak is detectable at 65–70 yr of age. Psoriatic patients less than 40 yr old at onset are much more likely to have affected first-degree relatives (Fig. 96-4A), to express known HLA susceptibility alleles (Fig. 96-4B), and to experience severe and recurrent disease.

HLA ASSOCIATIONS WITH PSORIASIS HLA-B13, -B57, and -Cw6 (major histocompatibility complex [MHC] Class I), as well as HLA-DR7 and -DQ9 (MHC Class II), all show highly significant associations with psoriasis, especially in juvenile onset disease (*see* Fig. 96-4B). In other words, each of these alleles is present significantly more often in cases than in controls. This

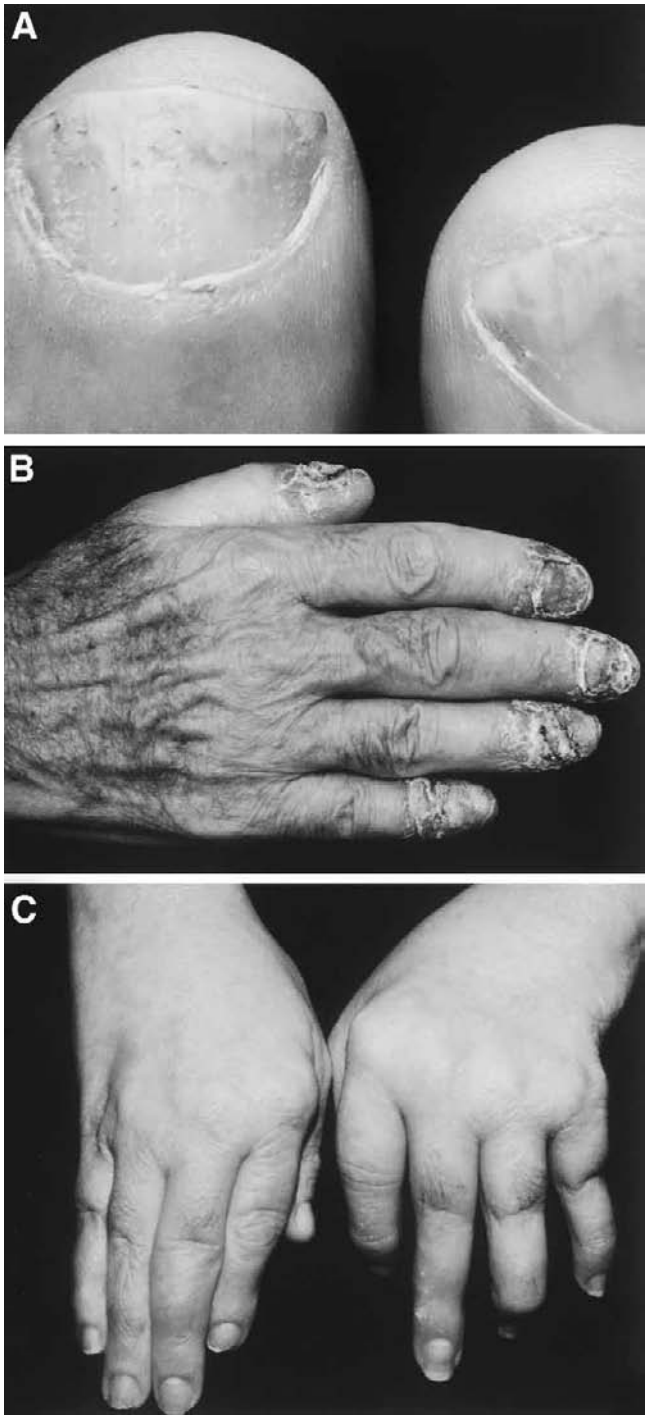

Figure 96-2 Psoriasis of the nails and joints. **(A)** Fingernail involvement. Note presence of pits, onycholysis, and oil-drop spotting. **(B,C)** Psoriatic arthritis. **(B)** Note fusiform swelling of the middle digit (enthesopathy), as well as accentuation of the distal interphalangeal joint involvement in association with severe nail disease. **(C)** Arthritis mutilans. reflects the presence of linkage disequilibrium (LD)—the tendency for particular alleles to be found on the same chromosome (haplotype) more often than would be predicted by chance. Strong LD extends across nearly the entire MHC. As a result, essentially all HLA haplotypes can be described in terms of recombinants of a relatively small number of "ancestral haplotypes." The allelic associations between psoriasis and HLA-B13, -B57, -Cw6, -DR7, and -DQ9 are well explained by known ancestral haplotypes (Fig. 96-5).

The existence of these associations is strong evidence for an MHC-linked determinant of psoriasis susceptibility, which has been named psoriasis susceptibility 1 (PSORS1). Highly significant evidence for PSORS1 has also been provided by genome-wide linkage scans. However, the strong LD characteristic of the MHC has complicated the search for the PSORS1 gene. There are approx 200 genes in the MHC, meaning that there are many potential candidates for PSORS1 other than the HLA genes themselves. Several laboratories have conducted LD studies using microsatellite repeats and single nucleotide polymorphisms in an effort to identify PSORS1. The objective has been to identify the shortest ancestral haplotype segment that retains the PSORS1 disease allele. These studies have implicated an interval of approx 600 kb extending from the tumor necrosis factor (TNF)-α gene to the STG gene and containing HLA-C. The critical interval has been refined to approx 300 kb, flanked centromerically by HLA-B and extending approx 50 kb telomeric to STG (Fig. 96-6). This interval contains 10 genes in addition to HLA-C, as well as several pseudogenes. The DNA sequence of this interval has been determined from two haplotypes known to confer risk of psoriasis, as well as five haplotypes known not to confer risk. Comparison of these sequences revealed that the only convincing coding sequence variations specific for the disease chromosomes are located in HLA-C and corneodesmosin. Both genes are attractive candidates, as HLA-C is involved in antigen presentation and in the regulation of natural killer (NK) cells, corneodesmosin is involved in epidermal differentiation, and both of these processes are markedly abnormal in psoriasis. Research is focused on determining which of these two genes carries the true risk allele. The hypothesis that both genes might jointly increase risk for psoriasis (perhaps together with additional genes on the same haplotype) is also being explored.

Psoriasis displays strong associations not only with HLA-Cw6, but also with another haplotype (HLA-B46-Cw1) common in Asia. Unlike HLA-Cw6, this haplotype does not appear to confer early age-of-onset. It is also important to note that psoriatic arthritis displays strong associations with HLA-B38 and HLA-B39 as well as with HLA-Cw6. Therefore, it seems likely that HLA-B and/or HLA-C alleles other than HLA-Cw6 can predispose to psoriasis and psoriatic arthritis. It will be important to elucidate what these alleles have in common, and how they differ.

NON-HLA GENES PSORS1 accounts for only approximately one-third of the total genetic liability to psoriasis, and only approximately 10% of individuals carrying HLA-Cw6 ever develop psoriasis. Several groups have carried out genome-wide linkage scans in search of non-MHC psoriasis loci. These scans have yielded multiple non-MHC candidate loci for psoriasis (PSORS2-9 and several unnamed loci). Only one locus outside the MHC has met generally accepted standards for independent linkage replication: PSORS2, located on chromosomal band 17q24-q25. The disease gene(s) residing in this interval remain(s) to be identified.

It is likely that several non-MHC genes, each of relatively small effect, act in concert with environmental factors to determine susceptibility to psoriasis. Such genes might regulate cutaneous immunity in general and might prove to be implicated in other inflammatory skin diseases such as atopic dermatitis. Many disease alleles are likely to be relatively old genetic variations common in the population and not highly penetrant. Because of their age, the disease alleles will be found in apparently unrelated

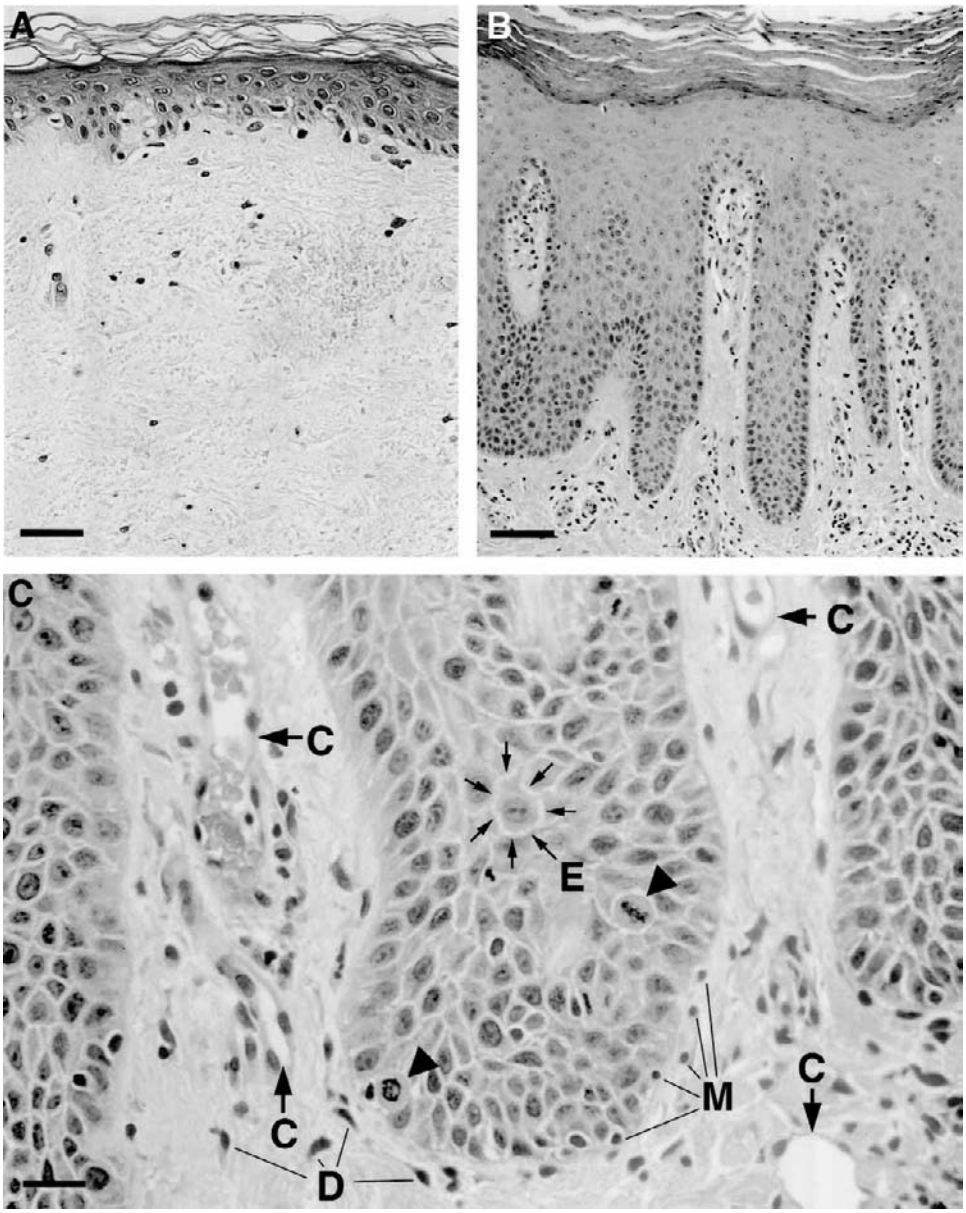

Figure 96-3 Histopathology of psoriasis. **(A)** Normal skin (scale = 60 μ). **(B)** Chronic plaque psoriasis (scale = 150 μ). Compared with normal skin, note striking regularity of epidermal downgrowth (acanthosis), loss of the granular layer, and retention of nuclei in the stratum corneum (parakeratosis). **(C)** Psoriasis lesion, high-power view (scale = 30 μ). families. These alleles will best be identified by tests of association (case–control, or family-based studies such as the transmission disequilibrium test), rather than tests of linkage. New technologies are emerging that will make systematic tests of association possible across the human genome, and they will be widely applied to psoriasis.

MOLECULAR PATHOPHYSIOLOGY OF DISEASE

Early lesions of psoriasis display mast cell degranulation and a modest lymphocytic infiltrate, as well as early inflammatory changes of capillary dilatation and papillary dermal edema. These changes appear to precede keratinocyte hyperplasia. The discovery that cyclosporine A (CsA) was effective in psoriasis provided functional evidence implicating T lymphocytes in this disease. Additional T-cell-specific immunosuppressants including FK 506, peptide T, anti-CD3 and -CD4 monoclonal antibodies, and cholera toxin-coupled interleukin (IL)-2 subsequently proved efficacious in limited studies, albeit not without side effects. Additional evidence for T cell involvement comes from reports of disease exacerbation after IL-2 and interferon (IFN)-γ therapy, and after bone marrow transplantation from a psoriatic donor. Conversely, complete clearing of severe psoriasis has been reported after transplantation from a nonpsoriatic donor. Also, the psoriatic phenotype can be induced after injection of $CD4^+$ T cells into symptomless psoriatic skin grafted onto immunodeficient mice. Thus, the case for T cell involvement is strong.

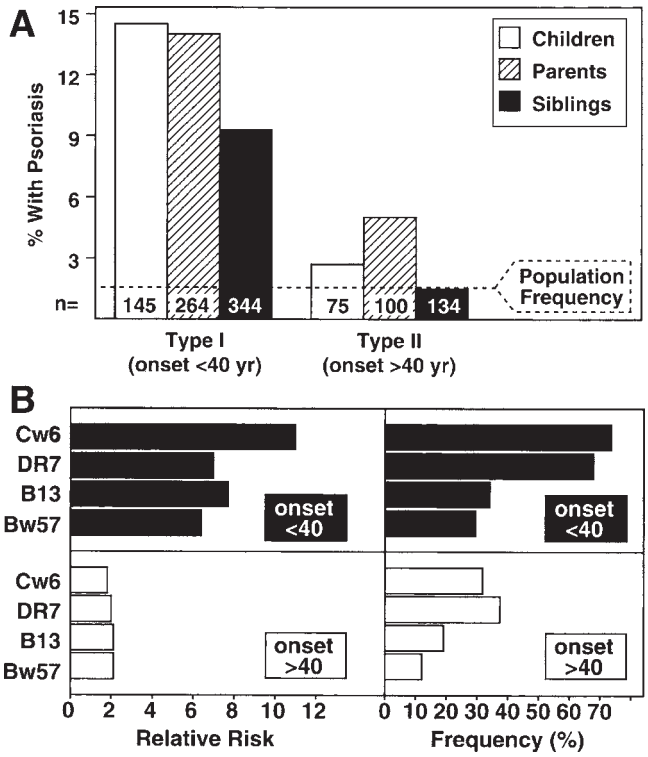

Figure 96-4 **(A)** Increased prevalence of affected relatives in early-onset (Type I) compared with late-onset (type II) psoriasis. **(B)** Increased relative risk and frequency of human leukocyte antigen-Cw6, DR7, B13, and B57 in juvenile onset psoriasis. Several lines of evidence argue for ongoing T-cell activation by antigen in the lesion itself. Psoriatic lesions contain increased numbers of activated dendritic antigen-presenting cells (APCs) and memory (antigen-activated) T cells. These memory T cells have been observed to proliferate in direct contact with APCs (Fig. 96-7). Also, expansion of T cells in psoriatic lesions is oligoclonal, as judged by the presence of specific rearrangements of the variable region of the β-chain of the T-cell receptor. These clones persist over time and in different lesions of the same patient, and are clearly expanded in skin lesions compared to the peripheral blood. This is the strongest evidence for ongoing T-cell activation by antigens (as opposed to cytokines alone) in psoriatic lesions. These observations fit with the genetic evidence implicating HLA-Cw6 in psoriasis, as HLA Class I molecules are involved in antigen presentation, and $CD8^+$ T cells, which recognize antigen in the context of HLA Class I, predominate in psoriatic epidermis. However, APCs usually take up antigens and present them in the context of MHC Class II, whereas MHC Class I is involved in the presentation of intracellular peptides such as those derived from viruses. An alternative pathology of "cross-presentation" has been implicated in tumor immunity. It is possible that this pathway is also involved in psoriasis.

Major abnormalities of APCs are also present in psoriatic lesions. APC numbers and activity are markedly increased in lesional psoriatic skin, and both are rapidly reduced by cyclosporine treatment. TNF-α stimulates maturation of immature Langerhans cells by promoting migration to the nodes and by inducing the key accessory molecules B7-1 (CD80) and B7-2 (CD86) on the surface of APC. These important molecules provide a "second signal" for T-cell activation (Fig. 96-8). TNF-α is also involved in recruiting a second class of APCs from the peripheral blood into the dermis once an infection is underway, and this class of APC appears to be markedly increased in psoriatic lesions. Once activated, T cells produce IFN-γ, which in turn stimulates APCs and monocyte/macrophages to produce TNF-α. TNF-α can also be directly produced by a subset of $CD8^+$ T cells. Thus, once activated, T cells appear to perpetuate a "vicious circle" of increased antigen presentation in psoriasis (*see* Fig. 96-7).

Shortly after activation by antigen, T cells differentiate along one of two pathways, termed T1 and T2. The T1 pathway evolved to activate macrophages to eliminate intracellular pathogens, whereas the T2 pathway evolved to promote antibody-mediated protection against extracellular parasites. Cytokines play a crucial role in determining not only which pathway a differentiating T cell will utilize, but also how that cell will regulate effector responses and how the balance between T1 and T2 differentiation will be maintained. IFN-γ and IL-12 can be considered key cytokines of the T1 pathway, whereas IL-4, -10, and -11 can be considered key cytokines of the T2 pathway. Expression of IFN-γ and IL-12 strongly predominate over IL-4, -10, and -11 in psoriatic lesions, indicative of a T1 pattern. Although the precise reason for T1 dominance is not clear, psoriasis can be triggered by streptococcal and viral infections of the upper respiratory tract, and APCs activated by viruses and certain bacteria produce large amounts of IL-12. In turn, IL-12 stimulates the production of IFN-γ by NK cells. Because NK cells are regulated by HLA-C and HLA-B, it is possible that the genetic defect at PSORS1 relates to inappropriate stimulation of NK cells, resulting in excessive production of IFN-γ and maintenance of the T1 state. Recently, IL-23 has also been implicated in psoriasis. IL-23 shares its p40 subunit with IL-12.

There appear to be three interrelated defects leading to the vicious circle of T-cell activation in psoriasis: (1) maintenance of antigen presentation at an inappropriately high level because of (2) a T1 state of T-cell differentiation dictated and maintained by the actions of IFN-γ and TNF-α. This chronic state of increased antigen presentation facilitates (3) breakdown of immunological tolerance, allowing self-peptides that resemble those of an initiating pathogen to cross-react with memory T cells activated by the initial, possibly infectious, stimulus.

As discussed, keratinocyte hyperproliferation is a prominent feature of psoriasis. Three theories have been advanced to explain how T-cell activation could trigger keratinocyte hyperproliferation in psoriasis. First, soluble factors from psoriatic T cells could stimulate keratinocyte proliferation. Second, keratinocytes might be injured by T cells as they invade the epidermis. Third, macrophages might perforate the basement membrane, leading to leakage of fibronectin into the epidermal compartment. Either of these latter events could activate the keratinocyte wound healing program, resulting in hyperproliferation. Activation of this program is accompanied by increased autocrine signaling through the epidermal growth factor receptor, leading to increased proliferation and upregulation of vascular endothelial growth factor. This, in turn, increases permeability and elongation of the dermal capillaries. Finally, cytokines such as IFN-γ and TNF-α stimulate keratinocytes to produce chemokines such as IL-8, which promote chemotaxis of polymorphonuclear leukocytes into the upper epidermis, and Mig and IP-10, which promote chemotaxis of T cells and macrophages into the dermis and epidermis. Thus, it appears that a persistent

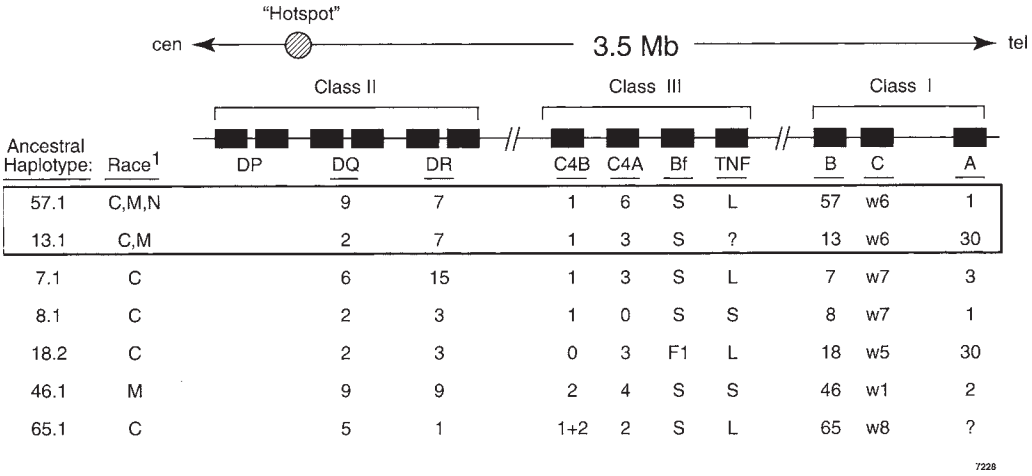

Figure 96-5 Map of the MHC, showing ancestral haplotypes. Depiction of MHC loci are incomplete and distances between them are not to scale. "Hotspot" indicates a region of high recombination resulting in loss of LD between HLA-DP and the remainder of the MHC. (Data from Degli-Epsoti et al., Immunogenetics 1992;36:345–356, Human Immunology 1992;34:242–252, and Wu et al., Hum Immunol 1992;33:89–97.) cen, centromere; tel, telomere; Mb, megabases; C, Caucasoid, M, Mongoloid; MHC, major histocompatibility complex; N, Negroid; TNF, tumor necrosis factor.

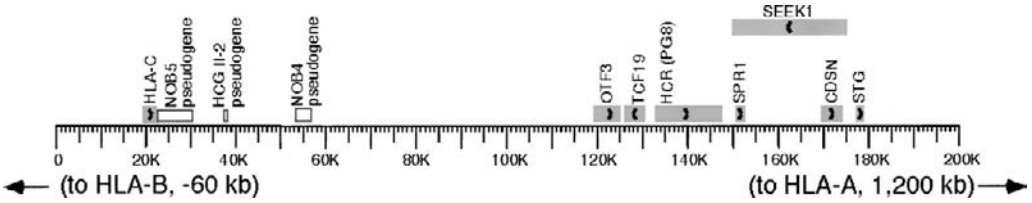

Figure 96-6 Gene map of the PSORS1 region. Note the existence of a cluster of genes extending from 100 to 160 kb telomeric to human leukocyte antigen-C. Open boxes indicate pseudogenes; shaded boxes indicate genes. Arrowheads indicate direction of gene transcription.

state of type 1 T-cell activation, centrally involving IFN-γ and TNF-α, can explain essentially all features of the chronic psoriatic plaque: T-cell activation, keratinocyte hyperproliferation, and vascular changes (*see* Fig. 96-7).

MANAGEMENT

In view of its genetic basis, lifelong duration, and low mortality, avoidance of toxicity is a cornerstone of psoriasis therapy. Treatment of moderate to severe psoriasis can entail substantial toxicity and demands thoughtful choices. Standard and novel psoriasis therapies are reviewed below in light of the immunological paradigm of psoriasis presented.

EMOLLIENTS Emollients have long played an important role in psoriasis therapy, presumably by improving barrier function. Loss of epidermal barrier function is a trigger for keratinocyte production of various proinflammatory cytokines including IL-8 and TNF-α.

CORTICOSTEROIDS/RETINOIDS/VITAMIN D Corticosteroids inhibit lymphocyte activation and the maturation of dendritic APCs. Systemic steroids were initially popular but are now little used because of their well-known systemic complications, as well as "rebound" flaring of disease on their withdrawal. In their stead, many different topical corticosteroid preparations of varying potency have been developed. Irrespective of their cellular site(s) of action, it is now clear that steroids, retinoids, and vitamin D derivatives exert their beneficial effects through binding to specific nuclear receptors, which serve as ligand-dependent transcription factors. The synthetic retinoid etretinate has been used to treat psoriasis systemically since the 1970s. Topical vitamin D3 derivatives and topical retinoids emerged as useful treatments for psoriasis in the 1990s. Steroids, retinoids, and vitamin D derivatives all have profound effects on keratinocyte growth and differentiation as well as on inflammation and immunity.

ULTRAVIOLET LIGHT Ultraviolet (UV) light treatment continues to be a mainstay of therapy for moderate-to-severe psoriasis. Therapy combining UVB light (290–320 nm) with crude coal tar was introduced in 1925, and the combination of psoralens with lower-energy UVA light (320–400 nm) followed in 1974. Initially, both psoralen UVA and B were thought to act directly on keratinocyte proliferation. However, both therapies induce immunosuppression, either by promoting apoptosis of activated T cells or by deviating the T-cell response from T1 to T2 through decreased production of IL-12 and increased production of IL-4.

METHOTREXATE Methotrexate is a highly effective oral antipsoriatic drug whose main dose-limiting toxicity is hepatic fibrosis. Methotrexate was initially thought to exert its effects through inhibition of keratinocyte proliferation. However, it is effective under doses and schedules of administration that fail to inhibit keratinocyte proliferation in vitro. It appears that this drug exerts profound anti-inflammatory effects by promoting the extracellular accumulation of adenosine.

CYCLOSPORINE/FK506 As discussed, CsA exerts potent antipsoriatic effects, with nearly immediate clearing of psoriasis when used in high doses. The drug is effective at doses as low as 2.5 mg/kg/d; however, renal toxicity is a problem even at low

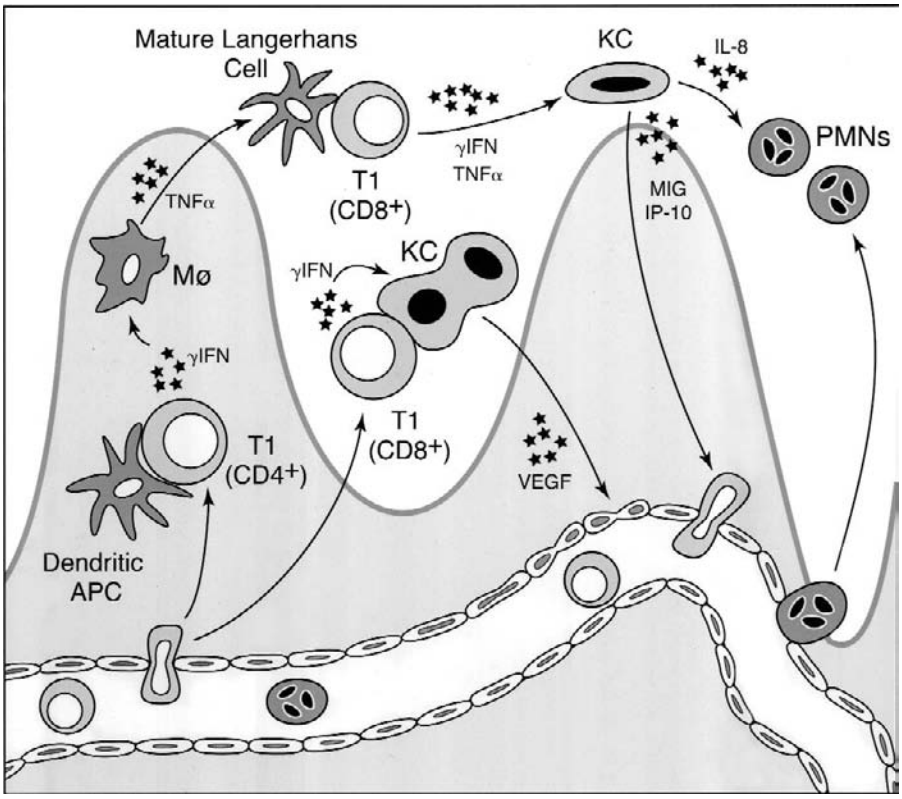

Figure 96-7 Immunopathogenesis of psoriasis. T cells are activated by mature Langerhans cells in the epidermis and by dermal dendritic cells in the dermis. T cells entering the lesion have a memory phenotype and are differentiated along the T1 pathway because of the influence of IL-12 produced by macrophages and dendritic cells, and interferon (IFN)-γ produced by T cells (and/or NK cells). Activated $CD8^+$ epidermal T cells can produce tumor necrosis factor (TNF)-α directly, whereas dermal $CD4^+$ T cells produce IFN-γ, thereby stimulating TNF-α production by macrophages (Mϕ) and dendritic APCs. IFN-γ might also promote keratinocyte proliferation, although epidermal injury produced by migrating epidermal T cells might also play an important role. Activated keratinocytes synthesize vascular endothelial growth factor, which might function to support the hyperactive dermal capillaries. The actions of IFN-γ and TNF on suprabasal keratinocytes cause them to secrete chemoattractants such as IL-8, Mig and IP-10. *See* text for additional details. doses with long-term use. CsA binds to cyclophilin, which is particularly abundant in T cells. The resulting complex inhibits the calmodulin-dependent protein phosphatase regulatory subunit calcineurin B, leading to the inability to translocate a component of the transcription factor NF-AT from the cytoplasm to the nucleus. This blockade of T-cell signaling greatly reduces the output of IL-2, which interacts with its receptor to expand the responding clone by stimulating T-cell proliferation. CsA also reduces expression of B7-1 and B7-2 and inhibits the production of IL-12 by dendritic APCs at clinically relevant doses. The former effect would reduce the overall levels of T-cell activation, whereas the latter would shift the T-cell maturation response from T1 to T2. FK506 is another calcineurin blocker, i.e., 5–10 times more potent than cyclosporine, but its therapeutic ratio is no better than that of CsA.

BIOLOGICALS Recombinant DNA and protein expression technologies have made it possible to manufacture large quantities of exact replicas of human proteins or fragments thereof, known as "biologicals," thereby avoiding the problem of hypersensitivity to foreign proteins. The principal biologicals in use are "humanized" monoclonal antibodies and fusion proteins. One type of fusion protein combines a human protein with a toxin, whereas the other fuses human receptors for proteins to the Fc portion of human immunoglobulin. A variety of immunosuppressive and anti-inflammatory proteins are being developed, and three have entered clinical use for the treatment of psoriasis and/or psoriatic arthritis, based on the immunopathological model of psoriasis previously presented. Because they are proteins, biologicals cannot be delivered orally or topically. Nevertheless, their target specificity allows them to be effective with only limited systemic toxicity, which is generally related to decreased immunological surveillance.

ANTI-TNF AGENTS Two anti-TNF-α biologicals have demonstrated substantial antipsoriatic efficacy in clinical trials: infliximab, a chimeric anti-TNF-α monoclonal antibody, and etanercept, a TNF-α receptor-immunoglobulin fusion protein. Etanercept has received FDA approval for use in psoriatic arthritis. With either agent, half to three-fourths of patients obtain a 75% reduction in involved total body surface area within 12 wk of treatment. This is approximately the same response obtained with cyclosporine, presumably because of interference with the antigen- and cytokine-driven vicious circle of T-cell activation depicted in Fig. 96-7.

Another biological approved for the treatment of psoriasis is alefacept, a fusion protein combining the extracellular domain of LFA-3 and the Fc portion of IgG. LFA-3 normally binds CD2 to provide T-cell costimulation (*see* Fig. 96-8). Alefacept might function by interfering with the CD2-LFA-3 interaction, or by causing NK cells to lyse $CD2^+$ memory T cells. Consistent with loss of

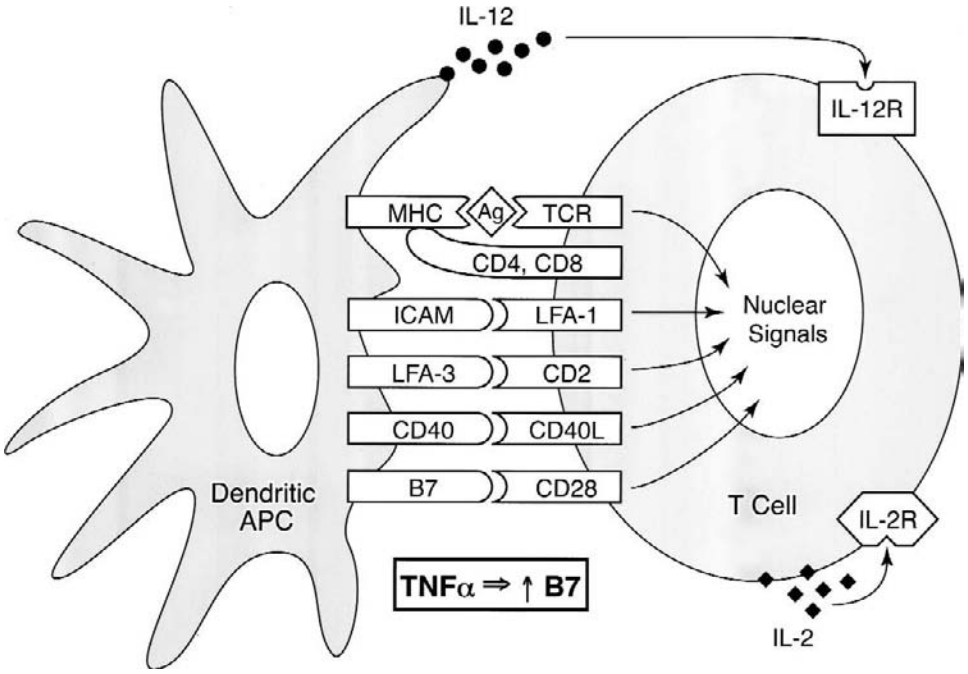

Figure 96-8 T-cell activation by APCs. The complex of antigenic peptide and major histocompatibility complex (MHC) binds to the T-cell receptor in the context of coreceptors CD4 (helper T-cells) or CD8 (suppressor/cytotoxic T-cells). The interaction of intercellular adhesion molecules and LFA-1 is critical for increasing the duration of the MHC-Ag-T-cell receptor recognition event, and is therefore depicted as part of the first signal. Interactions of CD2 with LFA-3, CD40 ligand (CD40L) with CD40, and CD28 with B7 send additional signals to the nucleus through different signal transduction pathways and are therefore called "Signal 2." When Signals 1 and 2 are received simultaneously, the T cell is activated, producing cytokines such as IL-2 and, in the case of psoriasis, IFN-γ, and TNF-α. IL-2 interacts with its own high-affinity receptor to promote T-cell proliferation, whereas IFN-γ and TNF-α support antigen presentation, keratinocyte proliferation, and the production of cytokines by keratinocytes (*see* text and Fig. 96-7). APC, antigen-presenting cell; TCR, T-cell receptor.

immunological memory, alefacept induces relatively long-term remissions in individuals who are helped by the drug.

Numerous additional biologicals are under development for psoriasis and other inflammatory disorders. These agents target various molecules responsible for T-cell activation and/or survival, control of the Th1/Th2 balance, or elaboration of the inflammatory response. Targets for blockade not already discussed earlier include LFA-1 and B7-1 (T-cell costimulation), CD3, CD4, IL-2 and IL-2 receptor (T-cell proliferation), IFN-γ, IL-12/IL-23, IL-12 (T-cell differentiation), and IL-8 (chemotaxis). In addition, IL-10 and -11 have yielded promising results in early therapeutic trials, as they should promote T2 differentiation.

FUTURE DIRECTIONS

The actions of nearly all antipsoriatic drugs can be understood in terms of immunosuppressive and/or anti-inflammatory effects, with T-cell activation as a likely primary target through the ternary complex of APC, antigen, and T-cell receptor in the context of appropriate accessory signals. Thus it is not surprising that various novel molecular approaches to blocking this activation event are in clinical trials. In addition to the biological agents described, studies suggest that picrolemus, an orally administered congener of FK506 that functions similarly to CsA, might be more specifically targeted to the skin than FK506. This agent might prove effective against psoriasis with fewer side effects than CsA.

As a genodermatosis, the question remains whether psoriasis will prove to be amenable to gene therapy. Direct correction of genetic defects might prove difficult if (as appears to be the case for PSORS1) the etiological allele is a common variant with important immunological functions. However, it might be feasible to introduce the various biologics discussed into the skin at the level of the gene, rather than the cognate protein. Under this scenario, gene therapy for psoriasis deserves serious consideration.

97 Atopic Dermatitis

Kefei Kang, Donald Y. M. Leung, and Kevin D. Cooper

SUMMARY

Atopic dermatitis, also known as atopic eczema, is a chronic inflammatory skin disease frequently seen in patients with a personal or family history of asthma and allergic rhinitis. There have been extraordinary strides made in the understanding of the immunopathogenesis of allergic diseases. In particular, this constellation of inherited illnesses is associated with activation of a specific group of cytokine genes encompassing IL-3, IL-4, IL-5, IL-13, and granulocyte-macrophage colony-stimulating factor. The molecular basis for selective activation of this cytokine gene cluster and their immunological consequences are being investigated. However, it is clear that allergic diseases result from a polygenic inheritance pattern that involves cytokine-gene activation and other less-well-defined gene products as well. In addition, the clinical expression of allergic diseases is highly dependent on a complex interaction between the host and its environment, for example, allergen exposure. This chapter reviews some of these developments and their clinical implications.

Key Words: Atopic dermatitis; eczema; eosinophil; keratinocytes; langerhans' cells; lymphocyte; mast cells; monocytes; pruritus; xerosis.

INTRODUCTION

Atopic dermatitis, also known as atopic eczema, is a chronic inflammatory skin disease frequently seen in patients with a personal or family history of asthma and allergic rhinitis. The term atopic dermatitis was first introduced in 1933 by Hill and Sulzberger in recognition of this close association between atopic dermatitis and respiratory allergy. Eczema (to boil out) is commonly used to refer to atopic dermatitis, but includes spongiotic dermatitis other than atopic dermatitis, so the term atopic eczema is used to specify that the type of eczema is the atopic dermatitis form, while retaining the commonly used parlance. There have been extraordinary strides made in the understanding of the immunopathogenesis of allergic diseases. In particular, this constellation of inherited illnesses is associated with activation of a specific group of cytokine genes encompassing IL-3, IL-4, IL-5, IL-13, and granulocyte-macrophage colony-stimulating factor (GM-CSF). The molecular basis for selective activation of this cytokine gene cluster and their immunological consequences are being investigated. However, it is clear that allergic diseases result from a polygenic inheritance pattern that involves cytokine-gene activation and other less-well-defined gene products as well. In addition, the clinical expression of allergic diseases is highly dependent on a complex interaction between the host and its environment, for example, allergen exposure. This chapter reviews some of these developments and their clinical implications.

DIAGNOSIS

Because of the lack of distinguishable clinical and laboratory parameters, the diagnosis of atopic dermatitis is largely based on the constellation of the major and minor clinical features. Although there are suggested features that are essential and important for the diagnosis, fully agreeable criteria need to be established. Progressive approaches to the diagnosis have been suggested by various study groups organizations, beginning with the widely used criteria of Hanifin and Rajika (Table 97-1). The Williams guidelines are useful for epidemiological studies (Table 97-2) and a simplification was used by Hanifin for United States-based epidemiology. A hierarchy of features for the diagnosis of pediatric atopic dermatitis has been suggested (Table 97-3).

Approximately 50% of patients develop atopic dermatitis by the first year of life, and an additional 30% between ages 1–5 yr. Nearly 80% of patients with atopic dermatitis eventually develop allergic rhinitis or asthma later in childhood. Many of these patients outgrow their skin disease as they are developing respiratory allergy. This observation is consistent with the concept that the clinical expression of allergic disease is determined in part from local tissue allergen sensitization and compartmentalization of the immune response in the skin vs the respiratory mucosa.

CLINICAL FEATURES

CLINICAL REACTION PATTERNS Several types of inflammatory skin lesions are commonly seen in atopic dermatitis. Acute lesions are intensely pruritic and characterized by erythematous papules over erythematous skin. These are associated with extensive excoriations, erosions, and serous exudate. Subacute dermatitis is characterized by erythematous, excoriated, scaling papules. Chronic dermatitis is characterized by thickened skin, accentuated skin markings (lichenification), and fibrotic papules. Acute episodes may occur during the chronic stage. At all stages of atopic dermatitis, patients usually have dry skin. Dyspigmentation is common. Skin distribution and reaction patterns vary according to the patient's age and disease chronicity. During infancy, the atopic dermatitis is generally more acute and primarily involves

Table 97-1
Diagnostic Features of Atopic Dermatitis (Hanifin and Rajika)

Major features (3 of 4 present)
Pruritus
Typical morphology and distribution of skin lesions
Chronic or chronically relapsing dermatitis
Personal or family history of atopy
Minor features (3 of 23 present)
Xerosis
Ichthyosis/palmar hyperlinearity/keratosis pilaris
Immediate (type I) skin test reactivity
Elevated serum IgE
Early age of onset
Tendency toward cutaneous infections/impaired cell-mediated immunity
Tendency toward nonspecific hand or foot dermatitis
Nipple eczema
Cheilitis
Recurrent conjunctivitis
Dennie-Morgan infraorbital fold
Keratoconus
Anterior subcapsular cataract
Orbital darkening
Facial pallor/erythema
Pityriasis alba
Anterior neck folds
Ichthyosis when sweating
Intolerance to wool and lipid solvents
Perifollicular accentuation
Food intolerance
Course influence by environmental/emotional factors
White dermagraphism/delayed blanch

Table 97-2
Diagnostic Guidelines of Atopic Dermatitis

Must have
An itchy skin condition (or parental report of scratching or rubbing in a child)
Plus 3 or more of the following
History of involvement of the skin creases such as folds of elbows, behind the knees, fronts of ankles, or around the neck (including cheeks in children under 10 yr)
A personal history of asthma or hay fever (or history of atopic disease in a first-degree relative in children under 4 yr)
A history of general dry skin in the last year
Visible flexural eczema (or eczema involving the cheek/forehead and outer limbs on children under 4 yr)
Onset under the age of 2 yr (not used if child is under 4 yr)

From Williams HC, Burney PGJ, Pembroke AC, et al. The UK Working Party's diagnostic criteria for atopic dermatitis III. Independent hospital validation. Br J Dermatol 1994;131:406–416 with permission.

Table 97-3
Hierarchy of Clinical Features for Diagnosis of Pediatric Atopic Dermatitis (American Academy of Dermatology Consensus Conference on Pediatric Atopic Dermatitis)

Essential features, must be present, and if complete, are sufficient for diagnosis
Pruritus
Eczematous changes
Typical and age-specific patterns (facial, neck, and exterior involvement in infants and children; current or prior flexural lesions in adult/any age; sparing of groin and axillary regions)
Chronic or relapsing course
Important features, seen in most cases for support of the diagnosis
Early age of onset
Atopy (IgE reactivity)
Xerosis
Associated features, help in suggesting the diagnosis
Keratosis pilaris/ichthyosis/palmar hyperlinearity
Atypical vascular responses
Perifollicular accentuation/lichenification/prurigo
Ocular/periorbital changes
Perioral/ periaucular lesions

On the exclusion of other skin conditions such as contact dermatitis, seborrhoeic dermatitis, cutaneous lymphoma, and so on, the diagnosis is proposed to be established based on the above features presented at International Atopic Dermatitis Symposium, Portland, Oregon, USA, 2001.

the face, scalp, and the extensor surfaces of the extremities. In older patients who have had long-standing skin disease, the rash is characterized by the chronic form of dermatitis with lichenification and localization to the flexural areas of the extremities. Facial and hand dermatitis can remain problematic.

PRURITUS Intense itching is the hallmark of atopic dermatitis. Patients with atopic dermatitis have a reduced threshold for pruritus. It is often worse in the evening and may be exacerbated by allergens, reduced humidity, excessive sweating, and irritants, for example, wool, acrylic, soaps, and detergents. The rubbing and scratching shown as superficial erosions or hemorrhagic crusts may initiate or exacerbate pathogenic events leading to the rash of atopic dermatitis. The mechanisms of pruritus remain unclear. Neuropeptides (NPs) are small amino acid compounds functioning as neurotransmitters and neuromodulators. They are also widely distributed in skin peripheral nerves. Vasoactive intestinal peptide (VIP), calcitonin gene-related peptide, and substance P (SP) are the most abundant NPs in human skin. VIP and calcitonin gene-related peptide are mainly around skin blood vessels, and eccrine sweat glands. Various inflammatory cells such as mononuclear leukocytes, mast cells, and eosinophils, important in mediating allergic disease, are also able to synthesize NP precursors in the skin and finally release smaller biologically active peptides. In atopic dermatitis, VIP levels are significantly higher in lesional skin and SP positive nerve fibers are present in most cases of atopic dermatitis. Close appositions of nerve fibers and mast cells were observed in atopic dermatitis skin. Further, α-melanocyte stimulating hormone, another NP produced in the skin, stimulates a dose-dependent release of histamine from isolated human skin mast cells. Taken together, higher availability of NPs in atopic dermatitis and an abnormal sensitivity of mast cells and blood vessels to these peptides may be involved in the mechanisms of pruritus. In addition to these molecules, anti-inflammatory drugs such as corticosteroids and calcineurin inhibitors are much more effective than antihistamines in controlling pruritus. Thus inflammation itself may lead to the release of a number of molecules involved in pruritus.

XEROSIS The xerosis in atopic dermatitis is different from icthyosis and from the dry skin in older individuals. It refers to persistent and generalized fine scaliness without visible clinical

inflammation (but histologically shows spongiosis) associated with an impaired barrier function of the stratum corneum. This is present in about 70% of atopic dermatitis patients. This barrier-disrupted skin shows markedly higher transepidermal water loss and lower skin surface hydration levels. Sphingomyelin (SM) deacylase activities are significantly increased in atopic dermatitis epidermis. This SM deacylase triggers metabolism of SM resulting in a ceramide deficiency that is closely associated with skin dryness in atopic dermatitis patients. The barrier-disrupted skin may cause atopic dermatitis skin to be highly susceptible to environmental offenders such as irritants, allergens, and microbes. Interestingly, percutaneous sensitization and elicitation with different allergens through barrier-disrupted skin vs normal intact skin differentially regulates the balance of T-helper type I (Th1) and Th2 cytokine expression. For example, picryl chloride induces a decrease of the expression of IL-2 and interferon (IFN)-γ but not for IL-4; house dust mite induces an increase of IL-4 but not IL-2 or IFN-γ. These data suggest that barrier-disrupted skin in atopic dermatitis not only causes dryness of the skin but also is actively involved in induction of Th2 dominant immune responses through the entry of environmental allergens.

ROLE OF ALLERGENS

Serum IgE levels are elevated in 80–85% of patients with atopic dermatitis; about 85% of patients have positive immediate skin tests or radioallergosorbent test® (RAST) for specific IgE to a variety of food and inhalant allergens. However, positive immediate skin tests to specific allergens do not always indicate clinical sensitivity and patients who outgrow atopic dermatitis frequently continue to have positive skin tests. Indeed, there is a distinction between symptomatic and asymptomatic hypersensitivity based on the observation that atopic dermatitis patients with positive food skin tests do not always have positive challenges to the foods implicated by IgE responses. These clinical observations suggest that the relationship between IgE and clinical disease is not exclusively dependent on IgE-mediated mast-cell degranulation.

Well-controlled, double-blind, placebo-controlled food challenge studies have, however, demonstrated that food allergens can exacerbate skin rashes in at least a subset of patients, particularly young children with atopic dermatitis. Importantly, elimination of putative food allergens in such patients results in significant improvement of their skin disease. As patients grow older, they outgrow their food allergy, but a majority of them become sensitized to inhalant allergens. Although sensitization to inhalant allergens in most cases reflects the development of coexisting respiratory allergy for example, asthma or allergic rhinitis, clinical studies suggest that inhalation or contact with aeroallergen may play a role in the exacerbation of atopic dermatitis.

CUTANEOUS INFECTIONS

Patients with atopic dermatitis have an increased tendency to develop viral, fungal, and bacterial skin infections. These infections are generally localized to the skin. Deep-seated infections suggest the possibility of hyperimmunoglobulinemia E syndrome or another immunodeficiency syndrome. Superficial fungal infections also appear to occur more frequently in atopic individuals. The potential importance of these dermatophyte infections is suggested by the reported reduction of atopic dermatitis skin severity following treatment with antifungal agents such as ketoconazole.

Viral infections include herpes simplex, vaccinia, warts, molluscum contagiosum, and papilloma virus. A potentially serious viral infection is herpes simplex, which can cause eczema herpeticum. Eczema vaccinatum is another severe and potentially fatal virus complication of atopic dermatitis with a mortality rate of 10–30% if untreated. Because of a potential risk of bioterrorist attack with smallpox, immunization of live vaccinia virus is being recommended for wide scale use. Atopic dermatitis patients should avoid contact with recent vaccinees and are advised not to receive vaccinia unless there is immediate risk of exposure to smallpox.

Considerable attention has focused on the contribution of *Staphylococcus aureus* colonization and infection to the severity of atopic dermatitis. *S. aureus* is found in more than 90% of atopic dermatitis skin lesions. Honey-colored crusting, extensive serous weeping, folliculitis, and pyoderma indicate bacterial infection usually secondary to *S. aureus* in patients with atopic dermatitis. The importance of *S. aureus* in atopic dermatitis is supported by the observation that not only patients with impetiginized atopic dermatitis, but also atopic dermatitis patients without superinfection, show clinical response to combined treatment with anti-staphylococcal antibiotics and topical corticosteroids.

Furthermore, *S. aureus* also secretes a group of toxins (staphylococcal enterotoxins: SEA, SEB) and toxic shock syndrome toxin-1 known to act as superantigens that stimulate marked activation of T cells and macrophages. Nearly half of atopic dermatitis patients produce IgE directed to these staphylococcal toxins. These findings suggest that local production of staphylococcal enterotoxins at the skin surface could cause IgE-mediated histamine release and thereby trigger the itch-scratch cycle that can exacerbate atopic dermatitis.

The mechanism of atopic dermatitis susceptibility to microbes has been studied regarding endogenous antimicrobial peptides known as cathelicidins and β-defensin. These peptides have significant antimicrobial activity against *S. aureus*. Antimicrobial peptide expression was significantly decreased in acute and chronic lesions from atopic dermatitis patients, but increased in psoriasis. This deficiency in the expression of antimicrobial peptides may account for the susceptibility of atopic dermatitis patients to skin infection with *S. aureus*.

IMMUNOHISTOLOGY

IMMUNOHISTOLOGICAL FINDINGS The histological features of atopic dermatitis depend on the acuity and therefore the duration of the skin lesion. Uninvolved or clinically normal skin of atopic dermatitis patients is histologically abnormal and demonstrates mild hyperkeratosis, epidermal hyperplasia, and a sparse dermal cellular infiltrate consisting primarily of T lymphocytes. Acute lesions are characterized by marked intercellular edema (spongiosis) of the epidermis, and intracellular edema noted as ballooning of the keratinocytes. A sparse epidermal infiltrate consisting primarily of T lymphocytes is frequently observed. In the dermis, there is a marked perivenular inflammatory-cell infiltrate consisting predominantly of lymphocytes, and occasional monocyte-macrophages. Eosinophils, basophils, and neutrophils are rarely present in the acute lesion. In chronic lichenified lesions, the epidermis is hyperplastic with elongation of the rete ridges, prominent hyperkeratosis, and minimal spongiosis. Increased numbers of Langerhans cells (LCs) are present in the epidermis, and macrophages dominate the dermal mononuclear cell infiltrate. Mast cells are increased in number but are generally fully granulated. Endothelial cells of the superficial venular plexus and deep venules are hypertrophied with enlarged nuclei and prominent nucleoli.

PATTERNS OF CYTOKINE EXPRESSION IN ATOPIC DERMATITIS SKIN LESIONS In humans and mice, two types of $CD4^+$ T-cell clones have been described, based on their pattern of cytokine secretion. Th1 cells secrete IL-2 and IFN-γ, but not IL-4, and IL-5. In contrast, Th2 cells produce IL-4, IL-5, and IL-13, but not IFN-γ. The patterns of cytokines expressed locally play a critical role in modulating the nature of tissue inflammation. Therefore, an analysis of cytokine expression at different clinical stages of atopic dermatitis is important for elucidation of its immunopathogenesis. The *in situ* hybridization technique has been used to investigate the expression of IL-4, IL-5, and IFN-γ mRNA in skin biopsies from clinically normal (uninvolved), acute (erythematous atopic dermatitis lesions of <3-d duration), and chronic (>2-wk duration) skin lesions of patients with atopic dermatitis. As compared with normal control skin, uninvolved skin of patients with atopic dermatitis had a significant increase in number of cells expressing IL-4 and IL-13, but not IL-5 or IFN-γ, mRNA. Acute and chronic skin lesions, when compared to normal skin or uninvolved skin of atopic dermatitis patients, in addition to having significantly greater numbers of cells that were positive for mRNA for IL-4 and IL-13, also had increased IL-5 producing cells. However, neither acute atopic dermatitis nor uninvolved atopic dermatitis skin contained significant numbers of IFN-γ mRNA-expressing cells. As compared with acute atopic dermatitis, chronic atopic dermatitis skin lesions had significantly fewer IL-4 and IL-13 mRNA-expressing cells, but significantly greater IL-5 and IFN-γ mRNA-expressing cells. These data indicate that although cells in acute and chronic atopic dermatitis lesions are associated with increased activation of IL-4, IL-5, and IL-13 genes, acute skin inflammation in atopic dermatitis is associated with a predominance of IL-4 and IL-13 expression, while maintenance of chronic inflammation is predominantly associated with increased IL-5 and IFN-γ producing cells accompanied by the infiltration of eosinophils and macrophages. Studies on the expression of cytokine receptor mRNA have shown that a high expression of IL-4 receptor is associated with acute atopic dermatitis while IL-5 and GM-CSF receptors are increased in chronic atopic dermatitis.

Studies have demonstrated overexpression of IL-16 in acute skin lesions, which may promote $CD4^+$ T-cell recruitment into the lesions. The overexpression of IL-12 and GM-CSF in chronic lesions is likely to enhance cell survival of eosinophils and macrophages in skin lesions, and may promote alteration in dendritic cells.

Confirming the findings in clinically acute vs chronic dermatitis, the biphasic pattern of T-cell activation has also been demonstrated in studies of atopic patch test reaction sites (Table 97-4). At early time points, 24 h after allergen application, increased expression of IL-4 mRNA and protein, which is derived from Th2 cell clones, is observed. In contrast, IFN-γ mRNA is strongly overexpressed at greater than 48 h but not at early time-points, suggesting early emergence of a mixed Th1 plus Th2 cytokine profile.

Interestingly, the increased expression of IFN-γ mRNA in atopic patch test lesions is preceded by a peak of IL-12 expression coinciding with the infiltration of macrophages and eosinophils, and both cell types are known to express IL-12. These observations give rise to the proposition that initiation of atopic dermatitis is driven by allergen-induced activation of Th2 type cells, and that the chronic type-I inflammatory response is driven by the infiltration of IL-12 expressing eosinophils and macrophages accompanying the initial Th2 response (Fig. 97-1).

Table 97-4
Cells and Cytokines in Atopic Dermatitis Skin Lesions

	Nature of skin lesion		
Cell type	*Uninvolved*	*Acute*	*Chronic*

IL-5	–	++	+++
IFN-γ	–	–	++
IL-12	–	–	++
IL-16	+	+++	++
GM-CSF	–	+	++

MOLECULAR BASIS OF IMMUNO-REGULATION

Based on observations from the previously mentioned immunohistological studies, T cells and T cell-derived cytokines play a central role in immune responses in atopic dermatitis. These responses intimately orchestrate the role of other immune competent cells such as antigen-presenting cells (APCs), eosinophils, mast cells, keratinocytes, and endothelial cells.

As with $CD4^+$ T cells, increasing evidence suggests that $CD8^+$ T cells can secrete either a Th1-like cytokine pattern or a Th2-like pattern. It has been recommended that T cells be referred to as type I (IFN-γ, IL-2 predominant) and type II (IL-4, IL-5, IL-10, IL-13 predominant), respectively, rather than referring to Th1, $Tc1_{(cytotoxic)}$ and Th2, $Tc2_{(suppressor)}$. In addition to the studies on cytokine production by Th1 and Th2 cells, the factors responsible for the polarization of the specific immune response into a predominant type-I or type-II profile have been extensively studied. Atopic dermatitis is a distinct model of type-I/II profile alterations in skin disease. The following focuses on underlying immunoregulatory abnormalities of cytokines and chemokines released from activation of T cells and other populations of immune competent cells in the different stages of atopic dermatitis (*see* Fig. 97-1).

LANGERHANS' CELLS LC are the predominant dendritic APC residing in the epidermis. In normal skin, there is a compartmentalization of LC phenotypes with epidermal LC: $CD1a^{high}$, $CD1b^-$, $CD36^-$, whereas dermal LCs are $CD1a^{low}$, $CD1b^+$, and $CD36^-$. In atopic dermatitis lesional skin, however, in addition to LC expressing $CD1a^{high}$, in both epidermis and dermis, a group of cells is frequently present at a distinct stage of maturation. APC in atopic dermatitis lesions with this type of phenotype have been termed inflammatory dendritic epidermal cells (IDECs) expressing both CD1a and CD1b as well as CD36, CD32, and high FcεR1. The difference between LC and IDEC has been studied by the activity of protein-tyrosine kinases (PTK). Atopic $Fc\varepsilon R1^{high}$ LC, after FcεR1 ligation, uniquely restrict PTK activity to target phospholipase C-γ (PTK substrate) for phosphorylation. Interestingly, IDEC only showed moderate PTK levels when compared with LC from normal skin. Furthermore, low to moderate PTK levels were observed in monocyte-derived DC, suggesting that IDEC may derive from circulating monocytes and may be different from LC. This implies that a functional FcεR1 signaling pathway in LC may only be active in atopic dermatitis. As a consequence, FcεR1 ligation leads to calcium mobilization and subsequent NF-kB activation in these cells. Thus, LC in atopic dermatitis may

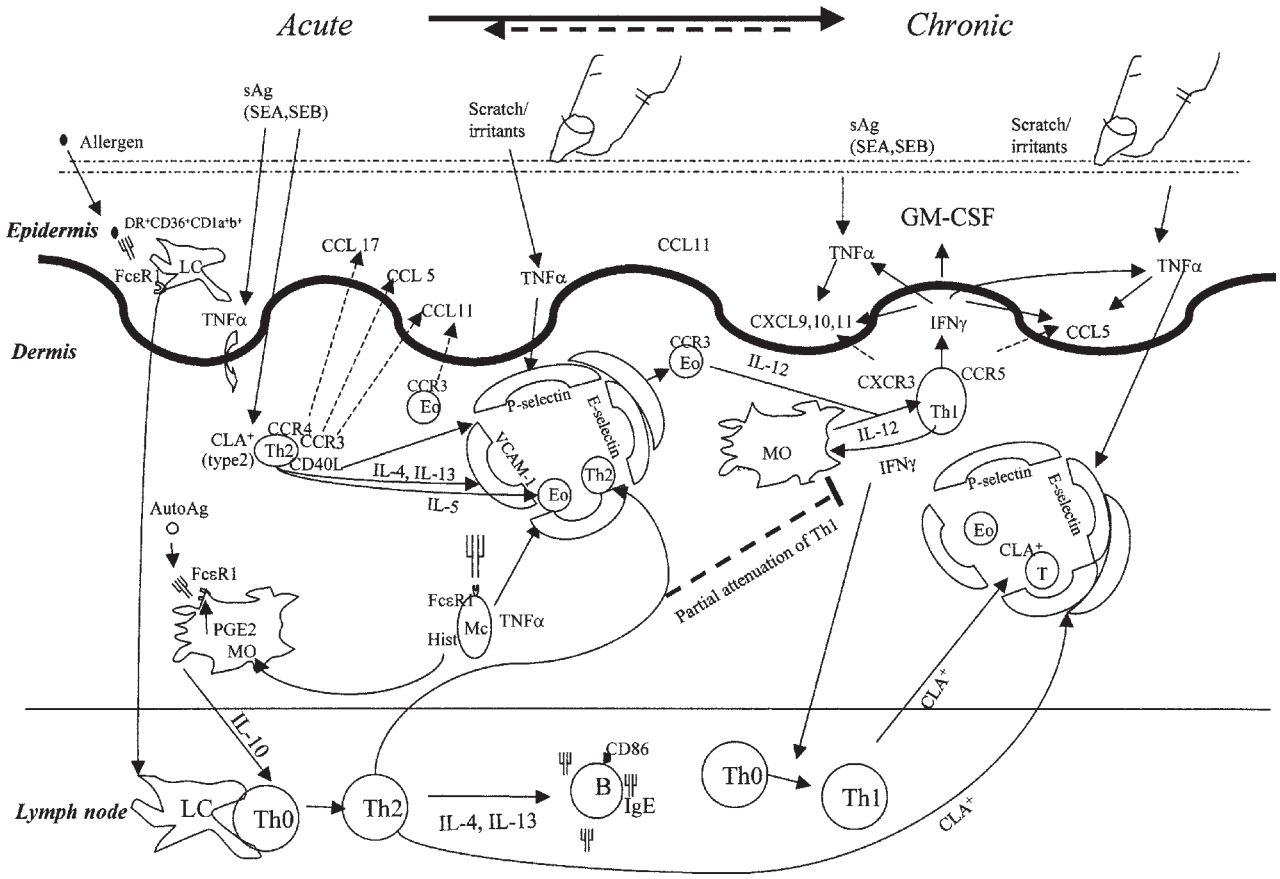

Figure 97-1 Molecular basis of immunopathogenesis in acute and chronic atopic dermatitis. In acute stage of atopic dermatitis, LC in the epidermis enable capture of allergens and autoantigens, which are then internalized, processed and packaged in major histocompatibility complex molecules on LC surface and induce activation of T cells in the draining lymph nodes. Increased monocyte PGE2 and IL-10 secretion directs T cell differentiation initially toward Th2 ($CCR3^+$, $CCR4^+$) with IL-4, IL-5, and IL-13 over-expression. Th2 cells (with cutaneous lymphocyte antigen molecule, CLA^+) are recruited to the skin preferentially with the help of chemokines produced by various cells in the skin, such as CCL17 (thymus and activation regulated chemokine), CCL-11 (eotaxin-1), and CCL5 (RANTES). B cells are associated with the production of IgE with the help of IL-4, and IL-13 secreted from Th2 cells. CD86 upregulation on B cells is associated with IgE synthesis. Activated keratinocytes also can be stimulated by nonspecific irritants, such as scratch and superantigens, and produce TNF-α, GM-CSF, and chemokines critical for type-II T cells (early) and type-I T cells (late). Moreover, activated mast cells (e.g., crosslinking with FcεR1 on the cell surface) highly release TNF-α, IL-4, and IL-13, and together with CD40L on activated T cells enhance the expression of P-selectin, E-selectin, and VCAM-1 on endothelial cells. These molecules further promote recruitment of cells from the blood. Atopic dermatitis has a tendency toward chronicity with frequently relapsing course. In chronic stages, GM-CSF is overproduced in the thickened epidermis and can function to sustain APCs as well as eosinophils and other leukocytes. Eosinophils are elevated in atopic dermatitis blood and migrate into the dermis along with monocytic cells and T cells. Eosinophils are a source of IL-12, allowing a transition to induction of Th1 differentiation with IFN-γ production. In turn, IFN-γ promotes monocytic/macrophagic cell IL-12, further promoting Th1 differentiation. Activated keratinocytes and mast cells produce TNF-α, upregulating the expression of P-selectin, and E-selectin, on endothelial cells, thus recruiting more leukocytes from the blood. Moreover, TNF-α, particularly in combination with IFN-γ promotes production of chemokines such as CXCL9 (Mig), 10 (IP-10), 11 (I-TAC), ligands for CXCR3, and CCL5, a ligand for CCR5 on Th1 cells, resulting in further recruitment of cells capable of type-I immune responses. However, this type-I immune response may differ from conventional DTH because of partial attenuation by predominant Th2 responses in atopic dermatitis.

act in two ways to influence inflammatory reactions by IgE-mediated antigen focusing, which allows for T-cell activation at much reduced antigen concentrations, and by production of proinflammatory cytokines and chemokines.

Further, LC bearing FcεR1 are also an important bridge for IgE to mediate delayed-type hypersensitivity (DTH) to allergens. T cells reacting to major histocompatibility complex-bound peptides from allergenic proteins may be expressed in eczematous skin lesions after application of aeroallergens to clinically uninvolved skin of atopic patients. Of course, the heightened state of activity of LC in atopic dermatitis lesional skin would also facilitate activation of T-cells reactive to foreign microbial antigens presented in classic fashion (bacteria, fungi), as well as T-cells reactive to superantigens and self-peptides, such that a complex, multiantigenic polyclonal T-cell response is generated.

MONOCYTES/MACROPHAGES In addition to LC, monocytes also have increased expression of high affinity IgE receptors in atopic dermatitis. Interestingly, this FcεRI aggregation prevents generation of monocyte-derived dendritic cells implying that this receptor is modulating the differentiation of monocytes. Furthermore, monocytes are the source of increased prostaglandin E (PGE) 2 secretion in atopic dermatitis; PGE2 secretion is correlated with abnormally increased cAMP-phosphodiesterase (PDE) activity in mononuclear leukocytes, particularly in monocytes of atopic dermatitis patients. In addition, histamine subsequently induces elevation of cAMP via stimulation of H_2 receptors on

monocytes. The increased cAMP-PDE activity and PGE2 secretion and cross-linking of FcεRI on monocytes results in increased atopic monocyte secretion of IL-10; IL-10 in turn inhibits Th1 response development and accentuates IL-4 secretion by Th2 cells and is likely active in initiating and flaring lesions and in the poor responses to fungal and viral infections in atopic dermatitis. In chronic lesions, however, monocytes are stimulated with IFN-γ from Th1 T lymphocytes, and may act in concert with eosinophils to produce IL-12 to further convert to Th1 phenotype during the chronic stage of the disease.

LYMPHOCYTES As mentioned, the predominant cell infiltrating atopic dermatitis skin is the T lymphocyte. Circulating T lymphocytes of atopic dermatitis patients are in a relatively more activated state, compared with those from normal control subjects. This heightened T-cell activation state is revealed by their elevated levels of secretory IL-2R, L-selectin, and the cell surface expression of HLA-DR, CD40L, and CLA, a phenotype of the homing antigen/allergen-reactive memory cells. This implies that a population of activated circulating T lymphocytes could represent skin-associated T-cell subset expansion with a low threshold for activation within the skin in patients with atopic dermatitis. Evidence for the relationship between CLA and cutaneous T-cell responses in atopic dermatitis comes from analysis of the CLA phenotype of circulating memory T cells in atopic dermatitis vs asthmatic patients who were sensitized with the house dust mite. When peripheral blood $CLA^+CD3^+CD45RO^+$ T cells were separated from $CLA^-CD3^+CD45RO^+$ T cells, the mite-specific T-cell proliferation response in patients with atopic dermatitis sensitized to dust mite was localized to CLA^+ T cells. In contrast, mite-sensitive asthmatics had strong mite-dependent proliferation responses in their CLA^- T-cell subset. The link between CLA expression and skin disease-associated T-cell effector function in atopic dermatitis was demonstrated by the observation that freshly isolated circulating CLA^+ T cells in atopic dermatitis patients, but not normal controls, selectively demonstrated spontaneous production of IL-4, but not IFN-γ. These observations strongly support the concept that, in human allergic diseases, immunological mechanisms exist to target memory Th2 cells to specific organs.

Studies on allergen-stimulated T-cells, at least in the acute and early stage of atopic dermatitis, reveal that IL-4 and IL-5 are overproduced relative to IFN-γ production. The paucity of IFN-γ in early lesions is supported by the fact that keratinocytes in epidermis of early atopic dermatitis do not express HLA-DR, a molecule that is induced by high levels of IFN-γ, such as occurs in psoriasis. This differs from the Th1 cells demonstrating increased IFN-γ, but not IL-4 and IL-5 in conventional DTH. Furthermore, Th2 cells are just as effective in inducing skin inflammation as Th1 cells. These data suggest that two indistinguishable cutaneous DTH reactions exist: the first is mediated by IFN-γ-secreting Th1 cells found in conventional DTH reactions; the second is mediated by IL-4- and IL-5-secreting Th2 cells and involves allergen-induced, cell-mediated reactions. Th2 dominance over Th1 in atopic dermatitis may be because of selective apoptosis of Th1 T cells.

A major consequence of IL-4 production during acute flares and lesion reinitiation is the effect on B lymphocytes to undergo isotype switching to IgE production, as well as upregulation of IL-4R and CD 23 (another IgE receptor) on B cells. Moreover, the high expression of B7.2 (CD86) on B cells of atopic dermatitis patients is correlated well with serum IgE levels, suggesting that CD86 plays a novel role in IgE synthesis.

IL-5 is another type-II immune response cytokine produced by T cells and elevated in early atopic dermatitis lesions, and is likely a critical factor in eosinophil participation in atopic dermatitis lesions.

GM-CSF produced by atopic dermatitis keratinocytes appears to be acting in conjunction with IL-5 to promote tissue and blood eosinophilia in atopic dermatitis. It is also important for basophil development and differentiation.

EOSINOPHILS Extracellular deposition of eosinophil, but not neutrophil, granule proteins can be found in atopic dermatitis lesional skin. These eosinophil granule proteins are also increased in the peripheral blood of patients with atopic dermatitis and are correlated with disease activity. Eosinophils also elaborate the lymphocyte chemoattractant factor, IL-16 (elevated in acute atopic dermatitis), and CCL5 (RANTES), a chemoattractant for lymphocytes as well as eosinophils. In addition, CCL11 (eotaxin), a chemokine specifically chemotactic for eosinophils, can be produced by various cells including eosinophils, lymphocytes, macrophages, and fibroblasts. Interestingly, human eosinophils can also produce biologically active IL-12 after treatment with type-II cytokines. Thus, IL-12 may promote switching of Th0 to Th1 subset in chronic lesions resulting in IFN-γ production. These data suggest that eosinophils play a pathogenic role in acute and chronic atopic dermatitis.

MAST CELLS/BASOPHILS Both mast cells and basophils originate from bone marrow progenitors, and mast cells complete their maturation after migrating into tissues. The number of mast cells may be increased in chronic lichenified lesions of atopic dermatitis. However, their significance in atopic dermatitis remains unclear. Both cells express high affinity FcεR1 on cell membranes. IgE crosslinking with FcεR1 on the cells results in histamine release and type I immediate hypersensitivity, but this is not directly relevant to atopic dermatitis skin lesions. Increased basophil histamine release occurs in atopic dermatitis, and may be related to the persistent pruritus in patients. This increased leukocyte histamine release is correlated with elevated cAMP-PDE activity, and could indicate that chronic intermittent mast cell degranulation is a continuous process in lesional atopic dermatitis, although mediators from mast cells other than histamine are likely related to the itch, because potent antihistamines do not result in clearing of atopic dermatitis pruritus.

Both mast cells and basophils, when activated, produce important type-II cytokines, such as IL-4 and IL-13. Mast cells also produce tumor necrosis factor (TNF)-α. These cytokines promote activation of B cells for IgE production and leukocyte migration through upregulation of adhesion molecules on endothelial cells. Mast cells and basophils also express the ligand for CD40 (CD40L), which contributes to B-cell IgE production independently of T cells.

Thus, the mononuclear cell infiltrate in the acute atopic dermatitis skin lesion likely reflects a combination of both IgE-dependent mast cell/basophil degranulation and Th2-cell-mediated responses elicited during acute exposures to allergen and other antigens or superantigens.

KERATINOCYTES Keratinocytes actively contribute to the pathogenesis of atopic dermatitis mainly by producing a diverse array of cytokines and chemokines. Keratinocytes are an important epidermal source of cytokines including IL-1, IL-6, IL-8, GM-CSF, and TNF-α. In this regard, any injury including mechanical trauma (rubbing and scratching) to the keratinocyte results in the release of cytokines that can induce inflammation through a number of actions, including the release of IL-1 and TNF-α. They are critical cytokines in the induction of adhesion molecules, such as endothelial cell

leukocyte adhesion molecule-1, intercellular adhesion molecule (ICAM)-1, and vascular cell adhesion molecule (VCAM)-1, which allow adhesion to endothelial cells and egress of lymphocytes, macrophages, and eosinophils into cutaneous sites of inflammation. At this stage, a variety of resident and infiltrating cells are then capable of secreting cytokines and mediators that sustain the inflammation. Atopic dermatitis therefore results from a combination of specific and nonspecific cellular mechanisms that serve to trigger and maintain skin inflammation.

GM-CSF, particularly in the chronic stage, is overexpressed in atopic dermatitis keratinocytes, and can be enhanced by IFN-γ and IL-1α. GM-CSF also promotes the survival, recruitment, and activation of dendritic cells, monocytes, T cells, and eosinophils, thus providing yet another mechanism for perpetuation of inflammation.

In addition to cytokines, keratinocytes are a major source of chemokines in skin, particularly in atopic dermatitis. CCL5, a ligand for CCR3 that is expressed in Th2 T cells, is a major chemokine produced by keratinocytes of lesional atopic dermatitis skin. CCL17 (thymus and activation-regulated chemokine), a ligand for CCR4, is elevated in atopic dermatitis skin; CCL17 plays an important role in recruiting $CD4^+$ Th2, CLA^+ memory lymphocytes.

Other chemokines elevated in atopic dermatitis, such as CXCL9 (Mig), CXCL10 (IP-10), and CXCL11 (I-TAC) are ligands for CXCR3, a chemokine receptor expressed on Th1 cells; Th1 cell IFN-γ and TNF-α can further induce keratinocytes to produce these chemokines, thus establishing another self-perpetuating mechanism of inflammation. Similarly, CCL5 (RANTES), a ligand for CCR5 on Th1 cells and on eosinophils, is also elevated in atopic dermatitis skin, and its production can be enhanced in keratinocytes with cytokines such as TNF-α. Once Th1 cells are recruited, they can induce apoptosis of keratinocytes mediated by IFN-γ, possibly accounting for spongiosis in atopic dermatitis lesions.

ENDOTHELIAL CELLS The recruitment of inflammatory cells, as mentioned, into lesional skin of atopic dermatitis requires traverse of blood cells through dermal venules likely following a chemokine gradient, guided by adhesion molecules. Activation of dermal venular endothelial cells is an essential step in this process. The adhesion molecules of endothelial cells, such as ICAM-1, VCAM-1, and E-selectin, can be upregulated by CD40L on activated T cells, and are critical for memory T-cell infiltration. Cytokines, such as TNF-α and IL-1α, from various cell sources in atopic dermatitis skin, induce similar upregulations. Additionally, the type-II cytokines IL-4 and IL-13 contribute to upregulated VCAM-1 expression, which may promote monocyte infiltration via VLAα4. An overview of the above immunological features of atopic dermatitis is shown in Table 97-5.

Taken together, the immunopathogenesis of atopic dermatitis is a complicated molecular-based network, involving the interaction of diverse cells with cascades of cytokines and chemokines that promote the continuation of inflammation. The main interactions of the above cells associated with acute and chronic stages of atopic dermatitis (*see* Fig. 97-1).

Table 97-5
Immunologic Features of Atopic Dermatitis

Phenotypically distinct and hyperstimulatory Langerhans and dendritic cells in atopic dermatitis epidermis and dermis
High expression and aggregation of the high-affinity IgE receptor FcεR1 on epidermal LC
Autoreactive T cells respond to lesional LCs
Increased IgE production (skin and blood)
Eosinophilia
Immediate skin-test reactivity to multiple allergens
Increased basophil spontaneous histamine release
Increased expression of CD23 on mononuclear cells
Expansion of lL-4-, IL-5-, and IL-13-secreting Th2-like cells
Chronic macrophage activation with increased secretion of GM-CSF, PGE2, and IL-10
Decreased numbers of IFN-γ-secreting Th1-like cells
Decreased CD8 suppressor/cytotoxic number and function
Partial attenuation of Th1 immune responses
Dysregulation of apoptosis in Th1 and Th2 cells
Increased soluble E-selectin, VCAM-1, and ICAM-1 levels in peripheral blood
Chemokine induction and release in the skin
Endothelial cell activation

"EXTRINSIC" VS "INTRINSIC"

Elevation of IgE is one hallmark feature of atopic dermatitis, especially in those patients who also have respiratory allergy. Elevated serum-IgE is also an important feature even in the patients without respiratory allergy. However, there is a group of atopic dermatitis patients in which serum IgE levels are within normal limits. Therefore, some authors have attempted to subtype atopic dermatitis in terms of the elevation of serum IgE. One group of atopic dermatitis patients has high levels of serum IgE, with polyvalent IgE sensitization against inhalant and/or food allergens in skin test, and this group is termed extrinsic atopic dermatitis (EAD). The other group has no specific IgE sensitization on skin testing or radioallergosorbent test and total serum IgE is not elevated; these patients are termed intrinsic atopic dermatitis (IAD).

Some clinical differences between IAD and EAD have been described. IAD tends to have later onset with mild female predominance. Eosinophilia is only moderate. The expression of IL-4 levels of T cells and $CD23^+$ B cells in peripheral blood, IL-5 and IL-13 levels derived from lesional skin and FcεRI expression on epidermal dendritic cells, are all lower compared with EAD. The expression of FcεRI, FcεRII, and IL4 Rα by monocytes is upregulated in EAD but not in IAD, although high expression of CD40 is found on monocytes both in EAD and IAD. IL-5 levels are significantly elevated in serum in EAD relative to IAD and normal. By contrast, IL-13 is significantly elevated in IAD relative to EAD, although both IL-13 levels are significantly higher than normal. This differs from the findings in lesional skin, in which IL-5 and IL-13 levels are all similarly elevated. However, consensus on whether IAD and EAD are distinct clinical entities has not been achieved. A study on atopy patch tests with house dust mites (*Dermatophagoides pteronyssinus* and *D. farinae*) in adults with low IgE (IAD) and high IgE (EAD) contradicted this concept by showing that the atopy patch test was positive in 47% of EAD, in 67% of IAD, and in 12% of nonatopic healthy subjects. The positivity of atopic dermatitis compared with normal was highly significant, but, IAD patients had similar or even higher positivity than EAD patients.

Enhanced PTK activity for phosphorylation of phospholipase Cγ1 was found in $FcεRI^{high}$ LC from atopic dermatitis patients. However, the fact that $FcεRI^{high}$ IDECs displayed similar amounts of PTK to that of $FcεRI^{low}$ LC from normal skin argues against the concept that PTK is a marker of IAD and EAD subgroups. Definitive segregation of subsets of atopic dermatitis will likely

require identification of genes or polymorphisms that define such subgroups.

GENETIC STUDIES

A familial predisposition to atopic dermatitis as a manifestation of atopy is well-established. For example, 60% of children with one affected parent and 80% of children with two affected parents develop atopic dermatitis. Similarly, in a study of 372 atopic dermatitis patients, a 59% incidence of respiratory allergy and a 73% incidence of a family history of atopy were found. The incidence of allergic asthma and allergic rhinitis in the families of patients without personal respiratory allergy was high at 73% and 32%, respectively. The incidence of atopic dermatitis in the family of the atopic dermatitis patients with or without personal respiratory allergy were 34 and 27%, respectively, suggesting that the inheritance of atopic dermatitis was not strongly associated with atopic dermatitis itself but was tightly associated with atopy, especially respiratory allergy. A further study on the familial aggregation of atopic dermatitis, allergic asthma and allergic rhinitis showed that concordance for atopic dermatitis is stronger between siblings than between parents and siblings. In addition, the higher risk of atopic dermatitis was from maternal rather than paternal atopy. A twin-based study has also been performed to clarify this genetic predisposition. There was more concordance for atopic dermatitis in monozygotic than for dizygotic twin pairs. The risk of having atopic dermatitis was 86% in monozygotic vs 21% in dizygotic twin pairs if the twin partner had the disease.

Clinical observations have been intriguing investigators to seek specific genes involved in atopy and atopic dermatitis. Two different approaches have been utilized. Linkage analysis is used to identify an association of atopic dermatitis phenotype with a specific gene located in the chromosome regions in atopic patients through successive generations of families with both affected and unaffected family members. The other is to investigate the association of gene polymorphisms of a specific gene with the atopic phenotype. Several gene regions or polymorphisms have been linked or associated with atopic dermatitis that are essential immunological factors thought to be involved in the pathogenesis of the disease. Chromosome 5q31 encodes the IL-4 gene cluster family, including multiple cytokine genes related to T-cell type-2 cytokines such as IL-4, IL-5, and IL-13. Because IL-4 is central to the induction of IgE synthesis by B cells, it is suggested that polymorphisms in chromosome 5q31 are linked to the genes controlling total serum IgE in atopy. Another candidate gene at chromosome 11q13 has been implicated in the IgE high-affinity receptor, which may play a role in handling of IgE-detected allergens. A gene for mast-cell chymase, a key element in atopic or allergic inflammation of the skin, is encoded at chromosome 14q11 and is suggested to be specifically linked to atopic dermatitis. Furthermore, chromosome 3q21 has been identified as another susceptibility locus for atopic dermatitis based on a study of 199 families with at least two affected siblings. Interestingly, a gene, serine protease inhibitor Kazal type 5, demonstrates a polymorphism underlying Netherton disease, which involves a Glu420→Lys substitution. This variant also shows significant association with atopy and atopic dermatitis in two independent panels of families. Taken together, atopic dermatitis is an important component of atopy with a poorly understood, polygenotypic basis and variable expressions influenced by environmental factors. Previously no specific single gene has been disclosed as a unique marker for this common hereditary allergic dermatitis.

ANIMAL MODELS

To explore the genetic susceptibility and pathogenesis of atopic dermatitis, animal models have been studied in murine systems. NC/Nga mice when raised in conventional (nonsterile) circumstances, spontaneously developed skin lesions that were clinically and histologically similar to human atopic dermatitis. These mice have a marked elevation of total IgE levels in plasma that correlates with clinical severity of dermatitis. In addition to having a high susceptibility to anaphylactic shock from ovalbumin, the tyrosine phosphorylation of Janus kinase 3 is strongly inducible in the B cells of these mice. These B cells produce much more IgE in the presence of soluble CD40L and IL-4, and are consistent with the character of B cells from peripheral mononuclear cells of atopic dermatitis patients. Furthermore, rIL-12 did not induce a normal production of IFN-γ in NC/Nga mice immunized with ovalbumin because of the low phosphorylation of STAT4, resulting in a failure of inhibiting IgE synthesis. Whether such an effect is present in human atopic dermatitis is under investigation. Progress in this area may be accelerated by the finding that a major quantitative-trait locus responsible for the skin lesion was located on chromosome 9.

RelB-deficient mice develop skin lesions similar to human atopic dermatitis. RelB is a member of Rel/NF-kB family, a common transcription factor involving the inducible expression of many proteins such as cytokines and cell adhesion molecules that are produced by and act on immune cells. RelB protein levels are markedly induced on dendritic cell maturation. Mice deficient in RelB are similar to patients with atopic dermatitis, revealing hyperkeratosis and epidermal hyperplasia histologically and have mainly infiltrating $CD4^+$ T cells and eosinophils in lesional skin. Furthermore, eosinophils and IgE levels are increased in the blood and serum. Interestingly, if RelB-deficient mice also lack peripheral T cells, the dermatitis does not develop, consistent with the concept that the skin lesions of atopic dermatitis are T-cell dependent.

Other studies focused on the elevated expression of IL-4 in the epidermis by transgenic mice. Epidermal overexpression of IL-4 promotes chronic, inflammatory, and pruritic atopic dermatitis-like skin manifestations with severe *S. aureus* infection. Another model relevant to atopic dermatitis is one in which mice receive epicutaneous sensitization with ovalbumin. These mice showed an induction of elevated serum IgE and ovalbumin-specific antibodies, comparable with the allergen sensitization in atopic dermatitis patients, as well as pruritic dermatitis. Such animal models may hasten development of clinical therapeutics for atopic dermatitis.

MANAGEMENT

Treatment of atopic dermatitis is directed at symptom relief, reduction of cutaneous inflammation and the avoidance of exacerbating factors, all critical for effective management. Factors to be considered and eliminated include irritants, allergens, and emotional stresses. Systemic antimicrobial therapy, in particular, antistaphylococcal antibiotics, is often necessary because atopic dermatitis skin has enhanced binding properties for *S. aureus* and, because of the frequent scratching, becomes secondarily infected. Maintenance of daily skin care with hydration of the skin by frequent use of emollients and appropriate use of topical steroids and immunomodulators to reduce skin inflammation is critical. Therapy must be individualized and is dependent on whether the

patient is experiencing an acute flare or managing chronic atopic dermatitis.

Because patients with atopic dermatitis manifest abnormalities in immune regulation, therapy directed toward correction of their immune dysfunction represents an alternative approach. In this regard, therapeutics using immunomodulators or immunosuppressive agents has emerged. Two topical macrolide immunomodulators were specifically approved for use in atopic dermatitis: tacrolimus (FK 506) and pimecrolimus (ASM 981). Both act as a calcineurin inhibitor; that is, they block T-cell activation by inhibiting the phosphatase activity of calcineurin and preventing nucleus translocation of nucleus factor activated T cells (NFAT). Interestingly, calcineurin is also functionally active in human keratinocytes inducing nuclear translocation of NFAT, and that regulation of the NFAT nuclear translocation in skin is cell-type specific. Thus, inhibition of this pathway in epidermal keratinocytes may partly account for effects at high concentrations of these calcineurin inhibitors in skin diseases. The major side effect of tacrolimus, but less of pimecrolimus, is burning at the site of application. Both drugs do not cause cutaneous atrophy seen with topical steroid use, because unlike corticosteroids, the drug class does not inhibit collagen synthesis. Thus, this class of compounds has significant potential for anti-inflammatory action without skin atrophy, making them particularly suitable for thinner skin such as face, neck, and flexural areas. Although cyclosporine, another calcineurin inhibitor, is effective as a systemic therapy for atopic dermatitis, systemic cyclosporine therapy did lead to mild renal and liver toxicity and is unlikely to be a candidate for long-term treatment of atopic dermatitis. Oral pimecrolimus is under development for potential use in atopic dermatitis.

With progress in immunology relating to the immunopathogenesis of atopic dermatitis, a variety of potentially therapeutic agents have been tried. Some of these therapies have been tested in human trials for atopic dermatitis, whereas others have been tried for the treatment of other T-cell mediated skin diseases such as psoriasis. These include anti-IgE antibodies, fusion proteins, and antibodies that block T-cell costimulatory signals, cytokines to block T-cell activation or survival or inflammatory cell infiltration, and topical PDE IV inhibitors to correct cyclic nucleotide regulation. Although some of these show promise, the protein therapeutics are somewhat limited because of the requirement for parenteral administration. Beyond the increased efficacy and reduced adverse effects, the advantage being sought is selective correction of immune defects rather than global immunosuppression.

For patients who are poorly controlled on conventional therapy, skin-directed phototherapies should be considered. UV light therapy may be a useful adjunctive therapeutic modality. UVB, UVA, long-wave UVA1, narrow-band UVB, combined UVA and UVB, and psoralen photochemotherapy all have benefits in atopic dermatitis. Under professional supervision, phototherapy can be effective and has anti-inflammatory effects in part because of its ability to inhibit lymphocyte trafficking, antigen-processing, and survival of memory T cells in the epidermis. Caution should be exercised especially in those recalcitrant patients undergoing long-term therapy, because of the potential increased risk of skin cancer.

FUTURE DIRECTIONS

This chapter highlights several important advances in the understanding of the immunopathogenesis of atopic dermatitis. The importance of APCs such as LCs, monocyte/macrophage, and their receptors, particular $Fc\varepsilon RI^{high}$, has been noted. Many critical cytokines involved in the pathogenesis of atopic dermatitis and the potentially important mechanisms by which inflammation occurs at the sites of allergic responses have been identified, including the observation that IgE has a multifunctional role in the pathogenesis of allergic inflammation. Aside from its involvement in IgE-mediated degranulation of mast cells/basophils, it is also involved in the activation of, and antigen presention by, LCs, macrophage/monocytes, and the stimulation of Th2 cells. However, the role of IgE in the "extrinsic" vs "intrinsic" atopic dermatitis needs to be elucidated. These important advances will allow scientists to target certain candidate genes to determine whether their abnormal regulation or altered function contributes to the molecular basis of atopy. Elucidation of the key genes involved in atopy is likely to provide new methods for classifying atopic diseases, particularly with respect to diagnosis, disease severity, and possibly response to therapy. Considering the complexity of multiple genes involved in atopy it is difficult to envision the use of gene therapy in the near future. Animal models are a valuable approach to this goal.

Novel immunological therapies for chronic allergic diseases are likely to include the depletion of pathogenic memory T cells, alteration of trafficking, or inhibition of cytokines and their cytokines targeting specific organs. Studies with experimental immunomodulatory and immunosuppressive agents are promising and serve as proof of the concept that therapies that downregulate T-cell function and cytokine secretion are effective in reducing the clinical severity of inflammatory skin disease. As the understanding of the immunopathogenesis of allergic responses continues to grow, manipulation of the immune response in atopic dermatitis and other allergic diseases is likely to become an exciting direction in the treatment of this fascinating group of illnesses.

98 Pemphigus Foliaceus, Pemphigus Vulgaris, Paraneoplastic Pemphigus, Bullous Pemphigoid, Herpes Gestationis, and Cicatricial Pemphigoid

Ning Li, David S. Rubenstein, Zhi Liu, and Luis A. Diaz

SUMMARY

Pemphigus and bullous pemphigoid represent two major classes of human autoimmune blistering disease. In pemphigus, the binding of pathogenic autoantibodies to desmosomal cadherins directly induce loss of keratinocyte cell–cell adhesion; whereas, antibody binding to the hemidesmosome protein BP180 induces subepidermal blistering by activation of complement and proteolytic activity. Progress in understanding the molecular pathogenesis of these disorders has led to precise diagnostic tests and effective treatment protocols.

Key Words: Acantholysis; autoantibody; BP180; bullous pemphigoid; cicatricial pemphigoid; desmoglein; desmosome; direct immunofluorescence; fogo selvagem; hemidesmosome; herpes gestationis; paraneoplastic pemphigus; passive transfer mouse model; pemphigus foliaceus; pemphigus vulgaris.

PEMPHIGUS VULGARIS, PEMPHIGUS FOLIACEUS, AND PARANEOPLASTIC PEMPHIGUS

Pemphigus is a group of autoimmune disorders characterized by spontaneous intraepidermal blisters and epidermal-specific autoantibodies. Blister formation occurs by the histologically distinctive loss of epidermal cell–cell adhesion, termed acantholysis. The two major forms of the disease are pemphigus vulgaris (PV) and pemphigus foliaceus (PF). Although PV and PF are diseases described all over the world, since the turn of the century an endemic form of PF has been observed in Brazil and Colombia. Endemic PF is also known as "fogo selvagem" (FS; wild fire). Before the advent of immunosuppressive therapy, the mortality from pemphigus was high.

Less common variants of pemphigus include paraneoplastic pemphigus (PNP), drug-induced pemphigus, pemphigus herpetiformis, and IgA pemphigus. The majority of PNP cases have been reported in association with underlying lymphoproliferative disorders. Clinical and histological features of PF, and less commonly PV, have been described in drug-induced pemphigus; penicillamine, captopril, penicillin, ampicillin, and rifampin are commonly associated with this variant. Pemphigus herpetiformis demonstrates the clinical features of dermatitis herpetifomis and the immunological features of pemphigus; however, limited or no apparent acantholysis is apparent on histological examination. Unlike other types of pemphigus, which are characterized by IgG autoantibodies, IgA pemphigus autoantibodies are of the IgA class. This section focuses on the molecular pathogenesis of PV, PF, and PNP.

The histological hallmark of PV and PF, epidermal cell detachment, was described in the 1940s. In PV, the epidermal cell separation occurs just above the basal layer of the epidermis; whereas, in PF, the cell separation occurs at the more superficial level of the granular-cell layer of the epidermis. In the mid 1960s Jordon and Beutner made the important discovery that PV and PF patients possess antiepidermal autoantibodies that are both (1) bound to the epidermal target and (2) present in patient sera. In the years following this observation, an appreciation developed for the diagnostic value of these autoantibodies.

Clinical and experimental data became available that convincingly demonstrated that these antiepidermal antibodies were indeed pathogenic. The autoantibody titers in patients correlate well with disease activity and are used to follow the therapeutic response of these patients. It was also documented that neonates born to PV mothers (and rarely in PF) developed a blistering disease caused by transplacental passage of maternal autoantibodies. Experimentally, it was found that the IgG fractions from PV and PF sera promoted cell detachment in primary epidermal cell cultures and in organ cultures of human skin. In the early 1980s, passive transfer experiments definitively demonstrated that PV and PF autoantibodies were pathogenic; intraperitoneal injections of PV IgG or PF IgG induced intraepidermal blisters in neonatal mice, duplicating the key clinical and histological features of the human diseases.

In 1990, a series of five patients who had a pemphigus-like syndrome associated with underlying neoplasms were characterized.

These patients showed distinct clinical, histological, and immunological features and the authors proposed the term PNP for this newly identified disease. The autoantibodies from these patients bound to the cell surface of both stratified and nonstratified epithelia. Additionally, the IgG fraction from PNP patients was shown to be pathogenic by passive transfer experiments in the mouse model.

The characterization of the epidermal antigens targeted by PV, PF, and PNP autoantibodies revealed that they were components of the desmosome and hemidesmosome (Table 98-1). The desmosome is a cell–cell adhesion organelle whose molecular constituents can be divided into core and plaque structural components. The desmosomal core contains transmembrane glycoproteins known as desmogleins (Dsg) and desmocollins that belong to the cadherin family. Molecular interactions of these proteins at the extracellular level bring about adhesive forces to keratinocytes by linking the cell surface. Through a variety of molecular interactions, the cytoplasmic surface of the desmosome is linked to the keratin intermediate filaments that form part of the cytoskeleton. In humans, four Dsg3 have been described, namely Dsg1, 2, 3, and 4. PF autoantibodies recognize Dsg1, mucosal dominant PV autoantibodies recognize Dsg3, and mucocutaneous PV sera contain antibodies to both Dsg3 and Dsg1. Sera from two PV patients tested also recognized the newly identified Dsg4, indicating that Dsg4 is an additional autoantigen targeted by some PV sera. In addition to Dsg1 and Dsg3, PNP autoantibodies react with desmosomal plaque proteins (desmoplakin I and II, periplakin, envoplakin) and hemidesmosomal proteins (BP230 and HD1/plectin), as well as an unidentified 170-kDa antigen.

CLINICAL FEATURES PV is the most common form of pemphigus in the United States and is characterized by the spontaneous development of blisters arising on normal appearing skin (Fig. 98-1A). The disease is more common in individuals of Jewish descent or Mediterranean origin. Although the disease onset is typically between the fourth and sixth decades of life, any age group may be affected. Clinical lesions are flaccid bullae that rupture easily, producing denuded areas of skin and erosions that are slow to heal. The disease usually begins in the oral cavity and then progresses to involve the skin (mucocutaneous PV), although some patients never develop skin lesions and their disease is restricted to oral mucosal surfaces (mucosal PV). Because of the fragility of the blisters, the oral lesions are predominantly erosions. In addition to the oral cavity, other mucosal epithelia may be affected including the esophagus, conjunctiva, larynx, vagina, urethra, cervix, and rectum. Mucosal and mucocutaneous PV exhibit distinct autoantibody profiles. Mucosal PV exhibits only anti-Dsg3 antibodies: whereas, both anti-Dsg3 and anti-Dsg1 antibodies can be found in mucocutaneous PV. Although rare, a transition from PV into PF has been reported.

Clinically, PF is characterized by superficial vesicles that rupture easily, producing erosions and crusts (Fig. 98-2A). The skin lesions in PF appear most commonly on the head and neck regions. In chronic cases, excoriated lesions may become hyperkeratotic, verrucous, or vegetating plaques. On occasion, the disease may progress to exfoliative erythroderma. In contrast to PV, the mucous membranes are spared in PF. The clinical, immunological and histological features of FS, the endemic PF variant, are identical to sporadic, nonendemic PF. Immunologically, both endemic and nonendemic PF are characterized by the presence of anti-Dsg1 autoantibodies. The sera of a small subset of endemic PF patients have anti-Dsg3 autoantibodies and the rare transition from PF to PV has been reported.

PNP occurs in the context of an underlying neoplasm. The most frequent neoplasms associated with PNP are non-Hodgkin's lymphoma, chronic lymphocytic leukemia, Castleman's disease, and thymoma. The disease is characterized by severe mucositis, skin lesions that may resemble erythema multiforme and lichen planus, and in some patients a life-threatening bronchiolitis obliterans. All patients present with a stomatitis involving the vermillion of the lips and 20% or more patients have pulmonary involvement. The presence of palmar and plantar blisters or other lesions is a unique feature that distinguishes PNP from PV and PF. The mortality of PNP is remarkably high, exceeding 90%; although, in some isolated reports the mucocutaneous disease of these patients responded to immunosuppressive therapy or removal of the underlying neoplasm.

DIAGNOSIS The diagnosis of pemphigus is based on clinical, histological, and immunological criteria. Biopsies from the lesional skin of patients with PV reveal intraepidermal vesicles occurring just above the basal-cell layer. Basal keratinocytes remain attached to the dermis, producing the histological "tombstone" sign (Fig. 98-1B). The dermis may show edema and inflammation with

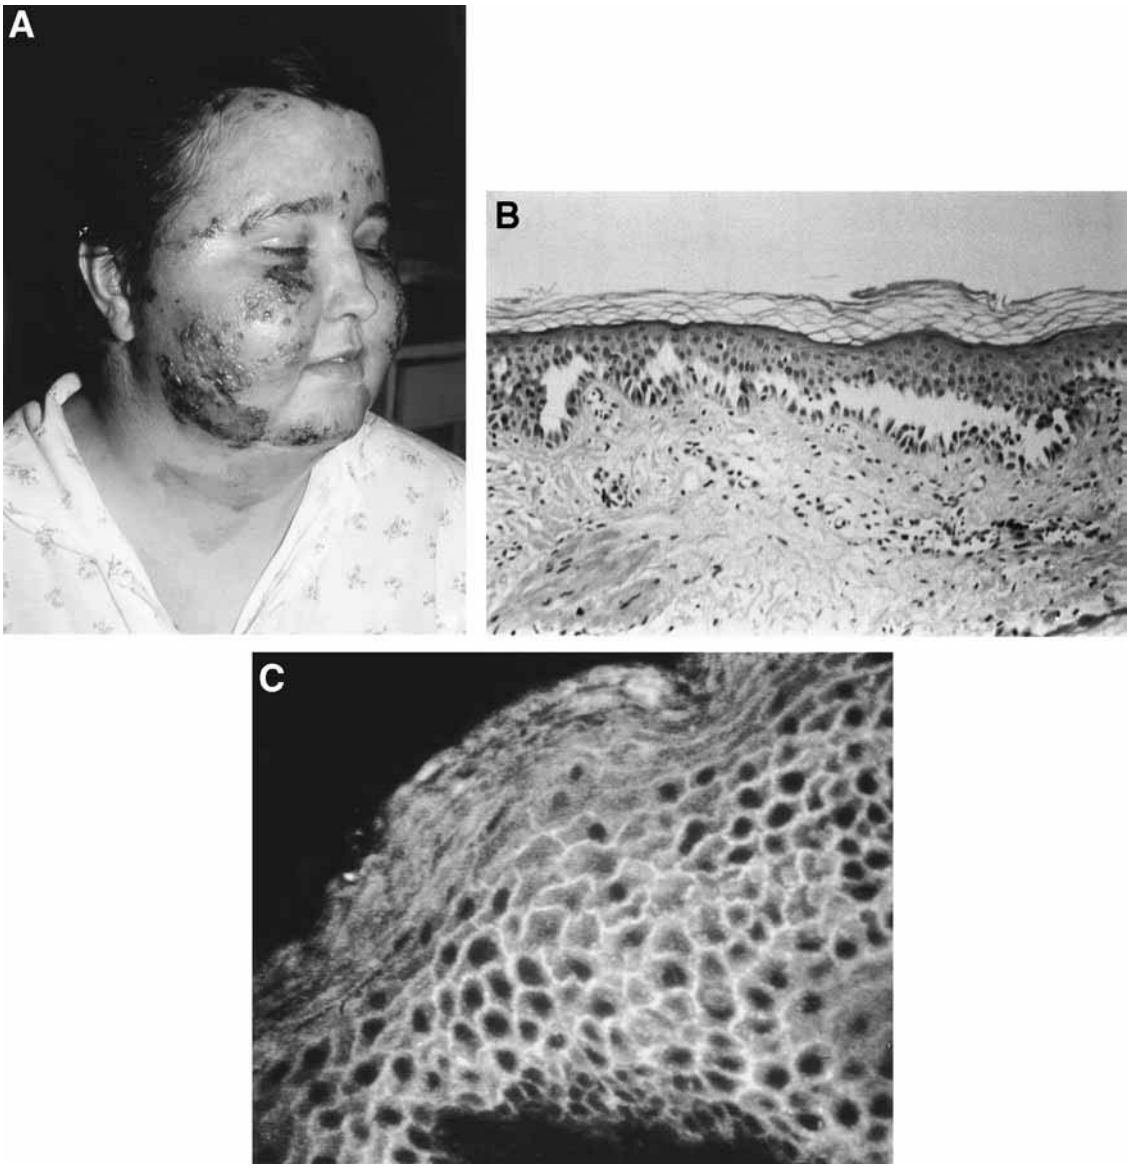

Figure 98-1 Clinical, histological, and immunological features of PV. PV patients typically have flaccid blisters and erosions that can become widespread **(A)**. Histologically, biopsies of PV show suprabasilar acantholysis, with the retention of the basal cells on the dermis **(B)**. Patients have both tissue-bound and circulating autoantibodies directed against the cell surface of the keratinocyte. **(C)** The results of indirect IF performed with PV serum using monkey esophagus as a substrate.

the presence of eosinophils in early lesions, and plasma cells in older lesions. Immunofluorescence (IF) studies are extremely helpful in confirming the diagnosis of pemphigus. Direct IF, performed on perilesional biopsies shows the deposition of IgG and/or C3 in the epidermal intercellular spaces in 100% of patients with active disease. Indirect IF studies of patient sera demonstrate circulating autoantibodies that produce an intercellular spaces staining pattern on stratified squamous epithelial substrates. Additionally, the diagnoses of PV can be made by specific detection of anti-Dsg3 autoantibodies by use of immunoblot, immunoprecipitation, or ELISA techniques.

The histology of PF also shows intraepidermal vesicles, but occurring high in the epidermis, within or just below the granular-cell layer (Fig. 98-2B). Older lesions of PF may also show hyperkeratosis and thickening of the epidermis. Indirect IF tests yield positive results in 80–90% of patients with active disease. Though occasionally PF autoantibodies may bind preferentially to the upper layers of the epidermis, and PV autoantibodies more suprabasilarly, in general the two disorders cannot be differentiated on the basis of indirect or direct IF (Figs. 98-1C and 98-2C). In most patients, the serum autoantibody titers correlate well with disease extent and activity. The detection of anti-Dsg1 autoantibodies by immunoblot, immunoprecipitation, or ELISA is helpful in confirming the diagnoses; however, more than half of PF sera fail to react with Dsg1 by immunoblotting, presumably because this technique destroys the conformational epitopes.

Histological analysis of oral mucous membrane biopsy specimens from PNP patients reveals suprabasal acantholysis, dyskeratotic keratinocytes, vacuolar change of the basilar epidermis, and epidermal exocytosis of inflammatory cells. Direct IF of human skin biopsies shows deposits of IgG and C3 on the cell surfaces, a staining pattern that is similar to PV. With a sensitivity and specificity of 75 and 83%, respectively, indirect IF of PNP serum on rat bladder epithelium is a routinely used screen. Desmoplakin,

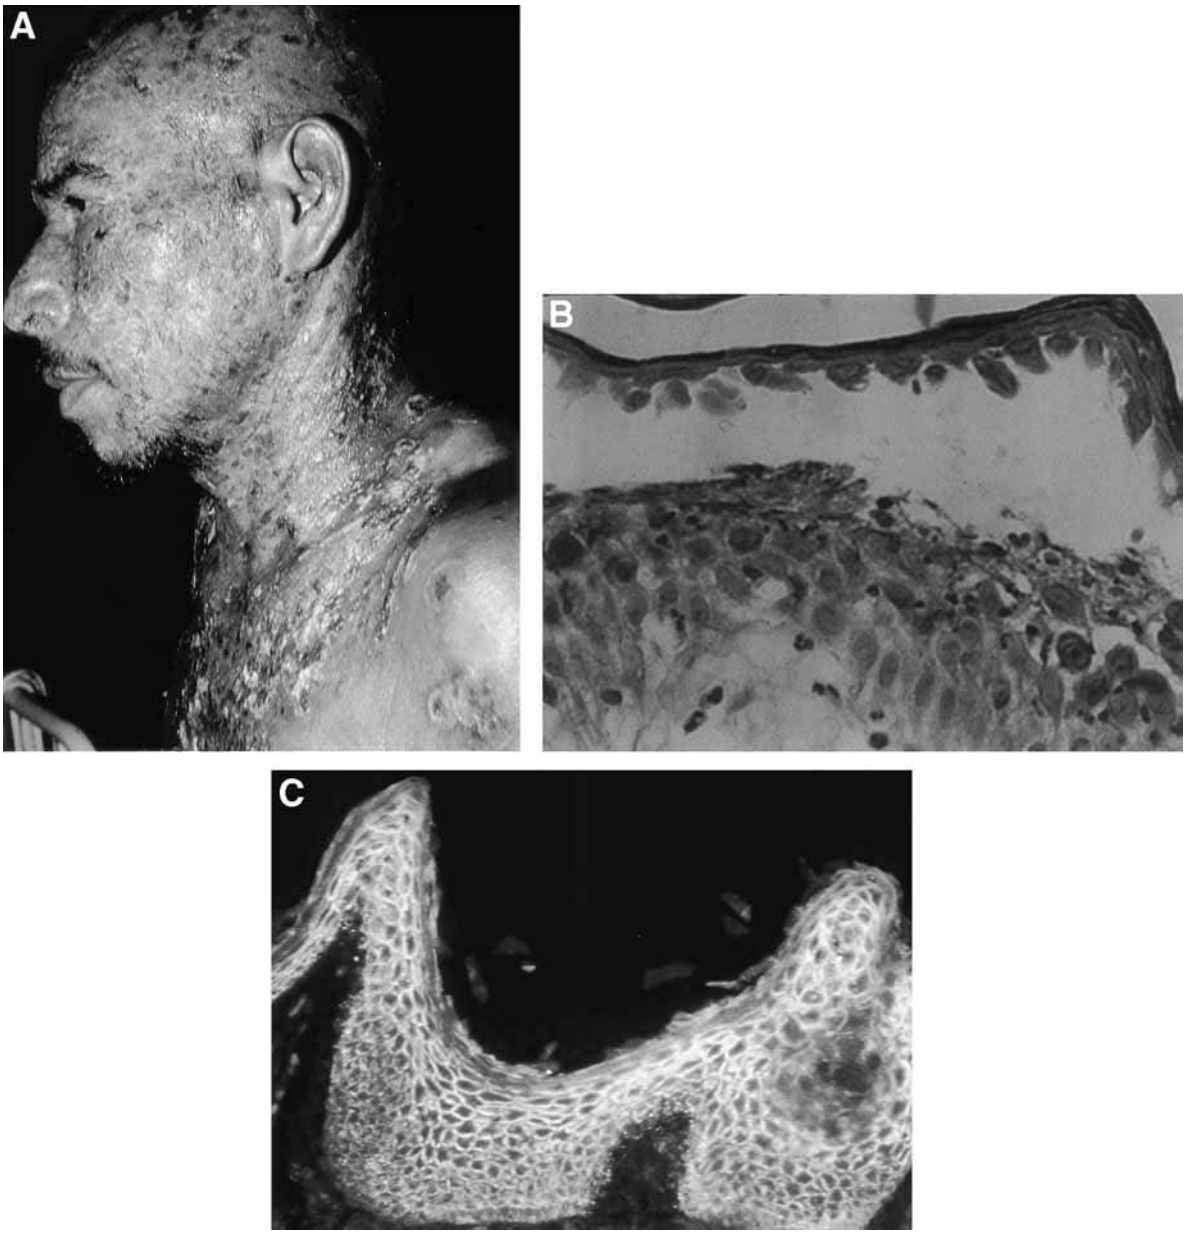

Figure 98-2 Clinical, histological, and immunological features of PF. This patient with endemic PF has widespread erosions and crusting on the head and neck **(A)**. A skin biopsy specimen shows an intraepidermal vesicle occurring in the granular-cell layer **(B)**. Indirect IF of this patient's serum shows intercellular spaces staining, using human skin as a substrate **(C)**.

but neither Dsg3 nor Dsg1, is expressed in rat bladder accounting for the failure of PV and PF sera to stain this tissue. The ability of patient sera to immunoprecipitate from keratinocyte extracts a complex of multiple antigens with molecular weights of 250, 230, 210, 190, and 170 kDa serves as the gold standard for the diagnosis of PNP.

GENETIC BASIS OF DISEASE Like many other human autoimmune diseases, PV, and PF are associated with certain human leukocyte antigen (HLA) haplotypes. Because of the high frequency of PV in Ashkenazi Jews, HLA associations in Jewish and non-Jewish Caucasian PV patients have been compared. Jewish PV patients share the extended haplotypes {HLA-B38, SC21, DR4, DQw8} or {HLA-B35, SC31, DR4, Dqw8}, whereas non-Jewish patients carry the haplotype {HLA Bw55, SB45, Drw6, Dqw5}.

High-resolution typing has revealed two susceptibility haplotypes for PV, the DRB1*04 (0402 or 0406), DQB1*0302 haplotype and the DRB1*14 (1401, 1404, or 1405), DQB1*0503 haplotype. Prevalent in Ashkenazi Jews, non-Jewish Caucasians, and Iranian patients, the DRB1*0402, DQB1*0302 haplotype is rare in Asian PV patients (Indian, Pakistani, and Japanese). Instead, DRB1*0406 along with DQB1*0302 was reported associated with Japanese PV. The DRB1*1401 allele is common in non-Jewish Caucasians and Japanese PV patients whereas DRB1*0404 is the most frequent allele in Indian and Pakistani patients. The DRB1*1405 allele is found associated with PV mainly in the Japanese population. It has been suggested that the association of DQB1*0503 with PV is primary whereas the association of various DRB1*14 alleles with PV is a secondary phenomenon owing to their linkage disequilibrium with DQB1*0503. The response

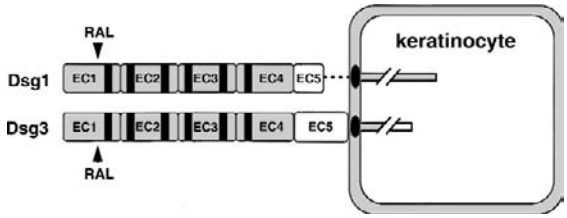

Figure 98-3 Schematic of Dsg1 and Dsg3. Dsg1 and Dsg3 are both transmembrane proteins with an intracellular, extracellular and a single transmembrane domain. The extracellular domains of both Dsg1 and Dsg3 contain four cadherins repeats (EC1-4). Within the cadherin repeats, the black bars represent calcium-binding sites, and the RAL is the putative cell–cell recognition site.

of Dsg3-specific T cells from PV patients is blocked by either anti-HLA-DR antibody or anti-DQ antibody, but not by anti-DP antibody, indicating that both DQB1*0503 and DR*14 alleles are relevant in the pathogenesis of PV. DQB1*0302 is associated with DRB1*0402 as well as other DRB1*04 alleles that are not susceptibilities for PV, indicating that the association of DRB1*0402, rather than DQB1*0302, is primary. These conclusions are supported by the observations that antigen-presenting cells expressing DRB1*0402 or DRB1*1401 are able to selectively present Dsg3 peptides to T cells from PV patients.

HLA alleles associated with FS have been studied in three ethnic populations in Brazil. The frequency of DRB1*0102 is significantly increased in Mestizos (Black and Caucasians) whereas the main susceptibility allele in Xavante Indians and Terena Indians is DRB1*0404. In addition, DRB1*1406 and/or DRB1*1402 are also increased in Xavante and Terena Indians. The different alleles associated with FS in the three populations may be because of the fact that DRB1*01 is absent in the two Brazilian Indian populations and the frequencies of DRB1*1402 and 1406 are low in Black and Caucasians. Nevertheless, a common epitope (LLEQRRAA) spanning residues 67–74 of the third hypervariable region of the DRB1 molecule is shared by these susceptibility alleles (DRB1*0102, DRB1*0404, DRB1*1402, and DRB1*1406).

The HLA alleles associated with nonendemic PF have also been studied in French, Italian, and Japanese patients. Similar to the findings in endemic PF in Brazil, DRB1*0102 and DRB1*0404 are strongly associated with PF in patients from France. In contrast, no such associations were observed in studies of Italian and Japanese PF patients. Instead, two PV susceptibility alleles, DRB1*1401 and DQB1*0503, had high frequencies in both Italian and Japanese PF patients. DRB1*1401 and DRB1* alleles (DRB1*0102, 0404, 1402, and 1406) associated with endemic PF all carry hydrophobic residues at position 26 and 67 and hydrophilic residues at position 70 on the DRB1 chain.

MOLECULAR PATHOPHYSIOLOGY The PF and PV target antigen genes Dsg1 and Dsg3 are located on chromosome 18. *In situ* hybridization and IF have been used to localize Dsg1 and Dsg3 in the epidermis. Dsg3 is expressed more strongly in the basal and lower spinous layers of the epidermis, whereas Dsg1 is expressed throughout the epidermis gradually increasing in the more superficial epidermal cell layers. The epidermal distribution of Dsg1 and Dsg3 correlates well with the level at which blistering occurs in PF and PV.

Sequence analysis of the Dsg1 and Dsg3 cDNAs demonstrates common features with the cadherin family of calcium-dependent cell adhesion molecules (Fig. 98-3). Both Dsg1 and Dsg3 are transmembrane proteins that have an N-terminal extracellular domain and a

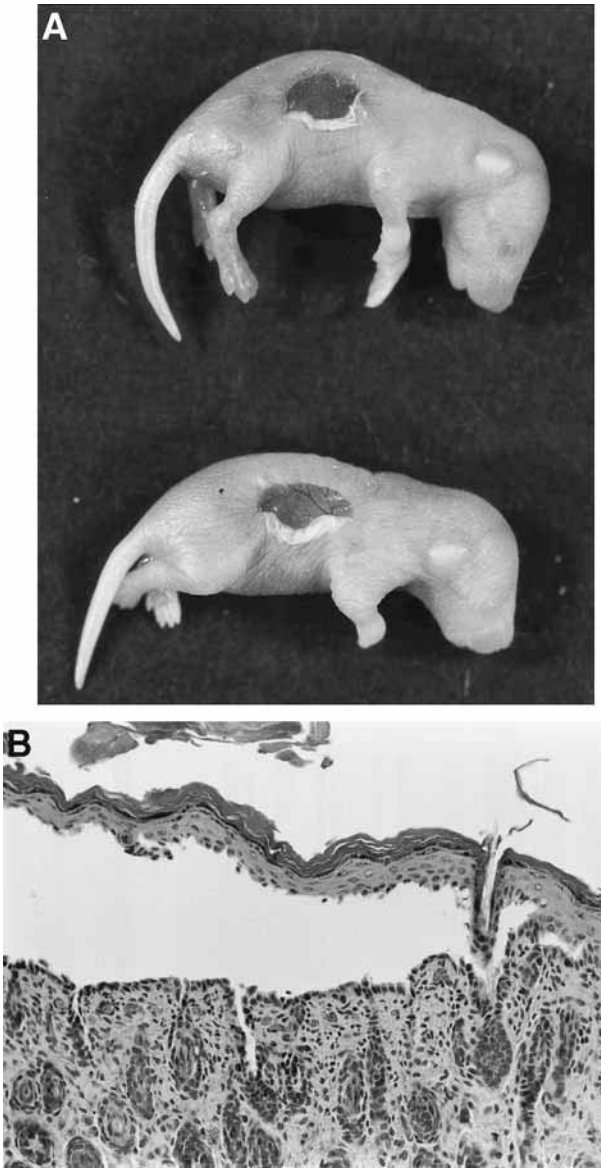

Figure 98-4 Passive-transfer mouse model of PV. Neonatal BALB/c mice injected with purified IgG from PV patient's sera reproduced the clinical **(A)**, histological **(B)**, and immunological features of the disease.

C-terminal intracellular domain. The extracellular region contains a series of five repeat domains, termed EC1–EC5. The first four of these domains are homologous cadherin repeats. A series of three pairs of calcium-binding sites are also located within the first four extracellular domains. These calcium-binding sites have been hypothesized to be crucial in cell–cell adhesion, and also appear to be important in autoantibody recognition. A three-amino acid sequence (RAL) near the amino terminus contains a putative cell–cell recognition site. The region just outside the transmembrane domain (EC5) shows the greatest divergence between Dsg1 and Dsg3, as a portion of this region is deleted in Dsg1. The intracellular domain of Dsg, through a series of protein–protein interactions involving plakoglobin, desmoplakin, and keratin, functions to link the desmosomal proteins to the intermediate filament cytoskeleton.

Following the experimental demonstration that PV and PF autoantibodies are pathogenic in the mouse model system (Figs. 98-4 and 98-5), efforts were concentrated in dissecting the molecular mechanisms leading to acantholysis. It has been well established that

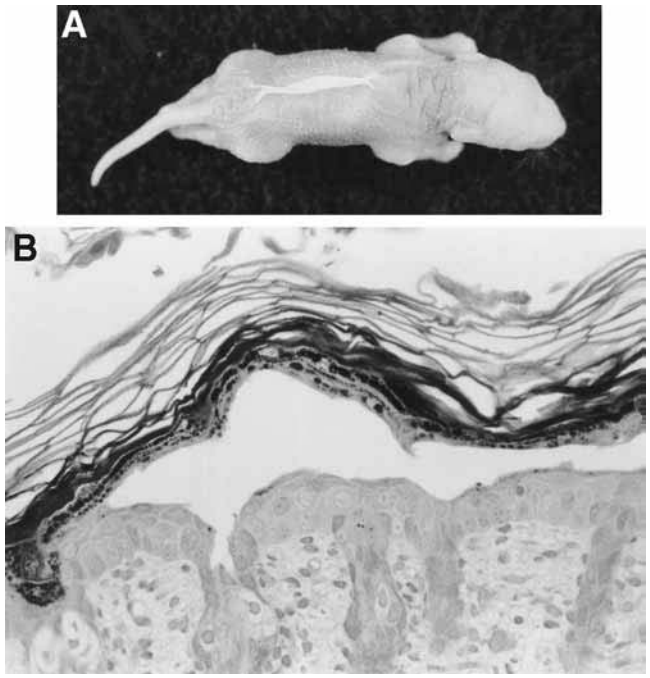

Figure 98-5 Passive-transfer mouse model of PF. Injection of purified IgG from the serum of a PF patient produces superficial erosions in neonatal BALB/c mice **(A)**. A biopsy shows acantholysis in the granular-cell layer of the epidermis **(B)**.

PV and PF autoantibodies induce epidermal cell detachment in the mouse model independent of complement activation, i.e., C5-deficient strains of mice and neonatal mice depleted of complement by cobra-venom treatment continue to develop extensive blistering disease when passively transfused with PF or PV IgG fractions. Furthermore, a series of studies has shown that $F(ab')_2$ and Fab fragments from PF and PV IgG are also pathogenic, suggesting that these autoantibodies may trigger cell detachment by simply binding to their target epitopes on the ectodomain of Dsg1 and Dsg3, respectively. This binding may impair the adhesive function of these molecules.

Investigations of PF and PV autoantibody pathogenesis have been aided by cloning and expression of the full-length ectodomains of Dsg1 and Dsg3. These studies prove convincingly that anti-Dsg1 autoantibodies in PF sera and anti-Dsg3 autoantibodies in PV sera are indeed pathogenic and responsible for inducing the lesions in patients' skin. Use of the baculovirus expression system has the advantage that both Dsg ectodomains are expressed as soluble glycoproteins that are highly immunoreactive with patient sera. The expressed Dsg 1 ectodomain has been used to purify Dsg1 specific autoantibodies from patients' sera and to subsequently show that the Dsg1-specific IgG are pathogenic in the mouse passive transfer model system. Moreover, preadsorption of patient sera with recombinant ectodomain of Dsg1 abrogated the pathogenic effect in the passive-transfer experiments. Similarly, affinity-purified anti-Dsg3 ectodomain antibodies from PV serum also induced skin lesions in neonatal mice; preadsorption of PV sera with Dsg3 ectodomain prevented both gross blistering and acantholysis in neonatal mice. Providing further evidence that loss of Dsg function leads to blister formation, Dsg3 knockout mice show oral erosions with suprabasilar acantholysis, resembling PV patients. Additionally, these Dsg3 knockout mice have been used to develop an active mouse model for PV.

To better understand how Dsg autoantibodies induce blister formation, attempts have been made to map the autoantibody binding sites on the Dsg polypeptide. However, these efforts have been complicated by the fact that although capable of binding to native Dsg, most PV and PF autoantibodies fail to bind to denatured Dsg, i.e., the Dsg structural motifs recognized by autoantibodies are conformationally dependent. Calcium-binding domains within the extracellular regions of Dsg1 and Dsg3 also modulate the structure of Dsg and subsequently, the optimal recognition and binding of autoantibodies. To bypass these conformational restraints, a domain-swapping epitope mapping strategy has been employed. Using molecular biology to insert regions of Dsg1 into the Dsg3 backbone (and vice versa), regions of the test antigen can be inserted into a polypeptide that retains the overall native structure. Using Dsg3 and Dsg1 domain-swapped molecules and competition ELISA, dominant PV and PF epitopes have been mapped to the N-terminal regions (amino acids 1–161) of both Dsg3 and Dsg1. A subset of epitopes within the EC1 domain, amino acids 26–87 of Dsg1 and 25–88 of Dsg3, were shown to be major antibody binding sites. More detailed mapping has demonstrated that some PF antibodies recognize an epitope consisting of Dsg1 residues His25, Cys28, and Ala29.

Using a similar domain-swapping approach and immunoprecipitation, profiles have been detected in endemic Brazilian PF patients that correlate with disease activity and clinical phenotype. Patients with active disease all possess anti-Dsg1 antibodies specific for the EC1 and/or EC2 domains, whereas patients in clinical remission have anti-Dsg1 antibodies against the EC5 domain. Within the same endemic focus of PF, anti-Dsg1 antibodies present in healthy individuals all recognize the EC5 domain of Dsg1. Additionally, antibodies from patients in the preclinical stage of the disease also target the EC5 domain of Dsg1, and the onset of clinical disease is accompanied by the emergence of antibodies against the EC1 and/or EC2 domain of the molecule. It was hypothesized that (1) an environmental antigen(s) in this region of endemic PF provokes the nonpathogenic anti-Dsg1 EC5 autoimmune response by molecular mimicry or by exposure to self-cryptic epitopes and (2) the pathogenic autoimmune response to EC1 and/or EC2 is a secondary event that occurs in genetically predisposed individuals by the mechanism of intramolecular epitope spreading.

Other potential mechanisms involved in pemphigus acantholysis have been suggested. For example, activation of keratinocyte plasminogen activator (PA) by PV and PF autoantibodies may trigger epidermal cell detachment. This hypothesis was reinforced by detecting elevated values of PA in epidermal cell cultures treated with PV or PF IgG. This elevation was abolished by previous treatment of the cultures with dexamethasone, which also abolishes the pathogenic effect of these antibodies. However, this finding could not be reproduced in vivo using the mouse model system. Moreover, PF and PV autoantibodies were pathogenic in PA knockout mice, demonstrating that PA is not necessary for antibody-induced acantholysis. Recent work has raised the possibility that binding of pathogenic PV autoantibodies to Dsg3 induce acantholysis by triggering intracellular responses, including phosphorylation of p38MAPK and heat shock protein 27, leading to collapse of the cytoskeleton and disruption of cell–cell adhesion. Importantly, inhibitors of p38MAPK prevent PV IgG induced cytoskeleton remodeling in primary human keratinocyte cultures suggesting that inhibiting these signaling pathways may be effective in treating pemphigus.

In addition to Dsg1 and Dsg 3, PNP autoantibodies are directed against a complex of antigens from keratinocytes that include

desmosomal plaque proteins (desmoplakins, periplakins, and envoplakins), a hemidesmosomal component (BP230), and an unidentified 170-kDa protein. The whole IgG fraction as well as affinity purified anti-dsg3 antibodies from PNP patients are pathogenic when tested by passive transfer experiments in the mouse model. The animals develop the skin phenotype of PV and show suprabasilar acantholysis in histopathology. Moreover, immunoadsorption of the PNP sera with recombinant Dsg3 eliminates the sera's pathogenicity in the mouse model. These findings demonstrate the pathogenic role of anti-Dsg3 antibodies in PNP sera. However, it is not clear what causes the different clinical phenotypes of PNP and PV. It has been speculated that both humoral and cellular mediated immune responses play a role in the pathogenesis of PNP.

Because the development of a humoral response requires T-cell activity, the identification of T-cell epitopes is important to understanding how autoimmune disease develops and progresses. Although several investigative groups have reported that peptides derived from Dsg3 induce the proliferation of T cells isolated from PV patients, no immunodominant T-cell epitope has been identified. The ectodomain of Dsg1 is also capable of stimulating T-cell clones from FS patients. Furthermore, a peptide derived from the EC5 domain of Dsg1 causes T-cell proliferation isolated from a subset of PV patients who possess both anti-Dsg3 and anti-Dsg1 antibodies. The autoreactive T cells in PV as well as in FS all have Th2-like cytokine profiles and Th2-dependent IgG4 is the predominant IgG subclass found in PV and PF/FS. Taken together, this suggests that autoreactive Th2 responses play an important role in the pathogenesis of PV and PF/FS.

MANAGEMENT/TREATMENT Despite the tremendous advances in the understanding of the molecular pathogenesis of PV and PF, the mainstay of treatment remains corticosteroids and other immunosuppressive agents. Before immunosuppressive therapy, the 5-yr mortality of PV approached 100%. The prognosis in PF was slightly better, with a 40–60% mortality rate. Despite the effective steroid and immunosuppressive therapy, the 5-yr mortality remains between 5 and 15%. The majority of cases of PV and PF require initial systemic steroids in doses that vary from 0.5 to 1 mg/kg/d of prednisone. In the small number of patients within this group who enter into clinical and serological remission, the steroids may be gradually reduced. To prevent relapses, steroid tapering is conducted over several months. Once the patient reaches a prednisone dose of 30 mg/d, tapering is continued by alternate day dosing. Some patients require additional immunosuppressive agents. Cytotoxic agents including azathioprine (1–2 mg/kg/d), cyclophosphamide (1–2 mg/kg/d), methotrexate (5–15 mg/wk), and mycophenolate mofetil (1–3 g/d) have been used in conjunction with prednisone to effectively control the disease.

Parenteral gold has been successfully used in the therapy of PV, but because of the incidence of side effects over long-term therapy including dermatitis, nephrotoxicity, and blood dyscrasias, its use has been limited. Other drugs occasionally reported to be effective in pemphigus include cyclosporine, etretinate, and dapsone.

In patients with refractory disease, plasmapheresis can be used as an adjunct therapy to acutely decrease the titers of circulating antibody; however, a rebound rise in autoantibody titers will occur if the patient is not concurrently treated with systemic immunosuppressive agents. Several reports have described the beneficial effects of intravenous Ig as an effective therapy for treatment resistant PV and PF. The mechanism by which intravenous Ig induces clinical and serological disease remission has yet to be defined. Rituximab, a chimeric anti-CD20 monoclonal antibody approved for use in CD20+ B-cell non-Hodgkins lymphoma, has shown promise for treatment refractory PV.

Patients on immunosuppressive therapy must be monitored for toxicity with a variety of laboratory tests including CBC, liver enzymes, creatinine, and urinalysis. Patients should be closely monitored for infection throughout the course of treatment. Patients on prednisone should be monitored for the development or worsening of conditions such as diabetes, hypertension, and osteoporosis that are exacerbated by systemic corticosteroids. Indirect IF studies of the patient's serum should be performed every 6–8 wk to monitor serological disease remission or relapse.

FUTURE DIRECTIONS There has been remarkable progress in characterizing the autoantibodies and target autoantigens in PV, PF, and PNP; however, the events that result in the production of these autoantibodies have not been defined. In essence, the etiology of pemphigus remains elusive. In this regard, because of the high incidence of disease and likely environmental factors that contribute to disease development, endemic PF offers a unique opportunity to identify the inciting agent and to begin to determine how cutaneous autoimmunity develops. Additional issues that need to be addressed include determining the (1) mechanism by which self-tolerance is broken, (2) T-cell epitope(s) implicated in promoting autoantibody production, and (3) the precise mechanism underlying acantholysis. The identification of B-cell and T-cell epitopes on Dsg3 and Dsg1 should pave the way for more specific therapies, including the induction of immunological tolerance. The availability of the active mouse model will be valuable for testing therapies including biological immunomodulatory agents.

BULLOUS PEMPHIGOID, CICATRICIAL PEMPHIGOID AND HERPES GESTATIONES

In 1953, Lever described the disease entity known as bullous pemphigoid (BP) as a subepidermal bullous dermatoses seen in the elderly. Subsequently IF techniques were used to demonstrate that BP patients have circulating and tissue-bound autoantibodies directed against antigens of the basement membrane zone (BMZ). The term "pemphigoid" applies to several different disorders that share the clinical appearance of vesicles and bullae, the histological finding of subepidermal blistering, and *in situ* deposition of autoantibodies at the BMZ (Table 98-1). Extensive skin involvement in the elderly population occasionally leads to significant morbidity. In addition, therapy with systemic corticosteroids and immunosuppressive agents may be associated with significant adverse effects.

CLINICAL FEATURES The precise incidence of pemphigoid is not known, but it is estimated to be twice that of PV. The incidence in Great Britain was estimated at 1/100,000/yr in 1985 and 7.63/million in France in 1995. There are three closely related pemphigoid diseases, namely BP, cicatricial (mucosal) pemphigoid (CP), and herpes gestationis (HG).

Bullous Pemphigoid BP appears to be a phenomenon of the aging immune system, with a peak incidence late in life. There is no known HLA class II gene that confers susceptibility for the disease; however, in the related disorder HG, approx 60–85% of patients are HLA-DR3 positive. Strikingly, approx 45% of women affected with HG are heterozygote HLA-DR3/DR4.

Often generalized BP has a predilection for the lower abdomen, inner thighs, groin, and axillae. The blisters are pruritic and appear on either normal skin or an erythematous, urticarial base (Fig. 98-6A). When blisters rupture, denuded areas may become crusted and occasionally invaded by pathogenic bacteria.

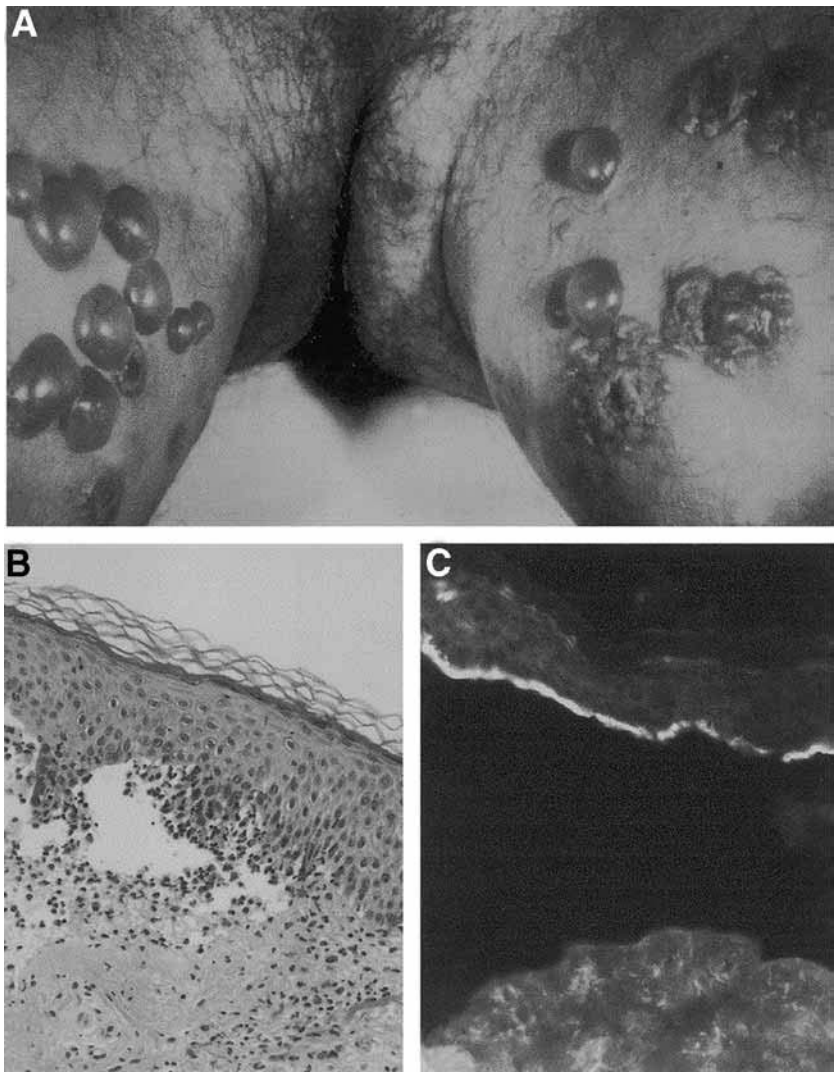

Figure 98-6 Clinical, histological, and immunological features of bullous pemphigoid. **(A)** Tense blisters and urticarial plaques develop on skin. **(B)** Histologically, biopsies of bullous pemphigoid show subepidermal bulla with an inflammatory infiltrate, including eosinophils, neutrophils, and lymphocytes. **(C)** Direct IF of skin section exhibits linear IgG deposition at the BMZ.

The course and prognosis of BP varies. Most treated patients go into a clinical remission within several months without need for further treatment.

Cicatricial Pemphigoid CP is a relatively rare condition characterized by chronic blistering and scarring of mucosal surfaces covered by stratified squamous epithelium. Involved organs include the ocular conjunctiva, nasal pharynx, oral pharynx, larynx, upper esophagus, and anogenital mucosa. The marked tendency for scarring in this disorder leads to high morbidity secondary to loss of vision, esophageal strictures, and fibrotic scarring of other mucous membranes.

Herpes Gestationis HG, also known as pemphigoid gestationis, is a relatively rare disease seen during pregnancy. The disorder often begins in the second or third trimester of pregnancy. It tends to recur in subsequent pregnancies and may be elicited by a challenge with oral contraceptives. Lesions tend to involve the abdomen and then spread peripherally. The lesion morphology is similar to that of BP.

LABORATORY DIAGNOSIS

Histopathology The histopathology of BP, CP, and HG are similar; examination of an early intact blister reveals a subepidermal blister with a mixed inflammatory infiltrate rich in eosinophils. The blister cavity contains serum, fibrin, and inflammatory cells (Fig. 98-6B).

Direct IF The ideal substrate for this test is a biopsy of normal-appearing skin adjacent to a lesion. A properly performed test from such a specimen is positive in essentially 100% of BP patients revealing a continuous linear deposition of C3 and IgG along the epidermal BMZ (Fig. 98-6C). Direct IF in HG and CP is similar to that of BP.

Indirect IF The most commonly used substrate for this test is monkey esophagus, although other stratified squamous epithelia such as normal human skin may be used. Most patients with BP have circulating IgG autoantibodies against the BMZ. These antibodies bind to the basement membrane macromolecules of stratified squamous epithelia. By the use of 1 *M* NaCl-split human skin as substrate, BP autoantibodies have been shown to bind to the epidermal side of the artificial split, a test useful in distinguishing BP from epidermolysis bullosa acquisita, an autoimmune subepidermal blistering disease in which the autoantibodies bind to the dermal side of the cleavage plane of salt split skin. By standard methods, indirect IF for antibody deposition is usually negative in HG; however,

anti-BMZ antibodies can be detected by complement-fixation amplification (HG factor assay) on intact or NaCl-split skin or by Western blotting. Of patients with CP, approx 25% have circulating anti-BMZ antibodies as detected by standard indirect IF. The site of autoantibody binding on NaCl-split human skin may be epidermal, dermal, or both.

Immunoelectromicroscopy On direct immunoelectromicroscopy (IEM), in vivo bound immune deposits (C3 and IgG) are seen in the lamina lucida of the BMZ as well as in the basal-cell hemidesmosomes. Similarly, circulating BP antibodies are directed against both the basal-cell hemidesmosomes as well as the lamina lucida on indirect IEM. The findings in HG are similar; however, in CP the autoantibodies localize to the hemidesmosomes, lamina lucida, and/or lamina densa.

AUTOANTIGENS AND AUTOANTIBODIES

Bullous Pemphigoid BP autoantibodies recognize two antigens, the hemidesmosome proteins BP180 and BP230. Both BP180 and BP230 have been cloned and characterized at the molecular level. The hemidesmosome is an organelle that mediates a stable interaction between the keratin intermediate filament proteins of the basilar pole of the keratinocyte and transmembrane adhesion molecules that anchor the basal cell to the underlying lamina densa of the basement membrane.

BP230 (also referred to as BPAg1) is an intracellular protein that localizes to the hemidesmosomal plaque and has significant homology with plectin and desmoplakins I and II. BP230 contains a central α-helical coiled–coil rod domain flanked by two globular domains. BPAg1 has been mapped to chromosome 6 (6p12-p11) in humans and to the proximal region of chromosome 1 in mice. BP230-specific autoantibodies recognize multiple epitopes on this molecule and belong to IgG and IgE immunoglobulin classes.

In contrast, BP180 (also referred to as BPAG2 and type XVII collagen) is a transmembrane protein with a type-II orientation (Fig. 98-7). Its amino-terminal region localizes to the intracellular hemidesmosomal plaque, whereas its carboxyl-terminal portion projects into the extracellular milieu of the BMZ. The extracellular region consists of 15 collagen domains separated from one another by noncollagen sequences. Mutations in the BP180 gene result in the nonlethal, but generalized blistering disease congenital epidermolysis bullosa, demonstrating the BP180's role in normal epithelial development. The BPAg2 has been mapped to chromosome 10 (10q24.3) in humans and to the distal end of chromosome 19 in mice. BP180-specific autoantibodies predominantly target epitopes located within the NC16A region of the molecule and are IgE, IgG1, and IgG4. Serum levels of anti-BP180 IgG and IgE are directly correlated with disease severity. Additionally, most BP patients have autoreactive T cells that recognize epitopes located in the extracellular region of BP180 and mainly in the NC16A domain. These T lymphocytes express CD4 memory T-cell surface markers and exhibit a Th1/Th2 mixed cytokine profile. These observations suggest that BP is a T- and B-cell-dependent and antibody-mediated skin autoimmune disease.

Herpes Gestationis HG autoantibodies react mainly with BP180 and, less frequently, with BP230. IgG autoantibodies in most HG sera recognize epitopes in the NC16A domain, which are different from those recognized by BP autoantibodies. Anti-NC16A autoantibodies belong to IgG1 and IgG3 subclasses. BP180-specific T cells react with NC16A and express a CD4+ Th1 memory phenotype.

Cicatricial Pemphigoid CP autoantibodies target multiple antigens, including BP180, laminin 5, laminin 6, β_4-integrin, and type-VII collagen. Isotypes of these autoantibodies are IgA and IgG. Among these autoantigens, BP180 is the most common. The majority of CP sera with BP180-specific CP autoantibodies react with epitopes in the C-terminal, NC16A, or central portion of the BP180 ectodomain. By indirect IEM, these anti-BP180 CP antibodies localize to the lamina lucida-lamina densa interface.

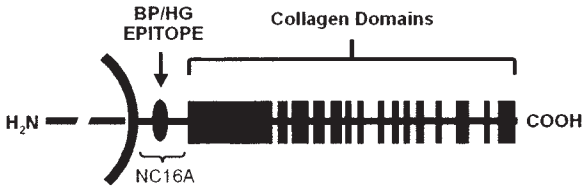

Figure 98-7 A schematic diagram of the structural organization of the human BP180 protein. The arch designates the transmembrane domain. The oval designates the NC16A antigenic site recognized by autoantibodies of bullous pemphigoid and herpes gestationis. The COOH-terminal extracellular region is made up of 15 interrupted collagen-like domains (black rectangles).

Laminin 5 (also referred to as epiligrin, kalinin, nicein, or BM600) is a heterotrimeric extracellular protein linking BP180 and α6β4 integrin with extracellular matrix components of the basement membrane. Anti-laminin 5 CP autoantibodies bind to the dermal side of NaCl-split human skin and localize to the lower region of the lamina lucida by IEM. Some CP patients have circulating autoantibodies reactive with the β_4-subunit of $\alpha_6\beta_4$-integrin or type-VII collagen.

IMMUNOPATHOLOGICAL MECHANISMS OF BLISTER FORMATION

BP and Herpes Gestationis Blister formation in BP and HG was thought to be an IgG autoantibody-mediated process; however, previous attempts to demonstrate the pathogenicity of patient autoantibodies had been unsuccessful. Antihuman BP180 NC16A autoantibodies fail to crossreact with the murine form of this autoantigen and thus cannot be assayed for pathogenicity in a conventional passive transfer mouse model. As an alternative, rabbit polyclonal antibodies were made against a segment of the murine BP180 protein homologous to human BP180 NC16A (mBP180 NC14A); purified rabbit anti-mBP180 IgG was then passively transferred to neonatal BALB/c mice. The injected animals developed a blistering disease that closely mimicked human BP, including in vivo deposition of rabbit IgG and mouse C3 at the BMZ and dermo-epidermal junction (DEJ) separation with an inflammatory cell infiltrate (Fig. 98-8). Further characterization of this IgG passive transfer model has revealed that subepidermal blistering is initiated by anti-BP180 antibodies and depends on complement activation, mast cell degranulation, and neutrophil infiltration.

Neutrophil infiltration is a prerequisite for experimental BP and the disease severity is directly correlated to the number of infiltrating neutrophils. Mice depleted of neutrophils are resistant to experimental BP. Blocking neutrophil infiltration abolishes subepidermal blistering. On activation through molecular interaction between Fc of pathogenic anti-mBP180 IgG and Fc receptors on the cell surface of neutrophils, infiltrating neutrophils release several proteolytic enzymes including neutrophil elastase (NE) and gelatinase B (GB). Mice lacking NE or GB are resistant to experimental BP. Although both GB and NE are capable of degrading the recombinant BP180 protein in vitro, only NE produces DEJ separation when incubated with skin sections. In vivo, NE compensates for the lack of GB, whereas GB cannot compensate for NE deficiency in the development of BP. In addition, the degradation of BP180

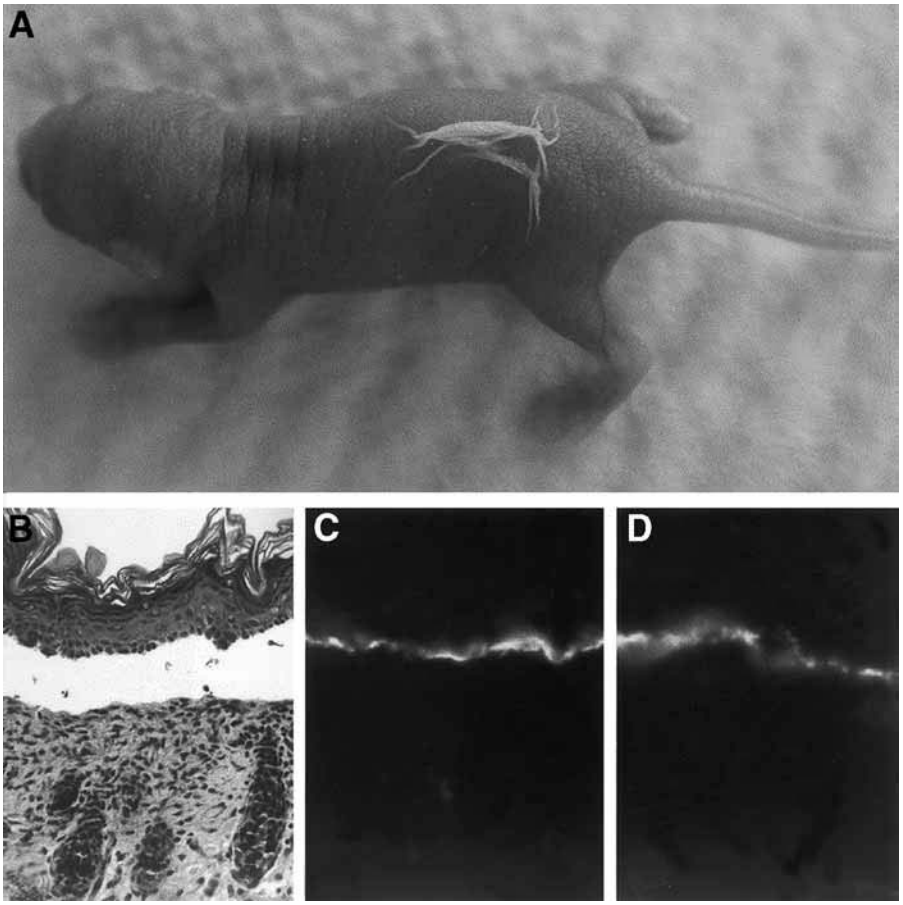

Figure 98-8 Passive transfer of rabbit anti-mBP180 IgG. Neonatal BALB/c mice are injected intradermally with rabbit anti-murine BP180 IgG. After 24 h, gentle friction elicits persistent epidermal wrinkling, producing the "epidermal detachment" sign **(A)**. Histological examination of lesional skin reveals dermal–epidermal junction separation with an inflammatory infiltrate **(B)**. Direct IF analysis shows deposition of anti-BP180 IgG **(C)** and murine C3 **(D)** at the BMZ.

in vivo depends on NE activity. Further dissection of this proteolytic event in experimental BP reveals a functional relationship between GB and NE; GB proteolytically inactivates α1-proteinase inhibitor, the physiological inhibitor of NE. Unchecked NE then cleaves extracellular matrix proteins including BP180 antigen, resulting in DEJ separation. In total, these studies provide compelling evidence that anti-BP180 autoantibodies are pathogenic and suggest an immunopathological mechanism of subepidermal blistering in BP.

The pathogenic role of anti-BP180 antibodies has been confirmed by other in vitro and in vivo studies. BP180NC16A-specific autoantibodies purified from human BP sera induce dermal-epidermal separation in cryosections of human skin in the presence of neutrophils. This study confirms earlier findings in which BP autoantibodies induced DEJ separation in human skin sections only in the presence of both leukocytes (mostly neutrophils) and complement. Like the rabbit anti-mBP180 IgG passive transfer model, rabbit antibodies directed against the extracellular domain of hamster BP180 (NC16A region) trigger BP-like subepidermal blisters in neonatal hamsters. In addition, although human BP blister fluid has high levels of both NE and GB, BP180 degradation by blister fluid depends on NE activity.

It is not clear what role, if any, antibodies specific for the BPAg1 play in the development of lesions. Passive transfer of human antibodies against the BPAg1 does not produce inflammation in murine skin. Rabbits that are immunized to the antigen and have circulating anti-BPAg1 antibodies do not develop cutaneous lesions, although these animals do exhibit an unusual inflammatory reaction to UV radiation. In this circumstance, erythematous doses of UV light produce marked epidermal inflammation and keratinocyte necrosis suggesting that antibodies against BPAg1 may result in secondary inflammatory events in vivo.

Cicatricial Pemphigoid Although anti-BP180NC16A antibodies have been shown to be pathogenic in BP, the pathogenicity of CP autoantibodies directed against the central portion and C-terminal portion of the BP180 ectodomain has not been demonstrated. In contrast, anti-laminin 5 CP antibodies have been demonstrated to be pathogenic by IgG passive transfer:

1. Rabbit anti-laminin 5 induced a subepidermal blistering disease in neonatal mice.
2. Human anti-laminin 5 autoantibodies induce subepidermal blisters in an experimental human skin graft model.
3. Mice receiving rabbit anti-laminin 5 Fab fragments developed CP.

These studies demonstrated that neither complement activation nor crosslinking of laminin 5 in epidermal basement membranes was required for induction of subepidermal blister formation in this animal model of a human autoimmune bullous disease. When incubated with normal human conjunctiva tissue sections, β_4-integrin specific autoantibodies from ocular CP sera induce BMZ separation suggesting that circulating anti-β_4-integrin autoantibodies are pathogenic in ocular CP.

MANAGEMENT Pemphigoid, a disorder with prominent inflammatory features, results from an abnormal immune response. In the absence of effective therapy, elderly patients with extensive erosions may develop complications including fluid loss, electrolyte imbalance, bacterial colonization with potential sepsis, and scarring. Therapy for pemphigoid is directed at suppressing the inflammation and/or the immune response.

Patients with generalized BP require systemic therapy; the most commonly used agents are the corticosteroids. Immunosuppressive therapy with azathioprine, cyclophosphamide, mycophenolate mofetil, and methotrexate has been used as steroid-sparing agents. Similar precautions as described in the treatment of PV and PF should be followed. Dapsone is effective in controlling the diseases in some BP patients. Potential side effects of dapsone include hemolysis, hepatitis, and peripheral neuropathies; monitoring for the development of these effects includes laboratory and physical examination at initial and subsequent visits. High potency topical steroids (e.g., clobetasol) under occlusion and systemic intravenous Ig are two additional therapies effective in BP management, particularly in patients in whom comorbid conditions may restrict the use of systemic immunosuppressive therapy. Animal model studies show that intravenous Ig is effective in treating BP, PF, and PV. The mode of intravenous Ig action in these autoantibody-mediated bullous diseases is to accelerate clearance of pathogenic antibody by saturating the IgG protective receptor FcRn. The failure of tumor necrosis factor-α knockout mice to develop blisters by passive transfer of BP180 antibodies suggests that anti- tumor necrosis factor-α biologics may have a future therapeutic role in BP. The treatment of CP and HG follows the same principles as that of BP.

FUTURE DIRECTIONS Extensive information has been derived about the molecular structure and biological functions of autoantigens in BP, HG, and CP. Animal models have confirmed the pathogenic role of some of these autoantibodies in the induction of skin lesions. Future research should be directed toward further dissection of the mechanisms of antibody-mediated tissue injury and the immune response that results in the production of pathogenic autoantibodies. The goal of such studies is to develop treatments of greater specificity and potency that have a more tolerable risk-benefit profile.

99 Systemic Lupus Erythematosus

Amr H. Sawalha, Luis A. Diaz, and John B. Harley

SUMMARY

Lupus is a serious, potentially life-threatening disease. Its natural history is to culminate in a crescendo of autoimmunity and organ involvement. Difficulty arriving at the diagnosis may delay institution of therapy, which although helpful brings new problems. The fundamental understanding of this disease has made major strides. There is no consensus on the likely etiological agent(s), though evidence implicates Epstein-Barr virus, and the genetic approach to understanding etiology is in its infancy. Nevertheless, efficacious treatments are anticipated in the plethora of new biologics likely to have therapeutic effects in lupus, essentially a disease of immune dysregulation.

Key Words: Clinical manifestations; EBV; genetics; lupus; serology; skin.

INTRODUCTION

Systemic lupus erythematosus (SLE) is multisystem autoimmune disease characterized by the production of autoantibodies against a host of nuclear antigens. *Lupus*, the Latin word for wolf, has been used for at least seven centuries to describe the malar rash that some think resembles an animal bite. The disease was recognized initially as a skin disease. Hebra and Kaposi were the first to report systemic involvement of the disease. Their work published in 1874 described the association of lupus with anemia, lung involvement, mental status changes, and death. In three papers published between 1895 and 1903, Sir William Osler described the systematic involvement of lupus, the first detailed description recognizing the multiple systems affected by the disease.

Lupus affects multiple organ systems including the skin, joints, mucous and serosal membranes, kidneys, blood, lungs, and nervous system. The disease is more common in females and in African Americans. Despite advances, the pathogenesis of SLE is still incompletely understood. This chapter discusses the epidemiology, clinical features, pathogenesis, etiology, and management of SLE.

EPIDEMIOLOGY

SLE is distributed worldwide and affects all ethnicities. Disease incidence in the United States ranges between 2 and 7.6/100,000/yr. The prevalence has been estimated between 12 and 50.8 lupus cases/100,000. As many as 85–90% of the lupus patients are females. The female predominance disappears in age groups younger than 14 yr and older than 64 yr, consistent with an important role for estrogens in this phenomenon, an idea that is also supported by data from animal models of lupus.

In the United States, SLE is more common and more severe in African Americans than in European Americans. Relative to European Americans, the African American lupus patients tend to have more discoid lupus (DLE), lupus nephritis, myositis, and pericarditis. However, African American lupus patients have less photosensitivity, malar rash, mouth ulcers, anticardiolipin, and lupus anticoagulant compared with European Americans. Interestingly, lupus appears to be much less common in Africa than it is in American blacks.

DIAGNOSIS AND CLASSIFICATION

There is no single test that establishes the diagnosis of SLE. Instead, the diagnosis rests on the presence of a complicated set of clinical and laboratory findings. Consequently, reliable diagnosis is usually the purview of an experienced clinician. Because lupus is so heterogeneous, patients may present with a range of different clinical findings. The American College of Rheumatology (ACR) classification criteria are used to standardize the various clinical features for research studies. According to these criteria, the patient is classified as having lupus if he or she meets at least four of the eleven criteria (Table 99-1). It should be remembered however, that the ACR criteria are classification and not diagnostic criteria. There are patients who well satisfy the criteria, but who do not have lupus and others who do not satisfy the ACR criteria, but clearly have lupus. As a guide to the scope and range of the usual manifestations of this disease, they are useful and have found their way into ordinary rheumatic disease clinical practice.

Several laboratory tests are useful in evaluating a patient suspected of having lupus. The most sensitive test for lupus is the presence of antinuclear antibodies (ANA), which is positive in approx 98% of lupus patients. ANA are present, however, in a variety of other autoimmune and infectious conditions, as well as in normal, especially older individuals. ANA are usually detected by indirect immunofluorescence (IF) assay using HEp-2 cell lines as substrate. The results are reported in titers and patterns. There are no ANA patterns that are diagnostic of lupus. Examples of immunofluorescent patterns found in lupus include speckled, homogeneous, rim or peripheral, nucleolar, and nucleolar with cytoplasmic IF (Fig. 99-1). Antidouble-stranded DNA (dsDNA) antibodies are also detected by indirect IF using Crithidia luciliae as substrate.

Table 99-1
The American College of Rheumatology Classification Criteria for Systemic Lupus Erythematosus, Updated 1997[a]

- Malar rash
- Discoid rash
- Photosensitivity
- Oral ulcers
- Arthritis
- Serositis (Pleuritis or pericarditis)
- Renal disorder (Proteinuria (>0.5 g/d or >3+) or cellular casts)
- Neurological disorder (Seizures or psychosis)
- Hematological disorder (Hemolytic anemia with reticulocytosis, leukopenia <4000/mcl, lymphopenia <1500/mcl, or thrombocytopenia <100,000/mcl in the absence of an offending drug)
- Immunological disorder (Positive lupus erythematosus cell preparation, antidouble-stranded DNA, anti-Sm, or false positive serological test for syphilis)
- Antinuclear antibody

[a]The patient is classified as having systemic lupus erythematosus in the presence of four or more criteria.

Other antibodies found in lupus sera are tested using other techniques, i.e., double immunodiffusion, enzyme-linked immunosorbent assay, immunoblotting or immunoprecipitation and using other cellular sources of antigen such as the extractable nuclear antigens that include Sm, nRNP, Ro (SSA), La (SSB), and others.

Some antibodies are sensitive and specific for lupus whereas others are relatively less specific. Anti-dsDNA, anti-Sm, and antiribosomal P antibodies are relatively specific for lupus and can be detected in approx 50, 20, and 10%, respectively, of lupus patients. Anti-Ro/SSA and anti-La/SSB autoantibodies are also common in lupus, being seen in approx 40 and 15% of lupus patients, respectively. Anti-Ro/SSA and La/SSB occur in a higher frequency in primary Sjögren's syndrome, at approx 60 and 35%, respectively. They are also associated with subacute cutaneous lupus and the neonatal lupus syndrome variably consisting of a lupus rash, heart block, and hepatitis in neonates. Virtually all of the patients with anti-La precipitins also have anti-Ro autoantibodies. This is thought to be explained by the presence of both La and Ro specificities on the same molecular particle in some circumstances. Anti-Ro and anti-La are associated with rheumatoid factor in lupus patients. Rheumatoid factor and anti-Ro are probably the most common lupus autoantibody specificities found in normal individuals.

Antinuclear ribonucleoprotein (nRNP) antibodies are also common in lupus at approx 40% of patients. When anti-Sm is present it is usually found with anti-nRNP. Both are more common in African Americans than in European Americans. Also, anti-nRNP is associated with mixed connective tissue disease, which some consider a variant of lupus and others consider a distinct entity. Mixed connective tissue disease is characterized by anti-nRNP, arthritis, myositis, and Raynaud's phenomenon.

CLINICAL FEATURES

SLE is an extraordinarily heterogeneous disease than can affect almost any organ system. Indeed, the disease is so heterogeneous that many patients may share no clinical feature and yet are appropriately diagnosed with this disease. The appreciation that these patients belonged together has been a recent development in the progress of clinical medicine.

GENERAL Fatigue, general weakness, weight loss, lymphadenopathy, and fever are common complaints; they often precipitate clinical presentation. Fever in lupus generally responds to corticosteroids. It is important to exclude infection to the extent practically possible as a cause of fever in any lupus patient, however, before starting steroid therapy. However, steroids can be life-preserving in the acute setting and withholding them may pose greater risk and danger.

CUTANEOUS More than 50% of patients with lupus erythematosus experience photosensitivity to sunlight. The sunlight ultraviolet (UV) spectrum causing photosensitivity falls within the UV-B range (causing sunburn reaction) and in some patients within the UV-A and visible range. Patients with lupus may show an intense sunburn reaction when exposed to sunlight (or UV light in tanning parlors) or may develop skin lesions in the following days or weeks of the exposure. In both situations the patients may experience exacerbations of their systemic disease. Drug-induced photosensitivity must be ruled out in these patients. These drugs include nonsteroidal antiinflammatory drugs (NSAIDs), phenothiazines, chlorothiazides, and tetracyclines. It must also be included in the differential diagnosis of photosensitivity diseases such as porphyrias, rosacea, pellagra, and so on that can be associated with this symptom.

Malar "butterfly" rash is a classic skin manifestation for SLE. The classic butterfly produces an erythematosus eruption involving the dorsum of the nose (body of the butterfly) and the malar areas (wings). This eruption typically spares the nasolabial folds. The eruption may vary from erythema, infiltrated papules and plaques with and without hyperkeratosis and less commonly erosions and vesicles (a typical example is given in Fig. 99-2). The malar areas of the face are thought to be the most sun exposed of bodily skin. The butterfly rash of lupus is often confused with common skin diseases such as rosacea, seborrheic dermatitis, and dermatophytosis. The malar rash in its classic appearance is almost pathognomonic of lupus. Other lupus manifestations should, however, always be sought.

Subacute cutaneous lupus erythematosus (SCLE) is used to describe a specific eruption seen in some patients complaining of intense photosensitivity. The SCLE eruption can be either annular with erythematous margins or psoriasiform plaques (Fig. 99-3). The rash typically appears on the sun-exposed areas. The resolved lesions leave areas of hyperpigmentation and hypopigmentation in its wake and do not usually lead to scarring. The most common sites of involvement are the chest, upper back, and the arms. The subacute cutaneous lupus rash can involve the hands, and when it does, it typically spares the knuckles. SCLE is associated with the presence of anti-Ro and anti-La autoantibodies.

Discoid lupus erthematosus (DLE) skin lesions are characterized by oval or elongated atrophic plaques. These plaques show central depigmentation and hyperpigmented or eythematous borders. The epidermis is thin and covered by hyperkeratotic scales and shows follicular plugging. The DLE lesions are commonly located on sun-exposed areas of the skin (Fig. 99-4). They can also be found on the scalp in which they produce scarring alopecia. Depigmented plaques, resembling vitiligo may be found in patients undergoing systemic therapy for lupus. About 5–10% of the DLE patients have the systemic form of lupus erythematosus. The histopathological examination of the skin lesions of lupus reveals epidermal atrophy with hyperkeratosis. There is vacuolar degeneration of the basal cell layer of the epidermis and a prominent

Figure 99-2 The butterfly rash in a young woman. The erythematous eruption involves the dorsum of the nose (butterfly's body) and the malar areas ("wings").

Figure 99-3 Subacute cutaneous lupus erythematosus producing annular inflammatory plaques on the back of a patient.

lymphohistiocytic inflammatory infiltrate in the upper dermis. This infiltrate is perivascular and concentrated around the skin appendages. In DLE lesions there is hyperkeratosis and follicular plugging and destruction of melanocytes. In addition to these findings, lesional skin from most lupus patients shows granular deposition of immunoglobulins and complement component (C3) along the dermal–epidermal junction (lupus band test) by direct IF. This IF pattern is also seen in approx 75% of sun-exposed nonlesional skin and 50% of nonsun-exposed nonlesional skin in SLE patients. It is thought that exposure to UV light increases apoptosis of the keratinocytes, therefore exposing nuclear antigens to the circulating ANAs (particularly anti-Ro) leading to complement mediated tissues injury. This hypothesis explains that skin involvement in SLE favors sun-exposed areas and is associated with the presence of anti-Ro autoantibody.

Alopecia may be present and can be either diffuse or localized. The localized lesions showing scarring and depigmentation are typical of DLE. Patients with lupus are also more likely to have concurrent alopecia areata, which can be distinguished from lupus related alopecia by the absence of IgG deposition in the dermal–epidermal junction. Alopecia was one of the original classification features for the ACR criteria, but was dropped on revision in 1982 after the data showed that this feature poorly discriminated lupus from other disorders.

Livedo reticularis is common in lupus and is associated with the presence of antiphospholipid antibodies. Livido reticularis usually involves the lower extremities producing a purplish network, "lace-like" pattern following the distribution of superficial blood vessels (Fig. 99-5). This cutaneous sign can be also seen in a variety of skin diseases including atheroembolism.

Vasculitic skin lesions are not uncommon in lupus and can progress to cause tissue necrosis and gangrene. The lesions of vasculitis may vary from persistent urticarial plaques, "palpable petechiae" and tender nodules. There could be underlying livedo reticularis as well. The vasculitis lesions show neutrophilic inflammatory injury of cutaneous blood vessels, producing the pattern known as leukocytoclastic vasculitis. Leukocytoclastic vasculitis in

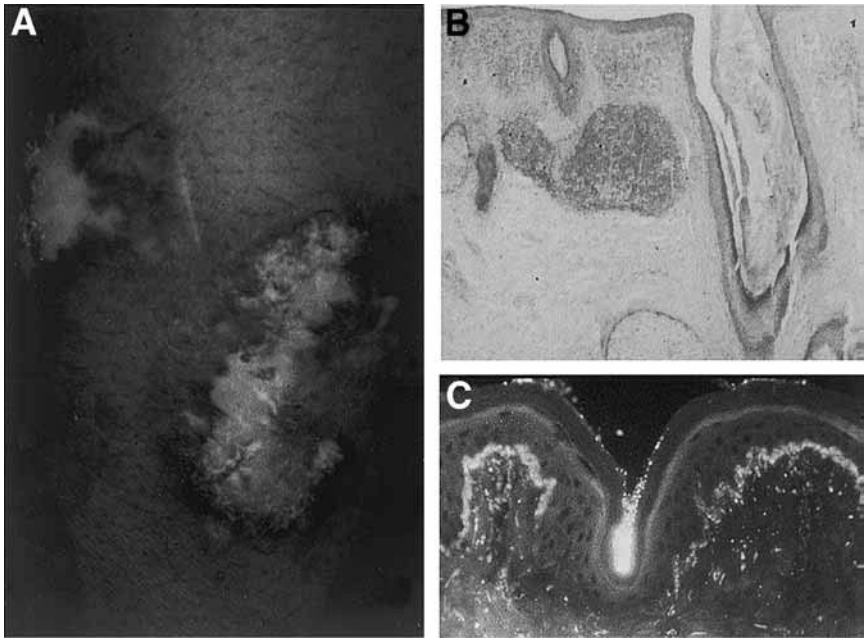

Figure 99-4 Classic clinical (**A**), histological **(B)**, and direct immunofluorescent **(C)**, findings in a clinical lesion of discoid lupus erythematosus. The lesions are atrophic depigmented plaques, which on histological examination show intense periappendigeal lymphocytic infiltrate in the dermis and epidermal atrophy and hair follicle plugging. There is also deposition of immunoreactants (immunoglobulins and complement) at the dermal–epidermal junction.

the absence of lupus erythematosus may be seen in other diseases such as Schonlein-Henoch purpura or drug-induced vasculitis.

Lupus panniculitis (also known as lupus profundus) is an inflammatory process of the subcutaneous tissue and deep dermis that should be distinguished from other forms of panniculitis such as erythema nodosum and infections. Clinically, these lesions are tender, indurated erythematosus nodules or plaques that may lead to lipoatrophy. The patients usually exhibit other cutaneous and serological signs of DLE or SLE. It is thought that suponification of the subcutaneous fat produced by inflammation leads to calcium deposition that may appear on X-ray images. Only a small proportion of lupus patients have panniculitis.

Although more classically seen in scleroderma, Raynaud's phenomenon occurs in about half of lupus patients. Raynaud's is arterial spasm of the arteries supplying digits of the hands or feet precipitated by cold exposure. The affected digit blanches, relative to unaffected digits, and may be painful and relatively numb. Cyanosis and postdilatation erythema are the last two phases of classic Raynaud's. Anti-nRNP autoantibodies are associated with Raynaud's phenomenon in lupus. Other less common skin features include urticaria, bullous lupus, splinter hemorrhages, and angioedema.

Oral ulcers and erosions are common in lupus. They typically involve the buccal mucosa and the border between the soft and hard palate, but can occur anywhere in the oral cavity or nasal passages. Oral ulcers and erosions can be seen in a variety of diseases, including aphthous ulcers, lichen planus and Behçet syndrome. The underlying process may be secondary to vasculitis or to involvement of the oral mucosa by the lupus process similar to that seen in DLE in the skin.

ARTHRITIS Joint involvement is the most common manifestation of lupus, affecting greater than 80% of patients. Typically, the arthritis is polyarticular and involves small to medium joints in a symmetric distribution, identical to the most common distribution of polyarthritis in rheumatoid arthritis. The small joints of the hand, the wrist and the knees are commonly involved. Involvement of the elbows, shoulder, or ankles occurs less frequently. Joint involvement in lupus can be deforming, but unlike rheumatoid arthritis, joint erosions are not seen. Deformities in lupus are probably related to chronic tenosynovitis and the ligamentous laxity resulting from chronic inflammation. Although joint deformities in lupus resemble rheumatoid arthritis, they are usually reducible. Morning stiffness is seen in approximately one-half of patients with lupus. Joint effusions are usually small. Acute swelling of a single joint should always raise suspicion of septic arthritis and usually merits evaluation for infectious causes.

RENAL Renal involvement is seen in approximately half of patients with lupus. The presence of anti-dsDNA antibodies is associated with renal involvement in lupus, whereas the combination of both anti-Ro and anti-La is associated much less with lupus nephritis. Satisfaction of the ACR criteria for renal involvement requires proteinuria at greater than 0.5 g/24 h or at 3+ by dip-stick in the absence of a quantitative test or active urinary sediment that contain casts made up of red blood cell, hemoglobin, tubular, granular, or mixed elements.

The World Health Organization has used renal biopsy pathology to classify lupus nephritis according to findings on light, IF, and electron microscopy (Table 99-2). Patients with mesangial disease of the glomeruli (class II) usually have no compromise in renal function. Conversely, patients with focal or diffuse proliferative changes in their glomeruli (class III and class IV) tend to have impaired renal function. The presence of active glomerular lesions in those patients is an indication for aggressive treatment with immunosuppressive medications. Patients with membranous glomerular disease (class V) tend to have a slower progression with a preserved renal function for many years. The World Health Organization class I is "nil" disease in which no pathological abnormalities are appreciated, but these patients usually have proteinuria as an indication for the biopsy.

Figure 99-5 Lupus patient showing the "livedo" pattern of livedo vasculitis and ulcerations secondary to injury to blood vessels of the skin.

Table 99-2
WHO Classification for Lupus Nephritis

(I)	Normal glomeruli
(II)	Pure mesangial disease
(IIIA)	Focal segmental glomerulonephritis
(IIIB)	Focal proliferative glomerulonephritis
(IV)	Diffuse glomerulonephritis
(V)	Diffuse membranous glomerulonephritis
(VI)	Advanced sclerosing glomerulonephritis

PULMONARY Pleurisy is not uncommon in SLE and occurs with or without pleural effusion. Patients typically complain of pleuritic-type chest pain, in which pain characteristically becomes intense with the movement of the pleural membranes relative to one another. To avoid the increased pain that accompanies deep breathing, patients take shallow and tentative breaths. Pleurisy may be accompanied with lupus pericarditis.

Acute lupus pneumonitis can be difficult to diagnose; it may be fulminant and deadly with an acute onset. This situation may be a treatment emergency for the underlying lupus process and yet cannot be easily and confidently distinguished from an infective pneumonia, except sometimes by biopsy, which may not be practical to obtain. Patients may present with cough, shortness of breath, and fever. Pulmonary hemorrhage is commonly part of the clinical picture. Lupus pneumonitis may also instead be chronic and then is associated with pulmonary fibrosis and pulmonary hypertension. Although not common, pulmonary vasculitis may occur and can lead to life threatening pulmonary hemorrhage.

CARDIAC Pleurisy or pericarditis satisfies the serosal involvement ACR criterion for the lupus classification. Pericarditis is commonly associated with pleurisy, and can be present with or without pericardial effusion. When present the effusion is usually small, although pericardial tamponade, sometimes repeatedly, does occur.

Myocarditis is a less common cardiac manifestation in lupus and is usually suspected in the setting of congestive heart failure or arrhythmias. Evidence of the verrucous lesions of "Libman Sacks" endocarditis is seen in up to 60% of lupus patients at autopsy. Large vegetations can result in significant valvular dysfunction and require valve replacement. Indeed, small lesions on the atrioventricular valves are especially common and are usually asymptomatic.

Patients with lupus have a higher risk for coronary artery disease and myocardial infarction from accelerated atherosclerosis, anticardiolipin antibodies, and coronary vasculitis. Indeed, the risk of myocardial infarction is a few 100-fold higher in menstruating lupus patients than in age and sex matched controls.

NEUROLOGICAL Among the various neurological manifestations of lupus, only seizures and psychosis are recognized as satisfying the ACR criterion of neurological involvement for the classification of lupus. Seizures occur in approx 10% of patients and can be focal or generalized. Psychiatric manifestations in lupus patients have been associated with the presence of antiribosomal P antibodies. Patients with lupus often suffer from cognitive impairment as well, which clouds judgment and makes compliance with medical advice and therapeutic regimens difficult. This is a poor prognostic indicator. Psychosis affects a small minority of lupus patients, though a much higher proportion have neurotic behavior that is also usually part of the disease process. The molecular and cellular mechanisms for the central nervous system manifestations are poorly understood.

Cerebrovascular accidents are because of anticardiolipin antibodies, accelerated atherosclerosis, small vessel vasculopathy, and rarely central nervous system vasculitis. This is also poorly understood area of lupus clinical medicine. Most autopsy studies fail to define central nervous system pathologies in lupus patients with clinical evidence of central nervous system involvement.

The nonspecific symptoms of headache and fatigue are especially common. Headache responds to the typical regimens now employed, but occasionally is a harbinger of serious problems. Fatigue is almost universal in lupus. Very little is available to help with this problem. Many of these patients also have fibromyalgia. Separating the mental health issues and somatization from the underlying illness can be especially challenging.

Other less common neurological manifestations of lupus include transverse myelitis, peripheral neuropathy, and movement disorders suggesting Guillain-Barré syndrome. Lupus can be also associated with cranial neuropathies, retinopathy, and chorea. Some patients develop myositis making difficult the differentiation of lupus from polymyositis or dermatomyositis.

HEMATOLOGICAL The hematological manifestations of lupus that are recognized for the purpose of classification by the ACR criteria include hemolytic anemia with reticulocytosis,

leukopenia (<4000/mcl), lymphopenia (<1500/mcl), or thrombocytopenia (<100,000/mcl). Anemia of chronic disease is probably the most common hematological manifestation in lupus. Idiopathic thrombocytopenic purpura can be especially deadly in lupus. About 10% of lupus patients who die do so with a process resembling idiopathic thrombocytopenia, and without effective intervention the process can be fulminant and rapidly evolving into a medical emergency. Idiopathic thrombocytopenic purpura and hemolytic anemia are formes frustes of lupus. Patients may present with idiopathic thrombocytopenia purpura or with hemolytic anemia without other signs or symptoms suggesting lupus and then develop other features of lupus in the subsequent months or years.

Thrombocytopenia is the most reliable predictor of death in lupus, having been found in virtually all of the reported studies of survival. The increased relative risk (RR) for death is as high as 40-fold in lupus patients with thrombocytopenia. There is no insight explaining why thrombocytopenia is associated with a poor prognosis.

OTHER FEATURES Abdominal pain may be explained by mesenteric vasculitis, pancreatitis, and lupus peritonitis. Budd-Chiari syndrome and splenic infarcts are associated with anticardiolipin antibodies. Patients with lupus can also present with lymphadenopathy, hepatomegaly or splenomegaly. Ocular findings can include keratoconjunctivits sicca, episcleritis, and retinal vasculitis.

Other features that can be seen in SLE are related to complications of treatment. These include gastrointestinal toxicity induced by the NSAIDs, various toxic effects resulting from prolonged use of systemic steroids including steroid-induced osteoporosis and avascular bone necrosis, and increased susceptibility to infections secondary to the various immunosuppressive medications used.

ETIOLOGY AND PATHOGENESIS

The etiology of SLE is poorly understood. Several genetic and environmental factors are thought to influence its development.

THE GENETICS OF LUPUS The evidence that lupus is a genetic disorder is convincing. First, familial aggregation is present in lupus families. Second, particular genetics associations are already known. Third, genetic linkage studies have consistently implicated a number of additional genes as fundamental to the pathogenesis of lupus. Fourth, many of the animal models of lupus have a genetic basis, consistent with genetic variation being important in lupus.

About 10% of lupus patients report a second family member with lupus and 20–40% of identical twins are concordant for lupus. Evidence for a genetic etiology for lupus is supported by familial clustering of the disease with the ratio of risk to a sibling being 10–20 times higher than the population risk of lupus.

The DR2 and DR3 alleles at human leukocyte antigen (HLA)-DR are clearly associated with lupus in Europeans. As is true for all human histocompatibility associations, the pathophysiology and mechanistic details that explain this association are not known.

Lupus is also associated with polymorphisms of at least *FcγRIIA* and *FcγRIIIA*, and perhaps other Fc receptor genes. In both cases the allele that binds IgG subtypes with lower affinity is associated with increased risk of lupus. These alleles are thought to have decreased capacity to clear immune complexes made up of the specific low affinity IgG subtypes. These genes are neighbors on the human genome at chromosome 1q22-24, in a region also known to have genetic linkage with lupus. These two Fc receptors are separated by only 20 kb of genomic DNA and are in linkage disequilibrium.

Alleles of *PDCD-1*, a T-cell transcription factor, have been implicated as responsible for the linkage at 2q37, first found in the Nordic pedigrees lupus multiplex directory.

Several other genes are thought to increase susceptibility to the development of lupus without producing consistently convincing evidence of genetic association. These include polymorphisms involving the *IL-10*, *FAS* and *FASL*, the mannose binding lectin genes, *Bcl-2*, *CTLA4*, the T cell receptors, prolactin, tumor necrosis factor, and its receptor.

Genome wide linkage studies for SLE have revealed some potentially important genetic polymorphisms that increase the susceptibility to lupus. At least five linkages have been established and confirmed including those at 1q23, 2q37, 4p16, 6p21, and 16q13, along with many others that have not produced such convincing results. Of these linkages convincing associations that may explain them are published with alleles at *FcγRIIIA* (1q23), *PDCD-1* (2q37), and *HLA-DR* (6q21). Many other genetic effects (>15) have been established and await confirmation. Completion of the human genome project and improved methods of analysis are anticipated to provide much more rapid progress toward a more complete genetic understanding than has been previously possible.

LUPUS AND THE COMPLEMENT SYSTEM The complement system is a key constituent of the immune response and plays a central role in protecting against infections. In lupus, the classic complement pathway is thought to have an essential role in the pathophysiology of the disease. Deposition of immune complexes in various tissues is followed by activation of the classic complement pathway that will induce inflammation, tissue injury, and damage characteristic of SLE. As a result, patients with active disease tend to have low complement components C3 and C4. Complement consumption is also measured by hemolysis of immunoglobulin-coated erythrocytes with the CH50 test. The use of complement assays to assess disease activity in patients with lupus has been controversial, but is a useful measure in some patients. In others complement assays are not very helpful for disease management.

Lupus is one of the diseases with depressed complement in the circulation. Others include some glomerulonephritides, cryoglobulinemia, and subacute bacterial endocarditis all diseases confused with lupus in other ways.

Interestingly, however, the relationship between lupus and the complement system is paradoxical. Deficiency in any of the components of the early classic complement pathway is associated with lupus. Patients with a complete deficiency of complement component C1q have greater than 90% probability of developing lupus. In addition, patients who have antibodies to C1q have a higher frequency of glomerulonephritis.

In complete complement component C4 deficiency, approx 75% of patients develop lupus. C4 is produced by two separate, but closely related and neighboring genes, *C4A* and *C4B*, located in the HLA region on 6p21, thereby confusing the complicated histocompatibility associations with lupus. Complete deficiency occurs when both genes on both chromosomes fail to produce the C4 proteins. Indeed, even partial deficiencies of C4 have been associated with lupus.

Complement component C2 is the most common of the lupus-associated deficiencies at about 1 in 10,000 persons. In C2 deficiency, skin manifestations are the predominant feature of a lupus-like picture. Anti-Ro autoantibodies may be more common

in this form of complement deficiency. The penetrance for lupus in C2 deficiency is low because most C2 deficient individuals are asymptomatic.

A lupus-like illness characterized by skin rashes, pyogenic infections, and a membranoproliferative glomerulonephritis, develops in 23% of complement component C3 deficient patients, but is rare.

Abnormalities in the complement receptor 2 (CR2), are also thought to have a role in the development of lupus as supported by various lupus mouse models. However, only meager evidence supports polymorphisms of complement receptor 2 being susceptibility factors in man.

The theoretical background explaining the association between complement deficiencies and lupus rests on the role of complement in clearing immune complexes from both the circulation and tissues. In addition, failure to process apoptotic cells by the complement may encourage autoimmunity. The paradox of complement being consumed in most patients and yet its deficiency being a risk factor for disease is presumably explained by immune complex activation in the former situation and failure to process immune complexes through the complement and complement receptor mediated pathways in the latter.

ENVIRONMENTAL FACTORS ASSOCIATED WITH LUPUS Several environmental factors have been associated with the development of SLE, including infectious and noninfectious agents.

Noninfectious Agents Hormones, especially estrogens, are thought to be important in the development of lupus. This idea is supported by the predominance of lupus in females and is supported by animal experiments that show worsening of lupus symptoms with estrogens and improvement with androgens. In addition, worsening of lupus during pregnancy suggests a role of estrogens in lupus.

Exposure to UV light is important in causing or worsening lupus, especially the cutaneous manifestations of lupus. It has been suggested that exposure to UV light accelerates apoptosis of the keratinocytes, which increases the binding of anti-Ro to induce inflammation and tissue injury. Photosensitive lupus patients should be advised to avoid sun exposure by wearing long sleeves and protective hats.

Other factors associated with lupus include smoking (RR approx 2–3), herpes zoster before lupus onset (RR approx 4.7), use of allergy medication (RR approx 4.7), night shift work (RR approx 5.7), asthma (RR approx 2.1), and hives (RR approx 1.8), though some of these have not been confirmed. Hair dyes and straighteners have been suspected, but are not established as risk factors for lupus.

Infectious Agents Several viral infections have been studied in the setting of SLE, including parvovirus, mumps, measles, the common human herpes viruses, and others. Results consistently and reproducibly suggesting association have not been obtained, and perhaps except for Epstein-Barr virus there is no strong evidence of viral involvement in the etiology of lupus. The data supporting Epstein-Barr virus in lupus are suggestive of a fundamental relationship with lupus, and these, along with the properties of the virus, make Epstein-Barr virus the strongest candidate for an important etiological factor.

The modern solid phase assay methods for viral infection are significant advances over the immunofluorescent and precipitin methods used previously. Indeed, association of Epstein-Barr virus has been shown in four different collections of lupus patients. In children and teenagers the RR is approx 50 with virtually all lupus patients showing serological responses consistent with having been infected. Because Epstein-Barr virus infects more than 90% of adults, there must be much more to the relationship than just the infection. Immunochemistry data are consistent with a structural antigenic relationship between Epstein-Barr nuclear antigen-1 (EBNA-1) of Epstein-Barr virus and the Sm B/B′ component of the spliceosome. EBNA-1 is expressed in the latent phase of the viral infection, tethers the viral DNA episome to human chromatin and preserves the viral DNA so that the infection continues in the daughter cells after replication. EBNA-1 initiates the latent viral DNA transcription and determines whether the latent or lytic program is followed. EBNA-1 is highly antigenic in most normal subjects, but is present in virtually all lupus patients tested. These results and other evidence are construed to support the hypothesis that lupus autoimmunity arises out of the EBNA-1 humoral immune response. According to this hypothesis, the association of lupus with Epstein-Barr virus infection is observed only because Epstein-Barr virus infection is required in order to develop an anti-EBNA-1 response.

Other properties of Epstein-Barr virus make this virus an attractive candidate etiological agent. Epstein-Barr virus infects B cells, and lupus is a disease of humoral immune dysfunction. Epstein-Barr virus induces autoantibodies and lupus appears to be mediated by autoantibodies. Epstein-Barr virus infection prevents normal B-cell apoptosis and prevention of normal apoptosis in B cells induces lupus in animal models. One mechanism involves an Epstein-Barr virus viral homologue of *bcl-2*, which has been shown to induce lupus-like autoimmunity. Epstein-Barr virus also has a Th-2 cytokine, viral IL-10, which is similar to human IL-10 and is expected to enhance humoral immune responses. A surprisingly large proportion of the normal human T cell repertoire (approx 7%) is directed against Epstein-Barr virus and once infected with the virus a person remains infected for life constantly emerging from the latent infection at a level sufficiently low to avoid immune destruction of infected cells. These features are also expected of an etiological agent for lupus. Only a few of the immune avoidance mechanisms of Epstein-Barr virus are probably known. Because this virus has been evolving with humans and predecessors for tens of millions of years, a number of effective immune avoidance mechanisms are likely to be discovered. The inhibition of EBNA-1 antigen presentation via a repeat sequence of Gly-Ala amino acids in the middle of the EBNA-1 sequence is one of these; it prevents the development of cytotoxic T cell responses directed against EBNA-1.

DNA METHYLATION AND LUPUS DNA methylation refers to the addition of a methyl group to position 5 of the cytosine residues in the CG pairs. Promoters of the active genes are typically hypomethylated, whereas methylation of promoter sequences renders the genes transcriptionally inactive.

A series of reports demonstrate a role for abnormal T-cell DNA methylation in the pathogenesis of lupus. Indeed, in both drug-induced and idiopathic lupus decreased T-cell DNA methylation results in the overexpression of methylation sensitive T-cell genes that induce T-cell autoreactivity. T cells treated with the methylation inhibitor 5-azacytidine demonstrate overexpression of the methylation sensitive genes *ITGAL* (CD11a), *TNFSF7* (CD70) and PRF1 (perforin) similar to T cells from active lupus patients. Furthermore, these cells become autoreactive, responding to self-class II MHC without the presence of the appropriate antigen in the antigen-binding

cleft of the class II molecule. The autoreactive cells also kill autologous or syngeneic antigen-presenting cells. Procainamide and hydralazine, two known lupus-inducing drugs, also inhibit T-cell DNA methylation and induce T-cell autoreactivity similar to 5-azacytidine-treated T cells. Subsequently, it was shown that procainamide directly inhibits the DNA methylating enzyme DNA methyltransferase 1 (Dnmt 1), whereas hydralazine inhibits signaling through the extracellular signal-regulated kinase (ERK) pathway, which regulates Dnmt 1 expression. Interestingly, T cells from patients with active lupus have reduced ERK signaling and a decreased Dnmt 1 activity, thus, resembling hydralazine-treated cells. Furthermore, inhibiting the ERK signaling pathway in T cells in vitro results in changes similar to those caused by 5-azacytidine, with the overexpression of the methylation-sensitive genes and T-cell autoreactivity in vitro. Moreover, T cells treated with either 5-azacytidine, procainamide or ERK pathway inhibitors, induce autoimmunity and a lupus like-disease when injected into syngeneic mice. These results suggest that changes in T-cell DNA methylation, when occurring in a genetically predisposed host, may be fundamental to lupus pathogenesis.

MANAGEMENT

The introduction of steroids in the 1950s had an enormous impact on survival in lupus patients. Steroid therapy appears to derail the crescendo of immune abnormalities and end organ injury that would otherwise be the disease's natural history in many patients. The introduction of various other therapeutic modalities has made further incremental progress such that survival is more than 90% 10 yr after diagnosis. The goal of management is to control the tissue injury and immune activation. Once the disease is controlled, the goal is to prevent relapses although minimizing risk from the side effects and toxicities of the medications. Several medications are used, including the nonsteroidal antiinflammatory medications, hydroxychloroquine, cyclophosphamide, azathioprine, methotrexate, and mycophenolate mofetil.

PREVENTION AND GENERAL MEASURES Education is an integral part in the management of SLE. Patients should be aware of various environmental factors that can trigger a relapse in their disease. Because many lupus patients are photosensitive, they should protect themselves from the sun or UV light exposure and should wear protective clothing and sunscreens. In addition, various photosensitizing drugs are better avoided, including thiazides, sulfonamides, tetracyclines, and amiodarone.

Pregnancy in lupus can be problematic. If the disease is in remission at conception or if the medical regimen that controls the disorder can be continued through the entire pregnancy, the chances are good that the pregnancy can be carried to term. If the underlying disease process is active at conception and is not or cannot be controlled, serious problems are more likely. Sometimes, physicians discontinue all of the lupus medications when patients become pregnant, which can have the unfortunate consequence of inducing disease activity that threatens the life of the mother and fetus.

Placentas are small in pregnancies; infarcts are often found. This problem is more frequent in patients with the antiphospholipid antibody, but occurs in other lupus patients, as well. The small placentas probably explain the difficulties that many mothers face in the third trimester with higher rates of toxemia and premature deliveries. Of course, other difficulties, such as renal insufficiency generate increased risk of complication from pregnancy, independent of the activity of the lupus that may have caused it.

Anti-Ro is associated with neonatal lupus, which consists of neonatal lupus dermatitis, congenital heart block, hepatitis, or thrombocytopenia. The rash spontaneously resolves without scarring. Heart block is permanent. In about equal shares, patients have hydrops fetalis, require pacemakers, or are asymptomatic. The spectrum of possible outcomes is extreme in this situation. Some experience has been interpreted to suggest that dexamethasone can delay or prevent complete heart block on the earliest evidence of a conduction abnormality (e.g., first or second degree heart block).

Poor social support is associated with poor prognosis in lupus patients. The factors responsible for this or for the more severe disease in lower socioeconomic groups are not known. Psychosocial and family support are important in the successful management of lupus.

MEDICAL TREATMENT NSAIDs are generally used in mild lupus symptoms. They are particularly helpful for musculoskeletal manifestations including arthralgia and arthritis, as well as fever and mild serositis. Iboprofen should be avoided because of its association with aseptic meningitis in lupus patients. To the extent possible, NSAIDs should be avoided in patients with lupus nephritis as they may further worsen renal function.

The natural history of SLE has changed significantly since the introduction of steroids in the early 1950s. However, the use of steroids is complicated by major toxic effects that limit use for prolonged periods. In general, high dose systemic steroids (60 mg/d) might be needed in a lupus exacerbation, but such high doses should not be continued more than 6–8 wk. However, high dose intravenous steroids can be lifesaving, as in the case of lupus central nervous system involvement or severe lupus pneumonitis. Side effects of systemic steroids are legion, but specifically include weight gain, hirsutism, diabetes, cataract, cardiovascular complications, and osteoporosis. Topical steroids are used to treat the various skin rashes associated with lupus, but can result in skin atrophy and telangectasias. For this reason, potent steroids are not usually used on the face, with the exception of DLE rash, which if left untreated can produce disfiguring scars.

Hydroxychloroquine is widely used in mild lupus, and it particularly improves the joint and skin manifestations. There is convincing evidence that hydroxychloroquine prevents lupus exacerbations in patients with relatively mild disease. Hydroxychloroquine can be associated with several side effects including gastrointestinal disturbance and skin rash. Though uncommon, the most feared complication is retinal toxicity and, therefore, most practitioners recommend periodic ophthalmological exam. Hydroxychloroquine may also be helpful in treating the dryness symptoms of secondary Sjögren's syndrome in lupus patients.

Several other medications used in the treatment of lupus include immunosuppressive therapies such as cyclophosphamide, azathioprin, and mycophenolate mofetil. Several promising biological agents are being actively evaluated for the treatment of lupus: rituximab, an anti-CD20 monoclonal antibody, anti-C5 complement monoclonal antibody and anti-IL-10 monoclonal antibody. Stem cell transplantation has been used with some success in treating severe lupus patients. Also, autologous stem cell transplantation is performed with high doses of immunosuppressive, cytotoxic agents.

100 Systemic Sclerosis

Chris T. Derk and Sergio A. Jimenez

SUMMARY

Systemic sclerosis is an autoimmune disease of unknown origin characterized by excessive deposition of collagen and other connective tissue macromolecules in skin and multiple internal organs, severe alterations in the microvasculature, and humoral and cellular immunological abnormalities. Although the most apparent and almost universal clinical features of systemic sclerosis are related to the progressive thickening and fibrosis of the skin, some degree of involvement of multiple internal organs is uniformly present even when not clinically apparent. This chapter will examine the clinical aspects and pathogenesis of the disease and review some promising therapies that have been and are being developed that might modify the natural course of this serious and often lethal disorder.

Key Words: Raynaud's phenomenon; systemic sclerosis; skin; scleroderma; TGF-β.

INTRODUCTION

Systemic sclerosis (SSc) is an autoimmune disease of unknown origin characterized by excessive deposition of collagen and other connective tissue macromolecules in skin and multiple internal organs, severe alterations in the microvasculature, and humoral and cellular immunological abnormalities. SSc is the most common and important among a group of chronic diseases of unknown cause characterized by induration and thickening of the skin (scleroderma, derived from *skleros* [hard] and *derma* [skin]) (Table 100-1). SSc is a complex and clinically heterogeneous disease with clinical forms ranging from limited skin involvement (limited cutaneous SSc; lcSSc) to forms with diffuse skin sclerosis and severe internal organ disease (diffuse cutaneous SSc; dcSSc), and occasionally a fulminant course (fulminant SSc).

Although the most apparent and almost universal clinical features of SSc are related to the progressive thickening and fibrosis of the skin, some degree of involvement of multiple internal organs is uniformly present even when not clinically apparent. Morbidity and mortality in SSc are substantial, and are related to the extent of the fibrotic and microvascular alterations, as well as to the severity and extent of visceral organ involvement.

Even though the pathogenesis of SSc remains elusive, an increasing number of investigations has helped to understand better some of the pieces of this complex puzzle. It was not until 1972 that a landmark study by LeRoy demonstrated an increased production of collagen in fibroblast monolayer cultures obtained from skin biopsies from patients with SSc. A wealth of knowledge has been gained since then regarding the clinical aspects and pathogenesis of the disease and some promising therapies have been and are being developed that might modify the natural course of this serious and often lethal disorder.

EPIDEMIOLOGY

Although Hippocrates was among one of many physicians of ancient times who described patients with "hard" and "stretched" skin, it is remarkable that clear descriptions of a disease with such obvious and apparent clinical manifestations was not more widely recognized or more precisely described until the 18th century. Indeed, it appears that the first concise report of scleroderma as the disease known today was by Carlo Curzio in 1752 who described a 17-yr-old woman admitted to a hospital in Naples. However, the term scleroderma was not used until Giovambattista Fantonetti, a prominent physician in Milan, employed it in 1836 to describe a 30-yr-old peasant woman who developed dark, tense, leathery skin, sparing only her face and breasts, which resolved in 3 mo. Although many different terms have been used through the years for this disorder, scleroderma has been the preferred term until 1945 when Robert Goetz coined the term *SSc* to reflect the systemic nature of this disorder.

SSc is the third most common connective tissue disease (following rheumatoid arthritis and systemic lupus erythematosus). It occurs more commonly in females (4–8/1 female to male preponderance), affects all racial groups and can present at any age, although the peak of disease onset occurs in the fourth and fifth decades. Familial SSc is rare and there is no conclusive evidence of genetic transmission of the disease.

The prevalence of SSc in the United States is generally accepted to be as high as 242–286 cases/million of population although it varies by ethnic background and geographic region. Of note is the high prevalence of SSc in the population of Choctaw American Indians of Oklahoma in whom the prevalence is as high as 469 cases/million. Disease expression also appears to be different among different ethnic groups; for example, Caucasians more frequently display limited skin involvement with less severe systemic manifestations, whereas, African Americans manifest more frequently diffuse skin involvement and more severe pulmonary manifestations.

EARLY SIGNS AND SYMPTOMS

In its early stages SSc might mimic other connective tissue diseases. Raynaud's phenomenon, the initial symptom in the majority

Table 100-1
Classification of Scleroderma

Systemic scleroderma or SSc
Diffuse cutaneous SSc
Limited cutaneous SSc
Overlap syndromes: polymyositis, systemic lupus erythematosus, rheumatoid arthritis
Localized scleroderma
Morphea: localized or generalized
Linear scleroderma
Scleroderma "En coup de sabre"
Scleroderma-like syndromes
Eosinophilic fascitis
Graft-vs-host disease
Nephrogenic fibrosing dermopathy/nephrogenic systemic fibrosis
Chemically-induced scleroderma
Eosinophilia-myalgia syndrome
Toxic oil syndrome
Vinyl chloride
Organic solvents
Silica
Bleomycin
Pentazocine
Pseudoscleroderma
Scleredema, scleromyxedema, cutaneous, amyloidosis, and others

Entrapment neuropathies (including carpal tunnel syndrome and trigeminal neuralgia)
Erectile dysfunction
Hypothyroidism (thyroid fibrosis)
Bladder fibrosis
Sicca syndrome

of patients, is characterized by cold- or emotion-induced episodic constriction of the digital arterioles, manifested by pallor, cyanosis and redness of the fingers or toes, accompanied by numbness, tingling, or pain. Raynaud's phenomenon might precede the onset of other SSc features by months or years; however, it ultimately develops in virtually all SSc patients. Although Raynaud's phenomenon is common among premenopausal women, only a minority of them develops a connective tissue disease, most commonly SSc. Puffy hands and forearms are often noted in early SSc. Arthralgia and sometimes a palpable tendon friction rub in wrists, ankles and other sites might be present at this stage of disease evolution. Diffuse hyperpigmentation and/or hypopigmentation of the skin accompanied by pruritus is a common early manifestation of SSc.

CLINICAL FEATURES

As mentioned, SSc displays both cutaneous and systemic visceral involvement. The most common clinical manifestations of SSc are shown in Table 100-2.

CUTANEOUS MANIFESTATIONS The most apparent and almost universal clinical manifestation of SSc is the progressive thickening and induration of the skin. Skin sclerosis is present in 95% of patients with SSc. In the remaining patients typical visceral involvement occurs in the absence of obvious skin sclerosis (scleroderma sine scleroderma). Thickened and hidebound skin generally first appears distally and progresses proximally. The skin is taut, shiny, and tightly adherent to the underlying subcutaneous tissues. The hands and face show the most pronounced changes, especially in the early stages of the disease. Early manifestations include pruritus and edema of the affected skin, which over time evolves into severely indurated skin that is firmly bound to the subcutaneous tissue. Skin involvement of the fingers (sclerodactyly) is accompanied by widening of the cuticles, and in the late stages, loss of soft tissue at the fingertips. The face assumes an expressionless appearance with loss of wrinkles. The nose becomes beaked, and the lips are thin and tightly pursed with radial furrowing around them. The maximal oral aperture is diminished (microstomia). Fibrotic tissue encroachment of the local hair follicles and sweat glands causes hair loss and diminished perspiration. As the disease progresses the sclerotic changes might affect the entire body.

Diffuse hyperpigmentation, similar to that seen in Addison's disease, can precede the onset of detectable skin thickening. In some patients, hyperpigmented hair follicles are surrounded by depigmented areas of skin, resulting in the characteristic "salt-and-pepper" pattern. Telangiectasias, representing dilated capillary loops, can be found on the hands, face, lips, and tongue. Mucosal telangiectasias are common and have been implicated as a source of nasal and gastrointestinal bleeding. Painful recurrent ulcerations develop at the fingertips and other areas in which the skin is tightly stretched and can become infected. Cutaneous calcifications because of deposition of calcium hydroxyapatite are

found at the fingertips, along the extensor surface of the forearms, and other periarticular and subcutaneous areas.

SKELETAL INVOLVEMENT Symmetric polyarthralgia involving the fingers, wrists, and ankles, occurs commonly in early SSc, but true arthritis and synovitis are rare. Contracture of the fingers resulting from fibrosis of the tendons as well as skin tightening can develop rapidly and result in loss of hand function. Carpal tunnel syndrome is occasionally seen in early SSc and might resolve spontaneously. Coarse leathery crepitus (tendon friction rub) can be palpated and often heard on active and passive motion of the wrists and ankles. Tendon friction rubs are virtually specific for diffuse SSc and might antedate progressive skin involvement. Roentgenograms might show characteristic resorption, and in advanced cases, complete dissolution of the distal end of the phalanx (acro-osteolysis). Many patients with diffuse SSc have an indolent myopathy, characterized by minimal elevation in serum muscle enzymes owing to focal muscle fibrosis and fiber atrophy. A minority of patients develop full-blown myositis with marked elevation in serum creatine phosphokinase and aldolase levels and typical inflammatory myopathy electromyographic changes.

VISCERAL INVOLVEMENT

Gastrointestinal Tract The gastrointestinal tract is the most frequent visceral organ involved in SSc. Esophageal abnormalities are found in up to 90% of patients. Incompetence of the lower esophageal sphincter and decreased or absent peristalsis in the lower two-thirds of the esophagus are characteristic of SSc. These abnormalities lead to symptoms of gastroesophageal reflux with intermittent retrosternal burning pain and regurgitation. The loss of coordinated and effective peristalsis affects the smooth muscle of the lower two-thirds of the esophagus and manifests as dysphagia and odynophagia. Chronic reflux and esophageal stasis might result in the development of esophagitis, Barrett's esophagus, and lower esophageal strictures. Reflux of gastric contents might result in hoarseness, cough, and aspiration pneumonitis. SSc is among the most common diseases associated with gastric antral vascular ectasia (watermelon stomach) and in some cases severe gastrointestinal hemorrhage might be caused by bleeding from these lesions. Barium esophagogram studies demonstrate incompetent lower esophageal sphincter, dilatation, and aperistalsis of the body of the esophagus, gastro-esophageal reflux and occasionally, lower esophageal strictures. Esophageal manometric studies are more sensitive and are particularly helpful in excluding other causes of dysphagia, such as polymyositis. Disordered motility might result in gastric distension, bacterial overgrowth in the small bowel with subsequent diarrhea and malabsorption, and pseudoobstruction. In long-standing colonic disease, wide-mouth sacculations (pseudodiverticula) are found.

Respiratory System Lung involvement is the leading cause of morbidity and mortality in SSc. Pulmonary fibrosis has an insidious onset and often a progressive course with increasing exertional dyspnea and limited exercise tolerance. Physical examination usually discloses fine inspiratory crackles at the lung bases. Pulmonary hypertension and cor pulmonale might develop in some patients even in the absence of pulmonary parenchymal involvement, particularly in those with limited SSc. Advanced pulmonary involvement can be detected as increased interstitial markings on a chest roentgenogram, but this is insensitive for detection of early lesions. High resolution CT of the chest is highly sensitivity for the diagnosis of SSc lung fibrosis and allows the early detection of alveolitis. Pulmonary function studies, especially the single breath diffusing capacity, are more sensitive and, therefore, are useful in establishing the presence of pulmonary involvement at an earlier stage. An isolated reduction of diffusing capacity in a patient with SSc suggests pulmonary hypertension.

Renal Involvement Renal involvement, considered to be the most deadly complication of SSc, develops in 15–20% of patients and usually occurs with an abrupt onset (scleroderma renal crisis). Patients with diffuse and rapidly progressive skin involvement are at the highest risk of developing scleroderma renal crisis. Malignant hypertension with headache and retinopathy, acute cardiac failure, myocardial infarction, stroke, and oliguria with rapidly progressive renal insufficiency characterize scleroderma renal crisis. Progression to renal failure and death occurs rapidly unless the diagnosis of renal crisis is established and aggressive treatment instituted promptly. Less dramatic renal dysfunction occurs with greater frequency in SSc and manifests as a reduction in renal functional reserve and intermittent mild proteinuria.

Cardiac Involvement Laboratory or pathological evidence of heart involvement is noted in 70–80% of SSc patients but clinically significant primary cardiac dysfunction is less common. Tachyarrhythmias and cardiac conduction disturbances detected by ambulatory Holter monitoring are frequent and associated with increased mortality. Pericardial effusion is found by echocardiography in many patients, but symptomatic pericarditis is rare. Cor pulmonale with right ventricular failure occurs in patients with pulmonary hypertension.

Other Visceral Involvement Peripheral neuropathy, particularly trigeminal neuralgia and carpal tunnel syndrome can occur, but the central nervous system is spared. Erectile dysfunction develops in many male patients, and can precede other SSc manifestations. The sicca syndrome is frequently found. Hypothyroidism is detected in one-third of patients, but is generally mild. Primary liver disease is unusual, but the concomitant occurrence of primary biliary cirrhosis has been documented in some cases.

LABORATORY FINDINGS

The diagnosis of SSc is generally made on clinical grounds. Laboratory data help define the type and extent of visceral involvement. The erythrocyte sedimentation rate and the serum levels of C reactive protein are usually normal. The antinuclear antibody test is positive in more than 90% of patients, and most characteristically shows a speckled or nucleolar immunofluorescence pattern in diffuse SSc and a centromere pattern in limited SSc. Antibodies to native DNA and Sm are typically absent. Antibodies to the kinetochore (anticentromere antibodies) are found in more than 80% of patients with limited SSc, occasionally in patients with diffuse SSc, and only rarely in patients with other connective tissue disorders. Of patients with diffuse SSc, approx 30–40% have serum antibodies reactive with the enzyme DNA topoisomerase I (termed Scl-70). Anti-Scl-70 antibodies are rare in patients with limited SSc and are not present in patients with other connective tissue diseases. Anti-Scl-70 and anticentromere marker antibodies are mutually exclusive, coexisting in only a few patients. The titers of these antibodies are not associated with the clinical course of the disease. Their presence; however, is helpful in classification of SSc patients into the limited or diffuse cutaneous subsets of SSc. The presence of these antibodies in an individual with isolated Raynaud's phenomenon identifies a patient at high risk for the subsequent development of SSc.

CLINICAL SUBSETS OF SSc

SSc is a clinically heterogeneous disease, with a spectrum of severity ranging from minimal sclerodactyly or limited skin sclerosis (limited SSc) to extensive and rapidly progressive diffuse skin involvement with severe derangement of critical organs (diffuse SSc). The latter clinical subset is associated with much higher and earlier mortality. Several clinical and laboratory features allow the distinction of these two subsets of SSc (Table 100-3).

Table 100-3
Clinical and Laboratory Test Differences Between Diffuse and Limited Cutaneous SSc

	Diffuse cutaneous SSc	*Limited cutaneous SSc*
Mortality	>60% at 7 yr	<15% at 7 yr
Raynaud phenomenon	<1 yr	>1 yr (decades)
Skin sclerosis	Truncal, acral	Acral
Lung involvement	Early: interstitial	Late: pulmonary hypertension
Renal involvement	Renal crisis	Rare
Cardiac involvement	Cardiac fibrosis	Rare
Autoantibodies (%)	90	90
Pattern (fluorescence)	Speckled/nucleolar	Centromere
Scl-70 (%)	30–40	0
Antitopoisomerase (%)	60	0
Anticentromere (%)	10	80–90
Antikinetochore (%)	5	95

COURSE AND PROGNOSIS

Unlike other connective tissue diseases, the course of SSc is not one of flares and remissions, but is often characterized by relentless progression. The highest mortality is seen in the first 2–5 yr of the disease. The prognosis of SSc is related to the extent of visceral involvement. Limited SSc has low overall mortality, whereas diffuse SSc has 50–60% mortality at 5 yr.

A grave prognosis is closely correlated with the presence of renal, pulmonary, and cardiac involvement. Early diagnosis, detection of the extent and degree of organ involvement, and treatment of specific organ involvement offer the best hope for reducing morbidity and mortality.

HISTOPATHOLOGICAL ABNORMALITIES

The pathological changes in SSc encompass a spectrum reflecting variable stages of development and progression of three major processes occurring in the affected tissues:

1. Connective tissue alterations with increased deposition of collagen and other connective tissue components in the extracellular matrix (ECM).
2. Inflammation, occurring predominantly in the early stages of disease and characterized by infiltration with mononuclear cells, mostly of the macrophage and T-cell lineages.
3. Microvascular disease, characterized by intimal proliferation, concentric subendothelial deposition of collagen and mucinous material, and narrowing and thrombosis of the vessel lumen.

Progression of the vascular and fibrotic changes and decrease in the inflammatory component lead to end-stage fibrosis and atrophy of the affected organs.

Histopathological findings in the skin include marked thickening of the dermis with massive accumulation of dense collagen causing epidermal atrophy, flattening of the rete pegs, and replacement of sebaceous and sweat glands, as well as hair follicles. A prominent inflammatory infiltrate mostly consisting of $CD4^+$ lymphocytes is often present at the dermal–adipose tissue interphase, especially in early lesions. The small vessels of the lower dermis show fibrous thickening but evidence of vasculitis is absent. In the lungs, fibrosis of the alveolocapillary membrane and the parenchymal interstitium accompanied by severe mononuclear cell infiltration and fibroblast proliferation occurs frequently, resulting in marked disruption of their architecture. Prominent vascular abnormalities with intimal proliferation and medial hypertrophy causing severe narrowing or complete obliteration of small vessels occur frequently. The renal lesions display severe narrowing and obliteration of the medium-sized arcuate arterioles from concentric medial hypertrophy, subintimal accumulation of loose connective tissue, and reduplication of the internal elastic lamina. The glomeruli frequently appear ischemic but there is no evidence of glomerulitis. Severe interstitial, perivascular, and periglomerular fibrosis might be present in cases of long duration. The renal lesion of scleroderma renal crisis might be histologically indistinguishable from that of malignant hypertension, with intimal proliferation of the interlobular and arcuate arteries and fibrinoid necrosis of the media. All other affected organs show various degrees of fibrosis and mononuclear inflammatory cell infiltration.

MOLECULAR PATHOGENESIS

The pathogenesis of SSc is extremely complex; numerous studies have examined several aspects of its intricate picture. Although the exact mechanisms involved are not well understood, three outstanding features are responsible for the clinical and pathological manifestations of the disease: excessive deposition of collagen and other connective tissue macromolecules in skin and internal organs, vascular lesions of small arteries and arterioles, and alterations of humoral and cellular immunity. It is not clear which of these factors is of primary importance or how they interrelate to cause the progressive fibrotic process in SSc. However, a crucial component in the pathogenesis of SSc is the persistent and unregulated activation of genes encoding various collagens and other ECM proteins. This is the most important difference between normal fibroblasts that promote normal wound healing and SSc fibroblasts that demonstrate an uncontrolled collagen production and tissue deposition resulting in pathological organ fibrosis.

POSSIBLE CAUSATIVE AGENTS It has been postulated that infectious agents might be the initial causative agents of autoimmune responses that result in autoimmune disorders including SSc. Autoantibodies in SSc have been considered to result from an antigen driven response either from an unspecified tissue injury or from "molecular mimicry." The concept of "molecular mimicry" suggests that the production of autoantibodies against self antigens is directed against these antigens because they contain epitopes that share structural similarities to viral or bacterial proteins. In the immunopathogenesis of SSc, herpesviruses, retroviruses, and human cytomegalovirus (HCMV) infections, among others, have been suggested as causative agents. Evidence supporting the role of retroviruses includes the demonstration of sequence homologies between the $p30^{gag}$ protein of retroviruses that cause leukemia in rodents and felines and the DNA topoisomerase I antigen, which is

the target of SSc-specific anti-Scl-70 antibodies, the demonstration that expression of certain retroviral proteins in normal human dermal fibroblasts causes increased expression of several ECM protein genes, and the detection of antibodies to specific retroviral proteins in the sera of SSc patients. The possible involvement of HCMV is supported by the observations of a higher prevalence of IgG anti-HCMV antibodies capable of binding the HCMV late protein UL94 and inducing apoptosis in human endothelial cells in patients with SSc, the increased prevalence of IgA HCMV in patients positive for Scl-70 autoantibodies, and the severe fibroproliferative vascular changes observed in HCMV infections. However, despite intensive study, there is no definitive evidence to conclude that SSc has a viral etiology.

Environmental agents have also been implicated in the development of SSc. Silica and metal dust exposure had been shown in case studies to be related to SSc, but studies have failed to confirm an association. However, exposure to organic solvent might be an important environmental factor triggering SSc. Indeed, some individuals exposed to vinyl chloride develop skin thickening, Raynaud's phenomenon, and digital ulcers. Other environmental factors implicated in the pathogenesis of SSc or SSc-like syndromes include certain pesticides, hair dyes, and exposure to fuel-derived fumes.

GENETIC FACTORS The contribution of genetic factors in the development and expression of SSc is strongly supported by the observation of familial clustering of the disease, the high frequency of other autoimmune disorders and autoantibodies in SSc family members, differences in prevalence and clinical manifestations among different ethnic groups, and the increased prevalence of certain human leukocyte antigens and major histocompatibility complex (MHC) alleles among different ethnic groups and among patients with different clinical types of disease or different pattern of autoantibodies. Although the concordance of SSc among identical twins is only 5.9%, suggesting that the heritability component is rather low; this frequency is still approx 300 times higher than that expected by chance alone. Furthermore, only a small group of twins has been studied (34 pairs) rendering it difficult to draw definitive conclusions.

The differences of MHC and human leukocyte antigen allele expression are evident when comparing the different haplotypes that have been identified to be linked to SSc expression among different ethnic groups. In the Choctaw American Indians, the human leukocyte antigen haplotypes related with disease expression are DRB1*1602, DQA1*0501, DQB1*0301, whereas in Caucasian populations from the United States and from Europe they are DRB1*1101, DRB1*1104, DQA1*0501, DQB1*0301, DRB1*0301, DQA1*0501, and DQB1*0201. Disease expression also appears to be different among different ethnic groups. African-Americans are more likely to harbor antitopoisomerase 1 antibodies and to present more severe visceral manifestations including a higher frequency of pulmonary fibrosis. In contrast, anticentromere antibodies are more common in Caucasians who also display higher frequency of limited disease with less severe systemic manifestations.

ROLE OF CELLULAR MICROCHIMERISM One hypothesis in the causality of SSc suggests that during pregnancy allogenic fetal or maternal cells cross the placenta in a bidirectional traffic and persist in the circulation and tissues of the mother or child, respectively, and that these engrafted foreign cells might become activated by a second event and might mount a graft-vs-host reaction that manifests as SSc. There are remarkable clinical, histopathological, and serological similarities between graft-vs-host disease and SSc, including esophageal, lung, and skin involvement, lymphocytic infiltration and fibrosis of affected organs and production of autoantibodies. Strong support to this hypothesis was provided by the demonstration of Y-chromosome sequences in DNA extracted from peripheral blood cells and in affected skin samples from women with SSc who had a previous male pregnancy. Microchimeric cells of maternal origin have also been identified in the circulation of offspring. These findings might explain, according to this hypothesis, the occurrence of SSc in nulliparous women and men.

Although some studies found that the frequency of Y-chromosome sequences in the skin of SSc women who had male offspring was similar to that of normal controls, quantification of microchimeric fetal cells showed significantly higher numbers in SSc patients indicating that it is the quantity and not only the mere presence of fetal cells that might contribute to the pathogenesis of SSc.

HUMORAL IMMUNE SYSTEM ALTERATIONS The presence of specific autoantibodies is one of the most common manifestations of SSc and more than 90% of SSc patients have antinuclear antibodies in their serum. Numerous autoantibodies have been described in SSc patients. Some of these are highly specific for SSc, whereas others are associated with different clinical manifestations of the disease (Table 100-4). Anti-Scl-70 antibodies were initially described to recognize a 70-kDa nuclear protein. Subsequently, it was shown that these antibodies react with a 110-kDa protein identified as DNA topoisomerase 1. These antibodies are almost exclusively present in sera from patients with the diffuse form of SSc. About 30–40% of patients with diffuse SSc harbor these autoantibodies with a higher prevalence seen in African-American patients. Anticentromere antibodies recognize several protein components of the trilaminar kinetochore. The most common anticentromere antibodies recognize three different antigens: a 17-kDa (CENP-A), an 80-kDa (CENP-B), and a 140-kDa (CENP-C) centromere protein. These antibodies are usually present in patients with the limited form of SSc and are seen in 80–90% of these patients. In contrast to anti-Scl-70 antibodies, anticentromere antibodies are only found in approx 10% of patients with diffuse SSc. These two autoantibodies are mutually exclusive, coexisting in the same patient only in rare instances. Several other autoantibody systems with various levels of specificity for SSc and organ involvement have been described in SSc patients.

ABNORMALITIES IN THE CELLULAR IMMUNE SYSTEM The presence of mononuclear cell infiltrates in affected skin and visceral organs from SSc patients has long been recognized. Early in the presentation of SSc, biopsies from affected skin show prominent macrophage and T-cell lymphocytic infiltrates. The cells in these early infiltrates are $CD14^+$ and express Class II MHC, suggesting that they are activated. Prior activation of peripheral blood T cells in patients with SSc is also evident by the increased expression of high affinity interleukin (IL)-2R on the T-cell membranes and the observation that sera from SSc patients contains a threefold higher level of serum IL-2. In more advanced stages of SSc, the majority of tissue-bound T-cell lymphocytes is $CD4^+$ (helper T-cells) expressing the activation marker class II MHC antigen DR. Although true in most cases, a few studies have shown an increased prevalence of $CD8^+$ cells in lymphocytic infiltrates from the skin and lungs. Most of the tissue infiltrating cells express α/β receptors

Table 100-4
Principal Autoantibodies in SSc

Autoantibody	*Target antigen*	*Clinical association*	*ANA pattern*
Anti-Scl-70	DNA topoisomerase I	Diffuse SSc	Speckled
Anticentromere	Kinetochore proteins CENP A (17 kDa) CENP B (80 kDa) CENP C (140 kDa)	Limited SSc	Centromere
Anti-RNA polymerase I	Complex of 210-14-kDa proteins	Progressive SSc, organ involvement	Speckled Nucleolar
Antifibrillin (U3 RNP)	Nucleolar protein of 34 kDa component of U3-RNP	Diffuse SSc	Nucleolar
Anti-PM-Scl	Complex of 110-20 kDa nucleolar and nuclear proteins	Polymyositis/SSc overlap	Nucleolar
Anti-nRNP	Nuclear ribonucleoprotein	Mixed connective tissue disease	Speckled
Anti-7-2-RNP	Nucleolar protein of 40 kDa complexed with 7-2 and 8-2 RNAs	Limited SSc	Nucleolar
Anti-NOR-90	Protein of 90 kDa localized to the nucleolar organizer region	Lung involvement	Nucleolar
Antimitochondrial	M2 complex of 70 kDa and 47 kDa proteins	Limited SSc associated with PBC	None
Anti-Ku	Nucleolar heterodimer of 70 kDa and 80 kDa polypeptide chains	Polymyositis/SSc overlap	Nucleolar
Anti-Th/To	RNAse MRP and RNAse P ribo-nucleoprotein complexes	Pulmonary hypertension	Nucleolar

rather than γ/δ receptors although γ/δ receptor bearing T cells appear to be predominant in bronchial alveolar lavage fluids of patients with SSc interstitial lung disease. Further expansion of T cells within the affected tissues appears to be oligoclonal as shown in studies of T-cell receptor transcripts in SSc skin. The expanded T-cell populations in affected SSc tissues are thought to release cytokines that initiate and/or perpetuate the fibrotic process as well as the endothelial and vascular alterations. Indeed, clones of T cells established from infiltrating lymphocytes isolated from affected SSc skin produce cytokines capable of modulating fibroblast proliferation and collagen production, as well as various endothelial cell functions.

Cytokines Numerous cytokines have been shown in in vitro studies to exert potent effects on various fibroblast functions and on the production and/or degradation of collagens. However, it is likely that the ultimate effects of these cytokines on fibroblast proliferative and biosynthetic activities depend on their concentration in the pericellular environment and on the relative proportions among a mixture of a large number of cytokines that often have opposing effects. The cytokines with most potent effects on connective tissue metabolism are ILs-1, -4, -8, and -10, the interferons (IFNs), particularly IFNγ, and tumor necrosis factor α and β (lymphotoxin).

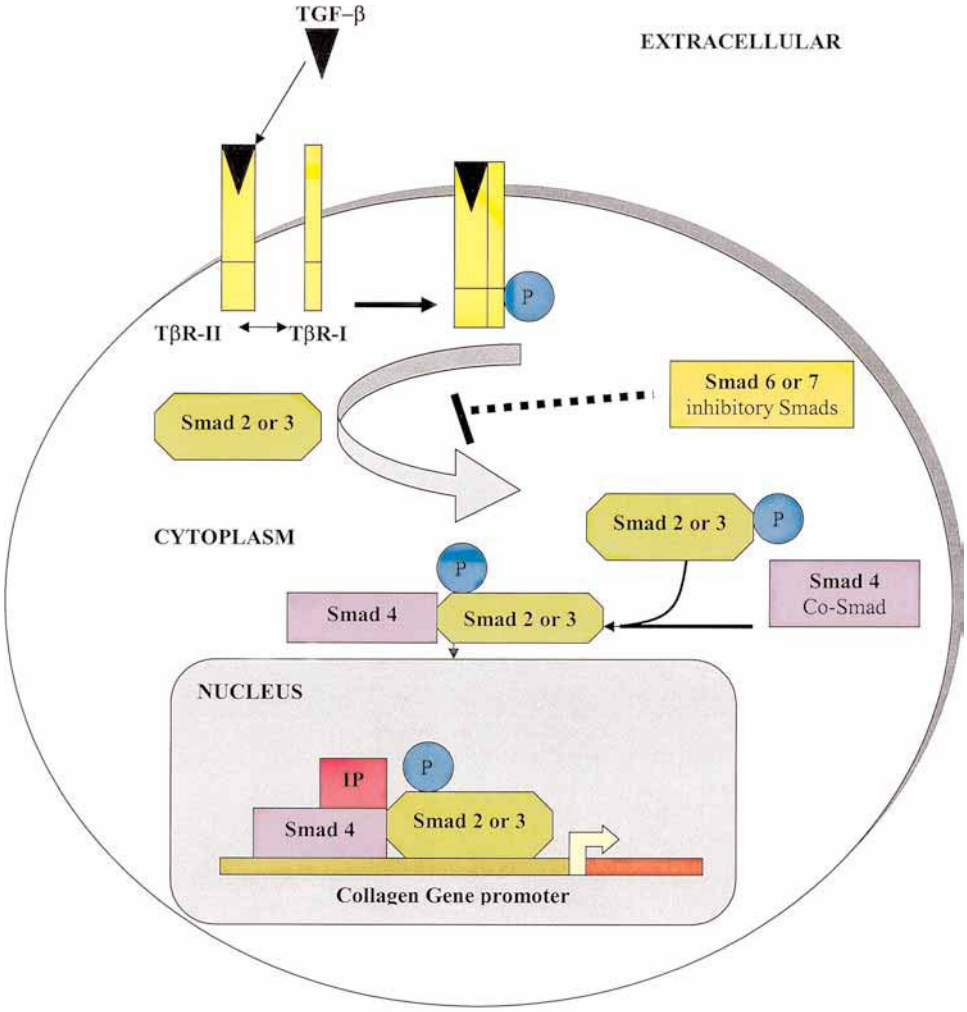
IL-1 has been shown in some studies to stimulate the synthesis of type I collagen, whereas in others, to inhibit it. IL-1 inhibits collagen production by lung and dermal fibroblasts, whereas it causes an increased production of collagen by kidney fibroblasts and synovial cells. The mechanisms involved in IL-1 modulation of type I collagen synthesis appear to be different among different cell types and are not clearly understood. The role of IL-1 in SSc pathogenesis has not been established.

IL-4 is considered to be one of the most important profibrotic cytokines. It stimulates fibroblast proliferation, chemotaxis, and ECM production. Furthermore, IL-4 has potent effects on adhesion molecule expression, a property of great relevance to the vascular alterations of SSc. IL-4 levels are increased in peripheral blood of SSc patients. Most of this increase appears to be related to an increase in an alternatively spliced form of the molecule, IL-4δ2. Functionally, IL-4δ2 acts as an IL-4 antagonist in the stimulation of human T and B cells whereas, on the contrary, it acts as an agonist in its effects on fibroblasts. The activation of T cells and the upregulation of IL-4 and IL-4δ2 in SSc provide further support for the crucial role that inflammatory cells play in the pathogenesis of the disease.

IFNγ is secreted by activated T cells and is the most potent collagen synthesis inhibitory cytokine known. It causes a remarkable inhibition of fibroblast proliferation and collagen production, decreasing mRNA levels of the interstitial collagens in normal as well as SSc fibroblasts, both in vivo and in vitro. IFN-γ also abrogates the stimulatory effects of transforming growth factor (TGF)-β on fibroblast collagen production. These effects appear to be mediated by transcriptional mechanisms. Although it was suggested that IFN-γ production by SSc lymphocytes was decreased, a direct role of this cytokine on the pathogenesis of SSc has not been demonstrated.

TNFα, a major cytokine product of macrophages is also released by activated T cells. TNFα has similar effects to those of IFN-γ on fibroblast proliferation and collagen production causing a dose-dependent inhibitory effect on types I and III collagen production at the transcriptional level, as well as an inhibitory effect on TGF-β stimulation of fibroblasts. The role of TNFα in the pathogenesis of tissue fibrosis in SSc remains controversial. Although in vitro studies have shown a potent antifibrotic effect, in vivo studies have suggested that it is required for the production of pulmonary fibrosis in animal models. Given the availability of potent and specific antiTNFα biological agents, it

is crucial to determine the precise role of this cytokine in the pathogenesis of SSc.



Growth Factors Since the discovery of the potent profibrotic and immunomodulatory activities of TGF-β, this growth factor has been considered one of the most likely molecules involved in the pathogenesis of SSc and other fibroproliferative diseases, and a plethora of publications have described studies focused on this subject. Three functionally and structurally similar isoforms of TGF-β exist in humans and they play important roles in embryonic development, immune responses, and regulation of tissue repair following injury. Activated monocytes from SSc patients secrete increased amounts of TGF-β and the upregulation of this cytokine/growth factor appears to play a crucial role in the development of fibrosis in patients with SSc. One of the most important effects of TGF-β is the stimulation of ECM synthesis as evidenced by a remarkable increase in the production of numerous molecules including collagens types I, III, V, and VI, as well as of other matrix proteins such as fibronectin and matrix glycoproteins. TGF-β also decreases the synthesis of collagen-degrading metalloproteinases and stimulates the production of protease inhibitors such as the tissue inhibitor of metalloproteinases-1. Small amounts of TGF-β appear to sensitize fibroblasts to its own effects and maintain them in a persistently activated state involving an autocrine mechanism that causes further production of TGF-β. It also appears that SSc fibroblasts express increased numbers of TGF-β receptors on their surface, which might account for the increased TGF-β-induced signaling and the resulting increased collagen production in these cells. Bioactive TGF-β binds to cell surface TGF-β II receptors (TβRII) in target cells to form a receptor complex. This receptor complex becomes activated and, in turn, it transphosphorylates the TGF-βI receptor (TβRI) causing its activation. Signaling from the phosphorylated TGF-βI receptor to the nucleus then occurs through the Smad family of proteins. Smad2 and Smad3 bind to the activated TGF-β receptor complex and they also become phosphorylated. Phosphorylation allows these proteins to form a complex with Smad4, which is a cytoplasmic protein involved in the translocation of the complex into the nucleus. Smad7 is an inhibitory Smad that can bind to the TGF-β receptor complex and prevent Smad2 or Smad3 phosphorylation. Once in the nucleus, Smad2/Smad4 or Smad3/Smad4 complexes bind directly to specific DNA binding sites in the promoter regions of target genes and activate their expression. The Smad3 complex binds to DNA sites in the promoter region of responsive genes with the help of intranuclear proteins that act as transcriptional partners. In contrast, Smad2 complexes do not appear to be able to directly bind to DNA promoter sites but instead exert their effect through other unidentified transcription factors or coactivator proteins. A diagrammatic representation of the TGF-β/SMAD pathway is shown in Fig. 100-1. More recent studies have provided additional details regarding the complex pathways of TGF-β modulation of expression of extracellular matrix genes and numerous other participating proteins such as SARA, smurfs, coactivators and corepressors, and others have been identified. Furthermore, it has become apparent that important TGF-β effects might be mediated by protein cascades independent of those of the classic SMAD pathway. These nonSMAD pathways involve members of the Rho family of proteins, numerous other intermediary steps such as protein prenylation, and kinase cascades involving novel proteins such as protein kinase Cδ, PKN, Rho kinase, and so on.

Connective tissue growth factor (CTGF) is another growth factor that appears also to play a crucial role in tissue fibrosis. In addition to a potent profibrotic effect, CTGF participates in angiogenesis, axial development of the musculoskeletal system, structural organization of connective tissue, and embryo implantation. TGF-β stimulates CTGF synthesis in fibroblasts, vascular smooth muscle cells, and endothelial cells. The CTGF produced by these cells in response to TGF-β stimulation in turn stimulates the synthesis of such ECM components as type I collagen and fibronectin in dermal and lung fibroblasts and very likely in endothelial cells.

Platelet-derived growth factor (PDGF) is a key inducer of monocyte chemoattractant protein 1 in SSc pathogenesis. In addition to its chemotactic properties, evidence suggests that monocyte chemoattractant protein 1 might participate in the fibrotic process by inducing the secretion of ECM components. The demonstrated overexpression of PDGF in SSc lesions and the selective upregulation of PDGF α receptors by TGF-β in SSc fibroblasts, indicate that PDGF ligand/receptor pathways are activated in these fibroblasts. Also, PDGF induces the profibrotic cytokine IL-6 in cultured SSc fibroblasts and is known to be a chemoattractant and potent mitogen for skin fibroblasts.

Finally, insulin-like growth factor-I is partially responsible for fibroblast proliferation in SSc patients with interstitial lung disease, thus playing a pathogenic role in the development of fibrotic lung changes in these patients. Insulin-like growth factor-I binding protein-5, which is the most conserved of the six identified IGFBPs, exhibits particularly high levels in affected skin fibroblasts from SSc patients as compared with unaffected and healthy control skin fibroblasts. Insulin-like growth factor-I binding protein-5 binds to collagen, fibronectin, and glycosaminoglycans such as heparan sulfate. Its binding to these ECM components decreases its affinity for insulin-like growth factor-I, resulting in increased biological activity of insulin-like growth factor-I, including its promotion of wound healing and increased tissue deposition.

DYSREGULATION OF CONNECTIVE TISSUE METABOLISM The most prominent clinical manifestations of SSc are caused by the exaggerated accumulation of collagen in the affected organs. The excessive collagen deposition in SSc is because of overproduction of this protein by fibroblasts. Regardless of the etiological event, the resulting alterations in the biosynthetic phenotype of collagen producing cells are crucial in the pathogenesis of SSc. Despite advances in the understanding of the regulation of collagen gene expression under normal conditions or under the effects of various cytokines and growth factors, the intimate mechanisms responsible for the pathological increase in the expression of collagen genes in SSc remain obscure. The exaggerated production of collagens by SSc fibroblasts largely results from increased transcription rates of their corresponding genes, although in certain conditions alterations in the stability of their mature transcripts might also contribute. Collagen is the most abundant protein in the body, and 28 different types have been described. Each has a highly specialized function in addition to providing the extracellular framework and tensile strength for such structures as tendons, skin, bone, blood vessels, and joint cartilage. Type I collagen is the most abundant collagen of the ECM of skin, and it represents 90% of the body's total collagen. In SSc it is mainly the upregulation of this collagen that produces the characteristic clinical findings. Although in the initial stages of fibrosis there is an increase in the proportion of type III collagen, eventually type I collagen becomes quantitatively the most abundant collagenous species and is, therefore,

SSc = systemic sclerosis; TGFβ = transforming growth factor beta; P = phosphorylation; TβRII = transforming growth factor beta receptor 2; TβRI = transforming growth factor beta receptor 1.

Figure 100-1 Diagrammatic representation of the TGF-β/Smad cascade of collagen gene activation.

largely responsible for the functional failure of the affected organs. Normal fibroblasts are capable of regulating collagen production according to the dynamic requirements of the ECM during development, differentiation, and repair. The regulatory mechanisms involved are complex: transcriptional regulation, modulation of mRNA stability and translation rates, and variation in the fraction of the newly synthesized collagen that is degraded before being secreted out of the cell.

Numerous studies have examined the normal mechanisms that regulate the initiation and rates of transcription of various collagen genes and their alterations in pathological states. As for most eukaryotic genes, the regulation of transcription rates of collagen genes involves precise interactions between specific nucleotide sequences present in the promoters and, often, in their first introns, with various transcription factors capable of recognizing and binding specifically to these sequences. The entire complement of regulatory elements in collagen genes and of transcription factors interacting with these elements is unknown.

One of the most extensively studied transcription factors is Sp1, a ubiquitously expressed zinc-finger protein that recognizes a GGGCGG sequence (GC box) widely distributed in the promoters of various Sp1-responsive cellular and viral genes. Several studies on the basal regulation of COL1A1 expression support the crucial importance of Sp1 in collagen gene expression regulation. Similar studies examining the role of Sp1 in the pathogenesis of SSc have shown that Sp1 appears to play a pivotal function in the activated expression of COL1A1. Increased Sp1 binding activity has been demonstrated in SSc fibroblast nuclear extracts in comparison to nuclear extracts from normal cells and increased Sp1 phosphorylation associated with increased expression of type I collagen genes has been found in these cells. Binding of Sp1 to its recognition sites has also been implicated in the regulation of expression of type I collagen genes under the influence of TGF-β. Indeed, a synergistic cooperative interaction between Sp1 and the TGF-β intracellular transduction pathways mediated by Smad3/Smad4 proteins in the stimulatory effects of the growth factor on COL1A2 transcriptional activity has been shown. Furthermore, specific inhibition of Sp1 and binding to its cognate elements within COL1A1 and COL1A2 employing DNA intercalators such as mithramycin, mitoxanthrone, and the doxyrubicin derivative, WP631, caused potent and selective inhibition of collagen gene expression in normal and SSc fibroblasts.

Sp1 binding and its transcriptional effects appear to be modulated by interactions with other nuclear proteins and coactivators involving protein–protein contacts between DNA-bound Sp1 and TATA-associated factors (TAFs) such as TAF110. Therefore, cell-specific differences in the activity of Sp1 might be because of the presence of different coactivators in different cells, or because differential posttranslational modifications of Sp1.

Another transcription factor that appears to play an important role in collagen gene regulation is the CCAAT-binding factor (CBF). It has been demonstrated that CBF interacts with TAF110. Thus, both CBF and Sp1 transcription factors are involved in a protein–protein interaction in the initiation complex of the collagen core promoter as shown in studies demonstrating that nuclear extracts from normal and SSc dermal fibroblasts contained COL1A1 protein complexes corresponding to Sp1 and CBF. These results strongly indicate that CBF and Sp1 play a crucial role in the regulation of COL1A1 transcriptional activity under normal conditions and in SSc.

In contrast with the stimulatory effects of Sp1 and CBF, another transcription factor, c-Krox, represses COL1A1 transcription through its binding to a specific region of the proximal human COL1A1 promoter.

Transcription factors might also bind to enhancer elements in the first intron of collagen genes to bring about transcriptional regulation. It is likely that interactions between transcription factors and these intronic elements might cause profound effects on the regulation of COL1A1 transcriptional activity in SSc. Indeed, intronic sequences cause a potent stimulation of the transcriptional activity of the COL1A1 promoter and these effects are even more noticeable in SSc fibroblasts.

ENDOTHELIAL CELL ABNORMALITIES Vascular dysfunction is one of the earliest clinical manifestations of SSc. Small blood vessels in affected tissues from SSc patients show perivascular cellular infiltration with activated T cells similar to that present in affected skin and internal organs. It has been postulated that cytokines or growth factors, such as TGF-β, secreted by these activated lymphocytes cause activation and injury of small vessel endothelial cells inducing their expression of MHC classes I and II antigens and adhesion ligand ICAM-1, and secretion of increased amounts of von Willebrand factor. As described, TGF-β causes an upregulation of CTGF that in turn induces an increased production of ECM components as well as an upregulation of PDGF. PDGF is a potent endothelial cell mitogen that causes increased endothelial cell proliferation. Also, in SSc a downregulation of vascular endothelial growth factor results in decreased and impaired neovascularization. Chemo-attraction of fibroblasts into the vessel wall and transdifferentiation of resident vessel wall fibroblasts into myofibroblasts occurs as a result of the effects of the locally secreted cytokines and growth factors, leading to increased collagen synthesis and deposition. Endothelial injury causes the subendothelium to be exposed to circulating platelets that eventually adhere to it and initiate fibrin deposition and intravascular thrombus formation. SSc vascular fibroproliferative lesions and intravascular platelet thrombosis inevitably result in a state of local hypoxia in affected tissues. Studies have demonstrated that local hypoxia can further cause tissue fibrosis by activation of collagen and TGF-β genes.

Vasodilation also appears to be impaired in SSc patients. Vasodilation is usually controlled by both endothelial and nonendothelial (neurological) mechanisms. Endothelial cells regulate vascular tone by secreting vasoactive substances such as nitric oxide and calcitonin-related peptide that are vasodilatory, as well as endothelin-I that is a potent vasoconstrictor. It appears that in SSc a relative deficiency of vasodilator molecules and a relative increase of vasoconstrictor ones in turn causes further vascular hypoxia and endothelial injury resulting in the production and release of additional cytokines from the activated inflammatory cells, thus maintaining the vicious cycle of endothelial injury and fibrosis. Indeed, several studies have demonstrated increased production of endothelin-I in affected SSc microvasculature as well as in parenchyma of affected tissues. The effects of vascular dysfunction in patients with SSc are most dramatic when they involve the pulmonary and renal arterioles, causing endothelial injury with subsequent intravascular thrombus formation as well as fibrous tissue deposition in the myointimal region of the vessels. The constellation of these multiple vascular alterations leads to renal crisis and pulmonary hypertension, respectively, which are the most prevalent causes of morbidity and mortality in patients with SSc. The novel therapeutic agents for pulmonary hypertension such as endothelin inhibitors have been generated from the understanding of its pathogenesis.

DIFFERENTIAL DIAGNOSIS

The diagnosis of SSc is based on the physical examination and presence of specific and characteristic clinical findings. Localized scleroderma (morphea and linear scleroderma) can generally be diagnosed by clinical examination. Other diseases characterized by skin thickening confined to the hands that need to be considered as part of the differential diagnosis include cutaneous amyloidosis, diabetic cheiropathy, vibration-related acrosclerosis, and reflex sympathetic dystrophy. Generalized skin thickening might also be seen in eosinophilia-fasciitis, the eosinophilic-myalgia syndrome, scleromyxedema, scleredema adultorum of Buschke, cutaneous amyloidosis, porphyria cutanea tarda, nephrogenic fibrosing dermopathy/nephrogenic systemic fibrosis, and human graft-vs-host disease. Although laboratory data is helpful in confirming the diagnosis, a full thickness skin biopsy including subcutaneous tissue and fascia is often necessary to exclude these diseases.

MANAGEMENT

Although numerous agents have been employed for the treatment of SSc no studies have conclusively proven the benefit of any one agent. Although some clinicians follow a minimalist approach and do not prescribe potentially effective disease modifying therapies, others have used such agents especially in patients with rapidly progressive diffuse disease. D-Penicillamine has been widely used to treat SSc owing to its potent inhibition of collagen crosslinking that causes an increase in the degradation of newly synthesized, noncrosslinked collagen molecules. Although several uncontrolled studies have shown improvement in the extent and severity of skin thickening and improvement in the overall survival rates, one prospective study comparing low vs a high dose of D-penicillamine failed to show a difference among the two therapies. Therefore, a placebo-controlled study is required to answer this question. Other immunosuppressive agents such as methotrexate have been used but have been shown to be ineffective in controlled trials. IFN-γ, one of the most potent inhibitors of collagen production by fibroblasts known, decreases skin thickening although its administration is complicated by an exacerbation of vascular events. Other immunosuppressive agents studied as

disease modifying agents for this disorder have been chlorambucil, azathioprine, 5-fluorouracil, relaxin, photophoresis, and cyclosporine, all of which are ineffective. Other agents that modify collagen biosynthetic pathways have been studied with questionable results, including colchicine, N-acetylcysteine, potassium aminobenzoate and minocycline. Aggressive therapy with immunoablation and autologous stem cell transplantation has also been employed but the procedure carries a high risk of severe side effects and high mortality.

Major strides in SSc management have been in the treatment of the various symptoms of SSc. Raynaud's phenomenon can often be improved by the use of sustained release calcium-channel blockers, α-adrenergic blockers, or both. Platelet inhibitors such as low-dose aspirin and/or dipyrimadole might also be added to the regime. In severe cases, stellate ganglion blockade or digital sympathectomy might provide significant symptom relief. In critical situations in which an acute ischemic event is threatening the viability of a digit, intravenous alprostadil has been used with varying success.

For the esophageal manifestations of SSc, the introduction of H_2 blockers and proton-pump inhibitors has dramatically decreased symptoms of gastroesophageal reflux and chronic esophagitis and stricture. Regarding diminished gastic emptying and decreased intestinal peristalsis, a setback occurred with the withdrawal of cisapride from the market although metoclopramide is used with some beneficial results. Bacterial overgowth caused by decreased peristalsis in the small intestine often results in weight loss, chronic diarrhea, and even malabsorption. Two weeks of alternating cyclic courses of broad spectrum antibiotics such as metronidazole, tetracycline, and amoxicillin might help decrease these symptoms. Persistent abdominal distention with nausea and vomiting suggests an intestinal pseudobstruction in these patients and surgical exploration should be avoided.

Pulmonary fibrosis is common in SSc patients with the diffuse form of the disease and early signs of lung involvement should be suspected in patients with dyspnea and a decreasing forced vital capacity or diffusing capacity for carbon dioxide on pulmonary function testing. Early evaluation by high-resolution CT and/or bronchoalveolar lavage might identify patients with alveolitis who are amenable to therapy with oral or intravenous pulse cyclophosphamide. Corticosteroids and other immunosuppressive drugs have proven remarkably ineffective in improving or preventing progression of interstitial fibrosis in SSc although numerous recent studies suggest that the oral or intravenous pulse administration of cyclophosphamide can stabilize or improve the pulmonary involvement in SSc. Pulmonary hypertension might occur as a complication of long-standing pulmonary fibrosis and in patients with limited SSc. Early evaluation by two-dimensional echocardiography and confirmation by right heart catherization is required to clearly define the severity of pulmonary hypertension. Calcium channel blockers do not affect the survival of these patients. In contrast, administration of prostacyclin analogs results in a reduction of mortality in this group of patients, although the need for a continued intravenous infusion is limiting. A longer acting prostacyclin analog, treprostenil, is more advantageous because it might be given by a subcutaneous pump-infusion. A remarkable improvement in the treatment of pulmonary hypertension, currently the most fatal complication of SSc, has been obtained following the introduction of an orally effective endothelin-1 receptor antagonist, bosentan. This drug has been shown to cause significant functional improvement and a remarkable prolongation in the survival of these patients.

The greatest success in the management of scleroderma has been in the treatment of scleroderma renal crisis. Before the advent of angiotensin converting enzyme inhibitors, the 1-yr survival of these patients was 16%. Today with the widespread use of angiotensin converting enzyme inhibitors in patients with early signs of scleroderma renal crisis, treated promptly and aggressively with these drugs, the survival rate has improved to 76%.

The study of SSc has evolved from the concept that the disease was purely because of collagen overproduction by affected fibroblasts to where it is possible to postulate distinct processes occurring in the initiating phases of this disease. The knowledge acquired in this search has already and undoubtedly will continue to uncover novel therapeutic targets that might result in the development of long awaited and effective therapeutic options.

Nonimmune

101 Diseases With Signaling and Transcriptional Abnormalities

David S. Rubenstein, Amy Stein, and Lowell A. Goldsmith

SUMMARY

Tuberous sclerosis, neurofibromatosis 1 and 2, hereditary hemorrhagic telangiectasia, anhidrotic ectodermal dysplasia, and incontinentia pigmenti are pathological processes that affect signal transduction and transcriptional regulation. Elucidation of the molecular defects underlying these disorders has led to a better understanding of the mechanisms by which the skin and other organ systems develop and regulate cell growth and differentiation.

Key Words: Activin receptor-like kinase-1; connexin-30; endoglin; ectodysplasin; hamartin; merlin; NEMO; neurofibromin-1; tuberin.

INTRODUCTION

To coordinate their function within multicellular organisms, individual cells communicate with one another. Signal transduction is the process by which they transmit information. It can occur within both solid organ and bone marrow derived tissues. Because cells are enclosed by a lipid bilayer, the cell membrane, specific mechanisms have evolved to enable cells to transmit signals across this membrane, whether the flow of information is from the outside in or the inside out. The variety of mechanisms by which cells transduce information across the cell membrane includes classic single pass or multipass transmembrane protein receptors, ion channels, and cell-adhesion proteins. Activation of these transmembrane signaling events typically initiates activation of second messenger systems or post-translational modification of cellular proteins that activate intracellular cascades to alter gene transcription or the structural biology and behavior of cellular machinery. This chapter reviews several skin diseases in which alterations in signaling systems result in skin disease.

TUBEROUS SCLEROSIS

CLINICAL PRESENTATION Tuberous sclerosis (TS) is an autosomal-dominant inherited disorder that involves the skin and internal organs. Typical cutaneous manifestations include angiofibromas (adenoma sebaceum), Shagreen patches (connective tissue nevi), periungual fibromas (Koenen tumors), ash leaf macules, and confetti style hypopigmented macules. TS-associated CNS tumors and hamartomas include cortical tubers, astrocytomas, and subependymal nodules. Clinical manifestations of CNS involvement include seizure disorder and mental retardation. Lymphangioleiomyomatosis of the lungs, almost always seen in women with TS, may result in repeat episodes of spontaneous pneumothorax. Renal angiomyolipomas and cardiac rhabdomyomas can also occur. The incidence of TS is estimated at 1 in 6000 live births. Approximately two-thirds of patients represent new mutations.

MOLECULAR BASIS AND DEFECTS Mutations in either the TSC1 or TSC2 tumor suppressor genes have been identified as the cause of TS. TSC1, which maps to chromosome 9q34, encodes the protein hamartin, whereas TSC2 maps to chromosome 16p13.3 and encodes the protein tuberin. The structure of these two proteins reflects their interaction with a variety of cellular signaling and structural proteins. Structure function analysis of the 130-kDa hamartin protein has demonstrated an N-terminal Rho GTPase-activating region that overlaps a tuberin binding site; regions in the hamartin C-terminus bind the ezrin-radixin-moezin (ERM) family of actin binding proteins. This ERM site overlaps a neurofilament-L binding site. Tuberin is a 198 kDa protein whose N-terminus binds hamartin. Tuberin also contains several coiled-coil domains, a leucine zipper, Akt/PKB-dependent phosphorylation sites, phosphorylation-dependent 14-3-3-binding sites, and potential transcriptional activation domains at the C-terminus. Hamartin and tuberin form a complex that inhibits cell growth by negatively regulating the function of S6 kinase 1 and the eukaryotic initiation factor 4E-binding protein 1. Additionally, through interactions with ERM family proteins, hamartin signaling regulates the formation of focal adhesions. In vivo work in the fruit fly *Drosophila melanogaster* has demonstrated a role for TSC genes in cell-cycle regulation and cell-size control.

DIAGNOSIS: CLINICAL AND LABORATORY The cutaneous manifestations of TS, particularly the hypopigmented macules, may be present at birth or develop as the child ages. The presence of hypopigmented macules and seizure disorder in an infant should alert the physician to the potential for TS. Because approximately two-thirds of new patients represent spontaneous mutations, a family history may not necessarily be elicited. Diagnostic criteria for TS include both major and minor features with a definite diagnosis requiring confirmation of either two major features or one major and two minor features. Major features include facial angiofibromas, periungual fibromas, three or more hypomelanotic macules,

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

Shagreen patch, retinal nodular hamartomas, cortical tubers, subependymal nodules, subependymal giant cell astrocytoma, cardiac rhabdomyoma, lymphangiomyomatosis, and renal angiomyolipomas. Minor features include pitting of the dental enamel, hamartomatous rectal polyps, bone cysts, cerebral white matter radial migration lines, gingival fibromas, nonrenal hamartomas, retinal achromia, confetti-like hypopigmentation, and renal cysts. In addition to full skin and ocular exams, the diagnostic workup should include an ECG, renal ultrasound, cranial CT or MRI, and neurodevelopmental testing.

MANAGEMENT/TREATMENT The management of TS involves diagnosing and treating the complications that arise from internal organ involvement. Involvement of multiple organ systems dictates a multispecialty approach including neurologists, cardiologists, nephrologists, and dermatologists. Infants suspected of having TS should be evaluated by CT or MRI to look for neurological changes such as subependymal califications and cortical tubers. Renal ultrasounds and echocardiograms aid in identifying renal angiomyolipomas and cardiac rhabdomyomas, respectively. Seizure disorders may be amenable to medical management. Surgical intervention may be considered for intractable seizures. Treatment strategies for managing the renal involvement include observation of small asymptomatic renal angiomyolipomas and selective arterial embolization or partial nephrectomy for hemorrhage or spontaneous rupture of larger tumors. The development of acute dyspnea should alert the clinician to the possibility of spontaneous pneumothorax with a chylous pleural effusion.

NEUROFIBROMATOSIS 1

CLINICAL PRESENTATION Also known as von Recklinghausen Disease, neurofibromatosis 1 (NF1) is an autosomal-dominant disorder of complete pentrance and variable expressivity characterized by neurocutaneous tumors and pigmentary alterations. Patients may have only a few clinical findings at birth or during childhood, but develop more characteristic lesions with age. One of the earliest findings that may be present at birth is light tan pigmented macules called café au lait macules. Axillary and inguinal freckling typically appears during late childhood or early adulthood. The pigmentary changes are thought to be a consequence of increased numbers of melanocytes and abnormal melanogenesis with the presence of giant pigment granules in lesional skin. Neurofibromas, benign tumors derived from the nerve sheath, may be numerous and have the appearance of pigmented skin tags, pedunculated masses, or subcutaneous nodules. Plexiform neurofibromas, which may mimic the appearance of a "bag of worms" beneath the skin, can undergo malignant degeneration to a neurofibrosarcoma (malignant peripheral nerve sheath tumor). Sudden growth and/or pain in a plexiform neurofibroma should alert the clinician to malignant degeneration. NF1 patients with NF1 microdeletions have a higher risk of developing neurofibrosarcoma.

Lisch nodules, small yellow-brown pigmented iris hamartomas, are an additional clinical feature present in more than 90% of affected individuals 6 yr of age and older. Optic gliomas may result in progressive vision loss. Although true mental retardation is uncommon, occurring in 4–8% of individuals, as many as 50% of NF1 patients experience variations in cognitive function that may manifest as a mild learning diasability. NF1 is associated with an increased risk of developing certain malignancies, including neurofibrosarcoma, malignant glioma, pheochromocytoma, carcinoid, rhabdomyosarcoma, and juvenile chronic myeloid leukemia. Hypertension and hypoglycemia appear to be more common in this disorder. The incidence of NF1 is estimated at 1 in 3000; approximately half of new NF1 cases may represent new mutations.

MOLECULAR BASIS AND DEFECTS NF1 results from mutations in the gene encoding neurofibromin-1 localized to chromosome 17q11.2. Neurofibromin-1 is a large multidomain cytoplasmic protein that regulates the ERK MAP kinase signaling cascade (Fig. 101-1), adenyl cyclase, and the cytoskeleton. The central region of neurofibromin-1 contains sequence similarity to the GTPase-activating protein family (GAP); neurofibromin GAP activity promotes formation of inactive ras-GDP. In this capacity, neurofibromin-1 functions as a tumor suppressor and downregulates mitogenic signaling mediated by the ras/ERK signaling cascade. Ras is inactive when bound to GDP. Signaling through transmembrane receptors activates ras through guanine nucleotide exchange factors in which GTP is exchanged for bound GDP on ras. Active ras-GTP then leads to activation of downstream components including Raf, MEK, and ERK through a series of sequential phosphorylation events, that results in activation of CBP/CREB mediated transcription and altered gene expression. Mutations resulting in NF1 are distributed throughout the coding sequence and lead to decreased ras inhibition. The resulting increase in ras signaling activates cellular proliferation and tumor formation in NF1.

DIAGNOSIS: CLINICAL AND LABORATORY The clinical diagnosis of NF1 requires two or more of the following features:

1. Six or more café au lait macules (each >5 mm in prepubescent children, but >1.5 cm in diameter in postpubescent individuals).
2. Two or more neurofibromas or at least one plexiform neurofibroma.
3. Axillary or inguinal freckling.
4. Optic gliomas.
5. Lisch nodules.
6. Osseus lesion (sphenoid dysplasia or long bone cortical thinning).
7. A first degree relative with NF1.

Commercial testing for NF1 concentrates on the neurofibromin truncations resulting from many NF1 mutations; however, a negative result by this approach does not exclude the diagnosis.

MANAGEMENT/TREATMENT Management of NF1 is focused on early detection and intervention for complications arising from the disorder. Screening for learning disabilities may be warranted in children who experience difficulties in school. Routine ophthalmolgic examination may identify early visual changes owing to optic gliomas. Painful or rapidly growing tumors require biopsy to exclude neurofibrosarcoma. Pedunculated neurofibromas are readily removed by simple surgical excision and may be warranted for tumors in areas prone to frictional trauma such as waistbands or for improved cosmesis.

NEUROFIBROMATOSIS 2

CLINICAL PRESENTATION Neurofibromatosis 2 (NF2) is an autosomal-dominant disorder of high penetrance (>95%) that manifests clinically as deafness owing to tumors of the eighth cranial nerve as well as CNS meningiomas and schwannomas, usually of the brain and spinal cord dorsal roots, respectively. The acoustic neuromas, which are more correctly termed vestibular schwannomas, are usually bilateral. Patients experience tinnitus and diminished hearing with the growth of these tumors.

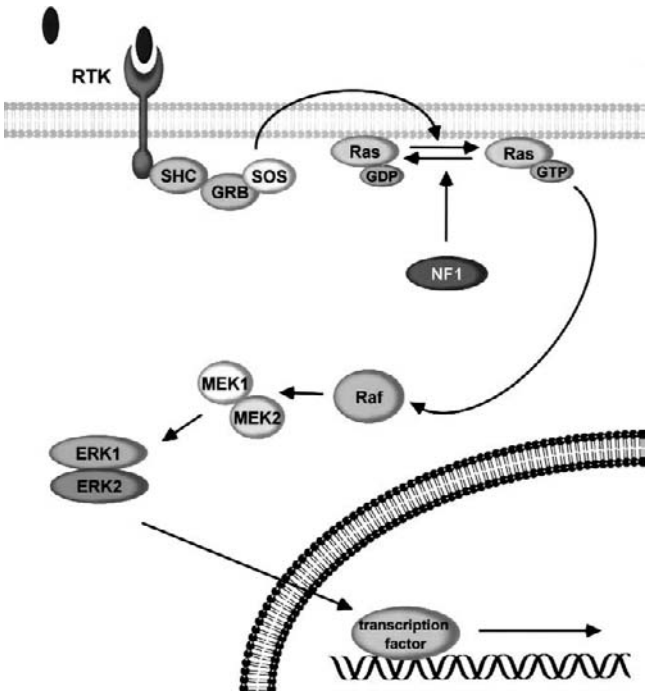

Figure 101-1 Mitogen activated protein kinase signaling and NF1. In this pathway, Ras is inactive when bound to GDP. Signaling through transmembrane receptor tyrosine kinases activates Ras through guanine nucleotide exchange factors in which GTP is exchanged for bound GDP on Ras. Active Ras-GTP then leads to activation of downstream components including Raf, MEK1/2, and ERK1/2 through a series of sequential phosphorylation events that results in activation of CBP/CREB mediated transcription and altered gene expression. NF1 contains GTPase activity, promotes formation of inactive Ras-GDP, and downregulates mitogenic signaling mediated by the Ras/ERK signaling cascade.

Some patients experience a distal symmetric sensorimotor neuropathy that may clinically manifest as muscle weakness or wasting. NF2 patients are predisposed to cataract formation. Skin findings in NF2 are much less numerous than in NF1, but include café au lait macules, and cutaneous and subcutaneous schwannomas. Neurofibromas are much less common in NF2. There does not appear to be a significantly increased risk of malignant tumor formation.

The incidence of NF2 is estimated to be 1 in 40,000. The rate of spontaneous mutation is high and up to 75% of patients with no family history may represent new mutations.

MOLECULAR BASIS AND DEFECTS NF2 is owing to mutations in the merlin (neurofibromin-2) gene that maps to chromosome 22q12.2. More severe forms of the disease arise from truncating mutations. Mutations resulting in single amino acid substitutions are associated with mild phenotypes. Merlin can be categorized as a tumor suppressor because of the resultant tumor formation with inactivation of merlin function. Merlin is structurally similar to the ERM family of proteins that mediates interactions between cell membrane glycoproteins and the actin cytoskeleton. Merlin has dual structural and signaling roles and may function as an adaptor protein that mediates signals allowing the cell to co-ordinate changes in adhesive state and differentiation. The precise mechanism of signaling is being studied and may involve signaling via PI3-kinase. Hepatocyte growth factor (HGF) stimulates schwann cell proliferation. By binding to the HGF-regulated tyrosine kinase substrate, merlin may function to downregulate signaling through the HGF-receptor (HGF-R).

DIAGNOSIS: CLINICAL AND LABORATORY The clinical diagnosis of NF2 can be made by the demonstration of bilateral cranial nerve masses by either MRI or CT, the presence of a unilateral cranial nerve mass and a first degree relative with NF2, or a first degree relative with NF2 and two or more of the following clinical features: neurofibroma, meningioma, glioma, schwannoma, and juvenile posterior subcapsular lenticular opacities.

Evaluation should include audiometry and ophthalmalogic evaluation with slit lamp examination and gadolinium, enhanced MRI of the brain and spine or CT. Nerve conduction studies and electromyography are useful in screening for neuropathy. Early diagnosis in some familial variants may be possible with linkage analysis or direct sequencing.

MANAGEMENT/TREATMENT Stereotactic radiosurgery and microsurgical resection have been used to treat acoustic neuromas.

HEREDITARY HEMORRHAGIC TELANGIECTASIA

CLINICAL PRESENTATION Hereditary hemorrhagic telangiectasia (HHT), an autosomal-dominant inherited disorder of high penetrance, also known as Osler-Weber-Rendu, is characterized by mucocutaneous telangiectases whose clinical manifestations include epistaxis and gastrointestinal hemorrhage. Punctate to several millimeters red, telangiectatic macules, or vascular papules are commonly found on the tongue, lips, conjunctiva, ears, and fingers. The vascular lesions typically appear during childhood and increase in size as the child grows to adulthood; approx 90% of patients have experienced an episode of epistaxis by 16 yr of age with a median age of onset at 12 yr. Arteriovenous malformations (AVMs) can be found in other tissues including the CNS, lungs, and liver. Migraine headaches occur with increased frequency; approx 50% of patients report a history of migraine with aura. Additionally, HHT has been associated with an increased incidence of spontaneous abortion. Pulmonary AVMs may result in heart failure; emboli originating from pulmonary AVMs can cause CNS infarcts and be a source for CNS abscess formation. Severe gastrointestinal hemorrhage requiring transfusions is not uncommon. Iron deficiency anemia may result from chronic hemorrhage.

The incidence of HHT is estimated to be 1 in 10,000.

MOLECULAR BASIS AND DEFECTS HHT results from aberrations in the transforming growth factor (TGF)-β signaling pathway (Fig. 101-2) resulting from mutations in either of two genes encoding (1) endoglin (ENG or HHT1) localized to chromosome 9q34.1 or (2) activin receptor-like kinase-1 (ACVRLK1, *ALK1*, HHT2) localized to chromosome 12q11-q14. Endoglin, expressed primarily on vascular endothelial cells, is a homodimeric membrane glycoprotein of 90 kDa subunits that binds to TGF-β1, TGF-β3, activin-A, BMP2, and BMP7. Endoglin antagonizes the inhibitory signaling of TGF-β1. *ALK1* encodes a protein that regulates blood vessel growth and repair. ALK1 is a type I serine-threonine kinase belonging to the TGF-β superfamily that is expressed primarily on vascular endothelial cells. ALK1 initiates signaling in response to both TGF-β1 and TGF-β3 and has been shown in vitro to bind activin-A. ALK1 signaling is mediated by phosphorylation of SMAD1 and SMAD5.

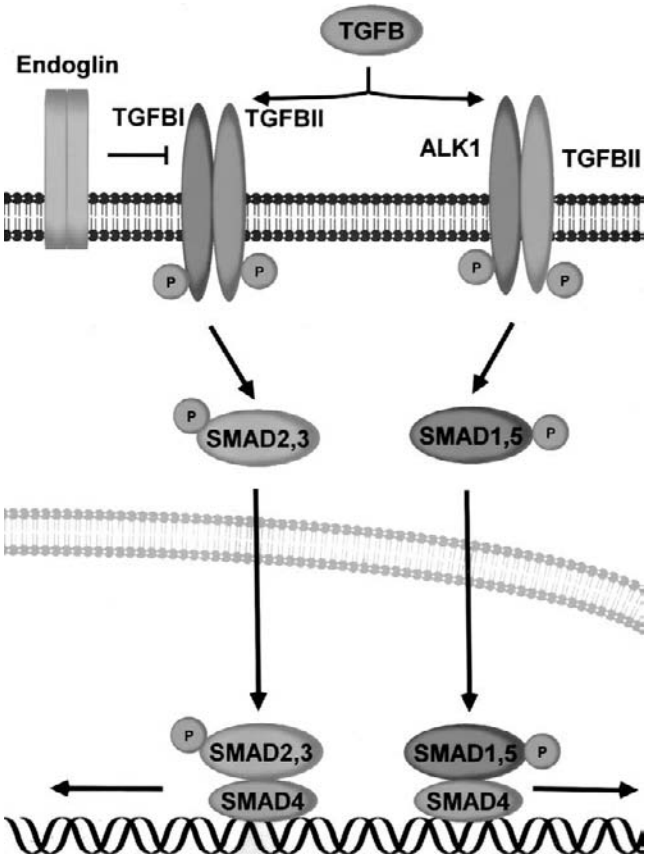

Figure 101-2 The TGF-β signaling pathway and HHT. The TGF-β superfamily (TGF-β) is comprised of a variety of related cytokines including TGF-β isoforms, activins, bone morphogenetic proteins, growth and differentiation factors, nodal and dorsalin. Members of this ligand superfamily activate signaling pathways by binding to heterodimeric cell surface receptors. In this model of HHT, vascular endothelial differentiation is regulated by two alternative signaling pathways. Extracellular TGF-β binds to TGF-β receptor I/II heterodimers (TGF-βI/TGF-βII) and activates transcriptional events, mediated by SMAD2,3/SMAD4 heterodimers, that regulate the resolution phase of angiogenesis. Alternatively, TGF-β binding to ALK1/TGF-β receptor II heterodimers results in activation of angiogenesis via SMAD1,5/SMAD4 heterodimeric regulation of transcription. Endoglin negatively regulates TGF-βI/II signaling. HHT results from mutations in either ALK1 or endoglin that increase SMAD2,3/SMAD4 mediated transcription relative to SMAD1,5/SMAD4.

Patients with defects in endoglin may have earlier onset and more severe disease than those with mutations in ALK1. For example, pulmonary AVMs appear to be much more common in patients with endoglin mutations.

DIAGNOSIS: CLINICAL AND LABORATORY Criteria for the diagnosis of HHT include a positive family history, frequent epistaxis, the presence of mucocutaneous telangiectases, and the presence of visceral AVMs. HHT Foundation International, Inc., consensus clinical diagnostic criteria require at least three features for a definitive diagnosis of HHT. With only two criteria, the diagnosis is not definitive, but should be suspected and patients monitored closely for the development of additional features and/or clinical complications. HHT is considered unlikely with less than two features, although special consideration for additional screening should be considered if one of the criteria is a positive family history. Work-up should include imaging studies to assess for the presence of AVMs in the CNS, lungs, and liver. Endoscopy may reveal gastrointestinal telangiectases. The diagnosis of HHT should alert the physician to monitor the patient for potential complications arising from involvement of internal organs. In young children of affected individuals, the presence of capillary nail-fold telangiectases should increase the index of suspicion for HHT as these nail-fold changes may precede the development of telangectases in other areas.

Genetic testing via sequencing of the entire suspected coding region as well as prenatal diagnosis is available. Select laboratories that offer this testing can be found by searching Online Mendelian Inheritance in Man.

MANAGEMENT/TREATMENT Management attempts to minimize and treat the complications arising from the vascular malformations and hemorrhage. Larger AVMs are sometimes amenable to surgical intervention. Iron deficiency should be treated with supplementation.

ANHIDROTIC ECTODERMAL DYSPLASIA

CLINICAL PRESENTATION Also called hypohidrotic ectodermal dysplasia or Christ-Siemens-Touraine Syndrome, anhidrotic ectodermal dysplasia is characterized by a markedly reduced ability to sweat. X-linked recessive is the most common inheritance pattern; however, autosomal-dominant and autosomal-recessive forms have been reported. Male infants may present at birth with a colloidon membrane or scaling that may be misinterpreted as a manifestation of ichthyosis. An additional

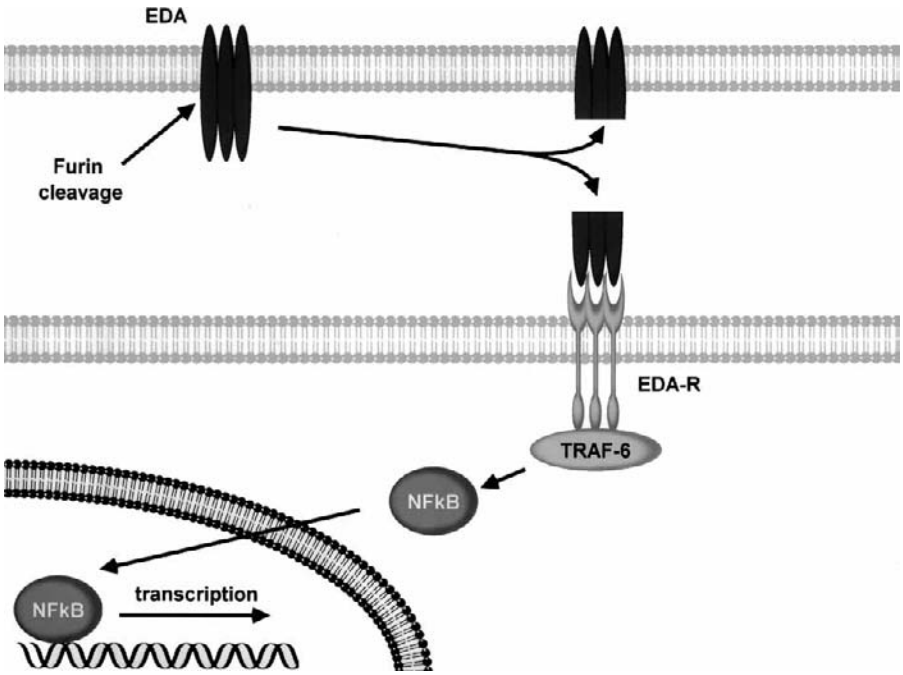

Figure 101-3 EDA signaling and anhidrotic ectodermal dysplasia. EDA is a transmembrane protein that forms homotrimers. Cleavage of EDA trimers by furin proteinases releases soluble trimeric EDA ligand that binds to the extracellular region of the trimeric EDAR, a member of the TNF-receptor protein family. When bound to EDA, the cytoplasmic tail of EDAR associates with TNF-receptor-associated factor-6 to initiate a signaling cascade that regulates NFκB-mediated transcription of target genes essential for the development of epithelial adnexal structures. Mutations in EDA result in the failure to activate this signaling pathway during the development of epithelial adnexal structures and cause anhidrotic ectodermal dysplasia.

feature is fine sparse blonde hair. Sweat pores are absent on physical exam and palmar creases are lost on the finger tips. Nail changes occur in 50% and include brittleness and ridging, but they are usually grossly normal. Recalcitrant atopic dermatitis is common. Because of the decreased ability to sweat, patients manifest elevated temperatures in warm environments. Infants may initially present because of repeated hospitalizations for high fevers with no identifiable infectious etiology. Other features include sebaceous hyperplasia as affected individual's age, hypodontia characterized by a few peg-shaped teeth or oligodontia, and focal patches of eczematous dermatitis. Frontal bossing, maxillary hypoplasia, saddle nose, and periorbital wrinkles characterize the typical facies. Affected males manifest the full clinical pattern, whereas the disorder is partially penetrant in female heterozygotes. Female carriers may be normal or manifest some features, predominately patchy focal hypotrichosis, in a distribution consistent with Barr body inactivation (lyonization). Female carriers may also demonstrate focal hypohidrosis and abnormal dentition. The incidence is estimated to be 1 in 100,000 live male births. All races are affected.

MOLECULAR BASIS AND DEFECTS Anhidrotic ectodermal dysplasia represents an inherited disorder in which transmembrane signaling is disrupted because of the failure to make a functional ligand capable of activating a receptor signaling pathway (Fig. 101-3) that is critical for development of epithelial adnexal structures. Anhidrotic ectodermal dysplasia has been mapped to the ectodysplasin-A (EDA) gene on chromosome Xq12-13.1. ED functions in the development of epithelial adnexal structures and its absence results in decreased numbers of hair follicles and sebaceous glands and reduced or absent eccrine sweat glands. ED is the ligand for the ED-A receptor (EDAR), a member of the tumor necrosis factor (TNF) receptor protein family. EDA is a transmembrane protein that forms homotrimers. Cleavage of EDA trimers by furin proteinases releases soluble trimeric EDA ligand that binds to the extracellular region of the trimeric EDAR. Occupancy of the extracellular ligand binding site of EDAR by EDA results in the binding of TNF receptor-associated factor-6 to the cytoplasmic portion of the EDAR. Subsequent transcriptional regulation is thought to be mediated by nuclear factor (NF)κβ.

The Lyon hypothesis explains why a heterozygous female can display a range of clinical abnormalities, including none. In females, there is early, random inactivation of one X-chromosome; therefore, the adult female is a mosaic of two populations of cells, those in which the maternal X is the active chromosome and those in which the paternal X is the active one. For instance, there may be an individual in which inactivation occurs in cell lines with the mutated X-chromosome; in this case, there are no abnormalities detected. However, in many X-linked diseases such as anhidrotic ectodermal dysplasia, some carrier females display clinical abnormalities; this implies that inactivation occurs in the mutant X-chromosome in some cell lines but in the normal chromosome in others.

DIAGNOSIS: CLINICAL AND LABORATORY The diagnosis can be established by the typical clinical features described. Prenatal diagnosis has been performed by skin biopsy and by fetoscopy and shows a complete absence of pilosebaceous units. Fetal analysis has been performed by chorionic villus biopsy.

MANAGEMENT/TREATMENT Because of their reduced ability to sweat, affected individuals are susceptible to hot

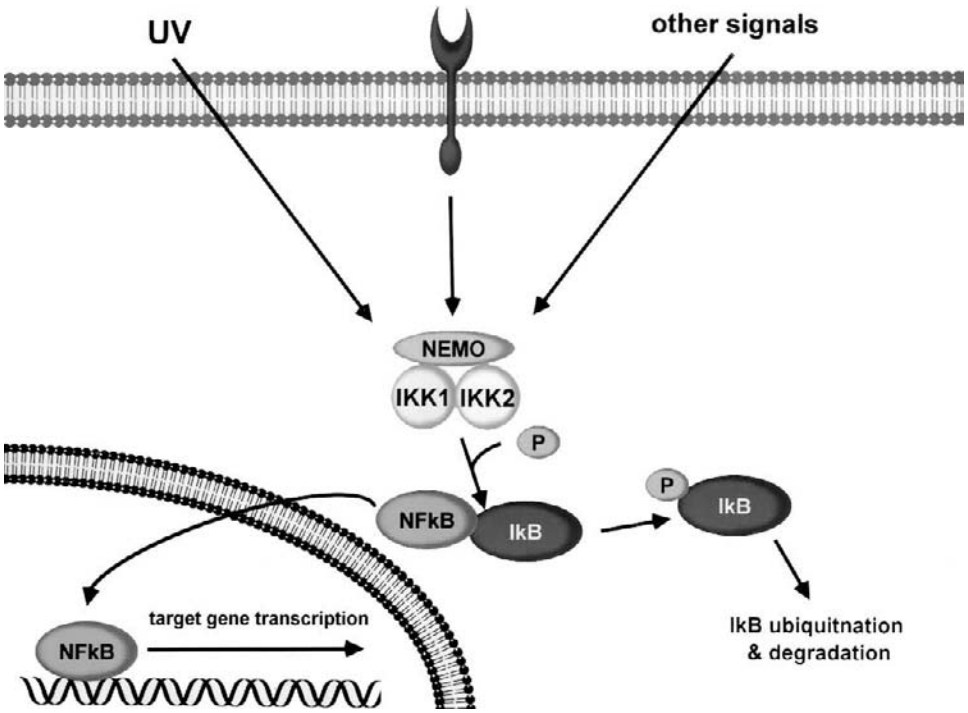

Figure 101-4 NFκB/IκB signaling. NFκB is a transcription factor that regulates a large number of genes implicated in apoptosis, cell growth, differentiation, and inflammation. NFκB is activated by many stimuli including UV light, growth factor receptors, and a variety of other signals (cytokines, lymphokines, drugs, and stress). NFκB activity prevents apoptosis induced by TNF-α. Various stimuli, including UV exposure and engagement of the TNF-α receptor, initiate a signaling cascade in which a multiprotein complex made up of NEMO, IKK1 and IKK2 phosphorylates IκB. Phosphorylated IκB releases NFκB, which subsequently translocates to the nucleus to regulate transcription of a variety of target genes that protect the cell against apoptosis. Loss of NEMO function results in the inability to transduce this antiapoptotic signal and renders mutant cells much more susceptible to apoptosis. The vesicular inflammatory phase of incontinentia pigmenti represents increased apoptosis of keratinocytes harboring NEMO mutations.

environments that may raise their core body temperature. Avoidance of such environments or modification by use of air conditioning is helpful. Referral for dental restoration is suggested in individuals with hypodontia.

RELATED DISORDERS Two other ectodermal dysplasia variants deserve mention. *Hidrotic ectodermal dysplasia* is an autosomal-dominant disorder resulting from mutations in the gene encoding connexin-30, a protein constituent of gap junctions. Patients with this disorder have normal sweating and teeth, but have sparse hair that may progress to total alopecia of the scalp and body as adults. In infancy and early childhood, the nails may be white, but become thick and dystrophic with time. Persistent paronychial infections are common and the palms and soles develop hyperkeratosis.

Hypohidrotic ectodermal dysplasia with immune deficency (HED-ID) is an X-linked recessive disorder that manifests clinically as an immune deficiency and developmental disorder of teeth, hair, and eccrine sweat glands. Affected male patients have low Ig levels and suffer from recurrent infections. Intravenous Ig and prophylactic antibiotics may be of benefit in treating the immune deficiency; however, the life expectancy is markedly shortened. Similar to anhidrotic ectodermal dysplasia, HED-ID results from defective ED signaling; however, the defect is in a downstream mediator of the EDA/EDAR signaling pathway. HED-ID is caused by mutations in the gene encoding NEMO (IKKγ) localized to chromosome Xq28. NEMO is a component of the multiprotein complex that phosphorylates IκB and results in release and translocation to the nucleus of the NFκβ transcription factor (Fig. 101-4). Interestingly, mutations in the gene encoding NEMO are also responsible for incontinentia pigmenti (IP, *see* next section). Mutation mapping has suggested that HED-ID may be caused by mutations affecting the C-terminus of the expressed NEMO protein, whereas the mutations resulting in IP have more marked effects on the structure and function of the NEMO protein resulting in male prenatal lethality.

INCONTINENTIA PIGMENTI

CLINICAL PRESENTATION IP is an X-linked dominant disorder also called Bloch-Sulzberger Syndrome characterized by the evolution of cutaneous lesions through four distinct stages. The first stage, consisting of erythema and vesicles, is present at birth or shortly thereafter and is followed by a second stage of verrucous papules and hyperkeratoses, a third stage of hyperpigmentation in adolescents and adults, and a fourth stage in which atrophy or scarring may be appreciated. The swirling patterns of involved skin in affected females represent the pattern of X-chromosome inactivation in postzygotic somatic cells, a process referred to as lyonization; normal skin represents cells in which the X-chromosome carrying the mutation is inactivated. The disease causes prenatal lethality in affected males. Additional clinical findings include nail dystrophy, abnormal teeth, and coloboma.

IP usually causes prenatal lethality in affected male fetuses; therefore, the disorder is seen in females. The few cases of affected

males are owing to Klinefelter's syndrome in which a second X-chromosome is present. The prevalence of IP is not known.

MOLECULAR BASIS AND DEFECTS Familial IP results from mutations in the NEMO gene (IKKγ) localized to chromosome Xq28. NEMO functions in NFκβ-IκB mediated signaling (Fig. 101-4). NFκβ activity prevents apoptosis induced by TNF-α. Various stimuli, including UV exposure and engagement of the TNF-α receptor, initiate a signaling cascade in which a multiprotein complex made up of NEMO, IKK1, and IKK2 phosphorylates IκB. Phosphorylated IκB releases NFκβ, which subsequently translocates to the nucleus to regulate transcription of a variety of target genes that protect the cell against apoptosis. Loss of NEMO function results in the inability to transduce this anti-apoptotic signal and renders mutant cells much more susceptible to apoptosis. The vesicular inflammatory phase of IP represents increased apoptosis of keratinocytes harboring NEMO mutations. New mutations may result from partial deletions of the NEMO gene secondary to genomic rearrangements during paternal meiosis.

DIAGNOSIS: CLINICAL AND LABORATORY The diagnosis is made by the typical staged progression of vesiculobullous lesions, followed by verrucous, whorled hyperpigmented and atrophic, hypopigmented phases, although patients without all stages are common. Deletion of exons 4–10 in the NEMO gene reportedly account for 80% of all mutations and serve as the basis for genetic screening and prenatal diagnosis.

MANAGEMENT/TREATMENT The initial vesiculobullous skin lesions, often misdiagnosed as herpesvirus infection, are self limiting and managed with local wound care. Patients with IP are at increased risk for seizure disorder and visual disturbances and should be monitored and treated accordingly.

102 Genetic Skin Diseases With Neoplasia

David S. Rubenstein

SUMMARY

The relationship between the molecular defects and cutaneous neoplasia in several genetic syndromes illustrates the key role played by a variety of proteins in cell growth, proliferation, and the repair of acquired genetic damage.

Key Words: ATM; *Adenomatous polyposis coli*; β-catenin; CYLD1; Gli1; helicase; kinase; nuclease; nucleotide excision repair; patched; smoothened; sonic hedgehog; tumor suppressor; XP complementation group.

INTRODUCTION

Multicellular organisms tightly regulate cell growth, proliferation, and migration. Without such regulation, rogue cells can disrupt the well-coordinated biology that enables these organisms to function. Such is the pathological phenomenon of neoplastic transformation that results in cancer. Genetic diseases in which the affected genes are involved in such regulatory processes lead to cancer. This chapter focuses on several genetic skin diseases as examples of this process. Tumor suppressors encode gene products in which inactivating mutations result in cancer. In contrast, cellular oncogenes encode gene products in which activating mutations result in cancer. Several examples of genetic lesions targeting tumor suppressors and cellular oncogenes highlight how disruption of these regulatory processes results in malignant transformation.

BASAL CELL NEVUS SYNDROME

CLINICAL PRESENTATION Basal cell nevus syndrome (BCNS), also known as Gorlin's syndrome, is an autosomal-dominant inherited disorder that presents with various developmental defects including frontal bossing, palmar and plantar pits, ondontogenic cysts, and bifid ribs. Additionally, there is an increased risk of developing some neoplasias, including medulloblastoma, meningioma, and rhabdomyosarcoma. Patients develop numerous basal cell carcinomas (BCC) of the skin at an early age.

Approximately one-third of patients may represent new sporadic mutations. In general, BCNS is a rare disorder. Despite the genetic predisposition to developing numerous BCCs, environmental factors, particularly exposure to ultraviolet (UV) radiation/natural sunlight and X-irradiation, are associated with increased numbers of tumors.

MOLECULAR BASIS AND DEFECTS The *PTCH1* gene (chromosome 9q22.3) is the mammalian homolog of the *Drosophila melanogaster ptc* gene that functions in hedgehog signaling during epithelial development and differentiation (Fig. 102-1). *PTCH1* encodes a multipass transmembrane protein that is the cell membrane receptor for the extracellular protein morphogen encoded by the sonic hedgehog gene. In the membrane, patched laterally associates with another transmembrane protein called smoothened. In this state, patched inhibits smoothened from activating downstream elements of the hedgehog-signaling pathway. When hedgehog binds to patched, the three-dimensional structure of patched is altered such that its affinity for smoothened is decreased, resulting in the dissociation of patched and smoothened. When not associated with patched, smoothened is then activated to initiate an intracellular signaling cascade that culminates in target gene regulation by Gli family member transcription factors.

PTCH1 mutations in BCNS result in a protein that can no longer bind to and prevent smoothened from activating this signaling cascade. One consequence of the inability to regulate this pathway is malignant transformation of the population of cells within the epidermis that give rise to BCCs. Because humans are diploid, patients with BCNS typically have one normal copy of the *PTCH1* gene in addition to the mutated gene. In BCNS, BCCs develop in cells in which this second copy of *PTCH1* is mutated, as often results from UV induced mutagenesis from natural sunlight exposure.

DIAGNOSIS: CLINICAL AND LABORATORY The diagnosis of BCNS is straightforward in patients presenting with the characteristic developmental abnormalities and a positive family history of the syndrome; however, new cases may represent sporadic mutations, so it is not always possible to elicit a positive family history. Nevertheless, in addition to the patient, it is worthwhile examining first-degree relatives for the presence of numerous BCCs, palmar and plantar pits, and frontal bossing. Histological examination of skin biopsies of suspected BCCs reveals the typical characteristics of BCC as seen in sporadic nonsyndromic BCCs, namely, a well circumscribed tumor of basaloid cells with peripheral palisading and often a retraction artifact during fixation that results in the appearance on H&E stains of a cleft between the tumor and the adjacent dermal stroma. X-rays can reveal skeletal abnormalities such as jaw cysts, rib defects, and calcification of the falx cerebri.

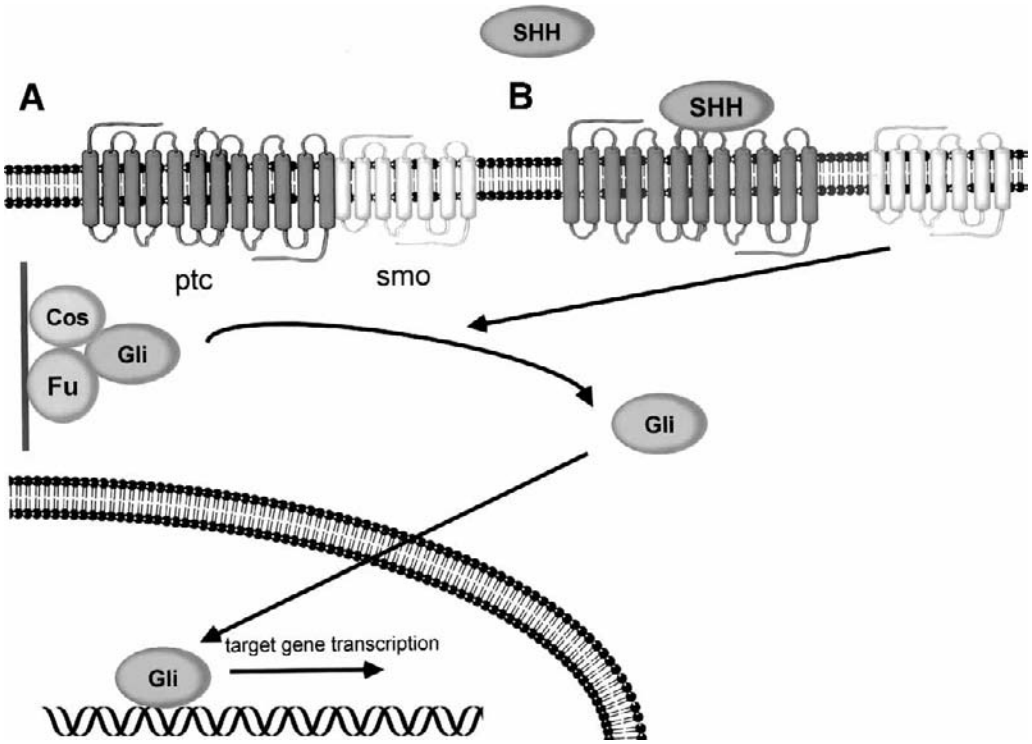

Figure 102-1 The hedgehog-patched signaling pathway and basal cell nevus syndrome. (**A**) Patched (ptc) is a multipass transmembrane receptor that laterally associates with and inactivates smoothened (smo). Gli, a transcription factor, is held inactive in a microtubule associated complex with Costal (Cos) and Fused (Fu). (**B**) When ptc is bound to its extracellular ligand Sonic Hegehog (SHH), smo is released and becomes activated to transduce a signal that results in release of Gli from the Cos/Fu complex. Gli translocates to the nucleus to regulate transcription of target genes. Ptc mutations in basal cell nevus syndrome and sporadic basal cell carcinomas prevent ptc from inhibiting smo with the result that this signaling pathway is constitutively active in mutant cells.

MANAGEMENT Management focuses on early diagnosis of the syndrome and photoprotective measures to minimize the risk of acquiring secondary UV-induced inactivating mutations in *PTCH1*. Avoidance of radiotherapy is advised; patients receiving X-ray therapy for medulloblastoma have developed numerous BCCs within the radiation field. Frequent full body skin examinations should be performed for the early diagnosis of BCCs. Traditional treatment methods for BCC include electrodessication and curettage, excisional surgery, and Mohs surgery. Because patients often present with numerous BCCs, on the order of hundreds, excision of all tumors by electrodessication and curettage or surgery may be impractical. Other modalities more amenable to treating numerous tumors include destruction by freezing with liquid nitrogen (cryotherapy) or topical application of the base pair analog 5-flourouracil. The use of the topical immunomodulatory agent imiquimod has garnered favor for the treatment of BCCs. Imiquimod stimulates the local production of interferon α; the activation and targeting of natural killer cells to the tumor may be one mechanism by which imiquimod works against BCCs. Topical vitamin A derivatives are being studied to determine their effectiveness for treating BCCs. Inhibitors of hedgehog signaling may also prove useful in the treatment of BCCs arising from BCNS as well as in the treatment of nonsyndromic sporadic UV-induced BCCs occurring within the general population. One such agent is a derivative of the plant alkaloid cyclopamine. As with the other disorders described in this chapter, patients and their families should be referred for genetic counseling. In some cases, fetal diagnosis has been performed with genetic techniques.

XERODERMA PIGMENTOSA AND RELATED GROUPS

CLINICAL PRESENTATION Xeroderma pigmentosa (XP) is a group of related autosomal-recessive genetic disorders that share an increased photosensitivity and a 1000-fold increased incidence in developing cutaneous malignancies as a result of genetic defects in the enzymes responsible for repairing damage to DNA. Signs of photodamage and aging, including numerous freckles, hypopigmentation and hyperpigmentation, xerosis, atrophy, and telangiectasia, appear within the first year of life. Patients characteristically develop premalignant actinic keratoses and numerous malignant cutaneous neoplasms such as BCCs and squamous cell carcinomas of the skin within the first decade of life; this contrasts sharply with the general US population in whom the median age of onset for nonmelanoma skin cancers is 60. Clustering of these neoplasms is noted on sun-exposed surfaces, particularly the face, head, and neck. Melanomas are reported in approx 5% of XP patients. Ocular findings occur in as many as 40% and include conjunctivitis, keratitis, ectropion, and corneal opacities that can lead to loss of vision. Ocular and oral cavity tumors, particularly squamous cell carcinomas of the anterior portion of the tongue, are also typical. Internal malignancies affecting both solid organs and the lymphoreticular system occur with increased frequency. Mild to severe neurological disease secondary to progressive axonal loss occurs in approximately one-third of patients, typically in XP complementation group A, and less so in C, D, and G. Neurological manifestations include hyporeflexia, mental retardation, seizure disorder,

and hearing loss. Patients with XP have a shortened life span with an estimated survival rate of 70% at age 40. Death is typically owing to invasive, metastatic neoplastic disease. The incidence of XP worldwide is estimated to be 4 per million, although the incidence in certain populations such as the Middle East may approach 25 per million. Within the United States, XPC is the most common XP complementation group.

MOLECULAR BASIS AND DEFECTS Seven complementation groups including genes encoding protein components of the DNA excision repair machinery have been described. Nucleotide exchange repair defective XP cells cannot repair pyrimidine/cyclobutane dimers. XP variant has the clinical features of XP, but has normal DNA excision repair, and results from defects in the gene encoding the DNA polymerase pol-η.

XPA and the *XPC* complex (along with the non-XP related *DDB* complex and *RPA*) encode nucleotide excision repair factors that are responsible for binding to and recognizing damaged DNA. *XPB* (3′ to 5′ DNA helicase) and *XPD* (5′ to 3′ DNA helicase) encode DNA helicases that are required to unwind the DNA prior to endonuclease cleavage of the damaged DNA. *XPG* and *XPF* (*ERCC1*) encode the nucleases. XPG is responsible for catalyzing the 3′ cleavage, whereas XPF (along with the ERCC1-subunit) catalyze the 5′ cleavage.

XPG may also serve as a cofactor for the hNTH1 glycosylase by facilitating the localization of the hNTH1 glycosylase onto damaged DNA containing oxidized pyrimidines in base excision repair. This additional non-nucleotide exchange repair function is likely responsible for the unique clinical phenotype of XPG patients who have features of traditional XP, developmental defects, as well as features of Cockayne Syndrome.

DIAGNOSIS: CLINICAL AND LABORATORY The diagnosis of XP should be considered when there is a history of severe photosensitivity with minimal exposure to natural sunlight or in those patients who have early onset photodamage as described. Cultured cells from XP patients demonstrate increased sensitivity to UV radiation. PCR based diagnostic tests are available for some XP complementation groups.

MANAGEMENT Minimizing the effects of UV radiation by photoprotection is critically important in the management of XP. Patients should undergo routine screening for early diagnosis and treatment of cutaneous malignancies. Chemoprophylaxis with systemic retinoids or cyclo-oxygenase-2 (COX-2) inhibitors should be considered. A strategy aimed at repairing UV-induced pyrimidine dimers using topical recombinant liposome encapsulated T4 endonuclease V is being investigated.

RELATED SYNDROMES Several other rare genetic disorders have been described in which mutations in helicases predispose the affected individuals to UV induced damage and neoplasia, including *Bloom syndrome*, *Werner's syndrome*, and *Rothmund-Thomson Syndrome*. Each of these disorders is from a genetic defect in one of the RecQ DNA helicases. The RecQ DNA helicases have been characterized in model systems. DNA helicases improve DNA replication accuracy during DNA elongation. Mutations that inactivate these proteins result in defective DNA repair and increased chromosome rearrangements. The resulting inability to repair UV induced mutations leads to the increased numbers of skin cancers observed in patients with these disorders.

Bloom syndrome, an autosomal-recessive disorder, is due to mutations in the gene encoding the BLM DNA helicase, and is characterized by photosensitivity and premature photoaging of the skin including facial erythema and telangiectasia. An additional feature includes a partial immunodeficiency manifested by increased frequency of respiratory and gastrointestinal infections. Systemic malignancies are common and include lymphoreticular malignancies, adenocarcinoma, and squamous cell carcinoma of the oropharyngeal and esophageal mucosa.

Werner's syndrome, an autosomal-recessive disease resulting from mutations in the gene encoding the WRN DNA helicase, causes premature aging of the skin and internal organ systems. In the skin, extreme early photoaging is characterized by premature graying and balding, atrophy, telangectasia, skin ulcers, and dyspigmentation. Affected individuals have an increased incidence of melanoma. Systemic involvement includes advanced atherosclerotic changes during childhood.

Rothmund-Thomson, an autosomal-recessive disorder caused by mutations in the *RecQL4* DNA helicase gene, is characterized by photosensitivity. Clinical features include poikiloderma (the triad of skin atrophy, pigmentary change, and telangiectasia) and limb defects.

ATAXIA TELANGIECTASIA

CLINICAL PRESENTATION Ataxia telangiectasia (AT), an autosomal-recessive disorder, results from inactivating mutations in the tumor suppressor gene that encodes the *ATM* gene. Patients develop progressive cerebellar dysfunction, ocular telangiectases usually by 3–5 yr of age, immune defects, gonadal dysfunction/infertility, and malignancies, typically B-cell lymphomas and T-cell leukemias. Immune defects include thymic hypoplasia, decreased serum Ig levels (IgG2 and IgA), and decreased cellular immunity. Frequent sinopulmonary infections is one of the more common manifestations of the immunodeficiency seen in AT. AT patients have elevated blood levels of alpha-fetoprotein.

The incidence of AT in the United States is estimated to be as high as 1 in 100,000 live births. Heterozygote AT carriers have an increased predisposition to developing a variety of cancers.

MOLECULAR BASIS AND DEFECTS Mutations in the *ATM* gene found on chromosome 11q23.3 are responsible for this disorder. *ATM* encodes a 3056 amino acid protein of 350 kDa that is constitutively expressed and localized to the cell nucleus. ATM is a protein kinase belonging to the phosphatidylinositol-3 kinase protein family. The *ATM* gene is large and numerous mutations have been described in this disorder, the majority of which result in premature termination and inactivation of the kinase activity of the ATM protein. ATM phosphorylates p53 at Ser15 and promotes p53 activation and stabilization during DNA responses induced as a result of exposure to ionizing radiation. ATM is one of the protein constituents of the BRCA1-associated genome surveillance complex that functions in sensing aberrant DNA structures and in regulating post replication DNA repair. The BRCA1-associated genome surveillance complex is made up of tumor suppressors, DNA damage sensors and signaling proteins.

ATM activation is one of the earliest cellular events in the response pathway to ionizing radiation (Fig. 102-2). Ionizing radiation results in double stranded breaks and changes in chromatin structure that are thought to activate ATM. Irradiation of cells in culture results in ATM autophosphorylation at serine^{1981} and subsequent dimerization. Cell cycle arrest is because of a series of phosphorylation events initiated by ATM. ATM phosphorylation of p53 causes activation of p21 and cell cycle arrest. Additionally, ATM binds to and phosphorylates BLM, the helicase that is defective in

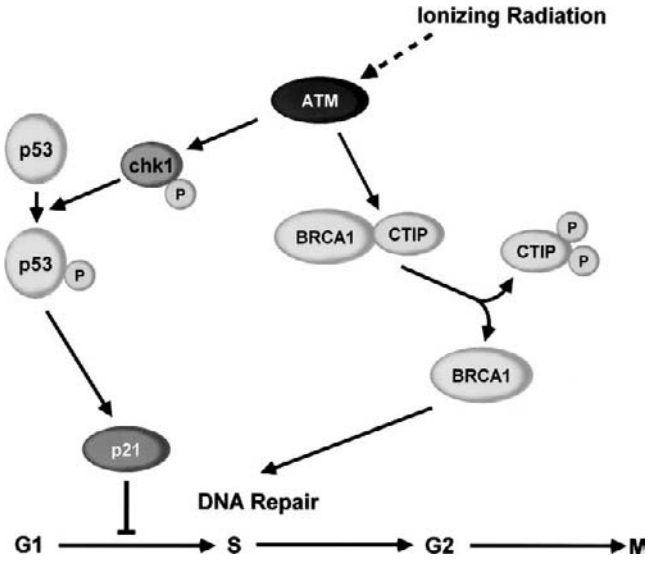

Figure 102-2 The ATM tumor suppressor. ATM, constitutively expressed and localized to the nucleus, is a protein kinase. ATM activation is one of the earliest cellular events in the response pathway to ionizing radiation. ATM phosphorylation of p53 causes activation of p21 and cell cycle arrest. Additionally, ATM phosphorylates CTIP resulting in release of BRCA1 and subsequent activation of DNA repair processes. Loss of ATM function disrupts this cell cycle arrest and DNA repair mechanism resulting in the accumulation of additional oncogenic mutations.

Bloom's syndrome. *ATM* knockout mice recapitulate many of the features of the human disorder demonstrating that loss of ATM function in AT leads to the observed phenotype. Loss of ATM results in increased sensitivity to ionizing radiation, and oxidation of macromolecules has been suggested to be one mechanism by which target organs are damaged in AT. In a mouse *ATM* knockout model of AT, cerebellar Purkinje cells were particularly susceptible to oxidative damage, which may suggest a mechanism for the ataxic phenotype observed in this disorder. Blockade of oxidative damage may provide an approach for treating this disease.

DIAGNOSIS: CLINICAL AND LABORATORY The diagnosis is suggested by early onset ataxia and oculocutaneous telangiectases. As described, elevated serum α-fetoprotein levels can aid in the diagnosis. Direct screening for specific mutations is of limited value; the *ATM* gene is large, approx 66 exons spanning 150 kb of DNA. Mutations that result in dysfunctional protein in a host of AT patients have been mapped throughout the *ATM* locus.

MANAGEMENT Because of the immune deficiency, AT patients should be closely monitored for infections and treated appropriately. AT patients are at increased for the development of lymphoreticular malignancies. The marked sensitivity to X-ray makes avoidance of this treatment modality essential in the management of neoplastic disease. Survival to adulthood is uncommon.

GARDNER'S SYNDROME

CLINICAL PRESENTATION This autosomal-dominant inherited disorder is a variant of the colon cancer associated syndrome familial adenomatous polyposis (FAP). It is completely penetrant and of variable expressivity. In addition to the numerous intestinal polyps that undergo malignant degeneration that characterize FAP, additional features of Gardner's syndrome include multiple epidermal inclusion cysts and intestinal and fibrous tumors. Congenital hypertrophy of the retinal pigment epithelium, jaw cysts, osteomas, and desmoid tumors, often at sites of surgical intervention, are other features of Gardner's syndrome. Patients develop malignant colonic tumors as young adults. Other associated malignant tumors include fibrosarcoma, meningioma, and leiomyosarcoma. The prevalence of FAP is estimated to be approx 1 in 13,500, although regional variation in prevalence rates has been observed. As many as 30% of cases may represent new mutations.

MOLECULAR BASIS AND DEFECTS Gardner's results from mutations in the gene encoding the APC protein. The gene localizes to chromosome 5q21. Various mutations have been described. Those within the central portion of the encoded polypeptide result in more severe phenotypes than those occurring in either the amino- or carboxy-termini. APC is a component of the Wnt signaling pathway (Fig. 102-3) and forms part of the multicellular protein complex that targets cytoplasmic β-catenin for ubiquitination and subsequent protoeosome mediated degradation. In the absence of functional APC, cytoplasmic and nuclear β-catenin accumulate, driving formation of a bipartite transcription factor between β-catenin and TCF/LEF family member proteins. Subsequent activation of target genes containing TCF/LEF response elements, such as c-*myc*, drives the proliferative changes that characterize the malignant phenotype observed in FAP/Gardner's. In addition, APC associates with microtubules. Mutant APC in FAP has decreased affinity for kinetochore associated microtubules and likely is responsible for the chromosome instability and aberrant chromosome segregation observed in APC mutant cells. Less severe FAP phenotypes result from mutations in the 5′ region of the gene encoding the N terminus of the protein, whereas more severe phenotypes result from inactivating mutations that affect the β-catenin binding function localized to the central region of the encoded APC protein. Other than the retinal pigmented lesions, no significant associations have been observed between the extraintestinal manifestations of FAP and specific *APC* mutations. Environmental factors and/or modifying genes may influence the presence of extraintestinal disease.

DIAGNOSIS: CLINICAL AND LABORATORY Diagnosis is based on the intestinal and extraintestinal clinical manifestations as described. The diagnosis is relatively straightforward in known kindreds; however, about 30% of FAP patients may represent new mutations. Gardner's syndrome should be considered in patients presenting with numerous epidermal inclusion cysts. A history of altered bowel habits and/or rectal bleeding should be queried and followed by screening colonoscopy. Palpation of nodules along the jaw should initiate a search for jaw osteomas using dental panoramic tomography; Gardner's syndrome is suggested by the finding of three or more jaw osteomas. Funduscopic examination for congenital hypertrophy of the retinal pigment epithelium is helpful in the diagnosis of suspected Gardner's syndrome, particularly in infants and young children because this finding may precede the development of intestinal polyps and epidermal cysts. Patients suspected of harboring mutations in the *APC* gene can be tested by screening for mutations in *APC* from peripheral blood lymphocytes. Direct sequencing for *APC* mutations in known kindreds facilitates prenatal diagnosis.

MANAGEMENT Because of the essentially 100% risk of developing colorectal carcinoma, annual screening colonoscopies are recommended in affected individuals from the age of 12 onward. The risk of developing gastric and duodenal tumors

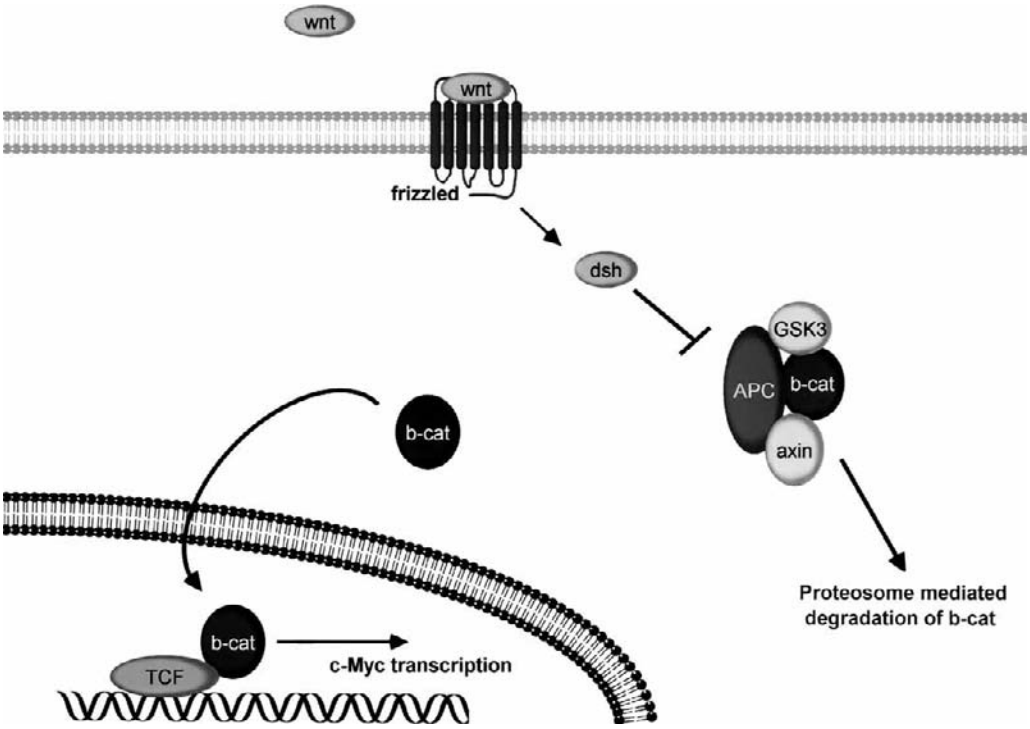

Figure 102-3 Wnt signaling and Gardner's Syndrome. β-catenin (b-cat) is constitutively synthesized, but fails to accumulate in the cytoplasm or nucleus because it is targeted for proteosome mediated degradation by a complex of proteins including APC, the serine threonine kinase GSK3, and axin. Wnts, a family of secreted polypeptides, bind to the cell membrane frizzled receptor to initiate a signal mediated by disheveled (dsh) that inhibits the APC/GSK3/axin mediated targeting and degradation of β-catenin. Cytoplasmic and nuclear β-catenin accumulate, driving formation of a bipartite transcription factor with TCF/LEF family proteins and transcription of a variety of target genes including c-*myc*. In Gardner's Syndrome, APC mutations result in constitutive activation of the downstream elements of the Wnt signaling pathway.

requires upper gastrointestinal endoscopic screening as well. Prophylactic colectomy has been advocated, but such patients still require surveillance for rectal and upper GI tumors. The use of nonsteroidal antiinflammatory drugs and in particular COX-2 inhibitors has been advocated for chemoprophylaxis. In vitro work has suggested that inhibition of COX-2 inhibits metastatic potential and promotes apoptosis of malignant cells.

FAMILIAL CYLINDROMATOSIS

CLINICAL PRESENTATION Familial cylindromatosis is an autosomal-dominant condition characterized by the appearance of multiple flesh colored papules, nodules, and tumors predominantly on the scalp and face. The tumors originate in skin structures such as hair follicles, eccrine, and apocrine glands. Cylindromas tend to affect the scalp, whereas trichoepitheliomas are found on the face. Confluent involvement of the scalp, which mimics the appearance of a turban, gives rise to the alternative designation of turban tumor syndrome. Although the cylindromas are benign neoplasms, malignant degeneration has been observed and the syndrome has been associated with other malignant neoplasms including BCCs.

Familial cylindromatosis is a rare disorder whose incidence has not been defined.

MOLECULAR BASIS AND DEFECTS Familial cylindromatosis is linked to a gene on chromosome 16q12-q13. The loss of the tumor suppressor CYLD1 is responsible for causing this disorder. Loss of heterozygosity in the *CYLD1* gene has been implicated in the development of nonsyndromic sporadic cylindromas. Mutations in the *CYLD1* gene result in either truncated nonfunctional protein or the absence of the encoded protein. *CYLD1* encodes a deubiquitinating enzyme that negatively regulates nuclear factor (NF)-κβ. NF-κβ has been well characterized as a critical component in signaling cascades that regulate cellular inflammatory responses. Engagement of transmembrane tumor necrosis factor receptor by tumor necrosis factor α causes tumor necrosis factor receptor trimerization. This results in TRAF recruitment; activation of the IκB kinase complex, phosphorylation and subsequent polyubiquitination and degradation of IκB. Degradation of IκB releases NF-κβ to translocate to the nucleus in which it activates transcription of target genes. CYLD1 catalyzes the removal of the polypeptide ubiquitin from lysine 63 of TRAF2, which prevents IκB phosphorylation, and dissociation of the NF-κβ–IκB complex. Activation of this pathway inhibits apoptosis. The growth of benign tumors in familial cylindromatosis is thought to be due to the inhibition of apoptosis resulting from loss of CYLD1.

DIAGNOSIS CLINICAL AND LABORATORY The diagnosis is straightforward in patients presenting with the characteristic clinical pattern of multiple scalp papules, nodules, and tumors. Biopsy of the scalp lesions reveals the typical histology of a cylindroma, namely irregular islands of basaloid cells within the dermis and subcutaneous tissues mimicking the pattern of a jigsaw puzzle. The facial lesions demonstrate numerous well-circumscribed dermal aggregates of basaloid cells with horn cysts and a fibrous stroma that characterizes trichoepitheliomas.

MANAGEMENT Surgical excision of the scalp tumors may improve cosmesis. The ability of aspirin or prostaglandin A1 to reverse the antiapototic effects of *CYLD1* mutations has suggested that these agents may be useful in the treatment of familial cylindromatosis.

103 Melanoma and Nevi

NANCY E. THOMAS

SUMMARY

Melanoma, which is increasing in incidence, is the most lethal skin cancer. Risk factors for melanoma include genotypic and phenotypic characteristics combined with environmental exposures. Germline mutations in *CDKN2A* and *CDK4* are thought to confer high susceptibility for melanoma. Polymorphisms in the melanocortin receptor-1 gene, which is central to melanin synthesis, confer low susceptibility for melanoma. In addition to germline alterations, somatic mutations in either *BRAF* or *NRAS* mutations have been found in a high percentage of melanomas. Nevi, which are one of the strongest risk factors for melanoma, also have *BRAF* mutations. Prevention, early diagnosis, and treatment remain important areas for future advancements.

Key Words: Braf; dysplastic nevus; early diagnosis; epidemiology; melanoma; mutation; nevus; pathology; p53; ras; somatic; staging.

INTRODUCTION

Melanoma is rapidly increasing in incidence and remains a potentially fatal disease with poor medical treatment options and controversial methods of prevention. Melanoma likely results from a series of mutations in critical genes (Table 103-1), with tumors emerging as a result of selection. Nevi (moles are synonymous), in particular dysplastic nevi, are thought to represent precursors for some melanomas. The risks for development of nevi and melanoma include both genetic and environmental factors.

CLINICAL FEATURES

The four clinical subtypes of melanoma have variable radial growth phases (Fig. 103-1). During radial growth phase, the melanoma is either *in situ* or has only single or small clusters of melanoma cells without mitoses in the papillary dermis. Superficial spreading melanoma is the most common subtype representing 60–70% of melanomas. Its location can be any anatomic site, and the radial growth phase is months to years. Nodular melanoma is less common, comprising approx 10% of melanomas. It also can be located at any anatomic site, but the radial growth phase is brief or unrecognized. Lentigo maligna melanoma consists of approx 10–15% of melanomas. It usually occurs on sun-exposed sites such as the head or neck and has a long radial growth phase (lentigo maligna) that extends, at times, to 15–20 yr. Clinically, it can mimic a solar lentigo. Acral lentiginous melanoma is the least common, representing approx 5% of melanomas, and occurs with relatively increased frequency in African American and Asian populations. It characteristically occurs on the palms, soles, or underneath the nail plate. For all subtypes of melanoma, the prognosis is closely related to the depth of the lesion at the time of initial excision.

Cutaneous melanoma, owing to loss of growth controls, generally presents as a changing, irregular pigmented papule or plaque. The *ABCDE* clinical criteria for diagnosis include asymmetry, irregular borders, color variegation, diameter greater than 6 mm, and evolution of the lesion. Melanomas are usually asymptomatic, with bleeding and ulceration typically only occurring as late changes. Of note, amelanotic melanoma, comprising 2–8% of melanomas, lacks visible pigment and can be any of the previously mentioned subtypes. Because most of the visual clues are absent in amelanotic melanoma, it is frequently misdiagnosed.

Benign acquired melanocytic nevi tend to be symmetric with smooth well-defined borders and homogeneous pigmentation. Acquired nevi develop after birth with a peak incidence between ages 22 and 25, with few developing after age 40. As nevi age, they are thought to evolve from junctional to compound to intradermal nevi, and then ultimately involute. Individuals older than 90 yr have few, if any, nevi.

Clinically, dysplastic nevi are moles with some of the *ABCD* characteristics of melanomas, but which generally are not as atypical clinically as melanomas. Histologically, dysplastic nevi are compound nevi with histological, cytological, and/or architectural atypia that is not as severe as that found in melanoma. However, poor correlation exists between the clinical and the histological criteria for dysplastic nevi; therefore, dysplastic nevi are not considered to be a distinct clinicopathological entity. However, the increased risk of melanoma based on clinical criteria for dysplastic nevi is consistent in diverse populations.

Congenital melanocytic nevi (CMN) are benign melanocytic neoplasms apparent at or shortly after birth. Congenital nevi are often larger than acquired nevi and can be classified into small (1.5 cm), intermediate (1.5–20 cm), or large (>20 cm). The color can range from tan to dark brown with various hues found within the same lesion. The surface can be papillated or smooth, and terminal hairs can be present.

The Spitz nevus, a benign melanocytic lesion, is most commonly a pink, red, or tan dome-shaped firm nodule; however a Spitz nevus can be macular, polypoid, or verrucous. Spitz nevi

often initially grow rapidly and then stabilize. The differential diagnosis histopathologically and clinically between Spitz nevi and melanoma can, at times, be extremely challenging. Despite well-established histopathological criteria for distinguishing Spitz nevi from melanoma, there are some atypical cases with overlap in features in which the diagnosis between a Spitz nevus and melanoma cannot unequivocally be made. Historically, Spitz nevi were called juvenile melanoma, adding to the confusion.

EPIDEMIOLOGY

Melanoma more than tripled in incidence among Caucasians between 1980 and 2003, bringing the estimated number of new invasive melanomas to 54,200 and *in situ* melanomas to 37,700, with 7600 deaths for the year 2003 in the United States. Melanoma is the fifth and seventh most common cancer in men and women, respectively. The lifetime risk of melanoma is 1.75% (1 in 57) in males and 1.23% (1 in 81) in females.

Melanoma risk is associated with genetic and environmental factors that are likely interrelated. Inherited risk factors include the fair phenotypic traits of red/blond hair, fair skin, easy burning/inability to tan, and light eye color. Red hair, fair skin, and freckling are associated with variants of the melanocortin receptor 1 (MC1R) gene, a low penetrance melanoma susceptibility gene. One-third of melanomas in Queensland, Australia may be attributable to *MC1R* variants. In addition, *MC1R* may increase melanoma risk in individuals with medium to dark complexions.

CDKN2A and *CDK4* are high penetrance melanoma susceptibility loci associated with proteins regulating the cell cycle. In melanoma-prone families, mutations in the *CDKN2A* gene, which codes for *p16* and the alternate reading frame protein (*ARF*) have been identified. *ARF* and *p16* are involved in the *p53* pathway and cell cycle control, respectively. *CDKN2A* mutations have been found in approx 5% of families with two or more affected first-degree relatives and 20–40% of families with three or more affected first-degree relatives. In a Queensland population-based melanoma study, 10.3% of high-risk families had a *CDKN2A* germline mutation, but mutations were rare (0.2%) among total cases. Germline mutations in *CDK4* have been identified in a few melanoma-prone families. In addition, melanoma risk is increased in xeroderma pigmentosum, heritable retinoblastoma, Li-Fraumeni syndrome (germline *p53* mutation), and Werner syndrome (Table 103-2).

Worldwide, the rate of melanoma tends to be higher in populations living closer to the equator and those living at higher altitude. Sun exposure is an important acquired risk factor for melanoma, with intermittent, recreational type exposure increasing the risk of superficial spreading melanoma and total sun exposure likely increasing the risk of lentigo maligna melanoma. In addition, the number of sunburns, especially severe childhood sunburn, is associated with increased risk of melanoma. PUVA, a treatment for psoriasis involving administration of ultraviolet (UV) A in combination with psoralen, increases the risk of melanoma above a certain number of treatments. Immunosuppression is also an acquired risk factor for melanoma.

Risk factors that could either be genetic or environmental include a personal history of melanoma and/or nonmelanoma skin cancer, a family history of melanoma, number of sunburns, and the number and type nevi. Familial melanoma, as defined by two or more first-degree relatives having melanoma, consists of 0.6–12.5% of melanoma depending on the geographic area, generally with higher percentages occurring in areas of higher melanoma incidence. An individual with a first-degree relative newly diagnosed with melanoma is considered to have a twofold increased risk of melanoma. However, family members who develop melanoma tend to have earlier age of onset, thinner melanomas, and be more likely to develop multiple primaries than sporadic cases. When family history is defined as three or more living relatives with a history of melanoma, familial melanoma consists of approx 1% of melanomas. Number of nevi is the most significant factor in predicting risk of melanoma in high-risk families.

Essentially, every study assessing nevi in association with melanoma risk has found number of nevi to be one of the strongest risk factors for melanoma. Although common nevi increase the risk of melanoma roughly two- to fourfold, dysplastic nevi (*see* clinical features) are associated with a greatly increased risk factor for melanoma in prospective clinical and cohort studies. Dysplastic nevi are relatively common, with an estimated prevalence of 7–18% in Caucasian controls from different populations. Although frequent in melanoma prone families, dysplastic nevi do not cosegregate with *CDKN2A* or *CDK4* mutations. The significance of an isolated dysplastic nevus is controversial; however, there is consensus that the lifetime risk of developing malignant melanoma is increased when many atypical moles occur in a person with a family history of melanoma.

Nevi may arise from a genetic-environmental interaction. Case–control studies show evidence of a role for sun exposure in the development of both common and atypical nevi. In Australia, children with increased numbers of nevi had more sun exposure and were more likely to have been sunburned than those with fewer nevi. Other studies also link sun exposure with number of nevi in children, adolescents, and adults using surveys. In addition, sun protection in children and adolescents decreases the number of nevi that develop. However, in highly sun protected children, different patterns of the distribution of nevi in males and females suggest that hormones may play a role. In addition, twin studies provide evidence of a genetic component in the development of common nevi. One twin study showed that the region containing the *CDKN2A* gene may also contain a locus affecting number of nevi.

Estimates of the incidence of congenital nevi vary from 1 to 2.5% of newborn infants. The risk of melanoma is highest in large congenital nevi and decreases as the size decreases. The risk is felt to be proportional to the number of melanocytes. Between 5 and 20% of patients with large congenital nevi will develop a melanoma within the nevus during their lifetime. The malignant potential of small and medium congenital nevi is more controversial.

Spitz nevi can occur at any age but are more frequent before age 30. The true incidence in the population is unknown, but it has been estimated that they constitute 1–10% of melanocytic nevi in children.

Xeroderma pigmentosum	*XP*	DNA excision repair
Werner syndrome	*WRN*	DNA helicase with roles in multiple DNA metabolic processes

MOLECULAR BASIS AND DEFECTS

MELANOMA

Germline Mutations *CDKN2A*, located at 9p21, is a major susceptibility gene for melanoma. It is transmitted as an autosomal-dominant trait in most affected families. It codes for two overlapping gene products, p16INK4A and p14ARF, that are differentially spliced and read on alternating reading frames such that they do not share the same amino acid sequence. Different first exons are utilized by the *INK4A* and *ARF* transcript, although both *INK4A* and *ARF* use the same second and third exons. Mutations in exon 1A affect only *INK4A*, whereas mutations in exon 2 can affect either of the two gene products. Some melanoma families also have a mutation in the 5′UTR of *CDKN2A*, which results in an aberrant initiation codon.

The p16INK4A gene product is a cell cycle inhibitor that binds to CDK4 and functions as a tumor suppressor. p16 has four ankyrin repeats that bind to CDK4, and the tumorigenic mutations map to sites of contact between p16 and CDK4. CDK4, with its regulatory subunit Cyclin D1, is required for the kinase activity. CDK4 is the key kinase that phosphorylates the tumor suppressor retinoblastoma protein (Rb), thereby freeing the transcription factor E2F. Rb is a tumor suppressor that is defective in hereditary retinoblastoma and central to arresting the cell cycle at G1. The Rb protein can interact with several members of E2F family to repress the transcription from E2F regulated promoters. E2F responsive genes include *Cyclin E*, *Cyclin A* and other gene encoding proteins and enzymes required for DNA replication.

p14ARF, also a tumor suppressor, works by a different mechanism. Human double minute 2 (HDM2- MDM2 in mice) binds to p53, targeting it for degradation. The ARF protein binds to HDM2, abrogating the degradation of p53. Mitogenic signals upregulate ARF, promoting p53-dependent apoptosis or arrest in cells with unscheduled proliferation. Mutations that affect ARF without affecting p16 are much less common than those affecting p16 alone or affecting both p16 and ARF.

CDKN2A mutations include more than 14 different mutations or small deletions. Mutations in the *p16* gene open reading frame are

highly penetrant, with melanoma eventually occurring in 55–100% of individuals with these mutations. Residence in a country with a high incidence of melanoma increases the penetrance, possible evidence for a role for UV.

An excess of pancreatic cancer has been found in some families with *CDKN2A* mutations. In families in which the mutation affects the ARF protein and not p16, there may be an association with neural tumors including astrocytomas.

CDK4, located at 12q14, has been reported to be mutated in three melanoma-prone families. The mutations occur in the p16 binding region of CDK4, rendering CDK4 resistant to p16 inhibition. Because there are few affected families, there is not much data; however, the penetrance, number of primary melanomas, risk of melanoma, and age at diagnosis for *CDK4* have been estimated to be similar to that for *CDKN2A* alterations.

Genetic Polymorphisms MC1R is a seven-pass transmembrane G protein-coupled receptor that controls the switch from pheomelanin (red/yellow pigments) to eumelanin (brown/black pigments) in mice. Stimulation of the *MC1R* receptor leads to activation of adenylate cyclase, resulting in an increase in cAMP production. This activation favors eumelanogenesis, which is important for the tanning response. Certain MC1R variants apparently are not as effective at switching from pheomelanin to eumelanin production.

Although there are more than 30 *MCR1* variants, most of the effect is because of a subset of variants. In humans, red hair, a recessive trait, and fair skin are significantly associated with three *MC1R* gene alterations (R151C, R160W, D294H). In addition, heterozygous *MC1R* variant carriers are at a two- to threefold increased risk of freckling, when controlling for skin type and hair color.

The three *MC1R* variants noted each confers a two- to threefold increased melanoma risk, with the effects from more than one affected allele being additive. In light skin individuals, when controlling for skin and hair type, the association between melanoma and *MC1R* variants disappears; however, in individuals with medium or olive/dark skin types, which normally are considered protective, carrying these particular *MC1R* variants may increase melanoma risk in comparison with individuals with similar skin types. It is possible that eumelanin is better at blocking UV than pheomelanin; that pheomelanin, its precursors or photoproducts are directly harmful by producing free radicals in response to UV; or that MC1R is involved in the modulation of growth and differentiation.

The estimated melanoma risk for *MC1R* variant carriers is 14% by age 50. *MC1R* increases p16 penetrance. *CDKN2A* mutation with consensus *MC1R* has 50% penetrance, whereas *CDKN2A* mutation with variant *MC1R* has 84% penetrance.

Somatic Mutations *BRAF* and *RAS* somatic mutations have been found in approx 60% and 10–30% of melanomas, respectively. *NRAS* mutations are much more common than *K* or *HRAS* mutations. Activating *BRAF* mutants can transform certain cell lines and activate kinase activity. *BRAF* V600E and *NRAS* mutations do not occur simultaneously in melanomas but, instead, have a reciprocal relationship. *BRAF* and *RAS* mutations have also been found in nevi.

RAS gene products, including HRAS, KRAS, and NRAS, are membrane-bound GTPases found mutated in several types of tumors. Based on mouse models, oncogenic *RAS* is important for both the genesis and maintenance of murine melanoma. In cultured human melanocytes, expression of *RAS* oncogenes can cause induction of complete melanoma phenotype and genotype.

The RAF family proteins, including RAF1, ARAF, and BRAF, are cytoplasmic serine/threonine kinases that phosphorylate mitogen-activated protein/extracellular signal-regulated kinases (MEKs) in the *RAF-MEK-extracellular signal-regulated kinase* (ERK)-MAP membrane-to-nucleus signaling module. RAF is recruited to the membrane by GTP-loaded RAS and then phosphorylated, resulting in the activation of the RAS-RAF-MEK-ERK-MAP pathway.

The RAS-RAF-MEK-ERK-MAP module transmits extracellular signals from the membrane to ERKs, which then translocate into the nucleus in which they phosphorylate and regulate transcription factors affecting cell cycle entry, differentiation, migration, adhesion, and gene regulation induced by growth factors. In addition, RAS is a known positive upstream regulator of phosphatidylinositol (3,4,5) triphosphate kinase (*PI3K*), which activates the survival kinase, serine/threonine kinase (Akt).

PTEN/MMAC1 (PTEN—phosphatase tensin and MMAC1—mutated in multiple advanced cancers), found at 10q23.3, is a tumor suppressor gene located on chromosome 10q23. It has homology with tyrosine protein phosphatases and tensin, the cytoskeletal protein that interacts with actin filaments at focal adhesions. PTEN, a dual lipid and protein phosphatase, is a tumor suppressor gene that reverses the growth signals induced by tyrosine kinases. PTEN is also involved in apoptosis and inhibition of cell spreading, migration and focal adhesion formation.

Germline mutations occur in Cowden disease, an autosomal-dominant syndrome in which there is an increase risk for breast and thyroid cancer, and in Bannayan-Zonana kindred, who have intestinal polyposis, vascular malformation, and hamartomatous growths such as subcutaneous and visceral lipomas.

PTEN mutations are found in approx 30–50% of melanoma cell lines. About 5–20% of uncultured metastatic melanomas have *PTEN* alterations; but only one in over 30 primary melanomas tested has an intragenic *PTEN* alteration. Allelic losses of the *PTEN* gene were found in 3/8 (38%) primary melanomas analyzed in one study.

PTEN protein expression, as detected by immunohistochemistry, was absent in 15% (5/34) and low in 50% (17/34) of melanoma samples in one study. However, metastatic melanomas were found with no PTEN expression that had no mutation or deletion of PTEN. Also metastatic melanomas were found that had weak *PTEN* staining. Of these, some had hemizygous allelic loss of *PTEN*, and others had no identifiable alterations. Based on these results, an epigenetic biallelic functional inactivation may occur in *PTEN*. In addition, lack of PTEN nuclear expression is associated with mitotic index, anatomic site, and presence of p53 expression.

A relative reciprocity of *NRAS* and *PTEN* mutations has been found in cutaneous melanoma cell lines, in which 51% had an alteration in either *PTEN* or *RAS*. Of these, 30% had an alteration in *PTEN*, 21% had a mutation in *NRAS*, and only one cell line had alterations in both *PTEN* and RAS alterations.

p53, known as the "guardian of the genome," helps maintain DNA integrity and genomic stability through cell cycle arrest. p53 senses genetic injury and arrests the cell at multiple cell cycle check-points, allowing cells time to repair damaged DNA. If genetic injury is too severe or cellular proliferation cannot be blocked, p53 can cause programmed cell death (apoptosis).

Approximately 20–25% of metastatic melanomas have *p53* mutations. The frequency of *p53* mutations in primary melanomas is not as well elucidated, but is reported to range from 1 to 2% to as high as approx 25%. In a study of nodular melanomas, 5 of 21 primary tumors (24%) were mutated. In addition, in a study of archived primary melanoma tissue, 28.5% of 35 mucosal tumors

and 17.6% of 34 head or neck tumors had *p53* mutations. Some of the mucosal and cutaneous melanomas had more than one *p53* mutation, some of which were on the same allele. One mucosal melanoma was found with mutations on different alleles. Mutations at dipyrimidine sites, considered UV fingerprints, were found in both mucosal and cutaneous melanomas.

Nearly all melanoma cell lines have mutations, deletions, or methylations of the *CDKN2A* gene. In primary melanomas, somatic mutations in *CDKN2A* are found in approx 10–30%. In addition, homozygous deletions of *CDKN2A* have been found in 10% primary melanomas. Also, approx 10% of primary melanomas and cell lines have hypermethylation of a 5′ CpG island of p16, causing silencing. Mutations and deletions in *CDKN2A* have also been found in metastases. A 540 C > T polymorphism in the 3′UTR of the *CDKN2A* gene, which may affect expression of both *p16* and *p14ARF* transcripts, was significantly higher in sporadic primary melanomas than in normal controls.

In melanoma cell lines, homozygous deletions of *CDKN2B*, which encodes $p15^{INK4b}$ have been found. In addition, rare *CDK4* mutations have been found in melanoma cell lines and sporadic melanoma tumors.

Other Genes A new melanoma susceptibility locus was found at 1p22, with linkage being strongest for families with an early age at diagnosis. Genes that may be affected in this region are those that code for the cell division *CDC7* (cycle 7–related kinase) and *TGFBR3* (transforming growth factor b receptor 3).

In addition, it has been suggested that in individuals with red, reddish-brown, or blond hair, *GST* (glutathione *S*-transferase) M1 null, *GSTT1* null, and *GST* null may be associated with an increased risk of melanoma.

Occasionally breast cancer families with *BRCA2* mutations have ocular melanomas that segregate with *BRCA2* mutations. In addition, a few sporadic ocular melanoma cases have *BRCA2* mutations.

Acral melanomas tend to show frequent gene amplifications occurring early in their progression. Using comparative genomic hybridization (CGH), amplifications have been found at *HRAS*, *cyclin D1*, *CDK4*, and the catalytic subunit of telomerase, *hTERT*. *Cyclin D1*, a subunit of *CDK4* and *6*, is required for making the holoenzyme needed for kinase activity and can act as an oncogene when amplified. A smaller proportion of superficial spreading melanomas have amplifications that tend to occur later in their progression. Also the *c-MET* is on 7q33, a region that is amplified in some human melanomas.

In 7% of melanomas, mutations of *FAS* (Apo-1/CD95), a cell-surface receptor in a cell death signaling pathway, have been found. These mutations are in the death domain, a region of the protein that is highly conserved and necessary for apoptotic signaling. In addition, other melanoma cases have shown *FAS* allelic loss. Silencing of the *FAS* promoter in melanoma can also occur by hypermethylation or through cooperating transcription factors.

In addition, some melanoma cells have completely lost expression of *TRAIL* receptors, which can be from the loss chromosome 8p22–21 or an epigenetic silencing mechanism. Upregulation of β-catenin mutations, through faulty mRNA splicing, or adenomatous polyposis coli tumor suppressor protein inactivation, can also occur in melanomas and may play a role in progression.

MELANOCYTIC NEVI Although it is suggestive, based on their frequent histological association and epidemiological data, that some melanomas arise from nevi, it is unproven. In addition it is unknown whether nevi are clonal. X-linked genes have been examined looking at X-inactivation, but conflicting results have been presented in different studies. There is also controversy regarding the importance of *p53* and *CDKN2A* alterations in dysplastic nevi, with different authors getting conflicting results. *BRAF* has been found in 86% of 7 congenital nevi, 88% of 42 intradermal nevi, 70% of 23 compound nevi, and 80% of 5 dysplastic nevi. *NRAS* mutations were found in 10/18 (56%) of congenital nevi in codon 61. One *NRAS* mutation in a dysplastic nevus has been reported. In a study of nevi histologically associated with melanoma, six out of seven associated nevi carried the same *NRAS* sequence (mutated or wild type) as the primary melanoma implying a clonal relationship.

CMN are generally larger than nevi acquired later in life. It has been theorized that this is from a longer period of proliferation because of telomeres being longer earlier in life. A mutation could result in a clonal proliferation of nevic cells; however, proliferation would stop because of the telomere checkpoint. Using CGH, proliferations arising in CMN have been analyzed and compared. In 86% of CMN with benign atypical nodular proliferations, numerical chromosome aberrations were found, which were not found in CMNs without these proliferations. These aberrations are different than those found in melanoma, which tends to have structural aberrations and different patterns of numerical aberrations. About 20% of Spitz nevi show multiple copies of an isochromosome 11p. Of the Spitz nevi with 11p copy increases, 70% have mutations in *HRAS*, codons 12, 13, or 61, which maps to 11p. In addition, one Spitz nevus without increase copy number of 11p also had a mutation in *HRAS*. No melanomas with histological features of Spitz nevi have been shown to have this alteration.

DIAGNOSIS: CLINICAL AND LABORATORY

The clinical *ABCDE* criteria, as noted, are used in the diagnosis of melanoma. Dermoscopy, a method combining surface magnification and either polarization or oil to eliminate reflection and refraction, improves diagnostic accuracy further. However, the gold standard for diagnosis remains pathological examination of biopsy specimens. Whenever feasible, the biopsy should be an excision or punch biopsy with complete removal of the lesion with narrow margins. An incisional biopsy that removes a portion of the lesion can be done when complete excision of the lesion for biopsy purposes would be difficult because of size or location. If the initial biopsy specimen is not adequate for diagnosis or staging, it should be repeated. The pathology should be read by a physician experienced in the histological diagnosis of melanoma.

MANAGEMENT

MELANOMA Genetic testing for melanoma susceptibility genes is not recommended.

The rationale is that most *CDKN2A* carriers, based on risk factors assessed by phenotype, family and personal history, are already known to be at increased risk of melanoma. These individuals should be counseled regarding sun avoidance and protection, self-examination, signs of melanoma, and encouraged to have yearly skin examinations. In addition, although the risk of disease based on *CDKN2A* has been studied, mutations are extremely rare (Table 103-3), confidence limits on estimates of risk are large, and penetrance varies with location in the world. Also, the risk of other cancers besides melanoma in *CDKN2A* mutation carriers is not well defined. Knowledge of mutation would not be expected to change clinical care, but instead might provide mutation negative

Table 103-3
Estimate of Percent Positive *CDKN2A* Mutations That Would be Found With Testing

Group	*% CDKN2A mutations*
Sporadic melanoma	0.2[a]
≥2 Affected first-degree relatives	<5
≥3 Affected first-degree relatives	20–40
Multiple primary melanomas	9–15
Patients with melanoma age <40	2[b]

Adapted from J Clin Oncol 1999;17:3245–3251.

individuals with a false sense of security. Mutation negative individuals in *CDKN2A* melanoma families are at increased risk of melanoma, possibly because of shared environmental risks and less penetrant genes.

Once a diagnosis of melanoma has been confirmed by biopsy, the disease should be staged. The updated AJCC staging system takes into account the Breslow depth (the depth from the epidermal granular layer to the deepest point of tumor invasion), Clark level if the depth is ≤1 mm, ulceration, whether in transit or satellite metastases are present, whether lymph node involvement involving micro- or macrometastases are present and whether distant metastases have occurred. At many centers, patients with a new diagnosis of invasive melanoma are offered lymphatic mapping and sentinel node procedure to determine if the melanoma has spread to the lymph nodes. If a sentinel lymph node biopsy is performed, it should be done before the wide excision.

The mainstay of treatment for melanoma remains surgical, with wide margins being taken around the melanoma or around the biopsy site, with the size of the margins determined by the depth of the melanoma. Additional surgical procedures may be indicated such as lymph node dissection if lymph node micro- or macrometastases are present. Surgical removal of isolated distant metastases may also be warranted.

High risk patients such as those with intermediate-thickness melanomas (1.0–4.0 mm) that are ulcerated, with deep primary melanomas (>4.0 mm), stage III disease, or who have had resection of distant metastases (stage IV) may be offered chemotherapy, treatment with biological agents or the option of a clinical trial. Once melanoma is found outside the regional nodal basis, prognosis is poor, with only 5% of patients being long-term survivors.

NEVI Management of nevi, especially dysplastic nevi, is controversial. Although dysplastic nevi may represent a precursor state for melanoma, it is likely rare that any one dysplastic nevus progresses to melanoma. Further work is needed in identifying how melanoma might arise from nevi and which nevi warrant removal.

Regarding giant CMN, in which there is a known increase in melanoma risk, the pros and cons of prophylactic excision must take into account melanoma risk, cosmetic outcome, and surgical complexity. Whether small congenital nevi should be prophylactically removed is controversial.

In addition, management of Spitz nevi is also controversial because of the diagnostic difficulty in discriminating them from melanoma. Atypical Spitz nevi warrant complete excision; at times, sentinel lymph node biopsy should be considered.

104 Disorders of Hypopigmentation

Julie V. Schaffer and Jean L. Bolognia

SUMMARY

This chapter reviews the clinical features and genetic bases of classic genodermatoses such as oculocutaneous albinism, piebaldism, and Waardenburg syndrome, with an emphasis on the understanding of their molecular pathophysiology. Other disorders of hypopigmentation with known genetic defects, such as Griscelli syndrome, are also briefly discussed, as is pigmentary mosaicism. The chapter is divided into three sections: oculocutaneous albinism, other inherited disorders characterized by diffuse pigmentary dilution, and inherited disorders characterized by circumscribed or linear hypopigmentation.

Key Words: Albinism-deafness syndrome; Chédiak-Higashi syndrome (CHS); Cross syndrome; Griscelli syndrome (GS); Hermansky-Pudlak syndrome (HPS); oculocutaneous albinism (OCA); piebaldism; Waardenburg syndrome (WS).

INTRODUCTION

The study of patients and animal models of inherited disorders of hypopigmentation has led to important advances in melanocyte biology and cell biology as a whole, from signaling pathways in embryonic development to mechanisms of intracellular organelle biogenesis and trafficking to the regulation of melanogenesis. The elucidation of the genetic bases of these conditions has provided insight into the pathogenesis of the individual disorders as well as important lessons in molecular medicine.

This chapter reviews the clinical features and genetic bases of classic genodermatoses such as oculocutaneous albinism (OCA), piebaldism and Waardenburg syndrome (WS), with an emphasis on the understanding of their molecular pathophysiology. Other disorders of hypopigmentation with known genetic defects, such as Griscelli syndrome (GS), are also briefly discussed, as is pigmentary mosaicism. The chapter is divided into three sections: OCA, other inherited disorders characterized by diffuse pigmentary dilution, and inherited disorders characterized by circumscribed or linear hypopigmentation. (Tuberous sclerosis is covered in Chapter 101).

OCULOCUTANEOUS ALBINISM

OCA represents a group of autosomal-recessive disorders characterized by diffuse pigmentary dilution of the skin, hair, and eyes. Although affected individuals have a normal number of melanocytes, the ability of these cells to produce melanin is either absent or reduced. Historically, OCA was divided into two major forms: tyrosinase negative and tyrosinase positive. Tyrosinase, the key enzyme in the melanin biosynthetic pathway (Fig. 104-1), catalyzes the initial rate-limiting conversion of tyrosine to dihydroxyphenylalanine (DOPA). In addition to this essential role as a tyrosine hydroxylase, human tyrosinase has DOPA oxidase, 5,6-dihydroxyindole oxidase, and perhaps 5,6-dihydroxyindole-2-carboxylic acid (DHICA) oxidase activities that regulate several other steps in the pathway. Patients with OCA were classically categorized based on clinical appearance, with tyrosinase-negative individuals having a more severe phenotype, as well as by the presence (tyrosinase positive) or absence (tyrosinase negative) of melanin production when anagen hair bulbs were incubated with tyrosine.

With the advent of molecular biology, determination of the genetic bases of the various forms of OCA has enabled more precise classification. As predicted, mutations in the tyrosinase (*TYR*) gene were found to be responsible for tyrosinase-negative OCA and a subset of tyrosinase-positive OCA (designated as OCA1A and OCA1B, respectively). Furthermore, mutations in several other genes cause tyrosinase-positive OCA, including *P* (OCA2), *t*yrosinase-*r*elated *p*rotein 1 (*TYRP1*; OCA3), and *m*embrane-*a*ssociated *t*ransporter *p*rotein (*MATP*; OCA4). In addition, the molecular bases of disorders of intracytoplasmic organelle biogenesis and trafficking, which result in an OCA phenotype (because of defective melanosomes) as well as other manifestations such as a bleeding diathesis (because of defective platelet dense granules), have been elucidated. Mutations in the *LYST* gene were found to cause Chédiak-Higashi syndrome (CHS), and mutations in eight different genes have been reported in patients with Hermansky-Pudlak syndrome (HPS).

CLINICAL FEATURES

Ocular Manifestations The presence of ocular stigmata is necessary for the diagnosis of OCA, and the severity generally correlates with the overall degree of reduction in melanin pigment. Because of a decreased amount of melanin in the retinal pigment epithelium (RPE) and in particular the fovea (Fig. 104-2A), patients with OCA have foveal hypoplasia and impaired visual acuity that ranges from 20/40 to legal blindness. Photophobia also occurs from the discomfort associated with excess light scatter in a hypopigmented fundus. In addition, patients exhibit nystagmus, strabismus, and a lack of stereoscopic vision, which are thought to be related to misrouting of optic fibers at the chiasm during development.

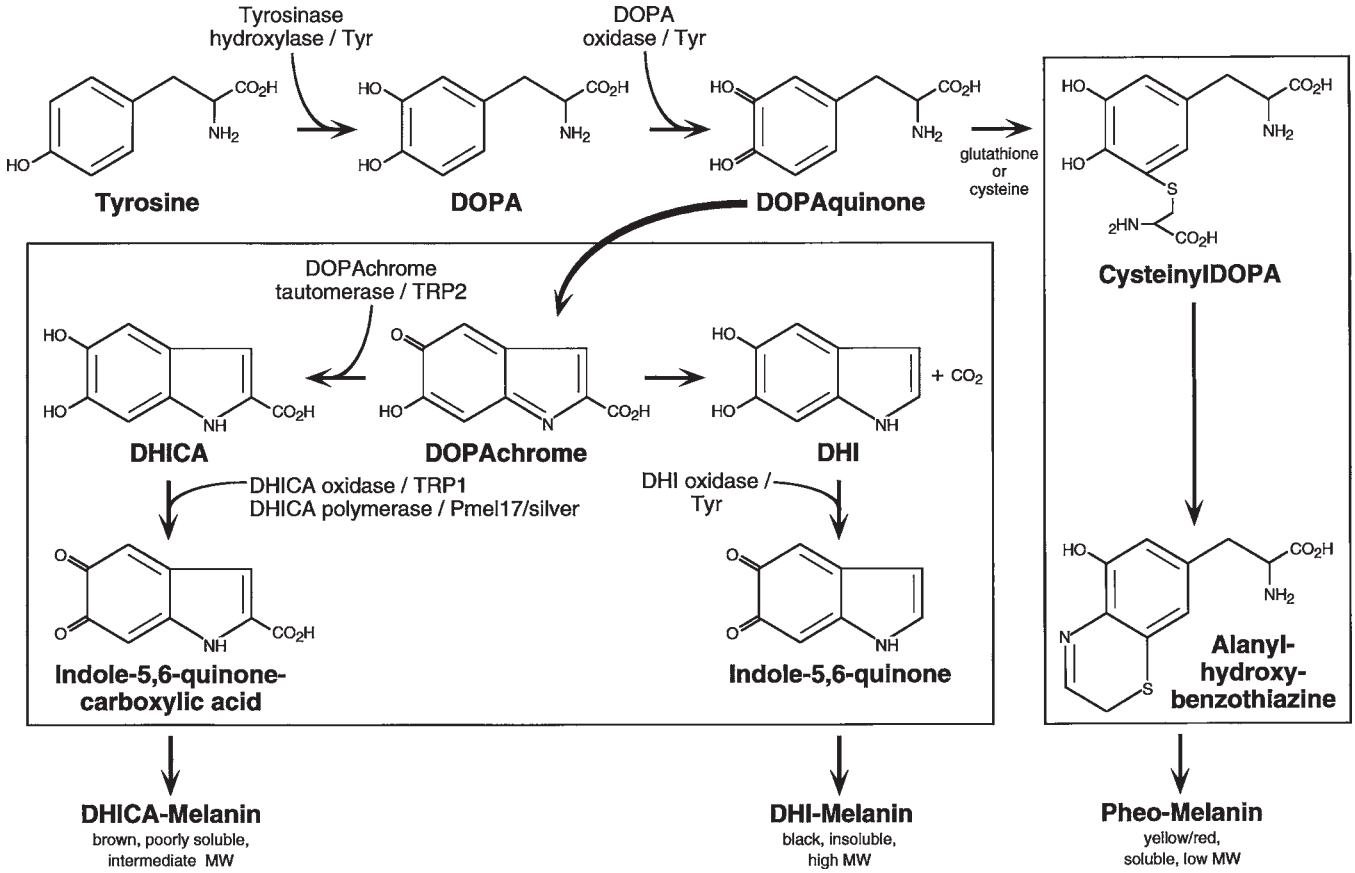

Figure 104-1 The melanin biosynthetic pathway, which includes the sites of dysfunction in OCA1 (tyrosinase) and OCA3 (TRP1). The two major forms of melanin in the skin and hair are brown-black eumelanin and yellow-red pheomelanin. Tyr, tyrosinase; DOPA, dihydroxyphenylalanine; DHI, 5,6-dihydroxyindole; DHICA, 5,6-dihydroxyindole-2-carboxylic acid; TRP, tyrosinase-related protein; MW, molecular weight. (Courtesy of Dr. Vincent Hearing.)

OCA1 In this autosomal-recessive disorder caused by mutations in both copies of the *TYR* gene, the clinical features reflect the amount of pigment that is produced in the skin, hair, and eyes. There are two subtypes of OCA1, depending on whether tyrosinase activity is reduced (OCA1B) or absent (OCA1A).

Individuals with OCA1A have pink skin, white hair, and gray-blue eyes at birth and throughout life (Fig. 104-2B). These are the patients who were previously referred to as having tyrosinase-negative OCA and, even with increasing age, they fail to produce any pheo- or eumelanin (*see* Fig. 104-1). Of all the patients with OCA, this group is the most susceptible to the development of cutaneous neoplasms, primarily squamous cell carcinomas, which can metastasize and lead to premature death, especially in those who reside in the tropics. Patients with OCA1A also have significant ocular manifestations including poor visual acuity (20/200–20/400+), and many are legally blind.

As expected, some mutations in *TYR* lead to a decrease rather than a complete lack of tyrosinase activity. Neonates with OCA1B are similar in appearance to those with OCA1A, i.e., they have pink-white skin and their hair is usually snow-white in color. However, as patients with OCA1B age they acquire more pigmentation (primarily via the production of pheomelanin, which requires less tyrosinase activity than the production of eumelanin); depending on their ethnic background, their hair can develop a yellow to reddish color, pigmented nevi can appear, and a tan can even develop in sun-exposed skin. This phenomenon, initially described in an Amish family, accounts for the term "yellow mutant" that was previously used in reference to patients with OCA1B. As with OCA2 (*see* below), some patients may not have a striking albino phenotype, but do exhibit characteristic ocular abnormalities. However, the ocular findings are less severe than in OCA1A.

In a variant of OCA1B referred to as the temperature-sensitive phenotype, patients have lightly colored hair in warm areas of the body such as the axilla, but darkly pigmented hair in cooler parts of the body such as the leg. First described in 1991, this phenotype is analogous to that of the Himalayan mouse or the Siamese cat in which darkly pigmented hairs on the ears, paws, and nose reflect a tyrosinase enzyme that has minimal activity at 37°C, but some activity at 35°C. Most patients with OCA1 are compound heterozygotes (different maternal and paternal alleles) and, as some patients have one "yellow mutant" allele and one temperature-sensitive allele, the boundary between these variants has become blurred. The degree of pigmentary dilution in OCA1B depends on the severity of the mutations (i.e., their impact on tyrosinase activity) as well as the ethnic background of the patient. The clinical spectrum also includes phenotypes previously referred to as minimal pigment OCA and platinum OCA.

OCA2 Two observations strengthened the hypothesis that there was at least one gene other than *TYR* involved in the pathogenesis of OCA: (1) the localization of *TYR* to human chromosome 11q; and (2) the pigmentary dilution seen in some patients with Angelman and Prader-Willi syndromes, both of which are associated with deletions

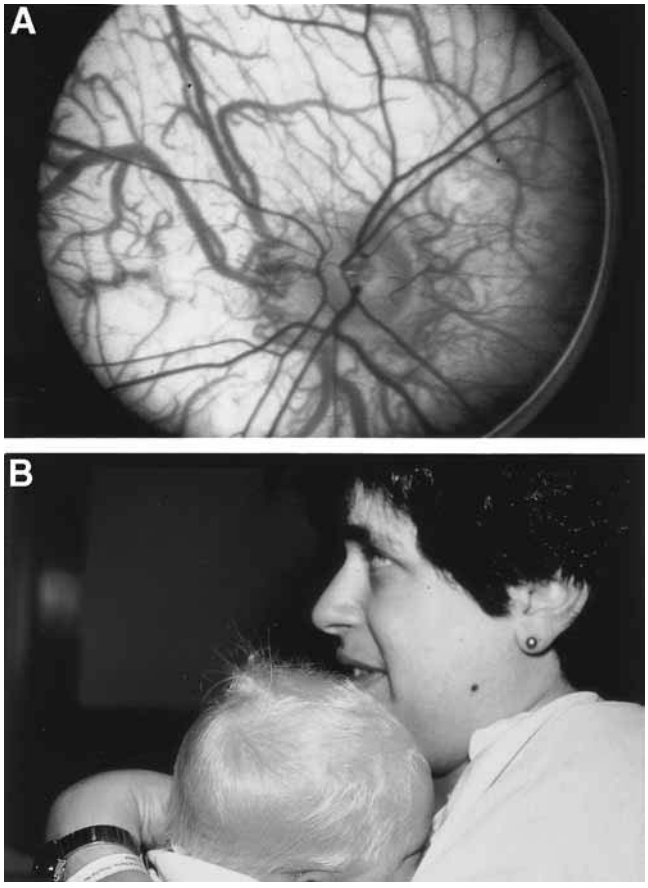

Figure 104-2 **(A)** Hypopigmented fundus in a patient with OCA1A. The vasculature is prominent because of the lack of pigment production in the retinal pigment epithelium. **(B)** A newborn with OCA1A who has white hair and pink skin. The pigmentary dilution is obvious when compared to her mother. (Courtesy of the Yale Residents' Slide Collection.)

of chromosome 15q11-q13. OCA2 is an autosomal-recessive disorder in which patients have mutations in both copies of the *P* gene located on chromosome 15q.

The phenotype of OCA2 is generally less severe than that of OCA1A, although an occasional patient has profound pigmentary dilution. As with OCA1B, the skin, hair, and eyes become darker as the patient ages; however, in contrast to OCA1B, the hair is usually not white at birth. The eventual level of pigmentation depends on the ethnic background of the patient, and some individuals, especially adults, may remain undiagnosed unless compared with first-degree relatives. A rather striking clinical finding seen in approx 1/2 of patients with OCA2 is the development of multiple large (5 mm–2 cm), stellate solar lentigines. The spectrum of pigmentation associated with OCA2 in Africa includes *brown albinism*, which manifests with light brown skin and hair together with ocular findings.

OCA3 Mutations in the *TYRP1* gene on chromosome 9p result in OCA3, also called *rufous* or *red albinism.* This condition, which has been described primarily in individuals of African or New Guinean heritage, typically results in brick- to mahogany-red or bronze skin, reddish-ginger hair, and red–brown to brown irides together with mild ocular abnormalities. Of note, one African-American infant with diffuse pigmentary dilution (compared to his fraternal twin) characterized by light brown skin and hair was found to have mutations in both copies of the *TYRP1* gene and no detectable TYRP1. Marked hypopigmentation of the skin and hair was also reported in two siblings with 9p- syndrome, a disorder characterized by craniosynostosis, midfacial hypoplasia, abdominal wall defects, and mental retardation. An explanation for the associated hypopigmentation was not obvious, given that only one copy of *TYRP1* was deleted in these children.

OCA4 In OCA4, the degree of diffuse pigmentary dilution of the skin, hair, and eyes varies depending on the underlying mutations in the *MATP* gene. Hair color ranges from white to yellow-brown, and patients may or may not develop increased pigmentation of the skin and hair over time.

Hermansky-Pudlak Syndrome In HPS, an autosomal-recessive disorder, diffuse pigmentary dilution of the skin, hair, and eyes as well as ocular findings resulting from defective melanosomes are accompanied by a bleeding diathesis secondary to an absence of platelet dense granules. In addition, an accumulation of ceroid lipofuscin because of defective lysosomes can result in pulmonary fibrosis and granulomatous colitis.

Chédiak-Higashi Syndrome Patients with CHS have mild diffuse pigmentary dilution (often with areas of hyperpigmentation in sun-exposed sites), silvery-blonde hair that is characterized by small, regularly spaced clumps of melanin microscopically, ocular findings, and recurrent pyogenic infections because of abnormal function of neutrophils, cytotoxic T cells, and natural killer cells. Abnormally large melanosomes and lysosomal granules are seen in the perinuclear area of melanocytes and granulocytes, respectively. Additional manifestations include a bleeding diathesis, progressive neurological deterioration, and an "accelerated phase" characterized by pancytopenia and lymphohistiocytic infiltration of the liver, spleen, lymph nodes, and other organs. The latter, which results from uncontrolled T cell and macrophage activation and may be associated with Epstein-Barr viral infection, typically leads to death by the age of 10 yr unless bone marrow transplantation is performed. However, approx 10% of patients with CHS follow a less severe clinical course and survive to adulthood, but eventually develop debilitating neurologic dysfunction.

EPIDEMIOLOGY It has been estimated that OCA1 and OCA2 account for 40% and 50% of OCA worldwide, respectively. In Caucasian Americans, both OCA1 and OCA2 have an incidence of approx 1/36,000. However, OCA2 is more common among African-Americans, with an incidence approaching 1/10,000, and in certain African tribes its frequency is as high as 1/1000. In addition, the frequency of OCA2 in the Native American Navajo population was reported to be at least 1/2000. OCA3 (rufous/red albinism) has an estimated incidence of 1:8500 in southern Africa, but thus far it has not been described in Caucasians or Asians. OCA4 accounts for approx 25 and 5% of albinism in Japan and Germany, respectively.

Although rare in most populations, the frequency of HPS is approx 1/1800 in the Arecibo region of northwest Puerto Rico; this disorder also has an increased incidence in individuals from certain areas of Holland. CHS is a rare disorder, and approx 300 cases have been reported.

MOLECULAR BASIS AND GENETIC DEFECTS

OCA1 Patients with OCA1 have mutations in both copies of the *TYR* gene located on chromosome 11q14–q21. There are five exons in *TYR*, and the entire gene spans more than 65 kb of genomic DNA. Translation of tyrosinase mRNA results in a 529-amino acid polypeptide, which contains two copper-binding sites, a transmembrane domain at the carboxy-terminal end, and an 18-amino

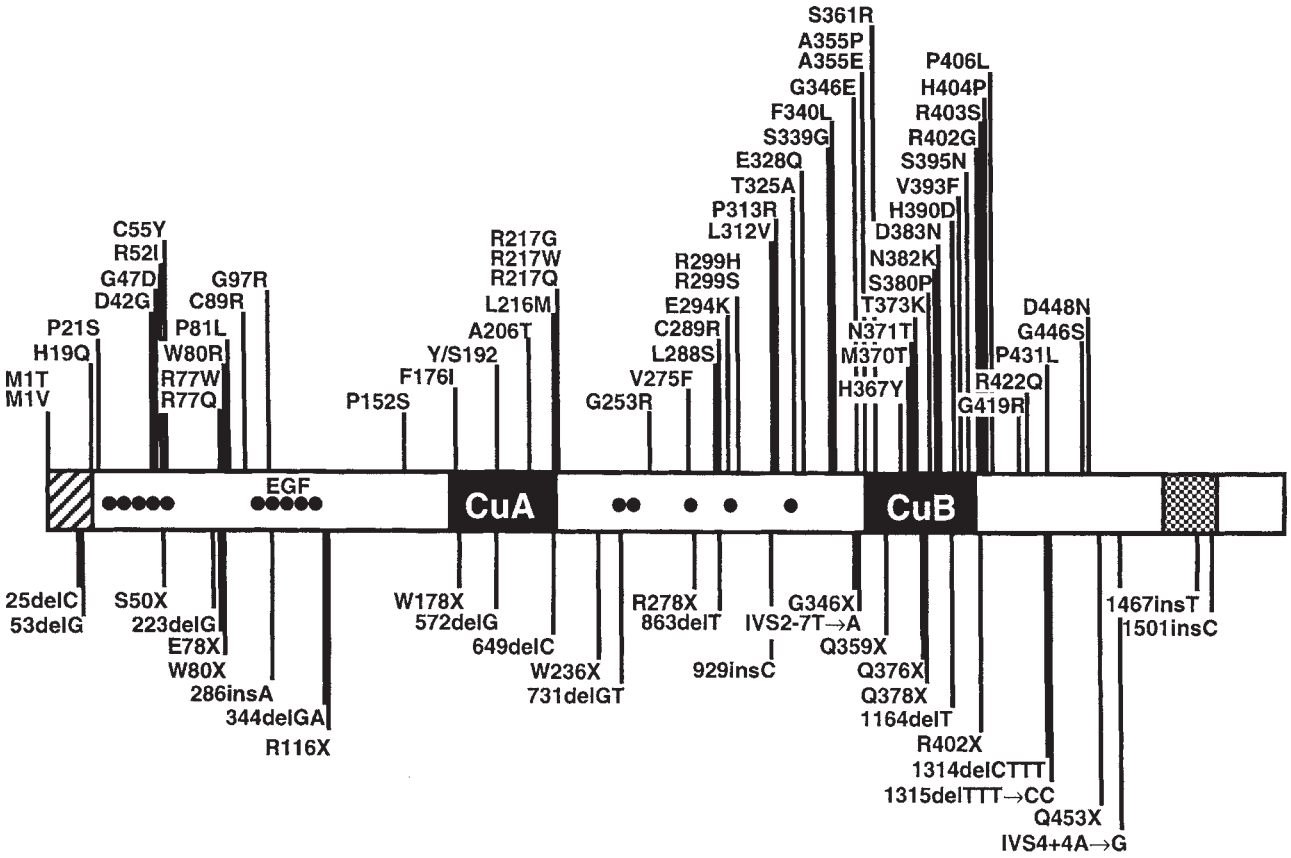

Figure 104-3 Locations of mutations in the tyrosinase gene that are associated with OCA1. CuA and CuB represent the copper-binding sites; *striped area*, signal peptide; *checkered area*, transmembrane region; *black dots*, locations of cysteine residues. *EGF*, epidermal growth factor-like region. *Top*, missense mutations; *bottom*, nonsense, frameshift, and splice-site mutations. (Reproduced from Oetting WS, King RA. Molecular basis of albinism: mutations and polymorphisms of pigmentation genes associated with albinism. Hum Mutat 1999;13:99–115. Copyright 1999 John Wiley and Sons. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley and Sons.)

acid leader peptide that is eventually cleaved. At least 115 different *TYR* mutations have been reported in patients with OCA1, and the associated phenotype depends on whether the mutations lead to a lack of enzyme activity (OCA1A) or a decreased level of enzyme activity (OCA1B). As noted, the majority of patients with OCA1 are compound heterozygotes and there is no predominant mutant allele in the general population.

Several types of *TYR* mutations have been described, including missense, nonsense, and splice-site mutations (Fig. 104-3). Some patients have also had frameshift mutations, but deletions are rare. In addition, two nonsynonymous polymorphisms (Ser192Tyr and Arg402Gln) are fairly common in Caucasian populations, with the latter resulting in temperature-sensitive enzyme activity. When the locations of *TYR* mutations are mapped, there is an obvious clustering near the amino-terminal end as well as within and flanking the two copper-binding domains (*see* Fig. 104-3). Tyrosinase is a copper-dependent enzyme, which makes the copper-binding sites logical locations for mutations in OCA1A and explains the diffuse pigmentary dilution seen in Menkes kinky-hair syndrome (which is caused by mutations in a copper-transporting ATPase) and rare cases of copper deficiency.

Although it was previously assumed that OCA1 resulted from catalytic malfunction of mutant tyrosinases, it is clear that the pathogenesis is more closely associated with tyrosinase processing in the endoplasmic reticulum (ER). During its synthesis by ribosomes, tyrosinase is translocated into the lumen of the rough ER, where molecular chaperones (e.g., calnexin) bind the nascent glycoprotein and regulate its folding. In patients with OCA1A and OCA1B, quality-control mechanisms "trap" misfolded mutant tyrosinase within the ER compartment, and it is subsequently degraded by proteasomes rather than being sorted to melanosomes.

A specific chaperone-assisted interaction between the two copper-binding domains of tyrosinase is essential for the acquisition of an ER-exit-competent conformation and enzymatic activity. *TYR* mutations that prevent this interaction, and thus the subsequent conformational change, result in ER retention and degradation of tyrosinase, whereas missense mutations in a histidine residue critical to copper binding do not interfere with export of tyrosinase to melanosomes. This explains the apparent paradox of severe OCA phenotypes resulting from mutations predicted to have minimal effects on tyrosinase structure and function, and mild OCA phenotypes associated with mutations at key sites of catalytic activity. Lastly, in vitro studies show that temperature-sensitive tyrosinase mutants fail to exit the ER at 37°C, but are properly folded and sorted to melanosomes at 31°C or with coexpression of wild-type tyrosinase.

Murine tyrosinase has been mapped to the *albino* or *c* locus on mouse chromosome 7. Pigment production has been observed in albino mice following the introduction of a minigene that

contained mouse tyrosinase cDNA plus the genomic 5′ noncoding flanking region.

OCA2 OCA2 is caused by mutations in both copies of the *P* gene, which spans 250–600 kb in chromosomal segment 15q11–q12 and contains 25 exons. The *P* gene is the human orthologue of the murine *pink-eyed dilution (p)* gene, and its 838-amino acid protein product has 12 membrane-spanning domains (Fig. 104-4A).

The P protein has an important role in eumelanogenesis, although its exact function is not known. Because its amino acid sequence is homologous to that of transmembrane transporters of small molecules and high concentrations of tyrosine can increase pigment production in *P*-null melanocytes, it was initially predicted that the P protein might serve to transport tyrosine across the melanosomal membrane. However, kinetic studies showed no difference between the melanosomes of wild-type and *P*-null melanocytes in the rate of tyrosine uptake. A second hypothesis is that the P protein regulates the pH of melanosomes and/or other organelles, potentially mediating neutralization of pH to optimize the activity and/or folding of tyrosinase. The restoration of pigment production in *P*-null cells by vacuolar H^+-ATPase inhibitors (e.g., bafilomycin A1) that are known to alkalinize (i.e., neutralize) organelles supports this theory. The majority of the P protein in melanocytes is actually located in the ER rather than in melanosomes, and abnormal processing and trafficking of tyrosinase occurs when the P protein is absent. In addition, it was observed that the P protein facilitates vacuolar accumulation of glutathione, a major redox buffer that is required for the folding of cysteine-rich proteins such as tyrosinase. The P protein may thus regulate the processing of tyrosinase via control of glutathione.

As with OCA1, most patients with OCA2 are compound heterozygotes. The types of mutations described include missense and splice-site mutations, in-frame deletions, and frameshifts. An intragenic deletion of the *P* gene involving exon 7 is a commonly observed mutant allele in Africans with OCA2. Many of the *P* missense mutations occur at residues that are conserved among homologous transmembrane transporter proteins, whereas some mutations that result in a milder phenotype occur at less well-conserved residues. In contrast to *TYR*, the *P* gene has >40 nonpathogenic DNA sequence polymorphisms. When Caucasians with tyrosinase-positive OCA are evaluated, an equal number have *TYR* gene mutations as have *P* gene mutations. In contrast, *P* gene mutations are found in the vast majority of Africans and African-Americans with tyrosinase-positive OCA.

Patients with Angelman or Prader-Willi syndrome plus OCA2 have a deletion in the maternal or paternal copy of chromosome 15, respectively, in addition to a mutation in the second copy of the *P* gene. Uniparental disomy is a less common cause of this constellation of findings. Conversely, generalized cutaneous hyperpigmentation has been reported in a patient with a *P* gene duplication.

OCA3 OCA3 (rufous/red albinism) is caused by mutations in both copies of the *TYRP1* gene on chromosome 9p23, a member of the *TYR* family that spans approx 25 kb and contains 9 exons. Although the murine *Tyrp1* gene maps to the *brown* locus, in humans brown albinism results from mutations in the *P* gene (*see* OCA2). TYRP1, a transmembrane protein with approx 40% amino acid sequence homology with tyrosinase, represents the most abundant melanosomal protein. Also known as gp75, it is detected by MEL-5 immunohistochemical staining. In mice and humans, the major function of TYRP1 is to promote eumelanogenesis by stabilizing tyrosinase, whereas in mice Tyrp1 also acts as a DHICA oxidase (*see* Fig. 104-1).

Only two mutations in the *TYRP1* gene have been reported (1104delA and S166X), both of which produce a truncated protein. Interestingly, these mutations result in the ER retention and early degradation of both mutant TYRP1 and wild-type tyrosinase, suggesting that tyrosinase and TYRP1 form a complex early during their processing in the ER.

OCA4 OCA4 is caused by mutations in both copies of the *MATP* (solute carrier family 45 member 2, *SLC45A2*) gene, which spans a region of approx 40 kb on chromosome 5p and contains 7 exons. Initially identified by its expression in melanoma cell lines and called *a*ntigen *i*n *m*elanoma-1 (*AIM1*), the *MATP* gene represents the human orthologue of the murine *underwhite* (*uw*) gene. A conserved mutation in the *Matp* gene causes the cream coat color in horses and diffuse pigmentary dilution in the mouse as well as the OCA4 phenotype in humans, and *Matp* mutations also result in generalized hypopigmentation in medaka fish. In addition, polymorphisms in the *MATP* gene are associated with physiologic variation in human pigmentation.

The MATP, like the P protein, is predicted to have 12 transmembrane domains (Fig. 104-4B), and it demonstrates homology to plant sucrose transporters. The expression of *MATP* during embryological development is similar to that of *TYRP1* and *TYRP2*, and there is evidence that its transcription is regulated by *mi*crophthlamia-associated *t*ranscription *f*actor (MITF), the "master gene" for melanocyte survival and melanogenesis. In melanocytes from mice with a homozygous mutation at the *uw* locus, tyrosinase processing and trafficking is disrupted and the enzyme is abnormally secreted from the cells within vesicles rather than being sorted to early melanosomes. Similar abnormalities have been observed in the setting of *p* gene mutations.

Several missense and frameshift mutations have been identified in patients with OCA4. A founder effect for the D157N mutation may account for the relatively high prevalence of OCA4 in East Asia.

Hermansky-Pudlak Syndrome HPS is an autosomal-recessive disorder that results from defective trafficking of organelle-specific proteins to melanosomes, lysosomes, and platelet dense granules. Mutations in eight different genes cause HPS in humans (Table 104-1). As at least 16 loci exist for HPS-like phenotypes in mice, additional genes are likely to be discovered in patients with this disorder.

Mutations in the *HPS1* and *HPS4* genes (corresponding to the murine *pale ear* and *light ear* genes, respectively) are the most common causes of HPS, and both result in a relatively severe phenotype with a significant risk of developing pulmonary fibrosis and granulomatous colitis. HPS patients from northwest Puerto Rico are homozygous for a 16-bp duplication in exon 15 of *HPS1*, which represents a founder mutation in this population. The *HPS1* and *HPS4* genes encode novel nonmembrane proteins that are components of *b*iogenesis of *l*ysosome-related *o*rganelles *c*omplex (BLOC)-3 and BLOC-4 (the latter representing a discrete module within the former). These complexes are involved in the trafficking of proteins to newly synthesized organelles.

The heterotetrameric adaptor protein-3 (AP-3) facilitates protein sorting to organelles via a different mechanism, in particular by binding to a di-leucine motif in the cytoplasmic domain of tyrosinase. Mutations in the *AP3B1* gene (*HPS2*; murine *pearl*), which encodes the β3A subunit of adaptor protein-3, have been reported in three HPS patients.

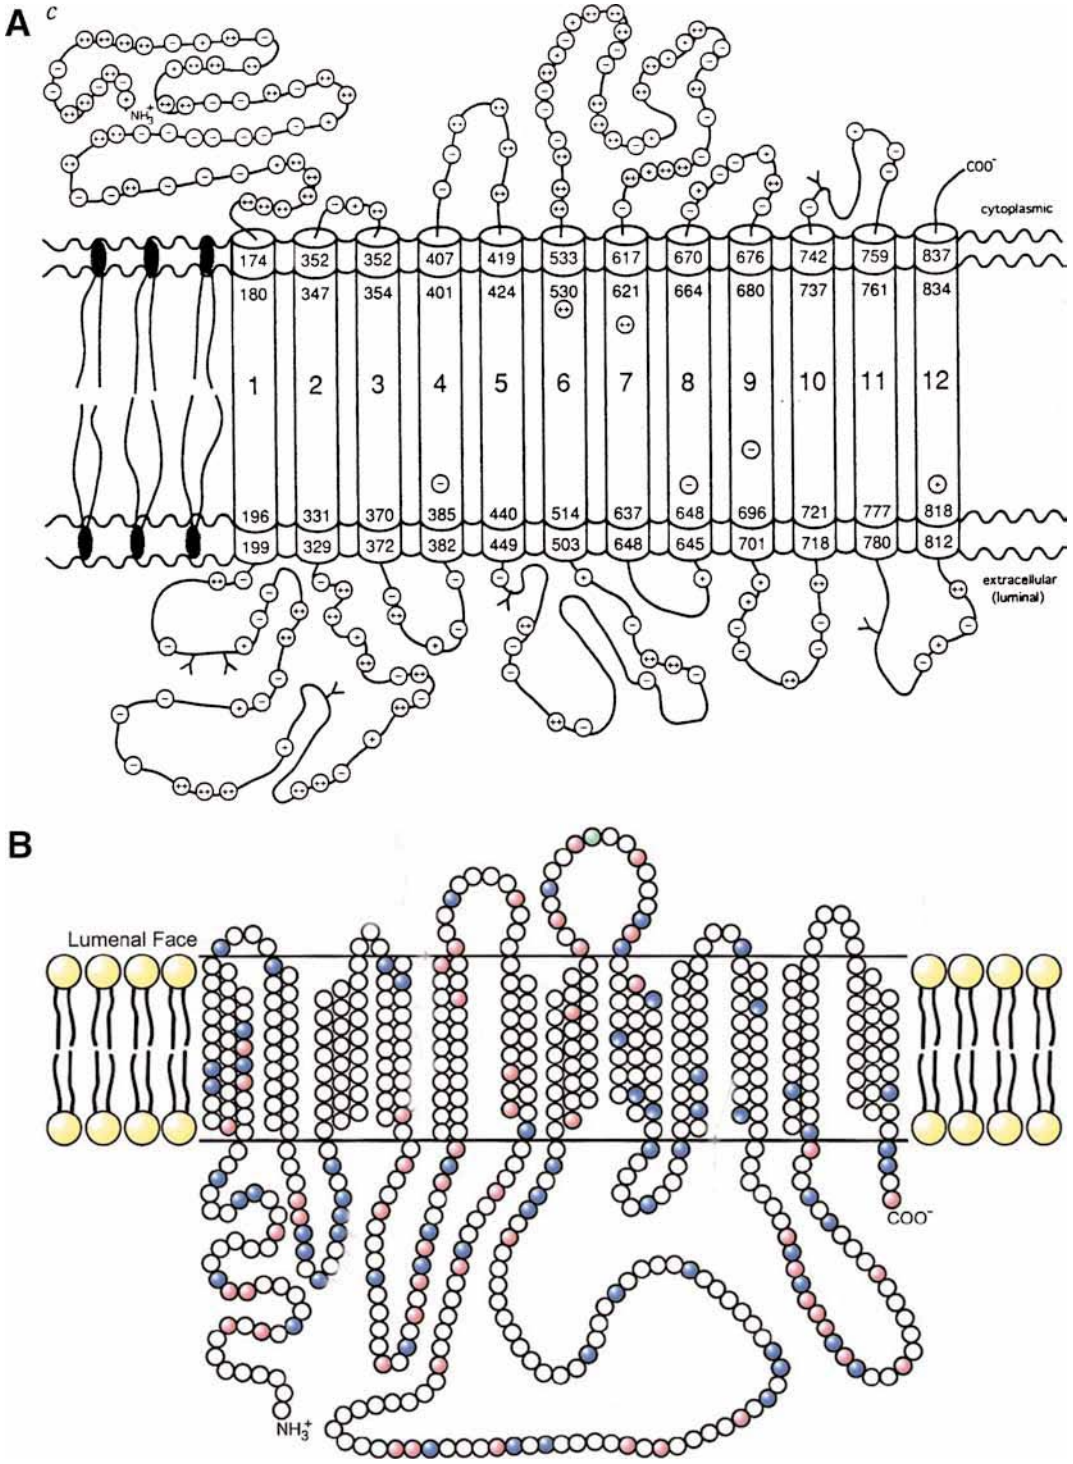

Figure 104-4 Proposed models for the arrangements of the P protein and membrane-associated transporter protein within the lipid bilayer**. (A)** The P protein, which is defective in OCA2, has 12 transmembrane domains. (Adapted from Rinchik EM, Bultman SJ, Horsthemke B, et al. A gene for the mouse pink-eyed dilution locus and for human type II oculocutaneous albinism. Nature 1993;361:72–76. Copyright Nature Publishing Group.) **(B)** The membrane-associated transporter protein, which is defective in OCA4, also has 12 transmembrane domains. (Adapted from with permission from the University of Chicago, Newton JM, Cohen-Barak O, Hagiwara N, et al. Mutations in the humanorthologue of the mouse underwhite gene (uw) underlie a new form of oculocutaneous albinism, OCA4. Am J Hum Genet 2001; 69:981–988.)

Mutations in the *HPS3* gene (murine *cocoa*) cause a relatively mild form of HPS. Initially described in a genetic isolate from central Puerto Rico, *HPS3* mutations have also been reported in Ashkenazi Jews and other non-Puerto Rican patients. The HPS3 protein is a member of the BLOC-2 complex and associates with clathrin, the main component of protein coats that assist in the budding of vesicles from the trans-Golgi network.

Table 104-1
Mouse Coat Color Genes That Have Been Cloned, Their Human Orthologues, and Associated Diseases

Murine locus	*Human locus*	*Human chromosome*	*Protein*	*Function*	*Associated human disease or phenotype*
Proteins with a role in melanogenesis					
Albino (c)	*TYR*	11q14-q21	Tyrosinase	Key melanogenic enzyme	OCA1A, OCA1B
Pink-eyed dilution (p)	*P*	15q11-q12	P protein	Tyrosinase processing via control of organelle pH and/or glutathione accumulation	OCA2
Brown (b)	*TYRP1*	9p23	Tyrosinase-related protein 1	Tyrosinase stabilization; DHICA oxidase (in mice)	OCA3 (rufous/red)
Underwhite (uw)	*MATP (SLC45A2)*	5p	Membrane-associated transporter protein	Tyrosinase processing and trafficking	OCA4; physiologic variation in pigmentary phenotype
Extension (e)	*MC1R*	16q24.3	Melanocortin-1 receptor	Stimulates eumelanogenesis	Red-hair-color phenotype, fair skin/hair, freckling; increased risk of melanoma and nonmelanoma skin cancers
Pomc1	*POMC*	2p23.3	POMC cleavage products include MSH and ACTH	Stimulates eumelanogenesis	Red hair, obesity, and adrenocortical insufficiency
	GGT	22q11	γ-glutamyl transpeptidase	Role in glutathione metabolism	Glutathionuria
Gray lethal (gl)	*GL*	6q21	Gray lethal	Role in pheomelanogenesis	Severe recessive osteopetrosis
Mottled (mo)	*ATP7A*	Xq12-q13	Copper-transporting P-type ATPase 7A	Copper transport	Menkes kinky hair syndrome; occipital horn syndrome
Toxic milk (tx)	*ATP7B*	13q14.3-q21.1	Copper-transporting P-type ATPase 7B	Copper transport	Wilson disease
Proteins with a role in organelle biogenesis (e.g., melanosomes, platelet dense granules)					
Pale ear (ep)	*HPS1*	10q23.1-q23.2	HPS1 (component of BLOC-3, -4)	Trafficking of organelle-specific proteins to melanosomes, lysosomes, and cytoplasmic granules (including platelet dense granules)	Hermansky-Pudlak syndrome
Pearl (pe)	*AP3B1*	Chr. 5	β3A subunit of adaptor protein-3		
Cocoa (coa)	*HPS3*	3q24	HPS3 (component of BLOC-2)		
Light ear (le)	*HPS4*	22q11.2-q12.2	HPS4 (component of BLOC-3, -4)		
Ruby-eye 2 (ru2)	*HPS5*	11p15-p13	Ru2 (component of BLOC-2)		
Ruby-eye (ru)	*HPS6*	10q24.32	Ru (component of BLOC-2)		
Sandy (sdy)	*DTNBP1*	6p22.3	Dysbindin (component of BLOC-1)		
Reduced pigmentation (rp)	*BLOC1S3*	19q13	BLOC1S3 (component of BLOC-1)		
Proteins with a role in organelle trafficking (affecting melanosomes, platelet dense granules and/or lysosomes, e.g., of leukocytes and natural killer cells)					
Beige (bg)	*LYST*	1q43	(cytosolic protein that interacts with SNARE proteins)	Regulates vesicle fission/fusion	Chédiak-Higashi syndrome
Oa1	*OA1*	Xp22.3	(G protein-coupled receptor)	May regulate vesicle fission/fusion in melanosome development	Ocular albinism 1
Proteins with a role in organelle transport (e.g., attachment of organelles to the actin cytoskeleton)					
Ashen (ash)	*RAB27A*	15q21	Rab27A	Ras-like GTPase; present in mature melanosomes	Griscelli syndrome 2
Dilute (d)	*MYO5A*	15q21	Myosin Va	Molecular motor that moves along the actin cytoskeleton	Griscelli syndrome 1
Leaden (ln)	*MLPH*	2q37	Melanophilin	Links Rab27A to myosin Va	Griscelli syndrome 3
Shaker-1 (sh1)	*MYO7A*	11q13.5	Myosin VIIa	Molecular motor that moves along the actin cytoskeleton; functions in the retinal pigment epithelium	Usher syndrome, type IB

Proteins with a role in melanocyte development (e.g., survival, proliferation, migration and differentiation)					
Dominant white spotting (W)	*KIT*	4q12	KIT receptor	Tyrosine kinase receptor	Piebaldism; adult mastocytosis; gastrointestinal stromal tumors
Splotch (Sp)	*PAX3*	2q35	Paired-box gene 3	Transcription factor	WS1, WS3; alveolar rhabdomyosarcomas
Microphthalmia (mi)	*MITF*	3p14-p12	Microphthalmia-associated transcription factor	Transcription factor	WS2
Slugh	*SLUG (SNA12)*	8q11	Snail homolog 2	Transcription factor	WS2
Piebald spotting (s)	*EDNRB*	13q22	Endothelin B receptor	G protein-coupled receptor on melanoblast/ganglion cell precursors	WS4
Lethal spotting (ls)	*EDN3*	20q13.2-q13.3	Endothelin-3	Ligand of endothelin B receptor	WS4
Dominant megacolon (dom)	*SOX10*	22q13	SRY box-containing gene 10	Transcription factor	WS4
	ECE1	1p36.1	Endothelin-converting enzyme 1	Proteolytic processing of endothelin-1, -3	Hirschsprung disease
Bcl2	*BCL2*	18q21.33	Bcl2	Inhibits apoptosis	B cell chronic lymphocytic leukemia or lymphoma
Other					
	DKC1	Xq28	Dyskerin	Telomere maintenance; associates with the telomerase RNA component	Dyskeratosis congenita, X-linked recessive
	TERC	3q21-q28	Telomerase RNA component	Telomere maintenance	Dyskeratosis congenita, autosomal-dominant
	IKBKG	Xq28	Inhibitor of κB kinase, γ subunit (NEMO)	Required for NF-κB activation	Incontinentia pigmenti; hypohidrotic ectodermal dysplasia with immune deficiency

OCA, oculocutaneous albinism; BLOC, *b*iogenesis of *l*ysosomal related *o*rganelles *c*omplex; NEMO, *N*uclear factor-κB *e*ssential *mo*dulator.

Positional candidate and transgenic rescue approaches were used to identify the genes mutated in the ruby-eye-2 and ruby-eye mouse models of HPS (*ru2* and *ru*), and the human orthologues, *HPS5* and *HPS6*, were shown to be mutated in patients with a mild form of HPS. The Ru and Ru2 proteins directly interact in the BLOC-2 complex. In addition, mutations in the *DTNBP1* gene (murine *sandy*), which encodes the dysbindin protein, and the *BLOC1S3* gene (murine *reduced pigment*) have been reported in patients with HPS (HPS7 and HPS8, respectively). Dysbindin and BLOC1S3 represent the first components of the BLOC-1 complex shown to be defective in human HPS, whereas mutations in several other components of BLOC-1 underlie HPS-like phenotypes in mice.

Chédiak-Higashi Syndrome CHS is caused by mutations in both copies of the *LYST* (*lys*osomal *t*rafficking regulator, *LYST*) gene on chromosome 1q43, the human orthologue of the murine *beige* gene. Frameshift and nonsense mutations that result in a truncated protein lead to a severe phenotype in which there is progression to a fatal accelerated phase during childhood, whereas missense mutations are associated with a milder phenotype and survival to adulthood.

The exact function of CHS1, a 3801-amino acid cytosolic protein that is expressed by most cell types, is not known. The amino-terminus contains a series of α-helical ARM/HEAT repeats thought to mediate membrane associations and vesicle transport, and the carboxy terminus contains a *be*ige *a*nd *C*hédiak-*H*igashi syndrome (BEACH) domain conserved within a family of proteins that regulates vesicle morphology. The CHS1 protein interacts with SNARE proteins, which play an important role in the fusion of intracellular organelles. In addition, an association between ceramide-induced protein kinase C down-regulation and organelle dysfunction in CHS has been proposed. Cells from patients with CHS have abnormally large, centrally located lysosomes and melanosomes, whereas overexpression of *CHS1* in fibroblasts results in unusually small, peripherally located lysosomes. CHS thus appears to be a disorder of vesicle trafficking, resulting from aberrant fission/fusion in a step downstream from the vesicle formation that is defective in HPS. In addition, generalized impairment of plasma membrane repair may contribute to the pathogenesis of CHS.

Diagnosis The diagnosis of OCA1A can be made on the basis of clinical findings in a child or adult and then confirmed by molecular analysis of the *TYR* gene. However, the latter is not necessary unless it provides information required for future prenatal screening or genetic counseling of family members. In patients in whom there is some pigment production, albeit reduced, clinical clues (e.g., color of hair at birth) can help to distinguish OCA1B from OCA2, but molecular analysis of the *TYR* and *P* genes is the most exact method for confirming the clinical diagnosis. Of note, approx 17% of individuals with OCA1 have only one identifiable *TYR* mutation, rather than the expected two.

If there is a clinical suspicion of OCA, but the patient has a rather subtle form of the disease (i.e., one that is associated with a significant level of pigment production), it is important to evaluate the first-degree relatives and to have an ophthalmologist perform a complete eye examination. In addition, a thorough medical history should be taken in patients with OCA, with special attention to recurrent infections or a bleeding tendency suggestive of CHS or HPS. Simple screening laboratory tests for these syndromes include examination of a peripheral blood smear for giant lysosomal granules within leukocytes and performance of a bleeding time. If the latter is prolonged, an absence of platelet dense granules on wet-mount electron microscopy can establish the diagnosis of HPS.

Other causes of diffuse pigmentary dilution of the skin, hair, and occasionally eyes should be considered and then excluded by lack of associated findings; these include Angelman, Prader-Willi and Apert (craniosynostosis, syndactyly, and acneiform eruptions) syndromes, phenylketonuria, histidinemia, homocystinuria, and infantile sialic acid storage disease. Pigmentary dilution limited to the skin and hair is seen in GS, *e*ctrodactyly, *e*ctodermal dysplasia, and *c*lefting (EEC) syndrome and Menkes kinky hair syndrome; copper or selenium deficiency, and kwashiorkor.

Another entity that overlaps clinically with OCA is ocular albinism (OA), a disorder that is usually inherited in an X-linked recessive fashion. The gene responsible for the most common form of X-linked OA (OA1; Nettleship-Falls) encodes a transmembrane protein thought to represent an intracellular G protein-coupled receptor that transduces a lumenal-to-cytosolic signal. The OA1 protein plays a role in melanosomal development, possibly regulating the budding of vesicles from the endolysosomal compartment or their fusion with melanosomes (functions that are especially critical in RPE cells). Microscopic examination of both RPE cells and melanocytes in patients with OA1 reveals macromelanosomes with a multivesicular appearance (reminiscent of the giant organelles seen in CHS). Interestingly, as occurs with abnormal tyrosinase in OCA1, mutations in *OA1* result in retention of the aberrant OA1 protein within the ER. Classically, individuals with OA were considered to have the eye, but not the cutaneous, findings of albinism. However, some patients with OA1 have hypomelanotic macules or a mild generalized pigmentary dilution when compared with unaffected siblings. It is important to note that mutations in the *TYR* and *P* genes have been described in the smaller group of patients with autosomal-recessive OA.

Prenatal screening for OCA1A and OCA1B has been performed successfully via molecular analysis of the *TYR* gene in amniotic cells after predetermination of the responsible mutations. Although not reported in the literature, such an analysis could potentially be utilized for other forms of OCA in which the genetic defect is known. Previously, scalp biopsies were performed between weeks 17 and 20 of gestation, and the diagnosis of OCA1A was based on the presence or absence of melanized melanosomes. Prenatal diagnosis of CHS by examining cultured amniotic fluid cells or chorionic villus cells for the presence of abnormally large acid phosphatase-positive lysosomes has also been reported.

Management The earlier in life the diagnosis of OCA is established, the sooner interventions that have an impact on development can be instituted. It is critical to assess visual acuity in each child and to provide corrective eyewear as well as access to products such as large-print materials that are specially designed for a visually impaired person. In addition, it is important to identify ocular abnormalities such as strabismus that can be corrected medically or surgically.

Because of the markedly increased risk for the development of ultraviolet radiation-induced cutaneous carcinomas, a sun-protection program needs to be instituted early in life. Most individuals receive the majority of their cumulative lifetime sun exposure by the age of 18 yr, which underscores the need for early intervention. Effective measures include avoidance of midday sun, application of sunscreens, and the use of hats and clothing made of tightly woven material. The closer a patient lives to the equator, the more important this aspect of clinical care becomes. For example, in a study of albinos from Tanzania, patients commonly developed advanced (>4 cm) cutaneous squamous cell carcinomas by their late 20s, and <10% survived beyond the age of 30 yr.

In patients with HPS, 1-desamino-8D-arginine (DDAVP) has been reported as a treatment for the associated bleeding diathesis, and the results of a clinical trial suggested that the antifibrotic agent pirfinidone may help to prevent pulmonary fibrosis. Allogeneic bone marrow transplantation has been used successfully in patients with CHS as well as GS (*see* GS).

Genetic counseling should be made available to all OCA families. Prenatal diagnosis of OCA1 can be performed as outlined above. Because there is no treatment that reverses the major forms of this genetic disorder, both patients and their parents can receive valuable information and support by joining the National Organization for Albinism and Hypopigmentation (http://www.albinism.org/).

OTHER INHERITED DISORDERS CHARACTERIZED BY DIFFUSE PIGMENTARY DILUTION

GRISCELLI SYNDROME GS is a rare autosomal-recessive disorder of organelle transport characterized by mild pigmentary dilution and silvery-colored hair with irregularly distributed clumps of melanin on microscopic examination, but not the ocular findings that are required for classification as OCA. Melanocytes in patients with GS are characteristically "stuffed" with melanosomes because of a failure of transfer to keratinocytes. Mutations in the *MYO5A* (murine *dilute*; encodes myosin Va), *RAB27A* (murine *ashen*), and *MLPH* (murine *leaden*; encodes melanophilin) genes cause GS1, GS2, and GS3, respectively. Primary neurological abnormalities occur in patients with GS1, whereas recurrent infections and an "accelerated phase" of pancytopenia and lymphohistiocytic infiltrates of multiple organs ("hemophagocytic syndrome"; *see* CHS) develop in those with GS2. Neither of these manifestations has been observed in individuals with GS3. It has been proposed that Elejalde syndrome (neuroectodermal melanolysosomal disorder) and GS1 represent the same entity.

Myosin Va, a dimeric molecular motor that moves along the actin meshwork beneath the plasma membrane, normally captures melanosomes when they reach the cell periphery. This occurs by linkage of Rab27A, a Ras-like GTPase present in mature melanosomes, to myosin Va via melanophilin. In GS, failure to securely attach melanosomes to the actin cytoskeleton causes them to "slip back" and accumulate in the center of the melanocyte. Mutations in *RAB27A*, but not *MYO5A* or *MLPH*, lead to defective secretion of lytic granules by cytotoxic T cells; this suggests that Rab27a function is mediated by different effectors in melanocytes and T cells.

Cross Syndrome Cross syndrome is a rare autosomal-recessive disorder of diffuse pigmentary dilution, with or without ocular findings such as nystagmus, in association with mental and growth retardation, spasticity, and athetosis. Patients may have silvery-blonde hair or an admixture of lightly and darkly pigmented strands of scalp, eyebrow and eyelash hairs. The molecular basis of Cross syndrome has not yet been determined.

ALBINISM-DEAFNESS SYNDROME (ZIPRKOWSKI-MARGOLIS SYNDROME) Albinism-deafness syndrome is a rare X-linked recessive disorder in which patients have diffuse pigmentary dilution of the hair and skin, with exception of the buttocks and genitalia. Over time, multiple hyperpigmented macules appear, resulting in a leopard-like appearance. Patients may also have congenital sensorineural deafness and heterochromia irides. The gene for this syndrome has been mapped to Xq26.3– q27.1.

INHERITED DISORDERS CHARACTERIZED BY CIRCUMSCRIBED OR LINEAR HYPOPIGMENTATION

PIEBALDISM

Clinical Features In contrast to OCA and its variants, piebaldism is an autosomal-dominant disorder characterized by discrete, circumscribed areas of leukoderma that are devoid of melanocytes. The lesions are present at birth and generally remain stable, with an increase in size in proportion to the growth of the child; an occasional patient has expansion or limited contraction of the areas of leukoderma over time. Piebaldism has a distinctive distribution pattern, involving the ventral trunk and mid portions of the extremities but sparing the dorsal midline, hands, and feet. The depigmented patches of piebaldism characteristically contain islands of normally pigmented or hyperpigmented skin. These café-au-lait-like macules sometimes line up at the border of the lesions, and may also be seen in uninvolved skin; the latter should not be misinterpreted as a sign of neurofibromatosis.

The frontal white forelock represents a classic finding in piebaldism that is present in 80–90% of patients. The underlying scalp is amelanotic, and there is often an associated V-shaped area of leukoderma on the mid forehead. Patients may also have poliosis of the medial eyebrows and eyelashes, and premature graying of scalp hair can occur. Associated systemic abnormalities are uncommon, and include Hirschsprung disease, mental retardation, cerebellar ataxia, and sensorineural deafness; although some cases of the latter may represent a forme fruste of WS or Woolf syndrome (piebaldism and deafness described in two native American brothers), at least one patient has been documented to have a *KIT* mutation.

The incidence of piebaldism in Caucasians is estimated to be approx 1/20,000–1/40,000, with an equal frequency in men and women. It can occur in all races.

Molecular Basis and Genetic Defects Piebaldism is caused by mutations in the *KIT* gene on chromosome 4q12, which encodes a transmembrane tyrosine kinase receptor that is expressed by melanoblasts, melanocytes, and other cell types such as mast cells. The extracellular ligand for the KIT receptor is steel factor (stem cell factor, mast cell growth factor), and its binding induces receptor activation via dimerization and autophosphorylation. During embryogenesis, the survival and migration of melanoblasts derived from the neural crest depend on interactions between the KIT receptor and steel factor.

As piebaldism is an autosomal-dominant disorder, a mutation in only one of the two copies of the *KIT* gene is required to give rise to the disease. A frameshift mutation that results in half of the KIT receptors being severely truncated and nonfunctional typically produces a mild phenotype, whereas a missense mutation that results in a single amino acid substitution can lead to a severe phenotype. Because dimerization is involved in receptor activation, a population of dysfunctional mutant receptors that "bind up" normal receptors, referred to as the dominant negative effect, is worse than a complete loss of mutant receptor function that leaves half of the normal level of receptor activity, referred to as haploinsufficiency.

In addition, heterozygous deletions of the *SLUG (SNAI2)* gene (also mutated in WS2) have been identified in patients with classic features of piebaldism who lacked a *KIT* mutation. Of note, mutations in either the *Kit* gene or the *steel* gene can lead to dominant white spotting in mice, but no mutations in the latter locus have

Table 104-2
Waardenburg Syndrome and its Variants: Inheritance, Associated Genes, and Clinical Features

Type	*Inheritance*	*Gene (locus)*	*Classic WS features*	*Other features*
WS1	AD	*PAX3* (2q35)	Dystopia canthorum (>95%) Increased frequency of white forelock, skin lesions of piebaldism, and synophrys	Spinal dysraphism, e.g., myelomeningocele (*rare*) Facial clefts (*rare*)
WS2	AD AR	*MITF* (3p14.1–p12.3) *SLUG* (8q11)	*Absence* of dystopia canthorum Increased frequency of deafness and heterochromia irides	
WS3 (Klein-WS)	AD[a]	*PAX3* (2q35)	As in WS1	Musculoskeletal anomalies of the upper extremities, e.g., hypoplasia, fusion of carpal bones, flexion contractures, syndactyly
WS4 (Shah-WS)	AR AR AD	*EDN3* (20q13.2) *EDNRB* (13q22) *SOX10* (22q13)	As in WS2	Hirschsprung disease (aganglionic megacolon) Central and autonomic nervous system dysfunction, neonatal hypotonia, arthrogryposis (*SOX10* mutations; *rare*)
Other variants				
Tietz syndrome	AD	*MITF* (3p14.1-p12.3)	Deafness	*Diffuse* pigmentary dilution of the skin, hair, and eyes Sparse eyebrows

Yemenite deaf-blind hypopigmentation syndrome	AD	*SOX10* (22q13)	Deafness White forelock and skin lesions of piebaldism	Nystagmus *No* Hirschsprung disease

AD, autosomal-dominant; AR autosomal-recessive; WS, Waardenburg syndrome.
[a]At least one patient has been found to be homozygous for a *PAX3* mutation.

been described in humans with piebaldism. However, somatic *activating* mutations in the *KIT* gene are often found in adult human patients with mastocytosis/mast cell leukemia and gastrointestinal stromal tumors.

Diagnosis The diagnosis of piebaldism is usually straightforward. As the major entity in the differential diagnosis is WS, patients should be evaluated for evidence of heterochromia irides, facial dysmorphism, and deafness.

Management The application of sunscreens and use of protective clothing should be encouraged. Successful treatment with autologous transplantation techniques (e.g., skin grafts or suspensions containing melanocytes) has been reported.

WAARDENBURG SYNDROME

Clinical Features The classic sextad of clinical features, as described by Waardenburg in 1951, is

1. Dystopia canthorum (increased distance between the inner canthi with relatively normal interpupillary distance; less of the medial portion of the sclera is visible and there is lateral displacement of the inferior lacrimal punctum).
2. A broad nasal root and hypoplastic alae nasi.
3. Synophrys.
4. Heterochromia irides (partial or total, or isohypochromia).
5. Congenital sensorineural deafness.
6. Cutaneous lesions of piebaldism.

WS has been divided into four subtypes that differ in their clinical manifestations and genetic bases. In addition to the findings noted in Table 104-2, premature graying of scalp hair, palmoplantar keratoderma and congenital heart defects have been reported.

The incidence of WS is estimated to be approx 1/50,000, and is equal in men and women. WS has been described in individuals of various ethnic backgrounds.

Molecular Basis and Genetic Defects Mutations in at least six different genes have been shown to cause WS (*see* Table 104-2). These genes encode regulatory proteins with important functions in embryonic development, including critical roles in the survival, proliferation, migration, and/or differentiation of neural crest-derived melanocyte precursors destined for the inner ear (in which melanocytes are critical to the ability to hear), iris and skin. Furthermore, melanocytes and enteric ganglion cells share a dipotent precursor in the developing neural crest, and interactions between endothelin-3 (EDN3) and endothelin B receptors (EDNRB) are found on these melanoblast/ganglion cell precursors. It is therefore

not surprising that mutations in both alleles of the *EDN3* gene or the *EDNRB* gene can produce a combination of WS and Hirschsprung disease (congenital megacolon because of lack of myenteric ganglion cells; WS4).

In addition to such receptor-ligand interactions, several transcription factors (i.e., proteins with the ability to bind to DNA and influence the activity of other genes) have functions essential to melanocyte development. MITF, the earliest known marker of commitment to the melanocyte lineage, has been implicated as the "master gene" for melanocyte survival as well as a key regulator of the promoters of the genes encoding tyrosinase and other melanogenic proteins. Heterozygous mutations in the *MITF* gene can result in WS2. MITF is also thought to transactivate the *SLUG* gene, which encodes another transcription factor expressed by neural crest-derived cells; homozygous loss-of-function *SLUG* mutations represent a second cause of WS2. Other transcription factors expressed by melanocyte precursors include paired box gene-3 (PAX3) and SRY box-containing gene 10 (SOX10), which have a synergistic role in regulating the expression of *MITF*. Mutations in the *PAX3* gene can result in WS1 or WS3, and the expression of *PAX3* in other neural crest derivatives such as craniofacial cells (e.g., those of the frontonasal prominence) and in the limb buds accounts for the facial dysmorphism and musculoskeletal abnormalities seen in these WS subtypes. Lastly, SOX10 plays a role in the development of melanoblast/ganglion cell precursors via activation of *RET* (the major gene implicated in Hirschsprung disease) as well as *MITF*, and it is also expressed in glial cells of the central nervous system (CNS). As a consequence, heterozygous *SOX10* mutations can produce a WS4 phenotype that is associated with neurological abnormalities.

Diagnosis Although the diagnosis is clear in patients with the complete syndrome, it can be more difficult to establish in forme fruste cases. An evaluation of hearing is important, and calculating the W index (a composite of the inner pupillary, inner canthal, and outer canthal distances) can help determine whether dystopia canthorum is present. Examination of family members can also be useful, as they may have other features of WS.

Management Early detection of associated deafness allows intervention via hearing aids and specialized education. Patients with Hirschsprung disease require surgical resection of the involved intestinal segment. Treatment options for associated leukoderma are as described for piebaldism.

PIGMENTARY MOSAICISM (HYPOMELANOSIS OF ITO)

A variety of names have been used for hypopigmented patches resulting from cutaneous mosaicism. Hypomelanosis of Ito, qualified as *with* or *without* systemic abnormalities, was previously the preferred term for patients with linear streaks and whorls of hypopigmentation. This pigmentary disorder overlaps considerably with systematized nevus depigmentosus, with presence at birth and stability over time as the only distinguishing features of the latter. However, this represents an artificial categorization, for both conditions are manifestations of mosaicism. Furthermore, as the genetic defects that cause hypomelanosis of Ito are extremely heterogeneous and, as a consequence, it is no longer thought to be a discrete neurocutaneous syndrome, the use of a more descriptive term such as pigmentary mosaicism with nevoid hypopigmentation has been advocated.

Clinical Features Nevoid hypopigmentation resulting from cutaneous mosaicism is often noted at birth, but may not become apparent until infancy or childhood. Classically, hypopigmented streaks and swirls follow Blaschko's lines as narrow bands. Hypopigmented patches with a block-like or phylloid configuration can also be seen. The latter pattern, which has a particular association with mosaic trisomy 13, is characterized by an arrangement of hypomelanotic lesions reminiscent of a floral ornament; it consists of leaf-like ovals and large pear-shaped or oblong elements. The hypopigmented lesions of cutaneous mosaicism can be widespread or limited in extent, with a unilateral or bilateral distribution. When the scalp is involved, circumscribed areas or whorls of lighter-colored hairs may be seen.

Associated systemic findings include central nervous system disorders (e.g., mental retardation and seizures), ocular, craniofacial, and musculoskeletal abnormalities. Of children who presented to a pediatric dermatologist at a tertiary care center with a diagnosis of hypomelanosis of Ito, approx 1/3 had systemic abnormalities, which usually became clinically apparent by early childhood. However, as localized areas of nevoid hypopigmentation in otherwise normal individuals, especially those with lightly pigmented skin, are often overlooked, the occurrence of systemic features in the general population is likely to be even lower.

Molecular Basis and Genetic Defects Mosaicism implies the presence of at least two clones of genetically different cells, which can arise via mechanisms including post-zygotic mutations, gametic half-chromatid mutations, somatic nondysjunction, and lyonization (functional mosaicism because of random inactivation during embryogenesis of one of the two X chromosomes in females). In the case of nevoid hypopigmentation, the clones have different pigment potentials. Because many genes have a role in the production, storage, and distribution of melanin, these processes can be disturbed by a variety of chromosomal rearrangements and gene mutations, and the cytogenetic abnormalities that have been detected in patients with nevoid hypopigmentation are highly heterogeneous. Of note, chromosomal mosaicism involving 15q11–q12, the location of the *P* gene, has been reported in at least two patients. In one study, 60% of patients with a diagnosis of hypomelanosis of Ito had evidence of mosaicism when karyotype analyses of both circulating lymphocytes and dermal fibroblasts were performed. Most of these patients were mosaic for aneuploidy or unbalanced translocations. In cases of nevoid hypopigmentation in which no mosaicism is demonstrated by cytogenetic examination, it is likely that either minor chromosomal abnormalities or mosaicism at the level of genes rather than chromosomes is present.

Hypopigmentation distributed along the lines of Blaschko, which reflect the streams of growth of embryonic tissues, typically occurs if two cell clones with different pigment potentials are established early in embryonic development. Differences between the rates of proliferation and the migration potential of the two cell clones, or a different time of origin of the mosaicism, may produce other configurations such as the checkerboard pattern or the phylloid pattern. As noted, the phylloid configuration of hypopigmentation has a particular association with mosaic trisomy 13.

Diagnosis In some cases with widespread involvement, determination of whether the patient has hypopigmented or hyperpigmented streaks can be difficult. As both are manifestations of cutaneous mosaicism, the distinction is not critical. Hypopigmentation along Blaschko's lines can also be seen in female carriers of Menkes kinky hair syndrome as a reflection of lyonization. It is important to exclude the fourth stage of incontinentia pigmenti (IP) by the lack of a history of vesicles, verrucous lesions, or hyperpigmentation following the lines of Blaschko. In

addition, the fourth stage of incontinentia pigmenti is characterized by cutaneous atrophy and a lack of hair follicles and eccrine glands. Lastly, patients with Goltz syndrome may have linear streaks of hypo- and/or hyperpigmentation as well as cribriform atrophy, telangiectasias, and fat herniations following Blaschko's lines.

FUTURE DIRECTIONS

The study of mouse coat color genes has been valuable in advancing the understanding of the molecular basis of integumental pigmentation, and a mouse model exists for almost every human disorder of pigmentation in which the genetic defect is known. To date, more than 60 of the genes underlying mouse coat color mutants have been cloned, and mutations that result in aberrant pigmentary phenotypes have been described for more than half of the corresponding human genes (*see* Table 104-1). However, there are still many mouse coat color genes (e.g., *steel* and 8 of the 16 mouse models of HPS) for which disease-causing mutations have not been discovered in the human orthologue. Just as genetic studies in albino mice and pink-eyed dilution mice shed light on the molecular pathophysiology of OCA1A and OCA2, respectively, so will the analysis of other mutant mice and the orthologous human genes provide insights into additional human disorders of pigmentation.

105 Epidermolysis Bullosa

Jouni Uitto, Gabriele Richard, and Angela M. Christiano

SUMMARY

This chapter highlights epidermolysis bullosa (EB) as a paradigm of heritable disorders of the basement membrane zone and illustrates the power of molecular diagnostics in blistering skin diseases by reviewing discoveries into the molecular basis of different forms of EB. In this chapter the following topics will be discussed: simplex forms of EB, junctional forms of EB, such as Herlitz and non-Herlitz JEB, dystrophic forms of EB, applications of mutation analysis in prenatal diagnosis, and gene therapy approaches.

Key Words: Epidermolysis bullosa; simplex; hemidesmosomal; junctional and dystrophic variants; pyloric atresia; muscular dystrophy; hemidesmosomes; anchoring fibrils; cutaneous basement membrane zone.

INTRODUCTION

Significant progress has been made in understanding the structural features of the epidermis and the dermal–epidermal junction, largely through molecular cloning of genes that encode proteins critical for the structural integrity of these cutaneous layers. Disturbances in the expression of the genes within the stratified layers of the dermal–epidermal adhesion zone provide the basis for different forms of heritable blistering skin diseases with divergent clinical presentations. This chapter highlights epidermolysis bullosa (EB) as a paradigm of heritable disorders of the basement membrane zone (BMZ) and illustrates the power of molecular diagnostics in blistering skin diseases by reviewing discoveries into the molecular basis of different forms of EB.

MOLECULAR COMPLEXITY OF THE CUTANEOUS BMZ

Electron microscopic examination of the cutaneous BMZ reveals several attachment complexes critical for integrity of the stable association of epidermis and dermis (Fig. 105-1), including hemidesmosomes (HD) that extend from the intracellular compartment of the basal keratinocytes to the lamina lucida in the upper portion of the dermal–epidermal basement membrane. Within the lamina lucida, the HDs interact with anchoring filaments (AF), thread-like structures that tend to concentrate below the HDs. At the lower portion of the dermal–epidermal attachment zone, fibrillar structures known as anchoring fibrils extend from the lamina densa of the basement membrane to the papillary dermis, in which they may associate with basement-membrane-like structures known as anchoring plaques. Alternatively, they may reinsert into the lamina densa forming U-shaped structures that entrap interstitial collagen fibers in the upper papillary dermis and secure the association of lamina densa with the upper dermis.

Molecular cloning and biochemical analyses of the cutaneous BMZ components have allowed elucidation of the structural and functional characteristics of numerous macromolecules that constitute these dermal–epidermal attachment complexes. First, HDs consist of at least four distinct proteins:

1. The 230-kDa bullous pemphigoid antigen (BPAG)-1, a noncollagenous protein that serves as an autoantigen in the acquired autoimmune disease bullous pemphigoid.
2. The 180-kDa BPAG-2, a transmembrane collagenous protein, also known as type-XVII collagen (COL17A1).
3. Basal keratinocyte-specific integrin $\alpha_6\beta_4$, which contributes to the anchoring of basal keratinocytes to the underlying basement membrane.
4. Plectin, approx 500-kDa adhesion molecule belonging to the plakin family of proteins.

Second, the AFs, which traverse the lamina lucida, consist of laminin 5, a distinct member of the laminin family of proteins. Laminin 5 consists of three constitutive subunit polypeptides, the α_3,- β_3,- and γ_2-chains, which form a characteristic cross-shaped trimeric structure. Finally, type-VII collagen is the major, if not the exclusive, component of anchoring fibrils. The primary structure of type-VII collagen has been determined through cDNA cloning, and the intron–exon organization of the entire gene has been elucidated.

Collectively, the data summarized above indicate that the cutaneous BMZ is a complex continuum of interacting macromolecules that form a network securing the stable association of the epidermis with the underlying dermis. Thus, genetic mutations resulting in abnormalities in any component of this network could result in a blistering skin disease, such as the variants of EB.

MOLECULAR BASIS OF DIFFERENT FORMS OF EB

The prototype of the diseases affecting the cutaneous BMZ is EB, a group of heritable mechanobullous disorders that manifest with considerable variability in clinical presentation and severity (Fig. 105-2). EB is also genetically heterogeneous, as both autosomal-dominant and autosomal-recessive forms are recognized. Traditionally, EB has been divided into three broad

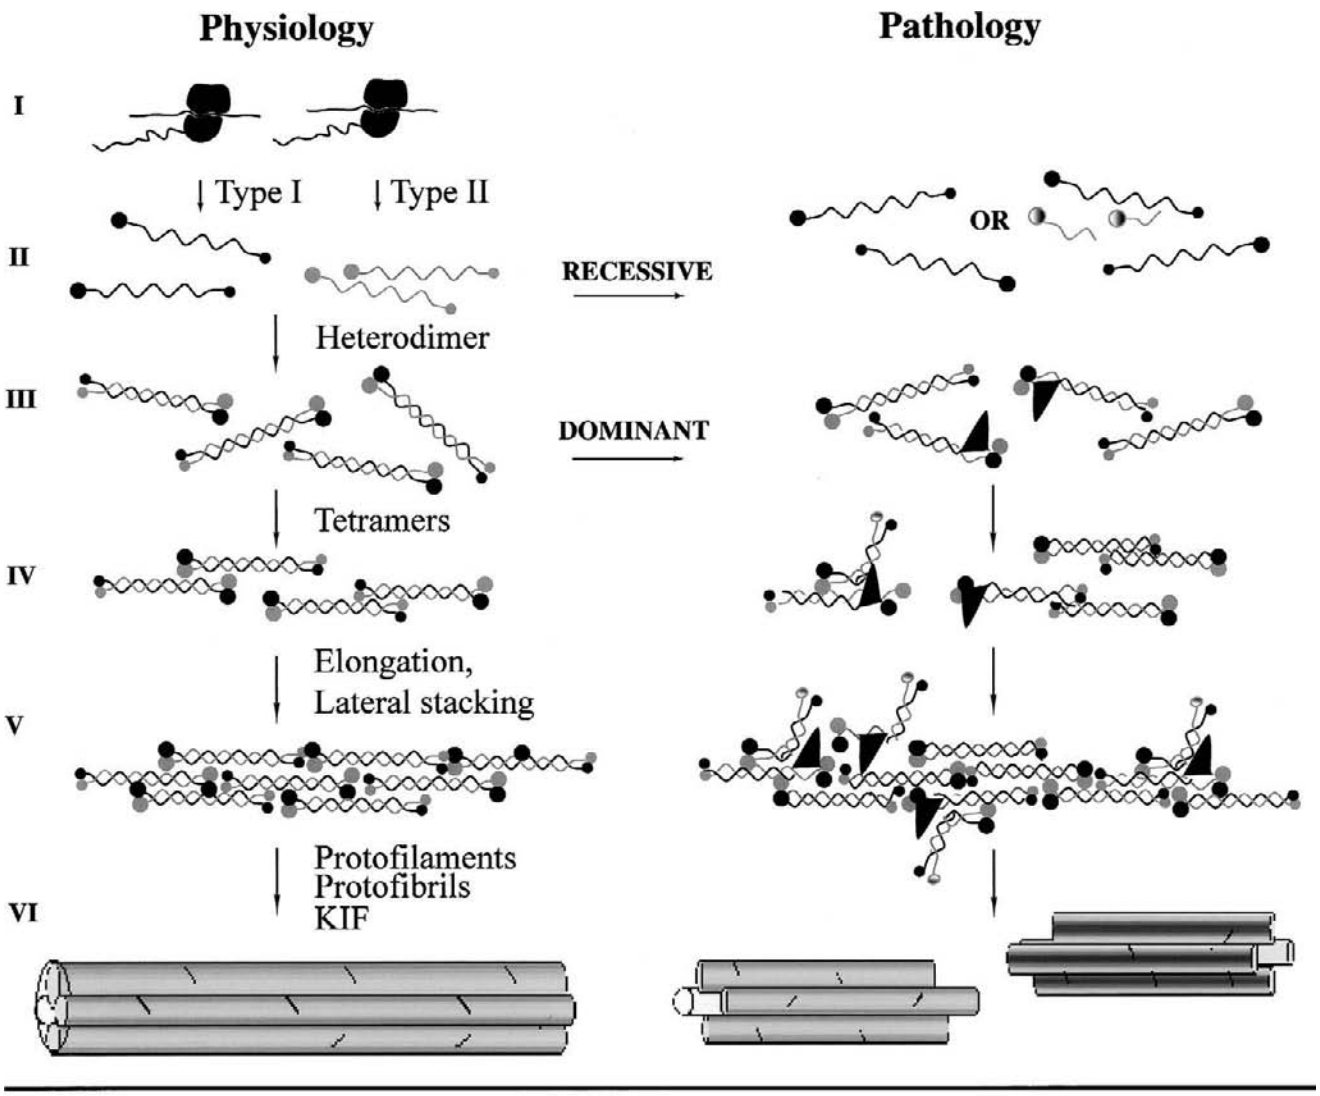
		LAMB3	1q32	Laminin-β_3-chain
		LAMC2	1q25-31	Laminin-γ_2-chain
Dystrophic	Sublamina densa	COL7A1	3p21.1	Type-VII collagen

[a]GABEB, generalized atrophic benign epidermolysis bullosa; EB-PA, epidermolysis bullosa with pyloric atresia; EB-MD, epidermolysis bullosa with late-onset muscular dystrophy.

categories based on the level of tissue separation within the cutaneous BMZ, as established by diagnostic transmission electron microscopy or by immunoepitope mapping (Table 105-1). In the *simplex* forms of EB (EBS), the tissue separation occurs within the basal keratinocytes, primarily as a result of mutations in the basal keratin genes, *KRT5* and *KRT14*. In the *junctional* forms of EB (JEB), tissue cleavage occurs within the dermal– epidermal basement membrane at the level of the lamina lucida, and the HD–AF complexes demonstrate ultrastructurally detectable abnormalities. In patients with the classic forms of JEB, specific mutations have been identified in the genes, *LAMA3*, *LAMB3*, and *LAMC2*, which encode the constitutive subunit polypeptides, α_3, β_3, and γ_2, of the anchoring-filament protein laminin 5, respectively. In the *dystrophic* forms of EB (DEB), the tissue separation occurs below the lamina densa at the level of anchoring fibrils, and the mutations reside in the type-VII collagen gene, *COL7A1*. In addition to the traditional classification—simplex, junctional, and dystrophic—a fourth category has been introduced, the *hemidesmosomal* variants, the molecular pathology involving the hemidesmosomal proteins (*see* Table 105-1). These include three clinically distinct variants of EB: generalized atrophic benign EB (GABEB), EB with pyloric atresia (EB-PA), and EB with muscular dystrophy (EB-MD). The corresponding mutations were identified in the genes encoding *BPAG2*, also known as type XVII collagen; the subunit polypeptides of the $\alpha_6\beta_4$-integrin; and plectin, a large adhesion molecule expressed in HDs as well as in the sarcolemma of the muscle.



In addition to their role in inherited forms of EB, several of these proteins serve as autoantigens in acquired bullous skin diseases of adulthood, such as bullous pemphigoid, herpes gestationis and paraneoplastic pemphigus, and unusual mutations in a few of them even result in inherited diseases that fall outside the spectrum of EB, attesting to their general importance in disease of the skin.

EBS—MUTATIONS IN THE BASAL KERATIN GENES, *KRT5* AND *KRT14*

Keratin proteins, the major constituents of epithelial cells, represent a large family of about 50 proteins that form 10 nm keratin intermediate filaments (KIF) and are expressed in tissue- and differentiation-specific patterns. KIF build a dense, 3D and highly dynamic cytoskeleton between the nucleus and the cell membrane, which provides both structural stability and flexibility, and ensures the mechanical integrity of different epithelial tissues (Fig. 105-3, top). Keratins are expressed in pairs of acidic (type I) and basic (type II) proteins, the genes for which cluster on chromosomes 17q12-q21 and 12q11-q13. Keratin monomers are organized as a central, α-helical rod of about 310 amino acids, flanked by variable, nonhelical head and tail domains (Fig. 105-3, bottom). The monomers form coiled-coil obligate heterodimers, which polymerize in overlapping and antiparallel fashion and assemble into intermediate filaments. In the epidermis, undifferentiated basal keratinocytes express the principal keratins K5 (type II) and K14 (type I), and to a lesser extent K15 (type I), whereas cells in the upper epidermis switch to the expression of the differentiation-specific keratin pair K1/K10, and in the granular layers also K2e. Other site-specific suprabasal keratins include K9 found predominantly in the palms and soles, and K6, K16, and K17, which are induced by trauma to the skin. Pathogenic mutations in 19 different keratin genes have been discovered in a wide range of epithelial fragility disorders affecting skin, mucous membranes, hair, nails, and sebaceous glands, in which the disease pathology, in general, corresponds to the expression pattern of the defective keratin proteins.

EBS was the first human keratin disorder to be discovered in 1991 and has become the prototype for understanding pathogenesis and genotype–phenotype correlations within this broad group of disorders. EBS is a clinically heterogeneous, congenital blistering

Figure 105-2 *(see Opposite Page)* Phenotypic presentation of selected clinical subtypes of EB. **(A,B)** EBS-DM type: **(A)** herpetiform grouped blisters, erosions and crusts in a generalized distribution; **(B)** severe diffuse palmoplantar keratoderma. **(C)** EB with muscular dystrophy. Note blisters, erosions and extensive muscle atrophy. **(D)** Junctional EB, Herlitz type: widespread areas of hemorrhagic blisters and denuded skin. **(E)** Dystrophic EB, autosomal-recessive type: note coexistence of erosions, ulcerations, scarring, and milia formation of the skin leading to a typical mitten deformity of the feet. **(F)** Dystrophic EB, autosomal-dominant type: note nail dystrophy, scarring and milia formation. Figure 105-3 *(Continued)*

disorder owing to fragility of basal cells of the epidermis. Three major subtypes have been recognized and share a common disease pathology with an abnormal KIF network, cytolysis of basal cells leading to intraepidermal blister formation and skin fragility, whereas the differentiation of keratinocytes in the upper layers of the epidermis remains largely undisturbed. The structural abnormalities confined to the basal compartment of the epidermis and mucous membranes result from faulty K5/K14 heterodimers because of mutations in their corresponding genes, *KRT5* and *KRT14*. Mutations in either gene can produce a comparable phenotype reflecting the genetic heterogeneity of EBS. *KRT5* and *KRT14* mutations are usually inherited in an autosomal-dominant manner and lead to substitution of conserved amino acid residues, having a deleterious, dominant-negative effect on the assembly of KIF and causing weakening of the cytoskeleton and cell fragility.

More than 80 distinct pathogenic mutations have been identified in EBS. The majority (up to 80%) are sporadic new mutations, which are not present in one of the parents of an affected person. Mutations are clustered at seven defined regions (*see* Fig. 105-3, bottom), and their relative position seems to dictate the severity of disease. Most mutations (approx 60%) occur at two "hot spots" corresponding to the beginning and end of the central rod domain, known as helix initiation peptide and helix termination peptide. Functional in vivo and in vitro studies have demonstrated that the helix boundaries are zones of overlap between keratin heterodimers during filament assembly and that mutant keratin molecules perturb proper keratin alignment, and thereby oligomerization, filament assembly, and integrity (*see* Fig. 105-3, top). Consequently, these "hot spot" mutations are consistently associated with a severe phenotype. Other mutation sites, such as the homologous domain in the head of type-II keratins or nonhelical linker and stutter motifs, are associated with a milder phenotype. The former region has been implicated in filament assembly and contains major phosphorylation sites whereas the latter regions provide crucial flexibility to the otherwise rigid α-helical rod. In addition, a few rare autosomal-recessive mutations leading to the "knockout" of a keratin in the basal epidermis have also been described in EBS.

EBS DOWLING-MEARA EBS Dowling-Meara (EBS-DM) is a common and the most severe subtype manifesting at birth with erythema, widespread blistering, erosions, and areas of denuded skin (*see* Fig. 105-2). Although spontaneous development of grouped blisters at any body site slowly improves with age, a progressive palmoplantar keratoderma becomes the chief complaint in adulthood. Other features of EBS-DM include involvement of mucous membranes, secondary skin infections and sepsis, nail dystrophy, milia, and healing with hypo- and hyperpigmentation of the skin. Typically, pathogenic defects are heterozygous missense mutations clustering at the highly conserved boundaries of the α-helical rod of K5 or K14. An arginine codon of the helix initiation peptide in K14 (R125) is most commonly mutated (>30% of patients), probably because it contains a hypermutable CpG dinucleotide. As a result, the arginine codon (CGC) is replaced either by one for cysteine (TGC) or histidine (CAC). Although most keratin gene mutations in EBS are dominant, recessive *KRT14* mutations have been identified in seven families, including predominantly nonsense and splice site mutations leading to premature termination of protein translation and ablation of the affected keratin. Although the "knockout" of *KRT14* usually results in severe EBS-DM, mutations in three families were noted to have a milder phenotype with minimal extracutaneous involvement.

KÖBNER SUBTYPE OF EBS The Köbner subtype of the simplex forms of EB is characterized by milder, generalized blistering of the skin without apparent clustering, often in response to minor trauma and induced by increased ambient temperature. Hands, feet, and extremities are most consistently affected, probably because of the greater mechanical trauma at these body sites. *KRT5* or *KRT14* mutations appear more widely distributed across the keratin polypeptides and may lie within and outside the highly conserved helix boundaries as well as in nonhelical linker segments.

EBS WEBER-COCKAYNE The simplex form of EB—Weber-Cockayne is the most common, relatively mild, localized subtype of EBS, in which serous blisters are confined to the hands, feet, and areas of friction or trauma. In contrast to the other EBS subtypes, blisters are usually not present at birth but develop later in life in response to mechanical trauma to the skin. The disorder worsens with sweating and at increased ambient temperature. Ultrastructural abnormalities of the cytoskeleton are far less severe than those seen in EBS-DM, and even essentially normal KIF ultrastructure has been reported. In this relatively mild form

Figure 105-3 *(see Opposite Page)* Physiology and pathophysiology of KIFs (top panel). Synthesis of type-I and type-II keratin polypeptides and their assembly into KIFs are depicted on the left side of the figure. The keratin mRNAs are translated on the ribosomes of epithelial cells, which synthesize these keratins (I). In the cytoplasm, a type-I and a type-II keratin polypeptide align in parallel and register (II) and oligomerize to obligate heterodimers (III). Pairs of heterodimers align in an antiparallel, mostly overlapping fashion to tetramers (IV), which subsequently polymerize to elongated chains packed into KIFs (V). The presence of a mutation in a keratin gene can lead to different pathological processes depicted on the right side of the figure. For example, mutations that introduce a PTC or affect mRNA splicing result in the synthesis of truncated polypeptides. Subsequent nonsense-mediated mRNA decay or enhanced degradation of the truncated polypeptide results in absence of the mutant protein and lack of formation of corresponding heterodimers and KIF, usually associated with severe disease (the simplex form of EBS-DM) (I). Alternatively, the truncated or altered keratin polypeptides can prevent the heterodimer formation and KIFs assembly (II). In autosomal-dominant keratin disorders, most mutations result in nonconservative amino acid replacements at sites of high sequence conservation (helix boundaries) (III). The mutant keratin polypeptides interfere in a dominant negative manner with head-to-tail interactions and proper alignment of heterodimers (IV) as well as elongation and lateral packing during KIF assembly (V), thus producing a severe phenotype. Mutations with a less severe phenotype reside outside the helix boundaries and may have a more subtle effect on KIF assembly or affect keratin phosphorylation or interaction with other proteins. Schematic diagram of a keratin protein depicting the structural domains and common mutation sites in EBS (bottom panel). The nonhelical head domain consists of E1, V1, and H1 (only in type-II keratins). The α-helical rod domain is composed of four segments, 1A, 1B, 2A, and 2B (with stutter-S), which are interrupted by nonhelical linker domains L1, L12, and L2. H2 (only in type-II keratins), V2, and E2 form the nonhelical tail domain. The highly conserved helix initiation and termination motifs (the regions containing the mutational hot spots) are striped. Common sites of dominant mutations and their EBS phenotypes are depicted above the diagram; the location of recessive mutations is shown below. The relative height of the bars reflects the relative frequency of mutations. White symbols: EBS with MP; Dashed symbols: EBS Weber-Cockayne; Black symbols: EBS-DM; Dotted symbols: Köbner subtype of EBS. The nature of mutations is indicated by the symbols: bars represent missense mutations, triangles represent nonsense and frameshift mutations leading to PTC, and stars represent splice site mutations.

of EBS, pathogenic mutations lie in most cases outside of the helix boundaries, elsewhere in the rod domain of K5 or K14, including the nonhelical L12 linker motif or in the amino-terminal homologous domain of K5. Dominant point mutations usually result in amino acid substitutions, but a small in-frame deletion in *KRT14* has also been described.

EBS WITH MOTTLED PIGMENTATION The simplex form of EB with mottled pigmentation (EBS-MP) is a rare form of EBS with generalized or acral blistering and small hyper- and hypopigmented spots that form a reticulate pattern. This variant is also associated with thickened, dystrophic nails and punctate palmoplantar keratoderma. The MP seems unrelated to skin blistering and corresponds with an increased number of melanosomes within basal keratinocytes, dermal macrophages and Schwann cells, as observed by electron microscopy. EBS-MP is caused by a heterozygous missense mutation in exon 1 of *KRT5* that results in substitution of proline 25 with leucine in the nonhelical head domain of K5. This mutation was consistently detected in each of seven unrelated families with EBS-MP tested to date. Preliminary investigations of this mutation revealed that the keratin 5 head domain might directly bind to a cytoplasmic dynein cargo complex transporting melanosomes, thus unraveling the basis for abnormal pigment distribution in this rare disorder.

JUNCTIONAL FORMS OF EB

JEB display a remarkable degree of genetic heterogeneity, with seven different genes implicated in its pathogenesis thus far. In JEB, tissue cleavage occurs within the dermal–epidermal basement membrane at the level of the lamina lucida or the overlying HDs, and ultrastructural abnormalities are evident in the HD–AF complexes.

THE HEMIDESMOSOME-ANCHORING FILAMENT COMPLEX The HDs extend from the intracellular compartment of the basal keratinocytes to the lamina lucida in the upper portion of the dermal–epidermal basement membrane. Within the lamina lucida, the HDs attach to AFs, thread-like structures that tend to concentrate below the HDs. Early biochemical studies identified five major components of the HDs, consisting of polypeptides with molecular masses of 500, 230, 200, 180, and 120 kDa; these were originally designated as HD1–HD5, respectively. HD2 and HD4 have since been shown to be identical to BPAG1 and BPAG2/COL17A1, respectively. HD3 and HD5 correspond to the β_4 and α_6-integrins, respectively, and HD1 corresponds to plectin. Plectin is localized to the cytoplasmic side of the HDs, in a distribution slightly above, yet almost indistinguishable from BPAG1, at the level of the cytoplasmic periphery of the HD inner plaque. The intracellular hemidesmosomal plaque is comprised of BPAG1, a noncollagenous protein of the plakin family, which serves as an autoantigen in an acquired autoimmune disease, bullous pemphigoid. BPAG2, a transmembrane collagen also known as COL17A1, together with $\alpha_6\beta_4$-integrin, extends from the intracellular compartment into the extracellular space, thus stabilizing the association of basal keratinocytes to the underlying basement membrane. Consequently, mutations resulting in abnormalities in any one of the protein components of the HD–AF network can give rise to the different forms of JEB.

MOLECULAR HETEROGENEITY OF JUNCTIONAL EB JEB display a considerable range of phenotypic heterogeneity, and on the basis of clinical severity, the disease has been traditionally divided into the classic, Herlitz (lethal) type, and a variety of non-Herlitz (nonlethal) forms. Within the nonlethal forms, several subtypes have been described based on the associated extracutaneous manifestations and the extent and severity of the blistering tendency. Three of these subtypes traditionally classified as non-Herlitz JEB have since been considered as the HD variants of EB (*see* below). The clinical heterogeneity of JEB reflects the repertoire of underlying genetic lesions demonstrated in as many as seven different genes. Mutations in different forms of JEB (including the hemidesmosomal variants) have been identified in the known genes encoding the macromolecular components of the HD–AF complex, with the exception of BPAG1. Careful examination of the mutation database in these genes reveals genotype–phenotype correlations that reflect the expression of the mutated genes, the types and combinations of the mutations, and the consequences at the mRNA and protein levels.

HERLITZ JEB: PREMATURE TERMINATION CODON MUTATIONS IN THE LAMININ-5 GENES Historically, electron microscopic studies on the skin of JEB patients first revealed ultrastructural abnormalities in the HD–AF complexes, and specifically, the HDs were found to be rudimentary and poorly formed. In the most severe, clinically devastating Herlitz type of JEB, immunofluorescence staining for laminin-5 epitopes suggested the complete absence of this protein. Subsequent to the cloning of genes encoding the three constitutive polypeptides of laminin 5, mutation detection strategies have revealed genetic mutations in each of the three genes, *LAMA3*, *LAMB3*, and *LAMC2*, encoding the α_3, β_3, and γ_2 chains, respectively. Most of these mutations are located in the LAMB3 gene, owing to the presence of two mutational hotspots (R635X and R42X) leading to recurrent mutations. It is noteworthy that in the Herlitz form of JEB, all mutations disclosed result in premature termination codons (PTC) in one of the laminin-5 chains, leading to markedly reduced levels of the corresponding mRNA transcript via nonsense-mediated mRNA decay, and the virtual absence of the corresponding protein.

NON-HERLITZ JEB: COMPOUND HETEROZYGOUS MUTATIONS IN THE LAMININ-5 GENES Laminin-5 gene mutations have been also discovered in the some of the nonlethal forms of JEB, however, the type and combinations of mutations specify a milder clinical phenotype. In some cases, only one of the mutations is a PTC in one of the laminin-5 genes. However, the other genetic lesion may consist of a missense mutation or an in-frame exon-skipping mutation, each of which would encode for some laminin-5 protein, albeit with impaired function. These observations suggest that polypeptides with an intact carboxy-terminal end are able to assemble into trimer molecules, which serve a partial function in the AFs. This interpretation is consistent with the observation that immunofluorescence microscopy performed with an antilaminin-5 antibody, such as GB3, is positive, although frequently attenuated, in the skin of nonlethal JEB patients.

LAMA3 mutations have been disclosed in laryngo-onycho-cutaneous syndrome or Shabbir syndrome, a recessively inherited disorder with some features of skin fragility. The disorder is typified by skin erosions, nail dystrophy and exuberant granulation tissue in specific epithelia, particularly the conjunctiva and larynx. Linkage mapping localized the gene to chromosome 18q11.2 in a region including the laminin-α_3 gene (*LAMA3*). Further analysis revealed that the *LAMA3* gene encodes three distinct proteins generated by alternative promoter utilization and internal splicing, which are designated laminin-α_{3a}, -α_{3b1}, and -α_{3b2}. The identical causative mutation in 15 LOC families is a frameshift mutation that is specific only to the laminin-α_{3a}-isoform. Thus, in LOC, only one LAMA3 isoform is affected, whereas in Herlitz JEB, the

mutations reside in a commonly utilized region among the three isoforms, leading to complete absence of all LAMA3 chains. These studies provide insight into the specific role of the N-terminal domain of laminin-α_{3a} in the granulation tissue response noted in Herlitz-JEB.

HEMIDESMOSOMAL VARIANTS OF JEB Whereas the molecular basis of many of the classic forms of Herlitz and non-Herlitz JEB are well defined on the basis of laminin-5 mutations, there is a group of patients in whom blisters form in and around the HD, and have therefore been called the "hemidesmosomal variants." Ultrastructural classification initially identified at least three groups of patients with EB whose blisters form at the level of the HD, and whose clinical phenotype is unlike any of the "classic" forms of EB. These three subtypes include GABEB, EB-PA, and EB-MD. Mutations have been identified in four HD-associated structural genes in patients with these rare forms of EB.

MUTATIONS IN BPAG2 IN GABEB Underscoring the genetic heterogeneity of the JEB is the demonstration of specific mutations in genes encoding structural components of the HDs. Specifically, mutations have been identified in the *COL17A1* gene in a subset of patients originally classified as a nonlethal JEB variant, known as GABEB. Clinically, these patients demonstrate a moderate blistering tendency associated with a characteristic constellation of extracutaneous involvement, including dystrophy of the fingernails, focal scarring alopecia of the scalp, loss of eyelashes, dental anomalies, and patchy macular hyperpigmentation. The mutation in the original GABEB family, described in a geographically limited area in Austria, is a PTC transmitted through many branches of the large inbred family. Subsequently, many different types of mutations in *COL17A1* have been observed in GABEB, including missense, nonsense, splice-site and insertions/ deletions, resulting in PTCs. Although there is slight variation in phenotypic severity, GABEB is uniformly nonlethal, and there does not appear to be a strict genotype–phenotype correlation with respect to *COL17A1* mutations, as compared with the laminin-5 genes. A dominantly inherited glycine substitution mutation in *COL17A1* was identified in a GABEB family, in which the proband had inherited a PTC on the second allele. Interestingly, all heterozygous carriers of the glycine substitution alone had markedly abnormal dentition and enamel pitting. Clearly, the glycine substitution mutation in COL17A1 also affects the basement membrane of the developing tooth, a previously undisclosed function for this transmembrane collagen.

IDENTIFICATION OF $\alpha_6\beta_4$-INTEGRIN MUTATIONS IN EB-PA EB-PA another rare subtype of EB, characterized by blistering of the skin and congenital PA, EB-PA, was previously classified as a nonlethal form of JEB, although the phenotypes can range from moderate to early postnatal demise. Mutations in the genes encoding the two polypeptides of the $\alpha_6\beta_4$-integrin receptor (*ITGA6* and *ITGB4*) have been identified in EB-PA. A survey of the reported mutations indicates that PTCs are associated predominantly with the lethal EB-PA variants, whereas missense mutations are more prevalent in nonlethal forms. However, the consequences of the missense mutations are position dependent, and substitutions of highly conserved amino acids within the individual integrin receptors may have lethal consequences. The phenotypic manifestation of PA from mutations in the *ITGB4* and *ITGA6* genes suggest a tissue-specific role for this integrin both in the skin and the gastrointestinal tract.

PLECTIN MUTATIONS IN EB-MD To determine which of the candidate proteins of the HD (BPAG1 or plectin) is responsible for making the connection between the HD and the keratinocyte intermediate-filament network, a knockout mouse was created targeting *BPAG1*. Whereas the HDs in these mice were largely normal, they lacked the inner plate and demonstrated a complete severance of the connection between the HD with the intermediate-filament network. The zone of mechanical fragility of the basal keratinocytes was restricted to the region of the HD, distinct from the ultrastructural findings in classic EB simplex, yet strikingly similar to the cleavage plane reported in "pseudojunctional" (now called HD variants) EB. Unexpectedly, the *BPAG1* knockout mice also developed late-onset muscular dystonia and neurodegeneration, and were found to be allelic to a naturally occurring mouse, dystonia musculorum. This constellation of phenotypic features together with the ultrastructural findings was highly reminiscent of the pathogenesis of EB-MD. On the basis of the striking similarities in the clinical phenotype of EB-MD and the *BPAG1* knockout mouse, it appeared likely that one of the two components of the hemidesmosomal inner plaque, BPAG1 or HD-1, would be involved in the pathogenesis of this disorder. Subsequently, BPAG1 was excluded as the cause of EB-MD, and it remains the only known hemidesmosomal component without an associated human genetic disease.

HD-1 was first described as an approx 500-kDa component of the HD, and was subsequently shown to be identical with plectin, an exceptionally large intermediate filament interacting protein, that was cloned independently. Plectin is a plakin family member with similarities to both desmoplakin and BPAG1, is highly conserved between rat and human, and has a wide tissue distribution, including the central nervous system and muscle. Plectin has a remarkable number of versatile binding affinities for other proteins, including vimentin, glial fibrillary acidic protein, the neurofilament protein triplet, keratin 5 and 14, and lamin B, suggesting that it can tether one filamentous network to another. Although plectin is expressed in nearly all cell types, its precise cytoplasmic localization is cell-type specific, and it can appear diffuse throughout the cell as a cytomatrix component, or in a restricted distribution as a focal adhesion protein.

Initial examination of biochemical and synthetic properties of cultured keratinocytes from patients with EB-MD using antibodies against plectin showed that this protein was completely absent in the cells of several patients with EB-MD. Typical presentation of EB-MD is neonatal blistering and late-onset muscular dystrophy with nail and tooth abnormalities. Severe mucocutaneous involvement, including laryngeal webs and urethral strictures, has also been reported. Although EB-MD is rare, most of the mutations reported result in PTCs on both alleles of plectin, either by nonsense, insertion/deletion or splicing mutations, and the phenotype in these patients is remarkably consistent manifesting with neonatal blistering and progressive muscle weakness from the first or second decade of life and thereafter. In some patients, small in-frame deletions or insertions have been disclosed with significantly milder phenotype and the onset of the muscle weakness on the third or fourth decade of life. Thus, continued identification of plectin mutations in patients with EB-MD will provide further insights into the phenotype–genotype correlations in this disorder as well as the relationship between the skin, the musculoskeletal and the nervous systems.

EB OGNA VARIANT: CAUSED BY A PLECTIN MISSENSE MUTATION Although several mutations in the plectin gene have been identified in recessively inherited EB-MD, a different type of mutation in plectin leads to a rare, dominant form of EB, known as the Ogna variant. The EB Ogna phenotype is owing to a specific missense mutation (R2110W) within the rod domain of

plectin. EB Ogna is not restricted to single Norwegian kindred as previously believed, because a German family with this phenotype was found to carry the identical mutation. Clinically, the EB Ogna patients demonstrate hemorrhagic blistering of the skin, but unlike patients with EB-MD, there is no muscle phenotype, and muscle biopsies from several EB Ogna patients revealed normal staining patterns with antibodies against plectin. Clearly, the genotype–phenotype relationships among plectin mutations in the different forms of EB are unusually complex and still emerging.

CONCLUSION JEB, including the HD variants, reflect mutations in at least seven different genes, and the specific clinical constellations result from the combination of different types of mutations within the mutated genes (*see* Table 105-1). Whereas the mechanistic consequences of these mutations have been explored at the mRNA and protein levels in many studies, the functional role of these components in HD assembly is also becoming increasingly clear through biochemical studies of protein–protein interactions. For example, an interaction between BPAG2 and α_6-integrin has been described, the disruption of HD assembly by a tailless β_4-integrin subunit was reported, and roles for the integrin receptors in mediating signal transduction continue to emerge. Whereas these components clearly represent functionally interdependent structural macromolecules in the dermal–epidermal adhesion zone, studies suggest a functionally dynamic and interactive role of some of these proteins in cell–matrix communication. Finally, it is noteworthy that despite an extensive survey of the seven genes involved in JEB, several families have proven negative for mutations, suggesting additional undisclosed candidate genes and uncharacterized protein components for this increasingly heterogeneous group of disorders.

DEB: COL7A1 MUTATIONS RESULT IN A SPECTRUM OF CLINICAL SEVERITY

DEB, which can be inherited in either an autosomal-dominant or autosomal-recessive pattern, demonstrate extensive variability in the clinical spectrum of severity. The less severe forms, such as dominantly inherited dystrophic EB (DDEB) or the mitis type of recessively inherited dystrophic forms of EB (M-RDEB), are characterized by a significant blistering tendency, but they lack the extensive mutilating scarring that is the hallmark of the severe, generalized, Hallopeau-Siemens type of recessive dystrophic EB (HS-RDEB). In addition to cutaneous manifestations, the dystrophic forms, particularly HS-RDEB, are associated with scarring of the esophagus and corneal erosions. Furthermore, the patients with HS-RDEB develop unusually aggressive, rapidly metastasizing squamous cell carcinomas primarily in the hands and feet. Thus, the combination of cutaneous and extracutaneous manifestations is associated with considerable morbidity and mortality in the most severely affected patients with DEB.

MOLECULAR GENETICS OF DYSTROPHIC EB Several lines of evidence initially suggested that type-VII collagen is the candidate gene/protein system harboring mutations in DEB. First, the ultrastructural diagnostic hallmark of DEB is an abnormality in anchoring fibrils, attachment structures that are made up of predominantly, if not exclusively, of type-VII collagen. In different variants of DEB, the anchoring fibrils can be shown by transmission electron microscopy to be morphologically abnormal, reduced in number, or even completely absent. Second, these ultrastructural observations are reflected by changes in the immunofluorescence pattern when antitype-VII antibodies are used for staining of the skin. In normal individuals, type-VII collagen epitopes are readily evident in a linear pattern at the dermal–epidermal junction, whereas the immunostaining is entirely negative in generalized HS-RDEB patients. In DDEB, the immunostaining reveals a near-normal pattern and intensity, whereas in M-RDEB, the staining can be attenuated, although clearly positive. These ultrastructural and immunofluorescent findings suggested that type-VII collagen was a candidate gene for mutations in the DEB. This suggestion was subsequently strengthened by demonstration of genetic linkage between the *COL7A1* locus on chromosome 3p21 and both dominantly and recessively inherited forms of DEB.

Subsequent cloning of the human type-VII collagen cDNA sequences allowed determination of the normal structure of type-VII collagen polypeptides. Elucidation of the intron–exon organization of the entire human type-VII collagen gene has revealed that the gene is highly complex, consisting of a total of 118 exons. However, *COL7A1* is relatively compact, and the exons are contained within approx 32 kb of human genomic DNA. The elucidation of the intron–exon organization of COL7A1 has provided necessary information to undertake mutation analysis of this gene in families with DEB. In fact, specific mutations have now been disclosed in >300 kindreds with different forms of DEB.

The wealth of information on specific mutations has allowed establishment of genotype–phenotype relationships in different forms of DEB. In normal skin, type-VII collagen molecules form antiparallel dimers that associate through their overlapping carboxy-terminal ends (Fig. 105-4). This association is stabilized by interchain disulfide bonds, and such stable type-VII collagen dimer molecules laterally aggregate to form anchoring fibrils. Thus, following the synthesis of type-VII collagen, several critical steps are required for proper assembly of anchoring fibrils. Consequently, mutations affecting the synthesis of type-VII collagen at the transcriptional or translational level, or those interfering with its supramolecular assembly to anchoring fibrils can result in DEB phenotype (*see* Fig. 105-4).

GENOTYPE/PHENOTYPE CORRELATIONS IN DEB

Severe, Mutilating HS-RDEB: PTC Mutations In COL7a1 In most HS-RDEB patients, the consistent genetic lesion is a PTC in both alleles of the affected individual. The major effect of a PTC mutation is reduction in mRNA abundance as a result of nonsense-mediated mRNA decay. This phenomenon is coupled to the splicing process itself, because the levels of unspliced, heteronuclear RNA are equivalent for both the mutant and wild-type alleles, and the decay is evident only on comparison of processed mRNA. The PTCs result in perturbations in synthesis of type-VII collagen mRNAs at the transcriptional level, which are then unable to provide templates for translation of functional polypeptides. Even if the mutant allele containing a PTC is expressed at reduced levels, the translated protein is truncated at its carboxy terminus and is unable to assemble into anchoring fibrils. These interpretations are consistent with the ultrastructural demonstration of complete absence of the anchoring fibrils in HS-RDEB, and negative immunofluorescence for type-VII collagen, thus explaining the extreme fragility of the skin, so characteristic of this phenotype (*see* Fig. 105-4).

Mitis RDEB: Missense and In-Frame Deletion Mutations In the mitis forms of RDEB, at least one, and in some cases both, alleles encode for a full length type-VII collagen polypeptide. However, this allele usually contains a missense mutation that can change the conformation of the protein such that the anchoring fibril assembly is perturbed. In some cases, one allele contains a missense mutation or in-frame deletion, whereas the second allele

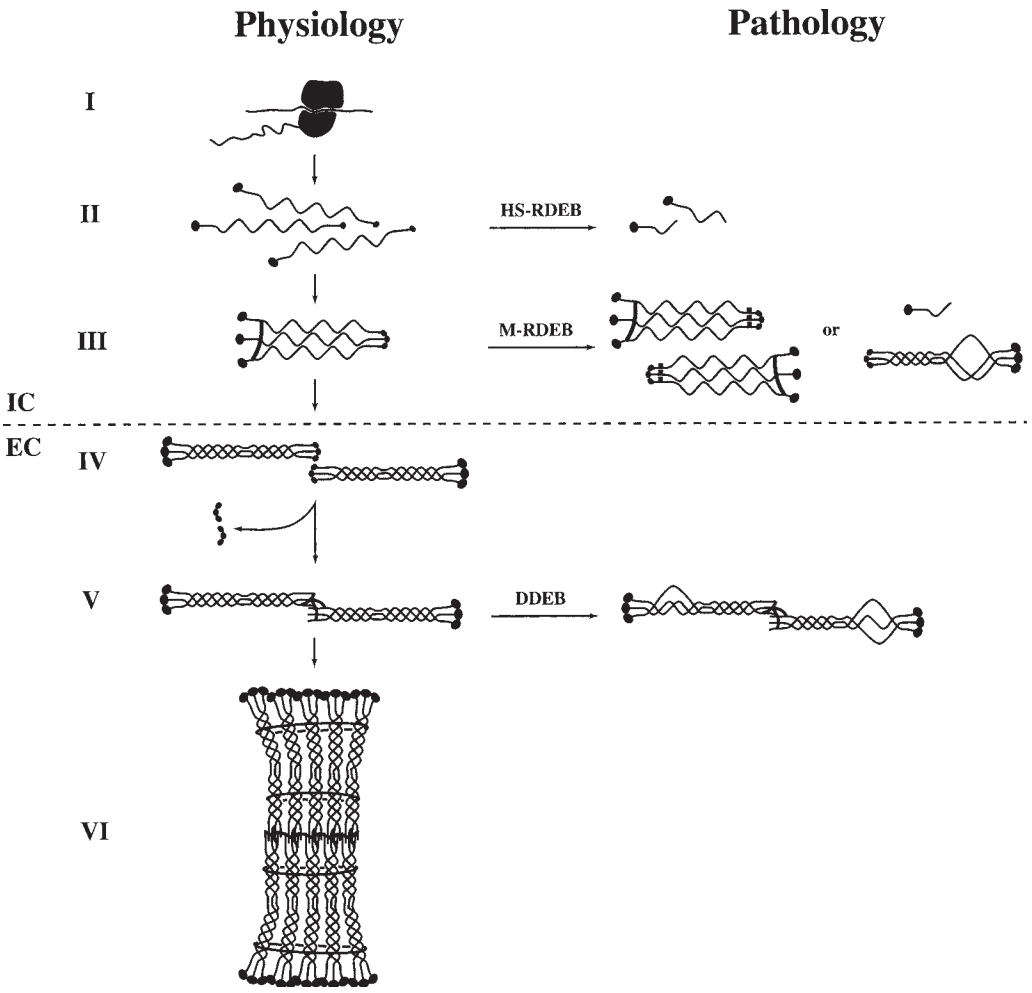

Figure 105-4 The physiology and pathology of type-VII collagen. Synthesis of pro-α_1(VII)-collagen polypeptides and their assembly into anchoring fibrils is depicted on the left side of the figure. The mRNA, approx 9 kb in size, is translated on the ribosomes of cells, such as basal keratinocytes, synthesizing type-VII collagen (I). Within the extracellular space (EC), two of these triple-helical type-VII collagen molecules align into an antiparallel tail-to-tail orientation with overlapping carboxy termini (IV). The molecules are processed by proteolytic removal of the NC-2 domains (•), and the association of the dimer is stabilized by disulfide bonding (V). Subsequently, a large number of the dimer molecules laterally assemble into anchoring fibrils that contain at both ends intact amino-terminal NC-1 domains with adhesive properties (VI). In the presence of genetic lesions in COL7A1, type-VII collagen pathology can manifest as different variants of DEB. For example, PTC mutations result in synthesis of truncated polypeptides unable to form anchoring fibrils, causing severe Hallopeau-Siemens type of recessive dystrophic EB (HS-RDEB). In a milder autosomal-recessive form, known as the mitis variant (M-RDEB), missense mutations of either the homozygous or compound heterozygous state, or in combination with a PTC *in trans* prevent the assembly of type-VII collagen dimers. In cases of dominant dystrophic EB (DDEB), glycine substitution mutations affecting the collagenous domain of type-VII collagen interfere with packing of the anchoring fibrils (Modified with permission of the McGraw-Hill companies, from Uitto J, Pulkkinen L. Epidermolysis bullosa: The Disease of the cutaneous basement membrane zone. In: Scriver CR, Beaudet A, Valle D, et al., eds. The Metabolic and Molecular Bases of Inherited Disease, 8th ed. New York: McGraw Hill, 2001; pp. 5655–5674.)

contains a PTC. The net result of the latter combination of mutations is a reduction in mutant RNA from the PTC allele at the transcriptional level, together with a mutation on the second allele, which is transcribed and presumably translated at normal rate, yet is likely to affect nucleation and assembly of anchoring fibrils (*see* Fig. 105-4). As a result of these more subtle mutations, combined with a PTC on the other allele, mutant full length type-VII collagen molecules may be able to assemble into anchoring fibrils, which are, however, unlikely to be stabilized by disulfide bonding (*see* Fig. 105-4). Thus, these attachment structures, although present, are weakened, resulting in moderately severe fragility of the skin, as observed in M-RDEB.

Dominant Dystrophic EB: Glycine Substitution Mutations In One Allele In dominantly inherited forms of EB, the recurrent theme of mutations is missense substitutions of glycine residues that occur within the collagenous domain of the type-VII collagen molecule, a region characterized by the repeating Gly-X–Y amino acid sequence. These mutated molecules are able to associate with polypeptides synthesized from the normal allele and interfere with their assembly through a mechanism known as dominant-negative interference (*see* Fig. 105-4). The glycine substitutions, therefore, destabilize the collagen triple helix, interfere with the secretion of the molecules, and render them susceptible to intracellular degradation, thus exerting their effect at the posttranslational level. Because type-VII collagen is a homotrimer consisting of three identical α_1(VII)-polypeptides, only one out of eight triple-helical molecules (12.5%) is entirely normal, assuming equal expression of the mutant and wild-type alleles. As a result, some normal type-VII collagen homotrimers can be assembled, consistent with ultrastructural demonstration of thin anchoring fibrils, positive immunofluorescence for type-VII

collagen, and the relatively mild clinical phenotype in DDEB. In addition to the classic forms of DDEB, glycine substitution mutations have been demonstrated in two clinical variants known as pretibial DEB and the Bart syndrome, proving that these subtypes are allelic to DDEB with mutations in *COL7A1*.

Collectively, the type and combination of mutations are able to predict, in general terms, the clinical severity and natural history of DEB. Because clinical severity represents a continuum in the spectrum of manifestations, the precise nature of the genetic lesions, their positions along the type-VII collagen gene, and the dynamic interplay of the two mutant alleles on the individual's genetic background, coupled with environmental influences, will determine the precise phenotype of the patient in DEB.

REVISIONS IN GENETIC COUNSELING IN DYSTROPHIC EB As indicated, DEB can be inherited in an autosomal-dominant or autosomal-recessive fashion. The diagnosis of classic HS-RDEB in a patient with severe, mutilating scarring, with clinically unaffected parents, is usually made without difficulty. Similarly, inheritance of a blistering tendency and a relatively mild scarring phenotype, with multiple affected family members in several generations, allows unequivocal diagnosis of dominantly inherited DEB.

The difficulties arise during the diagnosis and ascertainment of the inheritance pattern in patients with a relatively mild phenotype and clinically normal parents. By ultrastructural analyses, these patients often demonstrate the presence, but a reduced number, of anchoring fibrils, and immunofluorescence shows positive staining for type-VII collagen. Consequently, these cases are often diagnosed as dominant DEB, and were presumed to be caused by a new dominant mutation or reflecting parental germline mosaicism. This diagnosis has implications in terms of genetic counseling of the affected individuals. If their disease is truly a new dominant mutation, the risk of their offspring being affected is one in two (50%). In contrast, in cases of a recessively inherited M-RDEB, which can be clinically indistinguishable from *de novo* DDEB, the risk of their offspring being affected is low, approximately the same as in the general population, with the exception of consanguineous matings.

Unexpectedly, determination of the genotype and mutation analysis of several patients with relatively mild disease and ultrastructurally detectable anchoring fibrils with positive immunofluorescence staining for type-VII collagen has demonstrated that many of them are compound heterozygotes or have homozygous missense mutations inherited in a recessive manner and therefore the diagnosis is M-RDEB. For example, the first demonstration of type-VII collagen mutations in M-RDEB revealed the presence of a homozygous missense mutation, a methionine-to-lysine substitution (M2798K) at the carboxy terminal end of the molecule. Similarly, in other cases, a missense mutation in one allele, including a glycine substitution in the collagenous domain, together with a PTC mutation on the other allele, can result in M-RDEB. Finally, in a survey of a cohort of more than 400 families, in which distinct COL7A1 mutations were identified, only a limited number of cases appeared to be *de novo* dominant mutations, at least one of them being derived from the maternal germline.

Based on these considerations, for genetic counseling purposes, it is appropriate to consider each "new" case as a recessively inherited condition, unless proven to be dominant by mutation analysis. Reclassification of DEB on the basis of the underlying mutations clearly affects the likelihood of the affected individual having an affected offspring.

APPLICATIONS OF MUTATION ANALYSIS IN PRENATAL DIAGNOSIS

Precise understanding of the underlying mutations in different forms of DEB has several translational implications in terms of genetic counseling, DNA-based prenatal diagnosis, and gene therapy. Most immediately relevant to patient care is the development of DNA-based prenatal diagnosis, which can be performed as early as the 10th gestational week through chorionic villus sampling, or through amniocentesis from the 15th wk and beyond. In the severe DEB, such analyses can be performed either by direct mutation analyses or by genetic-linkage approaches, taking advantage of the fact that no evidence for locus heterogeneity has been observed in DEB. In contrast, in the case of JEB or EBS, in which significant locus heterogeneity exists, prenatal testing must be based on identification of specific mutations. These approaches have already been applied with outstanding success to DNA-based prenatal diagnosis in more than 200 families at risk for recurrence of the severe forms of EB, mostly HS-RDEB and hemidesmosomal junctional EB. Efforts are in progress to establish noninvasive prenatal testing by detection of mutations in fetal DNA present in the maternal circulation during the early stages of gestation. The genetic information also provides the basis for development of preimplantation genetic diagnosis through blastomere analysis, a technological advance that would obviate the necessity of termination of the pregnancy in case of an affected fetus, if elected.

GENE THERAPY APPROACHES

Precise understanding of the underlying mutations and subsequent demonstration of the functional consequences of such mutations at the mRNA and protein levels are obligatory prerequisites for the development of gene therapy approaches for this group of devastating skin diseases. It is conceivable that several forms of EB are realistic targets for genetic therapies of different forms of EB. Significant progress has been made to transduce keratinocytes cultured from patients with different forms of EB with transgene constructs using either viral vectors or nonviral approaches. However, because of the concern for mutagenesis resulting from integration of the viral vectors into the genome, exploration of alternative technologies has begun, including direct introduction of genetic material into the skin cells by biolistic particle bombardment ("gene gun"), use of ribozyme-mediated repair of mutant mRNAs by trans-splicing, and application of single-stranded oligonucleotides for targeted gene correction. Thus, establishing the genetic basis of different forms of EB has provided the necessary foundation for development of rationally designed gene therapy approaches to counteract these devastating skin diseases in the future.

106 Connective Tissue Disorders

The Paradigms of Ehlers-Danlos Syndrome and Pseudoxanthoma Elasticum

JOUNI UITTO AND FRANZISKA RINGPFEIL

SUMMARY

The extracellular matrix of connective tissue consists of a meshwork critical for organogenesis and homeostatic maintenance of tissues through complex protein supramolecular assembly and cell–matrix interactions. There are four principal groups of extracellular matrix components, viz., collagen, the elastic fibers, noncollagenous glycoproteins, and glycosaminoglycan/proteoglycan macromolecules. This chapter highlights the progress made in heritable disorders of connective tissue by discussing Ehlers-Danlos syndrome and pseudoxanthoma elasticum, conditions that result from abnormalities in the collagens and the elastic fibers, respectively.

Key Words: Collagen; Ehlers-Danlos syndrome; elastic fibers; glycosaminoglycan/proteoglycan macromolecules; noncollagenous glycoproteins; pseudoxanthoma elasticum.

INTRODUCTION

The extracellular matrix of connective tissue consists of a meshwork critical for organogenesis and homeostatic maintenance of tissues through complex protein supramolecular assembly and cell–matrix interactions. There are four principal groups of extracellular matrix components, viz., collagen, the elastic fibers, noncollagenous glycoproteins, and glycosaminoglycan/proteoglycan macromolecules. The members of these families assemble into contiguous and interacting networks with distinct structural and functional properties. In the skin, the principal components of the extracellular matrix of connective tissue are the fiber networks consisting of collagen and elastin. The genetic heterogeneity of collagen, a family of approx 25 closely related structural proteins, and the molecular complexity of elastic fibers, which consist of both elastin and a number of elastin-associated microfibrillar proteins, have been recognized. Understanding of the supramolecular organization of these fiber structures and their interactions with glycosaminoglycan/proteoglycan macromolecules as well as cellular components of the connective tissue, has allowed identification of critical metabolic and structural features that are prerequisites for normal physiological function of these proteins.

Considering the critical role of the extracellular matrix in organ development, homeostasis, and tissue repair, it is not surprising that alterations in the connective tissue components accompany clinical, both heritable and acquired, diseases. Specifically, primary genetic defects that affect collagen and elastic fibers can result in abnormalities that manifest as a group of disorders, the heritable disorders of connective tissue (Table 106-1). In addition to the primary genetic defects in the genes encoding the structural components of collagen and components of the elastic fibers, or enzymes that modify these proteins, the fibers' architecture can be perturbed by genetically unrelated pathological processes. This chapter highlights the progress made in heritable disorders of connective tissue by discussing Ehlers-Danlos syndrome (EDS) and pseudoxanthoma elasticum (PXE), conditions that result from abnormalities in the collagens and the elastic fibers, respectively.

CLINICAL AND GENETIC HETEROGENEITY OF THE EHLERS-DANLOS SYNDROME (EDS)

The first comprehensive description of the systemic nature of the connective tissue disorder, now known as the EDS, was published in 1892 by Tschernogobow. Drs. Ehlers and Danlos, Danish and French dermatologists, respectively, contributed to the clinical description in the early 1900s, and this constellation became known as EDS in 1936. The genetic nature of EDS was recognized in 1949, and the phenotype was subsequently suggested to result from defects in the collagen meshwork. The genetic heterogeneity of EDS was recognized in the 1960s, and the first molecular defects in the collagen synthetic pathway in humans with EDS were described in 1972.

The cutaneous features of EDS include hyperextensible and fragile skin, poor wound healing, molluscoid pseudotumors, and bruising tendency. The systemic findings include joint hypermobility, scoliosis, and in the "vascular" subtype, a significant risk of spontaneous arterial, intestinal or uterine rupture. Many individuals in the general population have features suggestive of EDS, such as loose jointedness, often encountered in certain ethnic backgrounds. Application of more stringent diagnostic criteria, however, including findings both in the skin and joints at a minimum, suggests that the overall incidence of EDS is approx 1 in 5000.

Table 106-1
Examples of Heritable Connective Tissue Diseases With Cutaneous Involvement

Defect	*Disease entity*	*Inheritance*
Structural	Ehlers-Danlos syndrome	AD, AR
	Cutis laxa	AD, AR, XR (NH)
	Osteogenesis imperfecta	AD, AR
	Epidermolysis bullosa	AD, AR
	Marfan syndrome	AD
	Lipoid Proteinosis	AR
Metabolic/Secondary	Pseudoxanthoma elasticum	AR
	Homocystinuria	AR
	Menkes syndrome	XR
	Occipital horn syndrome	XR
Unknown	Familial cutaneous collagenoma	AD
	Focal dermal hypoplasia	XD

AD, autosomal-dominant; AR, autosomal-recessive; XD, X-linked dominant; XR, X-linked recessive; NH, not heritable disorder.

Previously, EDS was divided into 11 distinct subtypes (types I–XI) based on clinical and genetic observations and molecular characterization. A consensus conference held in 1997, however, proposed a revised and somewhat streamlined nosology, consisting of six variants (Table 106-2). The molecular basis of the major forms of EDS is known and in most cases, the clinical manifestations are either from mutations in the genes encoding collagen polypeptide subunits (α chains) or in enzymes that modify the primary collagen translation product. In addition to collagen, mutations in tenascin-X, another extracellular matrix protein, have been reported.

The classic type of EDS (previously types I and II) is inherited in most cases in an autosomal-dominant fashion, although recessive families have been described. Major clinical features include considerable hypermobility of joints, scoliosis, and skin that is physically soft, velvety, hyperextensible and displays poor wound healing properties. The dermis is fragile and prone to easy bruising. Scars after trauma are atrophic, often resembling "cigarette paper." Varicose veins are common, and a significant number of classic EDS patients have cardiac defects, especially mitral valve prolapse.

The hypermobility type of EDS (previously type III) has an autosomal-dominant inheritance pattern. The prominent clinical features are generalized joint hypermobility and hyperextensible, smooth and velvety skin. Recurrent joint dislocations can cause chronic joint pain and eventually lead to osteoarthritic changes.

The vascular type of EDS (previously type IV) is inherited in an autosomal-dominant fashion. These patients have thin, translucent skin. They have a characteristic facial appearance with a thin, pinched nose, thin lips, hollow cheeks, and prominent "staring" eyes owing to decreased periorbital adipose tissue. Patients with the vascular type of EDS are at high risk for arterial and intestinal ruptures most often in the third or fourth decade of life, but they may occur earlier. Furthermore, women with this type of EDS are at high risk for uterine rupture during labor, often with catastrophic consequences.

The kyphoscoliosis type of EDS (previously type VI) is an autosomal-recessive condition, with generalized joint laxity, progressive kyphoscoliosis and scleral fragility. These patients often demonstrate severe muscular hypotonia at birth that leads to delayed gross motor development.

The arthrochalasia type of EDS (previously types VIIa and VIIb) is inherited in an autosomal-dominant fashion. It is characterized by severe generalized joint hypermobility with recurrent subluxations and congenital bilateral hip dislocations. In addition, patients have hyperextensible skin, tissue fragility, atrophic scars, and easy bruising.

The dermatosparaxis type of EDS (previously type VIIc) is an autosomal-recessive disorder with severe skin fragility and sagging, soft and redundant skin. These features are associated with easy bruising, premature rupture of fetal membranes, and occasionally, large umbilical and inguinal hernias.

As noted, the revised classification identifies only six distinct categories of EDS, based on pathognomonic descriptions and molecular diagnostics. Several previously described subtypes of EDS, some of them exceedingly rare and not well characterized, have been excluded from diagnostic considerations under the EDS category. These include the previous type V (X-linked variant), type VIII (periodontitis type), type X (fibronectin type), and type XI (large joint hypermobility type). In addition, the previous EDS type IX, an X-linked recessive condition, also known as the occipital horn syndrome, was excluded from the EDS classification. The occipital horn syndrome is allelic to the gene harboring mutations in Menkes syndrome, ATP7A, which encodes an ATP-dependent copper transporter protein. Reduced serum copper and serum ceruloplasmin levels suggest the diagnosis of the occipital horn syndrome, and mechanistically, reduced copper levels lead to low lysyl oxidase activity with consequent deficiency in collagen crosslinking. In that sense, the occipital horn syndrome is considered a secondary connective tissue disorder, the primary defect residing in copper metabolism.

THE COLLAGEN FAMILY OF PROTEINS

Early evidence suggesting that EDS is a connective tissue disorder was derived from histopathological and ultrastructural observations that revealed a thin reticular dermis and reduced as well as disorganized collagen fibrils. Collagen fibrils, as examined by transmission electron microscopy, often show considerable variability in their diameters, and occasionally large fibrils with an irregular contour can be noted. A particular characteristic is the hieroglyphic pattern of fibrils encountered in the dermatosparaxis type of EDS. Collectively, these observations suggested that the extracellular matrix is perturbed in EDS, and that the primary genetic defects may involve collagen biosynthetic pathways.

Critical for elucidation of the pathogenetic mechanisms leading to different variants of EDS has been the progress made toward understanding the complexity of the collagen family of proteins. Specifically, the collagen family is now known to consist of as many as 27 distinct proteins (types I–XXVIII), each collagen molecule being made up of three α-chain subunits. These collagen molecules may be either homotrimers (three identical α chains) or heterotrimers (i.e., consisting of two or three different kinds of polypeptides). These α chains are synthesized as precursor molecules, proα-chains, which, in addition to the central collagenous domain characterized by a repetitive Gly-X–Y peptide sequence, contain noncollagenous domains. There are more than 40 different proα-chains synthesized in mammalian tissues, each a distinct gene product. Many of these collagens are expressed in the skin, with diverse functional roles (Table 106-3).

Collagen is the major extracellular matrix component of the human dermis and accounts for approx 80% of the total dry

Table 106-2
Classification of The Ehlers-Danlos Syndrome

EDS type[a]	*Traditional classification*	*Clinical features*	*Inheritance*	*Mutated gene/protein*
Classic	I, II	Hyperextensible skin and joint hypermobility, atrophic scars, easy bruising	AD, AR[b]	COL5A1, COL5A2/α1- and α2-chains of type-V collagen; TNX/Tenascin-X
Hypermobility	III	Extensive joint hypermobility, pain, dislocations	AD	TNX/Tenascin-X
Vascular	IV	Thin skin, arterial, gastrointestinal or uterine rupture, bruising, small joint hypermobility, fragility of different tissues	AD	COL3A1/α1-chain of type-III collagen
Kyphoscoliosis	VI	Hypotonia, joint laxity, congenital scoliosis, ocular fragility	AR	Procollagen-lysine, 2-oxoglutarate 5-dioxygenase /Lysyl hydroxylase
Arthrochalasia	VIIa, VIIb	Severe joint hypermobility with congenital dislocation, skin involvement mild, scoliosis, bruising	AD	COL1A1, COL1A2/α1- and α2-chains of type-I collagen
Dermatosparaxis	VIIc	Severe skin fragility and hyperextensibility, bruising	AR	ADAMTS-2/Procollagen N-peptidase
Other[c]	V, VIII, X, XI			

[a]According to the 1997 Villefranche Consensus Meeting (from Beighton et al., 1998).
[b]Amongst the classic forms of EDS, those owing to type-V collagen mutations are inherited in an autosomal-dominant fashion, whereas those caused by tenascin-X deficiency are autosomal-recessive (*see* Fig. 106-1).
[c]The previous EDS type IX has been reclassified as occipital horn syndrome, a copper metabolism disorder allelic with Menkes syndrome.

Table 106-3
Genetically Distinct Collagens in the Skin

Collagen type	*Size of native molecule (Daltons)*	*Tissue distribution*	*Functional role*
Type I	285,000	Most connective tissues, including skin, bones, tendons, ligaments, and so on.	Major structural component providing tensile strength
Type III	285,000	Skin, lung, blood vessels; predominant in fetus	Contributes to tensile and elastic properties
Type IV	540,000	Basement membranes, anchoring plaques	Major structural component of basement membranes
Type V	300,000	Ubiquitous	Interaction of cell surface and the surrounding matrix; regulation of matrix assembly
Type VI	530,000	Extracellular microfibrils	Matrix assembly
Type VII	510,000	Skin, cornea, mucous membranes	Structural component of anchoring fibrils
Type XII	666,000	Similar to type I	Regulation of fibril diameter by association with type I
Type XIV	666,000	Similar to type I	Regulation of fibril diameter by association with type I
Type XVII	540,000	Cutaneous basement membrane zone	Stable association of basal keratinocytes to lamina lucida

weight of this tissue. The major collagens in the dermis are type I, with a chain composition of $[\alpha1(I)]_2\ \alpha2(I)$, which accounts for more than 80% of the total collagen in the skin. Type-I collagen is associated with type-III collagen, a homotrimer of $[\alpha1(III)]_3$, to form the major collagen fibers in the dermis. These fibers are responsible for the tensile properties of the dermis that allow skin to serve as a protective organ against external trauma. Associated with type-I/III collagen fibers are type-V collagen molecules, which consist of both α1(V) and α2(V) polypeptides. The role of type-V collagen in collagen fibrillogenesis is to regulate the fibril diameter. Consequently, mutations in any of the genes encoding type-I, type-III, or type-V collagens are expected to result in significant functional deficiencies in the collagen meshwork. This suggestion has been proven through identification of specific mutations in the corresponding genes in different variants of EDS (*see* Table 106-2 and Pathogenesis of Different Subtypes of EDS).

The principal cell type responsible for the synthesis of the major collagens in the skin, types I, III, and V, is the dermal fibroblast. However, genetically distinct collagens can be synthesized by different cell types, including basal keratinocytes of the epidermis that synthesize type-VII and -XVII collagens. The biosynthesis of all genetically distinct collagens involves a number of post-translational modifications, some of which occur in the intracellular and others in the extracellular space (Fig. 106-1). In the case of a prototypic collagen, such as the fibril-forming collagens type I and III, the primary translation products, the pro α chains, contain amino- and carboxyl-terminal propeptide extensions. The pro α chains are modified by a number of intracellular steps, including:

1. Cleavage of the signal peptide.
2. Hydroxylation of certain proline and lysine residues to form 3- and 4-hydroxyproline and hydroxylysine in reactions catalyzed by prolyl hydroxylase and lysyl hydroxylase, respectively.

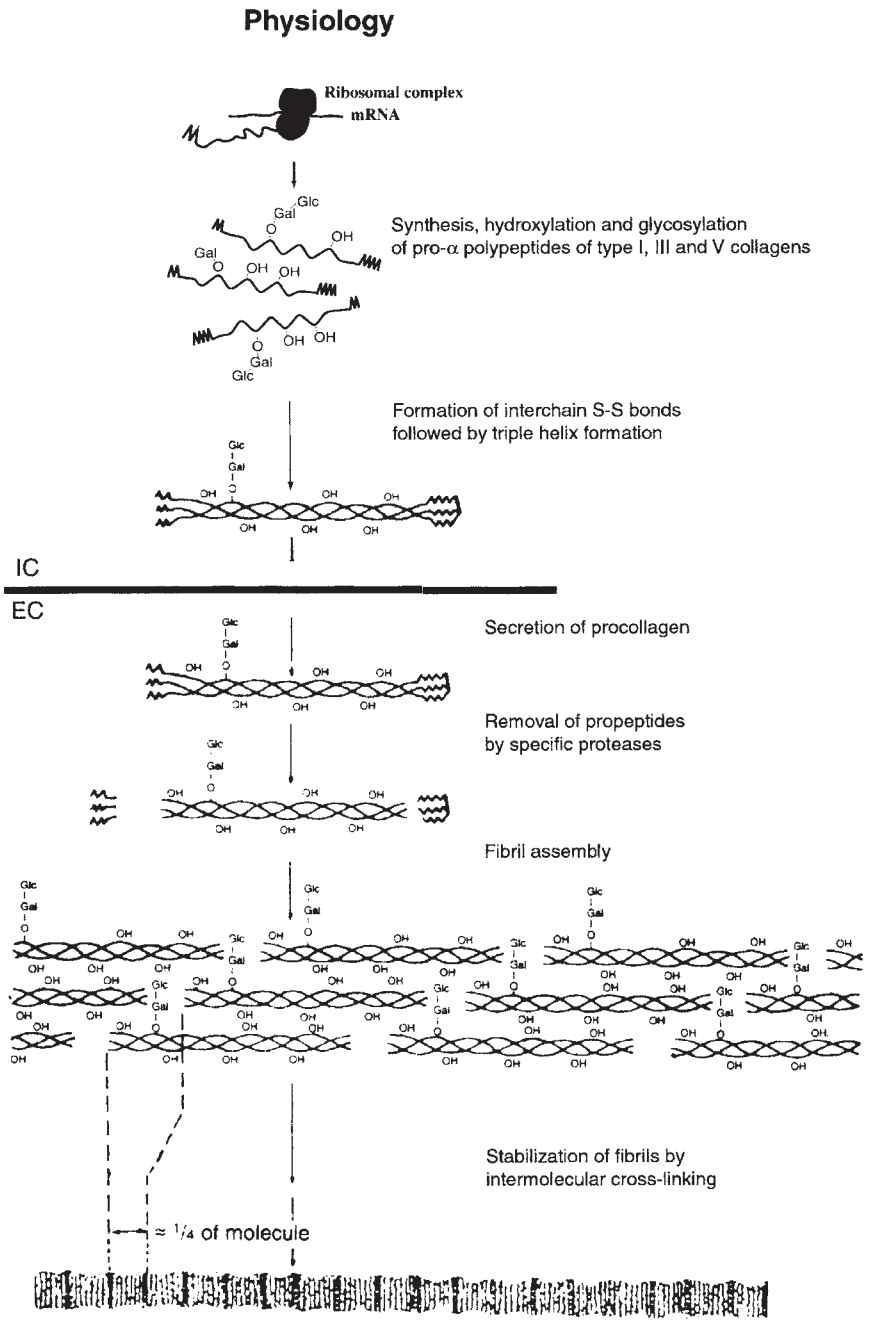

Figure 106-1 Schematic presentation of collagen biosynthesis, secretion, and fibril assembly under physiological conditions, and identification of pathological mechanisms leading to Ehlers-Danlos syndrome phenotype. Glc–Gal, glucosyl–galactosyl residue attached to the hydroxyl group (OH) of lysine residues; S–S bonds, disulfide bonds; AD, autosomal-dominant; AR, autosomal-recessive. (Modified from Uitto et al., 2003.)

3. Glycosylation of certain hydroxylysine residues to form galactosyl- and glucosyl–galactosyl hydroxylysine.
4. Glycosylation of selected asparagine residues.
5. Association of the carboxyl ends of the three collagen proα-chains stabilized by interchain disulfide bonding.
6. Folding of the central collagenous domain into a characteristic collagen triple helix.

The triple helical procollagen molecules are secreted into the extracellular space, and the amino and carboxyl-terminal propeptides are cleaved off by specific proteases (*see* Fig. 106-1). The processed collagen molecules are no longer soluble under physiological conditions, and instead, they self-assemble into microfibrils by nucleation and propagation, and these microfibrils associate to form larger fibrils and fibers. The supramolecular assembly of the fibers is finally stabilized by formation of covalent, lysine- and hydroxylysine-derived crosslinks, which are catalyzed by lysyl oxidase, a copper-dependent enzyme.

PATHOGENESIS OF DIFFERENT SUBTYPES OF EDS

At least three distinct mechanisms affecting different stages of collagen biosynthesis are involved in the development of EDS phenotypes:

1. Deficiency of collagen processing enzymes.
2. Dominant-negative mutations in the collagen α-chain genes.
3. Haploinsufficiency.

These general mechanisms are applicable to different subtypes of EDS, and the precise phenotype is dependent on the nature of the mutations and the types of collagen being affected. Also, as mentioned, mutations in the tenascin-X gene, *TNX*, can result in an EDS phenotype.

The first molecular defect described in collagen synthesis involves lysyl hydroxylase deficiency in a form of EDS, previously known as type VI and classified as the kyphoscoliosis type. Reduced enzyme activity from mutations in the corresponding gene, procollagen-lysine, 2-oxoglutarate 5-dioxygenase, results in a reduced hydroxylysine content of collagen polypeptides and an altered crosslinking profile on collagen fibrils.

The classic forms of EDS, characterized by moderate hyperextensibility of skin, marked joint hypermobility, atrophic scars and easy bruising, demonstrate considerable molecular heterogeneity. In most cases, dominant-negative mutations in *COL5A1* and *COL5A2* genes or haploinsufficiency in *COL5A1* gene are the predominant mutations. It has been estimated that 30–50% of all classic cases of EDS are caused by haploinsufficiency of type-V collagen. As a result, the collagen fibril diameter is irregular and occasionally increased as observed by transmission electron microscopy. These abnormal fibers apparently do not have the same tensile properties as normal fibers, resulting in clinical manifestations in the skin, joints, and small blood vessels.

Although all forms of EDS cause considerable morbidity, the vascular type (previously type IV) EDS can cause premature demise of affected individuals because of rupture of arterial blood vessels, lower intestine, or uterus during pregnancy. The vascular type of EDS can be caused by either dominant-negative mutations or haploinsufficiency of the type-III collagen gene, COL3A1, leading to a reduced amount of type-III collagen in small and variably sized dermal collagen fibers. These observations emphasize the critical role of type-III collagen in collagen fibrillogenesis in general. Furthermore, the findings that arterial blood vessels, including aorta, and the lower intestine are particularly rich in type-III collagen explain the propensity of these tissues to rupture, often with catastrophic consequences.

Both the arthrochalasia and dermatosparaxis types of EDS involve abnormal conversion of type-I procollagen to collagen. In the arthrochalasia type, mutations in the genes encoding the proα-chains of type-I collagen (*COL1A1* and *COL1A2*) can modify the cleavage site recognized by procollagen N peptidase. Consequently, the precursor forms of the α chains persist and these molecules containing either the amino- and/or the carboxyl-terminal ends are unable to assemble into functional fiber structures. As a result, dominantly inherited forms of EDS (previously known as types VIIa and VIIb) develop. Correspondingly, a conversion defect from deficient procollagen N-peptidase activity leads to the dermatosparaxis (previously known as type VIIc) type of EDS, a recessively inherited condition.

The role of tenascin-X in the pathogenesis of EDS became evident when a patient with adrenal hyperplasia and classic EDS was found to harbor a 30-kb contiguous gene deletion on the short arm of chromosome 6, the critical interval containing both the *CYP21* gene that encodes steroid 21-hydroxylase and the *TNX* gene encoding tenascin-X. Subsequently, it was demonstrated that tenascin-X was absent in the fibroblast culture medium and serum in these patients with EDS, and immunofluorescence in the skin was negative for this protein. Because tenascin-X is expressed in the tissues affected in EDS and is developmentally associated with collagen fibrils, it was proposed that this protein is directly involved in the pathogenesis of EDS in these patients. This hypothesis was confirmed by demonstration of null mutations in both alleles of the *TNX* gene, indicating that tenascin-X deficiency is an autosomal-recessive disorder with clinical features similar to those of the classic type of EDS. It should be noted, however, that the tenascin-X deficient patients lack atrophic scars, a major criteria for classic EDS, and wound healing is not consistently delayed. The reasons for these observations are not clear. Furthermore, observations have suggested that haploinsufficiency of *TNX* is associated with the hypermobility type of EDS. Nevertheless, the pathoetiological role of tenascin-X has been further confirmed by the development of *TNX* null mice, which exhibit progressive hyperextensibility and reduced tensile strength of their skin, features characteristic of patients with tenascin-X deficiency.

CLINICAL AND GENETIC FEATURES OF PSEUDOXANTHOMA ELASTICUM (PXE)

PXE was delineated as a clinical entity, distinct from xanthomas (hence pseudoxanthoma), over 100 yr ago. The relationship of eye findings, primarily manifesting with angioid streaks, and the cutaneous lesions was established by Grönblad, an ophthalmologist, and Strandberg, a dermatologist, both of Sweden; consequently, this condition is also known as Grönblad-Standberg syndrome. In addition to cutaneous and ophthalmological findings, cardiovascular manifestations, including weakened pulses in extremities leading to intermittent claudication, and in some cases early myocardial infarctions or gastrointestinal hemorrhages because of rupture of arterial blood vessels, complete this syndrome's classic presentation.

The incidence of PXE lies in the range of 1 in 100,000, although estimates vary widely. Women seem to be slightly more often affected than men (3/2), although this has been attributed by

some to more frequent reporting by females owing to cosmetic bias. There is no racial or ethnic predilection.

Although the onset of clinical symptoms in the skin is highly variable and may range from the first year of life to over 50 yr of age, most patients develop noticeable skin lesions around puberty. The earliest signs are yellowish papules that occur on the lateral neck. As the disease progresses, these papules appear in other flexural areas, such as the antecubital fossae, the axillae, and groin. Long-standing lesions eventually lose recoil and manifest as sagging skin on the affected sites. Lesions may also be found around the umbilicus, especially in multiparous women. PXE-like findings have been reported to occur in association with chronic renal failure and subsequent alterations in the calcium/phosphate homeostasis as well as in patients with β-thalassemia. Occasionally, skin lesions may be clinically or subclinically present in scars, a fact that may be used to make a diagnosis in the absence of lesions in predilection sites but presence of other clinical findings, such as ocular lesions, suggestive of PXE. When lesions are clinically obvious, routine histopathology by H&E stain usually demonstrates calcium deposits in the mid reticular dermis; otherwise special stains, such as Verhoeff-van Giesson (for elastin) or von Kossa (for calcium), are necessary.

Angioid streaks are often present on funduscopic examination at childhood or puberty but do not usually become symptomatic before the age of 40 unless there is significant trauma to the head. An elastic fiber-rich sheath behind the retina, Bruch's membrane, becomes progressively calcified, which causes fractures (angioid streaks) along which new fragile blood vessels form. Those rupture easily and lead to progressive impairment of visual acuity, primarily central vision loss. Other ocular manifestations include macular degeneration, optic drusen, and peau d'orange.

The most common cardiovascular symptom is intermittent claudication, which may be accompanied by absent palpable pulses. Another frequent association is with coronary artery disease and occasional early onset myocardial infarction. Hypertension resulting from renal artery stenosis, gastrointestinal bleeding and rarely intracranial aneurysms may occur. Cardiovascular manifestations are highly variable. Some of them are similar to those encountered in the aging population but tend to occur earlier in childhood or adolescence.

MOLECULAR BASIS OF PXE

Early genetic observations, including increased frequency of parental consanguinity, occurrence of the disease in multiple affected siblings with clinically normal parents, and the rarity of the disorder in successive generations, implied autosomal-recessive inheritance. Subsequently, however, the existence of autosomal-dominant variants was suggested. Furthermore, the genetic complexity has been compounded by indications that obligate heterozygous carriers in families with autosomal-recessive forms of PXE may show minimal manifestation of the disease.

The unifying diagnostic histopathological feature in PXE is calcification of pleiomorphic elastic structures in the skin. In addition to calcium deposition, there is an accumulation of a number of extracellular matrix components, including fibronectin and vitronectin as well as various proteoglycan/glycosaminoglycan macromolecules, in the lesional areas of the skin. Based on these observations, PXE was considered a prototype of connective tissue disorder with components of the elastic fibers serving as the candidate gene/protein systems. Uniformly, however, these candidate genes were excluded by genetic linkage analyses as the sites of mutations.

The molecular basis of PXE began to unravel in late 90s when several laboratories joined a coalition compiled by PXE International, a lay advocacy organization representing families with PXE and supporting research on this condition (*see* www.pxe.org). As a result of these efforts, the PXE gene was mapped by positional cloning approaches to the short arm of chromosome 16, and the critical interval was further narrowed to approx 500 kb within the chromosomal region 16p13.1. Examination of the human genome database revealed that this region contained four distinct genes with no apparent relation to the extracellular matrix of connective tissue in general or the elastic fiber system in particular. Subsequent sequencing of these four genes within the critical PXE interval resulted in identification of pathogenetic mutations in the *ABCC6* gene that encodes multidrug resistance associated protein 6, MRP6, a putative ATP-dependent efflux pump expressed at the basolateral membranes of hepatocytes and the proximal tubules in the kidneys. MRP6 is 45% homologous to the prototype protein within this family, MRP1, which is instrumental to cellular detoxification as well as chemotherapy resistance, properties not shared by MRP6. The protein is made up of three transmembrane domains and two nucleotide-binding folds that are located in the intracellular space (Fig. 106-2). Over 100 distinct mutations have been identified in the ABCC6 gene in patients with PXE. In addition to two recurrent mutations, R1141X and Del exons 23–29, which together account for about one-third of all mutant alleles, there is a spectrum of missense, nonsense and splicing mutations. Specifically, a number of missense mutations are predicted to interfere with proper function of the second nucleotide-binding fold. In vitro studies show that a synthetic glutathione conjugate can be exported through hepatocyte plasma membranes, and the transport ability of MRP6 is reduced by missense mutations in the second nucleotide-binding fold.

Although the exact pathomechanisms leading to PXE are not understood, one hypothesis suggests that PXE is a primary metabolic disorder. Accordingly, impaired excretion of an unidentified substance via urine or bile may lead to its reabsorption into the systemic circulation with subsequent damage to the elastic fiber network. Influx of calcium is a common phenomenon after trauma to elastic fibers as a secondary change. As a result of initial calcification, further fragmentation or disorganization of elastic fibers in the mid reticular dermis and the media of medium sized vessels as well as the fractures in Bruch's membrane behind the retina can occur. In the skin, this leads to inelasticity, loss of recoil and subsequent sagging. In the eye, neovascularization occurs at the sites of fracture, and these newly formed vessels are fragile and often rupture with trauma. In the arteries, alteration of elastic fibers leads to calcification of the elastic media and later the intima, which facilitates atherosclerotic peripheral vascular disease.

IMPLICATIONS OF MUTATION ANALYSIS IN PXE

Summary of the literature on the molecular genetics of PXE allows several conclusions. First, *ABCC6* appears to be the major, if not the exclusive, gene harboring mutations in different families with PXE. Although the overall mutation detection rate has been only 70–80%, there is no evidence of locus heterogeneity. It can be postulated that the reasons for the lack of detection of all putative mutations may be owing to large exonic deletions, splice-site mutations distant from the intron–exon junctions, or mutations in the regulatory sequences of the gene, possibilities that are not readily detectable by the mutation detection strategies in common use.

Second, some of the families examined consisted of affected individuals in two subsequent generations, a constellation suggestive

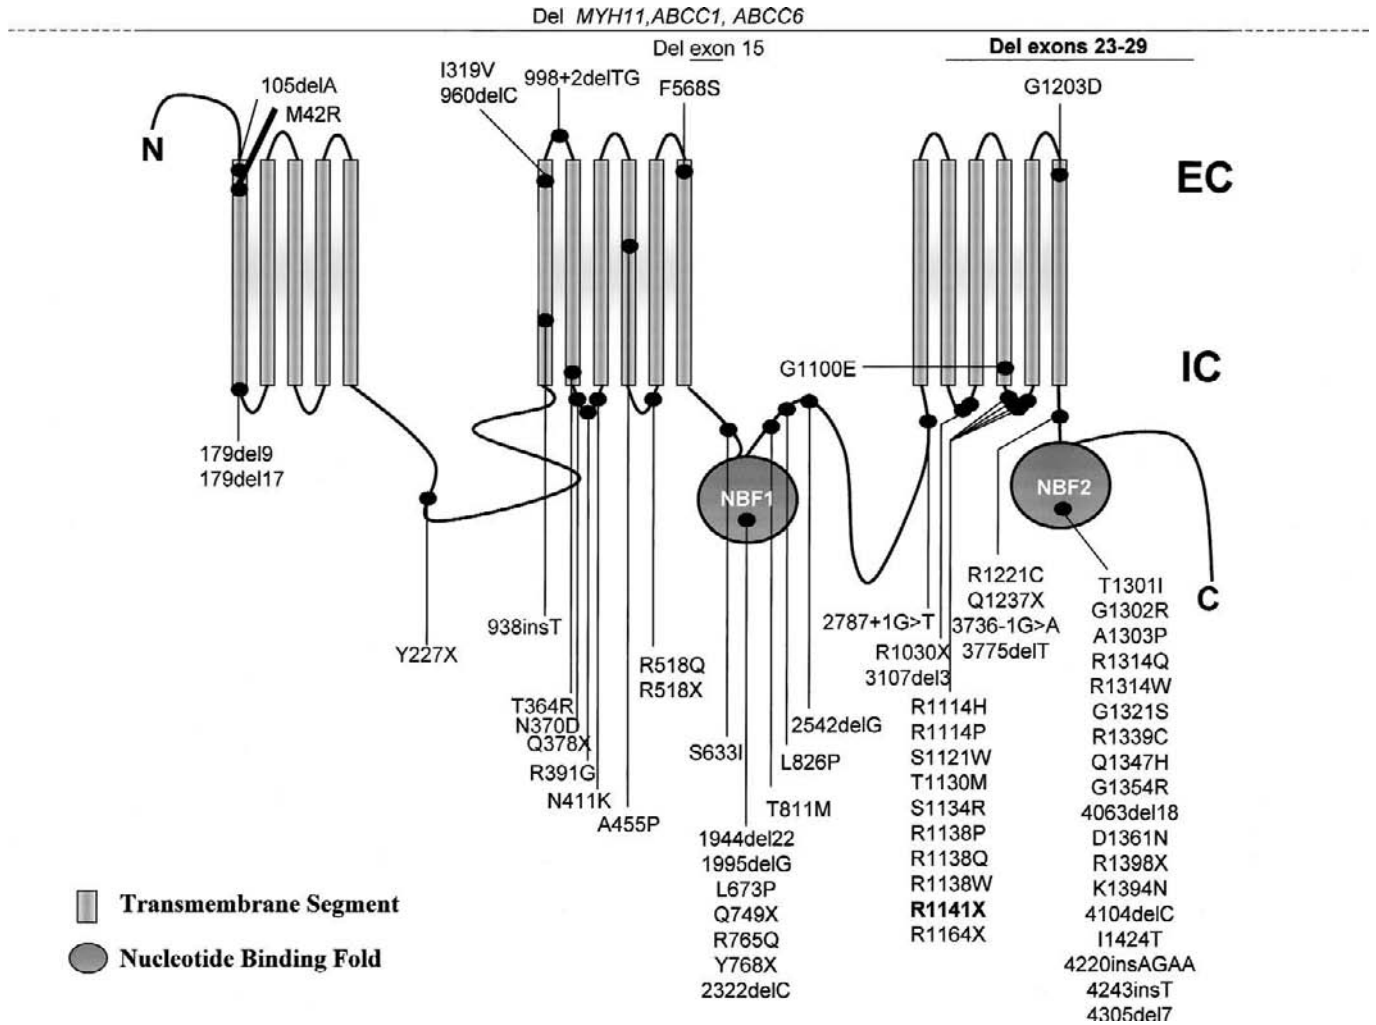

Figure 106-2 Schematic representation of MRP6, and an illustrative repertoire of pathogenic mutations identified in patients with pseudoxanthoma elasticum. Note that the protein consists of three transmembrane domains, comprising 5, 6, and 6 transmembrane segments, respectively. There are two intracellular nucleotide binding folds (NBF1, NBF2) critical for the ATP-dependent activity of the protein as a putative transporter molecule. Two recurrent mutations R1141X and Del exons 23-29, which account for up to one-third of all mutations disclosed thus far, are bolded. EC, extracellular; IC, intracellular space. (Modified from Ringfeil et al., 2001.)

of autosomal-dominant inheritance. However, molecular analysis found that the affected individuals were compound heterozygotes for mutations in both alleles of *ABCC6*. Thus in families with vertical inheritance of PXE in two generations, the clinical manifestations are from mutations in both alleles of the affected individuals, the pedigree structure being pseudodominant. Hence, there is no molecular evidence of an autosomal-dominant form of PXE, and the affected individuals harbor two mutations in the *ABCC6* gene, consistent with an autosomal-recessive inheritance pattern. This observation clearly has implications for genetic counseling of families at risk for recurrence of the disease.

Third, PXE demonstrates considerable intra- and interfamilial heterogeneity. For example, in some families the skin manifestations are prevalent with little eye involvement, whereas in other families ophthalmological findings and/or cardiovascular manifestations predominate. Attempts to delineate genotype/phenotype correlations, based on the known mutations in these families, have been unrewarding. Although environmental factors, hormonal status, diet, and cigaret smoking have been suggested to modify the phenotypic outcome in patients with PXE, the role of these factors, with the exception of smoking, is not clear. The findings suggest perhaps that the individuals' genetic background and the presence of modifier genes contribute to the overall severity of the phenotype.

Finally, identification of specific mutations in the families provides means of presymptomatic testing in individuals at risk for PXE and provides the basis for DNA-based prenatal testing and preimplantation genetic diagnosis, if desired.

107 Genetic Epidermal Diseases

Amy Stein and Lowell A. Goldsmith

SUMMARY

Profound changes in the epidermis occur associated with abnormal epidermal structural proteins and lipids. Abnormal suprabasal keratins cause blistering and scaling: epidermolytic hyperkeratosis. Other abnormal keratins are associated with marked deformed nails and prenatal teeth: pachyonychia congenita. Deficient transglutaminase an enzyme that cross-links epidermal proteins is associated with generalized scaling: lamellar ichthyosis. Males with deficient steroid sulfatase have associated brown epidermal scales. Defective fatty acid alcohol metabolism in addition to scaling has associated mental retardation and spastic diplegia: Sjogren-Larsson syndrome. Mutations in different calcium pumps are associated with scaling and sun sensitivity (Darier disease) or blistering especially in intertriginous areas (Hailey-Hailey disease). Connexins, when mutated, are associated with scaling of the skin and sometimes associated deafness.

Key Words: Cell envelope; connexins; Darier-White disease; epidermolytic hyperkeratosis; erythrokeratodermia variablis; Hailey-Hailey disease; harlequin ichthyosis; hidrotic ectodermal dysplasia; ichthyosis vulgaris; keratins; lamellar ichthyosis; Netherton's syndrome; pachyonychia congenita; Palmoplantar keratoderma; Sjogren-Larsson syndrome; trichothiodystrophy; X-linked ichthyosis.

INTRODUCTION

A large number of genetic defects, mediated through alterations of different biological molecules, affect the structure and function of the epidermis. Many of these diseases fit into classic clinical categories, which have been called ichthyosis, keratosis palmaris and palmaris for hundreds of years, or ectodermal dysplasias for many decades. The clinical classifications are still useful because they define the "forest" in which biochemistry and genetics identify the "trees."

Ichthyosis, derived from the Greek *ichthys*, fish, is not one disease but a heterogeneous group of skin disorders characterized by abnormal or altered epidermal differentiation (or cornification) resulting in generalized or localized scaly skin. Ichthyosis can present at birth or less frequently later in life. The disease can be limited to the skin or simultaneously involve internal organs, and phenotypically patients are similar despite different genotypes. These disorders have been classified clinically and histologically; the genetics and underlying pathophysiology allow better understanding and integration of genotype–phenotype relationships and development of novel therapies including targeting the mutated gene or resultant abnormal proteins.

PALMOPLANTAR KERATODERMA Palmoplantar keratoderma (PPK) is a heterogenous group of disorders characterized by hyperkeratosis or thickening of the palms and soles. The genetic mutations underlying many of these disorders have been elucidated. These genes encode structural proteins (including keratins and cornified cell envelope proteins), gap junction components, enzymes and desmosomal proteins.

CLINICAL PRESENTATION Age of onset, location and quality of scale, involvement of other areas of the body, family history, and histological features of the abnormal skin differentiate many of the different disorders of cornification and can focus the genetic testing. Specific diagnosis aids prognosis, treatment, and assessment of family members' risks of developing disease. Because of the frequent clinical heterogeneity and other variable factors that influence disease expression, precise diagnosis in some patients may be difficult.

PRENATAL DIAGNOSIS Molecular analysis of chorionic villus sampling or amniocentesis fluid can be done early in pregnancy when the given gene defect is known and the specific mutation is already identified in the family. Fetoscopy and fetal skin biopsy is rarely needed.

Prenatal diagnosis by mutational analysis has been successfully performed in epidermolytic hyperkeratosis (EHK), lamellar ichthyosis (LI) (transglutaminase 1 [*TGM1*]), Sjögren-Larsson syndrome (*fatty aldehyde dehydrogenase [FALDH]*), ichthyosis bullosa of Siemens (*K2e*), PIBI(D)S *(ERCC2/XPD, ERCC3/XPB)*, autosomal-recessive rhizomelic chondrodysplasia punctata (CDPX2) *(PEX7)*, X-linked CDPX2 (arylsulfatase gene cluster at Xp22) and Netherton's syndrome *(SPINK5)*. Sjögren-Larsson syndrome can be detected by measuring the FALDH enzyme activity in cultured amniocytes. The carrier status can be assessed for relatives with autosomal-recessive (AR) disorders with an identified mutation.

TREATMENT Therapies for the disorders of keratinization are symptomatic with the main goal of hydration, lubrication and desquamation (often incorrectly called keratolysis). Patients can thin some areas of hyperkeratosis with hydration followed by mild abrasives (sponges, buff puffs, or pumice stones). Humidifiers should be used in cold, dry environments. Patients need to avoid hot environments and moisten their skin to cool it to decrease heat stress associated with decreased sweating. Caution is advised with

widespread topical applications (i.e., salicylic acid) to prevent systemic toxicity owing to increased absorption secondary to the markedly abnormal barrier function. Nutrition is paramount as increased epidermal proliferation causes increased nutritional requirements. Percutaneous water loss can lead to increased caloric and protein requirements in childhood. A high degree of suspicion and subsequent treatment of secondary fungal infections is important; sometimes, the only sign is pruritus or a localized area of hair loss. Oral retinoids, usually necessary for years, can be particularly helpful in LI, bullous congenital ichthysiform erythroderma and erythrokeratoderma variablis (EKV), but the risks (including fetal abnormalities in pregnant women) vs the benefits need careful evaluation.

DISEASES WITH ABNORMAL STRUCTURAL PROTEINS

Disorders of two classes of structural proteins, the intracellular keratins—a large number of proteins within the intermediate filament suprafamily of proteins—and proteins composing the cell envelope, produce a variety of phenotypes that result in ichthyosis or keratoderma.

KERATINS

EHK/Bullous Congenital Ichthyosiform Erythroderma EHK is a rare disorder, occurring in 1/200,000– 300,000 births, with equal gender predilection. It is autosomal-dominant (AD) with up to 50% spontaneous mutations. There are reports of patients with EHK born to parents with linear epidermal nevi (hamartomas of the epidermis) along the lines of Blaschko, showing EHK on pathology and abnormal *K10* or *K1* expression. These epidermal nevi may represent somatic mosaicism for the gene for bullous congenital ichthysiform erythroderma.

At birth, EHK presents with generalized erythematous blisters, erythroderma, erosions, peeling, and some hyperkeratotic areas. These patients have an increased risk of cutaneous infections and sepsis. Over time, blister formation decreases but ichthyosis increases and becomes warty. These grayish brown verrucous scales often mainly involve the flexures and intertriginous areas. The hyperkeratotic areas have a corrugated pattern. Erythroderma lessens but remains throughout life. Patients often have a pungent odor resulting from colonization by *Staphylococcus* and fungi. EHK has striking clinical heterogeneity.

Although teeth, nails, and hair are usually normal, secondary alopecia may occur because of infection/hyperkeratosis, and heat intolerance is common. Palmoplantar hyperkeratosis is present in up to 60% of patients.

Mutations in K1 and K10, proteins that confer structural stability to keratin intermediate filaments in suprabasal keratinocytes, lead to keratinocyte fragility (particularly of the upper epidermis). There is increased epidermal proliferation. Many of the mutations are within residues of the highly conserved helical rod portions of the molecule responsible for intermolecular associations of the keratins.

Prenatal diagnosis is possible by direct DNA analysis of chorionic villus sampling or amniocentesis. Hyperkeratosis with lysis and tonofilament clumping in the granular layer is characteristic but not pathognomonic.

For newborns, monitoring of water/electrolyte balance and infection prevention is the primary approach.

Oral retinoids can be effective in decreasing the hyperkeratosis and rate of infection but caution is advised owing to the increased possibility of blistering. A mixture of 60% propylene glycol and water under plastic occlusion for 4–12 h several times weekly can be helpful. LacHydrin, 10% urea cream, 10% lactic acid in eucerin, glycolic acid lotions, topical Retin-A cream are also used. Soaks and gentle debridement of scale can aid patient comfort. Intermittent antibiotics (topical and oral) may be needed as bacterial infections are common and can lead to increased blistering.

Vorner's Syndrome (Diffuse Epidermolytic PPK) Vorner's Syndrome, also called diffuse epidermolytic PPK, has an AD inheritance. Disease presents at birth or during the first few months of life with well-demarcated, symmetric, yellowish thickening of the palms and soles with erythematous bases, and margins. Elbows and knees can be mildly involved. The skin is often described as having a "dirty" snake skin appearance. Occasional blistering on the hands and feet occurs. There are no associated internal manifestations.

Mutations in K9, a keratin specific to palmoplantar epidermis, have been identified. In addition, a K1 mutation has been reported in families with milder disease.

Biopsy of a weight bearing region on the thenar or hypothenar eminence reveals hyperkeratosis, acanthosis, papillomatosis, and epidermolysis in the spinous and granular cell layer.

Oral retinoids can be useful but can also lead to erosions. Topical therapies are often adequate.

Diffuse Nonepidermolytic PPK (Unna-Thost Disease) Diffuse nonepidermolytic PPK, also called Unna-Thost disease, is the most common inherited PPK. Its inheritance is AD with high penetrance and expressivity.

Patients present at birth or in infancy with well-demarcated, symmetric, often "waxy" appearing yellow thickening of the entire palms and soles with a sharp cut off at the wrist. Often there is a scleroderma-like constriction and tapering because of the skin thickening distal to the proximal interphalangeal joint. The dorsal hand is often affected. The fingernails have been likened to "parrot beaking" and display widening of the onychocorneal band. Marked hyperhidrosis is typical and secondary dermatophyte infection is frequent (reported in approximately one-third of patients). Hair and teeth are normal.

Mutations have been identified in an area on chromosome 12 containing a type-II keratin gene cluster. In addition, a mutation was detected in one family in the V1 region of K1, an area speculated to be involved in keratin–loricrin interaction.

Oral retinoids have favorable responses in some patients. Long-term systemic antifungals (i.e., itraconazole 100 mg daily) are useful when secondary dermatophyte infections occur. Topical salicylates are helpful.

Ichthyosis Bullosa of Siemens In ichthyosis bullosa of Siemens, inheritance is AD with variable expression between families. Similar to EHK, patients are usually normal at birth and in infancy, blistering occurs after minor trauma, usually localized to hands, feet and extensor arms, and legs. Blisters are usually small. Over time, patients develop dark brown hyperkeratosis primarily over the knees, elbows, dorsal wrists and hands, ankles and feet. About 50% have periumbilical hyperkeratosis. Many patients display characteristic erosion termed moulting/mausering (superficial shedding of the skin) given the higher level of epidermal involvement. There is no erythroderma.

Mutations in keratin 2e (type-II keratin cluster on12q11-13) expressed in the more superficial epidermis cause disruption of normal filament assembly. Emollients and keratolytics are used. The disorder is responsive to systemic retinoids.

Jadasshon-Lewandowsky Syndrome (Pachyonychia Congenita Type I) Pachyonychia congenita (PC) type-I inheritance is AD with more than 100 case reports described. The disorder

mostly involves plantar surfaces. Plantar calluses over pressure points form as late as 7 yr of age. Manual workers develop palmar calluses. Nail changes are present from birth to the first few months of life and are characterized by an upward "angulation" of the distal ends of all nails owing to wedge-shaped subungual hyperkeratosis. Paronychial infections occur in up to 70% of patients. Blistering may occur on the plantar surfaces. There are associated patchy or streaky thickened white areas of nonmalignant leukokeratosis of the mucous membranes. Follicular keratoses on the elbows, knees, and extensor extremities are seen.

Mutations occur in K6 and K16, keratins that normally are located in the palmoplantar epidermis, nail plate, hair follicle, sweat gland, oral mucosa, and larynx. K6 and K16 levels are increased in hyperproliferative epidermal cells such as occur in psoriasis.

Jackson-Sertoli Syndrome, and Jackson-Lawler PC (PC Type II) PC type II has AD inheritance. There are focal areas of often minor plantar keratoderma. Nail changes similar to PC type 1 are present at birth to the first few months of life. Multiple steatocystomas and epidermal cysts are seen. There is variable appearance of natal teeth but no oral lesions are seen. Some patients have been described with wooly or frizzy scalp hair and full eyebrows growing straight out.

Mutations occur in K6b and K17, keratins that are normally located in the outer root sheath of the hair follicle, nails, and basal layer of the palmoplantar epidermis. For mild cases, emollients and keratolytics are helpful. Retinoids have been used to improve the keratoderma and flatten the nails with some success.

CELL-ENVELOPE COMPONENTS

Lamellar Ichthyosis LI occurs in 1/300,000–500,000 births with an equal gender predilection. Almost all cases display an AR inheritance, although rare reports of AD transmission exist. At birth, patients' skin is erythrodermic and scaling; they often display ectropion and eclabium secondary to skin tautness. Affected infants often present with a *collodion membrane*, a translucent encasement. This membrane is taut and can interfere with respiration. It desquamates over the first 10–14 d of life, commonly leaving fissures and increasing the potential for dehydration, electrolyte imbalance, infection, and thermoregulation problems. They have large, dark, plate-like firmly adherent scales greatest over their lower extremities but also present in the flexures. Over time, the erythroderma fades in varying degrees but the scaling remains.

Patients may have mild or moderate PPK. There is no associated blistering, and lips and mucous membranes are usually spared. Teeth and nails are normal. Hair may appear thin, sparse, or absent (especially at the periphery) because of thick scale encasement. Patients are prone to secondary infections, especially fungal in origin. There is often associated heat intolerance because of thicker scales impairing the ability to sweat. Involvement is severe throughout life.

Mutations in *TGM1* have been identified in some families. This enzyme is important in the cornified cell envelope structure; mutations result in failure to properly crosslink cellular proteins, including involucrin, loricrin, and small proline-rich proteins. Transglutaminase also crosslink extracellular lipids, ceramides to cornified envelope proteins, particularly involucrin. There is increased epidermal proliferation. DNA analysis by sequencing confirms biopsy diagnosis in 70% of cases.

Lactic acid, urea, glycolic acid, calcipitriol, and tazarotene have been used topically. Systemic retinoids are used in severe cases. Typical collodion baby management should be implemented and includes monitoring of water/electrolyte loss and temperature. Newborns should be kept in a humidified incubator. Lubrication (wet compresses followed by bland emollients, i.e., Eucerin) of the membrane is important to help with desquamation. The patient should receive careful eye exams and may need artificial tears during the day and lubricants at night to avoid exposure keratitis. Overheating should be avoided.

Gottron's Syndrome (Symmetrical Progressive Erythrokeratodermia) Gottron's syndrome has AD inheritance with incomplete penetrance and variable expressivity. Up to 50% of cases are sporadic. This disorder is characterized by large, well-demarcated, fixed, symmetric, erythematous, hyperkeratotic plaques on the extremities, buttocks, and often on the face. Half of patients have palm/sole involvement. The trunk is usually spared. It appears shortly after birth, progresses slowly and then stabilizes in early childhood. Disease activity may decrease after puberty. There is a lack of variable, migratory erythema that is seen in EKV (discussed later). An insertional mutation has been identified in one family of loricrin (a cell envelope component). Standard keratolytics (lactic acid, glycolic acid, urea) are minimally effective. Psoralen ultraviolet A and oral retinoids may be useful.

Nonbullous Congenital Icthyosiform Erythroderma This disorder is considered to be a milder, erythrodermic variant of lamellar icthyosis. It occurs in 1/180,000–300,000 births. Incidence is equal in males and females. AR inheritance is displayed. Disease is apparent at birth with a common collodion membrane presentation. After shedding, the skin usually remains red, with generalized, fine, white scale. Generalized involvement of the face, palms, soles, and flexures occurs, but the mucous membranes are usually spared. There is minimal to no ectropion, eclabium, or alopecia.

Heat intolerance, owing to hypohidrosis from sweat duct obstruction by the hyperkeratosis, varies. Secondary dermatophyte infections of the skin and nails are common. The disorder is usually persistent but may improve after puberty.

A subset of patients with mutations in TGM1 has been identified. Two siblings with a defect in loricrin, a cornified cell envelope protein have been examined. Increased epidermal proliferation is a feature. Owing to increased epidermal proliferation, patients should be monitored for anemia and treated with iron if deficient. Simple emollients are useful. It is important to maintain a humid environment and monitor fluid and electrolytes.

DISEASES OWING TO DEFECTIVE CONNEXINS

Connexins are a family of proteins that aggregate and form intercellular gap junctions, important channels spanning the cell membrane between adjacent cells enabling cell–cell signaling. A gap junction is made up of two adjoining connexins on adjacent cells. This intercellular communication is vital for maintaining tissue homeostasis, growth development and control, as well as regulated cell response to stimuli.

Connexins 26, 30, 31 are found in stratified epithelia of the cochlea and epidermis; abnormalities can result in sensorineural deafness and/or skin disease. Connexin mutations have been identified in patients with EKV, deafness, and peripheral neuropathy, as well as Vohwinkel's syndrome and hidrotic ectodermal dysplasia (discussed later). Because connexin 26 is the predominant connexin in cochlear cells, these mutations are the leading cause of nonsyndromic AR hereditary hearing loss.

ERYTHROKERATODERMIA VARIABLIS, MENDES DE COSTA TYPE ERYTHROKERATODERMIA EKV is rare; approx 150 cases have been reported. It has AD inheritance with

variable expression and equal gender predilection. EKV usually presents at or shortly after birth and progresses until puberty. Two skin changes, usually involving the face, extensor extremities, trunk, buttocks, axilla, and groin, predominate: (1) migratory, sharply demarcated erythematous patches of varying shapes and sizes (few to many cm) that last for minutes to months and may be triggered by trauma and change in temperature, and (2) hyperkeratotic, sharply demarcated and often polycyclic, usually fixed plaques with a yellow–brown–gray scale.

Keratoderma of palms and soles and hyperhidrosis may occur. Hair, nail, and mucous membranes are normal.

Mutations have been found in *GJB3* (the gene encoding connexin 31) and *GJB4* (the gene encoding connexin 30.3), resulting in abnormal intercellular communication. Pathological changes include retention hyperkeratosis with normal epidermal proliferation. Isotretinoin and acitretin have resulted in complete clearing of the hyperkeratotic plaques and partial clearing of the erythematous patches. However, patients often relapse when off treatment.

KERATITIS-ICHTHYOSIS-DEAFNESS (KID) SYNDROME CONGENITAL ICHTHYOSIFORM SYNDROME WITH DEAFNESS AND KERATITIS Inheritance of keratitis-ichthyosis-deafness (KID) syndrome is most consistent with sporadic AD, but cases of AR inheritance have been suggested. It has equal gender predilection. Presenting at birth, patients have keratitis (with progressive corneal opacification), icthyosis, and deafness (most with severe neurosensory loss). Well-demarcated, orange to erythematous, keratotic, spiny plaques appear on the face and extremities more than the trunk. There is variable mild generalized hyperkeratosis.

Prominent follicular hyperkeratosis can cause scarring alopecia of the body, scalp, eyelashes, and eyebrows. Nails and teeth may be abnormal. Patients have increased risk of bacterial, viral, and fungal infections. PPK develops with a reticulated appearance resembling grained leather. Some patients experience hypohidrosis owing to occlusion. Dominant mutations have been discovered in *GJB2* (the gene encoding connexin 26) leading to disruption of intercellular signaling.

Unlike patients with other disorders of keratinization, these patients rarely benefit and may even worsen (i.e., corneal neovascularization) with systemic retinoids. Topical antibiotic therapy is often necessary and helpful. Patients should be referred to an ophthalmologist and otolaryngologist for frequent eye and audiological assessment and treatment of deficits (i.e., hearing aids, cochlear implants).

VOHWINKEL'S SYNDROME (KERATODERMA HEREDITARIA MUTILANS) Vohwinkel's syndrome, a rare disorder with AD inheritance, may be more frequent in females and whites.

Diffuse, honeycombed palmoplantar hyperkeratosis develops in early infancy. Patients often develop flexion contractures and constricting bands of the digits, especially the fifth digit, resulting in spontaneous autoamputation (pseudoainhum). The dorsal hands, fingers, and toes develop characteristic "starfish" keratoses; the extensor surfaces of the knees and elbows display linear keratoses. There is often associated mild to moderate, nonprogressive high-frequency sensorineural hearing loss. There are descriptions of nail changes, alopecia, onychogryphosis, spastic diplegia, and myopathy in some cases.

Mutations in connexin 26 are characteristic in the classic form of Vohwinkel's syndrome. Mutations in loricrin have been found in a patient with Camisa disease, a form of Vohwinkel's with normal hearing and diffuse, generalized ichthyosis associated with mutilating keratoderma.

Characteristic hyperkeratosis and "round" retained nuclei with hypergranulosis is seen on pathology. Oral retinoids are helpful for the keratoderma and pseudoainhum. Patients should have audiological testing.

PPK WITH DEAFNESS PPK presents in mid childhood and patients may also have involvement of the elbows and knees. Progressive sensorineural hearing loss presents at birth or infancy and may result in complete deafness.

There is an AD form that also has an associated connexin 26 mutation. Mutations in a mitochondrial gene encoding a mitochondrial serine tRNA (whose role is to add serine to protein chains during mitochondrial protein synthesis) have been identified.

Variable success has been reported with oral retinoids. Topical therapies used include saline compresses followed by gentle debridement and 60% propylene glycol in water under plastic occlusion overnight weekly. Hidrotic ectodermal dysplasia, owing to connexin mutations, is discussed later.

DEFECTS OF LIPID METABOLISM

X-LINKED ICHTHYOSIS (STEROID SULFATASE DEFICIENCY) X-linked ichthyosis occurs in 1/2000–9500 male births. It has an X-linked recessive inheritance, and thus is transmitted only to males by heterozygous normally appearing females. Patients have large, yellow-brown, firmly adherent scales on all body surfaces involved except the face, palms, and soles. The antecubital and popliteal fossae are relatively spared. The disorder is often regarded as the "dirty-neck disease" because of the clinical appearance of scale and the invariable lateral neck involvement. Skin peeling may occur within the first few days of life and is most apparent on extensor surfaces, although flexural areas are also involved. After this desquamation, disease is often not again apparent until 3–6 mo of age. Most female carriers exhibit minimal to no cutaneous changes. There is a seasonal variation but no improvement with age.

There is no associated keratosis pilaris or increased risk of atopy. Asymptomatic, diffuse corneal opacities in the posterior capsule or Descemet's membrane are seen on slit-lamp examination in 25–50% of males and some female carriers. Approximately one-third of patients are born after a pregnancy characterized by failure of spontaneous initiation or progression of labor; this results in postterm delivery and is because of the absence of placental sterol sulfatase. Cryptorchidism occurs in up to half of patients and there is an increased risk of testicular cancer independent of cryptorchidism.

In more than 80% of patients, there is a gene deletion at the STS locus on the short arm of the X-chromosome. Steroid sulfatase is one of a group of aryl sulfatases and its deficiency leads to an inability to hydrolyze cholesterol sulfate, causing an accumulation of cholesterol sulfate with a concomitant decrease in cholesterol and abnormal cornification; in addition, maternal urinary and serum estrogens are decreased. The disorder is characterized as a retention hyperkeratosis with normal epidermal proliferation.

Pedigree and clinical characteristics are usually sufficient to make a diagnosis. The disease is usually not severe enough to require prenatal diagnosis. Cholesterol sulfate levels are increased in serum, epidermis and scale. A diagnostic clue is increased motility of β-lipoproteins (low-density lipoproteins) on electropheresis. However, confirmation of the diagnosis requires an increased cholesterol sulfate level of serum, erythrocyte membranes and keratin. Decreased enzyme activity can be demonstrated in fibroblasts, keratinocytes, leukocytes, and prenatally in amniocytes.

Topical keratolytics (urea and lactic acid creams) or 60% propylene glycol under plastic occlusion overnight weekly are often helpful (earlier in treatment course, may require 5–7 nights/wk to remove excess scale). Testicular self-exam should be performed and patients should be referred to urologists when necessary.

KALLMAN'S SYNDROME Kallman's syndrome is characterized by anosmia (secondary to absence of olfactory lobe formation) and hypogonadotropic hypogonadism. Several patients have been found to demonstrate a contiguous gene syndrome that involves a number of nearby gene loci, including that of steroid sulfatase. As a result, these patients have X-linked recessive ichthyosis.

CHONDRODYSPLASIA PUNCTATA CDPX2 is a group of diverse diseases sharing common skin changes and congenital stippled epiphyses and skeletal alterations that affect growth. AR, X-linked dominant and X-linked recessive forms exist.

CONRADI-HUNERMANN-HAPPLE SYNDROME (LINKED DOMINANT CDPX2) Conradi-Hunermann-Happle syndrome is the most common form of CDPX2 seen by dermatologists. It presents in a mosaic pattern in females. Cutaneous changes are seen in almost all patients. At birth, patients exhibit icthyosiform erythroderma or a collodion membrane, which is replaced with linear hyperkeratosis or fine scale, follicular atrophoderma, pigmentary changes and variable hair problems usually along Blaschko's lines. Affected individuals may have asymmetric, mild lower extremity shortening. Stippled calcifications may no longer be present after puberty. Congenital, asymmetric cataracts occur in approximately two-thirds of patients.

CDPX2 may show anticipation, with increasing disease severity in successive generations. Mutations have been identified in a gene encoding emopamil-binding protein.

The disorder usually requires no treatment owing to resolution of the icthyosis over the first year. If any treatment is necessary, emollients are appropriate. Ophthalmology and orthopedics referrals are warranted.

RHIZOMELIC CDPX2 (PEROXISOMAL BIOGENESIS DISORDER COMPLEMENTATION GROUP 11) Rhizomelic CDPX2 is an AR, rare multisystem disorder characterized by rhizomelia (symmetric and severe dwarfism), stippled calcifications in cartilage because of premature calcification, joint contractures, congenital cataracts, severe mental retardation, and ichthyosis (in 25%, appearing as a fine "feather-like" scaling).

Mutations have been found in *PEX7*, a gene encoding Peroxin 7, a receptor that enables enzymes to function in the peroxisome. This leads to decreased levels of RBC plasmalogens and buildup of phytanic acid over time. Phytanic acid increases are characteristic of Refsum's disease.

REFSUM'S DISEASE (HEREDOPATHIA ATACTICA POLYNEURITIFORMIS, PHYTANIC ACID STORAGE DISEASE) Refsum's disease is a rare disorder with approx 100 cases reported, mostly in Scandinavians and people from Northern Europe. It has equal gender predilection and AR inheritance. Patients usually present in the first two to three decades with peripheral neuropathy, cerebellar ataxia, increased CSF protein, cranial nerve abnormalities (sensorineural deafness, tinnitus, and anosmia), retinitis pigmentosa with salt and pepper pigmentation, night blindness, miosis, ECG abnormalities, cardiomyopathy, renal tubular abnormalities, epiphyseal dysplasia, and other skeletal abnormalities. Variable ichthyosis, most similar to ichthyosis vulgaris, develops in adulthood after the eye and nervous system changes occur.

Mutations in *PAHX* (a gene encoding phytanoyl-CoA hydroxylase) and *PEX7* gene have been found, leading to deficiency in phytanoyl-CoA hydroxylase, a peroxisomal protein that catalyzes the oxidation of phytanic acid. As a result, there is an accumulation of phytanic acid in serum and tissues and replacement of the normal fatty acids in epidermal lipids and other body tissues. Phytanic acid is a fatty acid found in different dietary products including dairy sources, ruminant fats, and green vegetables. Increased epidermal turnover occurs as well. There are increased levels of plasma phytanic acid and lipid vacuoles in the basal and suprabasal layers of the epidermis.

Treatment consists of dietary restriction of foods containing phytanic acid and its precursors (green vegetables and animal fat) to less than 5 mg/d. Plasmapheresis and lipapheresis rapidly decreases phytanic acid levels. Therapy can arrest progression of skin and cardiac changes as well as neuropathy, but retinitis pigmentosa and hearing loss continues. Patients should be referred to a nutritionist, neurologist, cardiologist, ophthalmologist, and dermatologist.

X-LINKED RECESSIVE CDPX2 Skin changes are multiple: erythroderma, possible remnants of collodion membrane, whorled or linear atrophic or icthyosiform hyperkeratosis and follicular atrophoderma. Hair is often sparse, coarse, wiry, and lusterless; some patients develop scarring alopecia. Skeletal abnormalities observed include short stature and vertebral coronal clefting. Cataracts and deafness also occur.

A deletion has been detected in a gene encoding steroid sulfatase on Xp22. In addition, mutations in *ARSE* have been identified in five patients.

SJÖGREN-LARSSON SYNDROME Sjögren-Larsson syndrome is rare, with approx 200 cases reported. Inheritance is AR. At birth, patients display fine to generalized scaling. Erythema, if present, fades and is no longer present by 1 yr of age. Generalized ichthyosis with characteristic velvety orange or brown lichenification of the lateral and posterior neck, lower abdomen, and flexures is often present. The central face, scalp hair, and nails are usually spared. Patients often complain of intense pruritus, although sweating is normal. Spastic diplegia or tetraplegia with a scissor gait and mild to severe mental retardation (+/–grand mal seizures and altered speech) develop during the first 2–3 yr of life. Many patients are wheelchair bound by adolescence. Glistening white dots can be seen in the macula of the retina in 50–80% of patients after age 1 and are characteristic eye findings.

The defect leads to an accumulation of long chain fatty alcohols because of a deficiency in a *FALDH* gene, which codes for a microsomal enzyme that catalyzes the oxidation of medium and long-chain aliphatic aldehydes generated from the metabolism of fatty alcohol, phytanic acid, ether, glycerolipids, and leukotriene B4.

On electron microscopy (EM), epidermal cells display prominent golgi apparatus and increased density of mitochondria. In addition, there are abnormal lamellar inclusions in the cytoplasm of corneocytes. Dietary restriction of long chain fatty acids may help. Emollients and keratolytics can be useful. Patients should be referred to a nutritionist, neurologist and opthalmologist.

CHILD SYNDROME (CONGENITAL HEMIDYSPLASIA WITH ICHTHYOSIFORM ERYTHRODERMA AND LIMB DEFECTS) CHILD syndrome is apparent at birth. Inflammatory hyperkeratotic plaques with sharp midline demarcation and minimal contralateral involvement in a linear or segmental pattern are seen. The limb defects are ipsilateral to the ichthysosis and range from digital hypoplasia to complete absence of an extremity. There is variable internal involvement of the musculoskeletal, cardiovascular, central nervous system, renal, and genitourinary systems.

Mutations in two peroxisomal genes involved in cholesterol biosynthesis have been described. These genes encode emopamil binding protein (EBP) (3β-hydroxysteroid-δ-8-δ-7-isomerase) and NSDHL (NAD(P)H steroid dehydrogenase-like protein encoding a 3β-hydroxysteroid dehydrogenase).

Lyonization may occur producing a clinical pattern involving Blaschko's lines.

Treatment consists of referral to a dermatologist for topical treatment (although disease is difficult to control with the usual agents) and to an orthopedist and organ-specific specialist depending on internal organ involvement. CT/MRI should be performed on the side ipsilateral to the icthyosis.

CHANARIN-DORFMAN SYNDROME (NEUTRAL LIPID STORAGE DISEASE) Chanarin-Dorfman syndrome is rare; approx 30 cases, mainly from the Mediterranean, have been reported. Patients appear most similar to those with nonbullous congenital ichthyosiform erythroderma. They display generalized, fine white-gray scaling with varying degrees of erythema. At birth, affected individuals often present as a collodion baby with ectropion and eclabium. Variable, progressive extracutaneous disease develops later and includes cataracts, neurosensory deafness, psychomotor retardation, myopathy with elevated muscle enzymes, and abnormalities of the nervous system.

A mutation has been identified in *CGI-58* gene in nine families. CGI-58 is a member of a large group of proteins, mostly enzymes with unknown functions, but defects result in an alteration in the rates of synthesis and degradation of the major cellular phospholipids. Triglycerides accumulate in the cytoplasm of leukocytes, muscle, liver, fibroblasts, and other tissues in affected individuals. However, serum lipid levels are normal.

Peripheral blood smear demonstrates lipid vacuoles within granulocytes, eosinophils, monocytes, dermal cells, keratinocytes, and acrosyringia in patients and sometimes in carriers. On EM, electron lucent nonmembrane bound lipid droplets may be identified. Dietary intervention and keratolytics are the mainstays of treatment.

DISORDERS OF CALCIUM METABOLISM

DARIER-WHITE DISEASE (KERATOSIS FOLLICULARIS) Darier-White disease (DWD) has an AD inheritance with a high penetrance. The prevalence ranges from 1 in 50,000–100,000 individuals.

DWD is characterized by abnormal keratinization of the epidermis, nails, and mucous membranes. It usually begins in the first or second decades, often around puberty. There are multiple yellowish tan-brown greasy and pruritic papules on the nasolabial folds, forehead, scalp, chest, back, ears, and groin; these may coalesce into large, warty, malodorous plaques. The hair is intrinsically normal but there may be an abnormality resulting from the thick scale and crust. Punctate keratoses (raised or depressed) occur on the palms and soles. Nails are thin and may display a characteristic V-shaped scalloping and subungual thickening, longitudinal ridges, and red and white longitudinal bands. White, centrally depressed papules resembling cobblestones can be seen on the buccal mucosa, cheeks, hard and soft palate, and gums (larynx, esophagus, and rectum in rare cases). Patients display discrete hyperkeratotic papules on the dorsal hands and feet.

Disease activity frequently worsens with heat and humidity, ultraviolet B light, mechanical trauma, and lithium. Frequent bacterial and generalized herpes simplex infections can occur, but no immune abnormalities have been consistently reported. Recurrent parotid gland swelling often occurs from squamous metaplasia of the lining leading to obstruction. Affective disorders and diminished intelligence have been reported. There is a variant of DWD described with hemorrhagic macules and vesicles often in an acral distribution.

Multiple mutations (missense, alternative splicing, deletions, insertions, frameshift, and premature codon mutations) of the Ca^{2+}-ATPase isoforms (*SERCA2* and *SERCA2b)* have been identified. In contrast to the usual situation with enzyme defects in which the heterozygote is usually clinically normal, DWD exhibits haploinsufficiency whereby a deficiency of one copy of a gene leads to a genetic disease. This implies that the ATPases involved are not present in great quantities such that an insult (i.e., ultraviolet B or heat/humidity) on 50% the normal amount of enzyme results in phenotypic abnormalities.

Patients should wear sunscreens and avoid mechanical triggers. Topical (tazarotene, adapalene) and systemic (acitretin, isotretinoin) retinoids have been useful. Antibiotics are necessary for infections that cause disease exacerbations. Dermabrasion, lasers and surgical excision, and grafting have been utilized for hypertrophic lesions.

HAILEY-HAILEY DISEASE (BENIGN FAMILIAL PEMPHIGUS) Hailey-Hailey disease is of AD inheritance with variable penetrance. There is an equal gender distribution. Onset of disease is typically in the third to fourth decades. Patients develop flaccid blisters on an erythematous background; on presentation, these most often appear as fissured plaques in the axillae, groin, inframammary region, neck, and antecubital and popliteal fossae. Activity is often precipitated by friction, heat, and infection. The nails may have longitudinal white streaks.

Patients complain of severe pain, itching, and odor owing to the lesions. There are no extracutaneous manifestations and the disease generally becomes less problematic with time. A mutation has been described in *ATP2C1*, a gene that encodes an adenosine triphosphate-calcium pump in the golgi apparatus. It results in abnormal adhesion and acantholysis.

Topical (tetracyclines, fusidic acid, imidazoles) and oral (tetracyclines) antimicrobials are useful in some patients. Topical steroids can occasionally provide relief. Methotrexate and systemic retinoids have been used in recalcitrant disease.

One patient had brown papules characteristic of Darier's disease on the central chest and flanks as well as linear erosions and maceration in the axillae, groin and suprapubic region typically observed in Hailey-Hailey disease, which may imply that the signaling is not exclusive. This patient's particular mutation has not been characterized, but there may be a motif on the affected proteins that determines the final destination in the endoplasmic reticulum (as in Darier's) or the golgi (as in Hailey-Hailey); perhaps there is an enzyme in both locations such that the patient has both disorders.

OTHER MECHANISMS

NETHERTON'S SYNDROME (ICHTHYOSIS LINEARIS CIRCUMFLEXA) A rare disorder of AR inheritance, Netherton's syndrome is mainly described in case reports. Its incidence is estimated at 1/100,000 births.

Ichthyosis linearis circumflexa is characterized by the coexistence of ichthyosis, structural hair shaft abnormalities and atopy. It may present as a collodion baby or with generalized erythroderma at or around birth. Ichthyosis linearis circumflexa develops and is characterized by migratory, polycyclic and serpiginous plaques of erythema with a double-edged scale at the periphery; this usually does not occur until age two.

Affected individuals often have lichenification over popliteal and antecubital fossae and often complain of pruritus. There is often thick seborrheic dermatitis-like scaling on the scalp, eyebrows, and face. The hair is thin, slow growing, lusterless and fragile; the classic finding is trichorrhexis invaginata ("ball and socket" where the distal hair segment intussuscepts into the proximal part) or bamboo hairs from abnormal cornification of the internal root sheath. Trichorrhexis nodosa and pili torti can also be seen on examination of the hair shafts.

Atopy, manifested by atopic dermatitis, urticaria, and angioedema (especially to nuts and fish) and/or asthma, is a key component. Hypernatremia and dehydration can occur, secondary to transepidermal water loss in the neonatal period. Eosinophilia and increased IgE levels are often seen. There is mild to severe intellectual impairment. Patients are often of short stature and display failure to thrive in approximately one-third of cases. Recurrent skin and lung bacterial and candidal infections are often a problem. There have been early reports of patients with generalized aminoaciduria.

Mutations have been identified in *SPINK5*, a gene encoding lympho-epithelial-kazal-type related inhibitor, a serine protease inhibitor that may be involved in dampening the inflammatory response.

In the neonatal period, fluid and electrolyte support and monitoring for infections is of utmost importance to prevent dehydration. Treatment has included emollients for mild disease. There is an increased risk for systemic toxic effects with tacrolimus ointment and generalized topical steroids. Referral to an allergist for RAST testing may be appropriate.

TRICHOTHIODYSTROPHY (TAY'S SYNDROME AND IBIDS) Etymology of trichothiodystrophy reveals that tricho refers to hair, thio to sulfur, dys means faulty and trophy means nourishment. A rare syndrome of AR inheritance, less than 100 cases have been reported. Males and females are affected equally.

IBIDS refers to ichthyosis, brittle hair, intellectual impairment, decreased fertility, and short stature. At birth, patients may have a collodion membrane, but redness fades and a generalized ichthyosis develops varying from fine, translucent scaling to large, dark yellow–brown hyperkeratosis. The flexures may be spared. Patients may have irregular nails and PPK. Hypogonadism is manifested as cryptorchidism in males and impaired sexual maturation in females. There is an increased risk of infections. Scalp hair, eyelashes, and eyebrows are short, sparse, and brittle. Examination of hair shafts under light microscopy reveals trichoschisis (transverse fractures), pili torti, or trichorrhexis nodosa (transverse, frayed fractures). Under polarized light, the hair shaft has a tiger tail appearance with alternating light and dark bands. There is an abnormally low (<50% of normal) sulfur content in the hair. Some patients have been reported to have eczema, severe nail abnormalities, palmoplantar hyperkeratosis, and flexion contractures.

A spectrum of related syndromes is described with variable involvement of different systems. For instance, Tay's syndrome and photosensitivity is known is PIBI(D)S syndrome. These patients have mild, noncongenital ichthyosis. They usually lack hypogonadism and do not have an increased risk of skin cancer.

Mutations in the basal transcription factor TFIIH have been identified. It plays a role in the nucleotide excision repair of ultraviolet-induced damage (identical to xeroderma pigmentosa [XP] Group D but without cancers). Mutations have been found in *XP group D helicase gene (ERCC2/XPD)* and *XP Group B helicase gene (ERCC3/XPB)*. Amino acid analysis and microscopic evaluation of hair, DNA studies and phototesting can aid in the diagnosis.

Emollients and photoprotection are treatment approaches. Patients should be referred to dermatologists and other specialists based on symptoms and organ involvement.

PROTEOLYTIC ENZYME DEFECTS

PAPILLON-LEFEVRE SYNDROME (PPK WITH PERIODONTITIS) Papillon-Lefevre syndrome is of AR inheritance. There is an estimated prevalence of 1 in 4,000,000 and an equal gender distribution. In the first few months of life, patients develop symmetric involvement of palms and soles with punctiform accentuation especially along the palmoplantar creases. The dorsal hands, posterior heels including the Achilles tendon, elbows, and knees are involved occasionally. Severe periodontitis of primary and secondary dentition begins at 2–3 yr of age and is accompanied by generalized whitish discoloration of the oral mucosa, which resolves after all teeth are shed. An increased frequency of skin and systemic infection is reported.

There are reports of transverse grooves in nails, onychogryphosis, follicular hyperkeratosis, and hyperhidrosis. Calcification of the falx cerebri and choroid plexus is common and increases with age.

A mutation in the gene encoding a lysosomal protease cathepsin C has been identified. Cathepsins are thought to mediate enzymes integral in the formation and degradation of the cornified cell envelope.

Retinoids have been helpful for the PPK and periodontitis. Elective extraction of the affected teeth may prevent increased alveolar bone resorption. Antibiotics may be needed for recurrent infections.

DISEASES OWING TO SECRETED PROTEINS

MAL DE MELEDA (KERATODERMA PALMOPLANTARIS TRANSGRADIENS, ACROERYTHROKERATODERMA) Mal de Meleda is marked by AR inheritance. Most cases originate in the island of Meleda in the Adriatic Sea or southern Italy. At birth or early infancy, redness of the palms and soles develops and progresses to a diffuse, symmetric thickening that spreads to the dorsal hands and feet in a "glove and stocking" distribution. Knuckles, knees, and elbows can be affected. Constricting bands (pseudoainhum) around the digits leading to autoamputation have been described in a few patients.

Nail changes include koilonychia, subungual hyperkeratosis, longitudinal grooving, and onychogryphosis. Angular cheilitis and perioral erythema have occurred in some patients. Hyperhidrosis with bromhidrosis is a complaint occasionally. EEG abnormalities have been reported.

Mutations in the gene encoding SLURP1 (secreted mammalian Ly-6/uPAR-related protein 1) have been identified. SLURP1 is a secreted protein thought to be involved in cell adhesion and signaling.

Retinoids are helpful for the keratoderma and pseudoainhum but not the erythema. If there is no relief, surgery may be necessary to relieve the constriction.

RECENT FINDINGS

ICHTHYOSIS VULGARIS Ichthyosis vulgaris is the most common inherited disorder of cornification. It has AD inheritance with variable expression and equal gender distribution. Incidence is as high as 1 in 250 (to 1/2000).

Ichthyosis vulgaris often becomes clinically apparent within the first year (usually 3–12 mo) as mild to moderate scaling primarily involving extensor surfaces with sparing of flexures and the neck. Scale may be centrally attached but turned up at edges. Facial involvement is common, but legs are often the most severely involved. This disorder improves with age and in warmer, humid environments.

Keratosis pilaris is common. Hyperlinear palms/soles may be seen, but there is no underlying erythroderma. Up to 50% of patients have atopy (hayfever, asthma, eczema, or urticaria).

Molecular origin of ichthyosis vulgaris is unknown. There is decreased to no filaggrin and its precursor, profilaggrin. Filaggrin is an epidermal protein localized to keratohyaline granules important in the aggregation of keratin intermediate filaments. Recent finding implicate loss-of-function mutations in filaggrin. Homozygous mutations and compound heterozygotes were identified and 4% of Europeans had mutant alleles.

Biopsy reveals mild hyperkeratosis and an absent granular layer. On EM, there are small, poorly formed keratohyaline granules. Simple emollients (especially Vaseline after epidermal hydration) or those with alpha hydroxy acids or urea are helpful. The associated eczema requires treatment as well as the ichthyosis.

HARLEQUIN ICHTHYOSIS Harlequin ichthyosis occurs in less than 1 in 300,000 individuals. It has equal gender predilection and is most likely a heterogeneous mode of inheritance; AR and X-linked recessive reports exist, but most cases are sporadic.

Harlequin ichthyosis presents as massive, shiny, thick plates of red fissuring and cracking scale with sausage-like encasement of hands and feet, ectropion, and eclabium. Ears are deformed or absent; the nasal tip is flattened with eversion of nares. Mortality is high within the first few days to weeks and is usually from respiratory and feeding problems owing to severe constriction from the encasement. Eyebrows and eyelashes are usually absent. Patients are frequently premature. Those that survive the neonatal period usually display the phenotype of severe congenital ichthysiform erythroderma. A skin biopsy at 20–22 wk demonstrates premature keratinization. EM demonstrates an absence of lamellar bodies. Mutations in *ABCA12* cause the disease.

Etretinate (approx 1 mg/kg/d) and isotretinoin treatment within the first few days of life has been associated with desquamation of the membrane and subsequent survival in reported patients. Patients require close monitoring of fluid and electrolytes, temperature regulation, and signs/symptoms of infection.

ECTODERMAL DYSPLASIA

Ectodermal dysplasia is used to describe a diverse group of disorders characterized by aberrant development of the epidermal appendages or oral mucosa (hair, sebaceous glands, teeth, nails, or mucosal glands). Recalcitrant atopic dermatitis is common. Hypohidrotic ectodermal dysplasia, anhidrotic ectodermal dysplasia, Christ-Siemens-Touraine syndrome is discussed in Chapter 101.

CLOUSTON SYNDROME (HIDROTIC ECTODERMAL DYSPLASIA) Clouston syndrome is characterized by AD inheritance with variable penetrance. There is an equal gender distribution.

Hidrotic ectodermal dysplasia is marked by defects of the hair and nails and PPK. The scalp hair is patchy, wiry, brittle, and pale. Over time, this may result in complete alopecia of the scalp, body, and face. In infancy and early childhood, the nails may be white. Eventually, they may thicken and become dystrophic or absent. Nail plates are thick, short, slow growing, and onycholytic. Persistent paronychial infections are common.

Progressive palmoplantar thickening is frequent. Of note, sweating and teeth are normal.

Conjunctivitis and blepharitis, possibly secondary to lack of protection from eyelashes, occur. Patients have normal facial features.

Mutations in *GJB6* or *connexin 30* gene have been reported. Patients occasionally undergo nail matrix ablation for palliation. Wigs are often beneficial for cosmetic purposes.

AEC SYNDROME (ANKYLOBLEPHARON FILIFORME, ADENATUM-ECTODERMAL DEFECTS, CLEFT LIP AND/OR PALATE SYNDROME/HAY WELLS SYNDROME)

Ankyloblepharon Filiforme Adenatum-Ectodermal Defects, Cleft Lip and/or Palate Syndrome is associated with AD inheritance with complete penetrance and variable expression. At birth the condition resembles epidermolysis bullosa or congenital ichthyosis with erythematous, fissured, peeling skin, and superficial erosions. This sheds in 1–2 wk, leaving dry, thin skin. The scalp is almost always involved, often with chronic, erosive crusting dermatitis with granulation tissue. Recurrent bacterial infections are common. There may be patchy alopecia with remaining wiry, coarse, pale scalp hairs. Body hair is minimal to nonexistent. There is complete or partial fusion of the eyelids (ankyloblepharon filiforme adnatum) in approx 70% of infants. The strands may separate spontaneously or require surgical correction. Lacrimal obstruction or atresia occurs in approx 66% of patients.

A constellation of nail findings range from normal nails to thickened and hyperconvex to absent to deformed. Sweating is usually unimpaired but patients may describe subjective heat intolerance.

Cleft lip and/or palate affects 80% of patients. There may be malformed auricles and mild syndactyly of the second and third toes. Patients may have a decreased quantity or abnormally shaped and spaced teeth. Recurrent otitis media and secondary hearing loss are problematic. There are reports of associated hypospadias.

Mutations in the tumor suppressor gene *p63* (also known as *p51* or *KET*) have been discovered in affected patients. Light emollients are useful until the membrane sheds. Surgery may be necessary for ankyloblepharon, followed by proper ocular hygiene.

Continued meticulous scalp care with early treatment of infection is of utmost importance. Affected individuals benefit most from a multidisciplinary approach, involving a dermatologist, surgeon, nutritionist, speech therapist, orthodontist, and otolaryngologist.

108 Genetic Hair and Nail Defects

Marija Tadin-Strapps and Angela M. Christiano

SUMMARY

A wide spectrum of dermatological disease is characterized by altered hair and nail phenotypes. Even though genetic mechanisms involved in the regulation of hair and nail growth and development are not fully understood, there have been significant advances in the understanding of the general genetic principles. This chapter reviews developments and their clinical implications.

Key Words: Atrichia with papular lesions; desmosomes; human hairless (*HR*) gene; hypotrichosis simplex of the scalp; localized recessive hypotrichosis; Menkes disease; monilethrix; mouse *hairless* gene (*Hr*); Naxos disease; Netherton syndrome.

HAIR CYCLING DEFECTS: ATRICHIA WITH PAPULAR LESIONS

Atrichia with papular lesions (APL) is a rare autosomal-recessive form of total alopecia. Affected individuals are born without eyebrows and eyelashes, and never develop axillary and pubic hair. The scalp hair usually appears normal at birth, but falls out soon after. Defects in the human homolog of the mouse hairless gene (*Hr*) have been implicated as the molecular basis of this rare form of congenital hair loss.

CLINICAL FEATURES APL is characterized by normal hair growth at birth followed by a wave of hair shedding associated with the formation of follicular cysts and comedones. Affected individuals show normal hearing, teeth, and nails, and no abnormalities in perspiration. In addition, they have no growth or developmental defects.

DIAGNOSIS The most striking phenotypic characteristic of this disorder is the complete or almost complete alopecia soon after birth (Fig. 108-1A). In addition to hair loss, the affected individuals also exhibit grouped cysts and milia-like lesions in the skin (Fig. 108-1B). Owing to the similarity of this disorder to alopecia universalis, clinical diagnosis is usually made by the associated papules. Early diagnosis is important to avoid unnecessary treatments.

PATHOLOGY Morphogenesis of hair follicle occurs *in utero* and requires a series of interactions between dermal and epidermal tissues. Once the hair follicle is formed, hair growth proceeds in a cyclical fashion throughout life. Each hair cycle is initiated by a message sent from the dermal papilla, a group of mesenchymal cells, to the epithelial stem cells.

From: *Principles of Molecular Medicine, Second Edition*
Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

Molecular studies of hairless mice revealed several well-defined abnormalities thought to result in defects in the second hair cycle, and subsequently lead to complete alopecia. The hair matrix cells undergo massive and premature apoptosis that prevents dermal papilla from recruiting epithelial stem cells and initiating new hair cycles. These observations suggest that the hairless protein is involved in controlling the balance of the proliferation, apoptosis, and differentiation in the hair follicle and interfollicular epidermis.

Histologically, skin biopsy samples show absence of normal hair follicle structures with the formation of cysts and/or utriculi, and a reduced number of sebaceous glands (Fig. 108-1C).

The clinical picture of APL and histological findings (lack of hair follicles and presence of dermal cysts) are similar to vitamin D-dependent rickets. However, patients with vitamin D-dependent rickets also display osteomalacia, rickets, and hypocalcemia.

GENETIC BASIS Genetic analysis in a large Pakistani family of APL revealed linkage to chromosome 8p12 harboring the human hairless (*HR*) gene. *HR* is the human ortholog of *Hr* that maps to the syntenic region on mouse chromosome 14. This observation, combined with striking similarities between hairless mouse mutants and patients with APL made *HR* a candidate gene for this form of atrichia. Identification of mutations in *HR* underscored the genetic basis for this form of atrichia. HR is expressed in keratinocytes from hair-bearing skin and other epithelial tissues, and is most highly expressed in the brain. HR protein is a putative zinc finger transcription factor with structural homology to the GATA family.

MOUSE MODELS The phenotype of the patients with APL resembles that of hairless and rhino mice with the latter representing a more severe form of the mutant phenotype (Fig. 108-1D–F). These mice develop a normal first pelage up to the age of approx 14 d, after which all hair falls out and never regrows. In the rhino mice, hair loss is accompanied with progressive thickening of the skin as a result of excessive keratinization. The hairless and rhino phenotypes result from allelic mutations in the *Hr* gene.

MANAGEMENT There is no treatment for this rare form of genetic hair loss. However, advances in the field of molecular genetics will provide further insights into function of HR and other genes involved in the control of hair growth and cycling that could lead to development of therapies.

HAIR-SHAFT ABNORMALITIES

MONILETHRIX Monilethrix, also known as "the beaded hair syndrome," is a rare autosomal-dominant hair disorder with

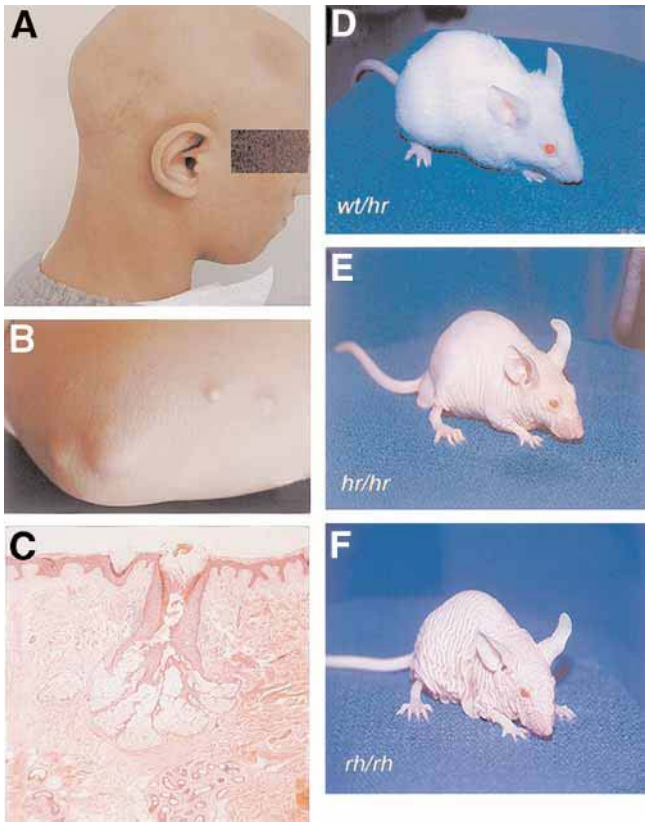

Figure 108-1 Features of the hairless phenotype in humans and mice. **(A,B)** Clinical presentation of patients with congenital atrichia with papular lesions. Note the complete alopecia of the scalp and characteristic skin lesions. The distribution and the number of papules vary. **(C)** Skin biopsy reveals the absence of normal hair follicles. Remnants of abnormal hair follicle structures and sebaceous glands are visible in the dermis. **(D–F)** Phenotypic appearance of a *hairless* heterozygous mouse (*wt/hr*), *hairless* homozygous (*hr/hr*), and *rhino* homozygous mice (*rh/rh*) at the age of approx 3 mo. Both *hr/hr* and *rh/rh* homozygous mice develop a normal first pelage, but start losing their hair soon after birth. The hair loss is usually completed within 1 wk after which mice remain completely naked. In the *rh/rh* mice, hair loss is accompanied with progressive thickening of the skin. *Hairless* heterozygous animals (*wt/hr*) are indistinguishable from the wild-type mice. (Please *see* color insert.)

variable expression. The disorder is characterized by perifollicular hyperkeratosis, and dystrophic alopecia of varying degrees that may develop periodically in the same individual. The disease is caused by mutations in two type-II hair keratin genes.

Monilethrix is clinically characterized by alopecia and follicular papules (Fig. 108-2A). Microscopically, the hair is beaded as a result of a periodic narrowing of the shaft with nodes and internodes (Fig. 108-2B). The nodes exhibit a high propensity to fracturing and weathering. Usually only the scalp is involved, but in some patients the secondary sexual hair, eyebrows, and eyelashes may also be affected. In severe cases, the distribution of the perifollicular papules may extend to other body areas such as abdomen and extremities. The most obvious characteristic of this disorder is beaded hair in association with alopecia and hyperkeratosis.

Linkage studies in monilethrix families mapped the locus to the type-II keratin gene cluster on chromosome 12q13. In humans, there are four type-II hair keratins: *hHb1*, *hHb3*, *hHb5*, and *hHb6*. Basic keratin 5 (*hHb5*) gene is expressed in the hair matrix, and the other three in the cortex of the hair shaft. Disease-causing mutations in the type-II hair cortex keratin gene (*hHb6)*, also known as *KRTHB6*, were identified in two different monilethrix families. This was the first evidence for hair keratins being involved in a hereditary hair disease. Subsequently, the same group identified mutations in the type-II hair cortex keratin gene (*hHb1* or *KRTHB1)* in a different family.

Genetic studies in more than 40 monilethrix families revealed nine different mutations of *hHb6* and *hHb1*. Interestingly, mutations in these two hair keratin genes have been reported in patients without family history of monilethrix suggesting a tendency for *de novo* mutations in this disorder.

Examination of the hair follicles from monilethrix patients with a light microscope reveals a series of nodes and internodes spaced at approx 0.7-mm intervals along the hair shaft. The regular periodicity of beading is asynchronous between follicles.

Because of the lack of an effective treatment for monilethrix, the principle for managing this disease is based on avoidance of hair trauma. Systematic administration of retinoids may induce some regrowth. Despite the fact that this disorder exists throughout life, some improvement has been reported with time and during pregnancy.

MENKES DISEASE Menkes disease is an X-linked recessive disorder characterized by early retardation in growth, pili torti or "kinky" hair, connective tissue disturbances, and focal cerebral and cerebellar degeneration. In addition, affected individuals show markedly reduced copper levels in the serum, brain, and liver, from a defect in intestinal absorption of copper. The disease was first described by Menkes in 1962 in a family of English-Irish origin with five affected males. The affected infants showed growth retardation at the age of few weeks and died during the first or second year of life. This is a relatively rare disorder with an estimated incidence of 1/100,000–250,000 live births. Identification of the gene for Menkes disease was facilitated by cytogenetic analysis of patients with chromosome X rearrangements.

Clinical presentation of Menkes disease includes steely, hypopigmented (white, gray, or silver) hair that easily breaks off leaving stubble of variable length. Affected individuals also show neurological symptoms such as seizures, developmental delay, and muscle hypotonia. Characteristic facial appearance includes pale skin with plump cheeks, a bowed upper lip, and broken, twisted eyebrows. Most patients die within the first 3 yr of life.

Diagnosis of Menkes disease is usually based on the examination of multiple hairs from scattered scalp sites for pili torti and determination of serum copper levels. Prenatal diagnosis of Menkes disease was previously based on biochemical determination of copper levels. However, because the cloning of the Menkes gene, direct mutation analysis has become the method of choice.

The Menkes gene encodes an evolutionary conserved copper-transporting P-type adenosine triphosphatase, *ATP7A*. *ATP7A* is normally expressed in nearly all human tissues, and the protein localizes to the trans-Golgi network of cells. Menkes gene regulates the absorption of copper in the gastrointestinal tract. The protein has a dual function inside cells: it delivers copper to cuproenzymes in the Golgi, and effluxes excess copper.

The mottled mouse represents the first of a family of Menkes mouse models to be identified. The clinical variability of the Menkes mouse models is a result of variable expression and varies from the classic Menkes (bridled mouse, macular mouse) and mild Menkes (viable bridled mouse, blotchy mouse) to embryonic lethal mutations (dappled, tortoiseshell). The mouse-*mottled* gene (*Atp7a*) was

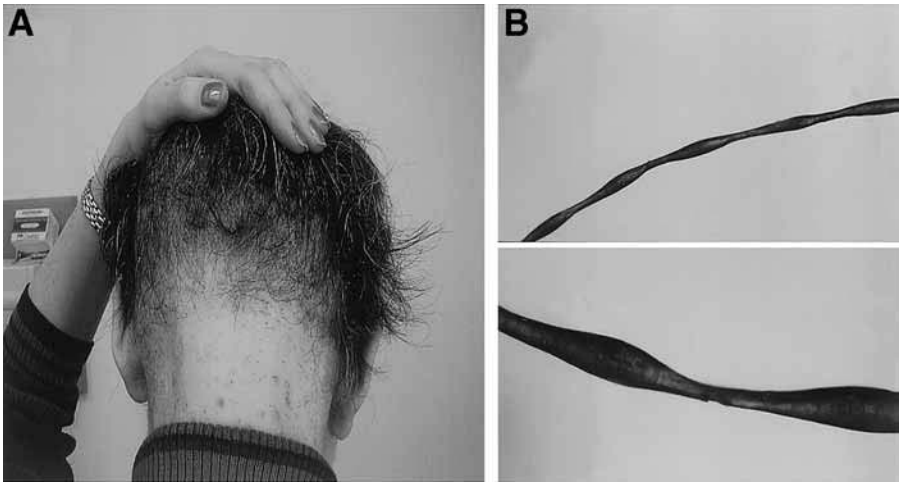

Figure 108-2 Clinical and microscopic findings in monilethrix. **(A)** Scalp alopecia in a case of monilethrix. Follicular hyperkeratosis is best seen in the occipital region. **(B)** Light microscopy images of hairs from monilethrix patients. Note the nodes and internodes giving the hair shaft its characteristic beaded appearance.

cloned following cloning of the human Menkes gene. Mutations in the *Atp7a* gene were identified in some of the mottled mutants.

Biochemically, Menkes disease is characterized by low concentrations of copper in plasma, liver, and brain resulting from impaired intestinal absorption, reduced activities of numerous copper-dependent enzymes, and inconsistent accumulation of copper in other tissues including skeletal muscle, kidney, duodenum, spleen, pancreas, and placenta.

In animals, copper deficiency results in changes in connective tissue owing to impaired formation of lysine-derived cross-links in elastin and collagen as a result of copper dependency of the lysyl oxidase involved in the initial modification of lysine. The striking hair changes are thought to result from defective formation of disulfide bonds in keratin because this process is copper-dependent.

Light microscopy of the hair follicles reveals flattened hair with closely grouped twists that are 0.4–0.9 mm in width. Twists occur in groups of 3–10 at irregular intervals. Hair-shaft twisting is usually at a 180° angle, but occasionally at 90° or 360°. Under scanning electron microscopy, scales appear normal.

Administration of copper–histidine or copper–EDTA has been used in treatment of Menkes disease with variable results. However, when copper–histidine is administered before the onset of neurological and developmental symptoms, prognosis can be somewhat improved.

NETHERTON SYNDROME Netherton syndrome (NS) is a rare autosomal-recessive disease characterized by congenital ichthyosiform erythroderma, a specific hair-shaft defect ("bamboo hair"), and atopic manifestations. First reported by Netherton in 1958, it is observed almost exclusively in females with a penetrance of approx 60%.

The most striking feature of this syndrome is the presence of the hair-shaft abnormality trichorrhexis nodosa et invaginata or "bamboo hair." The hair defect affects all hair to differing degrees. Nodular fractures of the hair shaft result in the lusterless appearance of the scalp hair. The hair is extremely fragile because of abnormal invaginations along the hair shaft. In some patients, the hair-shaft defects are more prominent in the vellus than the terminal hair. Eyelashes and eyebrows are usually sparse. Additional characteristics include congenital ichthyosiform erythroderma, and atopic diathesis. The dermatosis appears as redness and scaling affecting the face and other parts of the body. Other abnormalities reported in patients with NS affect the immune system, the metabolism of amino acids, and physical development. Failure to thrive is a frequent cause of death in NS infants.

NS is defined by a triad of symptoms, congenital ichthyosiform erythroderma, trichorrhexis invaginata, and atopy. The disorder may be confused with atopic dermatitis, but does not respond to corticosteroid treatment. Because of the similarity of clinical features of NS to infantile erythrodermas, the diagnosis is usually delayed until the development of "bamboo hair."

Ultrastructural and histological analysis of skin biopsies from NS patients indicates gross defects in keratinization, with abnormal invaginations in the keratogenous zone. Additional abnormalities, including twisting changes of the shaft and trichorrhexis invaginata can be revealed by scanning electron microscopy.

The disease locus for NS was mapped to 5q32. The *SPINK5*, serine protease inhibitor, Kazal-type 5, gene that maps to this region of chromosome 5 was considered a candidate for NS on the basis of biological function. *SPINK5* encodes the serine protease inhibitor LEKTI that has been suggested to play a role in extracellular matrix remodeling. Mutation analysis of *SPINK5* revealed different mutations in families with NS.

In some cases, successful treatment of Netherton's disease has been based on systemic administration of etretinate. The therapy based on oral rethinoids normalized the keratinization and improved clinical appearance of hair, but had no effect on the basic defect in copper metabolism. Topical treatment of Netherton's syndrome with tacrolimus ointment was reported to improve atopic dermatitis observed in NS patients.

CONGENITAL ALOPECIA, T-CELL IMMUNODEFICIENCY, AND NAIL DYSTROPHY The human "nude" phenotype is an autosomal-recessive disorder characterized by T-cell defect, congenital alopecia, and nail dystrophy. In most cases, the severe immunodeficiency results in premature death. Pignata et al.'s 1996 report of two sisters with T-cell defect, hair loss, and nail abnormalities was the first observation of an ectodermal disorder in association with primary immunodeficiency.

Affected individuals are born with a complete absence of scalp hair, eyebrows, and eyelashes, and without a properly formed

thymus. Severe T-cell deficiency is evident shortly after birth, and may result in death without bone-marrow transplantation.

Diagnosis for congenital alopecia with T-cell deficiency is based on observation of congenital hairlessness and athymia. Prenatal diagnosis is now possible by mutation analysis of *WHN* gene.

Histological analysis of the skin revealed that the mutant phenotype does not result from the absence of hair follicles, but from defects in keratinization within the hair follicle and in the interfollicular epidermis. Abnormal hair shafts fracture readily within the hair canal. Light and electron microscopy analysis revealed that the hair cortex is made up of abnormal globular aggregates. In addition, the cuticles of the inner root sheath (IRS) and the outer root sheath are missing.

The resemblance of the human phenotype to the nude mouse led to investigation of the human *WHN* gene as a candidate for this human disorder. Disease-causing mutations in the *WHN* gene were found in two sisters affected with severe functional T-cell immunodeficiency, congenital alopecia, and nail dystrophy. This was the first finding of the evidence of a human immunodeficiency caused by a gene expressed not in hematopoietic cells, but in specific epithelial cells.

Nude mice are the best known of mouse "balding" mice. These animals are hairless, show poor fertility, and have dysgenesis of the thymus. The hair defect also affects the vibrissae, thereby permitting early detection of mutants. Cloning of the mouse *nude* gene indicated that it encodes a protein with a presumptive DNA-binding domain of the winged helix type and a C-terminal transcriptional activation domain. The gene was named *winged helix nude* (*Whn*). The genomic sequence analysis of the nude mouse revealed a single base-pair deletion in exon 3 of the W*hn* gene that causes a frameshift and results in a premature stop codon in exon 6. However, W*hn* was renamed as *forkhead box n1* (*Foxn1).* The *Foxn1* gene is expressed in the thymus, the cells of epithelial origin in the skin, the developing nails, teeth, tongue, palate, nasal passages, and the developing lens epithelium and is thought to play a role in maintaining the balance between growth and differentiation.

Successful short-term treatment of immunodeficiency has been accomplished by bone marrow transplant. However, this had no effect on the improvement of the hair and nail phenotype.

DESMOSOME-RELATED DISEASES

Desmosomes are essential adhesion structures in most epithelia that link the intermediate filament network of one cell to its neighbors. The molecular components of desmosomes belong to the cadherin superfamily, the plakin family, and the armadillo repeat family. Cadherins can be divided into classic cadherins (including P, E, N, and VE-cadherin) and desmosomal cadherins. The desmosomal cadherins are made up of desmogleins (*Dsg*) and desmocollins (*Dsc*). Previously, this group of proteins contained six genes, three desmocollins (*Dsc1, 2, 3*), and three desmogleins (*Dsg1, 2, 3*). Identification of novel *Dsc* in mouse and human expanded this group to nine members in mouse, and seven in human and rat. Plakophilin1, 2, 3, and 4, and plakoglobin (PKGB) are four armadillo-like proteins found in desmosomes.

LOCALIZED AUTOSOMAL-RECESSIVE HYPOTRICHOSIS Localized recessive hypotrichosis (LAH) is a rare skin disorder characterized by hypotrichosis of the scalp, chest, arms, and legs. Defects in a novel DSG gene, *DSG4* have been identified in association with this form of hypotrichosis.

The most striking clinical characteristic of LAH is hypotrichosis that affects scalp, arms, chest, and legs. Facial hair, including eyebrows and beard, is also less dense, whereas axillary and pubic hair and eyelashes are not affected. The overall appearance of the skin is normal except for the patches of scalp in which small papules are visible, most likely as a consequence of ingrown hairs (Fig. 108-3A). There are no additional associated anomalies.

Diagnosis of LAH is based on hypotrichosis and presence of small patches of scalp papules. Clinically, this disorder differs from APL in the number and distribution of papules and the absence of total alopecia that is characteristic of APL. Sequence analysis of *DSG4* can be used in diagnosis of this rare skin disorder.

Histological analysis of the scalp skin from the LAH patients and lanceolate hair mice reveals abnormal hair follicles and shafts that are thin and atrophic (Fig. 108-3B). They often appear coiled up within the skin because of their inability to penetrate the epidermis. Another defect is a marked swelling of the precortical region, resulting in the formation of a bulbous "bleb" within the base of the hair follicle (Fig. 108-3C).

Examination of the skin from *Dsg4* deficient mice revealed thickening and hyperplasia in the epidermal layers. At the molecular level, it was determined that the mutant epidermis shows a hyperproliferative phenotype accompanied by disruptions in differentiation of hair matrix keratinocytes. Transmission electron microscopy of the epidermis from lanceolate mice revealed complete detachment of keratinocytes at the cell junctions in some areas, and the presence of small poorly formed junctions in the others (Fig. 108-3D,E).

Genome-wide linkage analysis in two consanguineous Pakistani families mapped the *LAH* locus to the region of chromosome 18 that harbors the cluster of desmosomal cadherin genes. Genetic and molecular studies in these families led to identification and cloning of a novel desmosomal cadherin gene, *DSG4*. Mutation analysis of the *DSG4* coding sequence revealed an identical homozygous 5-kb deletion in the affected individuals from the two kindreds.

Lanceolate hair mice have been suggested as models for several types of hypotrichosis. Mutant animals are smaller than their wild-type littermates, alopecic, and have abnormal vibrissae (*see* Fig. 108-3B). With age, affected animals develop noninflammatory, proliferative skin disease with follicular dystrophy. Lanceolate hair mice show a variety of hair follicle defects including periodic nodules along the hair shaft, spiral fractures, and lance-shaped tips that give this mutation its name. Cloning of the mouse *Dsg4* gene allowed identification of mutations in this gene that underlie lanceolate hair mutation.

Dsg4 is expressed in the hair follicles during the growth, or anagen, phase of the hair cycle. *In situ* hybridization studies detected *Dsg4* messenger RNA in the cells of precortex, hair matrix, and the IRS. This observation, combined with the fact that none of the other desmosomal cadherins are expressed in the inner layers of the hair follicle, and the observed hyperproliferative phenotype in *lanceolate* mice suggests a critical role of *Dsg4* in hair follicle differentiation.

NAXOS DISEASE Naxos disease is an autosomal-recessive disorder characterized by woolly hair, palmoplantar keratoderma, and cardiac abnormalities. The name Naxos was given in reference to Greek island of Naxos in which the first patients with this disorder were reported.

Cardiac abnormalities observed in Naxos patients include cardiomegaly, ECG abnormalities, and episodes of ventricular tachycardia suggestive of arrhythmogenic right ventricular dysplasia/cardiomyopathy. Cardiac anomalies usually do not

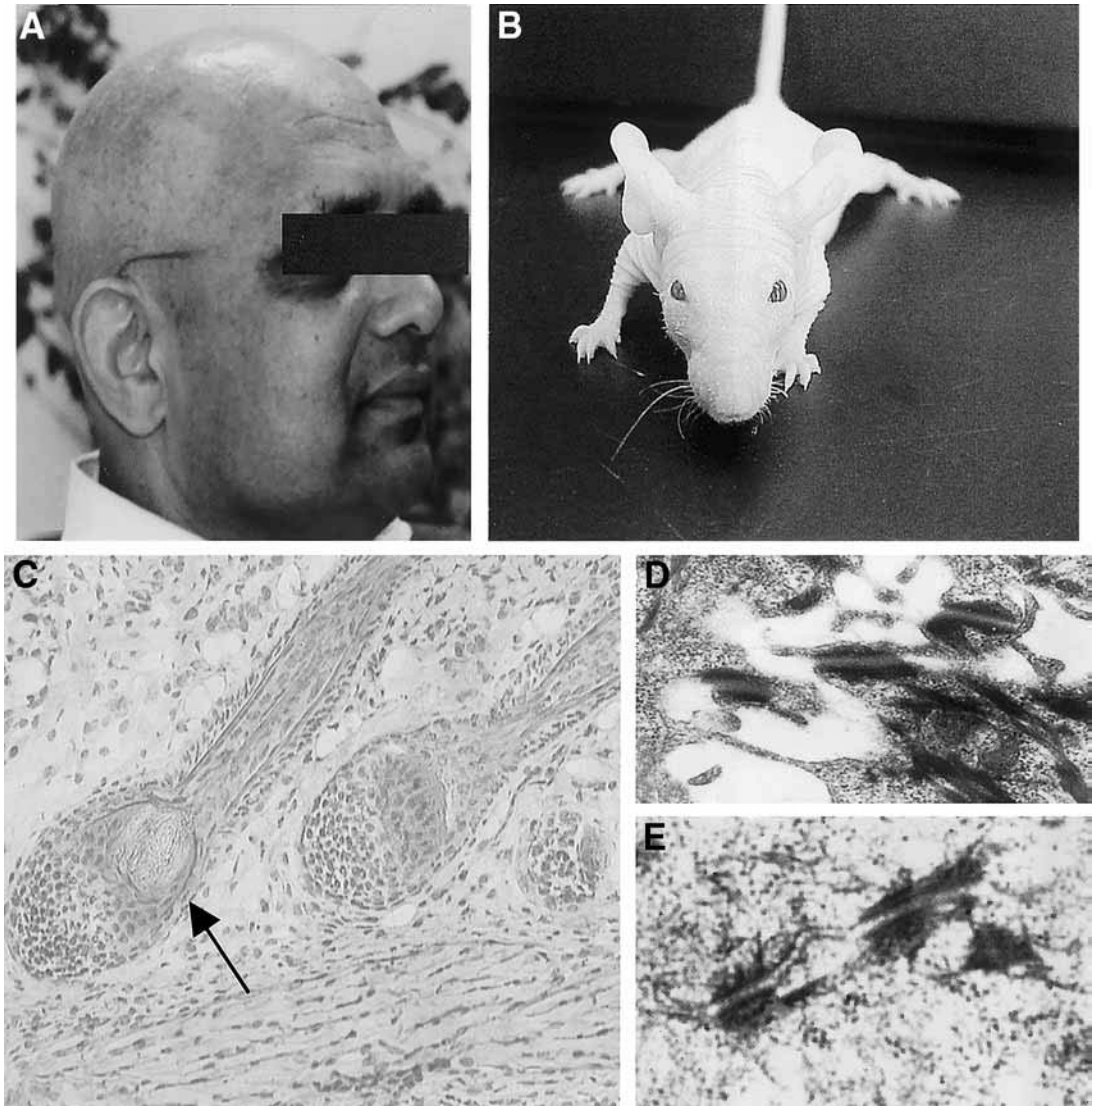

Figure 108-3 Features of the LAH phenotype in humans and mice. **(A)** Clinical presentation of the human LAH phenotype. Note sparse scalp hair and the bumpy scalp skin. **(B)** *lah/lah* mutant animal has sparse trunk hair and abnormal vibrissae. **(C)** Histology of a tail skin from an 8-d old lah^J/lah^J mutant mouse. Note the bulbous degenerative swelling "bleb" in the precortical region (arrow). **(D)** High magnification of disrupted desmosomes in the mutant skin. Desmosomes have been torn away from the adjacent keratinocytes, contrary to intact desmosomes observed in wild-type epidermis **(E)**.

manifest clinically before adolescence, and are variably progressive. A number of patients with Naxos disease suffer from heart failure in their early teenage ages resulting in premature morbidity. Affected individuals have dense, rough, and bristly hair that resembles steel wire (Fig. 108-4A). Palmoplantar keratoderma becomes evident during the first year of life and becomes more severe with age (Fig. 108-4B,C). Abnormal epidermis with keratosis is present in the areas of the body exposed to constant mechanical stress, such as soles of the feet, palmar folds, and medial sides of the fingers, whereas other areas are clinically unaffected.

Diagnosis of this disorder is based on the triad of cardiac anomalies, woolly hair present at birth and palmoplantar keratoderma, which can be epidermolytic or nonepidermolytic, from infancy. Most Naxos patients show echocardiographic evidence of enlargement of the right ventricle and a right ventricular band. There is a related autosomal-recessive condition of cardiomyopathy, wooly hair, keratoderma, and dilation of the left ventricle.

Phenotypic features observed in Naxos patients can be attributed to defects in desmosomal proteins. Desmosomes are important for the tight adhesion of many cell types, including those of heart and skin. Because both PKGB and desmoplakin (DSP) are involved in maintenance of cell junction integrity, it is not surprising that mutations in both of these genes have been implicated in Naxos disease's etiology.

In vitro studies of cultured human endothelial cells showed that inhibition of PKGB expression by microinjection of antisense oligonucleotides induces cell–cell dissociation in response to stress.

The gene underlying Naxos disease was linked to chromosome 17q21 and identified as *PKGB*. Subsequently, homozygosity for a 2-bp deletion in PKGB gene was found in a group of patients with Naxos disease. Defects in another desmosomal component, *DSP*, cause a type of Naxos disease. Patients harboring mutations in *DSP* have a more severe epidemolytic palmoplantar keratoderma, woolly hair, and dilated left venticular cardiomyopathy.

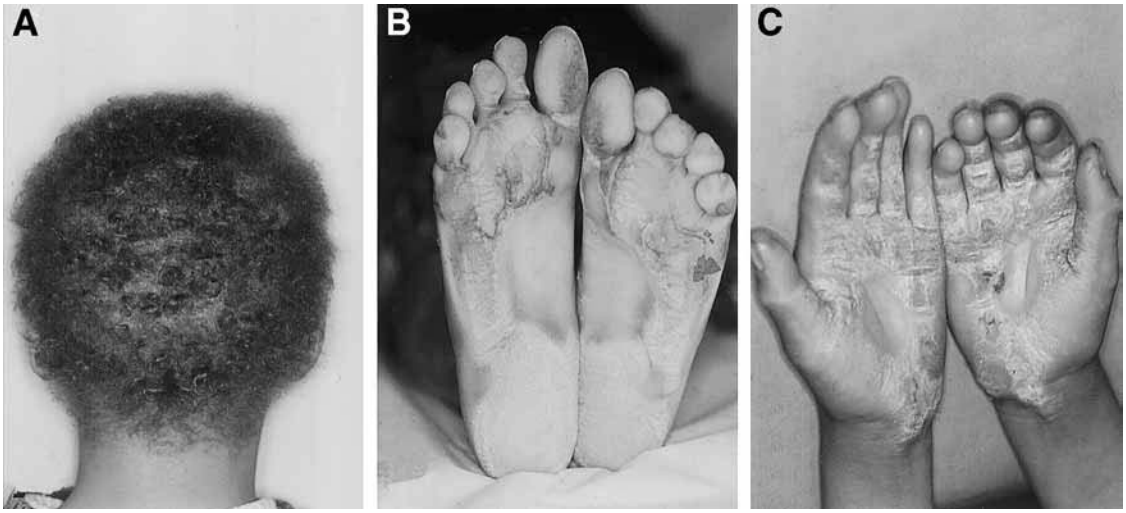

Figure 108-4 Clinical findings in Naxos disease. **(A)** Hair phenotype from a patient with Naxos disease. Note the "wool-like" appearance of the hair. **(B,C)** Palmoplantar keratoderma is evident on the soles and palms.

PKGB null mutant mouse embryos show reduced cell–cell adhesion and decreased myofiber compliance that results in death under increased mechanical stress at the onset of embryonic blood circulation around embryonic day 10.5. PKGB-deficient mice that survive until around birth show an additional skin phenotype. In these mice, epidermal desmosomes are disorganized and detached from the cytokeratin filaments.

CONGENITAL HYPOTRICHOSIS WITH JUVENILE MACULAR DYSTROPHY; P-CADHERIN DEFICIENCY Hypotrichosis with juvenile macular dystrophy (HJMD) is an autosomal-recessive disorder that was first described in 1935 by Wagner et al. The disorder is characterized by hair loss during the first months of life followed by a progressive macular degeneration during the first decade of life.

The affected individuals are born with normal hair but develop alopecia by the age of 3 mo. During puberty the regrowth of sparse, short hair sometimes occurs. Body hair is not affected. HJMD patients also developed progressive macular degeneration that culminates in blindness during the second to third decade of life, and slight peripheral renal dystrophy.

HJMD diagnosis is based on the observation of hypotrichosis in association with decreased visual acuity. Fundoscopy and visual electrophysiological testing are usually required. Electrophysiological studies can be used in diagnosis of retinal dysfunction.

Analysis of skin biopsies showed normal findings except for the reduced ratio of terminal vs vellus hairs. Light and electron microscopy studies of hairs obtained from affected patients revealed a number of hair-shaft abnormalities including fusiform beading along the hair shaft, owing to flattening of the shaft, pili torti, as well as scaling and folding of the hair shaft.

Mutations in cadherin 3, *CDH3*, encoding the adherens junction protein P-cadherin in patients with HJMD were the first finding of a cadherin molecule in the pathogenesis of a human hair and retinal disorder. P-cadherin is expressed in retinal pigment epithelium and in the hair follicles.

HYPOTRICHOSIS SIMPLEX OF SCALP Hypotrichosis simplex of the scalp (HSS) is a rare form of isolated alopecia. The disease is inherited as an autosomal-dominant trait with full penetrance. HSS results in almost complete loss of scalp hair, with onset in childhood. Genetic studies in families with HSS mapped the locus to chromosome 6p21.3.

The hair is normal at birth, but beginning in the middle of the first decade, HSS patients experience gradual and progressive loss of scalp hair that leads to almost complete alopecia by the third decade. A few sparse hairs of vellus type usually remain on the scalp. Usually, no scarring or inflammatory changes are present. There are no associated abnormalities of the beard, axillary and pubic hair, teeth, or nails.

Localized hypotrichosis and absence of papules make HSS clinically distinguishable from LAH and APL. Mutation analysis of the gene for corneodesmosin, *CDSN*, can be used to confirm the diagnosis. Light and electron microscopy of the hairs from early HSS patients show no structural changes, contrary to hairs from advanced hypotrichosis patients that reveal focal areas of defective cuticular structure. The number of hair follicles also varies, and can be normal or reduced.

The gene for HSS was mapped to 6p21.3. Analysis of genes in this interval led to identification of corneodesmosin, *CDSN*, as a candidate gene for this disorder. Nonsense mutations in *CDSN* were identified in three previously reported hypotrichosis simplex pedigrees. *CDSN* encodes a glycoprotein expressed in the epidermis and IRS of the hair follicles, and is a keratinocyte adhesion molecule. Corneodesmosin is located in the desmosomes of the upper living layers of the skin, and in related structures of the cornified layers, the corneodesmosomes. These intracellular structures are involved in desquamation, the shedding of superficial corneocytes, anucleated cells derived from keratinocytes, from the skin surface.

There is no effective treatment for desmosome-related diseases. However, identification of the genes involved in the etiology of these disorders has already proved helpful for diagnostic purposes. Designed pharmaceutical and genetic therapies are likely to be developed.

FUTURE DIRECTIONS

Despite major advance in the research of genetic basis of hair disorders, the effective treatment for the majority of these diseases does not exist. With the exceptions of Menkes disease and NS, for which some improvements can be accomplished by administration

of copper–histidine or copper–EDTA, and etretine, respectively, the management of the hypotrichosis phenotype has been primarily based on the avoidance of hair trauma. In some cases of keratin disorders, therapy based on oral retinoids improved clinical appearance of hair, but the basic defect was not corrected.

Advances in research of the genetic basis of diseases of hair and nails have provided a better understanding of the underlying pathological processes. This knowledge has been extensively used for disease prevention in the form of prenatal and perinatal DNA-based diagnosis, but development of gene therapies for these disorders is also in progress. Technologies are being developed for the correction of defective alleles in the form of antisense oligonucleotides and ribozymes. So far, these therapies have only provided temporary correction because corrected epithelial cells eventually get differentiated and lost by the process of desquamation. The challenge of effective therapy for genetic diseases of the skin resides in the ability to target skin stem cells. Even though this is not possible at the moment, advances in the field of skin biology are likely to lead to development of effective therapies for these devastating disorders.

ACKNOWLEDGMENTS

The original studies cited here were supported in part by the March of Dimes Birth Defects Foundation, and by the NIH USPHS grant RO1 AR44924. The authors would like to thank Drs. Andrey Panteleyev, Abraham Zlotogorski, Julio Salas, Ana Kljuic, and Hisham Bazzi for providing some of the clinical and histology photographs. We are grateful to Drs. Abraham Zlotogorski and Amalia Martinez-Mir for helpful discussions of the manuscript.

109 Metabolic Genetic Disorders With Prominent Skin Findings

CHRISTOPHER B. MIZELLE AND LOWELL A. GOLDSMITH

SUMMARY

Specific skin lesions associated with internal disorders result from metabolic defects. Excesses in specific aromatic amino acids owing to autosomal-recessive diseases cause distinctive skin lesions. Excess phenylalanine is associated with decreased hair and skin pigment, tyrosine excess with skin blisters and hyperkeratosis of the palms and soles, and homogentisic acid excess with deposition of colored polymers in the skin and cartilage. Excessive iron stimulates melanin synthesis in hemochromatosis. Storage of complete carbohydrates is responsible for vascular lesions in Fabry disease and fucosidosis. Genetic defects of porphyrin synthesis causes increased sensitivity to visible light leading to blisters. A defect in a urea cycle enzyme causes fragile hair in argininosuccinic aciduria.

Key Words: Alkaptonuria; argininosuccinic aciduria; erythropoietic protoporphyria; Fabry disease: fucosidosis; hemochromatosis; phenylketonuria; porphyria cutanea tarda; porphyrias; tyrosinemia II.

INTRODUCTION

Genetic disorders of general metabolism may have prominent skin manifestations; several of these diseases are discussed in this chapter. Three disorders are caused by enzymatic defects in aromatic amino acid metabolism: phenylketonuria (PKU), tyrosinemia II, and alkaptonuria. Two are storage diseases caused by disorders of lysosomal carbohydrate degrading enzymes: Fabry disease and fucosidosis. One is a defect in the urea cycle with distinctive hair findings. Iron storage in hemochromatosis leads to a prominent skin phenotype. Finally, enzymatic defects in the complex process of porphyrin synthesis lead to diseases with prominent photosensitivity.

PHENYLKETONURIA

PKU is an autosomal-recessive disease resulting from a deficiency of hepatic phenylalanine hydroxylase or its required cofactors and the resulting plasma and tissue levels of phenylalanine. Mental retardation, seizures, hypopigmentation, and eczematous dermatitis may result.

CLINICAL FEATURES PKU occurs in 1:10,000 births and is usually detected with neonatal screening. The characteristic cutaneous manifestations are blond hair, blue eyes, and fair skin that is often eczematous. These findings may be subtle and apparent only with comparison to other family members. The more serious problems occurring with untreated disease involve the central and peripheral nervous system with mental retardation, athetosis, restlessness, increased tendon reflexes and muscle tone, hyperkinesis, tremors, and seizures. Sclerodermatous skin changes are rare but striking and commonly present as indurated plaques on the thighs during the first year of life. They resolve with a phenylalanine-restricted diet.

GENETICS A single 100-kb gene on chromosome 12 codes for a 452 amino acid peptide. Pterin tetrahydrabiopterin is an essential component of the reaction and defects in its metabolism can increase phenylalanine levels. Mutations include null alleles without enzymatic activity, kinetic alleles with altered substrate or cofactor activity, and unstable alleles with increased turnover.

TREATMENT A low-phenylalanine diet prevents the neurological complications including the mental retardation.

TYROSINEMIA II

Tyrosinemia type II, Richner-Hanhart Syndrome, is resulting from an autosomal-recessive deficiency of hepatic tyrosine aminotransferase. The eyes, epidermis, and central nervous system are typically affected. This rare disorder has less than 100 reported patients with about half of Italian descent. The syndrome is found worldwide, with equal distribution among men and women.

CLINICAL FEATURES Skin manifestations are limited to acral surfaces with erosions or hyperkeratotic lesions of the palms and soles. Painful, nonpruritic, and often hyperhidrotic lesions typically begin during the first year of life. The pain can limit mobility and lead patients to continue crawling to avoid direct pressure.

Ophthalmological findings usually precede the skin involvement by weeks to months and early findings are tearing, redness, pain and photophobia. Corneal clouding and central or paracentral opacities are later signs. Mental retardation as well as normal mental development has been reported.

LABORATORY AND PATHOLOGICAL FINDINGS The hallmark finding is elevated blood and urine tyrosine levels. Deficient hepatic tyrosine aminotransferase leads to all of the metabolic effects including high levels of tyrosine and its metabolites. Routine histopathology of the skin or conjunctiva is typically nondiagnostic.

DIFFERENTIAL DIAGNOSIS Neonatal tyrosinemia is a common transient condition with decreased levels of p-hydroxyphenylpyruvic acid oxidase apoenzyme and a relative ascorbic acid deficiency contributing to the tyrosinemia, tyrosinuria, and increased tyrosine metabolite excretion. Treatment includes low protein diet and ascorbic acid supplementation. Hereditary tyrosinemia (tyrosinemia type I, tyrosinosis) is an autosomal-recessively inherited defect in fumaryl-acetoacetate hydrolase deficiency with severe liver and renal disease. Early in life, affected patients develop fever, edema, vomiting, a boiled-cabbage odor, hematuria, diarrhea, jaundice, hepatosplenomegaly, and Fanconi's syndrome. These patients are also at increased risk for development of hepatocellular carcinoma.

GENETICS The 454 amino acid tyrosine aminotransferase protein is cytoplasmic and is coded by a 10.9-kb gene at 16q22.1-22.3. R57Y is the common mutant allele in Italy but there are multiple mutations in the gene. There are no definitive genotype–phenotype relationships.

TREATMENT AND PROGNOSIS All patients presenting with atypical bullous and hyperkeratotic disease of the acral surfaces needs to be evaluated for possible tyrosinemia II as it is easily treatable. Dietary restriction of tyrosine and phenylalanine leads to rapid reversal of the skin and ocular findings with normalization of tyrosine levels. Early treatment prevents the associated mental retardation.

ALKAPTONURIA

Alkaptonuria is a rare (1:250,000) autosomal-recessive metabolic disorder resulting from a deficiency of homogentisic acid oxidase (HGO), the sole enzyme catabolizing homogentisic acid (HGA). Excessive HGA is excreted in the urine and accumulates in connective tissues. The disease is distributed worldwide with a higher incidence in certain areas such as Slovakia and Santa Domingo. Men and women are affected equally.

PATHOGENESIS HGO is an enzyme in the catabolic pathway of phenyalanine and tyrosine. Its cofactors include oxygen, ferrous iron, and sulfhydryl groups. HGO is inhibited by the quinones producing pseudo-ochronosis. HGA is colorless until oxidized when it obtains a black pigment. Patients with alkalinized urine are more likely to develop dark urine. A decrease in urinary pH prevents the oxidation of HGA after tubular secretion. The deposition in connective tissues is not well understood. HGA inhibits lysyl hydroxylase in chick embryos and weakens collagen. In addition, HGA may form crosslinks with collagen further decreasing its strength.

CLINICAL FEATURES Dark urine is dependent on oxidation that occurs after tubular secretion. Oxidation usually requires a urinary pH >7.0 or the absence of reducing substances such as ascorbic acid. A presumptive diagnosis is made under from a positive family history and discoloration of diapers with the use of alkaline soap. Before glucose oxidase urinary analysis, testing for urinary glucose with Benedict's solution produced an orange precipitate that turned black. Although the diagnosis can be made during childhood, it is typically made in the third or fourth decades with the presentation of connective tissue changes.

Clinically visible hyperpigmentation occurs in several organs including the skin, eyes, and various cartilaginous structures. Dark brown or black cerumen may be the presenting symptom. Some patients develop axillary hyperpigmentation especially in a glandular orifice pattern. The ear can be affected in several ways ranging from cartilage and tympanic membrane discoloration to calcification. Patients may complain of tinnitus or hearing loss. Cartilage in the larynx and trachea may be involved, but remains asymptomatic. Ocular findings include grayish-black scleral pigmentation, as well as corneal, conjunctival, and tarsal findings.

Disabling arthritis of multiple joints presents with recurring bouts of inflammation typically in the third to fourth decades. X-rays show early calcification of the intervertebral disk with narrowing of the intervertebral spaces. There may be eventual disk collapse with gradual decrease in height. Pseudogout may coexist with ochronosis.

The prostate and kidneys are frequently affected with pigmentation.

LABORATORY AND PATHOLOGICAL FINDINGS Alkaptonuric patients show no abnormalities on routine lab testing except for excretion of HGA. Sodium hydroxide added to a patient's urine leads to darkening of the urine and provides a presumptive diagnosis.

Skin biopsy can show yellow to light brown pigmented granules in dermal macrophages. Routine stains for melanin are positive and the pigment is resistant to 10% hydrogen peroxide.

GENETICS A 60-kb gene on 3q21-23 codes for HGA oxidase. Multiple mutations have been reported and in a large series, 81% of patients were compound heterozygotes.

The gene is at 3q21-q23.66 and has multiple mutations.

DIFFERENTIAL DIAGNOSIS The other main causes of dark urine are melaninuria, porphyria, myoglobinuria, bilirubinaria, and hematuria that should not be confused with alkaptonuria. Pseudo-ochronosis has been reported in blacks using hydroquinones for depigmentation and in patients treating their skin with carbolic acid.

TREATMENT AND PROGNOSIS Symptomatic relief with rest and analgesics is required for the arthritis, although many patients eventually need prosthetic joint replacement. Life-span is not typically affected despite the unremitting and progressive disease course. Nitisinone, a reversible inhibitor of 4-hydoxyphenylpyruvate (the enzyme proximal to HGA oxidase in the catabolic pathway), decreases HGA levels and is being evaluated clinically. Oral ascorbic acid is not an effective treatment.

FABRY DISEASE: β-GALACTOSIDASE A DEFICIENCY

Fabry disease is an X-linked recessive inborn error of glycosphingolipid metabolism resulting from abnormal β-galactosidase A, a lysosomal enzyme. Incidence is 1:40,000–60,000 in males. The enzymatic defect leads to deposition of neutral glycosphingolipids in lysosomes of most visceral tissues, especially the vascular endothelium.

CLINICAL FEATURES Males are almost solely affected with minimal manifestations in carrier females. Disease onset begins in childhood with periodic acroparesthesias, appearance of angiokeratomas, hypohidrosis, and characteristic corneal and lenticular opacities. With aging, the continued glycosphingolipid deposition leads to severe renal, cardiac and cerebrovascular involvement.

Severe and debilitating pain characterized as episodic crises or persistent burning pain begins early in the disease initially involving the palms and soles. The constant pain may be slightly less debilitating but is a nagging, persistent tingling or burning sensation in the hands and feet. Pain crises may be triggered by exercise, fatigue, emotional stress, or rapid changes in temperature or humidity. With advancing age, the periodic crises decrease in frequency.

Angiokeratomas progressively increase with age in size and number and are dark red to blue-black clusters of individual, punctate lesions. They tend to be symmetric and can be nonblanching macules or slightly raised papules. Common locations are the hips, lower abdomen and back, thighs, buttocks, penis, scrotum, oral mucosa, and conjunctiva. Anhidrosis or hypohidrosis from neuropathy are common.

The progressive infiltration of glycosphingolipid in the vascular system produces a variety of cardiac, cerebral, and renal manifestations including angina, myocardial ischemia and infarction, mitral valve prolapse, congestive heart failure, hypertension, mitral insufficiency, and cardiomegaly. Hypertension from renal vascular compromise may accentuate or accelerate these finding. Cerebrovascular disease resulting from multifocal small vessel disease leads to thromboses, basilar artery ischemia and aneurysm, seizures, hemiplegia, hemianesthesia, aphasia, labyrinthine disorders, or frank cerebral hemorrhage. Psychiatric disorders may also occur. Renal disease presents as proteinuria with gradual deterioration of renal function resulting in azotemia. In childhood, polarization microsocopy reveals birefringent lipid globules with characteristic Maltese cross structures both free in the urine and within desquamated urinary sediment cells. Death is commonly from vascular disease involving the kidneys, heart or brain.

Ocular involvement is most common in the cornea, lens, conjunctiva, and retina. A characteristic corneal opacity visualized with slit-lamp microscopy is evident in males and heterozygous females. This corneal dystrophy of Fabry disease is characteristic, but indistinguishable from the drug-induced phenocopy of chloroquine and amiodarone. Lenticular changes include a granular anterior/subcapsular deposit or a posterior cortex deposit. Visual impairment is uncommon despite the involvement of the cornea, retina, and conjunctiva. However, acute visual loss as a result of total central retinal artery occlusion is reported.

Pulmonary effects include chronic bronchitis, wheezing, or dyspnea. Lymphedema and priapism can result secondary to obstruction of lymphatics from glycosphingolipid deposition.

Cardiac Variants This phenotypic variant presents in affected males usually after age 40, later than the classic disease. Patients have retained β-galactosidase A activity. They have 1–5% of residual α-galactosidase activity, and usually have cardiac effects but not cutaneous manifestations.

Carrier Females The clinical course and prognosis of carriers differs greatly from the affected males. Females do not experience the ill effects of the disease as early as their male counterparts. Some patients eventually experience some renal and cardiac effects. About 30% of the females develop angiokeratomas and acroparesthesias, whereas most have the classic corneal dystrophy. Clinical findings depend on random X-inactivation and most obligate carrier females have no clinical manifestations.

GENETIC COUNSELING Both females and males can transmit the enzymatic defect as a typical X-linked recessive gene. Fabry disease has been detected prenatally with amniocentesis and chorionic villus sampling.

GENETICS β-Galactosidase A is coded by a single copy, seven exon gene at Xq21. There are no characteristic mutations and the disease is owing to multiple missense or nonsense mutations, splice defects or gene rearrangements.

DIFFERENTIAL DIAGNOSIS The use of a skin biopsy, ophthalmological examination, and demonstration of the birefringent inclusions in urinary sediment can help solidify a presumptive diagnosis. Deficient or absent β-galactosidase A on biochemical analysis is needed to confirm the diagnosis. Prenatal diagnosis can be performed by chorionic villus sampling at 9–10 wk of pregnancy.

TREATMENT Pain is the single most debilitating symptom; carbamazepine, diphenylhydantoin and gabapentin have been shown to decrease pain severity. Renal transplantation is likely to be required as renal insufficiency is the most frequent late complication. β-Galactosidase A replacement with recombinant enzyme has been approved, is effective and is under long-term study. Skin biopsy is useful for following the response to gene therapy.

FUCOIDOSIS AND OTHER GLYCOPROTEIN DISORDERS

Fucoidosis is a rare autosomally recessive lysosomal storage disease similar to Fabry disease and because of deficiency of β-L-fucosidase with accumulation of certain fucose-containing complex compounds in various tissues. It is divided into two forms: type-I (without angiokeratomas) and -II (with angiokeratomas).

CLINICAL FEATURES Accumulation of the fucose-containing compounds leads to many clinical findings. Major findings are mental retardation, seizures, and progressive neurological deterioration including anhidrosis. Visceromegaly, course facial features, angiokeratomas, delayed psychomotor development, cardiac problems, and an unusual variant of spondylometaphyseal dysplasia are often found.

Type I is the most severe, typically becomes apparent within the first 6 mo of life, and progresses with death usually before the age of 10. These infants have severe mental and growth retardation with continued deterioration of the brain and spinal cord. They may also have multiple gastrointestinal complications.

Type II also presents in the first year of life but is less progressive; patients live to their twenties. The clinical findings are the same as type I, but with the addition of angiokeratomas.

Angiokeratomas are described in β-mannosidosis (onset 1–6 yr) and juvenile sialidosis (onset 2–20 yr).

ARGININOSUCCINIC ACIDURIA

Argininosuccinic aciduria is an autosomal-recessive disorder characterized by cutaneous and systemic findings because of argininosuccinate lyase deficiency. This enzyme is essential in the urea cycle and its deficiency leads to citrullinemia and elevated blood ammonia levels. Hepatomegaly, mental retardation, lethargy, and ataxia are the main systemic findings, whereas brittle hair characterized as trichorrhexis nodosa is the major dermatological finding.

Argininosuccinic aciduria typically presents with failure to thrive and ammonia intoxication in neonates or during the second year of life with seizures, psychomotor retardation, and ataxia. The characteristic hair findings with trichorrhexis nodosa usually have a later onset.

HEMOCHROMATOSIS

Hereditary hemochromatosis (HH) is an autosomal-recessive inherited disease of iron deposition in multiple tissues throughout the body. Whites are most commonly affected. It is a relatively common inheritable disorder with approx 10% of the general population having an abnormal allele for the hemochromatosis gene. Major complications are from visceral deposition of iron, but cutaneous involvement is also seen. The classic tetrad includes cirrhosis, diabetes mellitus, skin hyperpigmentation, and cardiac failure.

Less common consequences include hepatocellular carcinoma, impotence, and arthritis.

HH is a genetically heterogeneous disorder with three different described subsets. Hemochromatosis type 1 is the most common and its gene, *HFE1,* is telomeric to the HLA-A locus on 6p. Two mutations in *HFE* have been described and both are missense mutations with resulting single amino acid substitutions. Juvenile hemochromatosis or type 2 has been mapped to1q21, whereas hemochromatosis type 3, an adult form, is located on 7q22. The clinical appearance of these variants can be similar except for their clinical onset. The underlying pathophysiology of all three is iron overload. Neonatal hemochromatosis is the most severe with rapid progression to death soon after birth.

CLINICAL FEATURES The classic tetrad of cirrhosis, diabetes mellitus, bronze hyperpigmentation of the skin, and cardiac failure may be the presenting findings, but earlier complaints should be investigated. Patients with solated asthenia, asthenia with arthralgia, or hypertransaminasemia should be screened for hemochromatosis. Other findings include amenorrhea, loss of libido, impotence, and symptoms of hypothyroidism.

General symptoms include chronic fatigue, weakness, lethargy, and apathy. Hepatomegaly is seen in more than 95% of affected patients and may be associated with other complaints of chronic liver disease. Until testing for the *HFE* gene was developed, liver biopsy and histological evaluation of tissue iron accumulation were required for diagnosis.

Cutaneous hyperpigmentation is seen in more than 90% of patients with idiopathic hemochromatosis. Skin discoloration is one of the earliest signs and is resulting from accumulation of hemosiderin-laden macrophages. The color has been described as slate gray, but is classically a brownish bronze. The color tends to be darker and more pronounced in sun exposed areas. Non-sun exposed areas that may be involved include the flexural folds, scars, and nipple areolae. Ichthyosiform alterations (in up to half of patients), skin atrophy, koilonychia, and hair loss may also be present.

Differential diagnosis of the cutaneous pigmentation is extensive and including drug-induced hyperpigmentation, actinic reticuloid, porphyria cutanea tarda (PCT) and other forms of liver disease such as alcoholic liver disease, nonalcoholic steatohepatitis and chronic viral hepatitis.

LABORATORY FINDINGS Screening tests include serum iron, ferritin, and transferrin. Genetic tests for C282Y and H63D mutations are available. Testing for these mutations is carried out as confirmation of diagnosis or screening in asymptomatic patients. Liver biopsy is no longer obligatory to establish the diagnosis, but may be needed in cases of cirrhosis.

Skin biopsy may confirm the diagnosis of HH if iron deposition is found in any area except the lower extremities where stasis could produce a false positive.

Serum iron is usually more than 150 mcg/dL with a transferring saturation of more than 45%. Ferritin is more than 500 ng/mL.

GENETICS A mutation (845 G to A) causes an amino acid change, C282Y, which is the most common mutation. Of the US white population, 61.5% are homozygous for the normal allele, 23.5% are heterozygoous for the H63D allele and 10.3% are heterozygous for the C282Y allele. Other rarer alleles are also present. Occasionally heterozygotes have clinical hemochromatosis.

TREATMENT AND PROGNOSIS Once the diagnosis is confirmed, treatment is fairly direct. Phlebotomy is the sole recommended treatment and is effective if able to be used. Genetic counseling is also recommended as well as screening for *HFE* mutations in first-degree relatives. Prognosis depends on the extent of organ involvement. Increased awareness and initiation of early treatment has led to higher survival rates than those treated inadequately.

PORPHYRIAS

The porphyrias are a group of acquired and inherited diseases involving the porphyrin-heme biosynthetic pathway. Eight enzymes contribute to the pathway and their deficiency or defectiveness produces an accumulation of specific porphyrin intermediate(s) and clinical disease (Table 109-1). Diagnosis of any of the porphyrias includes measurement of urinary, fecal, and plasma porphyrins. Table 109-1 lists the known porphyrias and their respective enzymes; those with skin involvement are shown in bold type. Except for PCT and erthropoietic protoporphyria (EPP), most of these diseases are rare. This section reviews PCT and EPP.

PORPHYRIA CUTANEA TARDA PCT (type 1, symptomatic porphyria, acquired hepatic porphyria, and chemical porphyria) is the most common of all the porphyrias and occurs as an inherited or acquired form. It is found worldwide with most studies demonstrating a male predominance. Urogen decarboxylase is deficient or nonfunctional. Three categories of PCT have been described. The most common is the sporadic form or PCT type-I, which has a deficiency of hepatic urogen decarboxylase restricted to the liver or resulting from hepatotoxic substances. Type II has autosomal-dominant inheritance and demonstrates urogen decarboxylase deficiency in all tissues. The third subset includes patients having a positive family history of disease as in type II, but with normal concentrations of a probably dysfunctional enzyme. PCT features are found in patients with variegate poryphyria.

Most of the PCT in the United States are of the type-I pattern and are often alcohol related. Other compounds and conditions that can produce PCT are estrogens (including treatment of men who have prostate cancer), hexachlorobenzene, iron, tetrachlorodibenzo-*p*-dioxin, and hemodialysis. Clinical findings are similar for all forms of PCT.

PCT patients have vesicles and blisters resulting from repeated trauma and sun exposure. The chronic damage with subepidemal blistering leads to scarring and milia formation. These two latter findings, useful to the attentive clinician, are seen even when the disease is quiescent. Unlike other porphyrias, PCT patients are unaware of the role of sunlight because they are not as photosensitive. Other clinical findings include hypertrichosis, hyperpigmentation, hypopigmentation, and sclerodermoid changes. Some or all of these may exist in any patient. Some studies have shown a direct correlation between elevated urinary uroporphyrins and sclerodermoid changes. The hypertrichosis is mainly facial and improves slowly with treatment of PCT. When these findings are seen in the clinic, a Wood's light can be used to fluorescence the patient's urine. The elevated urinary uroporphyrin demonstrates pink to orange fluorescence if the concentration is more than 1 mg/L.

Coexisting diseases can produce PCT or have been associated with it. Underlying infections need to be excluded in patients with PCT. Both HIV and hepatitis C has been reported in patients with PCT. PCT has been reported before the known infection and vice versa. Therefore, any patient with newly diagnosed PCT should be screened for possible hepatitis C and HIV. Diabetes mellitus and hemochromatosis are two systemic diseases that need consideration.

Table 109-1
Human Porphyrias and Related Enzyme Defects

Tissue	*Porphyria*	*Inheritance*	*Enzyme*
Erythyropoietic	**Congenital Erythropoietic Porphyria**	Autosomal-recessive	Uroporphyrinogen III (Urogen III) cosynthase
	Erythropoietic Protoporphyria (EPP)	Autosomal-dominant	Ferrochelatase
Hepatic	Acute Intermittent Porphyria	Autosomal-dominant	Porphobilinogen deaminase
	Variegate Poryphyria	Autosomal-dominant	Protoporphyrinogen (Protogen) oxidase
	Hereditary coproporphyria	Autosomal-dominant	Coproporphyrinogen (Coprogen) oxidase
	Porphyria Cutanea Tarda (PCT)	Autosomal-dominant, variable	Uroporphyrinogen (Urogen) decarboxylase
	ALA-dehydratase Poryphyria	Autosomal-recessive	ALA-dehydratase
Hepatoerythropoietic	**Hepatoerythropoietic porphyria**	Autosomal-recessive	Uroporphyrinogen (Urogen) decarboxylase

Diseases with skin manifestation are in bold type.

The frequency of the most common mutant hemochromatosis allele (C282Y) is increased in both Types-I and -II PCT.

Laboratory Findings The laboratory findings of PCT include elevated total body iron stores as seen in increased serum iron, ferritin, and transferrin. About 25% of patients have abnormal serum glucose and glucose tolerance tests. PCT patients excrete increased amounts of porphyrins in the urine. The three main features of abnormal excretion are:

1. Increased urinary excretion of uroporphyrin and other acetate-substituted porphyrins.
2. A distinctive pattern of isomer series I and III porphyrins (I > III).
3. Increased excretion of fecal isocoproporphyrin. A complete work-up includes analysis of liver transaminases, liver function tests, CBC, and serology for viral infections. Histopathology is also helpful demonstrating a pauciimmune subepidermal blister. Other characteristic findings include festooning, and thickened papillary vessel walls with a periodic acid–Schiff stain. Direct immunofluorescence shows deposition of C3 and IgG in a granular pattern at the dermal-epidermal junction and around vessel walls.
4. Plasma testing for most porphyrins simplifies diagnosis.

Treatment The treatment of PCT is often effective with the use of phlebotomy. The goal of phlebotomy is to induce an iron deficiency as iron can impede hepatic urogen decarboxylase. Iron also has other functions such as enhancing δ-aminolevulinic acid (ALA) synthases and irreversible binding to uroporphyrin, thus increasing levels of uroporphyrin. Antimalarials are used in patients where phlebotomy is not an option. Although it is thought that the antimalarials have photoprotective properties, their effect in the porphyrias is thought to derive from binding with porphyrins leading to rapid sequestration and excretion by the liver.

ERTHROPOIETIC PROTOPORPHYRIA The second most common porphyria is EPP (erythrohepatic porphyia, protoporphyria), which was first clearly defined in 1961 by Magnus et al. Ferrochelatase is the enzyme defect for this porphyria and is deficient in erythrocytes, mitogen-stimulated lymphocytes, and skin fibroblasts. Family studies have shown genetic heterogeneity with both autosomal-dominant and recessive patterns. EPP has been reported worldwide without any racial predilection.

EPP, unlike PCT, begins early in life with characteristic cutaneous photosensitivity and elevated protoporphyrin in erythrocytes, feces, and plasma. Owing to its insolubility, protoporphyrin is rarely found in urine. Acute attacks of EPP are characterized by marked photosensitivity including burning, stinging and pruritus. The affected areas are obviously photoexposed, but the nose, cheeks, and dorsal hands are particularly involved. The symptoms are usually seasonal, most frequent in spring and summer. The skin lesions include erythema, edema, urticarial lesions, and purpura. Resolution of these acute lesions usually leaves atrophic, waxy or pitted scars. The lips may have a pursed appearance and the dorsal hands may have dramatic scarring with a waxy appearance. Vesicular or bullous lesions are typically seen in temperate climates, but have been reported in the tropics. Patients seem to have a hardening effect as symptoms decrease with age. There is no erythrodontia, hypertrichosis, milia, sclerodermoid changes, or hyperpigmentation as in other porphyrias. Approximately 11% of patients develop a hemolytic anemia. Gall stones and hepatic failure have also has been reported, but seem to be relatively rare.

Laboratory Findings The diagnosis of EPP is made by measuring elevated levels of protoporphyrin in feces, erythrocytes and plasma. There may be elevated fecal and erythrocyte coproporphyrin. A blood smear may show red fluorescent erythrocytes. Histopathlogy may reveal endothelial cell damage, mast cell degranulation, and a polymorphonuclear cell infiltrate in the dermis. There is also marked thickening of the vessels in the papillary dermis as well as perivascular deposits mimicking lipoid proteinosis. The differential diagnosis includes polymorphous light eruption, hydroa vacciniforme, idiopathic solar urticaria, and the other porphyrias.

Treatment Treatment of EPP consists of β-carotene, topical sunscreens, antimalarial drugs, cholestyramine, and vitamins E and C. β-Carotene doses of 60–180 mg/d have been the most effective. The mechanism is thought to be β-carotene's ability to bind free oxygen radicals produced by the photo-excited porphyrins. Future therapies may include enzymatic replacement with ferrochelatase.

110 Heritable Conditions Affecting Tissues of the Oral Cavity

J. Tim Wright

SUMMARY

The oral cavity is made up of complex and diverse tissues that provide a variety of highly specialized functions ranging from nuerosensory (e.g., taste) to nutritional/digestive functions (e.g., salivary digestion and mastication). Not surprisingly there is a substantial portion of the human genome used in making these unique diverse structures and allowing them to function appropriately. Consequently there are hundreds of conditions affecting the soft and hard tissues of the oral cavity. Some of these conditions affect primarily or only the oral cavity, although others are associated with significant somatic manifestations. This chapter reviews some of these conditions providing the reader a framework for understanding hereditary pathologies of the oral cavity.

Key Words: Amelogenesis; cementum; dentin; dentinogenesis; ectodermal dysplasia; enamel; epidermolysis bullosa; gingival; hair; hypodontia; oral epithelium; teeth.

INTRODUCTION

The oral cavity is a complex system characterized by unique sensory and functional activities that involve highly specialized soft and hard tissues. The mucosal lining of the oral cavity is diverse in its structure depending on its location and function. For example, the tissue directly adjacent to the teeth and on the palate is highly keratinized to protect it from the mechanical and thermal trauma involved in mastication and eating. In contrast, mucosa lining the inner surfaces of the cheeks and the dental vestibules (trough between cheeks and teeth) has little or no surface keratin, has a flexible underlying dermis and is thus mobile allowing the tissues to move for functioning during swallowing, clearing food, and speech. The tongue is a highly muscular appendage that has a unique neurosensory system providing the mechanism for taste.

Complementing the sophisticated soft tissues of the oral cavity is the dental complex. Normally, humans have 20 primary teeth that are lost in childhood and 32 permanent teeth. Teeth are made up of highly specialized mineralized tissues (e.g., enamel, dentin, and cementum) that are supported by pulpal tissue internally and held in the jaws by the periodontal ligament. Each of these tissues is critical to normal function of the dentition and can be affected by hereditary conditions that produce unique structural and compositional defects. Clinical genetic studies coupled with knowledge derived from the Human Genome Project have tremendously advanced the understanding of the molecular basis and associated phenotypes for many hereditary conditions affecting the oral cavity. This chapter presents several of the more common hereditary conditions affecting the hard and soft tissues and provides tables listing other conditions and their associated genes.

HERITABLE CONDITIONS INVOLVING ORAL SOFT TISSUES

Multitudes of diverse hereditary conditions (Table 110-1) affect the soft tissues of the oral cavity and present unique and potentially devastating manifestations. For example, palmar-plantar hyperkeratosis (Papillon Lefevre syndrome), caused by mutations in the cathepsin C gene, is characterized by hyperkeratosis of the palms and soles of the feet and frequently knees and elbows. Interestingly this mutation is associated with severe and rapid periodontal destruction that leads to rapid loss of all the primary teeth and eventually the permanent teeth. The gingiva around the teeth becomes highly inflamed beginning shortly after tooth eruption, the periodontal attachment is destroyed and the teeth loosen and exfoliate with little or no root resorption. Other conditions such as epidermolysis bullosa (EB) can cause severe destruction of the oral soft tissues because of recurrent blistering whereas other disorders are associated with pigmentation changes of the mucosa that can be associated with increased risk for malignancy (e.g., Peutz–Jeghers syndrome, dyskeratosis congenita).

EPIDERMOLYSIS BULLOSA EB is a clinically diverse group of disorders having blister formation as their common feature and is discussed in detail in Chapter 105.

Depending on the specific protein involved and the associated abnormality, the clinical presentation variably affects soft as well as hard tissues in the oral cavity. All of the defective proteins responsible for skin fragility in EB are expressed in the oral soft tissues, although, because of the oral epithelium's unique structural and compositional characteristics, the oral mucosa may or may not display fragility similar to the skin. As with the skin, the

Table 110-1
Simple and Complex Hereditary Conditions Associated With Periodontal Disease, Mucosal Ulceration and Pigmentation, and Head and Neck Cancer

Condition	*Inheritance*	*Protein/function*	*Gene*
Periodontitis			
Papillon-Lefèvre syndrome	AR	Cathepsin C, lysozomal protease	*CTSC*
Haim Munk syndrome	AR	Cathepsin C, lysozomal protease	*CTSC*
Ehlers-Danlos IV	AD	Type-III Collagen	*COL3A1*
Leukocyte adhesion deficiency I	AD	Integrin-B2, neutrophil dysfunction	*ITGB2*
Mucosal blistering and ulceration			
Dystrophic epidermolysis bullosa	AD/R	Type VII collagen, anchoring fibrils	*COL7A1*
Junctional epidermolysis bullosa	AR	Laminin 5, anchors cells in basement membrane area by interaction with integrin B4	*LAMA3, LAMB3, LAMC2, ITGB4*
Mucosal pigmentation			
Peutz-Jeghers syndrome	AD	Serine threonine protein kinase	*STK11*
Dyskeratosis congenita	X-linked AD	Dyskerin, cell cycle function	*DKC1*
		Telomerase RNA component	*TERC*
Head and neck cancer			
Squamous cell carcinoma	Complex	Tumor necrosis factor family member	*TNFRSF10B*
Cowden disease	AD	Phosphatase and tensin homolog	*PTEN*
Basal cell nevus syndrome	AD	Patched-transmembrane transcription repressor	*PTCH*
Bloom syndrome	AR	RecQ protein-like 3-DNA dependent ATPase	*RECQL3*
Beckwith-Wiedemann syndrome	AD	Cyclin-dependent kinase inhibitor 1C, negative regulator of cell proliferation	*CDKN1C*

AR, autosomal-recessive; AD, autosomal-dominant.

frequency, magnitude, and depth of lesion formation and tissue separation ultimately determines the progression of the oral soft tissue manifestations in the different EB types and whether lesion healing is associated with scarring.

In the milder forms (e.g., most simplex subtypes) of inherited EB, there is only occasional blistering of the oral mucosa with small discrete vesicles that heal rapidly without scarring. Generalized recessive dystrophic EB has the most severe involvement of the oral mucosa characterized by microstomia, complete obliteration of the vestibule, and ankyloglossia (Fig. 110-1). With increasing age, structures such as the palatal rugae and lingual papilla typically become unrecognizable because of the presence of continuous blister formation and scarring. In contrast, localized or less severe cases of generalized recessive dystrophic EB do not show the same severity of oral scarring observed in the severe, generalized forms. For example, although the recessive dystrophic EB inversa subtype has marked oral involvement, there tends to be less scarring, with only mild to moderate microstomia, ankyloglossia, and vestibular obliteration. Although different mutations in the type-VII collagen gene have been related to the variable expression observed in EB, the relationship between genotype and phenotype has not been fully characterized.

Individuals with recessive dystrophic and junctional EB are at increased risk for the development of squamous cell carcinomas. Squamous cell carcinomas do occur in the oral cavity of these individuals necessitating diligent oral cancer examinations beginning in early to mid adolescence. Recessive dystrophic and junctional EB are often associated with severe dental problems including the development of rampant dental caries requiring aggressive preventative and restorative approaches. Affected individuals should be counseled regarding optimal caries prevention (e.g., fluoride consumption and dietary considerations regarding frequency and amount of carbohydrate ingestion) beginning by 1 yr of age.

Figure 110-1 The oral cavity of this young child with generalized recessive dystrophic epidermolysis bullosa (EB) displays the marked microstomia, severe dental crowding and rampant caries frequently associated with this form of EB.

HERITABLE CONDITIONS AFFECTING THE HUMAN DENTITION

Development of the human dentition involves a highly orchestrated series of events under strict genetic control. The developmental timing, location, morphology, structure, and composition of teeth are all primarily determined by cascades of molecular events that are regulated by hundreds of genes. Early embryonic requisites for tooth development include the differentiation of the oral ectoderm and the migration of neural crest cells into the craniofacial region in which tooth buds will ultimately form. By approx 6 wk of age (*in utero*) the oral ectoderm begins to proliferate at the future sites of primary teeth. As the oral ectoderm proliferates, it invaginates

Table 110-2
Simple Hereditary Traits Associated With Abnormal Tooth Formation

Condition	*Inheritance*	*Protein/Function*	*Gene*
Hypodontia			
Hypodontia—premolar, 3rd molar	AD	Muscle segment homeobox, transcription factor	*MSX1*
Oligodontia—incisor, molar	AD	Paired box gene, transcription factor	*PAX9*
Syndrome/hypodontia			
Hypohidrotic ectodermal dysplasia	X-Linked R	Ectodysplasin, early epithelial–mesenchymal interaction	*EDA*
Hypohidrotic ectodermal dysplasia	AD/R	Ectodysplasin receptor, binds ectodysplasin	*EDAR*
Incontenentia Pigmenti	X-Linked D	Nemo, NF κB essential modulator	*NEMO*
Witkop/Tooth and Nail syndrome	AD	Muscle segment homeobox, transcription factor	*MSX1*
Reiger syndrome Type I	AD	Paired like homeodomain transcription factor	*PITX2*
Ellis Van Creveld syndrome	AR	EVG protein	*EVG*
Ectodermal dysplasia, cleft, syndactyly	AR	Poliovirus receptor like1, mediates virus entry into cells	*PVRL1*
Enamel			
Amelogenesis imperfecta	X-Linked R	Amelogenin, enamel matrix protein	*AMELX*
Amelogenesis imperfecta	AD	Enamelin, enamel matrix protein	*ENML*
Junctional epidermolysis bullosa	AR	Laminin 5, anchors cells in basement membrane area by interaction with -Integrin β4	*LAMA3, LAMB3, LAMC2, ITGB4*
Tuberous sclerosis	AD	Hamartin and tuberin, complex together and inhibit growth	*TSC1, TSC2*
Tricho-dento-osseous syndrome	AD	Distalless homeobox transcription factor	*DLX3*
Mucopolysaccharidosis Type IVA	AR	Glactosamine-6-sulfatase, deficiency	GALNS

AR, autosomal-recessive; AD, autosomal-dominant.

into the underlying mesenchyme in which the neural crest-derived ecto-mesynchymal cells reside. The continued proliferation and expansion of the oral ectoderm allows the epithelial cells to contact and interact with the underlying ectomesenschyme cells thereby initiating the development of a tooth bud primordia. These early events in tooth development are largely regulated by the oral epithelium requiring the expression of numerous genes including transcription and growth factors. If these early epithelial driven developmental events do not occur, then a tooth will not form (e.g., such as occurs in many ectodermal dysplasias [ED]). Following the initiation of tooth formation by invagination of the oral epithelium, the tooth develops into its unique morphology and is made up of primarily the enamel, dentin, and cementum.

Dental enamel is the hardest tissue (approx 95% mineral by weight consisting predominantly of carbonate substituted hydoxyapatite) in the human body and provides the fracture and wear resistant outer covering for the tooth crown. Enamel is produced by ameloblasts derived from embryonic ectoderm that secrete a unique extracellular matrix, process this matrix, control the mineralization process, protect the formed enamel during tooth eruption and then become part of the epithelial attachment of the tooth to the gingiva. Dentin is the most abundant dental tissue and largely determines the size and shape of teeth. The unique structure and composition of dentin allow it to function as the substructure for the rigid enamel tissue, thereby imparting teeth with the ability to flex and absorb tremendous functional loads without fracturing. Dentin contains approx 60% mineral by weight and, unlike enamel, has a substantial organic component (20% protein with type-I collagen being the most abundant). Cementum is a unique tissue that covers the root surface and helps prevent the tooth from becoming fused to or resorbed by the adjacent alveolar bone. Cementum is the dental tissue that allows each tooth to be anchored by a fibrous network, the periodontal ligament, to the alveolar bone of the jaws. Given the complex molecular controls required for tooth formation and the unique and highly specialized tissues including the dental structures, it is not surprising that there are many hereditary conditions affecting the number, shape, size, and composition of teeth. Many syndromes with ectodermal manifestations have associated abnormalities of teeth and numerous hereditary disorders affect only the teeth and do not involve other tissues or systems (Table 110-2).

CONGENITALLY MISSING TEETH The presence of congenitally missing teeth is relatively common in humans with a prevalence that varies among races and the specific tooth type. In the general population, approx 5% of Caucasians have a congenitally missing permanent maxillary lateral incisor or premolar (the most commonly missing teeth excluding 3rd molars), whereas only 1% of African Americans have a congenitally missing tooth. Congenitally missing primary teeth are less prevalent than missing permanent teeth with the mandibular central incisor the most commonly missing primary tooth.

Many individuals presenting with a missing tooth have a family history of missing teeth. Although the molecular defects causing congenitally missing teeth are known to be heterogeneous, several specific genetic mutations have been identified. For example, missense mutations in the *MSX1* gene (a transcription factor gene) cause an autosomal-dominant trait of missing lateral incisors, premolars, and third molars that does not affect other tissues. Interestingly, a mutation in *MSX1* that introduces a premature stop that truncates the protein in the DNA homeodomain-binding region is associated with the Witkop tooth and nail syndrome. Mutations in the transcription factor gene *PAX9* are associated with unusual patterns of missing teeth that frequently include lower incisors. However, the number and type of missing teeth are variable even within the same kindred. Individuals with missing teeth can be offered genetic testing to determine if the molecular

Figure 110-2 This 4-yr-old male with hypohidrotic ectodermal dysplasias is congenitally missing 15 of the 20 primary teeth and has one conically shaped incisor.

basis of their condition is known and to help establish recurrence risk and variability of expression and association with syndromes. Management typically involves various prosthetic treatments and varies in extent and cost depending on the number and location of teeth missing.

Numerous hereditary syndromes have congenitally missing teeth as a characteristic. In some instances there may be only a few or no missing teeth (e.g., Down syndrome) or, as in the case of the ED, there can be multiple missing teeth (hypodontia) or no teeth at all (anodontia). There are more than 100 conditions classified as ED, many of which are associated with abnormal tooth development. Hypohidrotic ED, one of the better recognized and more common forms, is characterized by a decreased ability to sweat (hypohidrosis), sparse hair (hypotrichosis), and missing or malformed teeth (hypodontia) (Fig. 110-2). Any or all of the teeth can be missing and there are frequently conical shaped incisors. Genes for the classic X-linked recessive form and for an autosomal-dominant and recessive ED have been identified, allowing diagnostic confirmation in these ED types, which has been problematic because of phenotypic overlap between and variable expression of these conditions. Having a correct molecular-based diagnosis allows the family to obtain accurate genetic counseling.

Conical or misshapen teeth can usually be treated using bonding techniques to achieve a greatly improved esthetic appearance. Dental management of hypodontia or anodontia often involves the use of fixed and/or removable prostheses to replace the missing teeth to enhance oral function and facial esthetics. In children missing multiple anterior teeth it is important to provide dental prostheses before beginning school. The optimal age for treatment is generally dictated by the extent of treatment needed and the child's ability to cooperate during the required procedures and maintain the appliances after placement. Management of severe hypodontia or anodontia typically involves numerous treatment phases over the patient's lifetime. Many children with severe hypodontia or anodontia ultimately benefit from dental implants. Although each case must be evaluated individually, dental implant procedures are typically delayed until adolescence or early adulthood.

HEREDITARY CONDITIONS AFFECTING ENAMEL

Because enamel formation is a highly regulated process requiring many genes and occurs over a long period of time, it is not surprising that more than 100 genetic and environmental etiologies of abnormal enamel formation exist. Abnormal enamel matrix secretion and/or extracellular matrix processing are implicated in many of these developmental disturbances. Although premature cessation of ameloblast function can result in thin or pitted enamel, the processes involved in the development of hypomineralized enamel are apparently complex, and are less clearly understood.

Hereditary enamel defects can occur as part of a generalized condition or syndrome or as a defect involving only enamel. Many hereditary disorders affecting ectodermal tissues and the ectodermal/mesenchymal complex, such as the tricho-dento-osseous syndrome, incontinentia pigmenti, tuberous sclerosis, and junctional EB can have marked enamel involvement (Table 110-2).

Enamel defects associated with syndromic conditions vary substantially depending on the molecular defect and the gene's role in tooth formation. For example, in tricho-dento-osseous syndrome, an autosomal-dominant disorder caused by a mutation in the Distalless 3, homeobox gene (*DLX3*), the teeth have enamel hypoplasia that can be smooth or pitted and have taurodontism (elongation of the pulp chamber). Individuals with this condition also have kinky curly hair at birth and develop dense and/or thickened bone (both the cranium and appendicular skeleton are involved). The *DLX3* gene functions as a transcription factor regulating the expression of other genes and is important in hair, tooth, and bone formation.

Individuals with junctional forms of EB have varying severities of generalized enamel hypoplasia ranging from generalized pitting to a near complete absence of enamel. The molecular defects that cause junctional EB involve genes (i.e., laminin 5 associated genes and β4 integrin) that produce proteins essential to maintaining the integrity between the dermis and epidermis and are expressed by and apparently critically important in normal functioning of the ameloblasts and enamel formation.

Amelogenesis imperfecta (AI) represents a group of hereditary conditions (Table 110-2) that manifest enamel defects without evidence of generalized or systemic disorders. These conditions are clinically and genetically diverse and occur with varying frequency in different populations (about 1:14,000 in the United States and 1:6000 in Sweden). Autosomal-dominant and recessive as well as X-linked inheritance patterns have been documented for AI. The clinical phenotype ranges from thin enamel that is normal in color to enamel that is severely hypomineralized and readily abrades from the teeth as they emerge into the oral cavity. Depending on the AI type, the teeth can be extremely sensitive to thermal and chemical stimuli. There are 12 different mutations in the *AMELX* gene that is located on the X chromosome and codes for amelogenin, the most abundant enamel matrix protein. The *AMELX* mutations cause X-linked AI and enamel defects ranging from severe hypoplasia and very thin enamel to enamel that is of normal thickness but is hypomineralized and brown in color. There can be an increased retention of the amelogenin protein in the fully formed enamel and the enamel prism structure can be markedly altered. Collectively, these compositional and structural changes result in enamel that is optically altered (can appear brown to opaque white) and more poorly mineralized making it less wear resistant and weaker. The type of enamel defect appears to be related to the specific functional domain affected in the amelogenin protein providing an interesting genotype to phenotype correlation in the AMELX AI conditions. Different mutations

in the *ENAM* gene located on chromosome 4q21 can cause either a local pitted enamel defect or a generalized severe hypoplasia in which only a very thin enamel layer is present. The most common type of AI in North America is autosomal-dominant hypocalcified AI, characterized by enamel that is typically severely hypomineralized resulting in rapid enamel loss and severe hypersensitivity. The molecular basis for this AI type is unknown, however study of several large families segregating for this AI type showed the condition was not linked to any of the genes considered to be critical for enamel formation. The molecular etiology also is unknown for all the autosomal-recessive forms of AI.

Treatment of enamel defects is predicated on the diagnosis and specific nature of the enamel abnormality. For example, hypoplastic enamel that is well mineralized can frequently be treated effectively with bonding procedures to protect the teeth and enhance esthetics. Teeth with severely hypomineralized enamel generally are treated with restorations that cover the entire clinical crown (e.g., crowns). Infants with conditions known to be associated with enamel defects should be referred for dental evaluation and planning for future intervention by 1 yr of age. Early restorative treatment with stainless steel and white resin crowns by age 2 or 3 yr is often necessary in those AI types characterized by severe hypomineralization, which is frequently associated with rapid enamel breakdown and severe hypersensitivity.

CLINICAL AND COUNSELING IMPLICATIONS

Identification of the molecular basis of conditions affecting the soft and hard tissues of the oral cavity allows clinicians to accurately delineate entities that frequently present with similar manifestations. Defining the molecular etiology of a disorder allows clinicians to definitively determine the mode of inheritance (e.g., X-linked ED vs autosomal-dominant or recessive that can look phenotypically identical) and provide accurate genetic counseling and better predict prognosis. This information is critical for allowing parents to make decisions regarding subsequent births and for educating parents and patients about prognosis. Understanding the molecular basis of disease and how specific tissues are affected allows the clinician to select optimal treatment approaches (e.g., bonding vs crowns in specific AI types) and in some cases to apply special preventative and/or monitoring regimens (e.g., careful monitoring for development of oral cancer in recessive dystrophic EB and dyskeratosis congenita) to optimize the health of individuals affected by the diverse hereditary conditions of the oral cavity.

111 The Genetic Basis of Human Cerebral Cortical Malformations

Bernard S. Chang and Christopher A. Walsh

SUMMARY

Malformations of cortical development occur when the normal process of brain development is disrupted. With the widespread use of high-resolution neuroimaging, brain malformations are increasingly being recognized as a relatively common cause of refractory epilepsy, mental retardation, and other neurological disorders. The molecular and genetic bases of many cortical malformations have been elucidated in recent years, both expanding our understanding of the underlying biological processes in brain development and informing our approach to these disorders in clinical practice. This chapter highlights some of these malformations, including disorders of microcephaly, gray matter heterotopia, lissencephaly syndromes, and polymicrogyria.

Key Words: Cobblestone complex syndromes; heterotopia; lissencephaly; malformation of cortical development; microcephaly; neuronal migration disorder; polymicrogyria.

INTRODUCTION

The development of the cerebral cortex is an intricate process that culminates in the formation and organization of the most complex network in the human body, that of the neurons that reside in the ribbon of gray matter at the surface of the brain. Understanding of this developmental process has taken on new clinical importance, as disorders caused by disruptions in this process, termed malformations of cortical development (MCDs), are substantially more prevalent than previously recognized. In fact, MCDs are now a common diagnosis in cases of refractory epilepsy and mental retardation that were previously unexplained. The elucidation of MCDs on a molecular and genetic level has thus expanded understanding of the underlying biological processes at work, and influenced the approach to these disorders in common neurological practice. This chapter highlights some of the MCDs whose genetic foundations have been elucidated.

DEVELOPMENT OF THE CEREBRAL CORTEX

Initially, neuronal precursors proliferate in regions deep in the brain; most excitatory pyramidal neurons originate in a region lining the lateral ventricle (the ventricular zone), whereas inhibitory interneurons appear to originate from precursors in the ganglionic eminences of the embryonic brain. Neuronal precursors then migrate outward toward the brain surface to form the neurons of the developing cortex. The molecular mechanisms underlying this migration are still being elucidated, but the process extends over a long period spanning much of the first half of human gestation. Finally, the cerebral cortex, once populated with neurons, undergoes organizational changes during which gyration, lamination, and the formation of proper synaptic connections occur.

Edited by: M. S. Runge and C. Patterson © Humana Press, Inc., Totowa, NJ

CLASSIFICATION OF MCDS

Although the steps described earlier temporally overlap to a significant extent, and some disorders may result from abnormalities in more than one successive step, MCDs are often classified according to the developmental stage that is disrupted in their pathogenesis. Disorders of neuronal proliferation include both those with increased proliferation (such as megalencephaly, characterized by a larger cerebral cortex than normal) and those with decreased proliferation (such as microcephaly vera or small cortex). Disorders of neuronal migration lead to some of the most striking abnormalities of cerebral cortical architecture, because failure of some neurons to migrate properly to the brain surface can result in regions of misplaced neurons called gray matter heterotopia. Finally, disorders of cortical organization include those in which gyration and lamination are disrupted, such as polymicrogyria, as well as disorders of neuronal specification and/or maturation, such as focal cortical dysplasia.

DISORDERS OF PROLIFERATION

Primary Microcephaly (Microcephaly Vera) Microcephaly refers to the presence of a small head circumference, generally more than two or three standard deviations below the mean, and implies an underlying disorder of abnormally small brain size. Many forms of microcephaly have associated cortical abnormalities or dysmorphic features, but primary microcephaly (microcephaly vera) refers to those in which the gyral pattern and other aspects of brain anatomy are relatively preserved and other syndromic features are absent. Most patients have mild-to-moderate mental retardation as the predominant clinical finding. Radiologically, brain volumes are reduced but other anatomical abnormalities are absent.

Primary microcephaly is etiologically diverse and many cases likely arise from environmental insults during gestation. Most familial cases of primary microcephaly, however, appear to be inherited in an autosomal-recessive fashion. Five separate loci (MCPH1–MCPH5) have been mapped by homozygosity in consanguineous pedigrees (Table 111-1). No obvious clinical or

Table 111-1
Selected Genetic Disorders of Human Cerebral Cortical Development

Name	*Clinical features*	*Radiological features*	*Inheritance pattern*	*Chromosome locus*	*Gene*	*Molecular pathogenesis*
Primary microcephaly	Small head circumference; mild-to-moderate mental retardation	Small brain volumes with anatomy otherwise preserved	Autosomal-recessive	MCPH1 (8p23), MCPH2 (19q13), MCPH3 (9q34), MCPH4 (15q14), MCPH5 (1q31)	Microcephalin (at MCPH1), ASPM (at MCPH5)	Disorder of neuronal progenitor proliferation or survival (because of cell cycle, mitotic, or apoptotic mechanisms)
Cohen syndrome	Microcephaly, facial dysmorphism, joint laxity, retinal dystrophy	Small brain volumes, ?relatively enlarged corpus callosum	Autosomal-recessive	8q22	COH1	?
Bilateral periventricular nodular heterotopia	Seizures; normal cognitive function	Heterotopic gray matter nodules lining the ventricles	X-linked dominant (most common), autosomal-recessive	Xq28	Filamin A	Disorder of neuronal migration (?because of actin cytoskeletal mechanisms)
Subcortical band heterotopia	Mental retardation, cerebral palsy, seizures	Heterotopic gray matter bands between cortex and ventricles	X-linked dominant	Xq22	DCX/XLIS	Disorder of neuronal migration (because of microtubule-associated mechanisms)
Classic lissencephaly	Mental retardation, cerebral palsy, seizures	Smooth brain surface with increased cortical thickness	X-linked, autosomal-recessive	Xq22, 17p13	DCX/XLIS, LIS1	Disorder of neuronal migration (because of microtubule-associated mechanisms) or progenitor proliferation and survival (for LIS1)
Lissencephaly with cerebellar hypoplasia	Cognitive and motor delay, ataxia, seizures	Lissencephaly with dysplastic hippocampi and severe cerebellar hypoplasia	Autosomal-recessive	7q22	RELN	Disorder of neuronal migration (because of detachment from radial glial cells and/or microtubule-associated mechanisms)
X-linked lissencephaly with abnormal genitalia	Mental retardation, epilepsy, ambiguous genitalia	Lissencephaly with absence of corpus callosum	X-linked recessive	Xp22	ARX	Disorder of neuronal migration
Cobblestone complex syndromes (Walker-Warburg syndrome, muscle-eye-brain disease, Fukuyama congenital muscular dystrophy)	Developmental delay, congenital muscular dystrophy, eye abnormalities (in some)	Cobblestone appearance to cortex, often brainstem abnormalities and cerebellar microcysts	Autosomal-recessive	WWS: 9q34; MEB: 1p33-34; FCMD: 9q31	WWS: POMT1; MEB: POMGnT1; FCMD: fukutin	Disorder of neuronal overmigration resulting from dysfunctional glial limiting membrane (?because of impaired glycosylation of α-dystroglycan)
Bilateral perisylvian polymicrogyria	Oromotor dysfunction (predominant), developmental delay, seizures	Polymicrogyria around Sylvian fissures	Autosomal-dominant (most common), X-linked	?, Xq28	?	?
Bilateral frontoparietal polymicrogyria	Developmental delay, dysconjugate gaze, seizures, cerebellar signs	Polymicrogyria of frontoparietal predominance, ventriculomegaly, small brainstem and cerebellum	Autosomal-recessive	16q12.2-21	GPR56	?

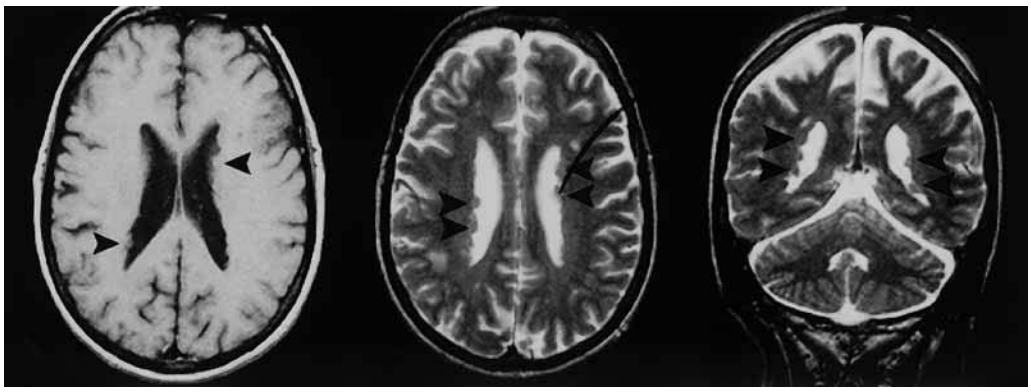

Figure 111-1 MRI appearance of bilateral periventricular nodular heterotopia. From left to right, the T1-weighted axial; T2-weighted axial; and T2-weighted coronal images demonstrate the heterotopic gray matter nodules that line the ventricular wall and protrude into the ventricular lumen (arrowheads). The black streak in the middle image is a mark made by the radiologist on the image to indicate one of the nodules.

radiological signs differentiate among cases linked to these different loci.

Understanding of the molecular pathogenesis of primary microcephaly has been advanced by the identification of the responsible genes at two of the MCPH loci. A novel gene at the MCPH1 locus encodes a protein, microcephalin, which contains a BRCA C-terminal domain. Such domains are present both in proteins controlling the cell cycle and in those involved in DNA repair. Because microcephalin is highly expressed in the ventricular zone of fetal mouse brain (in which neuronal progenitors proliferate), it is reasonable to speculate that disturbances of the progenitors' cell cycle or ability to repair lethal DNA mutations may lead to impaired proliferation or increased cell death and thus, ultimately, decreased brain size.

The second cloned gene, called *ASPM* and located at the MCPH5 locus, is the human orthologue of a *Drosophila* gene that is essential for normal mitotic spindle formation in neuronal progenitors. Because ASPM is highly expressed in the ventricular zone and ganglionic eminences of fetal mouse brain, impaired cell division in neuronal progenitors because of a mitotic spindle abnormality may also be a molecular mechanism leading to the phenotype of decreased cerebral cortical size. A hint at the importance of ASPM in cortical development comes from a comparison of the predicted protein structures of its homologues across multiple species. Progressing from the *C. elegans* homologue to asp in *Drosophila* to Aspm in mice and finally human ASPM, the salient difference is a marked increase in the number of repeated calmodulin-binding "IQ" domains, whereas the remainder of the protein is generally conserved. Although the function of these "IQ" domains is not known, these findings suggest that they play a key role in determining brain size.

Cohen Syndrome Many syndromic disorders feature small head size as an important clinical characteristic. One of these, Cohen syndrome, is an autosomal-recessive disorder over-represented in Finland that is characterized by cognitive and motor retardation, microcephaly, unusual facial features, joint laxity, retinochoroidal dystrophy, and intermittent neutropenia. Mutations in a novel gene called *COH1*, located on chromosome 8q22, have been found in patients with the classic Cohen syndrome phenotype. Analysis of the predicted protein sequence suggests that COH1 may have a role in intracellular protein transport and sorting. Further investigation into the genetic etiologies of other syndromic microcephaly disorders may reveal common molecular features that help to explain how cerebral cortical size is determined.

DISORDERS OF MIGRATION

Bilateral Periventricular Nodular Heterotopia Bilateral periventricular nodular heterotopia (BPNH) is characterized by the presence of heterotopic, or misplaced, nodules of gray matter that line the lateral ventricles deep in the brain, typically in a bilaterally symmetric fashion (Fig. 111-1). Patients most commonly have normal intellectual and neurological function except for seizures, which typically begin during the adolescent years. Pathologically, these nodules contain mature neurons with normal morphology but varying orientations and no laminar organization, whereas the cerebral cortex appears to maintain its normal six-layered architecture.

Early reports of families with BPNH described the presence of multiple affected females, a higher-than-expected rate of spontaneous abortions, and a shortage of male offspring, suggesting an X-linked dominant inheritance pattern. Subsequently, the responsible gene for BPNH was identified as *filamin A* (*FLNA*), located on chromosome Xq28. FLNA is an intracellular actin-crosslinking protein that is essential for cell locomotion. The leading pathogenetic explanation for BPNH is that heterozygous females (who express the mutant *FLNA* allele in half of their neurons because of X-inactivation) exhibit these periventricular nodules because some of their neurons fail to migrate away from the ventricular surface, whereas the remaining neurons migrate properly and form the normally layered cerebral cortex. Males hemizygous for the mutation (who carry the mutant *FLNA* allele on their only X chromosome and must express the mutant protein in all of their neurons) usually demonstrate prenatal lethality.

There is both genetic and phenotypic heterogeneity to this disorder, however. An autosomal-recessive form of periventricular heterotopia has been described, for example. In addition, it appears that prenatal lethality is mostly associated with null *FLNA* mutations, whereas males with less severe *FLNA* mutations (such as those that lead to distal truncation of the protein) may survive and demonstrate a typical X-linked BPNH phenotype similar to that seen in females. The phenotypic spectrum of FLNA abnormalities has been expanded further by the identification of *FLNA* mutations in patients with a number of congenital malformations affecting non-nervous system organs, including the craniofacial structures, skeleton, viscera, and genitourinary tract.

Subcortical Band Heterotopia Subcortical band heterotopia (SBH) or "double cortex" syndrome is a cortical malformation in which heterotopic bands of gray matter are present bilaterally, traversing the white matter between the cerebral cortex and the lateral ventricle in an orientation generally parallel to the ventricle. Most patients with SBH are females who have mental retardation, cerebral palsy, and epilepsy to varying degrees.

The responsible gene for this disorder was identified on chromosome Xq22 and labeled *doublecortin (DCX)* or *XLIS*, as males with mutations in this gene have a separate phenotype called X-linked lissencephaly, discussed later. In an analogous fashion to the suspected pathogenesis of BPNH, females may express the mutant *DCX/XLIS* allele in half of their neurons, which presumably fail to migrate fully to the cortical surface and form the subcortical heterotopic band of gray matter, whereas hemizygous males express the mutant allele in all neurons and demonstrate a more severe phenotype with a generalized disorder of migration affecting all cerebral cortical neurons.

The role of the DCX protein in neuronal migration has become increasingly clear. DCX is associated with microtubules and appears to serve a stabilizing function; its structure features novel microtubule-binding domains that occur in tandem. It physically interacts with LIS1, another microtubule-associated protein associated with a lissencephaly phenotype when mutated (*see* Classical Lissencephaly). LIS1 interacts with a complex of proteins that play a role in regulating microtubule dynamics. Therefore, the likely molecular mechanism of SBH pathogenesis is an alteration in microtubule function that impairs neuronal migration.

Non-Mendelian factors, such as reduced penetrance and somatic mosaicism, are commonly present in those with *DCX/XLIS* mutations and thus affect the clinical expression of these mutations. These findings have a significant impact on the questions of whether asymptomatic parents of children with SBH should be radiologically and genetically tested and how SBH patients and their parents should be counseled about recurrence risks in future offspring.

Classical Lissencephaly Classical lissencephaly is characterized by a smooth brain surface with an absence of gyri and sulci and by an abnormal cortical lamination, usually featuring four rather than six layers. The clinical presentation of lissencephaly involves mental retardation, cerebral palsy to varying degrees, and epilepsy including a number of different seizure types. Radiologically, the cortical thickness is increased and the gyral/sulcal pattern is simplified, with a smooth appearance to the cortical surface.

Two separate genetic etiologies lead to classical lissencephaly in its isolated form: hemizygous mutations in *DCX/XLIS*, described earlier, and heterozygous (dominantly inherited) mutations in *LIS1*, on chromosome 17p13. Although some radiological features help differentiate between *DCX/XLIS* and *LIS1* cases, in particular an anterior vs posterior predominance to the malformed cortex, the phenotypes are broadly similar. It was the study of Miller-Dieker syndrome, characterized by the combination of severe classical lissencephaly and associated facial dysmorphism, that led to the initial identification of the autosomal 17p locus for lissencephaly; it now appears that Miller-Dieker syndrome is caused by chromosome 17p deletions that encompass both *LIS1* and other neighboring genes.

As described earlier, the LIS1 protein (also known as PAFAH1b1 or the platelet-activating factor acetylhydrolase β-1 subunit) appears to interact both with DCX and with other members of a microtubule-associated complex, including NudE and NudEL. However, its other functions may be relevant to earlier steps in cortical development, particularly neuronal proliferation and survival. Therefore, although classical lissencephaly is usually thought of as primarily a migration disorder, it may be that two sequential molecular mechanisms play a role in this malformation's pathogenesis.

Lissencephaly With Cerebellar Hypoplasia Lissencephaly with cerebellar hypoplasia (LCH) is characterized by lissencephaly that is more severe frontally than posteriorly and is accompanied by severe hypoplasia of the cerebellum (often to the extent that only a portion of the vermis is present), dysplastic-appearing hippocampi, and a small pons. Clinical features in two original families who demonstrated LCH with autosomal-recessive inheritance consisted of severe cognitive and motor delay and seizures.

The identification of the gene responsible for LCH as *RELN* (located on chromosome 7q22) represented the culmination of a long series of investigations beginning with the reeler mouse, a spontaneously occurring mutant so called because of a staggering gait and originally described more than 50 yr ago. The reeler mouse exhibits an unusual cerebral cortical architecture, consisting of an "upside-down" cortex in which the normal six layers are essentially inverted. Cerebellar and hippocampal abnormalities are also present. Mutations in a mouse gene termed *Reln* were identified in reeler, and the discovery of the human orthologue followed. Because of the similarities between the reeler mouse and human LCH phenotypes, the human *RELN* locus was tested for linkage to this disorder and *RELN* gene mutations subsequently found in affected LCH patients.

The function of the reelin protein has been the subject of interest and investigation. Reelin binds the very low-density lipoprotein receptor, apolipoprotein E receptor 2, and extracellular matrix proteins such as integrins and protocadherins. In vitro experiments have demonstrated that reelin appears to cause migrating neurons to detach from the radial glial cells that serve as their guideposts, possibly through its interaction with integrins, which mediate cell–cell adhesion. In addition, reelin also participates in a signaling pathway through the transmembrane receptors listed earlier that may eventually affect proteins known to be associated with microtubule organization. Thus, the molecular pathogenesis of LCH may involve disrupted neuronal migration through more than one mechanism, including both cell locomotion and adhesion to radial glial guideposts.

X-Linked Lissencephaly With Abnormal Genitalia X-linked lissencephaly with abnormal genitalia (XLAG) is characterized by a distinctive form of lissencephaly that is worse posteriorly than anteriorly and features only a moderately increased cortical thickness. In addition, the clinical syndrome includes absence of the corpus callosum, hypothalamic dysfunction, severe epilepsy, and ambiguous male genitalia. Multiple loss-of-function mutations in *ARX*, the human orthologue of the Aristaless-related homeobox gene in *Drosophila*, have now been identified in patients with X-linked lissencephaly with abnormal genitalia. The predicted ARX protein contains two conserved domains, a DNA-binding homeodomain and a C-peptide (aristaless) domain whose function is not known, and is likely to play a role in transcriptional regulation.

Mutations in the *ARX* gene are one of the most striking examples of allelic heterogeneity in the field of developmental brain disorders. The range of phenotypes now linked to *ARX* mutations

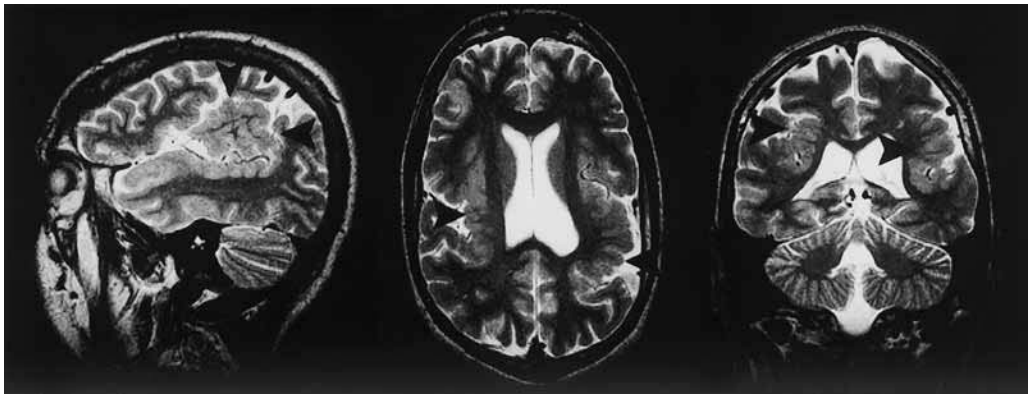

Figure 111-2 MRI appearance of bilateral perisylvian polymicrogyria. From left to right, T2, weighted sagittal, axial, and coronal images demonstrate the excessive number of small gyri (and irregular appearance of the gray–white junction) in the regions around the Sylvian fissure bilaterally (arrowheads).

encompasses such diverse disorders as infantile spasms, Partington syndrome (mental retardation with hand and wrist dystonia), nonsyndromic mental retardation, and autism. In one case, bilateral cerebral and cerebellar cysts, presumably developmental in origin, were seen.

Many of the documented *ARX* mutations lead to predicted polyalanine tract expansions, raising the possibility that toxic protein aggregation, similar to that seen in polyglutamine neurodegenerative disorders, might play a role in their pathogenesis.

Cobblestone Complex Syndromes Cobblestone complex (formerly "cobblestone lissencephaly" or type II lissencephaly) is a term applied to a group of brain malformations that are distinctly different from classical lissencephaly histologically. In cobblestone syndromes, the brain surface actually has an irregular appearance in some places, because of the presence of heterotopic tissue. This tissue consists of glioneuronal elements that appear to have overmigrated out of the brain through discontinuities in the glial limiting membrane at the brain surface. Cobblestone complex is typically seen in association with congenital muscular dystrophy (CMD) and is a defining part of the phenotype of such disorders as Walker-Warburg syndrome, muscle-eye-brain disease, and Fukuyama CMD. Clinically, these disorders range widely in severity: Walker-Warburg patients typically die in infancy, for example, whereas Fukuyama patients can survive into young adulthood. On radiological images, cobblestone complex is often associated with brainstem abnormalities and cerebellar microcysts.

Understanding of these syndromes' molecular pathogenesis has begun to coalesce with the identification of genes responsible for all three prototypic disorders. Fukuyama CMD is caused by mutations in the *fukutin* gene; the founder mutation present in Japanese patients is a retrotransposal insertion that leads to decreased protein expression. Muscle-eye-brain disease is associated with loss-of-function mutations in a gene called *POMGnT1*. Some patients with Walker-Warburg syndrome have mutations in the *POMT1* gene, although this disorder is genetically heterogeneous and other Walker-Warburg genes remain unidentified.

These three genes all appear to encode glycosyltransferases, enzymes that chemically modify other proteins by adding sugar groups. In these cobblestone disorders, one target, if not the major one, of these glycosyltransferases appears to be α-dystroglycan, a protein that forms part of the laminin-associated complex linking the cytoskeleton to the extracellular matrix. Because laminin abnormalities occur in CMD, the natural implication is that deficient glycosylation of α -dystroglycan is the molecular mechanism underlying the muscle disorder in these conditions.

Whether faulty α-dystroglycan modification is also responsible for the apparent overmigration of neurons in the brain is being investigated. The finding that mutations in a gene encoding a fukutin-related protein lead to CMD without any brain malformation suggests that the specific molecular defect underlying the migrational disorder may be elucidated by detailed functional studies of the glycosyltransferases encoded by these genes.

DISORDERS OF CEREBRAL CORTICAL ORGANIZATION

Bilateral Polymicrogyria Syndromes Polymicrogyria is a cortical malformation characterized by an excessive number of abnormally small gyri. Histologically, affected cortex is usually disorganized and lacks a normal six-layered architecture. Radiologically, polymicrogyria may be distinguished from other malformations such as pachygyria by the irregular "scalloped" appearance of the gray–white junction and an increase in the apparent cortical thickness. Although polymicrogyria can arise from environmental insults, several syndromes of region-specific symmetric polymicrogyria have been described, some or all of which are genetic.

Bilateral perisylvian polymicrogyria, for example, is a disorder in which the cortex surrounding the Sylvian fissure is polymicrogyric; often, the Sylvian fissure is abnormally oriented as well (Fig. 111-2). Clinically, patients have a highly distinctive presentation dominated by oromotor dysfunction, ranging in severity from a mild speech impediment to life-threatening feeding difficulties in infancy. Many patients also have mental retardation and seizures. The disorder appears to be genetically heterogeneous, with the most common inheritance pattern being autosomal-dominant. X-linked inheritance has also been seen in some families, and a locus on Xq28 has been reported.

Another region-specific symmetric syndrome, bilateral frontoparietal polymicrogyria, is an autosomal-recessive disorder characterized clinically by developmental delay, seizures, dysconjugate gaze, and cerebellar signs. Radiologically, the polymicrogyria is generalized but exhibits a decreasing anterior-posterior gradient, such that the frontoparietal regions are most severely affected. In addition, white matter signal changes, ventriculomegaly, and hypoplasia of the brainstem and cerebellum are also seen. Bilateral frontoparietal polymicrogyria is caused by mutations in *GPR56*, a gene on chromosome 16g that encodes an orphan G-protein-coupled receptor.

The regional specificity of the malformation in both these syndromes raises the possibility that the genes responsible for their pathogenesis may have an anatomic gradient of expression, or may interact with or be regulated by other factors that may have such a gradient. Alternatively, it may be that particular regions of the cerebral cortex have specific developmental features that make them more susceptible to certain malformative processes.

CONCLUSION

The elucidation of the genetic and molecular basis for many developmental malformations of the brain has been one of the most exciting and important advances in molecular neurology. Major strides in the use of two key investigative tools, magnetic resonance technology and molecular biology, have led to better understanding of how the cerebral cortex normally develops and an appreciation for the myriad consequences that can result when this process is disrupted. With the growing importance of MCDs in the diagnosis and treatment of epilepsy, mental retardation, and other neurological disorders, knowledge gained in this field has immediate relevance to clinical care. Future work on cortical development may allow us to provide more refined treatments and prognoses for those afflicted by these disorders.

112 Muscular Dystrophies

Molecular Diagnosis

ERIC P. HOFFMAN AND ERYNN S. GORDON

SUMMARY

Muscular dystrophies are generally genetic changes resulting in degeneration (and regeneration) of muscle. Mutations of 29 different genes can cause specific types of muscular dystrophy. The most common form of muscular dystrophy is Duchenne muscular dystrophy, caused by mutations in the dystrophin gene on the X-chromosome, resulting in an absence of the protein dystrophin. Mutations in the same gene cause the less common and less severe Becker muscular dystrophy, characterized by a partial deficiency of the dystrophin protein.

Key Words: Becker; Duchenne; Emery-Dreifuss muscular dystrophy; facioscapulohumeral; merosin; muscular dystrophy; myotonic dystrophy.

INTRODUCTION

Muscular dystrophies are generally genetic changes resulting in degeneration (and regeneration) of muscle. Mutations of 29 different genes can cause specific types of muscular dystrophy. The most common form of muscular dystrophy is Duchenne muscular dystrophy, caused by mutations in the dystrophin gene on the X-chromosome, resulting in an absence of the protein dystrophin. Mutations in the same gene cause the less common and less severe Becker muscular dystrophy, characterized by a partial deficiency of the dystrophin protein. Although mutations in dystrophin are commonly associated with muscular dystrophy in males, approx 10% of females with muscular dystrophy have a mutation in dystrophin resulting in symptoms because of skewed X-inactivation. The pathophysiology of dystrophin abnormalities involves instability of the plasma membrane of myofibers with chronic muscle deterioration leading to weakness. Two other relatively common types of muscular dystrophy include myotonic dystrophy and facioscapulohumeral dystrophy. Presentations of myotonic dystrophy vary greatly, ranging from neonatal lethality, to childhood mental retardation, adult distal weakness with myotonia, or early onset cataracts. Caused by an increase in size of a trinucleotide repeat (CTG) in the 3′ untranslated region of a protein kinase, it is dominantly inherited, with considerable variation in phenotype within families. The size of the expansion generally correlates with disease severity. The mechanism by which the expansion mutation causes the observed multisystemic and variable clinical features appears to be consequential to altered mRNA metabolism within cells. Facioscapulohumeral dystrophy is dominantly inherited and involves a deletion of a subtelomeric region of 4q, with a complex molecular pathophysiology.

Mutations of 26 additional genes for less common forms of muscular dystrophy have been identified. Many of these involve components of the myofiber plasma membrane and extracellular basal lamina (dysferlin [involved in vesicle traffic]; four different sarcoglycan genes [interact with dystrophin]; caveolin 3 [vesicle traffic]; fukutin, and fukutin-related protein [glycosidases]; collagen VI [three subunit genes]; and integrin α7).

One of the major structural components of the myofiber basal lamina, α2 laminin, causes approx 40% of neonatal onset disease, congenital muscular dystrophy. In addition to profound weakness at birth, these patients show marked abnormalities of white matter by MRI studies, yet are intellectually normal. Abnormalities in two nuclear membrane components cause either X-linked recessive (emerin protein) or autosomal-dominant (lamin A/C) Emery-Dreifuss muscular dystrophy (EDMD) with contractures and cardiac conduction defect. Another nuclear protein, poly(A)-binding protein (PAB) 2 shows a late-onset oculopharyngeal dystrophy. Mutations of calpain III, a muscle-specific membrane-bound protease, might be a relatively common cause of dystrophy in patients with normal dystrophin. Of the 29 genes causing muscular dystrophies, 15 fall under the umbrella of limb-girdle muscular dystrophy. Most patients carrying the descriptive diagnosis of limb-girdle muscular dystrophy have a recessively inherited disease, although rare families with late-onset dominant inheritance have been described.

Of the 29 genes for which mutations cause subtypes of muscular dystrophy, 13 result from abnormalities of the plasma membrane and adjacent basal lamina. Myofibers likely have a stringent requirement for a durable and resilient plasma membrane based on two features of its normal physiology and function. First, each contraction of the myofibrils leads to a rapid and dramatic redistribution of the cytoplasm, resulting in changes of the shape of the myofiber. These shape changes would be expected to impart considerable stresses on the plasma membrane. Second, the force generated by the myofibrils must be transduced to the extracellular matrix so that the muscle group can contract and generate force as a single coordinated unit. Thus, this force transduction must be transmitted through the plasma membrane, which must be strongly

reinforced to withstand these sheer forces. The study of human disease has been critical in both identifying components of the myofiber membrane cytoskeleton and in determining the relative functions of many of the components. Six distinct human inherited muscular dystrophies have been identified which are caused by deficiencies of the membrane cytoskeleton: one intracellular component (dystrophin; Duchenne muscular dystrophy), four transmembrane components (α-, β-, γ-, and δ-sarcoglycans) and one extracellular component (α2 laminin). The muscular dystrophies caused by deficiency of dystrophin or any of the four sarcoglycans are similar histologically and clinically. This observation suggests that the progressive muscle diseases caused by these proteins might all share a similar pathogenesis, namely, chronic membrane instability leading to progressive dysfunction of the muscle, and that all of the sarcoglycans and dystrophin are required for membrane stability. The deficiency of the extracellular component, α2 laminin, results in a more complicated and severe phenotype (congenital muscular dystrophy), with apparent involvement of the immune system in tissue pathology, and also abnormalities of myofiber regeneration. Other neonatal onset congenital muscular dystrophies result from defects in glycosylation of proteins, and thus their appropriate interaction between the myofiber plasma membrane and extracellular basal lamina.

PLASMA MEMBRANE PROTEIN DEFECTS IN CHILDHOOD AND ADULT ONSET DYSTROPHIES

Duchenne muscular dystrophy is one of the most common inherited disorders of humans and is the most frequent muscle disease (1/3500 live born males). Its high frequency in all world populations is a result of the high mutation rate of the gene, which in turn is largely a consequence of the enormous size of the gene (2.5×10^6 bp). Affected children are predominantly male, because of the X-linked recessive inheritance pattern, and appear normal until about 4–5 yr of age, when muscle weakness becomes obvious. Thereafter, weakness and muscle wasting progress relentlessly, leading to wheelchair confinement by age 14 yr, and death in the mid 20s.

The biochemical deficiency causing the disorder remained obscure until 1987, when the Duchenne muscular dystrophy gene was identified by positional cloning techniques. The gene, 10 times larger than the next largest gene, encodes a 427-kDa protein dubbed "dystrophin"; dystrophin deficiency is recognized to define Duchenne muscular dystrophy at the biochemical level. Mutations of the gene are deletions (55%), duplications (5%), and point mutations (40%). Partial dystrophin deficiency, often the result of in-frame deletion mutations compatible with production of dystrophin that lacks segments of amino acids, is diagnostic of the milder and more variable Becker muscular dystrophy. Presentations of Becker dystrophy include proximal weakness, myoglobinuria, myalgias, hyper- CKemia, and cardiac failure, and some patients might remain asymptomatic at advanced ages.

Female homozygotes do not exist because of the relative rarity of the disorder; females generally act as heterozygous gene carriers. However, approx 10% of females with unknown forms of muscular dystrohy express their symptoms as a consequence of heterozygosity for a dystrophinopathy. Most of these females show preferential inactivation of the X-chromosome containing the normal dystrophin gene (skewed X inactivation). Presentations of isolated female carriers vary as much as Becker muscular dystrophy in males, although the progression is often mitigated in the female patients. Overall, approx 20% of adult female carriers of Duchenne and Becker muscular dystrophy show some symptoms, including muscle weakness of varying severity, cardiomyopathy and left ventricle dilation.

Molecular diagnosis, genetic counseling, and prenatal diagnosis are well established in the dystrophinopathies. Dystrophin protein analysis of muscle biopsy, mutation analysis, and gene linkage analysis are all routinely used. The gene's large size complicates the use of linkage analysis in genetic counseling and prenatal diagnosis due to the 10% recombination within the gene, which results in some uncertainty in all linkage analysis. The high mutation rate leads to many "new mutations," which might affect a single egg or sperm or several eggs leading to the issue of gonadal mosaicism, in which a parent might have multiple affected children (because of multiple affected eggs) yet not be a carrier herself. Owing to the high production rate of sperm, gonadal mosaicism is not an issue for men but must be considered for all at risk carriers. The identification of dystrophin as a major component of the membrane cytoskeleton of muscle fibers permitted use of the dystrophin protein as a probe to isolate and characterize other components. Research has identified three complexes of proteins that interact with dystrophin near the plasma membrane and appear to provide one type of connection between the intracellular contractile myofibrils and the extracellular matrix (Fig. 112-1). Rare childhood-onset muscular dystrophies with autosomal-recessive inheritance patterns have been shown to be caused by mutations of four of the sarcoglycan proteins (Table 112-1). No disorders have been associated with the primary defects in any of the syntrophins or dystroglycan components, although dystroglycan is a target of specific glycosylation modifications, and deficiencies in these enzymes cause severe congenital muscular dystrophy (*see* Basal Lamina and Glycosylation Defects in Neonatal Onset Congenital Muscular Dystrophy).

The clinical and histopathological consequences of primary disorders of dystrophin and the sarcoglycans are similar, and it can be safely assumed that they share a common molecular pathogenesis. Models suggest that deficiencies of these proteins lead to membrane instability, which initiates acute (hyperCKemia, myofiber necrosis) and chronic responses (progressive fibrosis, failure of myofiber regeneration, and muscle wasting/weakness). The immune system might play a role in both the acute and chronic responses, and immune suppressants such as prednisone show some effect in slowing disease progression. Efforts at gene therapy are underway, although the refractory nature of mature myofibers to viral delivery systems and the unique nature and large amount of the target muscle tissue are hurdles facing this approach.

Three additional plasma membrane proteins cause muscular dystrophy: dysferlin, integrin α7, and caveolin 3. Dysferlin and caveolin 3 directly interact with each other, and caveolin 3 also binds to dystroglycan. Indeed, caveolin 3 and dystrophin appear to compete for the same binding site on dystroglycan, and might represent alternative microdomains providing support to the plasma membrane. Caveolins form lipid rafts and "caveolae" (invaginations of the plasma membrane), and are likely involved in regulating aspects of cell signaling. Integrins interact directly with laminins in the basal lamina, and provide a membrane cytoskeleton that appears complementary to that of the dystrophin membrane cytoskeleton. Consistent with the partial redundancy of the integrin- and dystrophin-based cytoskeletons, overexpression of integrin α7 rescues the pathology of dystrophin deficiency in mice.

BASAL LAMINA AND GLYCOSYLATION DEFECTS IN NEONATAL ONSET CONGENITAL MUSCULAR DYSTROPHY

In 1994, a subset of congenital muscular dystrophy patients were identified who showed complete lack of immunostaining for the

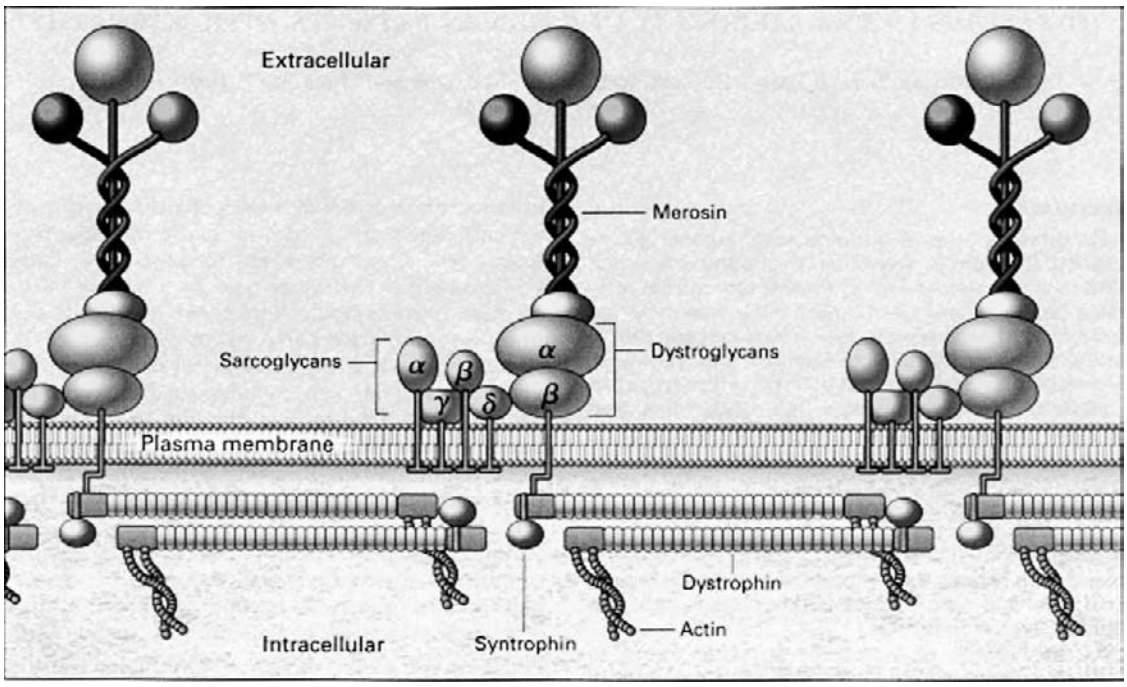

Figure 112-1 Schematic of proteins involved in muscular dystrophies. Shown is a segment of a myofiber plasma membrane, with the intracellular dystrophin-based membrane cytoskeleton, transmembrane sarcoglycans and dystroglycans, and extracellular basal lamina with laminin 2. Male Duchenne/Becker muscular dystrophy and isolated female dystrophinopathy patients are the result of abnormalities of the dystrophin protein, a common X-linked recessive disease. Rare autosomal-recessive childhood-onset dystrophies are caused by mutations in any one of the sarcoglycan proteins (α-sarcoglycan [adhalin], β-sarcoglycan, γ-sarcoglycan, and δ-sarcoglycan). Many cases of neonatal onset severe congenital muscular dystrophy are caused by deficiency of α2 laminin (merosin), which is the large subunit of laminin in the myofiber basal lamina. (From ref. Duggan DJ, Gorospe JR, Fanin M, Hoffman EP, Angelini C. Mutations in the sarcoglycan genes in patients with myopathy. N Engl J Med 1997;336:618–624. Copyright © 1997 Massachusetts Medical Society. All rights reserved.)

α7-laminin chain in their muscle biopsy. The α2-laminin gene has been mapped to chromosome 6q22-23, and mutations have been identified in affected patients. Merosin-deficient patients are relatively uniform in clinical presentation and progression: patients are floppy at birth, unable to raise limbs against gravity. Serum creatine kinase levels are elevated to 2000–10,000 IU/L (normal <200 IU/L). The muscle biopsy shows a dystrophic process, with degeneration of myofibers, and a marked increase in endomysial and perimysial connective tissue with fatty infiltration. One study found that 3 of 10 merosin-deficient patients were initially given the diagnosis of infantile polymyositis because of the presence of significant populations of inflammatory cells. This study documented focal inflammatory reaction in a young patient's muscle, with concentrations of B- and T cells resembling primary follicles, generally seen in spleen. These results suggested that earlier reports of the diagnosis of infantile polymyositis, with a presumed autoimmune etiology, could represent a possible histological finding in inherited α2-laminin deficiency. Both $CD4^+$ and $CD8^+$ cells are seen in large numbers, both distributed throughout the biopsy and in focal aggregates.

α2 laminin is one of the three components of the heterotrimeric muscle laminin molecule (*see* Fig. 112-1). The α2-subunit is present in muscle, the central nervous system (CNS), and Schwann cells, and replaces the more ubiquitous α_1 chain during the development of muscle tissue. The other two components, laminin β_1 and γ_1, are not tissue specific. Laminin is a major constituent of basal lamina of most cells, in which it complexes with collagen IV and other proteins to anchor cells in their tissue environment. α_2 laminin is involved in neurite outgrowth in the peripheral and CNS. Patients with α_2 laminin deficiency show dramatic white-matter changes by MRI, although there is no overt CNS dysfunction or intellectual impairment. There is a mouse model for merosin deficiency, d*y*/d*y*, and the mutation in the milder of two alleles have been identified. These mice show a phenotype similar to the human disease.
